Emerging data also support an important role for inflammatory cells and cytokines in the response after tubular injury.[63] Experimental animals demonstrate a prompt increase in serum IL-6 after renal ischemia. Immunohistochemistry demonstrates IL-6 colocalization with infiltrating macrophages in the outer renal medulla. Supernatant from S3 segment renal tubular cells injured by reactive oxygen species in vitro increases IL-6 production by macrophages in culture by six-fold.[64] IL-6 knockout mice had lower creatinine levels and histologic injury scores than wild-type at 24 hours after ischemic injury. In vivo depletion of monocytes-macrophages in experimental rats resulted in decreased tubular necrosis and renal tubular apoptosis after renal ischemia.[65] Histologic improvement in macrophage-depleted animals was associated with reduction in levels of renal messenger RNA for IL-6, TNFα, macrophage chemoattractant protein 1, and IL-1β within 23 hours after ischemia. In adults with ARF, elevation in serum

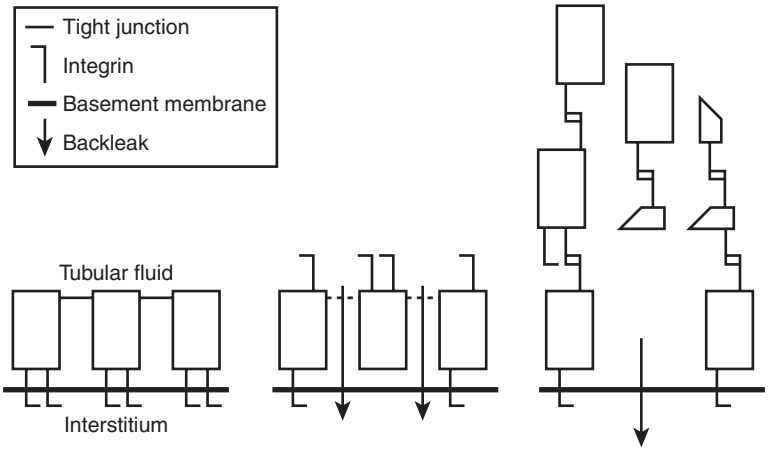

Figure 136-3 Schematic representation of the role of intratubular obstruction and back leak in ARF. *Left,* Normal tubular cells linked by tight junctions into an epithelial sheet that forms a selective barrier between the tubular fluid compartment and the interstitium. The tight junction regulates cell polarity, segregating molecules such as the integrins to the basal plasma membrane, forming the adhesive anchorage of the cell basement membrane junction. *Middle,* Ischemia-induced tight junction dysfunction leads to a loss of barrier function contributing to loss of polarity and integrin migration to the apical surface, as well as leakage of glomerular filtrate back into the interstitium. *Right,* Loss of basal anchorage molecules allows cells or cell fragments to exfoliate into the tubular lumen and adhere and aggregate with other exfoliated cells or fragments, contributing to increase in tubular pressure proximal to the obstruction. Tubular obstruction will oppose glomerular filtration, as well as accelerate back leak of tubular fluid across the denuded basement membrane. *(Modified from Lee DBN, Huang E, Ward HJ: Tight junction biology and kidney dysfunction,* Am J Physiol Renal Physiol *290:F26, 2006.)*

IL-6 at baseline and continuing for 2 weeks after injury has been observed in nonsurvivors versus survivors.[66] In fact, serum levels of IL-6, IL-8, and IL-10 all correlated with risk of death after ARF, though the association with IL-6 was the strongest. Polymorphisms of TNFα, IL-1β, IL-6, and IL-10 have been investigated in neonates in whom ARF developed after infection.[67] The allele frequency of variants of individual genes did not differ between those with and without ARF. However, the combination of variants TNFα AG and IL-6 GC or CC was found in 26% of those with ARF versus only 6% of those without ARF. What makes this somewhat unclear, however, is that IL-6 CC has been shown to be associated with lower serum IL-6 levels in healthy adults than in those with GC or GG alleles.

It is at the level of tubule that the ubiquitously expressed heat shock protein (HSP) system acts to promote stabilization of the ischemic renal tubular cell.[68-70] Thus transfection of both HSPs *HSP70* and *HSP27* has been shown to ameliorate facets of tubular cell derangement after ischemia. *HSP70* transfection lessens Na^+,K^+–adenosine triphosphatase detachment from cytoskeleton and may actually chaperone the ectopic protein because colocalization of HSP70 at the apical membrane with Na^+,K^+–adenosine triphosphatase has been observed. HSP27 is thought to maintain cellular integrity after ischemia by stabilization of the actin cytoskeleton. Genetic polymorphism of the *HSP70* gene has been studied in neonates. ARF developed in very-low-birth-weight infants homozygous for a less-active allele of HSP70 (A→G[1267]) substantially more often than in those with other genotypes, even when adjusted for established factors of renal failure in neonates.[71]

Ischemia induces redistribution of another protein—Na^+,K^+–adenosine triphosphatase, which is normally localized to the basolateral side of the epithelial cells.[72,73] This may, at least in part, be responsible for the increased urinary sodium excretion observed in ARF, a finding frequently used in establishing the diagnosis of acute tubular necrosis. In addition, increased distal sodium delivery may stimulate vasoactive substances that decrease renal blood flow through the tubuloglomerular feedback mechanism. Of interest, increased tubular sodium concentration has recently been shown to contribute to polymerization and gel formation by Tamm-Horsfall protein (secreted in the thick ascending limb), providing another link between dysregulated tubular Na^+ delivery, decreased tubular flow, and increased intratubular pressure.[74]

Significant tubular cell metabolic derangements occur with hypoxia, which further compound injury.[13,75-79] Adenosine triphosphate depletion leads to xanthine dehydrogenase conversion through increased protease action to xanthine oxidase. During reperfusion, the resultant conversion of accumulated tubular cell hypoxanthine to xanthine produces hydrogen peroxide and superoxide. Further oxidative stress in ARF may originate from mitochondrial respiratory electron transport chain and neutrophil-associated respiratory burst via the activation of membrane-bound reduced nicotinamide adenine dinucleotide phosphate oxidase, contributing to accumulation of superoxide and hydrogen peroxide. Oxygen radicals readily combine with nitric oxide to yield peroxynitrite, capable of lipid peroxidation and protein nitrosylation, leading to loss of cell viability. Production of nitric oxide in the renal tubule dramatically increases with hypoxia through tubular inducible nitric oxide synthase. Pharmacologic inhibition of inducible nitric oxide synthase or lessening of oxidative stress (through exogenous superoxide dismutase) lessened nitrotyrosine, a marker of peroxynitrite action, and decreased the peak creatinine after ischemia.[76] Moreover, a specific scavenger of peroxynitrite, ebselen, dramatically lessened peak creatinine after ischemia. *N*-acetylcysteine is a reactive oxygen scavenger currently in use for reduction of the occurrence of contrast nephropathy.[77] Edaravone, a scavenger of free radicals and inhibitor of lipid peroxidation currently used in humans for cerebral ischemia, has also been shown benefit in ischemic ARF in animals.[78] In this connection, a single nucleotide polymorphism in the coding region of reduced nicotinamide adenine dinucleotide phosphate oxidase subunit p22phox has recently been shown to impact response to renal injury.[79] Among 200 adults with ARF, those carrying the T allele (associated with higher plasma nitrotyrosine levels—a byproduct of superoxide and nitric oxide generation) showed an increased likelihood of dialysis requirement or hospital death.

In addition to direct feedback mechanisms that affect the glomerular hemodynamics, tubular injury also interrupts structural integrity, and this allows creatinine and other markers of glomerular filtration to permeate the tubules and return into the circulation (i.e., back leak) (see Figure 136-3). As noted earlier, disruption of the junctional complexes affects not only the epithelial cell polarity but also tubular permeability. Histologic and functional data in human and experimental ARF support a disruption in the integrity of tubular epithelium and the presence of back leak.[80-84] Loss of junctional complexes that encompass tight junctions, adherent junctions, desmosomes, and gap junctions are especially relevant to back leak. At least in part, tyrosine phosphorylation of proteins within adherent junctions alters paracellular permeability and likely contributes to back leak.[83] By reducing the clearance of GFR markers, as well as metabolic waste products, back leak contributes to the high levels of creatinine in the circulation and maintenance of azotemia in ARF. Persistent derangements of tight junction and adherens junction proteins (zonula occludens and beta, alpha catenins respectively) predominated in patients with sustained ARF with transtubular back leak after renal transplantation but was not observed in those with recovery of renal function.[84] Studies in adults with ARF have estimated that back leak constitutes 10% of the reduction in GFR.[12,81] In preterm neonates, however, back leak has recently been proposed as one of the explanations of transiently increased serum creatinine even without ARF, attributed to immaturity of the renal tubule.[85] Therefore it is reasonable to postulate that an immature renal tubule with back leak at baseline would be more prone to increase back diffusion of creatinine and other constituents of plasma ultrafiltrate in the setting of renal tubular structural disintegrity or functional disruption, though quantitation of this phenomenon has yet to be determined.

Repopulation of renal tubular segments by proliferating was part of the recovery process. Although tubule regeneration after injury is well recognized, mechanisms that underlie the cellular repopulation remain unsettled and include (1) proliferation of surviving dedifferentiating tubular cells that reenter the cell cycle, (2) proliferation and differentiation of resident stem or progenitor cells from within the kidney, and (3) transdifferentiation of cells that originate outside the kidney, notably, bone marrow–derived stem cells.[86-100] These observations have generated considerable excitement regarding mechanistic and therapeutic possibilities. Thus, 24 to 48 hours after injury, the presence of mitotic cells containing the mesenchymal marker vimentin and the renal developmental gene *PAX-2* suggests that dedifferentiation and proliferation of surviving epithelial cells participate in this process.[89,96] Experimental, as well as human, data confirm the ability of bone marrow–derived cells to become renal epithelial cells.[91-98] Bone marrow–derived cells engraft tubules and can differentiate into tubular epithelial cells and replace the damaged cells.[91,92,99] Although this finding is exciting, it is now believed that such replacement from the bone marrow contributes only a small percentage to regenerating tubules.[98-100] Furthermore, the observed beneficial effects of bone marrow–derived cells may relate to modulation of nonepithelial, for example, endothelial cells, especially within the peritubular vasculature,[16] as well as cell replacement–independent effects such as direct inhibition of cell death or inflammatory cell infiltration.[101] Intrarenal cells, as opposed to bone marrow–derived cells, have recently been identified as a source of epithelial cell regeneration after injury. In particular, the renal papilla appears to be a source of adult kidney stem cells.[88,102,103] A recent study that addressed the relative importance of intrinsic renal versus bone marrow–derived cells in tubular epithelial cell proliferation after ischemia-reperfusion injury found that the overwhelming majority (89%) of the proliferating epithelial cells were of intrarenal origin; only 11% of these cells originated from bone marrow–derived cells.[99] It is of interest that the study also noted that a large number of interstitial cells within the injured kidney were bone marrow derived. This finding was recently expanded by a study that traced the fate of bone marrow–derived cells and showed that approximately 32% of myofibroblasts present in the postischemic kidney originated from the bone marrow cells.[104] The study further showed that these cells have increased production of extracellular matrix and contribute significantly to fibrosis after renal ischemia. Overall, it is currently believed that marrow-derived cells may be an important source for regenerating tubular cells. However, caution is in order in considering cell-based therapies to encourage renal tubule regeneration as stem cells. Bone marrow–derived cells may take on unexpected phenotypes that may participate in progressive renal destruction observed after acute renal injury.

PLASMA COLLOID OSMOTIC PRESSURE

Theoretically, an increase in systemic plasma colloid osmotic pressure, which opposes filtration, will decrease the GFR. However, newborn infants normally have lower levels of plasma protein (6.5 mg/dL in term babies vs. 7.5 mg/dL in adults), which tends to increase the GFR. Furthermore, hyperoncotic states (e.g., dysproteinemia) are almost unheard of in neonates, and even severe dehydration-induced hemoconcentration is unlikely to be accompanied by changes in plasma colloid osmotic pressure sufficient to change the GFR.[105]

GLOMERULAR CAPILLARY ULTRAFILTRATION COEFFICIENT

In addition to alterations in the pressures and flows already described, changes in the glomerular membrane properties themselves can contribute to the depressed level of glomerular filtration in ARF. The glomerular capillary ultrafiltration coefficient (K_f) encompasses the capillary surface area available for filtration and the permeability property of the capillaries themselves. Although technical advances have permitted study of this parameter in numerous experimental diseases, difficulties relating to the size and accessibility for direct glomerular measurements in immature animals are evidenced by the paucity of information on K_f in ARF in neonates. It is known that K_f is low in immature animals and increases with maturation.[5] One experimental study also suggested that a decrease in K_f may lower the single-nephron GFR to a greater extent in immature than in adult animals.[106] Entities causing inflammatory, proliferative, and microangiopathic changes in glomerular capillaries, which are expected to decrease glomerular capillary permeability, are distinctly unusual causes of ARF in the neonate. Renal ischemia and nephrotoxins are the most frequent pathogenic factors. In these conditions, glomeruli are, morphologically (relatively), spared.[12,13] However, because of our lack of knowledge regarding the primary site determining the impedance to the filtrate, it remains unclear whether subtle morphologic changes noted in some forms of human and experimental ARF, that is, reduction in endothelial fenestrae, cause decreased glomerular capillary permeability. Moreover, changes in the permeability of glomerular capillaries do not necessarily require fixed structural alterations in glomerular anatomy. Instead, a decrease in K_f may occur by hormonal autacoid (AII, vasopressin, prostaglandins, leukotrienes, endothelins) regulation of contractile cells within the glomerulus, which modulates the capillary area available for filtration.[105] In this regard, both gentamicin and amphotericin B are well-known contributors to ARF in neonates, yet remain in common use because of their excellent antimicrobial activity. As a result optimal dosing in neonates continues to be a therapeutic goal.[107,108] Both antimicrobials cause a decrease in GFR in part through reduction in K_f, which appears to be mediated in part by mesangial cell contraction.[109-111]

SECTION XVII

Fluid and Electrolyte Metabolism

137 Fluid Distribution in the Fetus and Neonate

†Karl Bauer, Robert A. Brace, and Barbara S. Stonestreet

The most dramatic changes in body fluid compartments occur during intrauterine growth when approximately 4000 mL of water accumulates in the human uterus (2800 mL in the fetus, 800 mL amniotic fluid, and 400 mL in the placenta) and during the postnatal adaptation of the neonate from the "aquatic" intrauterine to the "terrestric" extrauterine environment. In relationship to body weight, the amount of total body water (TBW) and its distribution between the body fluid compartments are markedly different in the fetus and newborn than in the adult. This implies that, during the perinatal period, the associated volume-regulatory mechanisms are functioning at a level that is unique in comparison with that in later life. In addition, the amniotic fluid that surrounds the fetus is often considered to be an extension of the fetal extracellular space, again suggesting unique volume regulatory mechanisms before birth. This chapter starts with a review about TBW content and the regulation of fluid distribution during fetal life including the role of the lymphatic system and of the capillary membrane in mediating fluid homeostasis. The postnatal adaptation of the neonatal body fluid compartments is then described with special emphasis on the clinical implications of these physiologic changes. The last section focuses on the effects of perinatal events on the regulation of blood volume in the immediate postnatal period.

DEVELOPMENTAL CHANGES OF BODY FLUID VOLUMES DURING FETAL LIFE

Total Body Water

In 1961, Friis-Hansen[1] reported the developmental changes in the relative fluid volumes in humans from the early fetal period through adulthood. As shown in Figure 137-1, in the early fetal period, approximately 95% of the fetus is water. The proportion of total body weight that is water gradually decreases throughout the fetal period to reach 80% at 8 months gestation and 75% water at term. This reduction of TBW is caused by the accumulation of body solids during growth. In the first two thirds of gestation body solids increase because of the accretion of protein and minerals, whereas little fat deposition occurs. We know from postmortem chemical analyses that at 27 weeks gestation 86% of body weight is water, 12% is fat-free dry solids, and only 2% is fat.[2] Measurements in appropriate–for–gestational age (AGA) preterm infants with birth weights below 1500 g showed TBW contents of 83%[3] and no detectable fat accumulation in preterm infants when measured by dual photon absorptiometry.[4] During the last trimester of gestation the proportion of body solids increases from 14% to 24% of body weight because of the deposition of body fat, which is 2% of body weight at 27 weeks gestation and 10% to 15% of body weight at term.[2]

In human neonates born after intrauterine growth restrictions, the TBW content is increased compared with normal intrauterine growth. In small–for–gestational age (SGA) preterm neonates, the mean TBW content was 62 mL/kg higher than in AGA preterm neonates,[5] and in term SGA neonates mean TBW content was increased by 76 mL/kg[6] to 102 mL/kg.[7] The higher body water content in preterm SGA infants reflects the reduced deposition of fat-free dry solids.[8] In contrast, the increase in body water content in term SGA neonates reflects primarily the reduced deposition of fat, which usually occurs during the third trimester of gestation in fetuses with normal growth. Several lines of evidence indicate that adipose tissue is indeed reduced in SGA term neonates. Intrauterine growth restriction late in gestation resulted in fetuses with reduced abdominal wall fat thickness measured by ultrasound.[9] The percentage of adipose tissue estimated from dual photon absorptiometry with use of ^{153}Gd magnetic resonance tomography was 2% in term SGA neonates compared with 13% in term AGA neonates.[4] Moreover, a smaller skinfold thickness in SGA term neonates indicated less subcutaneous fat.[10] One recent study

† Deceased

using dual-energy X-ray absorptiometry analysis also found reduced fat contents in near-term SGA compared with normal term infants, although the differences did not reach statistical significance.[11]

Taken together these finding suggest that the decrease in TBW with gestation is due to the deposition of protein, minerals, and body fat during normal intrauterine growth. The increased TBW after intrauterine growth restriction reflects reduced protein and mineral deposition in preterm SGA neonates and primarily reduced fat deposition in term SGA neonates.

Extracellular and Intracellular Fluid Compartments

Concurrent with the decline in TBW content during fetal life, major changes occur in the distribution of fluid. The TBW compartment can be subdivided into the extracellular volume and the intracellular volume. Early in gestation, the extracellular volume is extremely large, accounting for 62% of body weight, and is more than twice the size of the intracellular volume. The relatively large extracellular fluid space during fetal life is because growth occurs by cell division rather than by cell growth and produces tissues with small cells surrounded by a broad layer of extracellular fluid. By enlargement of cell size during normal intrauterine growth in the second half of gestation, the intracellular space increases from 25% of body weight at midgestation to 32% at term, whereas at the same time the extracellular volume decreases from 62% to 43% of body weight.[1]

Intrauterine growth restriction, unless severe, seems to have little influence on the distribution of TBW between the intracellular and extracellular volumes. A disproportionate expansion of extracellular volume of 73 mL/kg was found only in a subgroup of neonates with severe growth restriction indicated by a reduced weight and length compared with neonates with moderate growth restriction indicated by reduced weight but normal length.[12]

Another factor that reduces the extracellular water content in the fetus is the decrease of hyaluronan in the extracellular matrix with advancing gestation. Hyaluronan has a high water-binding capacity and is the most abundant component of the fetal extracellular matrix during the early phase of rapid cell multiplication and migration. Proteoglycan and collagen have lower water-binding capacities, and their concentrations increase with the subsequent tissue condensation.[13]

The extracellular fluid compartment is functionally divided into the plasma and the interstitial fluid space. Little is known about factors that regulate the distribution of fluid between the plasma and interstitial space in human fetuses because in vivo measurements have been made only in animals. In late-gestation fetal sheep, the best estimate for plasma volume is 76 mL/kg.[14] Interstitial volume has been estimated to average three times this volume, or 235 to 240 mL/kg of body weight.[15,16] It should be noted that the ratio of interstitial fluid volume to plasma volume in the sheep fetus (3:1) is similar to that which occurs in the adult. But when this ratio is corrected for the roughly 30% of the fetal plasma that circulates outside the fetal body (i.e., in the umbilical cord and placenta) the ratio of interstitial-to-plasma volume becomes 4.4:1 in the fetus. This clearly indicates that the interstitial space of the fetus is expanded relative to that of the adult. The elevated interstitial volume is consistent with the observation that interstitial compliance in the ovine fetus is roughly 10 times that observed in the adult.[15] Because the weight-normalized fetal plasma volume (76 mL/kg) does not vary with fetal weight over the range of 1 to 4 kg fetal weight,[14] the large decrease in fetal extracellular fluid volume with advancing gestational age must be a reduction in interstitial fluid volume rather than plasma volume.

Blood Volume

The volume of blood circulating in the fetus is considerably greater than that in the newborn, because roughly one third of the fetal blood volume is contained in the cord and fetal side of the placenta.[17] Reported values for fetuses of several species are shown in Table 137-1. These data should be interpreted cautiously because the potential exists for major methodologic errors. Human data are derived from fetuses with anemia receiving intrauterine blood transfusions. The fetoplacental blood volume in the human fetus increases from 100 to 150 mL (130-200 mL/kg fetal body weight) at 25 weeks gestation to 300 to 350 mL (130-160 mL/kg fetal body weight) at 35 weeks gestation.[18,19] Total placentofetal blood volume in human neonates at term is approximately 120 mL/kg of which 70 mL/kg is in the fetus and 50 mL/kg in the placenta.[20] Changes in fetal blood volume can occur by fetal-to-maternal hemorrhage and by fetal-to-fetal transfusion in monochorionic twins. Large fetomaternal hemorrhages can induce acute hypovolemia and fetal death. Fetuses that survive a large fetomaternal hemorrhage are born with anemia. The more profound the anemia at birth the higher the risk for adverse neonatal outcome.[21] Fetofetal transfusion develops in monochorionic twins via placental vascular anastomoses. If a pressure imbalance exists between the twin circulations, for example via arteriovenous anastomoses, a net transfusion of blood occurs from one twin (donor) to the other (recipient). This results in hypovolemia, a decrease in interstitial volume, and oligohydramnios in the donor twin and hypervolemia, increased interstitial volume (hydrops), and polyhydramnios in the recipient twin.[22] Thus abnormalities in circulating fetal blood volume in the form of large fetomaternal hemorrhage and twin-twin transfusions result in considerable morbidity and mortality.

Lymph and Lymph Flow

The volume of fluid within the lymphatic system is small and averages only 1 mL/kg body weight in adult dogs as estimated from lymph flow dynamics.[23] An estimate of lymphatic volume in the fetus or neonate has not been made. However, it is reasonable to speculate that developmental changes exist in lymphatic volume.[24]

A few estimates of lymph flow in developing animals allow comparison with adult values. In studies in unanesthetized fetal sheep, thoracic duct lymph flow averaged 0.25 mL/minute/kg when low-resistance catheters were used and the lymph was returned to the fetal circulation.[25] Basal lymphatic flow rates in the fetus are substantially higher than those in the adult and may

be considerably higher than in the newborn. Thus the lymphatic system of the fetus must handle the increased interstitial fluid and the increased fetal lymphatic flow. In addition, a slight increase in central venous pressure can result in a dramatic decrease in the lymphatic flow rate. Therefore the fetus is particularly susceptible to the development of edema.

Even though lymphatic flow rates in the fetus and neonate are higher than those in the adult, the concentration of protein in the thoracic duct lymph displays an apparently uniform relationship to the plasma protein concentration. Under resting conditions, the thoracic duct lymph protein concentration averages 50% to 75% of the plasma protein concentration in the fetus, newborn, and adult. This does not mean that the absolute protein concentrations are the same, because fetal plasma protein concentrations increase during gestation and average a little more than half of adult values at term (although species-related differences exist).[23,25]

Both fetal and newborn sheep undergo an increase in left thoracic duct lymph flow after vascular volume expansion.[26,27] Extensive vascular volume loading increases the lymph flow rate to a maximum of 3.5 times normal, and draining the thoracic duct externally causes a rapid fall in fetal blood volume of 10% within 2 to 3 hours. Studies in the ovine fetus[28-30] have found that angiotensin II augments left thoracic duct lymph flow and atrial natriuretic factor suppresses lymph flow.

Maldevelopment of the lymphatic system can lead to lymphedema, congenital chylothorax, ascites, or hydrops fetalis. The dysplastic lymphatics obstruct the lymph flow and increase lymphatic pressure until lymph starts to leak into the surrounding tissues. The dysplastic lymphatics can be hypoplastic, hyperplastic, or lymphangiomatous. The pathogenesis is not completely understood, but members of the vascular endothelial growth factor and angiopoietin families seem to have an important role in lymphatic development.[31]

Amniotic Fluid Volume

The fetal membranes surround amniotic fluid. Amniotic fluid volume (AFV) is largely dependent on fetal organ function in the second half of gestation and is regulated within a narrow range to maintain fetal fluid status.[32] Therefore it can be regarded as one of the fetal body fluid compartments. During an uncomplicated pregnancy AFV shows a slow increase from 350 mL at 20 weeks gestation to 700 mL at term.[33] The chemical composition of amniotic fluid also changes with gestation. Up to around the 20th week it reflects that of fetal extracellular fluid because the skin of the fetus is permeable to the free exchange of substances. When fetal urine begins to enter the amniotic sac, amniotic fluid osmolarity decreases slightly compared with fetal blood and decreases further after keratinization of the fetal skin until it reaches values of 250 to 260 mOsm/kg water near term.

With progress of gestation, fetal organ function becomes more and more important for the regulation of AFV. After midgestation, the two primary sources of amniotic fluid are fetal urine and tracheal and pulmonary fluid secretion. After midgestation the fetus produces 300 mL/kg of hypotonic urine per day. This reduces amniotic fluid osmolarity and provides a large potential force for the outward flow of water across the intramembranous pathway. The fetus secretes 60 to 100 mL/kg of tracheal and pulmonary fluid each day, which serves to expand the airways and promote normal lung growth. This fluid is formed by an active secretion of chloride ions into the alveolar spaces, resulting in a progressive accumulation of fluid in the lungs as gestation progresses. Because the secretion of lung fluid is far in excess of that needed for volume expansion of the lungs, the excess lung fluid exits through the trachea. Rather than a gradual egress, fluid appears to flow out of the trachea in bouts and either is swallowed or enters the amniotic fluid.[34] In fetal lambs, the tracheal flow rate averages 4.4 mL/kg/hour during the latter half of gestation,[34-36] and, in a 24-hour period, this volume represents approximately 10% to 15% of body weight. The volume of fluid that resides in the airways during the fetal period depends on the developmental stage of the lungs. Volume is very low early in gestation and increases rapidly with the accelerated lung growth that occurs late in gestation. At term gestation in fetal lambs, lung liquid volume averages 45 mL/kg of body weight,[34] or slightly more than half of the plasma volume. This large volume suggests that lung liquid may be a potential source of fluid to the fetus; however, it is not certain how easily fetal lung fluid can be transferred to the circulation.

Removal of amniotic fluid occurs by fetal swallowing of approximately 200 to 250 mL/kg/day and by intramembranous absorption of amniotic fluid into the fetal blood, which perfuses the fetal surface of the placenta. Swallowing during the perinatal period is episodic, and the volume of fluid swallowed in one event may be as large as 100 to 200 mL, which is roughly equal to 3% to 5% of body weight. Increasing or decreasing intramembranous absorption seems to be the main way by which AFV is altered, although the precise mechanism of regulation remains elusive. The primary mechanism that drives intramembranous volume flow is not passive osmosis. Instead it has been suggested that amniotic fluid with all its dissolved solutes is transported across the amniotic membrane via bulk flow transfer by a yet unspecified vesicular transport mechanism.[37] Aquaporins may also take part in amniotic fluid absorption,[38] but it is not known what role they play or whether abnormalities in either their type or number contribute to fetal water-related disorders.

Near term the daily amniotic fluid turnover of 1000 mL is higher than the absolute AFV of 700 to 800 mL. Therefore AFV must be highly regulated to avoid oligohydramnios or polyhydramnios. Regulatory mechanisms for AFV act at three levels: (1) *Transfer of water between mother and fetus across the placenta*. Transplacental transfer is dependent on the existence of hydrostatic and/or colloid osmotic pressure differences between fetal and maternal vessels.[39] Placental water transfer between mother and fetus can serve as a reservoir to stabilize fetal extracellular volume and blood pressure. The intravascular infusion of large amounts of concentrated NaCl into fetal sheep did not result in fetal water accumulation as predicted but instead resulted in the transfer of all of the infused sodium and chloride across the placenta to the mother either against or in the absence of chemical concentration gradients.[40] The intravascular infusion of large volumes of physiologic crystalloid solutions in fetal sheep similarly resulted in the transfer of large amounts of water and solute across the placenta to the mother.[25] These observations suggest that a normal fetus can protect itself against both volume and salt overloads by rapid transfer of excess to the mother. Reduced fetal blood pressure releases fetal angiotensin. This increases the resistance in fetal placental precapillary vessels, reduces fetal placental capillary pressure, and thereby promotes water transfer from mother to fetus to restore fetal blood pressure.[41] (2) *Regulation of flow between the amniotic cavity and the fetus*. Increasing or decreasing intramembranous absorption appears to be the main mechanism to regulate flow between amniotic cavity and fetus. When fetal urine output is increased by intravascular infusion of physiologic saline solution, amniotic fluid volume increases by only a fraction of the infused volume because the excess amniotic fluid is absorbed through the intramembranous pathway.[25] (3) *Changes of maternal hydration*. Maternal hydration with water significantly increases AFV in oligohydramnios,[42] but this effect is seen only when hypotonic solutions are infused and maternal osmolality is reduced.[43]

CHANGES IN BODY FLUID COMPARTMENTS IN THE IMMEDIATE NEONATAL PERIOD

Prelabor Changes

Several observations collectively suggest that the fetus undergoes significant changes in its fluid status during the last few days, hours, and minutes before delivery. Studies have shown that the lungs begin to dry out several days before delivery,[34,44] in large part because the amount of fluid secreted by the lungs gradually decreases.[35] The reduction in fetal lung liquid secretion is mediated by an increased expression of epithelial sodium channels and sodium-potassium adenosine triphosphatase near birth, which changes epithelial cell ion transport from predominantly chloride secretion to predominantly sodium absorption. Epinephrine and other hormones (vasopressin, cortisol, and aldosterone), which are released just before and during labor, have a critical role in triggering this switch from liquid secretion to absorption.[45] Therefore infants born after elective cesarean section, who did not have the labor-induced clearance of lung liquid, have an increased risk for postnatal respiratory disease.[46] Relatively large increases in arterial pressure (20%) also occur in fetal lambs during the last few days before delivery.[47] If this pressure were transmitted to the capillaries, it would exert a major effect on the transcapillary distribution of fluid and perhaps protein.

Changes During Labor and Delivery

Although it was once thought that the amount of water in the newborn infant varied with mode of delivery, studies suggest that normal infants born vaginally or by cesarean section have an average water content of 75%, irrespective of mode of delivery.[48]

Blood volume decreases in both human and animal fetuses during labor and delivery. A decrease in circulating fetal plasma and blood volumes during labor and delivery by 18% and 12%, respectively, was found in fetal sheep.[47] These results are consistent with studies in humans. The umbilical vein hematocrit averages 44% in infants delivered by elective cesarean section without labor[49] and 51% immediately after delivery if labor has occurred.[20,50-53] Assuming that red blood cells (RBCs) are not released into the circulation with labor, this ratio of 44:51 demonstrates that the circulating blood volume is reduced by 14%. This corresponds to a reduction in plasma volume of 25%.

The mechanisms that mediate the loss of plasma during labor and delivery are multifactorial. Uterine contractions cause a direct compression or transformational change of the fetus.[54] As during a Valsalva maneuver, this elevates fetal vascular pressures, reducing circulating blood volume by 2% to 4%.[14,55] Furthermore, hypoxia reduces circulating blood volume in fetal sheep, resulting from a loss of plasma volume into the interstitial space.[56,57] The placenta may also contribute to the reduction in fetal blood volume during labor and delivery in that severe hypoxia may produce an in utero translocation of fetal blood out of the placenta and into the fetal body.[58] This leads to a rise in capillary pressure and the transcapillary filtration of fluid out of the fetal circulation. In addition, major changes in the plasma concentrations of many vasoactive hormones occur during labor and delivery. Although the effects of only a few hormones have been investigated, arginine vasopressin,[59] norepinephrine, cortisol,[60] and atrial natriuretic factor[16,61-63] have the ability to reduce the circulating blood volume and plasma volume when acutely infused into the circulation of fetal sheep at low to moderate rates. The umbilical cord concentrations of each of these hormones are elevated after vaginal delivery in humans, suggesting that these hormones may indeed play a role in mediating the shift of fluid from the plasma into the interstitial compartment at the time of labor and delivery.

Neonatal Weight Loss

Adaptation to extrauterine life represents a transition from aquatic to terrestric life and encompasses marked changes in body water content and fluid homeostasis. During the first postnatal days a weight loss of approximately 10% of birth weight occurs in healthy term neonates caused by a reduction of the extracellular volume.[6] A postnatal weight loss of up to 15% of birth weight occurs in low-birth-weight infants[64] and in extremely low-birth-weight infants.[65] Measurements of body water compartments demonstrated that this weight loss reflects a decrease in TBW. In low-birth-weight neonates with respiratory distress syndrome (mean birth weight 1558 g) the mean postnatal weight loss was 181 g (7.7% of birth weight). A concurrent reduction occurred in TBW by 183 mL and in extracellular volume by 204 mL.[66] These findings were confirmed in a more recent study in preterm neonates after normal intrauterine growth.[3] The postnatal weight loss of 7.8% of birth weight was caused by a reduction of the extracellular volume accompanied by a negative fluid and sodium balance. No evidence of tissue catabolism was found because body solids remained unchanged. Furthermore, nitrogen retention and energy intake was sufficient to meet energy expenditure by day 2.

Postnatal weight loss in SGA neonates differs somewhat from that of AGA infants. Postnatal weight loss in seven SGA preterm neonates (birth weight <5th percentile) with a mean gestational age of 35 weeks was only 5% and resulted from a proportionate reduction of body water and body solids.[67] This study included no information about fluid intake or diuresis and no AGA control group. In another study comparing five SGA preterm neonates (mean gestational age 35 weeks) with 14 weight-matched AGA neonates (mean gestational age 31 weeks) the SGA neonates had a maximal postnatal weight loss of only 2% compared with a maximal postnatal weight loss of 8% in the AGA control infants. On days 4 to 6 of life the SGA neonates had already regained birth weight, and no change was detectable in TBW or body solids, whereas, at the same postnatal age, body weight and TBW in the AGA neonates was significantly lower than at birth.[68] No differences were found in day-to-day fluid and energy intake during the first week of life between the SGA and AGA groups; however, the AGA infants had a higher urine output during this time interval. A possible reason for the attenuated postnatal increase in urine output in SGA preterm neonates is their altered hemodynamic adaptation. SGA preterm neonates did not exhibit the postnatal increase in cardiac output observed in the AGA neonates.[69]

It is important to emphasize that, in the management of fluids and electrolytes in low-birth-weight infants, the appropriate amount of weight loss needs to be anticipated and facilitated. When the normal contraction of the extracellular fluid volume was limited by liberal administration of IV fluids, the incidence of untoward outcomes such as patent ductus arteriosus, bronchopulmonary dysplasia, and necrotizing enterocolitis was increased in low-birth-weight infants.[70-73]

CHANGES IN BLOOD VOLUME IN THE IMMEDIATE NEONATAL PERIOD

Measurement of Red Cell Mass, Plasma Volume, Blood Volume, and Interstitial Fluid Volume

It is difficult to measure red cell mass, plasma, blood, or interstitial fluid volumes in the fetus and newborn (as well as in the adult) accurately because the methods are technically complex and time consuming. In the following paragraphs methodologic issues of body fluid measurements relevant for the interpretation of data are discussed.

Red Cell Mass

Red cell mass is determined as the dilution space of a known quantity of labeled erythrocytes. For a measurement blood is taken from the study subject, mixed with the erythrocyte label,

and then retransfused into the subject. The classic red cell label radioactive ^{51}Cr[74] is no longer acceptable for use in infants. More recently biotin has been validated as red cell label in adults[75] and in neonates.[76]

Plasma Volume

Plasma volume is measured as the dilution space of labeled high-molecular-weight substances (such as albumin or plasma proteins) after injection of a labeling substance into the circulation. For measurements in neonates radioactively labeled albumin[77] or albumin labeled with Evans Blue[78] or with indocyanine green[79] is used. These measurements frequently are corrected for loss of the label from the intravascular space by extrapolating the concentration-time curve backward to the time of injection. This requires several blood samples. Even with this correction, plasma volume tends to be overestimated for two major reasons: (1) All plasma labels are rapidly lost from the circulation through the capillary membranes of organs, such as the liver, which have high permeabilities even to high-molecular-weight substances. Extrapolating back to the time of injection does not correct for this loss because it is too rapid to be detected. (2) Most labels such as radioisotopes or dyes are not completely bound to the plasma proteins when injected into the circulation. The unbound labels are rapidly lost from the circulation and again lead to an overestimation of plasma volume. The extent of this overestimation has been explored in the unanesthetized sheep fetus. Fetal blood volume determined with radiolabeled albumin and fibrinogen was 11 mL/kg higher than blood volume determined with labeled RBCs (121 mL/kg vs. 110 mL/kg).[14]

Blood Volume

When blood volume is calculated from measured plasma volume or red cell mass and hematocrit, the hematocrit used is a potential source for error. It is well established that, because of rheologic factors, the hematocrit of the blood in the capillaries of the body (or in small-diameter glass tubes) is only 75% of the hematocrit in larger blood vessels. The net effect is to lower the average hematocrit within the body as a whole in relationship to that measured in blood sampled from large vessels such as the veins. To overcome this problem, investigators have advocated the use of a correction factor between 0.70 and 0.90 in the neonate, as well as in the adult. However, from a mechanistic viewpoint, it has been estimated that less than 10% of the blood in the body is in the systemic capillaries. If the hematocrit in capillaries is reduced by 25% compared with that of the large vessels as noted earlier, the whole body–to–large vessel hematocrit ratio should average 0.975. The mean body–venous hematocrit ratio measured in critically ill children was approximately 0.90.[80]

When blood volume is calculated from plasma volume and hematocrit, the errors in plasma volume measurement produce errors in blood volume determinations as well. Creasy and colleagues[81] have demonstrated that blood volume as determined with ^{51}Cr-labeled RBCs averaged 113.3 mL/kg in fetal sheep. In contrast, when ^{125}I-labeled albumin was used to estimate blood volume, it averaged 156.1 mL/kg. Thus, given the present state of the art, a RBC label provides a better estimate of blood volume provided that errors caused by unbound labels are minimized.

Measurement of Interstitial Volume

Interstitial fluid volume can be calculated as the difference between extracellular fluid volume and plasma volume. However, measurement of each of these volumes is subject to error. Extracellular volume has been measured as the volume of distribution of a variety of labels injected into the circulation. Each of these labels has a unique distribution space that does not exactly match the biologic extracellular volume. Therefore the comparison of extracellular volumes measured with different methods is difficult. Some of the labels (such as radioactive sodium ion) enter the cells or are metabolized and thus overestimate volume, but others (e.g., sucrose) do not penetrate the dense connective tissue water and thus measure only the readily exchangeable extracellular volume. Bromide and sucrose are the more widely used extracellular fluid markers in the newborn.[82,83] Bromide may not be adequate in the fetus because of transplacental losses,[82] and it has a considerable intracellular distribution during the fetal and neonatal periods.[83] Sucrose has been validated in neonates and children[84]; it does not enter cells and is not metabolized.

Fluid Distribution Between Intravascular and Interstitial Compartment

Few studies have simultaneously measured plasma and interstitial fluid volumes. In term baboon neonates, interstitial volume calculated from an extracellular volume of 392 mL/kg (corrected bromide space) minus a plasma volume of 50 mL/kg (Evans Blue) was 342 mL/kg. Thus the interstitial-plasma volume ratio was 6.8:1.[85] In human term neonates interstitial volume calculated from an extracellular volume of 376 mL/kg (corrected bromide space) minus a plasma volume of 43 mL/kg (Evans Blue) was 333 mL/kg; the interstitial-plasma volume ratio was 7.7:1.[7] In human preterm neonates (<1500 g) interstitial volume calculated from an extracellular volume of 444 mL/kg (sucrose space) minus a plasma volume of 46 mL/kg (Evans Blue) was 398 mL/kg. The interstitial-plasma volume ratio was 8.6:1.[3]

In contrast, the interstitial and plasma volumes in 1- to 3-week-old lambs have been reported to be 283 and 54 mL/kg, respectively.[82] The interstitial-plasma volume ratio of 5.2:1 is significantly lower than that calculated for the human newborn infant. Furthermore, in anesthetized newborn puppies, the interstitial volume is 172 mL/kg and the plasma volume is 82 mL/kg.[86] The interstitial-plasma volume ratio of 2.1:1 is considerably lower than the values for the human neonate and even lower than the ratio observed for the ovine neonate, suggesting that considerable differences may exist in the ratio of interstitial volume to plasma volumes in the newborns of different species. Some of these discrepancies appear to be related to differences in hematocrit at birth. For example, the high hematocrit of human neonates is associated with a low plasma volume, which, in turn, elevates the ratio of interstitial-to-plasma volume. In comparison, the much lower hematocrit in lambs produces a lower interstitial fluid–to–plasma volume ratio. Furthermore, methodologic differences may contribute to interstudy variability.

In principle, it is clear that the distribution of fluid between the intravascular and interstitial compartments depends on the equilibrium across the capillary membrane and the balance between capillary permeability and lymphatic function. Several important differences exist in the fluid homeostasis across the capillary membrane between the human fetus or neonate and adult. The fetus and neonate operate at low intravascular hydrostatic and oncotic pressures, and a high permeability of the capillary wall and a high lymphatic flow exist.

1. The intravascular hydrostatic pressure, which favors fluid movement out of the intravascular space, is low in the fetus and neonate. Mean blood pressure in the first 12 hours of life is 37 mm Hg for a 1000-g neonate and increases to 50 mm Hg for a term neonate.[87] The lower limit of mean blood pressure for extremely low-birth-weight infants is lower than that of more mature neonates and likewise increases over the first hours to days of life.[88]
2. The intravascular oncotic pressure is low because of low plasma albumin concentrations in the fetus and neonate, which increases from 2 g/dL at 24 weeks gestation to just above 3 g/dL at term.[89] Nonetheless, routinely increasing albumin concentrations in preterm infants has no therapeutic benefit.[90]

3. The capillary wall is much more permeable to albumin in the human neonate than in the adult. The transcapillary escape rate of albumin in term neonates is 18% to 20% per hour, which is approximately three to four times greater than in adults.[91] Studies in the sheep support this hypothesis in that the capillaries of the ovine fetus have a filtration coefficient five times that of adult values[15] and a permeability for plasma proteins 15 times that in the adult.[92] Capillary permeability to plasma proteins in the lungs may be the same in near-term fetal and neonatal sheep.[93]
4. It has been known for more than 60 years that lymph flow from subcutaneous tissue in anesthetized puppies is approximately twice that observed in adult dogs when expressed in relation to body weight.[94] Furthermore, lymph flow from the lungs is higher in anesthetized newborn lambs and puppies than in their adult counterparts.[61,95] Other studies in unanesthetized newborn lambs have also demonstrated higher pulmonary lymph flow rates.[92,93] These observations support the concept that the local, as well as whole body, lymph flow rates (in relation to body weight) are significantly greater in the neonatal period than later in life. The increased lymphatic flow during the neonatal period is probably indicative of the elevated interstitial volume in the neonate in relation to the adult and the higher capillary permeability.

Volumes Under Steady-state Conditions

Reported blood volumes in neonates at birth vary considerably for methodologic reasons. Blood volumes calculated from plasma labels tend to be higher than blood volumes calculated with red cell labels. In addition, with "late" cord clamping, neonates receive a placental transfusion and have higher blood volumes (Table 137-2).

No consistent differences exist in blood volumes at birth between term and preterm neonates, and blood volume in preterm neonates remains stable despite the postnatal reduction of extracellular volume during the first days of life.[3]

Intrauterine growth restriction is not necessarily associated with an increased plasma volume or red cell mass. Plasma volume measured by Evans Blue dilution in 14 term SGA neonates (37 ± 4 mL/kg) did not differ from that in AGA neonates (37 ± 6 mL/kg), and also no difference was observed in RBC volume (SGA: 69 ± 17 mL/kg; AGA: 63 ± 12 mL/kg) or blood volume (SGA: 105 ± 18 mL/kg; AGA: 101 ± 16 mL/kg) calculated from plasma volume and hematocrit.[96] Yet, in the subgroup of SGA neonates who had polycythemia after birth, blood volume was increased. Blood volume in SGA neonates with polycythemia calculated from hematocrit changes during exchange transfusion was 106 mL/kg compared with 86 mL/kg in AGA neonates with polycythemia.[97] The increased RBC volume can be the result of an adaptation to chronic intrauterine hypoxemia (as indicated by increased erythropoietin levels in SGA neonates) or the consequence of an acute placentofetal transfusion.

TABLE 137-2

Blood, Plasma, and Red Blood Cell Volumes in Newborns

Blood Volume (mL/kg)	Plasma Volume (mL/kg)	RBC Volume (mL/kg)	Neonate	Age (days)	Cord Clamping	Reference
85*	41†	41‡	Term	0-1	Variable	50
77†			Term	0	Early	51
103†					Late

*Determined with RBC plus plasma label.
†Determined with plasma label.
‡Determined with RBC label.

The relationship between blood and plasma volumes in the neonate has been explored in several studies. Neonates with high blood volumes also have high RBC volumes but decreased plasma volumes.[50,96] The weight-normalized RBC volume varies directly with the venous hematocrit, whereas plasma volume varies inversely with hematocrit (see Table 137-2).

The relationship between hematocrit and true circulating red cell mass has received considerable attention because RBC volume measurements are not available in daily clinical practice and the hematocrit is used routinely to estimate RBC volume to guide transfusion practices. Correlations vary from weak ($r = 0.5$)[98] to strong ($r = 0.907$)[99] between venous hematocrit and RBC volume in neonates. However, RBC volumes for individual neonates with a hematocrit of 30 ranged from 15 to 28 mL/kg even when a strong correlation was present. This range is of considerable clinical significance[99] and demonstrates that hematocrit is a relatively poor indicator of RBC volume.

Effects of Placental Transfusion

The single most important factor that affects blood volume and hence plasma volume in the newborn during the first few days of life is the extent of the placental transfusion that occurs at the time of delivery.[20,50,52,53] Total placentofetal blood volume decreases from 180 mL/kg fetal weight at 18 weeks gestation to 120 mL/kg at term of which 70 mL/kg is in the fetus and 50 mL/kg in the placenta.[20] The distribution of blood volume between neonate and placenta after delivery is influenced by a number of perinatal events. A fetoplacental transfusion that displaces blood from the fetus to the placenta occurs when the diameter of the umbilical arteries or the pressure gradient between the arteries and the umbilical vein increases. A fetoplacental transfusion is augmented by maternal hypotension, cord compression, holding of the infant above the placenta, or cesarean section. A placentofetal transfusion, which displaces blood from the placenta to the fetus, occurs when the diameter of the umbilical vein or the pressure gradient between umbilical vein and central veins in the fetus increases. Placentofetal transfusion is augmented by intrauterine asphyxia, uterine contractions, and increases in maternal uterine blood flow.[20]

The timing of cord clamping markedly influences the placental transfusion and neonatal blood volume. If the umbilical cord is clamped immediately after delivery, the hematocrit in the newborn infant averages 48% to 51% and is stable over a period of days.[20,50,52,53] However, if the cord is not clamped immediately and the newborn infant is positioned at or below the level of the placenta, the placenta gradually transfuses the neonate with blood, which reaches a maximum at 3 to 4 minutes after delivery.[20,52,53] This placental transfusion of 25 to 50 mL/kg represents an increase in RBC and blood volumes within the neonate of 50%.[52] With delayed cord clamping, the hematocrit gradually increases over 30 minutes to 2 hours to average 60% to 65%, or higher if the cords are stripped.[20,52,53] This increase in hematocrit is due to a loss of plasma from the circulation. Further increases in hematocrit occur over the next 2 hours, as a total of 30 mL/kg of plasma is lost from the circulation during the first 4 hours of life in infants with late cord clamping. This reduction in plasma volume is due largely to a shift of fluid from the intravascular into the interstitial space, although urine flow is elevated as well.[53] In a recent randomized controlled trial, blood volume in preterm infants (24-32 weeks gestation) after delayed cord clamping (74 ± 11 mL/kg) was significantly greater than after early cord clamping (63 ± 8 mL/kg)). Late cord clamping was more effective in increasing neonatal blood volume after vaginal

delivery than after cesarean section.[100] Placental transfusion has significant circulatory effects and increases neonatal blood pressure, central venous pressure, renal blood flow, and urine flow.[20] Therefore enhancing placental transfusion by late cord clamping has been used as a clinical therapy in term and preterm neonates. In term infants delayed cord clamping reduced the incidence of anemia in early infancy.[101] A reduction in the severity of respiratory distress syndrome,[102] less need for blood transfusions,[103] and a reduction in the incidence of intraventricular hemorrhage and late-onset sepsis[104] have been reported in randomized controlled trials after delayed cord clamping in preterm infants. In a meta-analysis, delayed cord clamping in preterm infants reduced the need for transfusion and the incidence of intraventricular hemorrhage. With delayed cord clamping, infants had higher hematocrit values and serum bilirubin levels but not to an extent that necessitated more therapeutic interventions.[105]

Responses to Hemorrhage

Perinatal blood loss of the fetus or neonate can occur after rupture of umbilical vessels, during premature placental separation, by bleeding of the fetus into the maternal circulation (fetomaternal transfusion) or into a twin fetus (fetofetal transfusion), or by internal bleeding, for example, cerebral or intraabdominal hemorrhage.

In adults of several species, including humans, dogs, rats, cats, and sheep, 24 to 48 hours is required for blood volume to return to normal after a loss of blood.[106] This restoration of volume occurs as plasma volume returns to or rises above normal, whereas RBC volume remains reduced. The time required for full volume restoration after hemorrhage in the fetus or neonate is shorter than in the adult. Fetal sheep restore twice the volume within 30 minutes after rapid hemorrhage as in the adult.[107] The ovine fetus also restores its blood volume to normal within 3 to 4 hours after a 30% hemorrhage over 2 hours[108]; that is in one tenth the time required in the adult.[106] This rapid restoration is mediated by a translocation of fluid and protein from the interstitial space into the vascular space but does not appear to be attributable to a net movement of fluid across the placenta.[62] Neonatal kittens and rabbits[109,110] were better able to tolerate blood loss than adults were, in that more blood had to be removed before arterial pressure decreased. This was attributed to a more rapid mobilization of interstitial fluid in the young animals in the first week of life. Neonatal lambs also rapidly restore their blood volume to normal after hemorrhage.[111]

Responses to Volume Loading

Intravascular Infusion of Isotonic Solutions

Rapid intravascular infusions of isotonic solutions, such as saline or Ringer's lactate, expand blood volume by only a fraction of the infused volume largely because of a loss of the infused fluid into the interstitial spaces. When adults of several species received intravascular infusions of isotonic crystalloid solutions, average intravascular retention was 20% to 50% of the infused volumes 30 to 60 minutes after rapid infusion. This is quite similar to the response in anesthetized newborn sheep, in that intravascular retention averaged only 30% to 40% after intravascular saline infusions.[26] Yet, in the unanesthetized ovine fetus, average intravascular retention after similar infusions was only 6% to 7% of the infused volume.[112] The reduced intravascular retention of crystalloid during fetal life is due largely to a high interstitial compliance–vascular compliance ratio, as well as a higher capillary filtration coefficient.[15] The increased capillary filtration coefficient permits very rapid fluid movements across the capillary membrane, and the high interstitial-to-vascular compliance ratio allows for extensive fluid shifts.

The reduced intravascular retention of fluid in the fetus compared with that of the adult may also be a primary factor in determining the urine flow responses to volume loading. It is well established that, after volume loading, normal adults will excrete the entire volume load through their kidneys over a period of several hours. Newborns of several species, including human and ovine, have a reduced capacity to excrete volume loads. This reduced excretory capacity can, in part, be attributed to the reduced intravascular retention.[113] With high intravascular retention in the adult, plasma renin activity and plasma concentrations of arginine vasopressin and atrial natriuretic factor all change in a direction appropriate for elevating urine flow. In the ovine fetus with a low intravascular retention, plasma arginine vasopressin and renin activity are unchanged, and atrial natriuretic factor undergoes only a transient increase.[113] Thus fetal urine flow rapidly returns to normal after rapid vascular volume expansion because the hormonal stimuli that promote urinary output are not maintained.[113] It has yet to be documented whether this is indeed the mechanism responsible for the diminished response to volume loading in human newborn infants.

Blood Transfusion

Similarly, after intravascular transfusions of blood only a percentage of the transfused volume remains intravascular. In human fetuses with anemia receiving intravascular transfusions, 31% of the transfused volume was lost from the circulation.[19] After late clamping of the umbilical cord in human neonates, plasma volume decreased from 50 mL/kg to 35 mL/kg 2 hours after receiving the placental transfusion.[51] The transcapillary escape rate of albumin increased with the magnitude of the placental transfusion.[114]

Responses to Hypoxia

Newborns with a history of fetal distress and birth asphyxia have elevated blood and plasma volumes (similar to those of normal infants with late cord clamping, even though the cord is clamped immediately after birth[115]). These observations suggest that prenatal hypoxia or asphyxia induces a placental transfusion before delivery. This is consistent with the observation that acute hypoxia promotes a translocation of fetal blood out of the placenta in sheep.[58] In addition, Yao and colleagues[115] have shown that 10 to 20 minutes of hypoxia immediately before delivery in sheep elevates plasma, RBC, and blood volumes in the newborn compared with lambs with early cord clamping. Linderkamp and co-workers[116] also observed that intrauterine hypoxia is associated with an elevated RBC volume in the newborn but that acute, intrapartum asphyxia is not associated with a predelivery placental transfusion. Thus evidence is ample supporting the concept that prenatal hypoxia causes a partial placental transfusion in utero, but its time course, exact extent, and reversibility are unclear.

It has been known for several years that postnatal hypoxia reduces blood volume in the human fetus because of a loss of plasma and proteins from the circulation,[117] but the causes of the reduced volume have not been explained. In the ovine fetus, this reduction in blood volume occurs rapidly and is linearly related to the reduction in arterial oxygen tension[56,57] (a 1% decrease occurs in blood volume for each 1 mm Hg decrease in arterial Po_2). The loss of plasma is undoubtedly due to an elevation of capillary pressure within the fetal body. This phenomenon occurs with no changes in fetal arterial or venous pressure during mild hypoxia (presumably because of vasodilation in selected organs) and is accompanied by increases in arterial and venous pressures with moderate to severe hypoxia.[57]

Fetal and Neonatal Body Water Compartment Volumes With Reference to Growth and Development

Water is the most abundant component of the body and is the solvent in which all metabolic reactions occur. Body water exists in compartments with diverse solute compositions that are separated by semipermeable lipid membranes. Thus, although recognizable anatomic boundaries exist, physiologically these compartments are interconnected.

COMPARTMENTALIZATION OF BODY WATER

Total body water (TBW) includes water both inside and outside of cells and water normally present in the nasorespiratory, gastrointestinal, and genitourinary systems. TBW can be theoretically divided into two main compartments (Figure 138-1). The *anatomic extracellular water* (ECW) includes all water external to cell membranes. *Intracellular water* (ICW) includes all water within cell membranes and constitutes the medium in which chemical reactions of cell metabolism occur. This compartment is heterogeneous and discontinuous; the interior of each cell is separated from the ECW and from the interior of other cells by the semipermeable cell membrane.

The anatomic ECW is functionally subdivided into *physiologic ECW* and *transcellular water.* The physiologic ECW constitutes the medium through which all metabolic exchange occurs; it includes *plasma* (intravascular water) and *interstitial fluid* (ISF). The ISF is the fluid that directly bathes the cells of the body. It is the ECW into which ions and small molecules diffuse freely from plasma. The composition of the physiologic ECF is fairly uniform throughout the body. In addition, potential spaces in the body (pericardial, pleural, peritoneal, and synovial) exist that are normally empty except for a few milliliters of viscous lubricating fluid and are considered to be part of the ISF compartment. Transcellular water includes water in extracellular compartments enclosed by an epithelial membrane, the volume and composition of which are determined by the cellular activity of that membrane. These heterogeneous compartments include the aqueous humor in the eye; the cerebrospinal fluid; and water in the nasorespiratory, gastrointestinal, and genitourinary systems.

ESTIMATION OF BODY WATER COMPARTMENT MASSES AND VOLUMES

All in vivo methods used to measure the mass or volume of body water compartments are of limited accuracy and precision. Accuracy of measurement is limited by the degree to which the assumptions on which methods are based are true. Precision is limited by biologic variability (body water compartment volumes may vary during the course of a day) and analytic error. Body water compartment volumes cannot be measured with a precision much greater than 2% to 5% in the healthy adult.[1-6] Therefore these techniques are better suited to estimate average body water compartment volumes in groups of subjects rather those of individual persons. Sutcliff[6] and Ellis[7] have published in-depth reviews of the techniques discussed in the following subsections.

Total Body Water

Desiccation

With this method, TBW is calculated as the difference in body mass before and after whole body desiccation to a constant mass at 100°C. Although it is most accurate, this technique is obviously not applicable to in vivo studies.

Densitometry

Fat has a much lower density (0.92) than lean body mass (LBM; 1.10). Therefore the proportion of body mass that is fat can be determined from whole body density by underwater weighing, as follows:

$$(4.570 / \text{Whole body density}) - 4.142$$

Whole body density must be corrected for air in the lungs and the gastrointestinal tract. The error in measurement of the former is the major source of analytic error with this method. LBM is calculated as the difference between total body mass and fat mass. This technique assumes that the density of fat and LBM are constant. This is more true for fat than for LBM, even in adults.[7-12] TBW mass can then be calculated from LBM, assuming that TBW is a constant 73.2% of the latter. This is a reasonable assumption for healthy young white adults. Still this proportion is not a constant in this population, only an average value. Moreover, for samples of very young or old persons or of persons of different ethnicity or with disease states, the proportion is different and population specific.

This technique is not applicable to the fetus, newborn, and infant because the density of LBM increases during development, the proportion of LBM that is water decreases during development, and substantial subject cooperation is required. Determination of body density by air-displacement plethysmography[13] obviates the last limitation, but not the others.

Indicator Dilution Method

This method is based on *Fick's principle:* if a known amount of a solute (indicator) is administered to a subject and limited to and distributed uniformly throughout a body water compartment, then the volume of that compartment can be calculated as the quotient of the amount administered and the concentration of the indicator in body water within the compartment of interest. The ideal indicator (1) is nontoxic; (2) is limited to and uniformly distributed throughout the body water compartment; (3) is not lost from the body during the time necessary for the indicator to distribute throughout the compartment evenly; (4) is metabolically inert; and (5) has a concentration that can be easily, precisely, and accurately measurable in small volumes of body fluid. No ideal indicators exist for measurement of any body water compartment volumes. Nevertheless, the indicator dilution method is the most reliable method of determining TBW and is the method used to validate other methods.

Figure 138-2 is a schematic diagram of the volumes of distribution of indicators used to estimate body water compartment volumes. Most are excreted in the urine, are metabolized, or exchange with components of body solids. All these properties will lead to overestimation of the volume of the body compartment, if

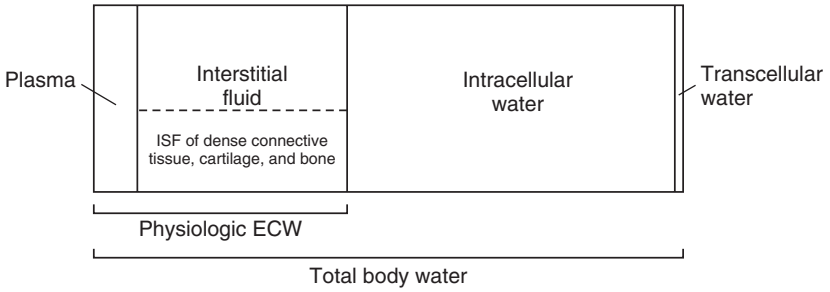

Figure 138-1 Body water compartments. The anatomic extracellular water (ECW) compartment includes the physiologic extracellular water compartment and the transcellular water compartment. *ISF,* Interstitial fluid. *(From Lorenz JM, Kleinman LI: Physiology and pathophysiology of body water and electrolytes. In Kaplan L, Pesce A, editors:* Clinical chemistry, *4th ed, St. Louis, 2003, Mosby.)*

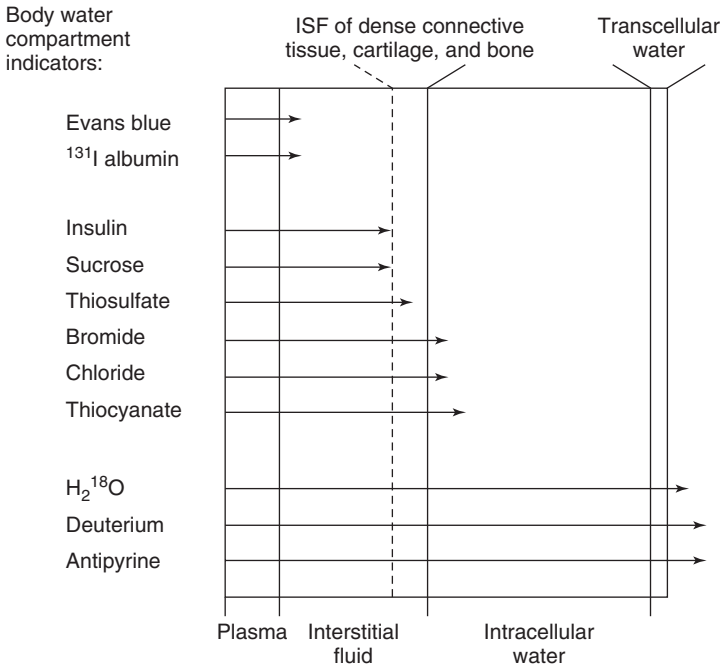

Figure 138-2 Apparent volumes of distribution of indicators used to estimate body water compartment volumes. *ISF,* Interstitial fluid.

corrections are not made. Depending on how the indicator is "lost" from the compartment, the rate of this loss, and the time required for the indicator to distribute uniformly throughout a body water compartment, two methods are used to determine an indicator's volume of distribution: the plateau method and the back-extrapolation method. Assumptions implicit in both methods are not strictly valid. Theoretically volume of distribution of a TBW indicator with the former method is greater than the true volume of the body water compartment, and it is less than the true volume of the body water compartment with the latter method.[14,15] In practice, however, both methods yield similar results in infants[16] and adults.[17]

Antipyrine, deuterium, and ^{18}O-labeled water are used as indicators of TBW volume. Antipyrine is less difficult to analyze than isotopes of water, but it is relatively rapidly metabolized. In addition, approximately 10% is protein bound. With the use of the back-extrapolation method to correct for metabolism, the antipyrine results in an apparent volume of distribution less than true TBW volume.[18] Measurement of isotopes of water requires elaborate equipment. Moreover, the volume of distribution of hydrogen water isotopes is approximately 4% higher than TBW measured by desiccation, as a result of exchange of nonaqueous exchangeable hydrogen atoms, mainly on carboxyl and hydroxyl groups.[19] $H_2{}^{18}O$ also exchanges with nonaqueous exchangeable oxygen atoms, but to a lesser extent—its volume of distribution is approximately 1% greater than TBW volume.[20,21]

As the result of the larger extracellular space in the term infant, the overestimation of TBW volume with deuterium, compared with that by desiccation and $H_2{}^{18}O$, is less than in the adult, that is, approximately 2%. This is because the ratio of TBW to protein is lower when a greater proportion of TBW is ECW and because protein is the primary nonaqueous source of exchangeable hydrogen atoms. This demonstrates the pitfalls of "correcting" indicator spaces in infants on the basis of data from healthy adults.

Bioelectrical Impedance Analysis, Single Frequency

Total body single-frequency bioelectrical impedance analysis (SF-BIA) is a frequently used bedside method of estimating TBW mass.[22,23] The advantages of this technique are that it is noninvasive, safe, simple, and rapid and the equipment is portable and inexpensive. It is based on the assumptions that only water can conduct electricity within the body and that the body is a homogeneous, perfect cylinder with a uniform cross-sectional area. Bioelectrical impedance is determined by measuring the voltage drop when a small electrical current (800 μA) is applied across the skin of the subject at a frequency capable of penetrating cell membranes (usually 50 kHz). The impedance is composed of two components: the resistance and the reactance. The magnitude of the resistance component seems to be well correlated with the volumes of distribution of tritiated water and deuterium.[5,24-26] TBW is calculated from resistance with a regression equation derived for the population of interest by using TBW volume determined

by a reference standard to correct for the previous assumptions. A major limitation of this technique is that the regression equations do not provide accurate estimates in populations other than those in which they were derived. Therefore prediction equations must be validated in or derived for each population in which they are used. Validation consists of comparison with a reference method. Another major limitation is that equations developed in normally hydrated patients are not valid for overhydrated or underhydrated individuals.[27,28] Apparently, electrolyte imbalances influence SF-BMI independently of fluid changes.[29] Furthermore, SF-BMI cannot accurately assess acute changes in TBW in individuals.[30]

Measurement of TBW using SF-BIA has been reported to compare favorably with the volume of distribution of $H_2{}^{18}O$ in neonates.[31-34] However, considerable variation exists in the regression equations used to predict TBW among these studies. It is unclear whether this variation is the result of differences in electrode position,[34,35] postnatal age,[31] gestational age,[34] birth weight, or possibly other factors. Moreover, derived regression equations incorporating body weight alone correlated as well as or better than (compared with those incorporating resistance measured with BIA) the volume of distribution of $H_2{}^{18}O$.[31,33,34]

Total Body Electrical Conductivity

Total body electrical conductivity (TOBEC) is an alternative bioelectrical technique for estimating TBW. Eddy currents are induced in the conductive tissues of the body by placing the patient in a coil that generates a time-varying low-energy electromagnetic field. These eddy currents, in turn, change the impedance of the coil. The difference in the impedance with the coil empty and the coil with the body in place is the TOBEC number. The latter is proportional to the conducting volume of the body, that is, to TBW. Estimation of TBW volume requires a regression equation, which (as with BIA) must be derived by using a reference standard. An instrument is available for infants. The TOBEC number has been shown to correlate well with the volume of distribution of $H_2{}^{18}O$ in healthy infants,[36] and a regression equation has been derived for healthy infants 2 to 12 weeks of age.[37] The major limitations of this technique are that the regression equation may not provide accurate estimates in populations other than that from which it was derived and the technique is applicable only to neonates who do not require support that would preclude safely placing them in the instrument. Moreover, the instrument is expensive and not portable.

Extracellular Water

Total Body Chloride

Total body chloride content, measured by neutron activation in vivo[38] or analysis of total body ash content, has been used to estimate the ECW volume. ECW is calculated as the quotient of total body chloride content and ECF chloride concentration, assuming that all body chloride is extracellular and is uniformly distributed throughout the ECW compartment. However, intracellular chloride exists, principally in red blood cells. Moreover, the apparatus required for neutron activation analysis is expensive, is difficult to calibrate, and requires irradiation. The last feature precludes the use of this method in infants and children.

Indicator Dilution

Inulin, sucrose, thiosulfate, and bromide are commonly used indicators to estimate ECW volume in neonates, infants, children, and adults. As illustrated in Figure 138-2, the volume measured depends on the degree to which the indicator leaks into cells or penetrates the ISF of dense connective tissue. Under normal circumstances, ISF does not behave as a simple aqueous solution. Solutes do not penetrate as easily into the ISF of dense connective tissue, cartilage, or bone. Therefore, when indicators are used to estimate ECW volume, it is more correct to refer to the value of the indicator *volume of distribution*. Correction of the volume of distribution of ECW indicators for volume of protein in plasma and (in the case of indicators that exist in solution as ions) for the Donnan equilibrium is required when the concentration of the indicator is measured in the plasma.[39]

The proportion of ECW contained in the ISF of dense connective tissue is lower in infants than in children and lower in children than in adults. Therefore differences between the physiologic ECW volume and the volumes of distribution of indicators for which diffusion into connective tissue ISF is limited (inulin, sucrose, thiosulfate) are less in the neonate than in the adult; these differences increase during development. Bromide penetrates connective tissue ISF well, but it is not completely limited to the ECW compartment; it diffuses to some extent into ICW, predominantly that of red blood cells. In disease states, bromide penetration into ICW may be even greater.[40] On the other hand, because bromide does not cross the blood-brain barrier, the bromide space does not include ECW of the brain. Because the brain ECW is 6% of total ECW volume in newborns compared with 1% in adults, the underestimation of the anatomic ECW volume resulting from bromide's failure to cross the blood-brain barrier is more pronounced in the newborn than the adult.

Bioelectrical Impedance Analysis, Multiple Frequency

Multiple-frequency bioelectrical impedance analysis (MF-BIA) can be used to estimate ECW volume. Theoretically, the most appropriate measure of ECW volume is given by impedance measure at zero frequency, because at this frequency current does not penetrate cell membranes.[41] However, measurement of impedance at zero frequency is not practical. Measurement of impedance over a range of frequencies allows resistance and reactance to be determined at each frequency. Reactance is then plotted against resistance, and the theoretic value of resistance at zero frequency is obtained by extrapolation of the curve to zero frequency.[42]

Measurement of TBW with use of MF-BIA analysis has been reported to compare favorably with the corrected bromide space in adults[5] and in preterm and term neonates.[43]

Plasma Water

Plasma water volume can be more accurately measured than ECW volume. Evans Blue and iodine-131–labeled serum albumin are commonly used indicators to estimate plasma volume. Both are uniformly distributed throughout the plasma water compartment, but both leak from the plasma water into the ISF compartment during the time required for distribution to occur. The rate of loss of these two indicators and their volumes of distributions are similar in the adult[44,45] and in the newborn.[46] However, the rate of loss is three- to four-fold greater in the newborn in the first day of life than in the adult—0.2% to 0.5% of the injected dose per minute.[46-48] Failure to correct for loss of the injected dose during the period necessary for uniform distribution throughout the plasma water compartment with use of the back-extrapolation method results in an apparent volume distribution greater than true plasma volume.

Interstitial Fluid

ISF volume cannot be directly measured. It is calculated as the difference between ECW volume and plasma water volume. Therefore its value depends on techniques used to estimate ECW and plasma water volumes and is subject to the errors of both techniques.

Intracellular Water

The volume of the ICW compartment is usually calculated as the difference between TBW volume and ECW volume. Therefore its value depends on techniques used to estimate TBW and ECW

volumes and is subject to the errors of both techniques. ICW volume calculated in this manner includes transcellular water.

MATURATIONAL CHANGES IN BODY WATER COMPARTMENT VOLUMES

TBW is 60% of body weight in average men and 50% of body weight in women. This difference between men and women is largely the result of differences in body fat. As a percentage of total body weight, TBW varies inversely with body fat content, from approximately 70% in very thin persons to less than 50% in very obese persons.

When the volume of distribution of thiosulfate is used to estimate the physiologic ECW volume, it is approximately 25% of body mass and one third of TBW volume in the average adult. Plasma volume is 5% of body mass. ISF volume is approximately 15% of body weight and one fourth of TBW. ICW water, calculated as the difference between the TBW and ECW mass, is equal to 35% of body weight and almost two thirds of TBW in the average adult. ICW mass calculated in this manner includes transcellular water, which has been estimated to be 1% to 3% of body weight.

The fraction of body mass that is water and the distribution of body water between the ECW and ICW do not remain constant during growth. Figure 138-3 is a compilation of body water compartment estimations from the literature.[49] Different methods were used to estimate body water compartment volume, and the data are cross-sectional. TBW expressed as a percentage of body mass gradually decreases during gestation and early childhood from approximately 90% during the first trimester to approximately 80% at 26 weeks of gestation to approximately 75% at term. It reaches a value approximating that in the adult at approximately 1 year of age. This change results from an increased accretion of body solids (protein, fat, and minerals) relative to water during development.[50-52] During this time, ECW (expressed as a percentage of body weight) decreases and ICW (expressed as a percentage of body weight) increases. Thus ECW becomes a lesser and ICW a greater proportion of TBW. ECW decreases from more than 50% of body mass during the first trimester to approximately 45% at 26 weeks to 40% at term. It reaches a value approximating that in the adult after 1 year of age. This decrease is the result of decrease in the proportion of body mass that is ISF during development, because plasma volume remains constant at 4% to 5% of body weight throughout life. This relative decrease in ECW and the increase in ICW during development are the result of changes in the proportions that various tissues contribute to total body weight (the proportion of water that is extracellular and intracellular differs among tissues) and changes in the proportion of water that is extracellular and intracellular within given tissues during development.[51] Of course, the absolute volumes of TBW, ECW, ICW, and plasma all increase with growth.

More recent longitudinal measurements of TBW (the volume of distribution of deuterium corrected for exchange of nonaqueous exchangeable hydrogen atoms) in healthy term infants (33 males and 43 females) at 0.5, 3, 6, 9, 12, 18, and 24 months of age obviate many of the problems inherent in the construction of the curve for TBW in Figure 138-3 from composite data. These data (Figure 138-4) show a more rapid decrease in the percent of body weight that is water than in Figure 138-3, largely as the result of larger increment in the percent of body weight that is fat, such that TBW per unit body weight is similar to that of the adult by 3 months.[15]

POSTNATAL CHANGES IN BODY FLUID COMPARTMENTS

Independent of the gradual changes in the proportion of body weight that is water and the changes in the proportions of TBW contributed by the ECW and ICW compartments during development, an abrupt and absolute decrease in TBW volume occurs in the first few days after birth.[34,53-58] It is controversial what proportion of this decrease in TBW is ECW or ICW, but the best evidence is that a disproportionate loss of water occurs from the ECW compartment in appropriate-for-gestational-age (AGA) very-low-birth-weight infants (Figure 138-5).[53-57] This decrease in ECW volume is the result of decrease in ISF volume, without change in plasma volume.[56,57] Older studies demonstrating an increase in plasma volume during the first hours of life in term and preterm newborns[48,59-63] describe a physiologic response to placental transfusion, the result of delayed cord clamping.

Although physiologic correlates of the postnatal diuresis and natriuresis have been described,[64-70] the *reason* for these is unknown. The disproportionate decrease in ISF precludes ascribing this decrease solely to catabolism. That it is physiologic is suggested by certain observations. First, relatively large differences in water and caloric intake are required to moderate this weight loss.[71-73] Furthermore, higher caloric intake has been correlated with less postnatal weight loss but no difference in the magnitude of ECW contraction.[47] Moreover, increases in ICW and body solids *per kilogram of body weight*, but not in ECW *per kilogram of body weight*, occur with subsequent weight gain.[53,57,74] Finally, fluid and sodium intakes high enough to prevent this decrease in ECW volume[75] have been associated with increased morbidity in premature newborns.[73,76,77]

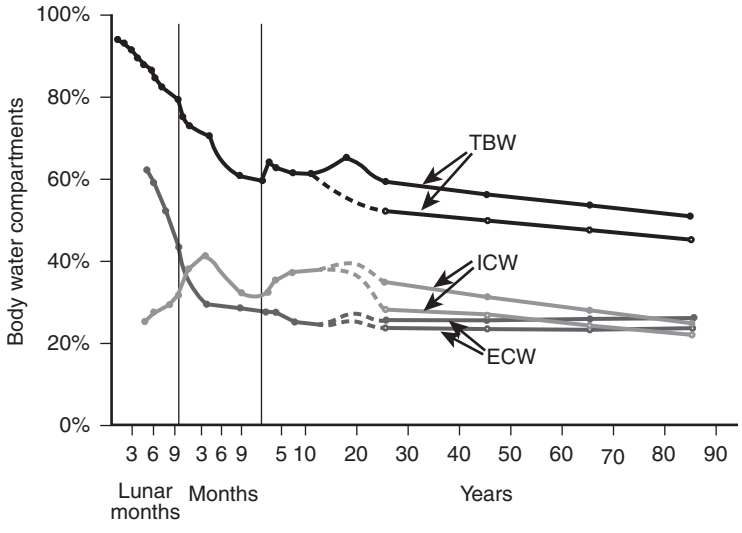

Figure 138-3 Change in body water and distribution with age. *(From Friis-Hansen B: Hydrometry during growth and aging. In Brozek J, editor:* Human body composition. Approaches and applications, *Oxford, United Kingdom, 1965, Pergamon Press).*

Data are more limited for term and small-for-gestational-age (SGA) infants. No studies exist of ECW volume before and after postnatal weight loss in term AGA infants. In the single study of the change in TBW with postnatal weight loss in AGA term infants, no change in the proportion of body weight that was water was associated with postnatal weight loss. These data are consistent with proportionate decreases in TBW and total body solids.[78] Bauer and colleagues[79] observed a decrease in body weight and TBW during the first week of life in preterm AGA infants (mean gestational age 31 weeks) but no change in body weight or TBW in weight-matched SGA infants (mean gestational age 35 weeks). Van der Wagen and associates[80] found that the proportion of TBW and total body solids remained constant during the period of postnatal weight loss and subsequent weight gain in SGA infants with a mean gestational age of 35.7 weeks. These studies suggest that postnatal weight loss, if it occurs, is the result of catabolism rather than reduction in ECW volume in the term and SGA infant. Conversely, Singhi and colleagues[81] found that nearly 90% of the decrease in TBW was the result of a decrease in ECW in both preterm AGA and gestational age–matched SGA infants. The reason for this difference between the studies of Bauer and associates[79] and van der Wagen and colleagues[80] and that of Singhi and associates[81] may be that the SGA infants in the first two studies were closer to term, whereas the SGA infants in the latter study were more preterm. Taken together, these data could be interpreted to be consistent with postnatal weight loss as the result of decrease in ECW in more premature infants and the result of catabolism in near-term infants, regardless of appropriateness for growth.

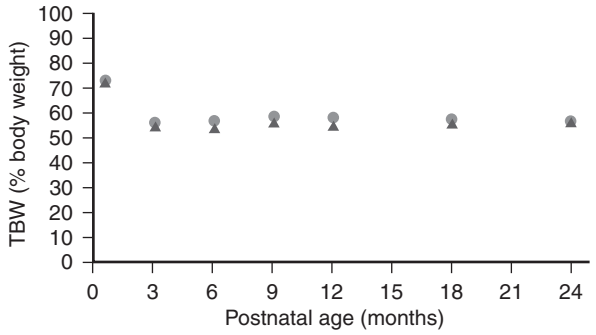

Figure 138-4 Longitudinal measurements of TBW, the volume of distribution of deuterium corrected for exchange of nonaqueous exchangeable hydrogen atoms, at 0.5, 3, 6, 9, 12, 18, and 24 months of age. *Open circles* depict males and *open triangles* females. *(Data from Butte NF, Hopkinson JM, Wong WW, et al. Body composition during the first 2 years of life: an updated reference,* Pediatr Res *47:578-585, 2000).*

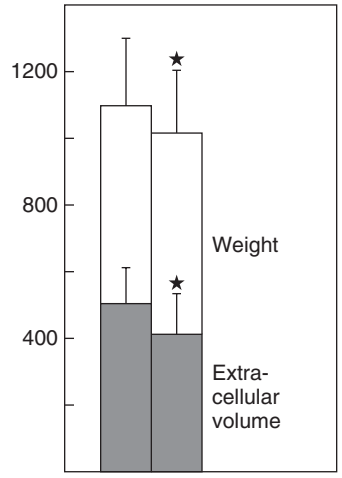

Figure 138-5 Body weight (in grams) and ECW volume (volume of distribution of sucrose, in milliliters) in 13 preterm AGA infants within the first 12 hours of life *(left bars)* and when postnatal weight loss exceeded 5% (*right bars;* average age, 84 hours). Error bars are SDs. $^{*}p < .001$ versus respective values within the first 12 hours of life. Mean weight loss was the same as the mean decrease in ECW volume. *(Modified from Bauer K, Versmold H: Postnatal weight loss in preterm neonates less than 1500 g is due to isotonic dehydration of the extracellular volume,* Acta Paediatr Scand Suppl *360:37-42, 1989).*

139 Pathophysiology of Edema

David P. Carlton

GENERAL CONSIDERATIONS

Edema is the clinical term used to describe excessive fluid accumulation in the adventitial tissue spaces of the body. Excess fluid accumulation results when the net rate of transvascular fluid filtration from the microcirculation is exceeded by the rate of fluid clearance from the interstitial space by lymphatics. Postnatally, edema occurs in the neonate in association with a variety of conditions, including respiratory failure, sepsis, and renal failure. Underlying all circumstances in which there is edema, a disturbance in the normal balance of total body salt and water is present, whether this occurs as a primary (e.g., anuria) or secondary (e.g., retention of fluid to preserve circulating volume) event.[1] Although renal or hormonal abnormalities may not be directly responsible for edema formation, nearly all conditions associated with edema have disturbances in these systems, and the resolution of edema ultimately occurs when normal renal and hormonal control of fluid and salt balance is established.

Total body water balance is a dynamic process during fetal development.[2] Early in gestation, total body water content is approximately 95% of total body weight, decreasing to approximately 75% of body weight at term, and then to near 60% of body weight by the end of the first year after birth. The fraction of total body water that comprises interstitial fluid declines during fetal development.

TRANSVASCULAR FLUID FILTRATION

Fluid movement across the endothelium is driven by forces that regulate fluid flux across a semipermeable membrane.[3] These forces are the hydrostatic and protein osmotic, or oncotic, pressures of the intravascular and interstitial spaces. The ostensibly quantitative expression of how these forces influence fluid filtration is shown in the equation.

$$J_v = K\{(P_{mv}Pi) - \sigma(\pi_{mv} - \pi_i)\} \qquad \text{(Equation A)}$$

where J_v represents net transvascular fluid flow, K is a coefficient that accounts for the permeability of the barrier and surface area for filtration, σ is the reflection coefficient of the barrier to protein, P_{mv} and P_i are the hydrostatic pressures of the microvascular compartment and interstitium, respectively, and π_{mv} and π_i are the osmotic pressures generated by the protein in the microvascular and interstitial spaces, respectively. For a barrier that is completely impermeable to protein, σ would assume the value of 1, and for a barrier across which protein moves without restriction, σ would assume the value of 0. The most complete analysis of fluid filtration across the endothelium would include values for σ that are specific for each plasma protein.

Countless attempts have been made to quantify each of the variables in Equation A for different organs in animals and in man. All experimental approaches involve assumptions about the validity of the values measured and thus all values so measured lack a sense of finality, particularly in the fetus and newborn.[4,5]

In most tissue spaces in the body, under most circumstances J_v is greater than 0. That is, the sum of forces regulating fluid filtration result in a net movement of fluid out of the microcirculation.[6] It is important to recognize, however, that fluid filtration processes are dynamic and at any one time, in any specific section of the microcirculation, filtration forces may not result in fluid moving into the interstitium, even though the net J_v of the tissue or organ is greater than 0. For instance, the clearance of alveolar liquid from the lung that occurs after birth takes place predominantly across the microcirculation and not by lymphatic channels.[7]

Intravascular pressure in the microcirculation, P_{mv}, can be measured by direct techniques using micropuncture and by indirect techniques using isogravimetric approaches.[8] It is unlikely that intravascular pressure remains constant across the entire fluid-exchanging surface because resistance to flow along the vessel results in a drop in pressure over the length of the vessel. Therefore P_{mv} is understood to be the net hydrostatic force for the surface area involved in fluid exchange, even if the hydrostatic pressure at the arterial end of the vessel might result in fluid filtration and hydrostatic pressure at the venous end might result in fluid reabsorption.

P_{mv} is influenced by the relative vascular resistances in the circulation before and after the fluid-exchanging regions.[9] An increase in upstream resistance or a decrease in downstream resistance reduces P_{mv} and fluid filtration. A decrease in upstream resistance or an increase in downstream resistance has the opposite effect on fluid filtration. The importance of considering the profile of vascular resistance distribution is that the effect of a change in arterial pressure on fluid filtration cannot be predicted with certainty. The redistribution of vascular resistance in response to an intervention or a change in condition ultimately determines whether transvascular fluid filtration is affected, and because resistance cannot be assessed clinically, the ability to predict whether a change in transvascular filtration will occur is difficult. For instance, alveolar hypoxia increases pulmonary arterial pressure in both adults and neonates, but alveolar hypoxia affects transvascular fluid filtration only in the newborn.[10-12]

Interstitial pressure, P_i, has been assessed by several different techniques, including porous capsule embedment, direct micropuncture, and cotton wick insertion into the tissue space.[8] It is not possible to assign a general value to P_i because it assumes different values depending on the tissue bed under study. Values that exceed atmospheric pressure and those that are subatmospheric have been measured.[13] Although P_i usually assumes a value near 0 mm Hg, changes in interstitial pressure in response to physiologic disturbances can be dramatic. For example, in tissue that has suffered thermal trauma, P_i may decrease manyfold over baseline values, thus, in part, accounting for the rapid accumulation of interstitial fluid seen with burn injuries.[14] The molecular mechanisms underlying control of interstitial pressure are not clear, but the binding of collagen molecules on the surface of adventitial cells may play a role, because antibodies to the β_1-integrin lowers interstitial pressure and prompts edema formation.[15]

Microvascular protein osmotic pressure, π_{mv}, has been the focus of investigation and clinical study in order to understand better whether changing this value can improve total body fluid balance.[16,17] In the strictest analysis, π_{mv} should be measured for each plasma protein constituent along with the corresponding σ, but like the aforementioned P_{mv}, a net value of osmotic pressure

generated by the sum of plasma proteins suffices to account qualitatively for the relative importance of plasma oncotic pressure to transvascular fluid filtration. The value of transvascular differences in protein osmotic pressure as an important feature of transvascular fluid filtration is highlighted by recognizing that the osmotic force of all components of the extracellular fluid is on the order of 5000 to 6000 mm Hg, but because these components pass unimpeded across the endothelial barrier of the microcirculation (that is, they have a reflection coefficient of 0), they exert no influence on fluid flux.[18] Because plasma proteins do not move with complete freedom across the circulation, they have a significant effect on fluid filtration, despite an osmotic pressure in plasma in the range of 10 to 20 mm Hg.

Interstitial protein osmotic pressure, π_i, has been measured by direct micropuncture techniques, implanted tissue capsules, and absorbent materials placed within the tissue space.[8,18] In vivo measurements of π_i have relied on collection of lymph from organs of interest, with the assumption that protein concentration of lymph is equivalent to that of interstitial fluid (likely a safe assumption under steady-state conditions when lymph is collected from afferent lymphatics).

The membrane parameter, σ, represents the sieving ability of a semipermeable membrane for protein. High values of σ imply that osmotic pressure differences across the vascular barrier will exert a greater effect on fluid flux than will lower values of σ. One can measure σ in vitro as the ratio between the measured and expected osmotic pressure generated by the protein of interest. Furthermore, the value of this coefficient can be estimated in vivo from experiments in which transvascular fluid filtration is maximized (i.e., under conditions in which protein flow is nearly all convective).

Equation A describes the driving forces for transvascular fluid movement, but a different mathematical relationship exists for describing transvascular protein movement. This relationship contains two components, one describing flow of protein as a result of convective movement:

$$J_s = (1-\sigma)\, P\, J_v$$

where Js is transvascular protein flow, σ is the protein reflection coefficient, P is the concentration of protein in the vasculature, and J_v represents net transvascular fluid movement. The second relationship describes the flow of protein as a result of diffusion:

$$J_s = K\,(P-L)$$

where K is the product of the permeability and surface area of the microcirculation, and P and L represent the concentration of protein in the vasculature and lymph (interstitium), respectively. Combining these two equations yields the equation that describes net total transvascular protein movement:

$$J_s = (1-\sigma)\, P\, J_v + K\,(P-L)$$

Under steady-state conditions, lymph contains all the transvascular protein filtered if no metabolism occurs in the interstitium, and thus J_s reduces to LJ_v. In this analysis, J_v is equal to lymph flow and L is equal to lymph protein concentration. Rearranging the above equation, simplifying it, and setting up experimental conditions in which lymph flow is maximized yields the equation $\sigma = 1 - L/P$.[19] When measured experimentally, σ is well over 0.5 in most tissue beds and usually in the range of 0.75 to 0.90, even in the neonate.[20] Capillary beds that contain fenestrations, as in the liver, represent little restriction to transvascular protein movement, and under such conditions σ would be low. On the other hand, capillaries in other vascular beds contain few if any discontinuous regions, and σ under these circumstances would be closer to 1. The closer σ is to unity, the greater the influence of plasma proteins on fluid filtration.[19]

The lower the value of σ, the less able are proteins to generate a force counteracting fluid filtration. This arises for two reasons. First, with a less restrictive barrier, π_i increases numerically toward π_{mv} because the sieving quality of the membrane is diminished. Second, any difference between π_{mv} and π_i is minimized as σ decreases. Thus under conditions in which the vascular barrier is injured, allowing a greater degree of protein leak, administration of protein intravenously to augment vascular protein osmotic pressure and reduce edema formation theoretically should have little, if any, effect. The administration of protein to affect fluid balance in some other fashion (for example, on barrier function per se or to provide other favorable effects unrelated to fluid balance [e.g., to maintain plasma drug binding]) may subserve a clinical benefit, but such a rationale would be independent of the presumed advantage of an increase in microvascular protein osmotic pressure on transvascular fluid filtration.

Finally, the coefficient K represents the product of barrier hydraulic conductivity and the surface area available for fluid filtration.[16] These two components of K are difficult to separate experimentally. Hydraulic conductivity itself is a function predominantly of the density of the pathways for liquid and solute movement and is not necessarily a measure of protein permeability. That is, more pathways, or pores, for solute and liquid exchange might exist under different conditions without the individual pathways being more permeable. Thus changes in K may occur with true alterations in liquid and solute permeability (that is, pathways that allow passage of larger proteins), but changes in K may occur simply with an alteration in the density of pathways for liquid and solute movement or with changes in surface area for filtration, as would occur when unperfused capillaries are filled.

Consideration of Equation A allows several general statements about fluid filtration under normal conditions during steady-state.[19] First, because there is always some degree of sieving across the microvascular barrier, the protein concentration in the interstitium is less than that in the vascular space. This difference in protein concentration yields a difference in protein osmotic pressures that is subtracted from the hydrostatic pressure difference term. In this sense, protein osmotic pressure attempts to balance the "edema-promoting" effect of microvascular hydrostatic pressure. Second, because there is net transvascular fluid filtration out of the circulation, the hydrostatic pressure difference term in Equation A must exceed the difference in osmotic pressure term when total body fluid balance is under consideration. There is no experimental evidence indicating the presence of net "active" transport of water and solute across the endothelium that would influence transvascular fluid flux.

Although the concepts expressed in Equation A serve physiologists and clinicians well when considering fluid balance in a general sense, the equation does not always allow a precise calculation of the change in fluid filtration (J_v) when one variable in the equation changes. This arises because a change in one of the variables in Equation A usually results in a change in one of the other variables, even if such a change is unexpected. For instance, under conditions in which microvascular hydrostatic pressure is increased, one might assume that transvascular flow will increase by an amount that can be arrived at arithmetically from Equation A. When P_{mv} increases in the presence of a stable vascular barrier, J_v increases, but as it does, interstitial protein concentration decreases. This occurs because the driving force for liquid exceeds the bulk flow of protein across the barrier because σ is greater than 0 for protein; there is no sieving of water. When interstitial protein concentration is reduced, the protein osmotic pressure difference between the vascular and interstitial spaces increases. Thus from Equation A, J_v will increase in response to an increase in P_{mv}, but as $(\pi_{mv} - \pi_i)$ becomes larger, J_v assumes a new steady-state value that is less than that predicted by the increase in P_{mv} alone. Additionally, if excess fluid expands the interstitium, interstitial pressure increases to some extent, although the magnitude of this change is not predictable because tissue space

compliance is not linear in the presence of increasing interstitial edema. This increase in tissue hydrostatic pressure also acts to slow transvascular fluid movement. Changes that occur in driving forces for filtration that counteract the change in the "edema-promoting" variable are referred to as the "edema safety factors." The implication of the edema safety factors is that increases in transvascular filtration are blunted because of the countervailing changes seen in other variables in Equation A.[8,16,18,19]

LYMPH FLOW MODULATION OF EDEMA

An increase in interstitial fluid volume can be conceptually understood as an inability of the lymphatic system to remove fluid at the same rate as has been filtered across the microcirculation. Lymphatics are present in most but not all tissue beds, and the brain, specific areas of the eye, and bone marrow are examples of organs that do not contain lymphatics.[19] With regard to fluid balance, lymphatics serve to transport not only water but also proteins back into the circulation. Without the return of protein to the circulation, protein concentration differences between the interstitium and circulation narrow. Lymphatics are located primarily in loose connective tissue spaces and appear to end bluntly. Like blood vessel capillaries, the smallest terminal lymphatics do not contain smooth muscle, but the presence of actin filaments in lymphatic endothelium suggests that the initial lymphatics may possess some limited contractile properties. As the lymphatic vasculature is traced centrally, valves appear, and smooth muscle cells surrounding the lymphatics are more consistently observed. Lymphatics ultimately drain into the central circulation through the thoracic and right lymphatic ducts. The movement of interstitial fluid from the tissue space into the terminal lymphatics requires a driving force. Experimental evidence points to the importance of both interstitial pressure and interstitial volume in modulating lymph flow. However, an increase in interstitial pressure alone, in the absence of a change in interstitial volume, would be unlikely to result in a hydrostatic pressure gradient sufficient to account for lymphatic filling. It is the combination of anchoring filaments attached to the external wall of the lymphatics and an increase in interstitial volume that results in a pressure gradient sufficient to account for initial lymphatic filling.[18,19]

Lymph drainage is not constant but varies with changes in filtration driving force.[16] Thus lymph drainage can also be considered an edema safety factor. Interstitial pressure is closely associated with lymph flow, but the relationship between interstitial pressure and lymph flow is not linear over all tissue pressures. Although an association exists between interstitial pressure and lymph flow, other factors also influence lymphatic clearance. One of the most important is the presence of valves within the lymphatics that provide directionality to flow.[19] Valves also reduce the direct influence of downstream outflow pressure on transendothelial fluid movement into the terminal lymphatics. Lymph is propelled centrally by extrinsic and intrinsic factors. Extrinsic forces include both passive and active muscular movement. Intrinsic forces are those associated with spontaneous lymph vessel contraction and relaxation. Motion associated with respiration and with blood vessel pulsation also contributes to lymphatic movement.

Effect of Outflow Pressure on Lymphatic Drainage

Lymph from large collecting vessels ultimately drains into the central circulation. If lymph drainage is obstructed, interstitial tissue volume increases and edema becomes obvious, implying that outflow pressure is an important variable influencing the effectiveness of lymph drainage.[21] Because the outflow pressure for the thoracic duct is the central venous circulation, an increase in central venous pressure should be an important factor influencing lymph drainage. Experimental evidence from fetal and adult animals confirms this supposition.[22-24]

MOVEMENT OF PROTEIN ACROSS THE MICROVASCULAR BARRIER

The specific site of fluid and protein transfer along the circulation is likely variable within an organ and among tissues. Venules, arterioles, and capillaries may each contribute to transvascular fluid filtration. Molecular size plays a role in transvascular filtration, with ease of transport into the interstitium being inversely proportional to size.[17] Proteins cross the endothelium through channels or pores and by transcytosis, but the magnitude of each to total transvascular protein movement is debated.[25] The importance of protein movement through pores of various sizes in the vascular barrier is highlighted by studies that show that protein moves into the interstitium closely linked to the flow of liquid, that is, moving by convection or bulk flow. In the lung, inhibitors of transcytosis do not significantly decrease transvascular protein transport, casting doubt on the importance of transcytosis as an important pathway for transvascular protein movement involved in fluid balance.[26]

The morphologic basis for an increase in microvascular permeability is not completely resolved. Under some conditions, gaps between endothelial cells can be seen microscopically, but this is not a consistent observation.[25] Intercellular proteins between endothelial cells are linked to actin and other intracellular structures that are thought to regulate microvascular protein permeability by rearrangement of the cytoskeleton. Cellular contraction is thought to be the means by which intercellular gaps are formed and thus permeability regulated.[27]

Like studies examining the morphologic basis for permeability changes, the molecular basis for changes in permeability is incompletely understood.[28-30] Clinically, inflammatory processes are frequently associated with changes in permeability. The molecular initiation of permeability occurs, at least in a number of circumstances, as a result of calcium-dependent events. Calcium entry appears to be regulated, at least in part, by potassium modulation of transmembrane potential and not through voltage-regulated calcium channels. An increase in intracellular calcium is thought to promote myosin light-chain phosphorylation by kinases and thus initiate contraction. Although mediator-induced changes in cytosolic calcium concentration are common, the fact that intracellular calcium may be influenced by novel means is shown by experiments in which surface molecules not thought to be receptors for the typical inflammatory ligands influence vascular permeability. A well-studied example is the ligation of the luminal surface integrin, $\alpha_v\beta_3$, on the microvasculature.[31] Another effect of an increase in intracellular calcium is the modulation of nitric oxide synthesis and the generation of cyclic guanosine monophosphate (cGMP). These mediators are known to affect vascular permeability, but the mechanism by which this occurs is unclear. Their effect may be indirect, perhaps by modulating the concentration of intracellular cyclic adenosine monophosphate (cAMP); cAMP blunts cell contraction and myosin light-chain phosphorylation, but it also may influence the expression of molecules important in intercellular binding and thus limit the ability of the cytoskeleton to influence permeability.[25]

SPECIFIC CLINICAL CONSIDERATIONS: CHANGES IN TRANSVASCULAR FLUID FILTRATION WITH INTRAVENOUS PROTEIN INFUSIONS

Intravenous infusions of solutions containing protein or dextran are frequently administered to patients with edema to increase plasma protein osmotic pressure, in the expectation that transvascular fluid filtration will be less after the plasma protein concentration is increased. Experiments that address this issue show

that infusing albumin in sufficient quantities to increase plasma albumin concentration by as much as 20%, or infusing dextran in sufficient quantity to increase plasma osmotic pressure by more than two-fold, have little effect on steady-state lymph flow.[32,33] However, if microvascular hydrostatic pressure is then increased, the additional plasma osmotic pressure blunts the expected increase in transvascular fluid filtration. The explanation for this response is not completely forthcoming, but likely results from changes in hydraulic conductivity and from changes in the distribution of vascular resistance, resulting in changes in effective P_{mv}.

Experiments evaluating hypoproteinemia in the neonate predictably show that lymph flow increases when protein is removed from the circulation.[20,34] The explanations for this response are conflicting, but at least in the newborn lamb increases appear to result from a decrease in transvascular protein osmotic pressure difference and an increase in vessel hydraulic conductivity, but not from an increase in protein permeability. Whether albumin plays some role in maintaining the health of the barrier wall is uncertain. In vitro information suggests that albumin per se favorably influences the endothelial barrier.[35]

The preceding discussion examines the issue of plasma proteins and fluid balance in the context of a normally permeable microvascular barrier. When barrier integrity is compromised, the movement of protein is less restricted, the reflection coefficient is reduced, and any effect of protein osmotic pressure on fluid movement is minimized. Consistent with this theoretic analysis, experiments in which the lung microvasculature has been injured show no change in fluid movement out of the pulmonary circulation with the infusion of albumin.[36] Thus any favorable effect of plasma protein osmotic pressure on transvascular fluid balance depends on the extent to which the endothelial barrier remains intact.

SPECIAL CONSIDERATIONS OF EDEMA IN THE FETUS

An edematous fetus, regardless of the etiology of the edema, is labeled with the diagnosis of hydrops fetalis. More than 100 different medical illnesses or conditions are associated with hydrops, but the pathophysiologic link between the condition and edema formation is not clear in many of these patients.[37] Approximately 75% of the cases of nonimmune hydrops in the United States occur in association with an identifiable disorder, and in the remainder the condition is labeled idiopathic.[38]

PROPOSED MECHANISMS OF EDEMA FORMATION IN PATIENTS WITH HYDROPS

From the foregoing discussion it is seen that edema may form if the driving forces for fluid filtration or vascular permeability increase without a concomitant increase in lymphatic drainage. Although disturbances in microvascular permeability could be relevant in explaining some cases of fetal hydrops, there is no evidence at this time that vascular protein permeability is significantly different, at least in the lung; in the fetus, neonate, or adult; or between hydropic and nonhydropic fetuses.[7,39,40]

A variety of hypotheses might explain the pathophysiology of hydrops, but one that is most compatible with the current experimental evidence is that elevation of central venous pressure is a critical element in the pathogenesis of fetal edema. Conditions that elevate central venous pressure are common in hydropic infants and thus provide a compelling clinical link for this hypothesis. An elevation in central venous pressure increases microvascular pressure upstream and thus enhances transvascular fluid movement. An increase in central venous pressure also impairs lymphatic drainage into the central circulation and thus increases interstitial fluid volume. If lymphatic drainage is completely interrupted (a limiting-case example of increased central venous pressure), the fetus becomes hydropic.[21] In experiments designed to evaluate more modest effects of disturbances in central venous pressure on lymph drainage, thoracic duct lymph flow was found to be inversely proportional and linearly related to outflow pressure. In these studies, increasing central venous pressure by only 5 mm Hg was impaired by nearly 50% the rate of lymph drainage.[24]

A helpful model that clarifies total body fluid dynamics in the presence of elevated central venous pressure is the fetal lamb that undergoes rapid atrial pacing. When fetal sheep are paced at rates of 300 to 320/minute, central venous pressure nearly doubles, without changes in systemic arterial pressure, plasma albumin concentration, or vascular protein permeability.[41,42] Fetal edema occurs quickly, sometimes within 12 to 24 hours, indicating excessive transvascular fluid filtration, impaired lymphatic clearance, or both. Thoracic duct lymph flow increases by nearly 50% when measured at an outflow pressure equivalent to central venous pressure under baseline conditions, but when measured at the central venous pressure induced by pacing, lymph flow is significantly reduced. Thus in conditions that increase central venous pressure, hydrops may be caused, or at least aggravated, by two distinct mechanisms: increased transvascular fluid entry and impaired interstitial fluid clearance.

Anemia is another human fetal condition often associated with hydrops. Exchange transfusion in fetal lambs sufficient to reduce hematocrit from 32% to 12% produces hydrops, but only if the anemia is associated with an increase in central venous pressure.[43] Whether edema develops may depend to a large extent on whether lymph drainage can accommodate the increase in fluid filtration.

In newborn sheep made hypoproteinemic, plasma protein osmotic pressure is reduced and transvascular fluid filtration increases, but no increase in interstitial fluid volume occurs, at least in the lung, because lymph flow increases to match transvascular filtration.[20,34] Likewise, in fetal sheep, simply lowering plasma protein oncotic pressure by removing protein from the circulation has no effect on total body water.[44] The lack of effect of hypoproteinemia on edema formation is likely a result of increased lymphatic drainage back into the central circulation. In isolated fetal hypoproteinemia, central venous pressure does not increase, and thus there is no impediment to lymph drainage back into the central circulation. The increase in fetal lymph flow is likely on the order of approximately 40%, similar to that seen in newborn lambs made hypoproteinemic.[20,34] Because fetal lymph flow can increase two- to four-fold over baseline values, increases in transvascular filtration prompted by hypoproteinemia can be easily accommodated by increases in fetal lymph flow.

Regulation of Acid-Base Balance in the Fetus and Neonate

The majority of the existing information on the regulation of acid-base homeostasis in mammals and humans was obtained from studies in adult subjects. With the current revo1ution in micromethodology and advances in understanding of developmental physiology and molecular biology, however, data have been accumulating on fetal and neonatal regulation of acid-base balance.

In general, acid-base homeostasis is tightly regulated by extracellular and intracellular buffer systems and respiratory and renal compensatory mechanisms of the organism.The normal range of H^+ ion concentration in the extracellular fluid is 35 to 45 mEq/L corresponding to a pH of 7.35 to 7.45. Under physiologic circumstances, volatile and fixed acids generated by normal metabolism are excreted and the pH remains stable.[1] Volatile carbonic acid is produced in the largest amounts, and it is readily excreted by the lungs in the form of carbon dioxide. Fixed acids, which include lactic acid, ketoacids, phosphoric acid, and sulfuric acid, are buffered principally by extracellular bicarbonate. The bicarbonate used in this process is then regenerated by the kidneys in a series of transmembrane transport processes resulting in the excretion of H^+ ions in the form of titratable acids and ammonium.

EXTRACELLULAR BUFFER SYSTEM

Using various acid-base pairs, the extracellular buffer system responds immediately to alterations in pH in a fashion represented by the Henderson-Hasselbalch equation. The carbonic acid–bicarbonate system is the most important component of this buffer system. Because the isohydric principle[2] allows one to follow the changes in the concentrations of a single acid-base pair as an indicator of acid-base homeostasis for the entire system, serial measurements of the carbonic acid-bicarbonate buffer system have been used to describe accurately the changes in both the experimental and the clinical settings.

INTRACELLULAR BUFFER SYSTEM

The most important components of the intracellular buffer system are the hemoglobin and intracellular proteins and phosphates acting as an intracellular H^+ sink and reservoir attached to the extracellular buffers. This system provides buffering at a slower rate compared to extracellular buffers and requires several hours to reach maximum capacity.[3]

RESPIRATORY COMPENSATORY MECHANISM

Because of the open nature of the carbonic acid–bicarbonate system, normal gas exchange in the lungs serves as an immediate regulator of acid-base homeostasis by maintaining a normal $PaCO_2$, thus eliminating the excess carbon dioxide generated by an acid load. Activation of the respiratory compensatory mechanism is necessary, however, to return pH further toward normal. Because the movement of bicarbonate across the blood-brain barrier is regulated by active transport mechanisms,[4] and, because the central respiratory drive is triggered by low steady-state values of the cerebrospinal fluid and not the plasma bicarbonate,[5]

a full activation of this system only occurs a few hours after the development of metabolic acidosis. Because carbon dioxide moves freely across the blood-brain barrier,[5] cerebrospinal fluid and cerebral interstitial fluid H^+ ion concentrations are altered more rapidly by respiratory acidosis, leading to an immediate activation of the respiratory compensatory mechanism in such cases.

RENAL COMPENSATORY MECHANISM

By altering renal H^+ excretion, renal compensation is the ultimate mechanism to adjust H^+ content in the body.[6] This system, however, requires hours to 2 to 3 days for a full response.

REGULATION OF ACID-BASE BALANCE IN THE FETUS

Fetal Extracellular Buffer System

The fetus has an intact extracellular buffer system. The carbonic acid–bicarbonate buffer system is especially important because it contains a volatile element, carbon dioxide gas. For the fetus, the placenta is the organ of respiration, and it quickly eliminates excess carbon dioxide generated by the development of fetal metabolic acidosis, provided that placental function, uterine and umbilical blood flows, and maternal respiratory status are uncompromised.[7]

Fetal Intracellular Buffer System

Although the fetus has a significantly smaller intracellular compartment compared with the child or adult, its intracellular buffering capacity is still considerably larger than the extracellular one.[7]

Fetal Respiratory and Renal Compensatory Mechanisms

The respiratory and renal compensatory mechanisms of the fetus are limited by its level of maturity and the surrounding maternal environment. The placentomaternal unit performs most of the effective compensatory functions.[7] However, the fetal kidney has the ability to contribute to the maintenance of fetal acid-base balance. For instance, ammonium excretion and thus generation of bicarbonate as well as sodium excretion has been documented to increase during the recovery period from hypocapnic hypoxia in the fetal sheep.[8]

Fetal Metabolic Acidosis

The most frequent cause of fetal metabolic acidosis is fetal hypoxemia due to abnormalities of uteroplacental function, blood flow, or both. Primary maternal hypoxemia or maternal metabolic acidosis secondary to maternal diabetes mellitus, sepsis, or renal tubular abnormalities is an unusual cause of fetal metabolic acidosis. During the course of fetal hypoxemia, metabolism becomes anaerobic, and large quantities of lactic acid accumulate. H^+ ions are buffered by the extracellular and intracellular buffering systems, and pH drops as plasma bicarbonate decreases. Because of the unhindered diffusion of carbon dioxide through the placenta,[9] restoration of fetal pH toward normal initially occurs through elimination of the volatile element of the carbonic acid-bicarbonate system via the maternal lungs. Lactate and other fixed acids cross the placenta more slowly,[7] however, so that effective maternal renal compensation of fetal metabolic acidosis is delayed. If fetal oxygenation improves, the products of anaerobic metabolism are also metabolized by the fetus.

Although metabolic acidosis stimulates fetal breathing movements,[10] the respiratory control system in the fetus is much less sensitive to changes in pH than after birth.[11] No physiologic significance, however, to this compensatory mechanism in utero is apparent.

Several lines of evidence indicate that the fetal kidney is able to excrete acid[12-14] and organic acids[15] as well as to generate more bicarbonate.[16] Studies in fetal sheep have found age-dependent increases in glomerular filtration rate (GFR), urinary titratable acid, ammonium, and net acid excretion.[12] Furthermore, a positive relationship has been demonstrated between changes in GFR and bicarbonate, sodium, and chloride excretions.[12,13] The fetal kidney, however, has a developmentally regulated limited ability to adapt to changes in fetal acid-base balance. In fetal sheep, in response to metabolic acidosis induced by the infusion of hydrochloric acid, blood pressure increases but the GFR does not change. Urinary titratable acid, ammonium, and net acid excretion increase without significant changes in renal bicarbonate absorption.[14] Evidence also indicates that the fetal kidney has the ability to increase bicarbonate reabsorption, at least during periods of volume depletion.[16] With regard to the human fetus, only limited information is available concerning renal acidification.[17] The physiologic importance of these adaptive fetal renal responses, however, is limited when compared with those in the postnatal period because the acid load excreted in the fetal urine remains within the immediate fetal environment and still has to be eliminated by the placenta or metabolized by the fetus.

Fetal Respiratory Acidosis

Fetal respiratory acidosis develops when prolonged maternal hypoventilation occurs with maternal asthma, airway obstruction, narcotic overdosing, maternal anesthesia, and magnesium sulfate toxicity. Fetal breathing movements increase, and the fetal kidney exerts a maturation-dependent limited response by reclaiming more bicarbonate in an attempt to restore the 20:1 ratio of bicarbonate to carbonic acid and thus increase the pH toward normal.[7] Obviously, only the renal compensation has some limited physiologic significance for the fetus in cases of respiratory acidosis.

Fetal Metabolic Alkalosis

Metabolic alkalosis rarely affects the fetus, but it may occur in hyperemesis gravidarum. As a result of the significant hydrogen chloride losses in this condition, bicarbonate is retained by the mother to maintain anionic balance with sodium in the serum. Because bicarbonate is transported slowly across the placenta, the development of fetal metabolic alkalosis lags behind that of the mother. Maternal hypoventilation then also tends to restore normal pH in the fetus as a result of the rapid movement of carbon dioxide across the placenta.

Fetal Respiratory Alkalosis

The *physiologic hyperventilation* of the pregnant woman causes a compensatory decrease in her serum bicarbonate concentration to approximately 22 mM.[7] Acute hyperventilation, however, may lead to the development of fetal metabolic acidosis because it induces uterine vasoconstriction.[18] In such cases, restoration of maternal carbon dioxide levels rapidly corrects both the abnormal uterine blood flow and the acid-base abnormality in the fetus.

REGULATION OF ACID-BASE BALANCE IN THE NEONATE

The neonate continues to undergo maturation of the overall adaptive responses to changes in acid-base homeostasis. Available information suggests that an abrupt increase in the sensitivity of the central respiratory control system to pH changes occurs at the time of delivery and that regulation of acid-base balance becomes tighter postnatally compared with that in the fetus.[11] The cellular mechanism responsible for the increased sensitivity of the acid-base balance regulation system is not known.

Neonatal Extracellular and Intracellular Buffer Systems

The neonate has well-functioning extracellular and intracellular buffering systems. Postnatally, the gradual increase in the intracellular compartment further enhances the overall buffering capacity.

Neonatal Respiratory Compensatory Mechanism

With postpartum establishment of the functional residual capacity, the neonate's lungs become the end organ of the respiratory compensatory mechanism to changes in acid-base balance. Respiratory acidosis induces immediate increases in ventilation because carbon dioxide diffuses freely across the blood-brain barrier.[5] In the case of metabolic acidosis, however, full respiratory compensation is delayed for a few hours until cerebrospinal fluid and cerebral interstitial bicarbonate completely equilibrate with plasma bicarbonate.[4]

The effectiveness of respiratory compensation depends on the maturity of the central respiratory control system and pulmonary function. Because central respiratory control is sensitive to changes in cerebral interstitial pH in the neonate,[4,11] the effectiveness of the postnatal respiratory response depends mainly on pulmonary function. Therefore neonates with parenchymal lung disease, especially if they are born prematurely, have a limited ability to increase ventilation in response to metabolic acidosis.

Neonatal Renal Compensatory Mechanism

As mentioned earlier, by regulating bicarbonate and acid secretion in response to changes in extracellular pH, renal compensation is the ultimate mechanism to adjust the H^+ content of the body. Although full activation of this system usually requires 2 to 3 days, alterations in renal acidification may be seen as early as a few hours after the development of acid-base disturbance.

The renal compensatory mechanisms of the neonate are immature, resulting in a developmentally regulated decreased ability to maintain acid-base balance.[19,20] Both renal microhemodynamic and tubular epithelial factors play a role in the limited renal compensatory capacity of the newborn.

Renal blood flow significantly increases after the immediate postnatal period, and the vasodilatory mechanisms appear to be functionally mature as early as 24 weeks gestation.[21] GFR is also low in the immediate postnatal period, and it increases as a function of both gestational and postnatal age.[22,23] The low GFR is one of the most important factors limiting the ability of the preterm and term infant to handle an acid load adequately.[19,20] Net renal acid excretion also depends on several gestational and postnatal age-dependent tubular epithelial functions.[20,24] Under physiologic conditions in the proximal tubule, four transport mechanisms regulate active acid extrusion and transepithelial bicarbonate reabsorption: the H^+-ATPase, the electrogenic $Na^+/3HCO_3^-$ cotransporter, the Na,K^+-ATPase-driven secondary active Na^+/H^+ antiporter, and the Na^+,K^+-ATPase-driven tertiary active Na^+-coupled organic ion transporter.[24] Because approximately 85% to 90% of the filtered bicarbonate is reabsorbed in the proximal tubule,[20,24] the function of these proximal tubular transporters essentially determines the renal threshold for bicarbonate reabsorption. The bicarbonate threshold is 18 mEq/L in the premature and 21 mEq/L in the full-term infant, and it reaches adult levels (24 to 26 mEq/L) only after the first year of life.[25,26] In the extremely premature neonate, however, the renal bicarbonate threshold may be as low as 14 mEq/L. Because renal carbonic anhydrase is present and active during fetal life,[27] and because its activity is similar in the 26-week-old, extremely immature neonate to that of the adult,[28] a developmentally regulated immaturity of the expression, molecular structure, membrane-assembly, or second-messenger and third-messenger function of the described proximal tubular transporters is most likely responsible for the low bicarbonate threshold during early development. Indeed, both the activity and the hormonal responsiveness of the proximal tubular Na^+,K^+-ATPase have been found to be decreased in younger rather than older animals.[29]

Medications used in the treatment of critically ill neonates may also affect proximal tubular bicarbonate reabsorption. For example, dopamine administration may potentially decrease the low bicarbonate threshold of the neonate[30] because the drug inhibits activity of the proximal tubular Na^+/H^+ antiporter.[31] Carbonic anhydrase inhibitors also decrease proximal tubular bicarbonate reabsorption by limiting bicarbonate formation and H^+ ion availability for the Na^+/H^+ countertransporter. Furosemide, acting on several transport proteins along the nephron, directly increases urinary excretion of titratable acids and ammonium.[32]

Under physiologic circumstances, the distal nephron reabsorbs the remaining 10% to 15% of filtered bicarbonate via transport mechanisms similar to those of the proximal tubule.[24] An important difference between proximal and distal tubular bicarbonate reabsorption is the absence of the carbonic anhydrase enzyme in the distal tubule.[24] Net H^+ ion secretion in the distal nephron continues even after the reabsorption of virtually all bicarbonate via active H^+ secretion and the ability of the distal tubular epithelium to maintain large transepithelial concentration gradients for H^+ and bicarbonate.[24] Among the endocrine factors influencing distal tubular acidification, aldosterone is one of the most important hormones.[24] By affecting the function of several different transport mechanisms, aldosterone stimulates net H^+ ion excretion in the distal nephron. The distal nephron of the premature neonate, however, has a developmentally regulated relative insensitivity to aldosterone.[26,33]

The secreted H^+ ions are excreted in the urine in the form of titratable acids (phosphate and sulfate salts) and as ammonium salts, which are formed by the combination of H^+ with ammonia.[24] Because the major constituent of titratable acid in the urine is $H_2PO_4^-$, drugs that decrease proximal tubular phosphate reabsorption and thus increase the delivery of phosphate to the distal nephron may increase the renal acidification capacity of the neonate. Indeed, by inhibiting proximal tubular phosphate reabsorption, dopamine has been shown to increase the excretion of titratable acids in preterm infants.[34]

Urinary excretion of titratable acid and ammonium increases as a function of gestational and postnatal age.[20] Because the ability to acidify the urine effectively is acquired by the age of 1 month even in very premature infants, however, distal tubular H^+ ion secretion appears to be inducible independent of the gestational age of the infant.[35]

Neonatal Metabolic Acidosis

The most frequent causes of increased anion-gap metabolic acidosis in the neonate are hypoxemia or ischemia secondary to perinatal asphyxia; severe lung disease; volume depletion; vasoregulatory disturbances; or myocardial dysfunction caused by immaturity, sepsis, or asphyxia. Severe metabolic acidosis caused by a neonatal metabolic disorder is rare but should always be considered. Interestingly, the type of anesthesia during caesarean section has also been suggested to influence neonatal acid base status. Indeed, according to a meta-analysis of the findings of 27 studies, cord pH was lower and base deficit was higher in newborns whose mothers received spinal anesthesia compared with those receiving general and epidural anesthesia.[36] Therefore, when assessing a neonate born via caesarian section that presents with metabolic acidosis in the immediate postnatal period, the type of anesthesia needs to be considered when searching for the etiology of the acid-base disturbance.

As discussed earlier, preterm neonates frequently present with a mild to moderate normal anion-gap acidosis, which is almost always the consequence of the low renal bicarbonate threshold of the premature kidney.[20,25,26] However, the use of carbonic anhydrase

inhibitors and parenteral alimentation, as well as the maturation related decreased sensitivity to aldosterone, may also contribute to the development of normal anion-gap acidosis in the neonate.[2,26,33]

In metabolic acidosis caused by the accumulation of lactic acid, H^+ ions are buffered by the extracellular and intracellular buffering systems; pH drops as plasma bicarbonate concentration decreases. Restoration of pH toward normal initially occurs through elimination of the volatile element of the carbonic acid-bicarbonate system via the lungs. This process, however, may be severely compromised in the sick preterm and term neonate with parenchymal lung disease. As described earlier, the renal compensatory mechanisms are also less effective because of the developmentally regulated immaturity of neonatal renal function. The main elements of the response of the neonatal kidney to metabolic acidosis in the immediate postnatal period are the attenuated increases in GFR, proximal tubular bicarbonate reabsorption, and distal tubular net acid secretion. A significant improvement in the overall renal response, however, occurs after the first month of life even in the premature infant.[20]

Neonatal Respiratory Acidosis

In the clinical setting, neonatal respiratory acidosis develops most frequently in preterm infants with respiratory distress syndrome. Although stimulation of the central respiratory center by the elevated interstitial carbon dioxide immediately increases respiratory rate and depth, carbon dioxide elimination by the lungs is usually limited because of immaturity and parenchymal disease. The kidneys reclaim more bicarbonate in response to respiratory acidosis. Especially during the first few weeks of life, however, renal compensation is limited by the developmentally regulated immaturity of proximal and distal tubular functions.

Neonatal Metabolic Alkalosis

Metabolic alkalosis most frequently develops in the preterm neonate who receives prolonged diuretic treatment for bronchopulmonary dysplasia. The respiratory response is a decrease in the rate and depth of breathing to increase carbon dioxide retention. This response may not be effective if the intubated neonate is relatively overventilated with the mechanical ventilator. In response to a metabolic alkalosis, urinary bicarbonate reabsorption and distal tubular net acid excretion decrease, resulting in a return of the extracellular pH toward normal.

Neonatal Respiratory Alkalosis

Neonatal respiratory alkalosis occurs most frequently secondary to fever and iatrogenic hyperventilation of the intubated preterm and term infant. Rarely respiratory alkalosis may be the presenting sign of a urea cycle disorder during the first days of life because rising ammonia levels may initially stimulate the central respiratory center. Renal compensation plays an important although limited role in cases of neonatal respiratory alkalosis.

SUMMARY

The fetus and the neonate exhibit a limited ability to maintain and regulate acid-base homeostasis. Regardless of the state of maturity, however, an abrupt increase in the sensitivity of acid-base regulation occurs with delivery. The mechanisms for this accelerated maturation are unclear.

Developmental Biology of Stem Cells: From the Embryo to the Adult

Stem cells are a popular topic at present in both the scientific literature and the lay press. The isolation of human embryonic stem (ES) cells has fueled speculation that these cells may be useful in the repair and regeneration of tissues and organs for a host of patient disorders. Much basic and translational research will be required to achieve the widely publicized therapeutic projections. It has become clear that the controlled differentiation of stem cells into specialized mature cells, the expansion of stem cells in vitro with retention of multipotentiality, and the best source of stem cells for a particular therapeutic application all remain to be determined. The topic of stem cells is further complicated by the realization that the methods used to isolate human ES cells require the sacrifice of a human embryo. Thus spiritual, ethical, and political ideologies have been brought into the ethical debate of when an embryo should be afforded moral status, and this ongoing argument has had major impact on the scientific conduct of human ES cell research in the United States. Some states have conceptually adopted and promoted human ES cell research through research-funding initiatives and political rhetoric, whereas other states have been opposed to the promotion of this area of science. It is unclear whether the controversy of determining how and when or if to assign moral status to the human embryo can be resolved.

This chapter introduces some basic principles and concepts in the broad field of stem cell biology, with emphasis on the important distinction between the two classes of stem cells: embryonic and adult. Stem cell terminology and discussion of the general categories of stem cells are presented first. The remainder of the chapter is organized in an ontologic approach with respect to emergence of cells with stem cell potential, beginning with a description of the totipotent properties of the zygote. Next, a discussion of selected aspects of murine ES cell biology is presented as an introduction to human ES cells, followed by a review of the discovery of human embryonic germ (EG) cells. Finally, several of the more commonly studied adult stem cell populations are discussed—the number of adult stem cell populations that emerge to sustain specified tissues and organs throughout life being too extensive to review in entirety. When appropriate, some discussion of the current use of stem cells in clinical medicine also is provided.

DEFINITION OF STEM CELLS AND STEM CELL TERMINOLOGY

The human body is composed of more than 200 different cell populations that are assimilated into multiple specialized tissues and organs of diverse functions. All of these cells are ultimately derived from the "mother" of all stem cells, the fertilized oocyte (zygote). Only the zygote and blastomere cells within the first few cleavage stage divisions possess the capacity to produce a complete organism. Whereas many tissues and organs, once fully formed, and the cell populations that make up these tissues are stable postnatally and do not require ongoing cellular replacement, other organs (e.g, blood, skin, and intestine) depend on a continuous influx of new cells to maintain tissue homeostasis throughout adult life. Thus not only are stem cells required for the initiation of embryo formation, but they also are critical for homeostasis of the adult organism.

Stem cells are defined as cells possessing the capacity to self-renew (cell division giving rise to at least one cell retaining all the properties of the parent cell) and the ability to proliferate and differentiate into one or all of the more than 200 cell types that make up the fully formed body.[1] The zygote and blastomeres within the first few cleavage stage divisions are *totipotent cells* that can form all of the cells of all tissues and organs that form an embryo. *Pluripotent stem cells* are defined as cells that can give rise to cells developing from all three embryonic germ layers: endoderm, ectoderm, and mesoderm. The primary difference between pluripotent and totipotent cells is the ability of the latter to give rise to trophectoderm cells that form the placenta and some of the extraembryonic membrances. Of importance, defining a stem cell as totipotent or pluripotent generally requires detailed analysis of donor stem cell progeny contribution to tissues and organs on adoptive transfer of cells into a recipient blastocyst or embryo, not just in vitro evidence of cellular gene expression that typifies an expression pattern observed in cells of a particular tissue or organ. For example, induced cell expression of albumin is not equivalent to proof that a cell has become a hepatocyte, even though albumin is predominantly expressed in hepatocytes.

Stem cells may be generally divided into ES and adult stem cell groups. ES cells are derived from the inner cell mass of the mammalian blastocyst.[2,3] Isolation of the inner cell mass cells followed by growth of these cells on preestablished cultures of murine embryonic fibroblasts defines the culture conditions sufficient for emergence of proliferating cells called *ES cells.* ES cells do not exist in vivo, but they develop in vitro from the cultured inner cell mass cells of the blastocyst. ES cells are pluripotent and display unlimited proliferative potential in vitro in the presence of embryonic fibroblasts. Murine ES cells also can be maintained in the absence of the feeder layers when they are fed high concentrations of leukemia inhibitory factor (LIF), the lone growth factor sufficient to maintain murine ES cell self-renewal divisions. Murine ES cells maintained under these conditions in vitro retain the potential to form a complete embryo when they are injected into a recipient blastocyst and are implanted in the womb of a pseudopregnant dam.[4]

A second form of stem cells derived from the embryo can be isolated from the developing gonads of fetal mammals.[5,6] By recovery of developing gonads, dispersion of the germ cells onto a layer of embryonic fibroblasts in vitro, and passage of the resulting colonies, the isolation of *embryonic germ (EG) cells* is readily accomplished. EG cells also are pluripotent, exhibit high proliferative potential, and must be maintained in culture similar to that for ES cells. ES and EG cells display similar capacities for differentiation into a variety of differentiated cell types in vitro.

Stem cells are said to differentiate when they divide, and at least one of the progeny commits to the activation of a new gene expression pattern or inactivation of the genes maintaining the stem cell state. These genetic changes cause the cells to take on new properties characteristic of mature cells of a particular tissue or organ. Just a few years ago, it was believed that once the ES or EG cells began the commitment process to differentiate into a mature cell type, these cells were no longer capable of reacquiring the pluripotentiality that is characteristic of a self-renewing ES or EG cell. As discussed later in the chapter, however, additional evidence has emerged showing that coexpression of a certain group of transcription factors is sufficient to permit even fully differentiated cells to regain pluripotent properties similar to ES or EG cells in vitro and in vivo.

Adult stem cells are cells residing in tissues and organs that maintain homeostasis by repleting cells lost to cellular senescence, disease, or injury. The most widely recognized organs with stem cells include bone marrow, skin, intestine, and liver. However, the brain, cornea, retina, skeletal muscle, and dental pulp also contain renewable stem cells, as may several other organs and tissues such as heart, skeletal muscle, bone, and lung. Adult stem cells also are called *somatic stem cells* to distinguish them from the germ cells of the adult organism. Adult stem cells in general fail to display the in vitro proliferative potential of ES or EG cells, although these cells obviously self-renew for the life of the organism (which otherwise would run out of blood, intestinal villi, skin, and so on). In general, adult stem cells display tissue-specific characteristics and differentiate into progeny specialized for the tissue or organ within which they reside. This fundamental tenet of biology is reflected in the clinical use of stem cells. Thus, when a patient needs a bone marrow transplant for a blood cell disorder, hematopoietic stem cells are transplanted as the donor tissue and not stem cells derived from another organ.

Some adult stem cell populations have been demonstrated to give rise to progeny in vitro and in vivo that normally are not derived from that type of stem cell. For example, some bone marrow cells have been found to differentiate into cardiomyocytes in mice after experimentally induced myocardial ischemia.[7] This ability of an adult stem cell of one tissue to generate mature cells of another tissue type has been called *stem cell plasticity.* This is a relatively new concept and is not yet mechanistically understood, although a growing body of evidence suggests that in many cases, the donor cells may fuse with injured host cells, thus giving the *appearance* of change to the host cell type.[8] Other evidence suggests that stem cell plasticity is a rare event, and it is unclear whether this phenomenon normally occurs to maintain homeostasis.[9]

A feature of most adult stem cells is the production of a variety of progenitor cell populations with varying levels of proliferative potential. For example, hematopoietic stem cell proliferation may cause one daughter cell to retain stem cell potential (self-renewal) but the other daughter cell to become a progenitor cell. The progenitor cell may retain the ability to proliferate into additional progenitor daughter cells, but it cannot regain the potential to recreate itself (self-renew). In a stepwise hierarchical fashion, progenitor cells become more committed to mature cell differentiation with each subsequent division, progressively losing their proliferative potential.

ES, EG, or adult stem cells may or may not be clonally derived, that is, a state when all of the cells in a population can be demonstrated to be the progeny of a single initiating stem cell. Several clonal human ES cell lines have been created.[10] Obtaining a clone of adult stem cells has been more difficult. Methods to isolate adult stem cells generally result in a mixture of stem and progenitor cells. However, hematopoietic stem cells are one adult stem cell type that have clearly been demonstrated to clonally reconstitute the entire hematopoietic system in lethally irradiated host animals.[9] This is an important point in considering the question of stem cell plasticity. As discussed further on, the term *stem cell plasticity* should be reserved for those instances in which it is clear that a single stem cell derived from one tissue can be demonstrated to give rise to a clone of progeny of another tissue, not just to a few scattered cells within that tissue.

EMBRYONIC STEM CELLS

Murine Cells

Isolation

Efforts to isolate murine cells with pluripotent properties began in the 1950s. Leroy Stevens observed that male mice of the 129 strain developed testicular teratomas, and cells from these tumors could be transplanted with recurrence of the teratoma.[11] Further studies revealed that fetal germ cells (derived from the 129 strain of mice) implanted in the testicle also could precipitate teratocarcinoma formation. The most profound insight provided by these studies, however, was that cells isolated from the inner cell mass of murine blastocysts also gave rise to teratocarcinomas on transplantation. Stevens called these cells *pluripotent ES cells,* the first such designation of inner cell mass–derived cells as ES cells.[12] However, the injected embryonic cells gave rise to carcinomas as well as teratomas in this model and later became known as *embryo carcinoma (EC) cells.*

Two independent groups of investigators reported in 1981 that cells from the inner cell mass of the murine blastocyst could be maintained in vitro in a pluripotent state under defined conditions that in some cases included addition of conditioned medium from cultured teratocarcinoma cells.[3,13] Growth of the cells from the inner cell mass required a co-culture system using preestablished murine embryonic fibroblast feeder monolayers. LIF was identified as the factor secreted by the embryonic fibroblast that was required to retain ES cells with high proliferative potential and to maintain pluripotency in vitro.[3] ES cells can now be maintained indefinitely without chromosomal aberrations under these culture conditions and contribute to the formation of extraembryonic, fetal, and germ cell lineages on reintroduction into donor blastocysts and transfer into the fallopian tubes of pseudopregnant female mice. In fact, if the murine ES cells are cultured with both LIF and bone morphogenetic protein-4 (BMP-4), serum-free defined culture medium conditions can be used.[14] This is a great advance for the field, because fetal calf sera are known to fluctuate in trace molecule concentrations from batch to batch, and such variability can lead to vast changes in gene expression and ES cell function.

Maintenance of Self-Renewal

The molecular mechanisms that maintain ES cells in a self-renewal state are not clearly delineated. It is clear, however, that signals generated during LIF binding to the cell surface LIF receptor are sufficient to maintain pluripotency.[15] LIF binding to a cell surface heterodimeric receptor results in activation of numerous molecules including nonreceptor tyrosine kinases. These kinases subsequently activate nuclear transcription factors including STAT3 (*s*ignal *t*ransducer and *a*ctivator of *t*ranscription-*3*). STAT3 activation alone is sufficient to maintain murine ES cells

in a self-renewal state with inhibition of cellular differentiation.[16] STAT3 proliferative effects on ES cells can be blocked by activation of the Erk (*e*xtracellular signal–*r*egulated *k*inase) pathway. A balance between the differentiating effects of Erk kinase activation and the proliferative effects of STAT3 activation appears to play a key role in determining whether ES cells are maintained in a pluripotent state.[17]

Another hallmark of pluripotent ES cell homeostasis is expression of the nuclear transcription factor Oct-4 (*oct*amer-binding transcription factor-*4*).This factor is present in the mouse zygote and is required for normal formation of the blastocyst and maintenance of the pluripotent state of the inner cell mass cells. Oct-4 also is highly expressed in germ cells. Evidence to date implicates specific control of the level of Oct-4 expression for maintaining the pluripotent state.[18] Overexpression of Oct-4 in ES cells leads to differentiation of the cells along the endoderm and mesoderm lineages, and diminished expression inhibits trophectoderm formation.To date, only a few of the target genes regulated by Oct-4 have been identified; transcription of some is inhibited and of others is increased by Oct-4 binding to target sequences in these genes. In general, the current theory is that Oct-4 may prevent expression of those genes required for ES cell differentiation.

In Vitro Differentiation

The ability to culture pluripotent cells in vitro has permitted novel insights into and greater accessibility of gene expression and cellular differentiation pathways than had been previously possible during attempts to study the murine post-implantation embryo in situ. Removal of LIF from the culture medium initiates murine ES cell differentiation. Plating LIF-deprived ES cells onto nonadhesive culture plates or semisolid medium (methylcellulose) or placing ES cells into suspended drops of culture medium induces the cells to form spherical structures called *embryoid bodies* (EBs).[19] Within the EB, cells derived from the embryonic germ layers develop with relationships similar to those of the developing embryo—embryonic endoderm on the exterior of the EB and mesoderm and ectoderm on the interior surrounding a fluid-filled cavity (yolk sac–like). ES cells present in the EBs differentiate into multiple mature cell types including neurons, pancreatic cells, blood cells, endothelial cells, cardiomyocytes, skeletal muscle cells, adipocytes, and numerous other cells.[20] By extrapolation, the ability of murine ES cells to proliferate extensively in vitro and to differentiate into specific cell types underlies the current enthusiasm for studying human ES cells as a future means to create mature cells to replace aged or damaged cells in human patients.What remains to be determined are the specific cell-to-cell interactions within the EBs that result in the emergence of all three germ layers and resulting progeny, because ordered positional information is lacking in the spherical EBs (no obvious anterior-posterior axis, Hensen's node, or primitive streak is present).[14]

Human Cells

Isolation and Characterization

The isolation and characterization of human ES cells were reported in 1998.[2] In this landmark study, infertile couples donated cleavage-stage human embryos, after informed consent and institutional review board approval of the study. From the 36 donor embryos, 20 were successfully grown to the blastocyst stage (day 5 after fertilization), immunosurgery was then performed to remove the trophoblast cells, and inner cell mass cells were plated on murine fibroblast feeder cell layers (similar to derivation of murine ES cells). Five ES cell lines from five separate embryos were derived, and each continuously proliferated for 6 months; all were successfully cryopreserved.The karyotype of the ES cells was normal; three lines were female and two were male.A murine fibroblast monolayer was required to prevent the ES cells from differentiating on the tissue culture plates. However, when the ES cells were allowed to overgrow and "pile up" on the feeder layers, the cells underwent differentiation. Addition of human LIF to the human ES cells plated in the absence of mouse feeder layers failed to maintain ES cell pluripotency and growth.Therefore one early notable difference between murine and human ES cells was the inability of LIF to maintain ES cell pluripotency in the human cells.

The morphology of human ES cells is somewhat similar to that of murine ES cells. Both demonstrate a high nuclear-cytoplasmic ratio with prominent nucleoli. Human ES cells form colonies in vitro that are not as compact as murine ES cells but are similar to rhesus monkey ES cells. Human ES cells express the cell surface markers SSEA-3 (*s*tage-specific *e*mbryonic *a*ntigen-*4*) and alkaline phosphatase. Oct-4 expression is high, consistent with the self-renewal potential of these cells. Like murine ES cells, human ES cells express high levels of telomerase, an enzyme that lengthens telomeres that normally shorten with each cell division.Telomere length maintenance is a property of self-renewing stem cells and some cancer cells.

The most favored test of human ES cell pluripotency consists of injection of the cells into immunocompromised mice followed by observation for development of subcutaneous teratomas.[2] Analysis of the tissue in the teratomas has demonstrated that derivatives of all three embryonic germ layers are present. Two cloned human ES cell lines were derived from one of the original ES cell lines.[10] The cloned human ES cells formed teratomas in vivo similar to the original ES cell population.This result confirms that the progeny of a single human ES cell retains pluripotency, even though these cells have been "passaged" extensively in vitro.

In Vitro Differentiation

Advances in the in vitro differentiation of human ES cells into specific lineages have been reported.[21,22]The addition of retinoic acid and nerve growth factor to cultured human ES cells was reported to enhance neuronal cell differentiation significantly. The differentiated cells demonstrated extensive outgrowth of neuronal processes and expression of neuron-specific molecules. Co-culture of human ES cells with murine bone marrow or yolk sac cell lines induced hematopoietic differentiation in vitro.[23] The ES cell–derived hematopoietic cells expressed known human hematopoietic cell surface antigens and transcription factors.When they were plated in colony-forming cell assay cultures containing hematopoietic growth factors, numerous hematopoietic progenitor populations were identified. Hematopoietic cell maturation appeared to be normal. Finally, plating of human ES cells in conditions that promote EB formation resulted in spontaneous contractions in 8.1% of the EBs.[24] Cells from the areas of spontaneous contractions expressed cardiac-specific proteins and messenger RNA (mRNA) for cardiac-specific transcription factors, and they displayed morphologic evidence of sarcomeric organization and intercalated disk formation connecting adjacent cells. In addition, the ES cell–derived cells exhibited cardiomyocyte-like calcium ion transients that were synchronous with the recorded contractions and responded to both positive and negative chronotropic agents.These data suggest that human ES cells can be differentiated into neurons, hematopoietic cells, and cardiomyocytes in vitro. At present, it is unknown whether these cells would function in vivo, a critical experimental hurdle for which new transplantation models may be required.

Potential Uses

ES cells may hold the potential for replacing cells and tissues lost to a variety of devastating illnesses. Neurologic diseases, diabetes, heart failure, end-stage kidney disease, and liver failure are a few areas in which availability of a replenishable source of cells and tissues may provide new therapeutic alternatives. In addition, ES cells differentiated into certain tissues may serve as a powerful

in vitro screening method for new pharmacologic agents, teratogens, and environmental toxins. To achieve these breakthroughs, however, much research is required to address the following questions[25]:

- What mechanisms maintain human ES cells in a pluripotent state?[26]
- What cellular and molecular signals are required to activate human ES cells to begin differentiating into a single specialized cell type?
- Are human ES cells homogeneous or heterogeneous?
- Do all human ES cells pass through a stem or progenitor stage during the process of cellular differentiation?
- What stage of differentiation of human ES cells will be most optimal for transplantation?
- How will differences in transplantation antigen expression between the human ES cell–derived transplantable tissue and the host be overcome?

ADULT STEM CELLS

Hematopoietic Stem Cells: Murine Cells

Isolation

More is known about the hematopoietic stem cell than about any other stem cell population. In fact, hematopoietic stem cells currently represent the only stem cell population used in standard therapeutic regimens in human patients. The mouse model has been an invaluable tool in the search for the hematopoietic stem cell that began more than 50 years ago.

Whole-body irradiation was noted to depress hematopoiesis and cause life-threatening pancytopenia (conditions in which all blood types are diminished in number in the bloodstream) in exposed mice. However, the mice could be protected from radiation-induced hematopoietic impairment if the spleen of the irradiated animal was shielded from the radiation beam or if hematopoietic cells from another mouse were infused into the radiation-exposed animal.[27,28] Confirmation that blood cells—and not plasma—conferred radiation protection was reported soon after.[29] In 1961, Till and McCulloch[30] provided evidence that a single blood cell precursor (colony-forming unit–spleen cell) present in the bone marrow could be identified in vivo by intravenously injecting the donor marrow cells into a lethally irradiated recipient animal and examining the host spleen for blood cell–containing colonies 8 to 12 days later. This experimental method advanced the study of blood cell production by supporting the concept of a transplantable hematopoietic precursor population that could produce numerous progeny in vivo and led the way to identification of hematopoietic stem cells—a landmark feat recognized by awarding of the Lasker Award to Drs. Till and McCulloch in 2005.

Several assays of stem cell function have subsequently been developed. The current standard is to measure stem cell function by transplanting donor test cells into a lethally irradiated mouse and then documenting that donor-derived cells have replaced host blood cell lineages over a prolonged period (4 months).[31] Analysis for donor-derived cells in the host requires distinction of the exogenous and endogenous cells. Male-to-female mismatch transplants, use of congenic mouse strains that differ at one or two genetic loci, use of gene transfer to mark the donor cells, and application of fluorescent labeling dyes to the donor cells all have been successfully used to identify donor cells in the host. As a surrogate for the in vivo analysis of stem cell function, several in vitro assays whereby hematopoietic stem cells are cocultured with stromal cells and the co-cultures are examined for prolonged production of colony-forming cells in vitro have been reported. A good correlation between the in vitro assays and in vivo repopulating activity has been reported in studies identifying stem cell activity in adult murine bone marrow cells.[32]

In mice, hematopoietic stem cell repopulating activity appears to be conferred by two populations of cells.[33] Some transplanted cells demonstrate the capacity to reconstitute the bloodstream of the lethally irradiated host for several months and rescue the animal from pancytopenia (the irradiation kills the cycling hematopoietic progenitor cells, so that on loss of mature platelets and neutrophils in the postirradiation period, hemostasis capability and host defense cannot be maintained). However, these short-term repopulating cells do not continue to produce circulating blood cell progeny after 3 to 4 months subsequent to transplantation, and the bone marrow of animals reconstituted with these cells is devoid of donor stem cells that are capable of repopulating the hematopoietic system of a secondary recipient mouse on transplantation. By contrast, long-term repopulating hematopoietic stem cells do not display the ability to acutely rescue the host animal from the sudden deprivation of hematopoietic progenitor cells, but if the animal is given some short-term radioprotective cells, the stem cells produce hematopoietic progeny for the life of the primary recipient, and bone marrow from the primary recipient animal is capable of repopulating secondary recipient mice. Only recently have these two populations and even more committed progenitor cell populations been identifiable and amenable to isolation and study.[34]

Various techniques have been used to isolate hematopoietic stem cells. Stem cells can be separated from more committed cells using velocity sedimentation, adhesion, or exposure to chemotherapeutic agents. One useful method for isolating hematopoietic stem cells from mice takes advantage of the finding that stem cells express a variety of proteins and carbohydrates on their cell surface, some which appear to be hematopoietic-specific. If monoclonal antibodies to these cell surface proteins are labeled with fluorescence-emitting molecules, the stem cells with bound antibodies may be analyzed and isolated by flow cytometry.[35] In the mouse, expression of antigens such as stem cell antigen-1 (Sca-1), c-Kit, CD150, CD34, CD38, CD43, CD44, CD45, Thy-1, and AC133, along with high expression of the ABCG2 transporter protein and low expression of RNA- or DNA-binding dyes, enriches for hematopoietic stem cells.[36,37] Stem cells do not express markers that commonly are expressed by myeloid and lymphoid lineages (lin) and therefore are described as lin^-. In studies using multiparameter sorting, murine hematopoietic stem cells have been reportedly purified to homogeneity.[38,39]

Characterization

The site of hematopoietic stem cell residence changes during murine ontogeny.[40] Hematopoietic cells first appear in the yolk sac on embryonic day 7.0 (E7.0). Although the immediate precursor of the first hematopoietic progenitor cells has not yet been identified, hematopoietic cells are known to emerge from the mesoderm cells that emigrate into the yolk sac after migrating away from the primitive streak during gastrulation. Stem cell activity has been identifiable in the yolk sac as early as E9.0 but only if the donor cells are infused into sublethally myeloablated newborn mice.[41] The first stem cells to repopulate lethally irradiated adult mice appear in the region of the developing gonads, mesonephros, and aorta on E10.[42] More recent evidence demonstrates that all of the hematopoietic progenitor cells that initially seed the fetal liver (before hematopoietic stem cell seeding) and give rise to circulating red and white blood cells and platelets are derived from the yolk sac. Stem cell activity is present in the fetal liver on E11.0, although more recent studies indicate that substantially greater stem cell expansion occurs in the placenta from E11 to 13 than in the fetal liver.[43] By E14, however, the fetal liver is the sole organ with both hematopoietic stem and progenitor cell potential, and subsequently this activity is sequentially found in the blood, spleen, and marrow just before and after birth. The liver becomes significantly depleted of hematopoietic stem cells after 2 weeks of life, although some stem cell activity

can be identified in circulating blood and thus in all organs in the adult mouse; an estimated 100 to 200 stem cells continuously circulate in the mouse systemic circulation.[44] The spleen and marrow compartments are lifelong sites of hematopoietic stem cell production in the mouse. A direct comparison of hematopoietic cell–repopulating ability of stem cells from each of these sites has not been conducted; however, fetal liver hematopoietic stem cell repopulating ability is nearly two-fold that of marrow-derived hematopoietic stem cells.

Murine hematopoietic stem cells are estimated to be present at a frequency of 1 per 10,000 to 1 per 100,000 bone marrow cells. The hematopoietic stem cells with the greatest repopulating potential in adult mice are characterized by preferential existence in a quiescent state.[45] Most of these cells are arrested in the G_0 stage of the cell cycle. Two estimates of the turnover of the stem cell pool have been reported. In young adult mice, 8% of the stem cell pool in one study randomly entered the cell cycle daily.[46] Using another method of analysis, hematopoietic stem cells were estimated to display a half-life (the time required for 50% of the cells to divide) of approximately 19 days.[47] Of interest, commitment of hematopoietic stem cells to the progenitor compartment results in an increase in the frequency of cells in cycle. One estimate of the total number of cell divisions required to produce a mature blood cell from an initiating hematopoietic stem cell ranges from 17 to 19.5, for an overall net amplification of approximately 170,000- to 720,000-fold.[48]

The behavior of hematopoietic stem cells can be allocated into four general activities in the marrow environment: self-renewal, differentiation, migration, and apoptosis. Each of these activities is briefly discussed next. The mechanisms that regulate the overall activity state of the marrow stem cell population, however, remain elusive.

Self-Renewal Ability

Self-renewal divisions are difficult to prove in vitro. Such events clearly occur in vivo with bone marrow transplantation, when the stem cell must not only repopulate all the mature blood cell lineages but also expand the stem cell pool to normal levels. Co-culture of hematopoietic stem cells with certain hematopoietic stromal cells in vitro has permitted documentation of self-renewal divisions, as evidenced by maintenance or slight expansion of repopulating activity on transplantation.[49,50] Certain growth factors—stem cell factor, LIF, and thrombopoietin—appear capable of stimulating hematopoietic stem cells to undergo limited self-renewal division in vitro.[51] Overexpression of the transcription factor HOXB4 permits extensive proliferation of hematopoietic stem cells in vivo and in vitro, with retention of repopulating ability implying numerous self-renewal divisions.[52] Novel approaches such as identifying specific genes that are expressed in different populations of stem cells with differing repopulating potentials may provide new insights into the mechanisms regulating hematopoietic stem cell self-renewal.[53]

Differentiation

The stem cell theory of hematopoiesis states that the hematopoietic system can be viewed as being composed of a continuum of functionally distinct hematopoietic cell compartments. Once the commitment decision is made by a dividing stem cell, the progenitor cell gives rise to progressively more lineage committed hematopoietic progenitor cells and eventually mature blood cells. It remains unclear whether the commitment process occurs randomly (stochastic theory) or is deterministic (controlled by growth factors or other factors released into each specific microenvironment in which the stem cells reside). Nevertheless, evidence suggests that progenitor cells in each functional compartment express distinct combinations of cell surface markers that permit isolation and determination of the stage of hematopoietic commitment of these cells.[34]

Migration

Migration of hematopoietic stem cells through the circulation into developing organs is a hallmark of early fetal and neonatal hematopoiesis. Evidence confirms that hematopoietic stem cell migration throughout the systemic circulation is a consistent feature even in adult mice.[44] At present, it is unclear whether certain organ vascular beds sequester the circulating stem cells or whether the stem cells are randomly distributed throughout the systemic circulation. Progress has been made in identifying strategies to mobilize large concentrations of stem cells into the circulation using growth factors and chemotherapeutic agents; however, the mechanisms regulating the constitutive release, circulation, and reentry of stem cells into the marrow compartment remain elusive.[54] Recent use of transgenic and knockout mice models with hematopoietic specific targeting strategies has permitted new insights into identification of the role of specific molecules in hematopoietic stem cell homing during development in the mouse.[43]

Apoptosis

The size of the hematopoietic stem cell pool remains relatively constant. One mechanism to regulate pool size is to control the rate of stem cell division tightly (see earlier). A backup mechanism is to stimulate apoptosis of stem cells if excessive numbers are produced. Evidence that apoptosis is an active component of normal hematopoietic stem cell homeostasis is derived from experiments in which overexpression of the anti-apoptotic protein Bcl-2 results in significant expansion of the total hematopoietic stem cell pool in transgenic mice.[55] Hematopoietic stem cells readily undergo apoptosis in vitro if they are not supplied with appropriate growth factors, serum, or hematopoietic stromal cells for co-culture.

Hematopoietic Stem Cells: Human Cells

Isolation

Identification of the human hematopoietic stem cell has relied heavily on correlations between murine and human in vitro hematopoietic colony-forming cell assays and murine transplantation experiments. Correlative data also have been obtained from canine and nonhuman primate transplantation models. Several xenotransplantation models in which human hematopoietic stem cells are infused into immunodeficient mice or preimmune fetal sheep in utero have permitted identification of cells with properties of human hematopoietic stem cells.[56,57] However, the current standard for defining stem cell activity ultimately must rely on effective engraftment and repopulation with the test cells in a human patient.

The history of hematopoietic stem cell transplantation in human patients spans less than 50 years.[58] E. Donnall Thomas and colleagues[59] reported that careful filtering of human marrow to remove fat and bone particles allowed large amounts of marrow to be infused into patients, although with little clinical improvement. Many unsuccessful reports followed these early transplantation attempts and led to several decades of intense research in animal models aimed at elucidating the complex biologic and immunologic barriers that need to be overcome, including graft-versus-host disease (GVHD), histocompatibility mismatch, and alternatives to total-body irradiation as a pretransplant conditioning method.[58] Improvements in all aspects of clinical transplantation have resulted in a growing number of transplant recipients; in 2000, more than 18,000 patients received a bone marrow transplant.

While the scientific foundation for effective clinical transplantation was being investigated, advances in the culture of marrow cells led to identification of human hematopoietic progenitor cells.[36] As in the mouse, human hematopoietic stem and progenitor cells can be isolated using monoclonal antibodies and flow

cytometry. CD34 is an antigen expressed by most hematopoietic stem and progenitor cells, although endothelial cells also express this antigen. Some hematopoietic stem cells do not express CD34, and it is unclear whether these cells are the precursors for the CD34-expressing population. Furthermore, some patients who receive CD34-expressing bone marrow cell transplants have demonstrated multilineage engraftment more than 7 years after the procedure, indicating that the $CD34^+$ cells possess long-term repopulating ability. Other antigens expressed by the human hematopoietic stem cell population include c-Kit, Thy-1/CD90, CD133, and the ABCG2 transporter protein.[60] The presence of this transporter protein results in rapid efflux of many different molecules including certain DNA dyes, allowing for selection of DNA dye low-staining stem cells referred to as a *side population profile* on the flow cytometer.

When bone marrow cells are first depleted of all cells expressing mature blood cell lineage markers (lin) and are then selected for CD34 expression ($CD34^+lin^-$), the frequency of hematopoietic stem cells in the enriched population ranges from 1 per 200 to 1 per 500.[61] As noted earlier, analysis of human hematopoietic stem cell number and function is often inferred from experiments performed in vitro or from in vivo xenotransplantation assays. Plating of human marrow cells in colony-forming assays (to enumerate progenitor cell activity) or in co-culture with stromal cells to evaluate the proliferative potential of the cells may reflect the population of cells that retains the most potential. Intravenous administration of human hematopoietic cells into immunocompromised mice or the preimmune sheep fetus permitted assay of the ability of the human hematopoietic stem and progenitor cells to home to the marrow compartment and to produce committed progenitor and mature cells in vivo.[61] Although these types of stem cell transplantation models clearly have limitations, no better surrogate for human clinical transplantation currently exists.

Characterization

The site of human hematopoietic cell production also varies during in utero development. Although the exact site of origin of human hematopoietic stem cells remains elusive, evidence suggests that the intraaortic clusters of cells identified in the month-old embryo may be one of the first sites composed of hematopoietic stem and progenitor cells.[62] The human fetal liver is a prominent site of hematopoiesis for much of the gestational period. Circulating hematopoietic cells that engraft in immunocompromised mice have been identified in the second trimester. Umbilical cord blood is enriched in hematopoietic stem and progenitor cells; preterm infant cord blood is more enriched for these cells than cord blood derived from full-term infants. Umbilical cord blood cells engraft 10 to 50 times better than adult marrow hematopoietic cells on transplantation into immunocompromised mice.[63] Proliferative potential in vitro is higher in cord blood hematopoietic cells than in adult marrow progenitor cells. No direct comparison of the hematopoietic repopulating ability of marrow cells isolated from young versus old subjects has been performed to date.

Administration of granulocyte colony-stimulating factor to human subjects results in mobilization of hematopoietic stem and progenitor cells into the systemic circulation. Combining granulocyte colony-stimulating factor or AMD3100 (a small-molecule inhibitor of CXCR4 ligand binding) administration with leukapheresis permits isolation of an enriched population of peripheral blood transplantable cells.[64] Stem cell mobilization has become a preferred method for isolating cells for clinical transplants because of the increased numbers of cells recovered and the earlier neutrophil and platelet recovery in the conditioned patient.[36]

Human hematopoietic stem cells are difficult to maintain in culture. Most methods developed for expansion of hematopoietic cells ex vivo have resulted in large increases in the number of committed progenitor cells, with loss of the stem cells. This is particularly true for culture conditions relying solely on combinations of recombinant growth factors to induce the cellular proliferation. The addition of extracellular proteins or certain endothelial or stromal cell lines appears to improve the ex vivo maintenance of the most primitive hematopoietic progenitor and stem cells while inducing overall cellular expansion.[65,66]

Therapy for Human Clinical Disorders

Bone marrow transplantation is a potentially useful therapy for various cancers of the blood including acute lymphoblastic and myeloblastic leukemia, chronic myelogenous leukemia, Hodgkin disease, multiple myeloma, and non-Hodgkin lymphoma[36] Transplantation can be performed using autologous (the patient's own) cells or allogeneic (another person's) cells. Cells from the bone marrow or mobilized cells in the peripheral blood can be used for either type of transplant. Although autologous cells can be transplanted without concern for whether the cells will be rejected or induce GVHD, these cells may harbor the very transformed cells that the patient is receiving chemotherapy to eradicate. Application of flow cytometry or other cell-sorting strategies (e.g., immunomagnetic beads) to isolate hematopoietic stem cells can provide graft cells free of detectable tumor cells.

The use of allogeneic grafts for hematopoietic reconstitution in patients with cancer is rational because these donor cells are not contaminated with the cancer cells. However, both bone marrow and mobilized peripheral blood grafts contain T lymphocytes that will recognize host tissues as foreign on transplantation and will induce GVHD unless the host and the donor share the same histocompatibility antigens (human leukocyte antigens [HLAs]). HLA typing of the donor and the host is routine, to obtain the best possible match. Because of the polymorphic nature of HLA genes, the probability of a match between a host and a sibling is only 25%. Of interest, recent studies suggest that transplantation of mesenchymal stem cells provide some amelioration of GVHD in transplant recipients.

In certain circumstances, the provision of donor-derived T cells in an HLA-matched allogeneic graft may cause a "graft-versus-leukemia" (GVL) response and may actually help to kill the transformed cells in the patient. In fact, once transplanted cells have engrafted and the patient has recovered from any GVHD, peripheral blood lymphocytes from the graft donor can be recovered and infused into the patient to provide a stronger GVL effect. This strategy has been used successfully in patients with chronic myelogenous leukemia.[58] More recent data indicate that cord blood–derived donor cells may give rise to less severe GVHD disease but also provide less GVL effect.

Allogeneic grafts are currently useful in the treatment of inherited blood disorders. Aplastic anemia, β-thalassemia, Blackfan-Diamond syndrome, sickle cell anemia, severe combined immunodeficiency, X-linked lymphoproliferative syndrome, and Wiskott-Aldrich syndrome are some of the candidate diseases for bone marrow or cord blood hematopoietic stem cell transplantation.[58] Single-gene metabolic defects such as Hunter syndrome and Hurler syndrome and certain forms of osteopetrosis also are amenable to bone marrow transplantation.

Umbilical cord blood is becoming a favored graft source when a suitable HLA-matched donor is not available. Mismatched umbilical cord blood appears to engraft with less GVHD in pediatric or adult patients when compared with partial mismatched marrow or peripheral blood grafts. The primary concern with using umbilical cord blood as a source of donor cells is that the number of hematopoietic stem cells in the cord blood sample may be limiting for large adult patients. Efforts to expand the hematopoietic stem and progenitor cells in cord blood samples remain experimental (see earlier). Recent success has been achieved with coadministration of two separate units of allogeneic cord blood

cells in adult patients with leukemia, after use of less aggressive myelosuppressive regimens.[67]

Neural Stem Cells

The central nervous system (CNS) is composed of hundreds of different types of neurons, astrocytes, and oligodendrocytes. Although the CNS is susceptible to the same environmental, genetic, metabolic, and infectious stressors as for other tissues in the body, the neuronal cell types were thought to differ from cells in other organs in being completely postmitotic. Numerous studies since the early 1990s, however, provided compelling evidence that neurogenesis occurs in the adult brain, and cells are being continuously generated in some portions of the adult CNS.[68] Furthermore, more recent techniques have permitted isolation of the neural stem cells (NSCs), and methods to expand, differentiate, and transplant these cells are being developed. Such rapid progress has been exceeded only by the growing hope of anticipated benefits generated by families of patients and patients suffering from CNS disorders.

Neurogenesis in the adult brain occurs in primarily two areas: the dentate gyrus of the hippocampus and the olfactory bulb in humans, rodents, and nonhuman primates.[69] The *neural progenitor cells* (NPCs) that give rise to the new neurons in the dentate gyrus of the hippocampus are derived from the subgranular zone of the dentate gyrus. The neuronal progeny and glial progeny of the NPC are formed in the granular layer of the dentate gyrus after migration of the NPC into this layer. Functional connections with other neurons in the hippocampus are established in as few as 4 to 10 days after neuronal differentiation is initiated in the NPC progeny. NPCs that seed the olfactory bulb are derived from the anterior part of the subventricular zone (layer of cells beneath the ependymal lining cells of the lateral ventricles).[70] Migration of the NPCs from the subventricular zone to the olfactory bulb occurs through a rostromigratory stream composed of specialized astrocytes. Cell-to-cell communication between the NPC and the astrocytes is mediated by secreted glycoproteins on the surface of the NPC. Disruption of these important cellular interactions results in diminished NPC migration and a reduction in the size and organization of the olfactory bulb.

Like the hematopoietic system, the neuropoietic system is a hierarchy with fully mature cells composing the base and NSC composing the apex of the pyramid. NSCs give rise to NPCs, which give rise to unipotent committed neural or glial progenitors. Unlike with the hematopoietic system, little is known of the kinetics of neuronal turnover. Young rats appear to generate 9000 new neurons daily in the dentate gyrus, or approximately 0.1% of the total granule cell population.[71] Another estimate suggests that in the mouse, one new neuron is generated daily for every 2000 existing neurons. Whereas neurogenesis (and the presence of NSCs) persists throughout adulthood in mammals in the dentate gyrus and olfactory bulb, the rate of neurogenesis diminishes with age.

Like other adult stem cells, NSCs are defined as CNS cells that can give rise to themselves in a self-replicating way but also can give rise to neurons, astrocytes, and oligodendrocytes. In vitro assays of neurosphere formation have proved useful in identifying the clonal proliferative behavior consistent with NSC. The standard method for isolating NSCs begins with dissecting tissue from a region in a fetal or adult brain known to harbor NSCs.[68] The tissue is disaggregated, and cells are plated in the presence of growth factors, such as epidermal growth factor or fibroblast growth factor-2. NSCs present in the cultured tissue spontaneously form spherical structures. These neurospheres are highly proliferative and can be expanded into large numbers of cells. By withdrawing epidermal growth factor or fibroblast growth factor-2 or adding other morphogens, NSCs can be differentiated into specific cell types in vitro or can be transplanted in vivo, whereupon the NSCs become incorporated into various central and peripheral nervous system cell types.[69]

NSCs have been difficult to isolate directly from CNS tissue. Successes in using specific monoclonal antibodies and flow cytometry have led to reports of NSC isolation from human fetal spinal cord and CNS tissue. These human NSCs express the cell surface AC133 antigen but not CD34 or CD45.[72] Single-sorted cells were capable of initiating neurosphere cultures and could be recloned with retained neurosphere potential. Other similar enrichments of NSCs have been reported in rats and mice using both positive and negative selection strategies.[70] These techniques will permit rapid progress in understanding the growth and expansion requirements of NSCs and will permit comparisons of the molecular regulation of NSC self-renewal with other adult stem cell populations.

Although a detailed study of the biology of NSCs will require considerable time, use of neural tissue for human clinical transplantation has already proved feasible. What types of grafts will be the most desirable? Human fetal CNS tissue has proved effective in providing symptomatic relief in patients with Parkinson disease; however, technical and ethical issues may preclude provision of sufficient numbers of cells for wide application.[70] NSCs cultured to large cell concentrations would appear to be an ideal source of cells. Whether the NSCs isolated from fetal CNS tissue or adult tissue display similar in vivo repopulating ability has not been directly tested. The report of isolation of NPCs from postmortem human olfactory bulb, dentate gyrus, and the subventricular zone of the forebrain suggests another potential source of transplantable NPCs.[73] Finally, ES cells can be differentiated into numerous neuronal cell types and may serve as a source of cells for repair of CNS damage; particular interest in the research community centers on the use of these cells to treat spinal cord injury.

Hepatic Stem Cells

The murine liver is formed by migration of foregut endoderm cells into the septum transversum on E8.5. Interactions between the endoderm cells and both cardiac mesenchymal and endothelial cells are critical for liver formation.[74] The foregut-derived cells begin expressing alpha fetoprotein on E9.0 and albumin soon thereafter. Further differentiation into hepatoblast cells occurs over the next 24 hours. Several days later (E12), the bipotent hepatoblast cells begin to proliferate rapidly as they differentiate into hepatocytes and cholangiocytes (biliary tract precursors). Distinct patterns of gene expression along the primary cellular lineages in the liver are demonstrable from E16 onward.[75] The basic lobular structure of the liver is not fully formed until several weeks after birth. One interesting feature of liver development is the inverse relationship between the level of hematopoiesis in the rodent fetal liver and the synthetic, metabolic, and enzymatic functions of the organ. As the liver function rapidly increases over the first 2 weeks of postnatal life, the hematopoietic function of the liver diminishes.

In terms of regenerative capacity, the mature liver is unique among solid organs.[76] Up to two thirds of the fully mature rodent liver may be resected, and within 1 to 2 weeks thereafter, compensatory growth and restoration of cellular numbers and function by the remaining cells will have occurred. Technically, the lost structures in the resected liver are not replaced or regenerated; instead, the remaining liver simply expands to the original mass of the organ. Surprisingly, this liver expansion results from proliferation of 70% to 90% of the hepatocytes in the unresected portion undergoing proliferation. It has been estimated that the proliferative capacity of adult hepatocytes is sufficient for repopulation after up to two-thirds liver resection without the need to recruit progeny from liver stem or progenitor cell populations. To date, the mechanisms regulating the overall mass and turnover of liver parenchymal cells remain obscure.

Under certain experimental circumstances, recruitment of hepatocytes from precursors can be demonstrated. In such instances, proliferation and differentiation of the hepatic stem and progenitor cells can be induced only with a concomitant block in the proliferative ability of mature hepatocytes[76] Thus treatment of rodents with irradiation, carcinogens (ethionine, 2-acetylaminofluorene, and 3-methyl-4-dimethylaminobenzene), RNA and protein synthesis inhibitors (D-galactosamine), or DNA-alkylating agents (retrosine) has been used to generate a proliferative population of epithelial cells called *oval cells* in the periportal region.[76] Oval cells initially proliferate in the canals of Hering (luminal channels linking the hepatocyte canalicular system to the biliary tree) and then differentiate into hepatocytes and bile duct cells in mice and rats treated with the aforementioned injurious agents.[77] The finding that differentiating oval cells recapitulate hepatocyte and bile duct gene expression patterns in a sequence similar to that seen during embryonic liver development strengthens the evidence that oval cells serve as a stem cell population for the liver.

Proof that oval cells repopulate the liver requires in vivo transplantation data. Limited hepatocyte and bile duct repopulation occurs in normal adult mice transplanted with oval cells isolated from D-galactosamine–treated rodents.[76] When the recipient animals underwent two-thirds partial hepatectomy alone, oval cell engraftment was observed, but proliferation was again limited. High levels of engraftment were observed only when the cells were transplanted into mice with ongoing liver injury (incurred as an inherited metabolic defect). By contrast, transplantation of oval cells from E12 to E16 rat fetal livers into normal adult hosts led to long-term engraftment of both hepatocytes and bile duct cells in up to 10% of therecipient livers. Whether this difference in liver repopulation represents a difference in mouse and rat biology, or in young versus older donor oval cells, remains to be determined.

Specific reagents to isolate hepatic stem and progenitor cells remain elusive. Suzuki and associates[78] used monoclonal antibodies and flow cytometry to isolate murine fetal liver progenitor cells expressing the α6 integrin and the β1 integrin. Fetal liver hematopoietic progenitor cells do not express this combination of integrins. In addition, the murine fetal liver progenitor cells did not express c-Kit, a tyrosine kinase receptor that is expressed by fetal liver hematopoietic stem cells. Some evidence has been presented that the pancreas possesses cells capable of differentiating into hepatocytes. Putative hepatic stem and progenitor cell populations from human liver and bone marrow also have been reported.[79] More controversial are several reports that bone marrow or hematopoietic stem cells possess the capacity to differentiate into hepatocytes and bile duct cells in vivo (see later discussion of stem cell plasticity).[39,80] More recently, the contribution of bone marrow–derived cells to liver repopulation has been reported to be due largely to fusion of myelomonocytic cells with injured hepatocytes, at least as measured in one genetic model of liver regeneration.[8]

In sum, the rodent liver possesses remarkable regenerative ability. Mature hepatocytes may be induced to proliferate and compensate for up to a loss of two thirds of a mature liver. When the mature hepatocytes are inhibited in their proliferation, oval cells proliferate and differentiate to produce hepatocytes and bile duct cells. Whether oval cells or other stem cell populations participate in maintaining the hepatic parenchyma during homeostasis or participate in restoring normal hepatocyte numbers during liver regeneration remains to be determined.

Although human liver transplantation has been used in clinical medicine for many years, basic information on potential liver stem cell participation in liver regeneration after transplantation is limited. This paucity of data may be a result of the immunosuppressive regimens that are required to permit allogeneic liver transplantation and concern for effects of this treatment regimen on the transplanted organ. Alternatively, cellular rejection of the transplanted organ also may complicate interpretation of the homeostatic turnover of hepatocytes and role of liver stem cells in the process. Nonetheless, transplantation of a portion of the liver from living donors has proved to be quite successful, with regrowth of the organ in both donor and recipient suggesting robust regenerative abilities of the human hepatocyte.[81]

Other Epithelial Stem Cells

Skin, hair follicles, and intestinal villi are all examples of tissues that must undergo rapid and continual self-renewal. The outer layer of human epidermis is sloughed, with continued replacement by differentiating cells moving upward from a basal layer in the dermis.[82] Cells in the basal layer display slow but persistent cell division. Within this layer are epidermal stem cells and transient amplifying cells (progenitors). In view of the fact that the human epidermal layer completely turns over every 3 weeks, and that transient amplifying basal cells divide only three to six times before differentiating into epidermal cells, the self-renewal capacity of the epidermal stem cells is astounding.[83]

Hair follicles are composed of an outer root sheath that is contiguous with the epidermis, an inner root sheath, and the hair shaft.[84] Proliferating cells that give rise to the inner root sheath and the hair shaft are located at the base of the follicle and compose the dermal papilla. In human adult skin, the proliferative capacity of the dermal papilla cells is cyclically exhausted, and the lower segment of the hair follicle regresses upward toward the permanent epithelial portion of the follicle called the *bulge.*[85] Follicle stem cells reside in the bulge and can regenerate the dermal papilla on receiving appropriate signals.[84] These follicle stem cells also are capable of regenerating epidermis and play an important role in the repair of wounds and burns to the epidermal layer. In vitro, a single human follicle stem cell can generate an enormous number of progeny (1.7×10^{38})—more epidermal cells than are required to cover the body surface of an adult human.[1]

The architecture of the small and large intestinal lining is unique, with extensive folding of the epithelial cells to form crypts and fingerlike projections called villi.[86] Such an arrangement increases the overall surface area of the intestinal lumen to permit maximal interaction of ingested nutrients with the epithelial cells for efficient absorption. As in the epidermis, newly formed cells move in a polarized fashion as a column of cells from the lower part of the crypt upward to an adjacent villus, where migration occurs along the villus until the cells are shed at the villus tip. The absorptive functions of the cells are operative during the migration from the base to the tip of the villus. The entire migratory passage from newly formed cell in the crypt to sloughed cell at the villus tip is thought to occur within 5 to 7 days.[87] In both the small and large intestine, villi are composed of enterocytes, mucus-secreting goblet cells, and peptide hormone–secreting enteroendocrine cells. An additional cell called the *Paneth cell* is present in small intestinal villi. Paneth cells participate in innate immune defense of the gut by sensing pathogenic microbes and secreting microbicidal peptides.

The unique architecture and migratory route of the epithelial cells permit specific identification of the position of each cell during maturation. In the mouse, each adult intestinal crypt is thought to contain four to six stem cells, each giving rise to dividing transit cells. These cells give rise to up to six generations of daughter cells that form the 250 cells composing the mature villus.[88] During the lifetime of a mouse, intestinal epithelial stem cells in each crypt produce 3.3×10^5 cells, suggesting that each stem cell may undergo a thousand cell divisions. In humans, the number of stem cell divisions may be as high as 5000.[87]

The increasing use of human skin grafts to treat large areas of denuded skin (major trauma or burn injury) has proved to be

quite effective in reducing overall morbidity and mortality for these injuries. Obviously, the ability to expand human skin cells in vitro relies on the stem cell and transient amplifying cell populations recovered from the host to generate enormous numbers of mature keratinocytes.[85] Further modifications to promote accelerated vascularization of the applied tissues will only enhance the use of this cell therapy in human subjects.

Advances in transplantation of human small intestine are steadily emerging and may provide some measure of hope for effective management of newborn infants who have suffered catastrophic losses of intestinal tissue through necrotizing enterocolitis, congenital atresia, or volvulus.[89] Elucidation of how to isolate, expand, and reconstitute injured intestine with intestinal stem cell–derived progeny is eagerly anticipated, although derivation of a functional peristaltic bowel from a completely engineered three-dimensional construct seems many years away from clinical application.[90]

INDUCED PLURIPOTENT STEM CELLS

A recent series of landmark papers may provide a method to generate induced pluripotent stem cells (iPSCs) from somatic cells of male or female mice. Mouse embryonic or adult fibroblast cells were reprogrammed to express ES-like properties by retroviral introduction of Oct-3/4, Sox2 (*S*RY [sex-determining region Y]-b*ox* protein *2*), c-Myc, and Klf4 (*K*rueppel-*l*ike *f*actor *4*) transcription factors and then selection for cells with up-regulated expression of the transcription factor Fbx15.[91] These cells could commit to differentiate into progeny from multiple germ layers, generate chimeric embryos after blastocyst injection, and form teratomas on injection into immunodeficient mice. However, the DNA methylation and gene expression patterns were not similar to those in mouse ES cells, and the iPSCs did not form viable chimeric mice upon injection into recipient blastocysts.

An advance in the procedure with forced expression of the same four fundamental transcription factors, but with selection for up-regulation of Nanog expression, has led to the isolation of reprogrammed murine fibroblasts that now are ES-like in appearance, proliferation, differentiation potential, and germline competency.[92] A precautionary note from these studies was that in nearly 20% of the offspring produced by the chimeric mice, tumors developed that appeared to be related to reactivation of c-Myc expression. Finally, another group of investigators have confirmed that expression of the four transcription factors Oct-3/4, Sox2, c-Myc, and Klf4 in mouse fibroblasts resulted in DNA methylation, gene expression, and chromatin state that were similar to those of ES cells.[93] Of note, the cells derived from mouse fibroblasts could generate live chimeric mice when injected into tetraploid blastocysts.

Although similar studies have not yet been successful in human cells, these data are encouraging that methods are developing that reconstitute an ES-like state from somatic cells. If such methods are shown to be feasible, subsequent studies could permit generation of patient-specific iPSCs for cell-based therapies for genetic or acquired disorders. Challenges in future work will be to develop methods of gene insertion without use of retroviral vectors and to ensure that the introduced genes are under strict inducible control, to avoid the emergence of tumors as reported in some murine studies.[92]

Developmental Biology of the Hematopoietic Growth Factors

HEMATOPOIESIS

Hematopoiesis is defined as the process of blood cell production. Although it is highly variable, all blood cells have a finite life span. For example, red blood cells circulate for 120 days, platelets for nearly 10 days, and neutrophils for only about 6 hours.[1] Under normal conditions, blood cells are replenished at a constant pace that maintains the concentrations of circulating cells within a narrow range and effectively masks the magnitude and complexity of the process. In a 70-kg adult approximately 200 billion red blood cells and 70 billion neutrophils must be released into the circulation and replace the damaged and senescent cells on a daily basis. The mechanisms regulating the precise number of circulating blood cells in each lineage and the turnover of each cell lineage remain elusive, although the concentrations of some hematopoietic growth factors appear to play a direct role in this process.[2]

Development of in vitro methods for the culture of hematopoietic cells has permitted analysis of the effects of soluble and membrane-bound growth factors on the survival, proliferation, and differentiation of hematopoietic stem and progenitor cells. Numerous growth factors have been characterized at the protein and nucleic acid level. The goal of this chapter is to review basic concepts of hematopoiesis and to provide an overview of some of the growth factors and their cognate receptors that are critical for normal hematopoiesis. We review basic concepts of ligand-receptor interactions and initiation of intracellular signaling pathways, and highlight differences in growth factor responsiveness of hematopoietic cells during in utero and postnatal development.

STEM AND PROGENITOR CELLS

Background

The hematopoietic system may be characterized as a hierarchy of cell intermediates progressing from the primitive stem cell to mature cells of specific blood cell lineages (Figure 142-1). A single stem cell can sustain the entire hematopoietic system for the lifetime of a mouse in certain experimental systems.[3,4] Stem cells generally exist in a quiescent state, but 8% of the stem cell pool is renewed daily in young mice.[5] Some of the daughter cells of the stem cell divisions may commit to differentiate and may become more highly proliferative multipotent progenitor cells. These cells, in turn, give rise to more proliferative bipotent progenitor cells that eventually produce unilineage committed progenitor cells. The total cellular amplification that occurs from the time of a single stem cell division to production of a mature blood cell is estimated to be 720,000-fold as a result of at least 17 cell divisions.[6]

Hematopoietic Stem Cells

Analysis of hematopoietic stem cell function has been most reliably understood from the standpoint of functional reconstitution of the hematopoietic system of a lethally irradiated host. In the mouse, multilineage reconstitution of hematopoiesis in a lethally irradiated recipient for more than 4 to 6 months after transplantation constitutes the full definition of a hematopoietic stem cell.[7] In the human system, such experimental proof cannot be undertaken in patients. However, in practical terms, hematopoietic stem cell function has long been demonstrated in patients who have undergone bone marrow transplantation using allogeneic donor bone marrow, umbilical cord blood, autologous marrow, or mobilized peripheral blood.[8] Both in vitro and in vivo experimental systems have been developed to test for human hematopoietic stem cell function.

In vitro systems for culture of hematopoietic stem cells can be divided into stromal-dependent and stromal-independent systems. Preplating of stromal cells onto culture dishes followed by addition of hematopoietic stem cells (with or without growth factors) to establish a co-culture can result in retention of hematopoietic stem cell function ex vivo and, in some cases, expansion of stem cell function.[9-14] Transplantable activity can also be maintained and expanded in stromal-independent cultures in the presence of stem cell factor (SCF), thrombopoietin, insulin-like growth factor-2, and fibroblast growth factor-1.[15] Several xenotransplantation models have been developed to assess human hematopoietic stem cell function in vivo. First, human cells can be transplanted and will engraft in the marrow of immunocompromised mice.[16,17] The extent of human hematopoietic stem cell expansion and differentiation can then be examined in the marrow of the mice with transplantations. Implantation of human fetal thymic and bone fragments into the immunocompromised mice (producing human hematopoietic microenvironments in the mouse) permits a more detailed analysis of human stem cell differentiation into lymphocyte and erythroid populations.[18] Finally, human hematopoietic stem cells engraft in the marrow of fetal sheep in utero and produce human hematopoietic progeny long term in the sheep postnatally.[19,20]

Understanding the innate properties of hematopoietic stem cells has been advanced through the development of techniques to isolate and characterize murine cell populations (using the foregoing assays).[3,4,21] Human hematopoietic stem cells have also been isolated using monoclonal antibodies and flow cytometry and are characterized by expression of the cell-surface antigens AC133, CD34, Thy-1 (low level), rhodamine-123 (low level), and Hoechst 33342 (low level), but not CD33, CD38, human leukocyte antigen-DR, and antigens expressed by mature cells of each lineage.[22-24] Using a combination of antimetabolite treatment and addition of growth factors in vitro will enhance enrichment for human hematopoietic stem cells.[25]

An alternative method for identifying both murine and human hematopoietic stem cells is based on efflux of a DNA-binding dye, Hoechst 33342. A small cell population, termed the *side population,* is identified by a characteristic fluorescence pattern after staining with Hoechst 33342 detected in both far red (>675 nm) and blue (450 nm) emission channels. The side population has been detected in both mouse and human bone marrow and contains the long-term hematopoietic stem cell expressing low or negative levels of CD34.[26] In addition to enriching for hematopoietic stem cells, the side population protocol can be used to identify stem cells in other tissues including skeletal muscle and epidermis.[27,28] Additional specific cell surface markers have been identified in murine systems that refine hematopoietic stem cell identification. These include endoglin, an ancillary transforming growth factor-β receptor, and prion protein, a highly conserved

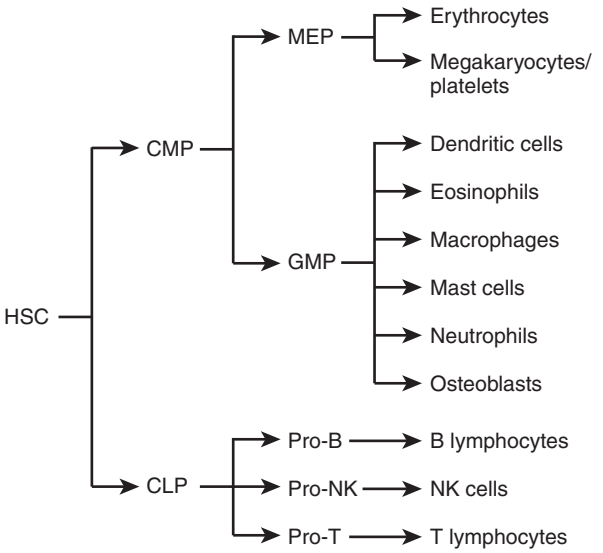

Figure 142-1 Pluripotent hematopoietic stem cells *(HSC)* give rise to committed hematopoietic progenitor cells, common myeloid progenitor *(CMP),* common lymphoid progenitor *(CLP),* granulocyte/macrophage progenitor *(GMP),* and megakaryocyte/erythrocyte progenitor *(MEP),* which undergo clonal expansion and differentiation under the permissive support of hematopoietic growth factors.

glycoprotein associated with the glycosylphosphatidylinositol anchor on hematopoietic cells.[29,30] Although hematopoietic stem cell isolation protocols have advanced significantly, current techniques are enrichment, rather than purification protocols.

Substantial evidence supports the hypothesis that the stem cell population resides in a dormant state with respect to the cell cycle. At any given time, only a few stem cells enter the cell cycle, undergo clonal expansion, and supply all the hematopoietic cells to maintain homeostasis. Prolonged residence in the G_0 or the noncycling state is thought to permit sufficient time to repair damaged DNA that may have accumulated during previous cell divisions and to diminish the chance of a clonal proliferative abnormality.

The concept of defining stem cell identity has undergone change with evidence that adult stem cells derived from one tissue are capable of differentiating into other tissue types.[31] For example, bone marrow can give rise to cells typical of other tissues. These stem cells can be derived from the hematopoietic or stromal compartments of the bone marrow. Indeed, bone marrow stem cells also give rise to cell types typical of other tissues such as muscle, brain, heart, and liver. Likewise, there are examples of nonhematopoietic tissue-specific stem cells reconstituting blood after intravascular injection into irradiated mice.[27,28,32] These and other findings suggest a previously unrecognized degree of plasticity in stem cell function. It appears that cell fate changes are a natural property of stem cells and may be involved in physiologic repair of tissue damage throughout life. In this revised paradigm, stem cell refers to a biologic function that can be induced in many distinct types of cells. Homing signals may result from local damage and influence the migration of stem cells to specific sites. The microenvironment including contact with surrounding cells, extracellular matrix, and growth and differentiation factors is likely to play a key role in determining the function of a stem cell.

Hematopoietic Progenitor Cells

The discovery of in vitro culture systems to examine hematopoietic progenitor cell formation as isolated colonies has enabled study of the categorization, functional analysis, and growth factor requirements of the various hematopoietic progenitor cells.[33-35] Figure 142-1 schematically depicts the hierarchy of hematopoiesis from the stem cell to mature blood cells of each lineage. In general, the hierarchy can be divided into myeloid and lymphoid pathways. Progenitor cells that form colonies containing neutrophils, erythrocytes, macrophages, and megakaryocytes (common myeloid progenitor) reside at the pinnacle of the myeloid pathway. These multipotent progenitors no longer possess the self-renewal properties of the stem cell, but they are considered as a primitive progenitor based on the capacity of these cells to give rise to progeny of multiple lineages. These cells are also highly proliferative and give rise to numerous progeny of more committed progenitors. As the progenitor cells become more committed to a particular lineage, one can begin to identify certain combinations of growth factors that appear to be required for the survival, proliferation, and full maturation of those cells.

The number of hematopoietic growth factors and cytokines that have been identified and characterized and the genes cloned is growing rapidly. Although these factors exhibit either stimulatory or inhibitory functions when they are evaluated in culture as single agents, most exhibit more complex actions when they are tested in combinations with other growth factors. Many hematopoietic growth factors have functions that extend outside the hematopoietic system. Interleukin (IL)-6 regulates certain aspects of immunologic, neuroendocrine, hepatic, and renal functions.[36] Furthermore, several hematopoietic growth factors are known to orchestrate functions affecting cells at different stages of hematopoietic differentiation. For example, injection of granulocyte colony-stimulating factor (G-CSF) into murine and human subjects triggers cycling of stem cells and mobilization into the systemic circulation, but it participates in a specific way to support the proliferation and maturation of lineage-committed neutrophilic progenitor cells.[37]

HEMATOPOIETIC MICROENVIRONMENT

Ontogeny of Hematopoiesis

Hematopoiesis is tissue specific and developmentally regulated. The first blood cells to appear in the murine and human embryo are formed in the extraembryonic yolk sac. Within 72 hours in the mouse, and 4 to 6 weeks in the human, blood cells are beginning to be formed in the liver.[38] The liver predominates as the site of hematopoiesis in the mouse until 3 to 4 days before birth, when circulating cells seed the spleen and bone marrow compartments. After birth, the liver diminishes in hematopoietic cell production and no longer serves as a primary hematopoietic site by 2 to 3 weeks of age, whereas the spleen and marrow serve as lifelong sites of blood cell production.[39]

Remarkably, hematopoiesis in cultured embryonic stem (ES) cells largely recapitulates embryonic events. For example, distinctly timed waves of primitive and definitive erythropoiesis develop in vitro from embryonic stem cells in a fashion that parallels the onset of these developmental stages in early embryos.[40] Keller and colleagues[41-43] discovered a transient progenitor in early embryoid bodies, termed blast-colony-forming cell, which gives rise to primitive erythrocytes, definitive lineages, and endothelial cells. Nishikawa and colleagues[44] identified a developmental hierarchy in ES cell differentiation in which hematopoietic cells arise from a precursor expressing endothelial cell markers. They also identified single progenitor cells capable of hematopoietic and endothelial differentiation. Together these studies established lineage relationships between the first murine hematopoietic precursors and verify the existence of the hemangioblast. Gene-targeting studies have identified numerous transcription factors and signaling molecules important for generation and maintenance of murine ES cell–derived hemangioblasts.[45-48] Recently, Huber and co-workers[49] identified hemangioblasts from the primitive streak of the early mouse embryo.

Importantly, these progenitors have similar properties to ES cell–derived blast-colony-forming cells.

Hematopoietic stem cell development, differentiation, and homeostasis are directed by transcriptional regulators, which control gene expression under the influence of signals from the microenvironment.[50] Commitment steps require the activation of lineage specific genes and concomitant repression of conflicting or unnecessary genes. This balance involves the concerted actions of multiple transcriptional activators, repressors, and epigenetic modifiers. Many of the key hematopoietic transcription factors were first identified in leukemic cells. Subsequently, using knockout studies in animal models, important roles for these protooncogenes were discovered in normal hematopoietic stem cell development of lineage differentiation.[51] Because many of these regulators are required for blood cell development and survival of the embryo, conditional gene targeting strategies made it possible to define the role of these factors at later developmental stages.

Yolk Sac

The first cells to form in the yolk sac are unique products of this organ and are called *primitive erythroblasts.* These are large red blood cells that express embryonic hemoglobin molecules and retain their nucleus even as circulating blood cells.[52] Primitive erythroblast progenitor cells are first identifiable on embryonic day 7 and are no longer detectable in the yolk sac by day 9. The primitive erythroblasts formed retain the ability to proliferate, and a rapid expansion in cell number occurs over a 48-hour period. The only other mature blood cells formed during this time include macrophages and a rare number of megakaryocytes.

Yolk sac hematopoiesis is not restricted to the formation of primitive erythroblasts. Evidence indicates that large numbers of definitive hematopoietic progenitor cells are also formed in the yolk sac, but they do not mature in this organ.[53,54] Circumstantial evidence suggests that the definitive progenitor cells (so called because these cells are like progenitors formed in the liver and marrow) enter the circulation, migrate via the bloodstream to the developing liver, enter the liver, and complete the differentiation process to mature blood cells.

Aorta-Gonad-Mesonephros Region

Hematopoietic cells are also formed in the embryo in sites other than the yolk sac and liver early in embryogenesis. The anatomic site in which the primordial germ cells coalesce to form the nascent gonads and the mesonephros forms is called the *aorta-gonad-mesonephros* region. Along the ventral wall of the aorta in this region, one can observe clusters of hematopoietic cells that appear to emerge from the endothelium.[55] Evidence suggests that this region may be the site of the first hematopoietic stem cells to emerge in the murine and human embryo.[55] Similar clusters of hematopoietic cells have also been identified in the vitelline and umbilical arteries and in the yolk sac, where stem cell activity can also be demonstrated to exist.[56] Apparently, the hematopoietic stem and progenitor cells formed in the aorta-gonad-mesonephros region do not mature in this site but must also migrate to other organs, such as the liver, to differentiate into mature cells.[57]

Placenta

The placenta has also been identified as a major source of hematopoietic stem cells during fetal life.[58] The murine placenta functions as a hematopoietic organ housing a large pool of hematopoietic stem cells during midgestation. The onset of hematopoietic activity parallels that of the aorta-gonad-mesonephros region; however, the placental hematopoietic stem cell pool expands to 15-fold more hematopoietic stem cells than the aorta-gonad-mesonephros region. Expansion of the placental hematopoietic stem cells occurs before and during expansion of hematopoietic stem cells in the fetal liver. Placental hematopoietic stem cells express Sca-1, CD34, CD31, and other hematopoietic stem cells specific markers and transcription factors, and they are found in the embryonic vasculature of the placental labyrinth.[59]

Fetal Liver

As the principal site of hematopoiesis shifts to the fetal liver in week five to eight of human gestation, the total content of hematopoietic progenitor cells increases 10- to 100-fold compared with the yolk sac. As in the yolk sac, erythropoiesis continues to predominate over granulocyte production.[60] In fact, the concentration of granulocyte and macrophage progenitors may even decrease during the transition of hematopoiesis from yolk sac to fetal liver. It remains unclear whether this paucity of granulocytic differentiation is secondary to diminished hepatic production of granulocytic growth factors or results from insensitivity of the fetal liver colony forming units–granulocyte macrophage to granulopoietic factors.

Bone Marrow

The transition of human hematopoiesis from the liver to the bone marrow occurs over the third trimester of intrauterine life. The microenvironment in the bone marrow has been well defined anatomically and is known to consist of osteoblasts, barrier cells, endothelial cells, macrophages, fibroblast cells, mesenchymal stem cells, and adipocytes.[61,62] Barrier cells are the major component of the stroma.[63] These fibroblast-like cells are located around the venous sinuses and form a sheath around the abluminal surface of the endothelium. Some barrier cells are interspersed within the hematopoietic elements in the marrow and extend cell processes that interact with the maturing hematopoietic cells. Macrophages constitute a second major cell type in the microenvironment. These cells are particularly important for erythrocyte maturation because macrophages engulf the extruded nuclei of the maturing red cells. Macrophages also secrete growth factors that promote progenitor cell survival and maturation. Adipocytes and endothelial cells provide supportive roles to the maturing hematopoietic elements, but they may also directly modulate progenitor cell function via secretion of cytokines and growth factors.

Migration of hematopoietic stem cells through the blood and across endothelial vasculature to hematopoietic niches in the bone marrow and other hematopoietic organs is termed *homing.* Homing is required for seeding of the bone marrow by hematopoietic progenitors during fetal development. Similarly, homing is operative in adult bone marrow homeostasis and certain physiological roles are amplified during stress-induced recruitment of leukocytes from the bone marrow and during stem cell mobilization for host defense and repair. Homing is a multistep process that involves signaling by stromal-derived factor 1 (or CXCL12) and SCF, activation of lymphocyte function-associated antigen 1, very late antigens 4 and 5 and CD44, cytoskeletal rearrangement, membrane type 1, matrix metalloproteinase activation, and secretion of matrix metalloproteinase 2 and 9. Rolling and firm adhesion of hematopoietic stem and progenitor cells to endothelial cells in marrow sinusoids under blood flow is followed by migration across the endothelium and extracellular matrix. Stem cells finalize their migration by selective access and anchorage to specialized niches in the extravascular space of the endosteum and in periarterial sites.[64]

The cytokine G-CSF is the most widely used agent for mobilizing hematopoietic stem cells in experimental and clinical settings. CXCL12 and its receptor CXCR4 are known to be a key ligand-receptor pair responsible for retention of hematopoietic stem cells in bone marrow.[65] Work by Katayama and colleagues[66] provides a mechanism for G-CSF–induced mobilization of hematopoietic stem cells and suggested that sympathetic nervous system may regulate stem cell trafficking. This work built on findings by Frenette and colleagues[67] that mice

deficient in the UDP-galactose:ceramide galactosyltransferase (Cgt) exhibited severely impaired mobilization response to G-CSF. Cgt is essential for synthesis of sulfatide by mediating addition of UDP-galactose to ceramide. The mobilization defect could not be linked to the lack of sulfatide and thus involved an indirect mechanism. These investigators speculated that impaired adrenergic nervous system transmission might play a role in the mobilization defect. The sympathetic nervous system has been previously established as a regulator of bone formation. Takeda and co-workers[68] demonstrated that adrenergic signals directly regulate osteoblast function. Katayama and colleagues[66] examined the *Cgt−/−* mouse model and other genetic and pharmacologic models exhibiting impaired nerve conduction. These included mice lacking dopamine β-hydroxylase (*Dbh−/−*) that have deficient synthesis of norepinephrine; mice subjected to pharmacologic disruption of catecholaminergic neurons through postnatal injections of 6-hydroxydopamine and mice treated with β-blockers (Figure 142-2). Each model exhibited decreased hematopoietic stem cell mobilization in response to G-CSF. Osteoblast suppression was not observed and CXCL12 levels remained intact in these models. Involvement of adrenergic activity in stem cell mobilization was further bolstered by observations that norepinephrine levels decreased in bone following G-CSF administration, signifying its release, and that a β_2-adrenergic agonist could restore the mobilization of stem cells in mice lacking dopamine β-hydroxylase.

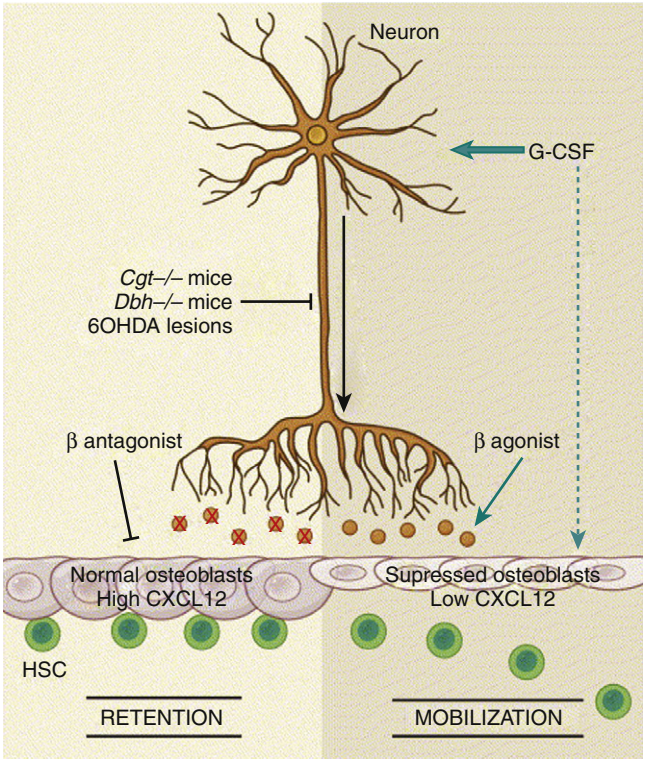

Figure 142-2 Signals from the sympathetic nervous system modulate localization of hematopoietic stem cells to the endosteal niche in bone. Granulocyte colony-stimulating factor *(G-CSF)* activation of peripheral noradrenergic neurons *(thick arrow)* with an unknown mechanism *(dashed arrow)* induces mobilization of hematopoietic stem cells *(HSCs)* through the suppression of osteoblasts and a decrease in CXCL12. HSC mobilization by G-CSF was studied in mouse models with defects in nerve conduction.[66] These models include mice deficient in UDP-galactose:ceramide galactosyltransferase (*Ctg−/−*); mice deficient in dopamine β-hydroxylase (*Dbh−/−*); mice injected postnatally with 6-hydroxydopamine *(6OHDA),* which disrupts catecholaminergic neurons; and mice treated with β blockers (β antagonists). Additionally, a β_2-adrenergic agonist rescues the mobilization defects in mice deficient in dopamine β-hydroxylases and augments G-CSF–induced mobilization in control mice. These studies demonstrate that noradrenergic signals from the sympathetic nervous system are critical mediators of G-CSF–induced mobilization. *(From Larsson J, Scadden D: Nervous activity in a stem cell niche,* Cell *124:253, 2006.)*

GROWTH FACTOR EFFECTS ON STEM AND PROGENITOR CELLS

Factors Influencing Hematopoietic Stem Cells

Certain growth factors are required for primitive hematopoietic stem cells to survive in a quiescent state, whereas others trigger cycling of progenitors once committed to a differentiation pathway. Some data suggest that G-CSF, IL-3, and SCF may act as survival factors for murine hematopoietic stem cells in vitro.[69,70] Other studies, using enriched murine bone marrow progenitor cells, demonstrated that IL-3 and SCF, but not G-CSF, supported survival of G_0 progenitors.[71] Studies by Leary and colleagues[72,73] demonstrated that IL-3 and granulocyte-macrophage CSF (GM-CSF) maintain survival of human primitive progenitors in G_0 phase, whereas IL-6, IL-11, and G-CSF do not promote survival of these dormant progenitors in vitro.[73]

Several factors have been identified that appear to be involved in triggering division of dormant hematopoietic stem cells. IL-1 and IL-3 have been shown to act synergistically in supporting proliferation of murine hematopoietic stem cells.[74,75] Mapping studies of murine blast cell colony formation demonstrated that IL-6, IL-11, G-CSF, and SCF act synergistically in support of colony formation from quiescent progenitors.[76-79] Similarly, synergism between IL-1 and IL-3 has been demonstrated in cultures enriched for human marrow progenitor cells.[80]

Lineage-Specific Factors

Major technologic advances in deriving mature tissues from murine ES cells have advanced our knowledge of hematopoietic growth factor requirements for specific lineage derivation. Two different experimental systems are used to generate blood precursors from ES cells: formation of embryoid bodies (EBs)[41] and induction of hematopoietic differentiation on stromal cells.[81] Upon removal from feeder layers and cytokines that maintain their pluripotency, ES cells form EBs, aggregates of differentiated cells including mesodermal derivatives capable of hematopoietic differentiation. The emergence of hematopoietic progenitors in this culture can be tracked by the appearance of lineage-specific markers through gene expression, immunohistochemistry, flow cytometry or methylcellulose culture assays. In this fashion the effects of specific manipulations such as cytokines, medications, or gene targeting can be analyzed.

Differentiation of ES cells on stromal lines provides a second means for inducing hematopoiesis. The most common line is OP9, a line established from the calvaria of newborn *op/op* mice, which lack functional macrophage colony-stimulating factor (M-CSF).[81] OP9 cells enhance hematopoietic development by providing a supportive microenvironment for differentiation. The absence of M-CSF inhibits survival of monocyte-macrophage cells, which tend to outgrow other lineages in culture systems using wild-type stroma.

Early studies showed that mixtures of hematopoietic cell types developed in ES cell differentiation cultures. More recently, methods were refined to generate relatively pure populations of specific lineages (Table 142-1). The methods were established using murine ES cells, but these are being adapted for use in human cells.

TABLE 142-1

Generation of Specific Hematopoietic Lineages

Hematopoietic Lineage	Cytokines
Erythroid	Major: EPO, KL Other: Insulin, IGF-1, IL-9
Megakaryocytes and platelets	Major: TPO Other: IL-6, IL-11
Neutrophils	Progenitor expansion: bFGF, IL-6 IL-11, KL, LIF, OSM Differentiation: G-CSF, GM-CSF, IL-6
Eosinophils	IL-3, IL-5, GM-CSF, Eotaxin
Mast cells	IL-3, KL
Macrophages	IL-1, IL-3, M-CSF, GM-CSF
Dendritic cells	Progenitor expansion: GM-CSF, IL-3 Differentiation/Maturation: IL-4, TNF-α, LPS, anti-CD40
Osteoclasts	M-CSF, RANKL
B lymphocytes	Flt-3 ligand, IL-7
T lymphocytes	Flt-3 ligand, IL-7
NK cells	Flt-3 ligand, IL-6, IL-7, IL-15, KL

bFGF, Basic fibroblast growth factor; *EPO,* erythropoietin; *G-CSF,* granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *IGF,* insulin-like growth factor; *IL,* interleukin; *KL,* Kit ligand; *LIF,* leukemia inhibitory factor; *LPS,* lipopolysaccharide; *M-CSF,* macrophage colony-stimulating factor; *NK,* natural killer; *OSM,* oncostatin; *RANKL,* receptor activator of nuclear factor κB ligand; *TNF,* tumor necrosis factor; *TPO,* thrombopoietin.

Erythroid cells

When 7- to 8-day-old EBs are disaggregated and plated into methylcellulose culture with erythropoietin and Kit ligand (also called SCF), the majority of resultant cultures are erythroid.[41] Methods to derive definitive erythrocytes from ES cells were advance by Carotta and colleagues[82] who developed conditions in which EB-derived immature erythroid progenies can be expanded 10^7-fold. This approach relies on dexamethasone to promote erythroid progenitor self-renewal. Removal of dexamethasone from culture and adjustment of cytokines results in terminal differentiation.

Megakaryocytes

Culturing ES cells on OP9 stroma in the presence of thrombopoietin enriched for a population of megakaryocytes with functional features characteristics including proplatelet production and fibrinogen binding after exposure to platelet agonists.[83,84]

Neutrophils

Greater than 75% enrichment of neutrophils from cultured ES cells was achieved by inducing maturation of EB-derived hematopoietic progenitors on OP9 cells with added cytokines.[85,86] The resultant neutrophils exhibited signature markers, chemotactic responses, and superoxide production.

Eosinophils

Eosinophils were generated by Hamaguchi-Tsuru and colleagues[87] by differentiation of EB cells on OP9 stroma with IL-5 in the presence of either IL-3 or GM-CSF. The capability to generate and study eosinophil-enriched populations at defined stages of development and function may be useful in understanding human conditions such as allergy and asthma.

Mast Cells

EB-derived hematopoietic progenitors cultured with IL-3 and Kit ligand generate pure populations of mast cells that can be expanded in vitro.[41,88] Upon transplantation into mast cell deficient mice ($Kit^w/Kit^{w\text{-}v}$), ES-cell derived mast cells proliferate, mature, and mediate immunoglobulin (Ig) E-dependent immune responses.

Macrophages

Macrophages can be produced from ES cells using either EB or OP9 systems. ES-derived macrophages express Mac-1 and F4/80, a macrophage specific antibody.[81]

Dendritic Cells

Dendritic cells (DCs) are potent antigen-presenting cells that can promote either immune responses or self-tolerance. ES-cell–derived DCs expand in the presence of IL-3 and GM-CSF and are induced to mature by tumor necrosis factor-α and IL-4 plus lipopolysaccharide or by anti-CD40.[89,90] ES-derived DCs, like bone marrow-derived DCs, express characteristic markers, process antigens, and stimulate T-cell responses in mixed leukocyte reactions.

Osteoclasts

Osteoclasts, which are derived from hematopoietic stem cells, are involved in bone resorption and remodeling. Cytokines that promote osteoclast maturation from ES cells include M-CSF and receptor activator of nuclear factor κB (NFκB) ligand. Osteoclast production is augmented by ascorbic acid, dexamethasone, and 1α,25-dihydroxyvitamin D_3.[91-93]

B and T Lymphocytes

Nakano and colleagues[81] cultured ES cells on OP9 stroma with IL-7 to produce early B lymphocytes. These cells were predominantly IgM− and had completed diversity-joining gene rearrangement; however, a small proportion differentiated into IgM+ cells that expressed complete μ chain mRNA. B cell maturation progressed further when ES cells were exposed to IL-7 in combination with Flt-3 ligand.[94]

Differentiation of T lymphocytes from ES cells is complicated by developmental requirement of thymic stromal interactions in vitro. de Pooter and colleagues[95] differentiate ES cells on OP9 stroma then reseed FLK1+CD45− cells into fetal thymic organ cultures. Although the fraction of T cells is low, normal CD4 and CD8 thymic subsets were generated.[95] Recognizing the importance of Notch signaling in T-cell development, the same group of investigators developed OP9 cells that express delta-like-1 notch ligand. Differentiation of T cells on this modified stroma allowed more complete T-cell maturation including γδ and αβ T-cell receptor bearing cells.[96]

Natural Killer Lymphocytes

Natural killer (NK) cells represent an important arm of the innate immune system involved in destruction of cells that fail to express correct major histocompatibility complex class I receptors. NK cells derived from ES cells exhibit the capacity to kill certain tumor lines and major histocompatibility complex class I–deficient lymphoblasts.[97]

RECEPTORS

Cytokine Receptor Families

Hematopoietic growth factor receptors have been categorized (based on similarities in extracellular genetic characteristics) into several families of receptors (Figure 142-3).[98-100] Some receptors contain structural domains characteristic of two or three subgroups within the cytokine superfamily of receptors. For instance,

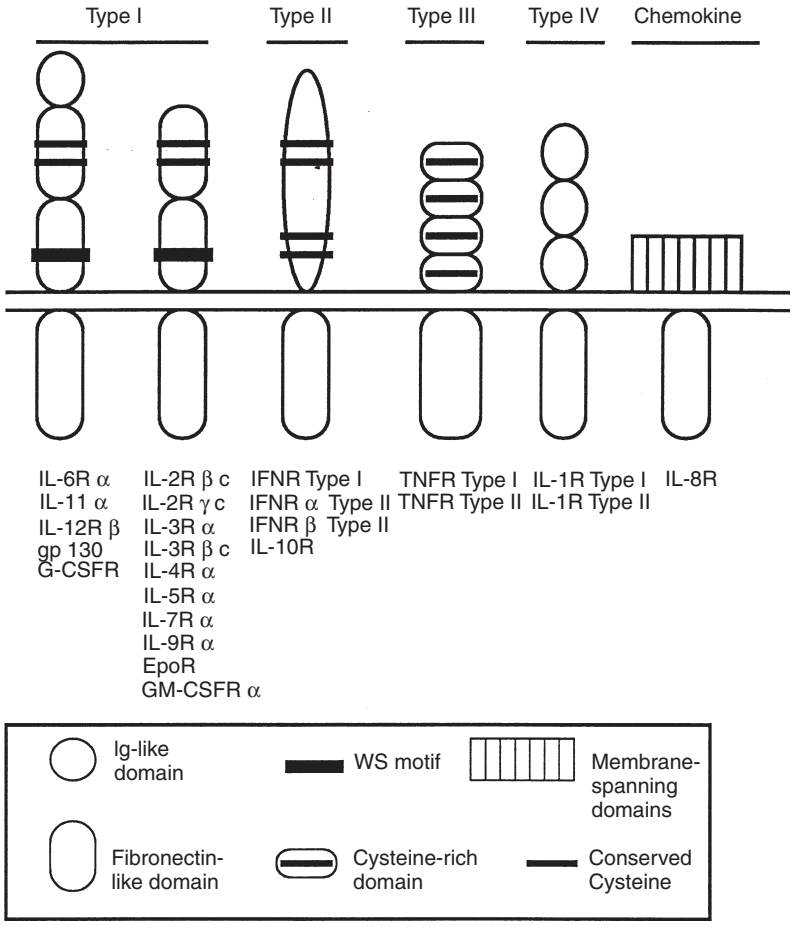

Figure 142-3 Cytokine receptors have been grouped into related families based on presence of conserved structural elements in their extracellular domains. Type I receptors (including interleukin [IL]-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-9, IL-11, IL-12, granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage CSF [GM-CSF], and erythropoietin [EPO] receptor chains) are characterized by the presence of fibronectin-like domains, conserved cysteine residues, and the WS motif (a highly conserved region containing a tryptophan-serine-1 amino acid–tryptophan-serine motif). Type II receptors, which possess several conserved cysteine residues, include the interferon (IFN)-α, IFNβ, IFNγ, and interleukin (IL)-10 receptors. Type III receptors include two varieties of tumor necrosis factor (TNF) receptors (types I and II), which are characterized by repeated cysteine-rich domains. The IL-1 receptors are characteristic of type IV class of receptors (immunoglobulin superfamily receptors). Several members of the type I family also include immunoglobulin-like domains (IL-6Rα, IL-11Rα, IL-12Rβ, G-CSFR, and gp130). The IL-8 receptor differs from other receptors because it includes seven transmembrane domains. This structure is characteristic of the chemokine receptors.

the receptors for IL-1, IL-6, SCF (c-kit), and M-CSF (c-fms) contain extracellular immunoglobulin-like domains, placing them in the immunoglobulin superfamily. IL-1 receptors are distinct from other type I cytokine receptors such as IL-6R because they lack the tryptophan serine (WS) motif, fibronectin-like domains, and conserved cysteine residues. The receptors for SCF and M-CSF differ from other hematopoietic growth factor receptors in that they contain intrinsic intracellular protein tyrosine kinase motifs that are involved in signal transduction. The IL-2Rβc, IL-3Rα, IL-3Rβc, IL-4Rα, Il-5Rα, IL-6Rα, IL-6Rβc (gp130), IL-7Rα, IL-9Rα, IL-12Rβ, EpoR, G-CSFR, and GM-CSFR belong to the type I family of receptors and share several highly conserved protein motifs.[101-107] The structural similarities among these conserved regions suggest that members of this receptor family evolved from a common ancestral gene. Other cytokine receptors include the interferon (IFN) group (IFNR type I, IFNRα type II, IFNβ type II, and IL-10R), which possess a common binding domain characterized by cysteine pairs at both the amino-terminal and the carboxyl-terminal, and the tumor necrosis factor (TNF) group (TNFR type I and type II), which contain several cysteine-rich domains.[108] The IL-8 receptor belongs to still another family of receptors, the chemokine family. Structurally, it differs markedly from other cytokines because it contains seven transmembrane domains.[109,110]

Although cytokine receptors are clearly evolutionarily related, their intracellular domains exhibit little homology.[111] Furthermore, a lack of protein kinase–related sequences is conspicuous in most family members even though ligand-receptor interaction triggers a cascade of tyrosine phosphorylation within target cells.[112] Moreover, although cytokine receptor family members do not belong to the protein kinase family, they use protein kinase activity to propagate their intracellular signals. The finding that intracellular domains of cytokine receptors lack sequences known to be important in signal transduction suggested that associated molecules must be responsible for propagating the signal intracellularly. Cytokine receptors can be subdivided into two distinct groups based on the mechanism by which they associate to transduce their signal. One group of receptors forms homodimers for signal transduction (e.g., EPO), and the second group consists of receptors that require two distinct subunits to produce effective high-affinity ligand binding and signal

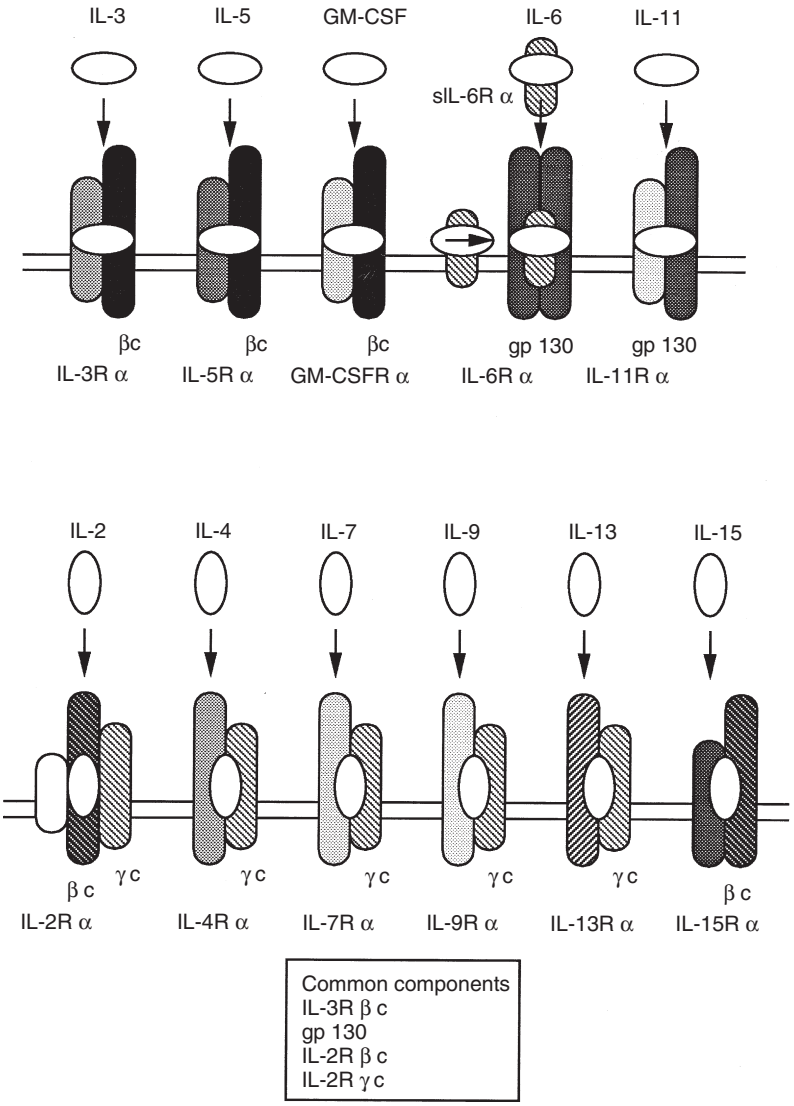

Figure 142-4 Cytokines and hematopoietic growth factors bind to their specific α-chain receptors to form low-affinity complexes that do not initiate signal transduction. Subsequently, they form high-affinity complexes capable of signal transduction by interacting with other α-chains to form homodimers as with erythropoietin (EPO) *(not shown)* or by interacting with common chains (interleukin-2Rβc [IL-2Rβc], IL-2Rγc, IL-3Rβc, and gp130) to form heterodimeric complexes. *GM-CSFR,* Granulocyte-macrophage CSF receptor.

transduction.[113] The βc chains are shared by several receptors in this family. For instance, the IL-3Rβc forms heterodimers with IL-5R and GM-CSFR after ligand binding to form a high-affinity interaction that is capable of propagating intracellular signals. Similarly, the IL-6Rβc (gp130) chain is shared with IL-11R, and the IL-2γc chain is shared with IL-4R, IL-7R, IL-9R, and IL-15R[114] (Figure 142-4).

Specificity of Cytokine Action at the Receptor Level

Cytokine action can be regulated at two major levels: outside and inside the target cell (Figure 142-5).[115] Outside the target cells, cytokine effects are determined by the amount of cytokine produced and the duration of its availability in the microenvironment. The half-life of a cytokine and the presence or absence of a matrix that concentrates or sequesters the cytokine affect the duration of its effect. The expression of cytokine receptors on the surface of cells determines what cells surrounding cytokine-producing cells can respond to the cytokine signal. Cell-cell interactions between cytokine-producing cells and responding cells also affect the duration and magnitude of the cytokine's effect.

Soluble Growth Factors and Growth Factor Receptors

Growth factor regulation at the level of the receptor occurs by several distinct mechanisms. First, receptors may be restricted to specific cell types. Second, receptor number on the membrane surface may differ because of varying receptor mRNA expression, receptor degradation, or internalization. Third, receptor affinity may be modified by other membrane proteins or by availability of shared common receptor chains. Finally, membrane-bound receptors may be cleaved to soluble forms or, alternatively, secreted directly as soluble receptors. Soluble receptors found in serum include sIL-1RII, sIL-4R, sIL-6Rα, sIL-6Rβ, TNFR I, TNFR II.[116] Soluble IL-1RII is believed to act as a scavenger of circulating IL-1. Complexes of IL-6 and it soluble receptors can function as agonists or antagonists.[117] Soluble TNF receptors, TNFR I and TNFR II, protect against proteolysis.

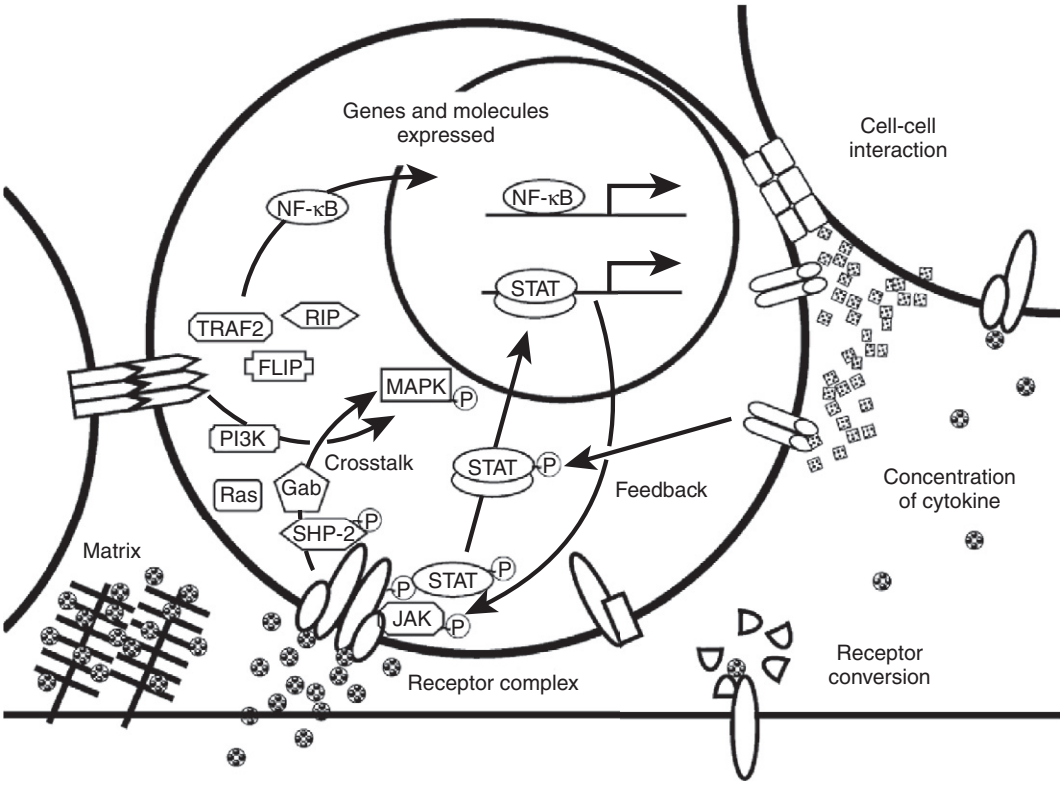

Figure 142-5 Extracellular (receptor-mediated) and intracellular (signal transduction) factors involved in determination of cell specificity of a cytokine. *(From Ishibara K, Hirano T: Molecular basis of the cell specificity of cytokine action,* Biochim Biophys Acta *1592:281, 2002.).*

Two mechanisms responsible for generation of soluble receptors are differential splicing of the receptor pre-mRNA (which results in formation of receptors lacking the transmembrane portion of the receptor molecule) and proteolytic cleavage of the membrane-bound form (releasing the extracellular portion of the molecule).[118]

The actual physiologic role of the soluble receptors depends on the relative concentrations of growth factor–receptor complexes, the individual components, and their dissociation constants. In the case of IL-6, circulating levels are generally 10 pg/mL or less in normal individuals, whereas the soluble receptor concentrations are approximately 70 ng/mL.[119,120] With a dissociation constant of 1×10^{-9} mol, all IL-6 in the serum should be present in complexes with soluble receptors. Therefore it would be anticipated that this interaction would antagonize the effects of IL-6. In fact studies by Narazaki and colleagues[121] demonstrated antagonist activity in complexes of IL-6, IL-6R, and gp130. In contrast, in vitro studies suggest that soluble IL-6 receptor complexes may propagate an agonist IL-6 effect on cells not expressing the IL-6R subunit but expressing the gp130 chain.[122,123] Thus IL-6 and IL-6 receptors shed from one cell type could alter ligand binding and act on a cell type not expressing IL-6R but expressing gp130. Such interactions have been documented in hepatoma cell lines and in hematopoietic cells.[117,124]

SIGNAL TRANSDUCTION

Inside cells, the cytokine signals are regulated at the plasma membrane, in the cytoplasm, and in the nucleus. Upon binding of a cytokine to its specific receptor, a given set of transduction pathways is activated based on the kinases and phosphatases constitutively associated with the given receptor. The cytoplasmic tail of each receptor has multiple structures that determine the signaling pathways by recruiting kinases, phosphatases, and transcription factors. Adapter molecules play pivotal roles in providing positive or negative regulation of certain pathways and integration of multiple pathways. The gene set transcribed by a specific transcription factor helps determine the biologic output. Additionally, a given target cells receives multiple signals through independent receptors and these signals converge or engage in cross-talk inside the cell.

Tyrosine kinase–based signaling can be initiated both by receptors possessing intrinsic tyrosine kinase and by receptors lacking an intrinsic tyrosine kinase. Hematopoietic growth factors possessing intrinsic tyrosine kinase activity include SCF and M-CSF. Factors such as GM-CSF and the interleukins lack intrinsic catalytic activity, but they trigger signaling activity through cytoplasmic tyrosine kinases. The carboxyl-terminal portion of these receptors, although lacking motifs involved in known catalytic activity such as the protein tyrosine kinase domains, contains highly conserved motifs in the intracellular membrane proximal region.[112,125,126] These structures are instrumental in triggering downstream signaling events.

Common features of the intracellular signal transduction mechanism of cytokine receptors are noteworthy. First, ligand binding to monomeric forms of these receptors alone is generally insufficient to initiate signal transduction; however, once specific ligand binding has occurred, the receptors are capable of forming homodimers or heterodimers that initiate signal transduction.[111] Second, several receptor subunits are shared with other hematopoietic growth factors.[127] Third, on binding of the specific ligand and dimerization of the receptor subunits, autophosphorylation and transphosphorylation can occur, and they initiate a cascade of tyrosine phosphorylation of sites intrinsic to the intracellular portions of the receptors and also on nonreceptor protein tyrosine kinase molecules associated with the intracellular domains

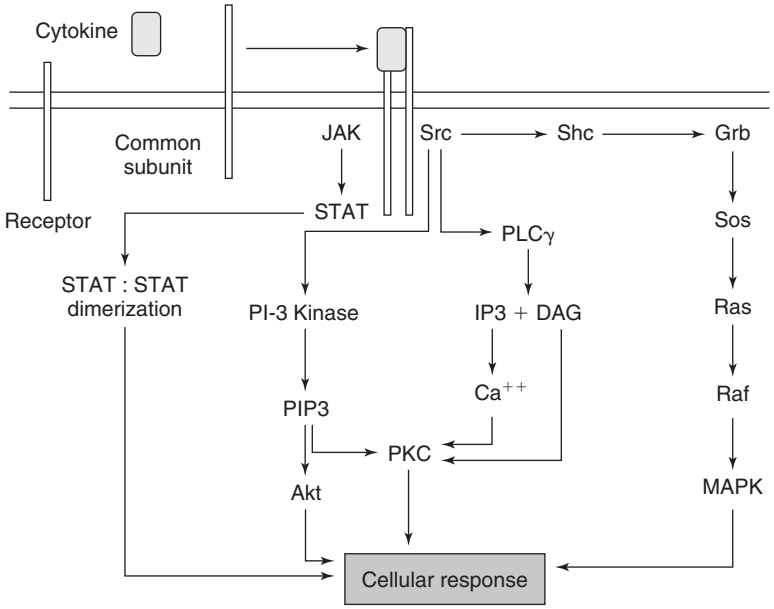

Figure 142-6 Transduction of external signals across the cell membrane is accomplished by binding of a cytokine with its specific receptor. The receptor then forms dimers with a common receptor chain to form a high-affinity complex. This association initiates a cascade of tyrosine phosphorylation both on the intracellular domains on the receptor itself and on receptor-associated tyrosine kinase molecules. One family of nonreceptor tyrosine kinases is the JAK proteins. The phosphorylation events lead to docking of STAT proteins. These interactions lead to phosphorylation and dimerization of STAT proteins, nuclear translocation, and transcription of cellular response genes. Receptor phosphorylation can activate other receptor-associated tyrosine protein kinases such as Src. Activation of Src triggers activation of phosphatidylinositol 3-kinase *(PI-3 kinase)* and phospholipase Cγ *(PLCγ)*. Tyrosine kinases also trigger activation of the serine threonine kinase Raf through the coupled proteins Shc and Grb, the nucleotide exchange factor Sos, and the small G-protein Ras. Raf activates mitogen-activated protein kinase *(MAPK)* to regulate cellular responses.

of the cytokine receptors. Signal transducing proteins containing Src homology 2 (SH2) domains associate with the phosphotyrosine residues on the activated receptor and activated nonreceptor protein tyrosine kinases and, in turn, are activated and propagate the signal downstream.[128] This interaction affords another level of specificity on biologic actions of cytokines as each particular receptor interacts with its own specific subset of SH2-containing proteins.[129] The key features of the signal transduction process are illustrated in Figure 142-6.

Several families of nonreceptor protein tyrosine kinases have been isolated and have been implicated in cytokine signal transduction. These include molecules in the Src family, the Syk-ZAP70 family, the Btk-Tec family, and the Janus kinase (JAK) family.[112] The mechanisms by which these factors mediate downstream events have not been fully defined; however, the interactions between the JAK and Src proteins and several downstream factors have been partially characterized.

JAK Protein Tyrosine Kinases

One family of protein tyrosine kinases recognized to be involved in cytokine signaling is the JAK family. Early clues implicating the involvement of a receptor-associated tyrosine kinase was drawn from the observation that purified growth hormone receptor exhibited kinase activity.[130] Members of the JAK family were isolated by polymerase chain reaction technology using degenerate primers based on a conserved catalytic domain.[131] Evidence pointing to the role of this family of proteins in cytokine signaling was provided by genetic complementation studies in a cell line defective in type I IFN signaling.[132] This mutant line was rescued by transfection of these cells with genomic DNA encoding Tyk2, a member of this kinase family. Similar studies on IFNγ provided evidence for Jak1 and Tyk2 in type I receptor signaling and Jak1 and Jak2 in the IFN type II signaling mechanism.[133] The JAK family of protein tyrosine kinases has been found to be a critical component in signaling through certain cytokine receptors including IL-2R, IL-3R, IL-4R, IL-5R, IL-6Rβc (gp130), IL-7R, IL-12R, and EPOR.[134] Each receptor appears to associate with distinct members of the JAK family. For instance, IL-2R associates with JAK1 and JAK3, whereas the EPOR associates only with JAK2.[134] A restrictive interaction of the cytokine receptor intracellular domains with specific signal transduction elements, such as Jak protein kinases, is one mechanism regulating the specificity of growth factor action.

Dimerization of the cytokine receptor induced by ligand brings JAK proteins in proximity with each other, resulting in cross-phosphorylation.[134] This interaction is somewhat restrictive because JAK1 and JAK3 always bind in conjunction with other family members, whereas JAK2 binds to receptors alone.[112] Thus JAK2 molecules are capable of cross-phosphorylating each other, whereas the other JAK proteins appear to require interaction with related family members to effect optimal activation.[112] The observation that patterns of JAK protein phosphorylation are distinct in different cell lines may provide insight into the functional pleiotropism of cytokines.[134,135]

The JAK proteins appear to associate with the box 1 motif in the membrane proximal portion of cytokine receptors. This region exhibits a high degree of sequence conservation.[136] Presence of the box 1 motif is critical in the mitogenic response to several cytokines.[137] Although the downstream signal propagating events that follow JAK protein phosphorylation are not fully understood, its role in activation of one family of latent transcription factors, called STATs (signal transducers and activators of transcription), has been characterized. In addition, the phosphorylation of cytokine receptors by JAK proteins potentiates the interaction between the receptor complex and other signal

transducing molecules such as those containing SH2 regions.[138] STAT proteins, present in the cytoplasm, become activated on interaction with activated Jak proteins. The phosphorylated STAT proteins form homodimers or heterodimers with peptides containing SH2 domains; these dimers are subsequently transported to the nucleus, where they function as transcription factors.[135-138]

SRC Protein Tyrosine Kinases

Src is the prototype for a family of tyrosine kinases that includes at least nine members: Src, Fyn, Yes, Lyn, Hck, Fgr, Lck, Blh, and Yrk.[139] All Src members contain a site near the N-terminus signaling for myristoylation and, in many cases, for palmitoylation, which direct the association of these proteins with cellular membranes. C-terminal to this region is the Src homology 3 domain that promotes protein-protein interactions with proteins exhibiting left-handed polyproline type II helices.[140,141] The next adjacent domain toward the C-terminus is the SH2 domain. The SH2 domain is the binding site for phosphotyrosine-containing proteins. This domain is frequently found in phospholipase Cγ, phosphatidylinositol-3-kinase, Shc, and STAT proteins, which are involved in tyrosine kinase–based signal transduction.[129,140] The SH2 domains of Src kinases mediate interactions of these proteins with receptor-type protein tyrosine kinases and with protein substrates. C-terminal to the SH2 domain is the catalytic domain. Phosphorylation of Tyr416 in the catalytic domain is required for optimal activity. In addition, the presence of a conserved tyrosine (Tyr527) in the C-terminal tail region is essential for the phosphorylation-based activity characteristic of Src tyrosine kinases. Multiple Src family members have been observed in hematopoietic cells; however, it is not known to what extent selective roles exist for each Src family member or whether redundancy exists in Src-based signal transduction.

Ras GTPase Superfamily

Members of the Ras guanosine triphosphatase (GTPase) superfamily modulate many signal transduction pathways. These proteins are low-molecular-weight GTP-binding proteins that act as molecular switches in regulating many different signaling pathways in virtually all cells.[141] Approximately 60 Ras family members have been identified to date in mammalian cells. GTPases exist in an inactive (guanosine diphosphate–bound) and an active (GTP-bound) conformation. Guanine nucleotide exchange factors catalyze the release of guanosine diphosphate and allow GTP to bind. In the active, GTP-bound state, Ras interacts with target proteins to promote a cellular response. An intrinsic GTPase activity, catalyzed further by GTPase-activating proteins, returns Ras GTPase to its inactive, guanosine diphosphate-bound state (Figure 142-7).

Striking features of the Ras superfamily include the diversity of membrane receptors and upstream regulators that can activate these GTPases, the diversity of cellular targets that can interact with an individual GTPase, and the extensive cross-talk that exists among GTPase-regulated signal transduction pathways.[141] Numerous examples of the coordinated activation and functional cooperation between Ras superfamily members at the molecular and cellular level have been described in animal cells. The best characterized of these functions are cell proliferation, gene expression, and actin-based cell motility.

Cell-cycle progression depends on cyclin-dependent protein kinases in which activity vacillates periodically during growth and division of cells.[142] The critical role for Ras in cell-cycle progression was suggested by experiments in which Ras activity was disrupted by microinjection of anti-Ras neutralizing antibodies or by expression of a dominant mutant interfering with endogenous Ras expression. These manipulations prevented mitogen-induced progression through G_1 and entry into S phase of the cell cycle.

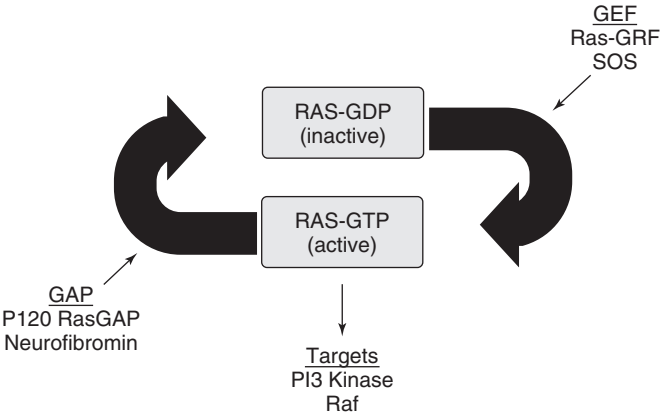

Figure 142-7 Ras interacts with multiple guanine nucleotide exchange factors *(GEF),* guanosine triphosphatase–activating proteins *(GAP),* and target proteins. The figure shows only a few examples of many interacting proteins identified to date. *GDP,* Guanosine diphosphate.

More recent studies have determined that the proliferative effects of Ras are dependent on signaling input from other Ras family members, Rho and Rac (Figure 142-8).[136,143]

The link between Ras superfamily GTPase activity and hematopoietic growth factor–induced proliferation and differentiation has been elucidated through in vitro and in vivo experiments. Overexpression of Ras-related GTPase, *Rac1*, enhanced the proliferative signal provided by GM-CSF in cultured cells.[144] Expression of a dominant negative Ras mutant (*ras*T17N) partially suppressed proliferation of cultured cells in response to GM-CSF. Studies to delineate M-CSF and GM-CSF receptor activation revealed differential modulation of the macrophage scavenger receptor A through the Ras signaling pathway[145] (Figure 142-9).

The role of neurofibromin, the protein encoded by the *NF1* tumor suppressor gene, in Ras signaling and hematopoietic cell proliferation has been examined in vitro and in vivo using a genetic approach. Humans and animals with mutations in *NF1* are predisposed to juvenile myelomonocytic leukemia. A hallmark of both human juvenile myelomonocytic leukemia cells and murine Nf1-deficient myeloid progenitors is a selective hypersensitivity to GM-CSF.[146] Whereas homozygous NF1-mutant ($NF1^{-/-}$) embryos die in utero, adoptively transferred $Nf1^{-/-}$ fetal liver cells consistently induce juvenile myelomonocytic leukemia–like disorder in irradiated recipients.[147] GM-CSF appears to play a central role in establishing and maintaining this phenotype in vivo.[148] Primary $NF1^{-/-}$ hematopoietic cells exhibit constitutive activation of the Ras-Raf-MAP kinase signaling pathway and enhanced cell proliferation in response to SCF and IL-3 or GM-CSF.[147]

DOWNSTREAM SIGNALING MECHANISMS AND SPECIFICITY

Down-stream from cytokine receptor-mediated events complex signal transduction interactions act to modify the ultimate cellular response (see Figure 142-5). Variable sets of signaling molecules, balancing of contradictory signals, feedback, and cross-talk lead to specific downstream gene expression events and cellular response.

Set of Signaling Molecules Determines Specificity

Different cell types express different sets of signaling molecules associated with the same cytokine receptor. For example, in cord blood hematopoietic progenitors the activation pattern of IL-15–dependent transcription factors is dependent on the maturation

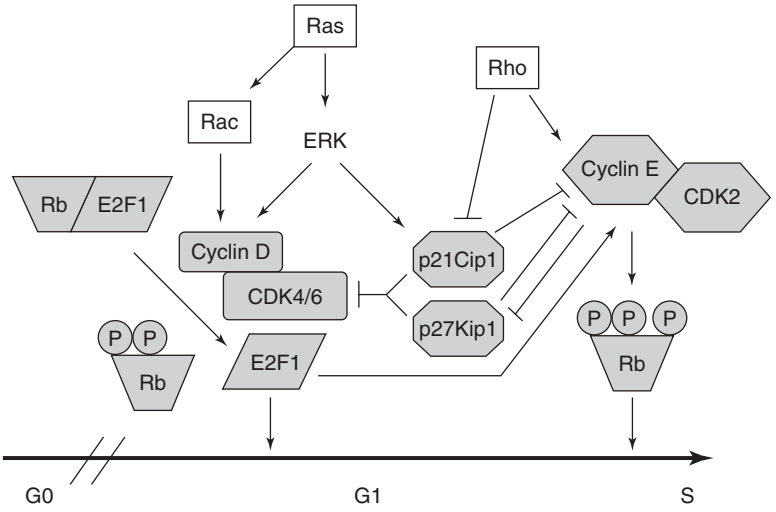

Figure 142-8 Influence of Ras and Ras family members Rho and Rac on cell-cycle progression. Cell-cycle regulatory proteins targeted by Ras, Rho, and Rac signal transduction pathways are shown. Cyclin D is a major target for Ras and Rac, whereas Rho acts primarily downstream of the CDK inhibitors $p21^{Cip1}$ and $p27^{Kip1}$. Rac and Ras act synergistically to activate cyclin-dependent kinase 4 (*CDK4*) and CDK6 through mechanisms to induce cyclin D transcription and assembly of cyclinD-CDK4 and 6 complexes at an early stage of G_1. The principal activity of these complexes is to phosphorylate Rb protein and thus allow activation of early-region-2 (E2F) transcription factors that regulate genes required for the G_1/S transition. Under circumstances in which Ras expression leads to cell-cycle arrest caused by induction of $p21^{Cip1}$, Rho can suppress the induction of $p21^{Cip1}$, thus enabling Ras to stimulate cell-cycle progression. Rho also regulates cell-cycle progression by inducing degradation of the CDK inhibitor $p27^{Kip1}$ through cyclin E/CDK2 activity. *ERK,* Extracellular regulated kinase.

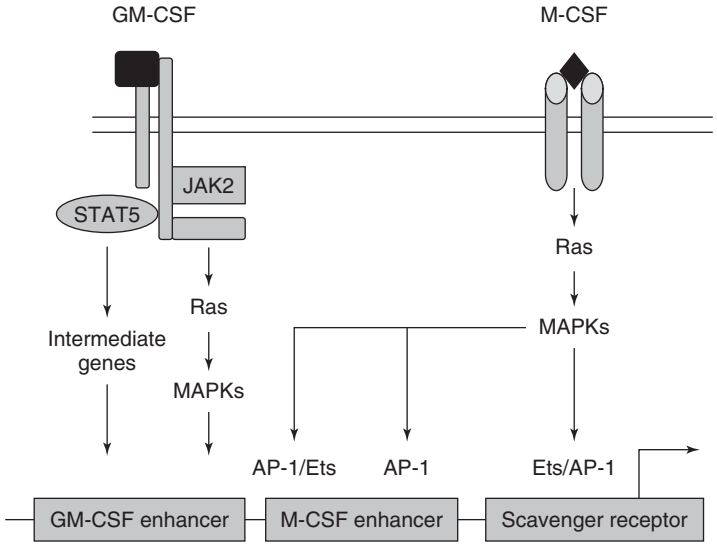

Figure 142-9 Mechanism for transcriptional control of scavenger receptor A *(SR-A)* by granulocyte-macrophage colony-stimulating factor *(GM-CSF)* and macrophage-CSF *(M-CSF).* Activation of SR-A by GM-CSF is dependent on a distinct enhancer element located upstream of the M-CSF–dependent enhancer. The GM-CSF enhancer is occupied by constitutively expressed transcription factors that, on regulation by Ras, activate immediate to early transcriptional responses. Sustained expression of SR-A in response to GM-CSF may be directed in part by transcription factors that are targets of STAT5 SR-A activation by M-CSF occurs through AP1- and Ets-mediated pathways. These transcription factors are targets of a Ras-dependent mitogen-activated protein kinase *(MAPK)* cascade that controls their level of expression and activities. *AP-1,* Activator protein-1; *Ets,* e twenty-six specific.

status of the progenitor cells and the form of IL-15. In freshly isolated unprimed cord blood progenitor cells, exposure to soluble IL-15 only activates NFκB.[149] In these cells nuclear translocation of NFκB is increased by short-term contact with a membrane-bound form of IL-15 (mb-IL-15). In the same cells cultured for 5 days in vitro in the presence of SCF and Flt-3L and therefore committed to the pro-NK pathway, soluble IL-15 triggers activation of STAT3. In contrast, short-term contact with mb-IL-15 activates STAT5 and STAT6.

Balance of Contradictory Signals Determines the Cell Specificity

Simultaneous activation of multiple pathways that produce contradictory signals is common in the signal transduction of cytokine receptors. For example, IL-6 can simultaneously induce growth promoting and growth suppressing signals through gp130 in the murine leukemia M1 cell line. When STAT3 activation

is suppressed, gp130 stimulation favors growth-promoting signals rather than growth-suppressing signals.[150] Similarly, signal transduction through gp130 can activate cell cycle transition from G_1 to S phase in a STAT3 dependent manner, and simultaneously, can induce a p21 cyclin-dependent kinase inhibitor that opposes these STAT3 dependent signals.[151] These contradictory signals arise from distinct regions of gp130. The balance of these contradictory signals determines the specificity of the biologic effect.

Modulation by Feedback or Cross-talk Determines the Specificity

Modulation of signals by feedback can be positive or negative. A cytokine signal conducted by activation of gp130, JAK, and STAT3 by tyrosine phosphorylation can be rapidly terminated by dephosphorylation. This occurs by a negative feedback circuit through recruitment of SH2-containing phosphatase, SHP-2, which is recruited to tyrosine 759 of gp130.

Feedback

Two families of proteins, the SOCS and protein inhibitor of activate STAT (PIAS) families are involved in less direct downregulation of cytokine signals. The SOCS family is comprised of eight members, SOCS-1 through SOCS-7 and cytokine-inducible SH2-containing protein (CIS). [152] Each of these proteins contains two regions of homology: a central SH2 domain and a SOCS box and a C-terminal 40 amino acid motif. SOCS-1 binds all four JAK kinases through its central SH2 domain and inhibits their kinase activity. In vitro studies have shown that SOCS-1 inhibits the STAT activation induced by IL-4, IL-6, interferon, and leukemia inhibitory factor.[153,154] SOCS-1 also inhibits Tec kinase and Vav function. SOCS-3 mRNA expression is induced by leukemia inhibitory factor, IL-2, IL-6, and IL-11.[154-157] Overexpression of SOCS-3 inhibits signaling of each of these cytokines.[115] Cytokine-inducible SH2-containing protein is a negative regulator of STAT5 activation in response to several cytokines including erythropoietin (EPO), IL-2, and IL-3. SOCS-1 deficient mice die perinatally due to excessive interferon responses.[158,159] SOCS-3–deficient mice die embryonically, likely due to excessive erythropoiesis.[160]

The binding of STAT to DNA also negatively regulates cytokine signaling. PIAS bind to STAT molecules blocking the DNA-binding activity and inhibiting STAT-mediated gene activation. PIAS1 blocks STAT1-mediated gene activation in response to interferon.[161] Similarly PIAS3 blocks DNA binding of STAT3 and its downstream effects.[162]

Cross-Talk at Receptor Level

Cross-talk between the IFNγ receptor and the IFNα/β receptor, which are localized to the calveolar membrane domain, is important for maximal antiviral response by IFNγ.[163] In mouse embryonic fibroblasts lacking IFNγ receptor, the IFNγ-induced antiviral response is impaired. Downstream IFNγ-I–induced STAT1 activity is diminished and formation of interferon-stimulated gene factor 3 is undetectable. In a similar manner, IFNβ null mouse embryonic fibroblasts lack IFNγ-induced STAT1 activation and antiviral response. Provision of exogenous IFNβ at a low concentration rescued the IFNγ antiviral response without activation of STAT1. This indicates the importance of constitutive subthreshold IFNα/β signaling at the receptor level for generation of a full IFNγ antiviral response.[163]

Cross-Talk Between Cytosolic Transcription Factors

Distinct cytokine signaling pathways are enacted through cytosolic interactions involving of several types of signaling molecules, such as adaptor proteins, kinases, phosphatases, and transcription factors. One example of cytosolic cross-talk between signaling molecules is IL-11 signaling in activated macrophages. IL-11 is a cytokine that displays antiinflammatory properties. IL-11 reduces lipopolysaccharide-induced TNF-α, IL-1β, IL-6, and IL-12p40 mRNA levels in activated macrophages. IL-11 acts to maintain levels of cytosolic NFκB inhibitors—IκB-α and IκB-β—thus inhibiting NFκB transcriptional activation.[164]

PLEIOTROPY AND REDUNDANCY OF CYTOKINE FUNCTION

Regulation of hematopoietic growth factors clearly occurs on many levels, including production (quantity and location), interaction with other factors, receptors (location, cell type, soluble versus membrane bound), and signal transduction mechanisms. *Pleiotropy* describes the property in which cytokines exhibit many different effects on various tissue and cell types. *Redundancy* refers to the property of cytokines in which two or more factors mediate similar biologic effects on the same cell type.

A cytokine designated IL-11 was cloned in 1990 based on its capacity to produce a mitogenic activity for the IL-6–dependent cell line T1165.[165] Even though IL-11 is not similar in structure to IL-6, the two cytokines exhibit certain similarities in their spectrum of biologic activities.[166,167] IL-6 and IL-11 have been shown to share the common signal transduction element, gp130.[168] Moreover, several cytokines share common chains to form heterodimers to effect signal transduction. The redundancy in function of several of these cytokines may, in part, be attributed to downstream actions of shared receptors.

Redundancy of cytokine function is not solely the result of shared receptor signal transduction elements. M-CSF and GM-CSF are both responsible for various aspects of macrophage differentiation and function. Although they do not share receptors, activation of M-CSF and GM-CSF receptors results in expression of the macrophage scavenger receptor A. Both receptors use components of the Ras signal transduction pathway to effect this response. However, M-CSF exerts its action by engaging the M-CSF–dependent enhancer recognized by activator protein-1 and cooperating Ets domain transcription factors, whereas activation of scavenger receptor A by GM-CSF is dependent on a distinct enhancer located immediately upstream of the M-CSF enhancer (see Figure 142-9).[145]

MATERNAL AND PLACENTAL PRODUCTION OF GROWTH FACTORS

Placental Production of Hematopoietic Growth Factors

The precise role and significance of growth factor production by placental tissues in maintenance of viable pregnancy and in the labor process are far from complete; however, it is likely that they are involved in two distinct regulatory processes: the neutralization of the immune response against the fetus and the provision of an environment conducive to the maturation and differentiation of the fetus.[169] From the immunologic standpoint, pregnancy has been likened (in the borrowed terms of transplant immunology) to the presence of a fetal allograft. Furthermore, the aggressive nature of the implantation event has appeared to some investigators to be similar to tumor invasion. Although certain similarities exist, the immunology of pregnancy exhibits unique features.

The components required to mount an immune response against the fetopaternal antigens are present in the maternal decidua. In addition to foreign antigen, antigen-presenting cells and effector cell are present. Despite this milieu, several mechanisms seem to abrogate the T-cell–mediated immune response at the fetomaternal interface. Although the mature T cells and NK cells are capable of migrating to the decidua and recognizing foreign antigen, they do not express their cytotoxic effects in this microenvironment. Certain mechanisms appear to act in concert to inhibit T-cell proliferation and cytotoxicity. First, the decidua produces large quantities of prostaglandin E_2 during

the first trimester.[170] Prostaglandin E_2 has been shown to down-regulate T-cell activation and IL-2 production. Second, the steroid hormones, which provide functions essential for maintenance of pregnancy, also exert significant immunologic functions. For instance, dehydroepiandrosterone (DHEA) dramatically enhances the production of IL-2 by stimulated lymphocytes. During pregnancy, DHEA levels decrease by approximately 50% because of rapid conversion of DHEA to estriol and other estrogen metabolites. Estrogens indirectly inhibit IL-2 production and accentuate IL-4 production through potentiation of the activity of 1,25-dihydroxyvitamin D_3. IL-4 effects a T-helper 2–type response that down-regulates cell-mediated cytotoxicity and phagocytic functions and favors humoral immunity.

Although the adaptive immune system appears to be inhibited by the physiologic alterations in the uterus during pregnancy, cells within the fetomaternal interface produce several hematopoietic growth factors. Among these are IL-1, IL-4, IL-6, IL-8, GM-CSF, M-CSF, tumor growth factor-β, and TNF. Production of these factors during gestation appears to be tightly regulated and to follow a specific sequence of expression. These cytokines can exhibit dichotomous functions. For instance, expressed at the proper time, concentration, and location, growth factors may promote trophoblast growth, whereas if they are expressed in abnormal amounts or sites, they may have pathophysiologic actions such as facilitating the onset of preterm labor.

Transport of Factors Across the Placenta

Studies in sheep have demonstrated that no transplacental transfer of erythropoietin (EPO) occurs.[171] Moreover, in vitro studies of EPO transport across the perfused human placenta provide evidence that Epo does not cross the placenta. However, no studies have been published to address whether the transplacental transfer of EPO occurs in vivo in humans.[172]

Studies in rats demonstrated that G-CSF (at least in small quantities) can cross from the maternal to the fetal circulation.[173] Although transfer appears to be meager, in one animal study it was sufficient to improve survival of rat pups subsequently exposed to group B streptococci.[174] Administration of recombinant G-CSF to humans resulted in transplacental passage of G-CSF in an amount capable of stimulating fetal granulopoiesis.[175] The mechanism underlying this transfer is uncertain, but it does not require an intact G-CSF receptor.[176] The physiologic relevance of transplacental passage of maternally derived hematopoietic cytokines remains to be delineated.

DEVELOPMENTAL ASPECTS OF INTERACTION BETWEEN HEMATOPOIETIC GROWTH FACTORS AND HEMATOPOIETIC PROGENITORS

Developmental Differences Between Adult and Fetal Progenitors

Developmental differences have been identified among hematopoietic progenitors from various sources. For instance, differences exist between fetal liver–derived and adult bone marrow–derived progenitors. Fetal liver progenitors exhibit a rapid cycling rate, rapidly expanding pool size, accelerated in vitro maturation time, increased sensitivity to Epo, and decreased sensitivity to GM-CSF compared with adult marrow progenitors.[60] Furthermore, circulating hematopoietic progenitor cells derived from umbilical cord blood differ from those derived from adult human bone marrow in that a subset of cord blood progenitors grows in methylcellulose cultures in the absence of added growth factors. Hematopoietic progenitors obtained from fetal subjects also differ from those obtained from adults. For instance, Roodman and colleagues[177] observed that by including dexamethasone with cultures of human fetal progenitors, fewer erythroid colonies and fewer normoblasts per colony developed. These reductions were not observed when progenitors from adults were subjected to the same conditions.[177] In addition, Christensen and colleagues[178] observed that high concentrations of EPO in vitro resulted in a dose-dependent down-modulation of neutrophil production from fetal, but not from adult, colony forming units–granulocyte macrophage.[178] A third difference between fetal and adult progenitors was observed by Emerson and associates[179] and by Valtieri and colleagues,[180] who reported that EPO alone induced erythroid burst formation from embryonic and fetal burst-forming units-erythroid, whereas burst-forming units-erythroid of adult origin required GM-CSF or IL-3 in addition to EPO. A fourth difference is that some fetal progenitors undergo clonogenic maturation in the absence of added growth factors or when they are stimulated with factors such as IL-11 that, as single agents, do not support maturation of progenitors from adults.[167,181] Other studies suggest that the progenitor cells or their progeny express growth factors, IL-3, and GM-CSF, and thus support clonal expansion in an autocrine or paracrine fashion.[182]

Experiments to delineate the effects of hematopoietic growth factors on fetal hematopoietic progenitor cells have demonstrated differences in the actions of these factors on fetal versus adult progenitors. For instance, the presence of early-acting factors (IL-6 and SCF) initiates clonal expansion in vitro in the absence of other growth factors added to the culture. In addition, IL-11 enhances cycling of both committed multipotential and lineage-specific colonies from cord blood, but it does not induce cycling of adult progenitors derived from bone marrow.[167,181-183]

Effects of Hematopoietic Growth Factors on Nonhematopoietic Tissues During Embryonic and Fetal Development

SCF appears to have a critical role in embryonic and fetal hematopoietic development. Schmitt and colleagues[184] observed that SCF and c-*kit* were among the factors expressed in undifferentiated embryonic murine stem cells. The importance of SCF and its interaction with the c-*kit* receptor during early development are illustrated by murine strains with mutations at the W locus encoding the c-*kit* product, and mice with the mutation of the SL locus encoding SCF protein.[185,186] Both strains exhibit pleiotropic developmental defects, not only in hematopoiesis, but also in gametogenesis and melanogenesis.

The utilization of homologous recombination to generate transgenic mouse models with deletion of specific growth factors has shed light on the role of these factors during development and their relative importance in normal hematopoietic homeostasis. The GM-CSF knock-out mouse illustrates this point well.[187] It was expected that a mouse homozygous for defective GM-CSF alleles would exhibit defects in hematopoietic development. Such is not the case, because these mice do not exhibit detectable hematopoietic defects. Rather unexpectedly, they develop a form of alveolar proteinosis. Whether the pathophysiology observed in this defect results from defective alveolar macrophage function, pulmonary epithelial function, or a combination of both is unclear.

Mice deficient in both GM-CSF and M-CSF gene products (genotype $GM^{-/-}$ $M^{-/-}$) have been generated by interbreeding GM-CSF–deficient mice with M-CSF–deficient osteopetrotic mice.[188] These mice exhibit coexistent features of both deficiency states, yet they still have circulating monocytes and phagocytic tissue macrophages. This would indicate that factors other than GM-CSF and M-CSF are capable of supporting macrophage lineage differentiation. These mice (like the GM-CSF–deficient mice) exhibit a form of chronic lung disease that is more severe than that of GM-CSF deficiency alone, a finding implicating M-CSF in modulating the pulmonary disease associated with GM-CSF deficiency in vivo.

Several hematopoietic growth factors including EPO, G-CSF, GM-CSF, IL-6, IL-8, IL-11, TPO, and their respective receptors have

been identified in nonhematopoietic tissues of the human fetus and neonate. EPO receptor has been identified in murine cell lines of neuronal origin, in cultured murine embryonic neurons, and in the brain and spinal cord of rodents.[189,190] The presence of EPO was also identified in the cerebrospinal fluid of normal and preterm infants.[191] Subsequently, EPO and its receptor were identified in the central nervous system of human fetuses as early as 5 to 6 weeks after conception.[192] The expression of EPO and EPO receptor mRNA in the spinal cord remained relatively constant from 7 to 16 weeks gestation, whereas they both increased in the brain as gestation progressed. By immunohistochemical analysis, *EPO* and *EPO* receptor are localized to the periventricular germinal zone at 5 to 6 weeks gestation.[193] By late gestation, EPO and EPO receptor localization has diverged; EPO is localized primarily in neurons, and EPO receptor reactivity is localized most prominently in astrocytes. In vitro studies of neuronal cell lines subjected to hypoxic conditions and glutamate-induced injury demonstrated a protective effect of EPO.[190,192] In vivo studies in animals also demonstrated a protective effect of EPO in ischemic brain injury models.[194,195] The role these hematopoietic factors play in neurodevelopment and homeostasis remains to be identified.

G-CSF and G-CSF receptor are present in virtually all organs between 8 and 24 weeks gestation.[196,197] Their distribution in the intestine and kidney changes with progression of gestation. In preterm and term neonates, G-CSF protein concentration has been examined. GM-CSF protein and mRNA are detected during human fetal development in the lung, spleen, adrenal gland, and neuronal tissue.[198] The cell types expressing GM-CSF include macrophages, neurons, and glial cells.

IL-11 is a hematopoietic growth factor that also affects nonhematopoietic tissues. IL-11 is produced by alveolar and bronchial epithelial cells in large amounts and may play a significant role in pulmonary inflammation. Additionally, both IL-11 and its receptor are expressed in epithelial cells of the gastrointestinal tract.[199] IL-11 interacts with gastrointestinal epithelial cells and reversibly inhibits its proliferation of intestinal crypt stem cell lines. This activity may play a role in normal intestinal growth and in resistance to injury. IL-11 has been evaluated for its protective effects in several models of gastrointestinal disease, including acute chemical-induced colitis and chronic inflammatory bowel disease in transgenic animals expressing human leukocyte antigen-B27 and β_2-microglobulin.[200] IL-11 has also been used to ameliorate damage in a model of ischemic bowel injury, a murine burn model, and a rat model of short bowel syndrome.[201-203] IL-11 administration increased survival rates and decreased bacterial translocation in these models.

DEVELOPMENTAL DIFFERENCES IN PRODUCTION OF CYTOKINES BY MATURE EFFECTOR CELLS

Some cytokines regulating pivotal functions required for activation of immune effector cells are synthesized in diminished quantities by human neonates compared with adults. Production of IFNγ and of IL-6 is decreased by circulating leukocytes derived from neonates compared with adults.[204-206] The role of these factors in the immune response to certain bacterial and viral pathogens is underscored by experiments involving IFNγ– and IL-6–deficient mice generated by homologous recombination and by studies using neutralizing antibodies to these factors.[206-209] IFNγ–deficient mice manifest severely impaired defenses against both bacterial and viral pathogens. IL-6–deficient mice exhibit defective cytolytic activity of T cells in response to viral infections and diminished capacity to recruit immune cells to sites of infection after experimental bacterial inoculation. The mechanism underlying these developmental defects has not been fully defined; however, diminished production of IL-12 by antigen-presenting cells may contribute to diminished IFNγ responses. Investigations of neonatal monocyte-derived dendritic cells revealed a selective defect in IL-12 synthesis at the protein and mRNA level in response to lipopolysaccharide, CD40 ligation, or polynucleotides.[210] Moreover, these investigators found that neonatal dendritic cells were less effective than adult dendritic cells in stimulating IFNγ production by allogeneic adult T cells. This deficit was corrected with addition of recombinant IL-12. Deficiencies in production of these factors could account for impairment in certain aspects of host defenses observed in the newborn period.

Two hematopoietic growth factors, GM-CSF and G-CSF, which exhibit significant effects on myeloid clonal expansion and differentiation, are also produced in diminished quantities by neonatal blood mononuclear cells compared with adult cells.[211,212] Although GM-CSF receptor numbers and binding affinity appear to be similar between adult and neonatal blood mononuclear cells, GM-CSF gene expression by these cells is clearly lower in cells derived from term neonates. Similarly, monocytes from term human neonates produce significantly lower quantities of G-CSF in vitro than cells derived from adults. Furthermore, developmental dysregulation of G-CSF expression appears to be more pronounced in cells of preterm neonates. Studies in mice demonstrate similar decreases in expression of IL-6 and G-CSF in vivo.[206] Diminished production of GM-CSF by phytohemagglutinin- and phorbol myristate acetate–stimulated newborn mononuclear cells compared with adult mononuclear cells is secondary to posttranslational regulation of mRNA stability. The precise molecular mechanisms responsible for the differences in regulation of G-CSF between neonates and adults have not been delineated; however, currently available data support a posttranscriptional mechanism.[213]

Developmental Granulocytopoiesis

FETAL GRANULOCYTE PROGENITORS

The first circulating blood cells during embryonic development are derived from the extra embryonic mesoderm of the yolk sac (YS), and as the embryo develops, the anatomic site of hematopoiesis subsequently switches to the liver and then to the marrow.[1] The hematopoietic stem cells (HSC) seeding these organs include YS-derived HSC, which appear to be a transient embryonic population, and definitive stem cells arising from the aorta-gonad-mesonephros (AGM) region within the embryonic splanchnopleuric mesoderm. The origin of the AGM-HSC is not clear, but they are located in the ventral aspect of the dorsal aorta in the preumbilical region near the anterior limb bud level and are observed between 30 and 37 days gestation.

Hematopoiesis from the YS continues from the 3rd through the 8th to 10th week. Before liver colonization with HCS, the placenta appears to be a substantial reservoir of HCS.[2] The origin and fate of these placental HCS are under investigation. There is overlap with hematopoiesis in the YS, placenta, and liver, with the latter beginning about the 5th week and continuing through 20 to 24 weeks. Hematopoiesis is observed in the marrow by the 11th week,[3] when committed granulocytic progenitors are first seen in the clavicular marrow followed by mature neutrophils in the marrow from the 14th week onward. In the fetal liver, although neutrophil progenitors are abundant, mature neutrophils are not identifiable.[4]

Pluznick and Sachs[5] and Bradley and Metcalf[6] first cultured hematopoietic progenitor cells in semisolid media and termed this variety of progenitor a *colony-forming unit* (CFU). They observed that when grown in appropriate conditions, some CFUs gave rise to clones containing mixtures of blood cells, including macrophages, monocytes, neutrophils, and erythrocytes. These CFUs were termed *CFU-MIX* or, if the colony contained granulocytes, erythrocytes, megakaryocytes, and macrophages, *CFU-GEMM*. Other CFUs gave rise to colonies containing only one or two cell types. Those developing neutrophils only were termed *CFU-G* (granulocyte), those with only macrophages or monocytes were termed *CFU-M*, those with neutrophils plus macrophages or monocytes were termed *CFU-GM*, and those with only megakaryocytes were termed *CFU-Meg*.[7] Other progenitors develop into colonies of normoblasts and have been divided conceptually into two classes. The more primitive variety give rise to a large burst of normoblasts and are termed *BFU-E* (burst-forming units—erythroid) and the more mature variety "e" give rise to a smaller clone of normoblasts and are termed *CFU-E* (colony-forming units—erythroid). The mechanisms underlying this process of lineage commitment are now beginning to be understood.[8] The effect of biomechanical forces as critical regulators of hematopoiesis is a new field of investigation,[9] as is the prevention of apoptosis as a mechanism for hematopoietic progenitor cell growth and development.[10]

Umbilical cord blood and fetal blood have a 10- to 50-fold higher concentration of CFU-GM than does the blood of adults.[11] However, this may not indicate that the mass of CFU-GM per kilogram body weight is higher in the fetus than in the adult. In fact, animal studies indicate that the opposite is true; namely, compared with adults, the fetus has relatively few granulocytopoietic progenitors but has a much larger proportion of progenitor pool in the blood.[12] Similar findings are reported for CFU-MIX.[13] Further evidence of a small granulocytopoietic pool in the fetus comes from studies of soluble FcRIII (sCD16), which is derived from apoptotic neutrophils. Its low concentration in plasma of preterm neonates may reflect a low total body neutrophil mass. The low sCD16 levels of premature infants reach adult values by the fourth postnatal week.[14]

Although relatively fewer in number per kilogram body weight, a higher proportion of the CFU-GM in the fetus are actively cycling, compared with CFU-GM of adults.[11-13] This high proportion in cycle may be a mechanism for increasing neutrophil production needed to build a sizable neutrophil reserve pool in preparation for birth and to keep pace with the rapid rate of somatic growth in the second and third trimesters.

Basic differences have been postulated in hematopoietic progenitors of fetal versus adult origin. Emerson,[15] Valtieri,[16] and Holbrook[17] and their colleagues observed that fetal BFU-E undergo clonal maturation in the presence of erythropoietin alone, whereas BFU-E of adult origin require other factors (such as granulocyte-macrophage colony-stimulating factor [GM-CSF], interleukin-3 [IL-3], or IL-9) in addition to erythropoietin. Gardner and co-workers[18] reported a similar phenomenon for fetal CFU-GM; namely, a fraction of fetal CFU-GM undergoes clonal maturation when IL-6 alone is included in the tissue culture, whereas CFU-GM from adults require other factors as well. Schibler and associates[19] reported a similar finding with IL-11. Some of this apparent difference between fetal and adult progenitors might be explained by environmental differences rather than intrinsic differences in progenitors. Evidence for this was provided by Schibler and colleagues,[20] who observed transcripts for GM-CSF and IL-3 in fetal but not adult $CD34^+$ and noticed that the "factor independence" of fetal progenitors was ablated by adding neutralizing anti-GM-CSF and anti-IL-3 antibodies to the cultures. On this basis, they speculated that the factor independence ascribed to fetal hematopoietic progenitors was the result of self-generation of factors in the culture dish.

FETAL HEMATOPOIETIC MICROENVIRONMENT

Hematopoiesis in the fetal liver is predominantly erythropoietic, but in the fetal bone marrow, it is predominantly granulocytopoietic.[21] However, when progenitors from either organ are cultured in vitro, they are capable of producing both erythrocyte and granulocytes.[22,23] Thus the local microenvironment appears to determine the fate of fetal hematopoietic progenitors (Figure 143-1). Clearly, the microenvironment changes with maturation, which likely explains differences in the pattern of developmental hematopoiesis.[24] The microenvironment includes a complex amalgam of cellular elements, growth factors, extracellular matrix, and biomechanical factors. The cellular elements consist of macrophages, reticular cells, adipocytes, and endothelial cells, whereas the extracellular matrix includes collagen and a variety of glycoproteins such as hemonectin and fibronectin.[25]

Roles of cellular elements of the microenvironment are being defined (Figure 143-2). Mesenchymal stem cells are multipotent and can generate various microenvironmental components, and these cells have a role in the switch of hematopoiesis between YS,

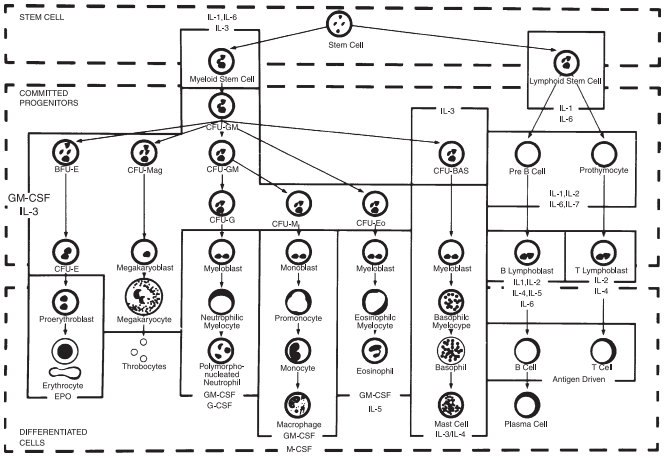

Figure 143-1 Hematopoietic development and regulation of myeloid committed progenitors.

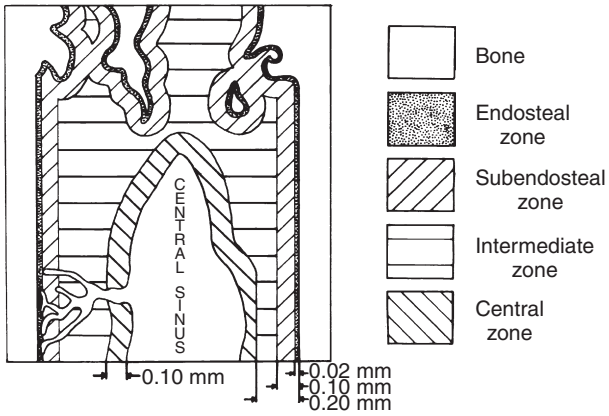

Figure 143-2 Scale drawing of the stereologic zones used for the determination of hematopoietic colony cell distribution. *(From Lambersen RH, Weiss L:A model of intermedullary hematopoietic microenvironments based on stereologic studies of the distribution of endocloned marrow colonies,* Blood *63:287, 1984.)*

placenta, liver, and marrow.[26] Among the factors generated by mesenchymal cells are cytokines and growth factors.[27] For instance, clones of normoblasts associate physically with macrophages that have long branching processes encircling the developing normoblasts.[28] Similarly, in vitro erythroid colonies generally develop around a nesting macrophage.[25] In contrast, clones of granulocytes associate with reticular cells that have fibroblast-like appearance and function.[28] These reticular cells not only serve to hold the cells in proximity but also bind specific glycoproteins needed for granulocytic development. As granulocytic cells mature in the matrix, they lose their binding sites for adhesive molecules and are released into circulation.

Differences in stromal cell populations were postulated as a mechanism explaining the difference between fetal and adult hematopoietic microenvironments. However, Bethel and colleagues[29] did not find a difference in stromal cellular elements comparing fetal liver, fetal marrow, and adult marrow and speculated that the cellular portion of the microenvironment was not the relevant feature.

Extracellular matrix components have also been postulated as a mechanism explaining differences between fetal and adult hematopoietic microenvironments. Heparan-sulfated proteoglycans can bind to tumor growth factor-β, basic fibroblast growth factor, IL-3, GM-CSF, and IL-7.[30] Osteonectin can immobilize platelet-derived growth factor. In addition, ECM can bind to cell surface glycoproteins. Fibronectin, collagens, and laminin are ligands for integrins, which not only control anchorage, spreading, and migration of hematopoietic cells but are also involved in various intracellular signaling cascades. Hyaluronan is a ligand of CD44 and, in several systems, facilitates cell-cell adhesion and cell migration.[31]

Collagens I, III, and IV have been found in the adherent cell layer of long-term marrow cultures.[32]Their specific roles have not been defined, but Zuckerman and colleagues,[33] using a murine long-term bone marrow culture system and a proline analogue *cis*-4-hydroxyproline (CHP) to inhibit collagen synthesis, demonstrated that collagen is important in long-term cultures. Using various concentrations of CHP, they documented decreased cellularity, decreased synthesis of collagen, and decreased hematopoietic growth.

Proteoglycans are among the regulators of the hematopoietic microenvironment. For instance, erythropoietic suppression induced by polycythemia involves an increase in marrow content of sulfated glycosaminoglycans.[34] Chondroitin sulfate and hyaluronic acid are increased in the marrow of SI/SI^d mice, who have a defective marrow microenvironment.[35] In contrast, stimulating glycosaminoglycan synthesis promotes hematopoietic proliferation.[36]

Proteoglycans and glycosaminoglycans are involved in cell adhesion to the extracellular matrix. Del Rosso and co-workers[37] showed that mature granulocytes did not normally adhere to the extracellular matrix, but if treated with hyaluronidase, most did. Treatment of stroma with heparitinase reduced adhesion of immature marrow granulocytes to the stroma. Glycosaminoglycans may function indirectly to stimulate hematopoiesis. Gordon and colleagues[38] showed that glycosaminoglycans from the bone marrow stromal layer were capable of trapping GM-CSF. Fibronectin did not trap GM-CSF, and glycosaminoglycans from fetal liver adherent cells were not able to trap GM-CSF. Thus different proteoglycans or glycosaminoglycans may have different roles in hematopoiesis.

Hemonectin and fibronectin are extracellular matrix molecules with hematopoietic functions. Hemonectin is associated with granulocytic development,[39] whereas fibronectin is involved in erythroid development. Developing erythroid progenitors express fibronectin receptors, which they lose as they mature, suggesting that fibronectin may be involved in the release of erythroid cells from the bone marrow.[40] Mechanisms whereby the granulocytopoietic microenvironment operate, including the genes involved and the role of oxygen, are being studied.[41,42]

NEUTROPHIL MITOTIC AND MATURATION COMPARTMENTS

The life cycle of a neutrophil has been conceptually divided into three phases, representing time spent in the (1) marrow, (2) blood, and (3) tissues. It is assumed that neutrophils move through this system approximately in order, as if in a pipeline. The initial part of the pipeline involves commitment and clonal maturation of progenitors within the marrow. The earliest neutrophilic precursors are capable of cell division and thus are referred to as the "mitotic compartment," also known as the *neutrophil proliferative pool* (NPP). This compartment is composed of myeloblasts, promyelocytes, and myelocytes.

As neutrophils mature, their capacity to undergo cell division is lost. Neutrophils that can no longer divide are housed in the marrow for the purposes of maturation and storage as a ready reserve of cells to be released from the marrow into the blood on demand. This stage in neutrophil development is termed the "maturation compartment," also known as the *neutrophil storage pool* (NSP). This compartment consists of the metamyelocytes,

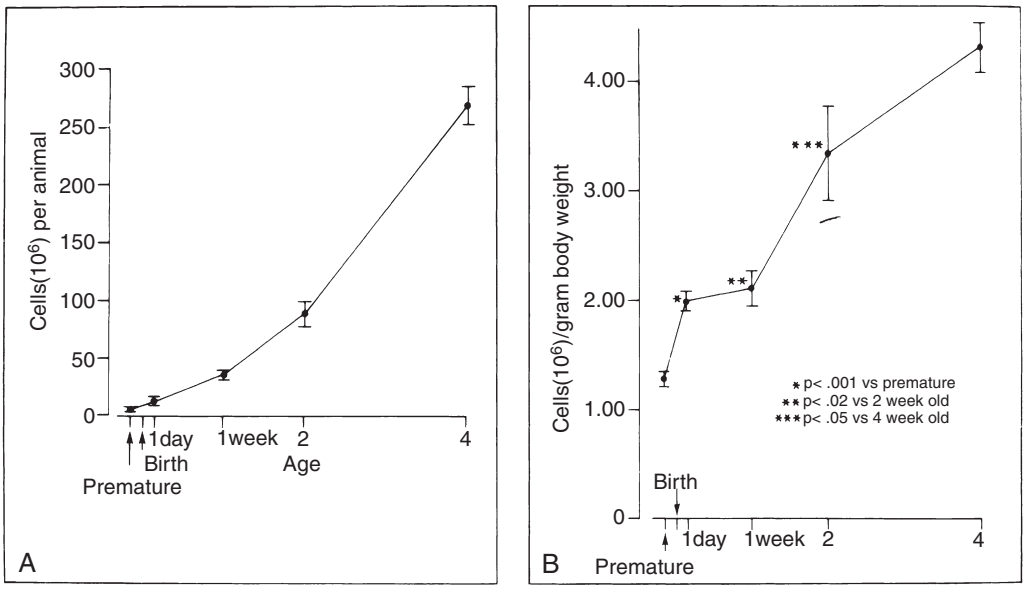

Figure 143-3 A, Neutrophil storage pool size at various ages in the developing rat. Each point represents the mean of 8 to 12 animals ± SE. **B,** Neutrophil storage pool size per gram of body weight at various ages in the developing rat. Each point represents the mean of 8 to 12 animals ± SE. *(From Erdmann SH, Christensen RD, Bradley PP, et al: Supply and release of storage neutrophils: A development study,* Biol Neonate *41:132, 1982.)*

band neutrophils, and segmented neutrophils in the marrow. Studies in fetal and newborn rodents indicate that the liver and spleen house a significant fraction of the NPP and NSP,[43] but in human neonates, only the marrow, not the liver and spleen, houses neutrophil production and storage.[44]

Studies in adults indicate that under steady-state conditions, four to five cell divisions occur among cells in the NPP.[45] Similar studies have not been reported for neonates. Studies using tritiated thymidine incorporation and $DF^{32}P$ labeling indicate that the NPP contains about 2×10^9 cells/kg body weight and the NSP about 6×10^9 cells/kg.[46] Adult rats also have an NSP that contains about 6×10^9 cells/kg; however, no neutrophils at all are observed before about 14 days gestation. By 19 days gestation (term = 21 days), rats have a NSP of 0.9×10^9 cells/kg, and by term, the NSP has increased to 1.2×10^9 cells/kg (Figure 143-3).[43] Although the size of the NSP has not been quantified in human neonates, it appears from studies of human abortuses that no neutrophils are present before 14 weeks gestation and the number per kilogram body weight at 22 to 24 weeks gestation is far fewer that at term.[44] It also appears that, in contrast to rodents, granulocytopoiesis in the human fetus takes place almost exclusively in the bone marrow.[47] Although the spleen contains CFU-GM, these appear to be within the blood circulating through. Histologic sections of fetal spleen fail to show any nests of granulocytopoietic activity, and RNA extracted from fetal spleen fails to reveal transcripts for neutrophil-specific growth factors. Similarly, differential cell counts, histologic sections, and RNA studies of human fetal liver reveal little, if any, granulocytopoiesis in that organ, and the fetal liver does not exhibit nests of granulocytopoiesis. Thus the fetal spleen and liver contain granulocyte progenitors but are probably not normally active sites of granulocytopoiesis.[44]

CIRCULATING AND MARGINATED BLOOD NEUTROPHIL POOLS

Neutrophils released from the marrow enter the blood where they distribute into two compartments of approximately equal size: the circulating and the marginal pools. Neutrophils in the former compartment are freely circulating, whereas those in the marginal compartment are temporarily adherent to endothelial cells, generally in the postcapillary venules. In normal adult humans, the total of these two compartments (termed the *total blood neutrophil pool*) contains about 0.6×10^9 cells/kg body weight; with about one half of the cells (0.3×10^9 cells/kg) in each (circulating and marginal) pool.[46]

In the marrow, the proportion of band to segmented neutrophils is much higher than in the blood. On that basis, it is likely that a selective release of segmented neutrophils occurs from the marrow, whereas band neutrophils generally remain behind to mature. The mechanisms controlling release are only partly understood. G-CSF can induce such release,[48] as illustrated by G-CSF-deficient mice,[48] and so can hydrocortisone and related corticosteroids.[46] Some evidence exists that a factor derived from the activation of C3 can induce NSP release as well.[49]

After epinephrine administration, neutrophils are rapidly released from the marginated compartment and enter the circulating pool.[46] The neutrophilia thus produced persists only for 30 to 45 minutes. No change in differential cell count accompanies this demargination; thus the proportion of segmented neutrophils is the same in the marginated and circulating neutrophil pools. The opposite movement of neutrophils, from the circulating to the marginated pool, occurs for a period of 1 to 2 hours after experimental intravenous administration of endotoxin. Newborn infants with strenuous crying can experience neutrophil demargination and can double their blood neutrophil concentration within 3 to 5 minutes.[50,51] A mild demarginating response is also reported to occur in preterm infants after erythrocyte transfusion.[51]

The half-life of neutrophils in the blood of adult humans, measured by autologous $DF^{32}P$ labeling, is about 6.3 hours,[52] and this agrees closely with studies using ^{3}H-TdR (7.4 hours).[53] Similar studies on neutrophils from human fetal subjects have not been reported. However, studies on cord blood neutrophils suggest a lower rate of spontaneous apoptosis compared with adult cells. The significance of these findings remains to be determined. It is likely that neutrophils leave the blood and enter the tissues randomly, rather than according to their age as is the case for

TABLE 143-1

Fetal White Blood Cell and Neutrophil Counts

Gestational Age (wk)	White Blood Cells ($\times 10^3/mm^3$)	Neutrophils (%)
18-20	4.2	5 ± 2
21-22	4.19	5.5 ± 3.5
23-25	3.95	7.5 ± 4.5
26-30	4.44	8.5 ± 2.5

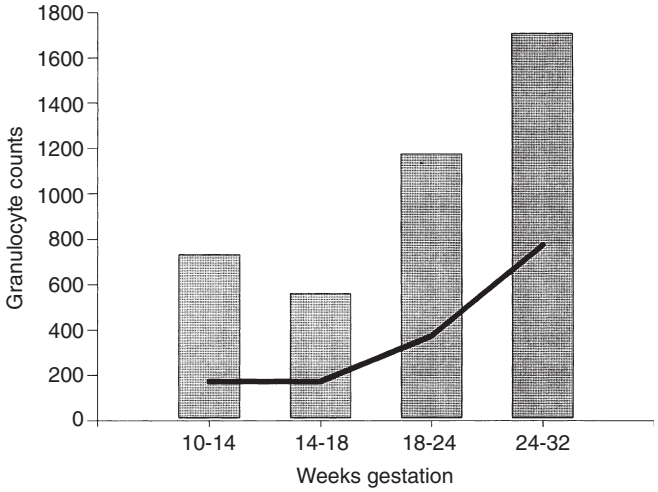

Figure 143-4 Mean and range of neutrophil counts at 10 to 14, 14 to 18, 18 to 24, and 24 to 32 weeks gestational age. *(From Thomas DB, Yoffey JM: Human foetal haemopoiesis. I. The cellular composition of foetal blood,* Br J Haematol *8:290, 1962.)*

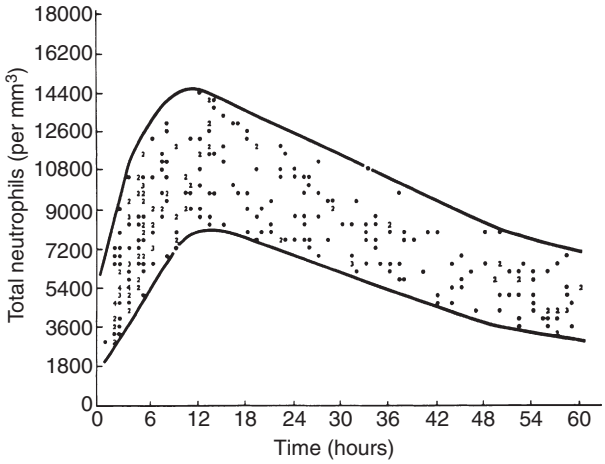

Figure 143-5 The total neutrophil count reference range in the first 60 hours of life. *(From Manroe BL, Weinberg AG, Rosenfeld CR, et al: The neonatal blood count in health and disease,* J Pediatr *95:89, 1979.)*

erythrocytes and platelets. This theory is supported by the observation that transfused, labeled neutrophils appear in the blood and saliva simultaneously.[54]

After their short time in the blood, neutrophils move through vessel walls to enter the tissues. Within minutes of developing a local site of tissue damage or infection, adherence of neutrophils to the endothelium and their subsequent migration into the tissues can be observed. Studies on fetal sheep show that after intraamniotic exposure to endotoxin, the number of circulating neutrophils initially decreases by 4 hours owing to egress into the tissues, followed by an increase over the next 6 days.[55] After the initial adherence of the neutrophil to an endothelial cell, it projects pseudopodia and forces a passageway between endothelial cells. The length of time that neutrophils spend in the tissues and their fate there are not completely clear. Labeled neutrophils are found in saliva, although they are not found in the salivary ducts.[54] This is presumably due to migration of neutrophils into the gingiva. Loss of neutrophils has been observed into the urine, and through the lungs, liver, spleen, and gastrointestinal tract.[55] Not all neutrophils are used by encountering infectious organisms because the size of the marrow and blood neutrophil pools is essentially the same in germ-free and normal mice.[54]

Reference ranges for circulating neutrophil varies with gestation. The proportion of neutrophils in early gestation is on the order of 5% (Table 143-1). In samples obtained by hysterotomy at 26 to 30 weeks gestation, neutrophils constitute 8.5% of the leukocytes, or only about 350/μL.[56] Playfair and associates[57] studied blood counts from fetuses obtained from pregnancies terminated by either hysterotomies or vaginal abortion. Those delivered vaginally had much higher neutrophil counts than did those delivered operatively. Neutrophil counts can be higher for up to 3 days in preterm infants after antenatal maternal administration of betamethasone when the drug is administered close to delivery.[58]

There is a doubling of the neutrophil count from 14 to 18 weeks gestation and a fourfold increase by 24 to 32 weeks gestation (Figure 143-4)[59] At birth, the neutrophil count is much higher still. Manroe and co-workers[60] published neutrophil reference ranges in term neonates during the first 28 days after birth. Peak neutrophil counts occurred between 12 and 24 hours postnatally (Figure 143-5), with the 95% confidence limit ranging from a low of 7800 to a high of 14,500/μL. Counts then decreased, achieving a stable lower value of 1750 by 72 hours of life. The stable upper limit of the next 28 days was achieved at about 6 days.

Mouzinho and colleagues[61] revised the reference ranges for blood neutrophil concentrations in very-low-birth-weight infants (see Figure 143-5). Serial counts were obtained between birth and 28 days of age from 63 infants of 29.9 ± 2.3 weeks gestation. No difference in the upper limit of normal was observed between those very-low-birth-weight infants and the more mature infants reported by Manroe. Concentrations of greater than 14,000/μL at 12 hours and greater than 9000/μL after 48 hours defined neutrophilia. However, the very-low-birth-weight infants had a wider range of counts, encompassing substantially lower values compared with mature infants; neutropenia was defined as a concentration less than 2000/μL at 12 hours of life and less than 100/μL after 48 hours. Lower counts in healthy very-low-birth-weight infants were also reported by Prober and colleagues.[62]

Altitude (>4800 feet above sea level) appears to have an elevating effect on neonatal neutrophil counts of term (Figure 143-6) and preterm (Figure 143-7) infants.[63] If the effect of altitude is not taken into account, neutrophilia can be overdiagnosed, and, erroneously, neonates with a normal complete blood count can be labeled as having neutrophilia (Figure 143-8).[64]

NEUTROPHIL ANTIGENS IN THE FETUS

The expression of specific granulocyte antigens has been reviewed by Bux.[65] In 1926, Doan[66] observed that serum from some patients agglutinated leukocytes. Although techniques for measuring leukoagglutinins have improved over the years, the field of recognition of granulocyte antigens has been plagued by an inherent tendency of granulocytes to agglutinate. Neutrophil-specific antigens were initially discovered by Lalezari and Radel[67] while studying neonatal neutropenia. Numerous other antigens

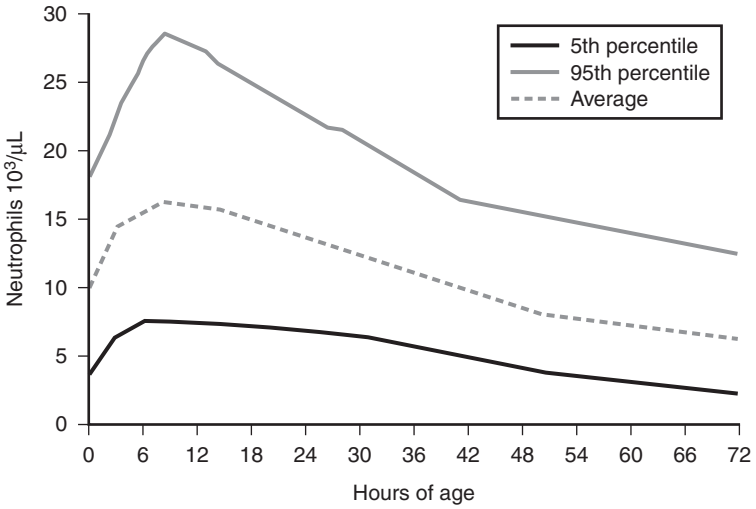

Figure 143-6 Reference ranges for blood neutrophil concentrations at altitude (>4800 ft) during the first 72 hours after the birth of neonates of more than 36 weeks gestation. *(Modified from Schmutz N et al:* J Perinatol *28:275, 2008.)*

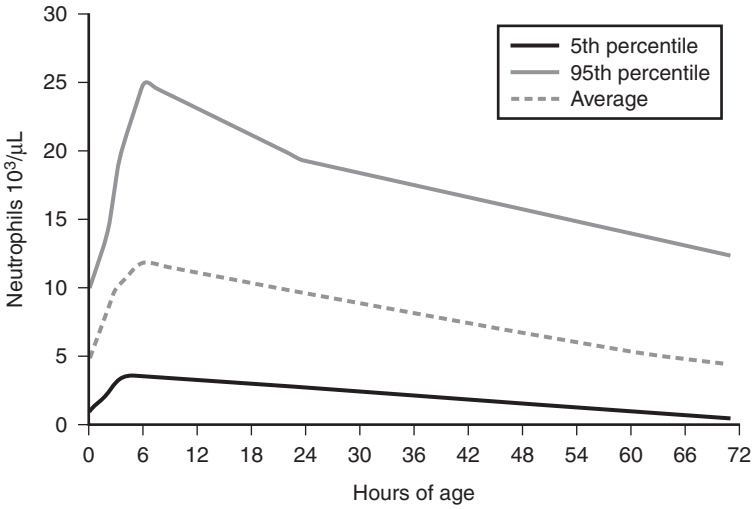

Figure 143-7 Reference ranges for blood neutrophil concentrations at altitude (>4800 ft) during the first 72 hours after the birth of preterm neonates (28 to 36 weeks gestation). *(Modified from Schmutz N Henry E, Jopling J, et al: Expected ranges for blood neutrophil concentrations of neonates: the Manroe and Mouzinho charts revisited,* J Perinatol *28:275, 2008.)*

have been added subsequently and can be broadly classified into three subgroups: (1) antigens with expression limited to granulocytes (such as NA, NB, NC, ND, NE, HGA-3, and LAN), (2) antigens that can also be detected on other cell types (such as HGA-1, Mart, and Ond), and (3) antigens distributed throughout the body (such as the HLA system and antigen 5b). In the original nomenclature, the letter *N* stood for neutrophil-specific antigen, followed by a capital letter designating a specific gene locus and a number designating a certain allele at that locus. As is apparent from the previous list, a number of antigens described later did not follow this convention, and the subsequent molecular characterization of the antigens showed that some of these were actually identical to each other.

A new nomenclature proposed by the Granulocyte Antigen Working Party of the International Society of Blood Transfusion (ISBT) attempted to address these anomalies.[68] It named the well-defined granulocyte alloantigens as HNA, which stands for "human neutrophil alloantigen." Glycoprotein location of the antigen is coded by a number (e.g., location on FcγRIIIb is denoted as HNA-1). Different polymorphisms of the same glycoprotein are designated alphabetically, in order of the date of publication (HNA-1a, -1b, and so on). The genes coding for glycoproteins are named according to the guidelines of the International Workshop on Human Gene Mapping (e.g., Fcγ receptor IIIb is abbreviated to FCGR3B). The allelic variants of the gene are then designated with Arabic numerals and are separated from the gene designation by an asterisk (e.g., FCGR3B*1). For the naming of newly detected antigens, the use of acronyms is permitted until their eventual inclusion in this system.

The HNA system currently comprises seven antigens that are assigned to five glycoproteins (Table 143-2). This classification does not include NB2, NC1, ND1, NE1, SAR, LAN, LEA, CN1, and RED antigens. NB2 is not the antithetical antigen to NB1 and may in fact be identical to 9a. NC1 seems to be identical to NA2. ND1 and NE1 are solitary representatives of other presumed systems that have been associated with autoimmune neutropenia, but specific antisera against these two antigens are no longer available, and hence testing is not possible. The other antigens are still being characterized. A detailed description of individual antigens can be found elsewhere.[65]

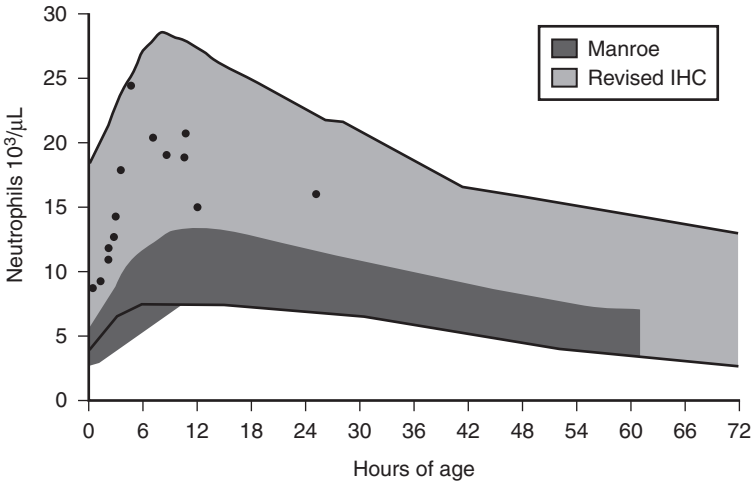

Figure 143-8 The blood neutrophil concentration and the age (hours) after birth when the complete blood count was drawn are shown by *black squares*, one for each of 14 patients admitted to the neonatal intensive care unit (NICU) for antibiotic treatment. Superimposed on these 14 black squares are the Manroe reference range (Texas) and the Intermountain Healthcare reference range (Utah). The 14 neonates were mistakenly thought to have a elevated neutrophil count and on that basis were admitted to the NICU for intravenous antibiotics. *(Modified from Lambert RM, Baer VL, Wiedmeier SE, et al: Isolated elevated blood neutrophil concentration at altitude does not require NICU admission if appropriate reference ranges are used,* J Perinatol *29:822-825, 2009.)*

Modified from Bux J: Molecular genetics of granulocyte polymorphisms, *Vox Sang* 78(Suppl 2):125, 2000.

Neutrophil-specific antigens have been identified on mature adult neutrophils, myeloid precursors, and cord blood neutrophils. The other antigens seen on the neutrophils include those of the HLA system and the red cell antigens. Class I HLA antigens (HLA-A, -B, and -C) are seen on neutrophils and their precursors in the bone marrow, although it is not known whether these are intrinsic or are passively absorbed from the plasma. Class II HLA antigens have not been described on neutrophils but are present on immature granulocytes. Red cell antigen groups expressed on neutrophils include the polylactosaminyl glycolipids bearing Ii, Le^x, and P systems. Although the antigens of the ABO systems were initially reported to be present, subsequent investigations have provided evidence to the contrary. Similarly, the MN, Rh, Kidd, Duffy, Kell, and Kx antigen systems are not present on the surface of granulocytes.

Neutrophil antigens inherited from fathers but not present in mothers may cause an antibody response during gestation. Antineutrophil antibody can cross the placenta to the fetal circulation and cause severe neutropenia in the fetus and newborn infant. A wide variety of antigenic targets, including HNA-1, HNA-2, and HNA-3, NC1, SH, SAR, LAN, LEA, CN1, and possibly HLA have been identified in ANN. In the United States, one half of all the cases of ANN are mediated by antibodies that bind to HNA-1a, -1b, or -2a antigens. Estimates of the frequency of ANN vary from 0.2% to 20%, although the incidence of granulocyte-specific antibodies is likely to be higher. Although self-limited, alloimmune neutropenia can be associated with serious infections and death.[69] A mortality rate as high as 5% has been reported. Antineutrophil antibodies may also develop as an isolated autoimmune phenomenon and may be seen even in premature neonates. The etiologic reasons for autoimmune neutropenia of infancy (AINI) are not exactly known, but associations with parvovirus B19 infection and β-lactam antibiotics have been reported. Suggested mechanisms include development of cross-reacting antibodies due to molecular mimicry, changes in endogenous antigens, enhanced HLA expression, or loss of suppression of clones of self-reacting lymphocytes. HNA-1a (NA1) autoimmunization has been linked with HLA-DR2, indicating the involvement of immune response genes. However, the occurrence of AINI in only one of monozygotic twins suggests that genetics may not be the sole responsible factor. Like ANN, these infants also present with minor infections such as otitis media, respiratory tract infection, gastroenteritis, or cellulitis, or the AINI may be diagnosed only by chance after detection of neutropenia. AINI is a self-limited disorder, with a median duration of about 30 months (range, 6 to 60 months), and 95% recover by 4 years of age. Neutropenia, in rare instances, may also be seen in newborn infants born to mothers with autoimmune neutropenia, owing to transplacental passage of her antineutrophil autoantibodies. A review of these disorders can be found elsewhere.[70]

The therapy for immune-mediated neutropenia in neonates is supportive, and a prompt clinical response can usually be obtained with the use of recombinant hematopoietic growth factors such as the granulocyte colony-stimulating factor (G-CSF). Antibiotic prophylaxis has not been shown to be effective. Exchange transfusion has been suggested as a way to lower the antibody titer, but this therapy has not been subjected to adequate testing. Steroid therapy has not been shown to be effective. These disorders are self-limited, but infection must be treated promptly.

ACCELERATING NEUTROPHIL PRODUCTION IN THE FETUS AND NEONATE

In the near-term and term rat, neutrophil production occurs at such a marked pace that significant further increases in neutrophil production might not be possible.[71,72] At 14 days gestation (term = approximately 21 days), no neutrophils whatsoever are observed in the fetal rat liver, marrow, spleen, or blood. The remarkably rapid development of neutrophils just before and after birth result in a total body sum of neutrophils of 1.2×10^6/g at birth and 5×10^6/g by 4 weeks of life.[53] To achieve this, granulocyte progenitors appear to be cycling at nearly maximal capacity.[71,72] Indeed, during the experimental infection of newborn rats, cycling of granulocyte progenitors does not appear to increase beyond that observed in the baseline, noninfected state.

In adult mice, inoculation with *Escherichia coli* results in a rapid, marked acceleration of neutrophil production.[73] This increase is preceded by an increase in G-CSF transcripts within hematopoietic and nonhematopoietic organs (particularly in the lungs). Mice who lack the G-CSF gene (because of homologous recombination knockout experiments) fail to accelerate neutrophil production during bacterial infection and have an extremely high mortality rate from infection.[74] In contrast to adult mice, newborn mice inoculated with *E. coli* fail to develop a marked increase in G-CSF transcripts in hematopoietic or nonhematopoietic organs, fail to accelerate neutrophil production, and have a high mortality rate from infection.[73] Thus the capacity of newborn mice to accelerate neutrophil production during infection appears to be limited at least in two ways: by an already rapid rate of production in the noninfected state and by lack of prompt production of G-CSF after bacterial inoculation.

It is not clear to what extent the observations on neutrophil production during infection made in rodents apply to human neonates.[75] Although certain parallels are likely, it does not appear that neutrophil production in the noninfected human fetus is maximal, and human neonates do appear capable of generating G-CSF during an infectious challenge, although perhaps not as responsively as do adults (Table 143-3). For example, during chorioamnionitis, maternal and fetal blood concentrations of G-CSF increase from their baseline low levels (generally <5 pg/mL) to 2000 to 4000 g/mL.[76] The concordance of maternal and fetal G-CSF blood concentrations during chorioamnionitis has led to the speculation that G-CSF produced in tissues of maternal origin (such as decidual macrophages) crosses from the maternal to the fetal circulation.[76] This hypothesis is supported by the finding that during chorioamnionitis, low concentrations of G-CSF messenger RNA transcripts are found in the fetal blood, but high concentrations are present in the mother's blood.[76] Stallmach and Karolyi[77] observed that during chorioamnionitis, granulocyte production increases in the fetus, in fact, expanding to sites in the liver and spleen that do not normally contain granulocytopoietic activity. Thus granulocytopoiesis in the human fetus is clearly capable of increasing above the baseline, noninfected rate. However, in neonates with sepsis-induced neutropenia, serum and urine G-CSF concentrations are significantly higher than those with low neutrophil counts from other causes. These findings suggest that the G-CSF receptors might already be saturated in neonates with sepsis-induced neutropenia and raise the possibility that recombinant G-CSF (rG-CSF) therapy may not be highly effective in these patients.[78]

If transplacental passage of G-CSF from the mother to the fetus occurs during chorioamnionitis, it is likely that rG-CSF administered before delivery would also cross from the maternal to the fetal circulation. This possibility has been tested in pregnant rat model by Medlock and colleagues[79] and Novales and colleagues.[80] They observed that a single dose (50 μg/kg) of G-CSF given to pregnant rats 1 day before delivery resulted in maternal peak G-CSF serum concentrations of 1200 ng/mL and fetal peak serum concentrations of 1.5 ng/mL. Despite the relatively low apparent transplacental passage, this concentration of G-CSF in the fetal rats constituted a significant increase above their normally undetectable baseline G-CSF concentrations. Moreover, the increase in G-CSF concentrations was sufficient to stimulate fetal neutrophil production, elevate blood neutrophil concentrations, and improve the outcome of pups that were subsequently inoculated with group B streptococci. Calhoun and associates[81] performed a human counterpart study, by administering rG-CSF (one dose of 25 μg/kg) to 11 women about to deliver an extremely preterm neonate. As in the rat model, transplacental passage of a small quantity of G-CSF was detected, and in those infants born 24 to 72 hours after the maternal treatment, neutrophilia of 5 to 7 days' duration was observed. It is not clear, however, whether human fetuses might derive benefit from antenatal rG-CSF treatment in the same manner as was shown in the pregnant rat model.

Several clinical trials have tested the hypothesis that rG-CSF administration to neonates with sepsis will alleviate neutropenia and reduce mortality. Gillan and colleagues[82] reported a dose-dependent biologic effect of rG-CSF in human neonates. They studied 42 neonates who had presumed bacterial infection during their first 3 days of life and were randomized to receive a placebo or 1.0, 5.0, 10.0, or 20.0 μg/kg body weight/day of rG-CSF for 3 consecutive days. A significant, dose-dependent increase in blood neutrophil concentrations was observed, and a dose-dependent increase in the size of the marrow neutrophil reserve was also seen. Neutrophil C3bi expression was significantly increased 24 hours after starting at least 10 μg/kg. The rG-CSF doses were well tolerated in all infants. Since then, the efficacy of rG-CSF in neonatal sepsis has also been examined by Schibler,[83] Bedford Russell,[84] Miura,[85] Barak,[86] and Kocherlakota[87] and their colleagues. In a meta-analysis based on these studies, 73 rG-CSF recipients had a lower mortality than their 82 controls.[88] However, when the nonrandomized studies were excluded, the analysis did not remain statistically adequate. Makhlouf[89] and La Gamma[90] and their co-workers have

similarly reported successful use of rG-CSF to treat neutropenia in neonates delivered to women with pregnancy-induced hypertension. rG-CSF therapy is generally well tolerated in neonates, although reductions in platelet counts have been reported. However, it is unclear whether the thrombocytopenia is caused by rG-CSF administration or the underlying sepsis. With longer-term rG-CSF therapy, greater vigilance is needed in view of reports of leukemic transformation (described in a child with Kostmann syndrome),[91] anti-G-CSF antibodies, and osteopenia.

Recombinant GM-CSF (rGM-CSF) has been given to a limited number of human neonates. Cairo and associates[92] administered either placebo or 5.0 or 10.0 μg/kg/day of rGM-CSF to 20 neonates. Very-low-birth-weight infants (<1500 g) began treatment in their first 72 hours of life and received daily treatments for 7 days. Within 48 hours of beginning the drug, significant dose-dependent increases in circulating neutrophil and monocyte concentrations were observed. Tibial marrow aspirates revealed an increase in neutrophil reserves, and neutrophil C3bi receptor expression was increased within 24 hours of beginning treatment. Bilgin and co-workers,[93] in a prospective, randomized study, administered rGM-CSF to 30 patients for 7 consecutive days.

Twenty-five patients from the rGM-CSF group and 24 from the conventionally treated group had early-onset sepsis, and the remaining 11 patients had late-onset sepsis. The rGM-CSF-treated group showed significantly higher absolute neutrophil counts and a lower mortality rate. In a more recent multicenter randomized trial (the PROGRAMS trial), prophylactic rGM-CSF corrected neutropenia but did not reduce sepsis or improve survival and short-term outcomes in extremely preterm, small-for-gestation neonates.[94]

rGM-CSF has also been evaluated as prophylaxis against nosocomial infections in very-low-birth-weight infants. Carr and colleagues[95] administered 10 μg/kg of rGM-CSF to 75 noninfected newborn infants with less than 32 weeks gestation, initiated within the first 72 hours, for 5 days. Prophylactic GM-CSF therapy abolished neutropenia in treated infants, including those with and without sepsis, during a 4-week period after study entry. Although the rGM-CSF recipients had fewer symptomatic, blood culture–positive septic episodes than controls, the difference did not reach statistical significance. Similar results were obtained in a large, randomized, placebo-controlled trial in 264 very-low-birth-weight neonates weighing less than 1000 g. rGM-CSF was administered prophylactically at a daily dosage of 8 μg/kg for the first 7 days and then every other day for 21 days. The treated infants had higher absolute neutrophil counts, but the incidence of confirmed nosocomial infection did not differ from controls.[96]

In a systematic review of the efficacy of rG-CSF and rGM-CSF in the treatment or prevention of neonatal infections, Carr and colleagues[97] analyzed seven treatment studies of 257 infants with suspected systemic bacterial infection and three prophylaxis studies comprising 359 neonates. The addition of rG-CSF or rGM-CSF to antibiotic therapy in preterm infants with suspected systemic infection did appear to reduce immediate all-cause mortality. However, in a subgroup analysis, the 97 infants in the three treatment studies who had clinically significant neutropenia ($<1.7 \times 10^9$/L) in addition to systemic infection at trial entry showed a significant reduction in mortality by day 14 (relative risk, 0.34 [95% confidence interval (CI) 0.12, 0.92)]; rate difference, −0.18 [95% CI, −0.33, −0.03]; number needed to treat, 6 [95% CI, 3 to 33]). In these prophylaxis studies, however, rGM-CSF did not significantly reduce mortality.

The benefits and risks of recombinant myeloid growth factor therapy for conditions in the fetus and newborn infant are still being defined. Despite evidence of benefit from animal studies and promising clinical trials, the evidence currently available is insufficient to support the routine use of rG-CSF or rGM-CSF in neonatal sepsis.[98] Further studies are needed in neonatal subgroups with a particularly higher risk for sepsis because preliminary evidence suggests that such an approach may be more effective. The newer, longer-acting polyethylene glycol–conjugated or glycosylated forms of G-CSF also hold promise as viable therapeutic alternatives.

144 Developmental Erythropoiesis

Robin Kjerstin Ohls

ERYTHROCYTE KINETICS

Sites and Stages of Fetal Red Blood Cell Production

Extraembryonic Erythropoiesis

Extraembryonic erythropoiesis begins in the fetal yolk sac by 14 days gestation.[1,2] Small nests of nucleated blood cells are present in the mesenchymal and endodermal layers of the yolk sac.[3] These red blood cells, called hematocytoblasts, are the product of primitive megaloblastic erythropoiesis, and they differ from erythrocytes formed later in gestation when definitive normoblastic erythropoiesis occurs. Primitive erythroblasts are nucleated, macrocytic, and 20 to 25 μm in diameter. They are characterized by a mean cell volume (MCV) of more than 180 fL and on histopathologic examination demonstrate a characteristic fine nuclear chromatin pattern and a polychromatophilic cytoplasm containing abundant hemoglobin.[1,3] Red blood cells enter the embryonic circulation at 3 to 4 weeks gestation, coincident with joining of the vitelline and umbilical circulations.[4]

Intraembryonic Erythropoiesis

Definitive normoblastic erythropoiesis of the fetus begins in the liver during the early first trimester.[5] By 6 to 8 weeks gestation, the liver replaces the yolk sac as the primary site of red blood cell production, and by 10 to 12 weeks, extraembryonic erythropoiesis has essentially ceased. Red blood cell production occurs in the liver throughout the remainder of gestation, although production begins to diminish during the second trimester as bone marrow erythropoiesis increases (Figure 144-1). Erythroblasts are first noted in the marrow at 8 to 9 weeks gestation.[5] By the end of the third trimester, almost all erythropoiesis is taking place in the bone marrow, although residual erythropoiesis may continue in the liver, and it may be found in other sites. In rodents, the spleen also is a site of erythropoiesis before the onset of marrow red blood cell production. As with the liver, this site ceases production shortly after birth.[6] It is unclear whether the spleen contributes to erythropoiesis in the human fetus. Although erythroid precursors have been identified as early as 6 to 7 weeks gestation in human splenic tissue,[7] it is not clear whether such cells are actually developing within splenic tissue or whether they are simply part of the circulation.[8]

Ontogeny of Stem Cells

Red blood cell precursors in the yolk sac are extremely primitive cells, and they may either disappear or seed other areas in which erythropoiesis later becomes prominent. The *unicentric theory* proposes that all hematopoietic stem cells originate from the yolk sac and then migrate from one hematopoietic site to another. Moore and Metcalf[9] demonstrated circulating pluripotent stem cells in the peripheral blood just before the development of liver erythropoiesis. These workers suggested that the development of intraembryonic hematopoiesis requires an intact yolk sac, and that migration of stem cells from the yolk sac to hematopoietic tissue is necessary for the development of intraembryonic hematopoiesis. The development of other organ systems through migration of cells (such as neural crest tissue) gives credence to this theory.

The *multicentric theory* suggests that formation of a new clone of hematopoietic stem cells occurs at different sites of hematopoiesis during fetal development. Yolk sac cells are capable of producing granulocytic, megakaryocytic, and erythroid colonies when transplanted into adult irradiated recipients and in conditioned newborn recipients[9,10]; this observation supports the view that fetal stem cells possess the capacity to be pluripotent and that their differentiation is controlled by microenvironmental factors.

Marrow, Liver, and Blood Differential Counts

Table 144-1 presents the differential counts for fetal liver, marrow, and circulating blood according to gestational age.[11-14] The liver of the midtrimester human fetus is the primary organ of erythropoiesis, with myeloid-to-erythroid ratios ranging from 0.07 at 14 to 17 weeks to 0.2 at 21 to 24 weeks gestation.[11] By 24 weeks, the composition of the fetal bone marrow begins to resemble that of adult marrow, differing by the presence of a large number

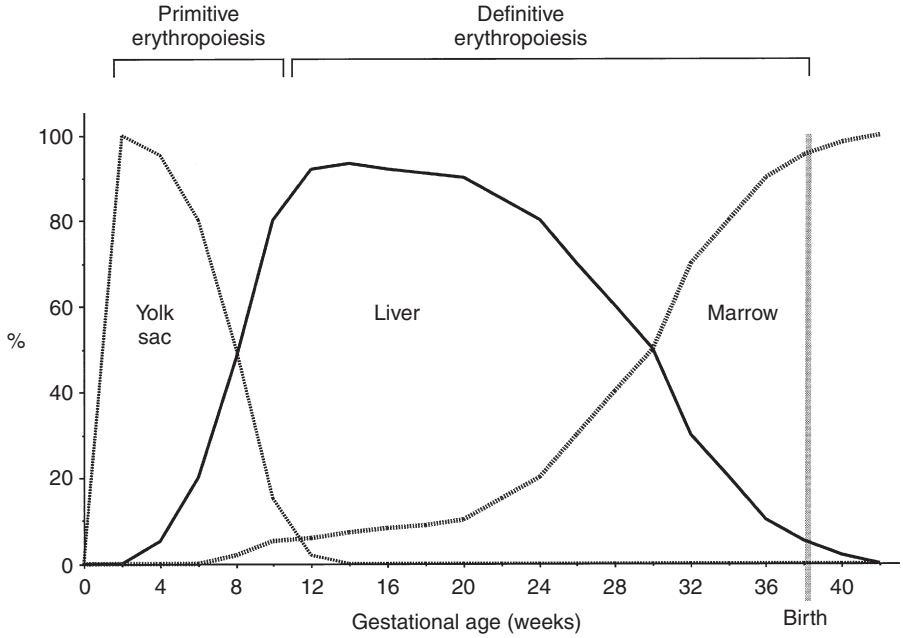

Figure 144-1 Sites and stages of fetal erythropoiesis. Primitive erythropoiesis begins in the yolk sac at 2 to 3 weeks after conception. By 12 weeks gestation, the liver has become the primary erythroid organ. The liver is the primary source of red blood cells from 12 to 24 weeks gestation, and the bone marrow is the primary source of red blood cells after 24 weeks gestation.

of stromal elements, the absence of plasma cells and lymph follicles, and an overall increased cellularity in the fetal marrow. Unlike in adult marrow, large fat cells are not present in fetal bone marrow. Between 18 and 22 weeks gestation, the mitotic index of the fetal bone marrow becomes virtually identical to that of adult bone marrow. The fetal bone marrow myeloid-erythroid ratio starts to exceed the normal adult bone marrow ratio (1.5 ± 0.4) early in midgestation and remains elevated even at the time of birth.

Progenitor Cell Concentrations

Studies of bone marrow cells in tissue culture have identified specific committed red blood cell precursors, termed *erythroid progenitors,*[15-18] on the basis of their characteristic growth in vitro. When bone marrow cells are placed in semisolid media culture systems for 5 to 7 days, an erythropoietin (Epo)-sensitive erythroid progenitor cell, termed a *colony-forming unit–erythroid* (CFU-E), clonally matures into a single cluster containing 30 to 100 normoblasts (Figure 144-2). An erythroid-specific progenitor that is less well differentiated than a CFU-E (and therefore a more primitive cell) is termed a *burst-forming unit–erythroid* (BFU-E). At 12 to 14 days after bone marrow cells are placed in culture, a BFU-E develops into a large, multicentered colony of normoblasts, in which each center contains 200 to 10,000 normoblasts. Finally, the most primitive erythroid progenitor cell identifiable through in vitro culture is termed a *colony-forming unit–granulocyte, erythrocyte, macrophage, megakaryocyte* (CFU-GEMM, or CFU-mix). As with the BFU-E, at 12 to 14 days after marrow cells are placed in culture, this multipotent progenitor develops into a mixed colony of both normoblast clusters and granulocyte-macrophage clusters.

The ability of an organ to produce red blood cells is based on the number of progenitor cells it contains, as well as the growth factors stimulating those cells to proliferate. Determination of erythroid progenitor numbers obtained from cell suspensions of liver, marrow, spleen, and blood of midtrimester human fetuses (Table 144-2) showed twice the number of multipotent progenitors and erythroid progenitors in the fetal liver as in marrow.[8,11,12] Erythroid progenitors from fetal liver also appeared to be more sensitive to Epo (the primary erythroid growth factor) than those from fetal marrow. Progenitor cell concentrations in the spleen were nearly identical to concentrations in the circulation.[8,12] Whether the progenitors isolated from liver and from marrow represent different subpopulations of progenitors (e.g., populations that express different erythroid growth factor receptors, different receptor numbers, different receptor affinity, or different cycling rates) remains to be determined.

Regulation of Erythropoiesis

Erythropoietic regulation in the human fetus differs markedly from that in the adult. In the adult, erythropoietic regulation primarily involves maintaining the red blood cell mass. By contrast, constant and dramatic changes characterize erythropoiesis in the embryo and fetus. The astonishing rate of somatic growth and the resultant need for continual increase in the fetal red blood cell mass necessitate an extraordinary erythropoietic effort. Moreover, as a consequence of its relatively low oxygen tensions and high metabolic rates, fetal tissue requires a system of oxygen delivery that differs significantly from the adult system.

Erythroid Growth Factors

The production of erythrocytes, from pluripotent stem cell to mature red blood cell, is governed by various growth factors. These erythropoietic growth factors are produced by accessory cells such as liver macrophages and marrow stromal cells, and they stimulate maturation, growth, and differentiation at various stages of red blood cell production. The progenitors involved in red blood cell production and the factors that stimulate their cellular maturation are depicted in Figure 144-2. Although these growth factors all facilitate production of red blood cells, none plays a more important regulatory role than that of Epo. Epo is a 30- to 39-kDa glycoprotein that binds to specific receptors on the surface of erythroid precursors and

stimulates their differentiation and clonal maturation into mature erythrocytes.[19,20] The gene for Epo is located on chromosomal region 7q21-22.[21] In the human fetus, Epo is produced principally by cells of monocyte-macrophage origin residing in the liver. Postnatally, Epo is produced almost exclusively by peritubular cells of the kidney.

Other growth factors besides Epo play a role in the differentiation and clonal expansion of erythroid progenitors. These include granulocyte-macrophage colony-stimulating factor (GM-CSF)[15]; stem cell factor (SCF) (also known as c-Kit ligand)[22]; and the interleukins IL-3, IL-6, and IL-9.[23-25] Thrombopoietin, a growth factor involved in platelet production whose receptor is similar in structure to the Epo receptor, also stimulates erythroid colony formation.[26] IL-3 and GM-CSF were the first growth factors noted to have erythroid-stimulating properties, initially described as "burst-promoting activity." In combination with Epo, these factors synergistically stimulate differentiation and proliferation of BFUs-E and CFUs-GEMM.

SCF is a multipotent growth factor that, in combination with other factors, supports clonal maturation of hematopoietic progenitors. Murine studies indicate that SCF may be expressed during embryogenesis, thereby affecting embryonic and fetal erythropoiesis. In vitro studies show that SCF alone stimulates clonal maturation of fetal (but not adult) multipotent progenitors. Erythroid progenitors isolated from term cord blood are more responsive to SCF, alone and in synergism with GM-CSF and IL-3, than adult marrow progenitors.[22]

Term circulating erythroid progenitors also are more sensitive to IL-6 and IL-9 than are adult progenitors.[24] IL-6 is a multifunctional, 22- to 26-kDa glycoprotein cytokine involved in B cell stimulation and immunoglobulin production, acute phase reactions, and induction of hematopoietic progenitors from a noncycling (G_0) phase into an active cycling (S) phase. IL-6 alone supports clonogenic maturation of newborn cord blood BFUs-E and CFUs-GEMM and induces progenitor cell cycling.[24] IL-9 also is a multipotent cytokine and is similar to IL-6 in its ability to stimulate primitive erythroid progenitors and multipotent progenitors isolated from cord blood.[25] Insulin-like growth factor-I (IGF-I) has been shown to cause clonal expansion of erythroid progenitors isolated from adult marrow,[27,28] but its effects on fetal progenitors are still being determined.

Unique Features of Fetal Progenitors

Fetal erythroid progenitors respond in a slightly different fashion from that observed for adult erythroid progenitors. In addition to the features noted earlier, fetal progenitors appear to be more sensitive than adult erythroid progenitors to Epo.[29] Specifically, BFUs-E of fetal origin develop more rapidly into erythroid colonies, and the colonies generally contain significantly more normoblasts. In addition, BFUs-E from adult bone marrow require a combination of Epo plus another factor, such as IL-3 or GM-CSF, to mature clonally; however, many fetal BFUs-E mature in the presence of Epo alone.[30] Studies have shown that fetal clones produce GM-CSF and IL-3, which may explain their unique capability for growth factor independence and autostimulation.[31]

Control of Erythropoietin Production

Erythropoiesis in utero is controlled by erythroid growth factors produced by the fetus, not the mother. Epo is the primary regulator of erythropoiesis in adults and appears to be the controlling factor for fetal erythropoiesis, especially during late gestation. Epo does not cross the placenta in humans,[32,33] monkeys, or sheep,[34] although it has been reported to do so in mice.[35] In the mouse, suppression of maternal erythropoiesis by hypertransfusion does not suppress fetal erythropoiesis.[36] In humans, stimulation of maternal Epo production does not result in stimulation of fetal red cell production.[37]

The exact mechanism regulating the expression of Epo is unknown, but it is thought to be controlled by an oxygen-sensing mechanism in the liver and kidney.[38] Both hypoxia and anemia stimulate erythropoiesis by stimulating messenger RNA

(mRNA) transcription and Epo protein production.[39] Promoter and enhancer elements within the Epo gene are responsive to hypoxia, as well as to cobalt exposure in vitro.[40] In animal models, the liver-sensing mechanism has a decreased sensitivity to hypoxia, producing one-tenth the amount of Epo in response to comparable stimuli in the kidney.[41,42] The liver also appears to require more prolonged hypoxia to achieve an Epo response.[43,44] Other hormones or factors have been shown to enhance Epo production or its effects, either in vivo or in vitro.[45,46] These factors include testosterone,[47] estrogen,[48] thyroid hormone,[49] prostaglandins,[50] vitamin E,[51] and lipoproteins.[52]

It is not known what factors regulate the switch of Epo production from the liver to the kidney. Renal production of Epo is not necessary for normal fetal erythropoiesis.[53] The lack of renal contribution to Epo production is illustrated by the normal serum Epo concentrations and normal hematocrits in anephric fetuses.[54] In the sheep, Epo production in both the liver and the kidney is highest at 60 days gestation (term being 140 days in this species).[55] Epo production in the fetal liver decreases by 90 days gestation; however, increased renal production of Epo continues until 130 days gestation, when production falls to levels seen in adult sheep.

Studies in human fetal and neonatal kidney obtained from postmortem specimens also report measurable quantities of Epo mRNA,[56] and quantitative mRNA studies in 10 to 24 weeks gestation human fetuses reveal that the fetal kidney produces approximately 5% of the amount of Epo mRNA that the fetal liver produces during the second trimester.[57] Thus it appears that regulation of Epo gene transcription differs between liver and kidney in utero.

Mechanisms by which gene expression can be differentially regulated are through methylation of promoter and enhancer regions of a gene, and through deacetylation of histones.[58-62] Increased methylation generally results in decreased gene expression, while histone deacetylation causes relaxation of DNA structures and allows gene expression to occur.These two mechanisms may also be involved in developmental Epo gene expression, in that methylation of the enhancer region (leading to decreased expression) of the Epo gene in developing human kidney during the second trimester was much greater than in the liver.[63]

Epo levels have been measured in cord blood during the third trimester, and these levels gradually increase throughout later development.[64-66] From Epo measurements made in cord blood from infants of laboring and nonlaboring mothers[67] and from infants undergoing labor stress,[68-72] it seems that individual cord Epo levels primarily reflect hypoxic stress during labor and delivery. Serum Epo concentrations at birth normally range from 5 to 100 mU/mL. For comparison, serum Epo concentrations in anemic, nonuremic adults may be as high as 300 to 400 mU/mL.[73]

Red Blood Cell Indices in the Fetus and Neonate

Red Blood Cell Concentrations and Hematocrit

Red blood cell indices change during gestation and continue to change through the first year of life. Circulating red blood cell concentrations gradually increase during the second trimester, from 2.85 ± 0.36 × 10^6/μL at 18 to 21 weeks to 3.82 ± 0.64 × 10^6/μL at 30 weeks[12] (Table 144-3). At term, circulating red blood cell concentrations range from 5.0 to 5.5 × 10^6/μL.[74] In parallel with increasing red blood cell concentrations, hematocrit values increase from 30 to 40% during the second trimester and continue to increase to term values over the latter part of the third trimester. Term hematocrit values range from 50% to 63%, with some variability noted because of delayed clamping of the umbilical cord.[75] Values also are dependent on the sampling site. Capillary hemoglobin concentrations measure as much as 3.5 g/dL higher than venous samples.[76]

Hemoglobin

The hemoglobin concentration gradually rises during gestation.[77] At 10 weeks gestation, the average hemoglobin concentration is approximately 9 g/dL.[78] By 22 to 24 weeks, fetal hemoglobin values reach 11 to 12 g/dL, and by 30 weeks, the hemoglobin concentrations are 13 to 14 g/dL.[12] Premature male infants reach term cord hemoglobin values earlier than premature female infants,[79] possibly because of the erythropoietic effects of testosterone.[47]

Hemoglobin concentrations are relatively constant over the last 6 to 8 weeks gestation, and at term the average hemoglobin concentration is approximately 16 to 17 g/dL.[80-82] At birth, a 1- to 2-g/dL rise in hemoglobin may result from transfusion of placental blood at delivery.[75,83] An increase in hemoglobin by 2 hours of postnatal life occurs in most infants, resulting from a decrease in plasma volume. By 8 to 12 hours of life, the hemoglobin concentration achieves a relatively constant level. Red blood cell production decreases significantly at birth, so by the end of the first postnatal week, hemoglobin concentrations gradually decline.[75] The decrease in red cell production after birth is predominantly the result of the increased availability of oxygen in the extrauterine environment, which greatly reduces Epo production and endogenous erythropoiesis. The continued fall in hemoglobin concentration over the next several weeks results from (1) decreased red blood cell production, (2) a shortened red blood cell life span of the fetal erythrocyte, and (3) plasma dilution and an increase in blood volume related to growth. The nadir of hemoglobin concentration in full-term infants is seen at approximately 8 weeks, with an average hemoglobin concentration of 11.2 g/dL.[74,78] This value gradually rises, so that by 6 months, the average term infant has a hemoglobin concentration of 12.1 g/dL. Altitude may have a modest effect on the postnatal changes in hemoglobin concentration. Infants living at an elevation of 1600 m had higher hemoglobin concentrations (by 0.4 g/dL) by 6 months of age than infants living at sea level.[84,85]

The average decline in hemoglobin concentration in preterm infants weighing less than 1500 g is remarkably different from that in term infants. This is partly because of phlebotomy losses that invariably occur in preterm infants, as well as the effects of transfusions on endogenous erythropoiesis. Such infants reach a nadir of hemoglobin, which averages 8 g/dL at 4 to 8 weeks of age.[86] Tables 144-4 and 144-5 demonstrate relationships among

birth weight, chronologic age, and red blood cell indices in term and preterm infants.[74,78,85-89]

These data do not always apply to infants born small for gestational age, in whom placental insufficiency and secondary polycythemia are common.[83,90] Infants of diabetic mothers, infants of smoking mothers, and infants born at higher altitudes also tend to have higher hemoglobin concentrations at birth.[84,91,92] In growth-restricted infants born to hypertensive mothers, the blood supply to the placenta and the capacity to deliver oxygen to the fetus both are diminished. Accelerated erythropoiesis is thought to be part of a compensating mechanism designed to raise oxygen-carrying capacity to maintain an adequate supply to the fetus. In infants of diabetic mothers, increased metabolic demands of the fetus (resulting from increased glucose availability) may account for the higher fetal oxygen needs and the compensatory increase in hemoglobin concentration by the fetus. The increased red blood cell mass in infants of diabetic mothers is not thought to result from higher maternal levels of hemoglobin A_{1c} (a high-affinity hemoglobin capable of decreasing the oxygen transferred to the fetus). In smoking mothers, the increase in fetal carbon monoxide and the subsequent decrease in oxygen available from hemoglobin constitute the likely cause of the compensatory increase in hemoglobin levels in the fetus.

Mean Cell Volume

The size of the red blood cell gradually decreases during development. The MCV is more than 180 fL in the embryo, falls to 130 fL by midgestation, and decreases to 115 fL by the end of pregnancy. By 1 year of age, the MCV reaches an average of 82 fL.[88] Similar to cells of other organs in the infant born prematurely, the MCV of preterm infants declines quickly after birth, and the postnatal changes in MCV appear to be related to chronologic age rather than postconceptual age.[87] The mean corpuscular hemoglobin concentrations remain relatively constant, and the value for mean corpuscular hemoglobin decreases slightly.[92]

Blood Volume

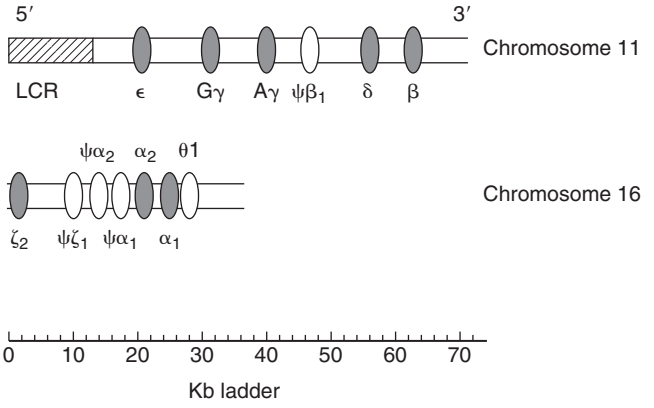
The placenta and umbilical cord contain 75 to 125 mL of blood at term, or approximately one fourth to one third of the fetal blood volume.[74] Umbilical arteries constrict shortly after birth, but the umbilical vein remains dilated, and blood flows in the direction of gravity. Infants held below the level of the placenta can receive half of the placental blood volume (30 to 50 mL) in 1 minute. Conversely, infants held above the placenta can lose 20 to 30 mL of blood back into the placenta in 1 minute.[93] The blood volume of infants with early cord clamping averages 72 mL/kg, and the volume of infants with delayed cord clamping averages 93 mL/kg. Preterm infants have slightly larger blood volumes (89 to 105 mL/kg), owing to an increased plasma volume. By the age of 1 month, blood volumes in term infants average 73 to 77 mL/kg.

Fetomaternal Red Blood Cell Transfer

Maternal and fetal circulating cells may, at various times, cross the placental barrier. Fetal contamination of the maternal circulation can occur before delivery, as evidenced by studies of maternal blood group immunization. Approximately 50% to 75%

of pregnancies are associated with some degree of fetomaternal transfer of blood. This event is uncommon in the first trimester (3%). Volumes of fetal transplacental transfer are relatively small, usually on the order of 0.01 to 0.1 mL, but on occasion they may be much greater. Approximately 1 pregnancy in 400 is associated with fetal transplacental bleeding of 30 mL or greater, and 1 pregnancy in 2000 is associated with a potential fetal transplacental hemorrhage of 100 mL or more.[94] The overall risk for occurrence of Rh immunization in an Rh-incompatible pregnancy is 16% if the fetus is Rh-positive and ABO-compatible with its mother. This risk is 1.5% if the fetus is Rh-positive and ABO-incompatible. Fetal transfer of cells to the mother occurs during abortions as well (an approximately 2% incidence of such transfer with spontaneous abortion and a 4%+ to 5% rate if induced).[95] Because fetal hemoglobin is resistant to acid elution, cells containing fetal hemoglobin can be distinguished from cells containing hemoglobin A. The Kleihauer-Betke stain of peripheral maternal blood uses this characteristic of fetal hemoglobin to detect fetal cells in the maternal circulation,[96] although results with blood smears from mothers with diseases that result in increased fetal hemoglobin synthesis (such as maternal sickle cell disease, maternal thalassemia, and maternal hereditary persistence of fetal hemoglobin) are not reliable. Diagnosis of fetomaternal hemorrhage also may be missed when both mother and infant are ABO-incompatible. In such instances, the fetal cells are rapidly cleared from the maternal circulation by maternal anti-A or anti-B antibodies.

ERYTHROCYTE BIOCHEMISTRY



Hemoglobin Synthesis

During fetal erythropoiesis, an orderly evolution of the production of different hemoglobins occurs. Eight globin genes direct the synthesis of six different polypeptide chains, designated α, β, γ, δ, ε, and ζ. These globin chains combine in the developing erythroblast to form seven different hemoglobin tetramers: hemoglobin Gower 1 (ζ_2-ε_2), hemoglobin Gower 2 (α_2-ε_2), hemoglobin Portland (ζ_2-γ_2), fetal hemoglobin (α_2-γ_2), and two types of adult hemoglobin (α_2-β_2), known as hemoglobin A_1, and α_2-δ_2, known as hemoglobin A_2.

Globin Genes

The globin genes are organized into two clusters (Figure 144-3). The α-like genes are located along a 20-kB distal segment of the short arm of chromosome 16. The cluster contains three functional genes (α_1, α_2, and ζ_2), three pseudogenes (evolutionary remnants of genes that are not expressed because of inactivating mutations that prevent production of a functional globin protein), and one gene of undetermined function (a globin-like gene without inactivating mutations). The β-like gene cluster is located along a 60-kB segment of the short arm of chromosome 11, and it contains five functional genes—β, δ, $^{A}\gamma$, $^{G}\gamma$, and ε—and one pseudogene. Within each complex, the genes are all in the same 5′-3′ orientation, and they are arranged in the order in which they are expressed during development.[97]

The α genes are duplicated in humans. Each α gene is approximately 4 kB long, interrupted by two small nonhomologous regions. Within each gene are intervening sequences (introns) that do not code for any protein structure, although the entire gene is transcribed into mRNA. The exons and first introns of the two α-globin genes have identical sequences, but the second intron of α_1 is nine bases longer and differs by three bases from that of the α_2 gene. Despite the high degree of similarity or *homology* between these two genes, the sequences diverge in the 3′ untranslated regions, 13 bases beyond the TAA stop codon. Because of these sequence differences, the relative output of the two genes can be measured. α_2 mRNA is produced two to three times more abundantly than α_1 in fetal liver and marrow and in fetal and adult erythrocytes.[97]

Embryonic:	Hemoglobin Gower 1	$\zeta_2\varepsilon_2$
	Hemoglobin Gower 2	$\alpha_2\varepsilon_2$
	Hemoglobin Portland	$\zeta_2\gamma_2$
Fetal:	Hemoglobin F	$\alpha_2\gamma_2$
Adult:	Hemoglobin A	$\alpha_2\beta_2$
	Hemoglobin A_2	$\alpha_2\delta_2$

Figure 144-3 Organization of the globin genes. The *bottom line* reflects the scale in kilobases. Transcription of mRNA takes place from the 5′ to the 3′ end, and for both chromosomes the genes are arranged in order of their developmental activation. The *upper segment* represents the beta-like globin genes on the short arm of chromosome 11, and the *lower segment,* the alpha-like genes on the distal short arm of chromosome 16. Regions of the gene that code for primary globin proteins are shown as *shaded ovals,* and regions that code for pseudogenes (ψ-non-expressed remnants possessing a number of inactivating mutations that prevent transcription and translation into functional globin protein) are shown as *open ovals.* θ1 is a globin–like gene without inactivating mutations. The locus control region *(LCR)* is shown as a *hatched segment.* The composition of embryonic, fetal, and adult hemoglobins also is provided.

The ζ gene appears to be critical to normal fetal development. In a murine model, both α and ζ gene expression can be measured from the onset of erythropoiesis in the yolk sac.[98] In addition, expression of both genes occurs concomitantly within the same cells. Expression of ζ gene occurs predominantly through the first 6 to 8 weeks of gestation, although minute quantities of ζ-globin can be measured in fetal and neonatal red cells.[99]

Like the α_1 and α_2 genes, the $^{G}\gamma$ and $^{A}\gamma$ genes appear to be virtually identical over a span of 1.5 kb, suggesting a mechanism for gene matching during evolution. Amino acid sequencing of normal cord blood has shown that either glycine ($^{G}\gamma$) or alanine ($^{A}\gamma$) is present at the 136 position in the γ-chain.[100] Short-chain organic acids, such as butyrate and acetate, increase γ gene promoter activity. This activity can be enhanced even further by incorporation of sections of the β gene locus control region.[101,102]

The β-globin gene cluster occupies a region of approximately 17 kb on the short arm of chromosome 11.[103] Each of its constituent genes, their flanking regions, and large stretches of the regions between them have been sequenced. Studies suggest that the transcription factor NF-E1 (nuclear factor–erythroid 1) regulates increased β-globin gene expression during erythroid maturation. Deletion of the NF-E1 binding site in the upstream

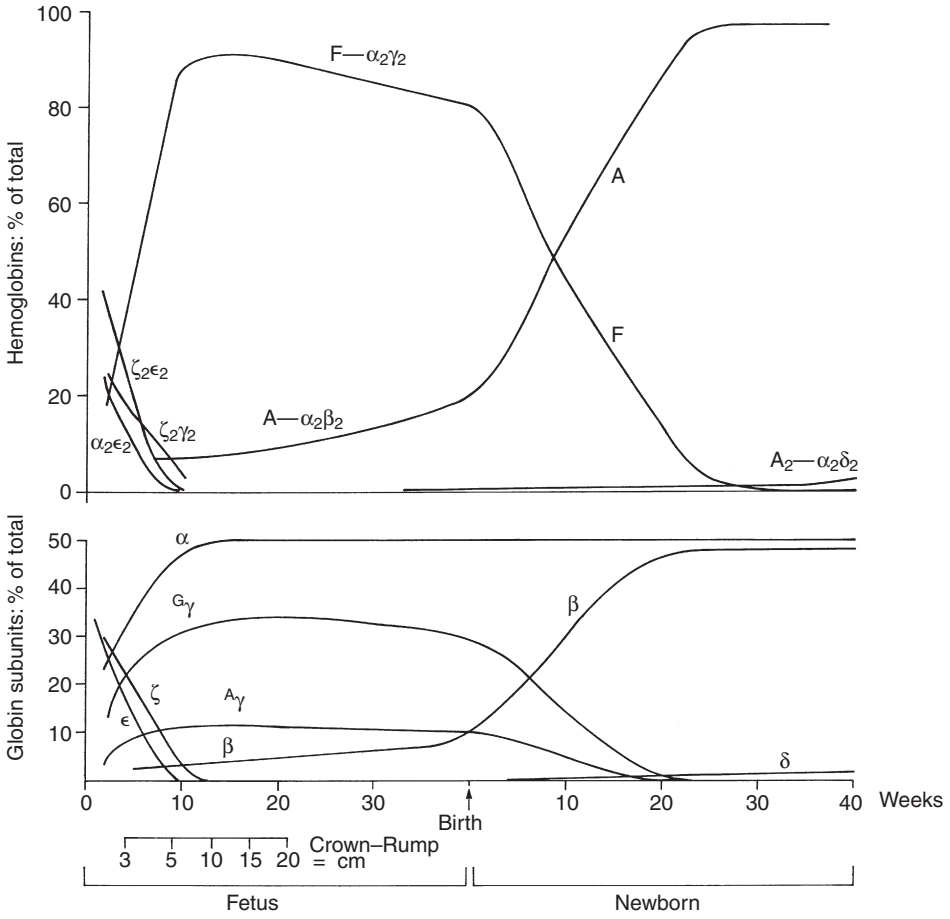


Figure 144-4 Changes in hemoglobin tetramers *(top)* and in globin subunits *(bottom)* during human development from embryo to early infancy. *(From Bunn HF, Forget BG:* Hemoglobin: Molecular, Genetic and Clinical Aspects, *Philadelphia, 1986, WB Saunders, p 68.)*

segment of the β-globin promoter blocks induction of transcription in murine leukemia cells.[104]

δ-Globin gene expression occurs early at the erythroid progenitor stage. By the reticulocyte stage, no δ-globin mRNA synthesis can be detected. The δ-globin gene promoter functions at a much lower level than the β-globin gene promoter, resulting in significantly lower levels of δ-globin mRNA production. Evidence suggests the presence of a globin promoter–specific silencer element located upstream of the δ-globin gene.[105] Moreover, δ-globin mRNA is less stable than β-globin mRNA, which probably accounts for the early cessation of δ-globin synthesis and the low levels of hemoglobin A_2 compared with hemoglobin A_1.

The ε gene is located 5′ of the other β-like genes, and it is expressed during embryonic development. The ε gene is similar in sequence to the γ genes. A silencing element of the promoter region may be responsible for inactivating gene expression after the embryonic stage.[106] The only known mutation that results in persistent expression of this globin gene occurs in trisomy 13, in which the switch from ε- to γ-globin production is delayed.[107]

Globin Chain Synthesis

It has been possible to analyze the patterns of globin chain production at early ages of embryonic development during the transition from yolk sac (primitive) to hepatic (definitive) erythropoiesis. Still to be elucidated is why primitive erythroid progenitors programmed to produce one type of hemoglobin, such as Gower 1, give way to definitive progenitors programmed to produce a different type of hemoglobin, such as fetal hemoglobin. Quantification of globin gene synthesis reflects production by numerous red blood cells, and production of a specific hemoglobin usually is reported as a percentage of the total hemoglobin measured. Studies evaluating hemoglobin production by erythroid colonies in culture, however, show that individual cells in a colony produce predominantly one type of hemoglobin.[108]

During weeks 4 and 5, the main globin chains synthesized are ζ, δ, and ε (Figure 144-4). During weeks 6 and 7, α-, δ-, ε-, $^{G}\gamma$-, and $^{A}\gamma$-chains are produced in the remaining primitive erythroblasts, and α-, ε-, $^{G}\gamma$-, and $^{A}\gamma$-chains are produced in definitive erythrocytes. By week 7 to 8, εε- and ζ-chain synthesis is no longer detectable, and the main globin chains produced are α, $^{G}\gamma$, and $^{A}\gamma$. Production of β-chain is just barely detectable at this time and gradually increases so that by 10 weeks, it makes up 10% of total non–α-chain production.[109] As soon as β-chain production occurs, genetic disorders associated with β-chain synthetic or structural abnormalities may be detected in utero, a finding suggesting an asynchronous transition from ζ- to α- as compared with εε- to γ-chain production, with the ζ-to-α switch occurring slightly earlier.[110]

From week 10 to approximately week 33 of gestation, the main globin chains synthesized are α, $^{G}\gamma$, $^{A}\gamma$, and β. Assessment of the output of the two linked α-globin genes by mRNA analysis suggests that they are expressed in the ratio of α_2 to α_1, ranging from 1.5:1 to 3.0:1 throughout fetal life. This ratio does not appear to change during development and is the same as that observed in normal adults. The relative rates of $^{G}\gamma$-chain and $^{A}\gamma$-chain production also are constant throughout fetal life at a $^{G}\gamma/^{G}\gamma$ ratio of approximately 3:1.[100] It is not known whether these pairs of genes are initially activated at this ratio; however, this production ratio is reached early in development.

Somewhere between 32 and 36 weeks gestation, the relative rate of β-chain synthesis increases and that of γ-chain production declines, so at birth, β-chain synthesis makes up approximately 50% of non–α-chain synthesis. It generally is held that the transition from fetal to adult erythropoiesis starts at 30 to 36 weeks after conception, but the rate of the transition has been controversial.[109] A gradual transition from fetal to adult hemoglobin synthesis occurs, starting in the first trimester.[110,111] Considerable variation among infants is usual, however, because many infants show prolonged dependence on fetal hemoglobin. After birth, the level of γ-chain production steadily declines and that of β-chain production increases, so by the end of the first year, γ-chain synthesis reaches the low level characteristic of adult life. The normal range of postnatal fetal hemoglobin production is shown in Figure 144-5. Over the first few months of life, the $^{G}\gamma/^{A}\gamma$ ratio changes from 3:1 to 2:3, although this ratio is variable in adults.[112-114]

δ-Chain production has been observed as early as 32 weeks. Activation of δ gene lags behind that of β gene, so the adult β/δ synthesis ratio is not attained until 4 to 6 months after birth.

Hemoglobin Production

Developmental changes in the production of the various hemoglobins are depicted in Figure 144-4. Before the onset of other chain formation, unpaired globin chains may form tetramers, resulting in the presence of ε4.[115] Almost immediately thereafter, α- and ζ-chain production begins, and hemoglobins Gower 1 (ζ_2-ε_2), Gower 2 (α_2-ε_2), and Portland (ζ_2-γ_2) are formed.[116] By 5 to 6 weeks of gestation, hemoglobins Gower 1 and Gower 2 constitute 42% and 24% of the total hemoglobin, respectively, with fetal hemoglobin (α_2-γ_2) making up the remainder. By 14 to 16 weeks, hemoglobin F constitutes 50% of the total hemoglobin, and by 20 weeks, it forms more than 90% of the total.[117,118] Small quantities of hemoglobin A (α_2-β_2) are found beginning at 6 to 8 weeks of gestation. The increase in β-chain production occurring between 12 and 20 weeks gestation accounts for the sudden rise in hemoglobin A found at the end of the first trimester of pregnancy. Tetramers of γ chains (γ4, or hemoglobin Barts) and β-chains (β4, or hemoglobin H) can be found in conditions in which α-chain synthesis is impaired or absent, such as the α-thalassemia syndromes.

Fetal hemoglobin is easily distinguished immunologically and biochemically from adult hemoglobin. The most significant physiologic characteristic of fetal hemoglobin is the decreased interaction with 2,3-diphosphoglycerate (2,3-DPG). 2,3-DPG binds to deoxyhemoglobin in a cavity between the β-chains and stabilizes the deoxy form of hemoglobin, resulting in a reduced hemoglobin oxygen affinity. 2,3-DPG binds less effectively to the γ-globin chains, because of the differing amino acid sequence in the non–α-chain. Consequently, 2,3-DPG does not reduce the oxygen affinity of hemoglobin F as much as that of hemoglobin A.

Other differences in physical properties exist between fetal and adult hemoglobin. Hemoglobin F is more soluble in strong phosphate buffers than hemoglobin A.[96] Hemoglobin F is oxidized to methemoglobin more easily than hemoglobin A, and it has a considerably greater affinity for oxygen than adult hemoglobin as a result of differences in binding to 2,3-DPG. Fetal hemoglobin is resistant to acid elution, which allows differentiation of cells containing fetal hemoglobin from cells containing hemoglobin A.[96]

$^{G}\gamma$-Chains represent 70% to 80% of the total γ-chains in the blood of the fetus and newborn. This fraction falls to approximately 40% by the age of 5 months. This unique difference in $^{G}\gamma$-chain production found in the fetus helps to distinguish fetal hematopoiesis from that found in later life. Under stress, the older infant and adult revert to this intrauterine form of fetal hemoglobin structure. This reversion often occurs in leukemic states in children and adults, and in other conditions as well.[119,120] The delay in the switch of fetal hemoglobin to hemoglobin A has been noted in conditions of maternal hypoxia,[121] in infants small for gestational age,[122] and in infants of diabetic mothers.[123,124] Elevated levels of fetal hemoglobin may have protective effects in some disease states: One study suggests that a high fetal hemoglobin level in sickle cell patients may be a predictor of increased adult life expectancy.[125]

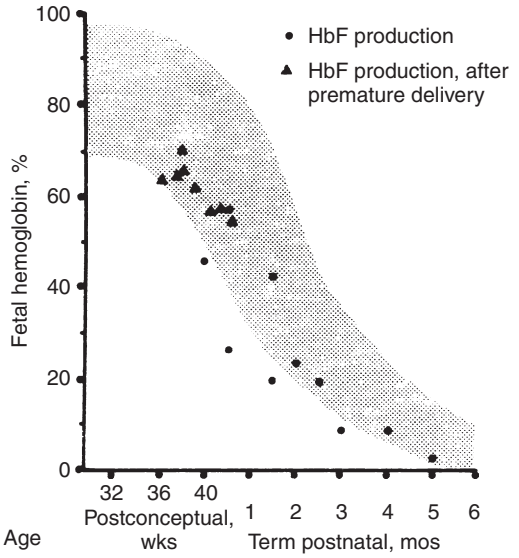

Figure 144-5 Postnatal changes in percentage fetal hemoglobin (Hb F) *(shaded area).*[60-64] *Triangles* represent postnatal production by reticulocytes in premature infants, and *dots* represent cord and postnatal reticulocyte production in term infants. Percentage Hb F present reflects Hb F production over the previous weeks, whereas rate of Hb F production is a result of the current proportion of Hb F produced by reticulocytes present and is thus lower as the Hb F–to–Hb A switch progresses. *(From Brown MS: Fetal and neonatal erythropoiesis. In Stockman JA, Pochedly C, editors:* Developmental and Neonatal Hematology, *New York, 1988, Raven Press, p 258.)*

The postnatal decline of fetal hemoglobin production and of the intercellular distribution of fetal and adult hemoglobins has been extensively examined over the first few months of life. Immediately after birth, a brief rise in hemoglobin F occurs, followed by a steady decline (see Figure 144-5). Studies of the intercellular distribution of hemoglobin F, using the relatively insensitive acid elution technique, have shown that over the first few months of life the distribution of hemoglobin F is quite heterogeneous. At 3 months, the distribution of hemoglobin F becomes bimodal, with populations of cells that contain acid-resistant hemoglobin F and populations of adult "ghost" cells. These observations suggest that fetal hemoglobin-containing cells are replaced by a population of cells containing adult hemoglobin during the early postnatal period.

Profound changes occur in the rates of red blood cell production immediately before birth and during the first few months after birth. On a body weight basis, red blood cell production during the latter months of gestation is significantly greater than that in adult life. Immediately after birth, erythropoiesis is considerably reduced, presumably as an adaptation to the extrauterine environment, and red blood cell production occurs at a low level for the first few weeks of life. It is clear from globin chain synthesis studies that a steady and linear decline in γ-chain synthesis occurs during the period of reduced neonatal erythropoiesis. Newly synthesized red blood cells appearing in the circulation when erythropoiesis resumes contain predominantly adult hemoglobin. These observations may explain the short plateau in the proportion of fetal hemoglobin (but not absolute levels) after

birth and the appearance of predominantly adult hemoglobin–containing cells during the second and third months of life. These findings, together with the results of analyses of the intercellular distribution of fetal and adult hemoglobin by sensitive immunologic methods, suggest, although they do not prove, that the transition from fetal to adult hemoglobin production occurs in the same erythrocyte population. This conclusion also is consistent with the patterns of fetal and β-chain production in red cell colonies grown from neonatal blood.[126]

Studies show that the type of globin chains produced at different stages of development are not closely related to the site of erythropoiesis. It appears that ζ- and ε-chains are synthesized in both primitive and definitive cell lines. Moreover, the switch from γ- to β-chain production occurs synchronously throughout the liver and bone marrow during the later stages of fetal development. The transition from γ- to β-chain synthesis is most closely related to postconceptional age and not chronologic age.[119] Thus premature infants continue to synthesize relatively large quantities of γ-chains (and fetal hemoglobin) until 40 weeks gestation.

Erythrocyte Metabolism

The mature red blood cell differs from other cells in the body in that it has no nucleus; it consequently lacks the ability to engage in de novo protein synthesis. It has no mitochondria or ribosomes, no cellular machinery for nucleic acid or deoxyribonucleic acid synthesis or for the Krebs cycle of intermediary metabolism, and no electron transport system for oxidative phosphorylation. Thus cellular metabolism is dependent on a limited supply of preexisting enzymes. These enzymes, coenzymes, and the substrates of glucose metabolism interact with hemoglobin and the red blood cell membrane to perform all the primary functions of the red blood cell, the most important being oxygen transport.

Important functions of red blood cell metabolism include maintaining adequate amounts of energy in the form of adenosine triphosphate (ATP), producing reducing substances to act as antioxidants, and maintaining appropriate amounts of red blood cell 2,3-DPG to assist in the modulation of hemoglobin's oxygen affinity. Energy metabolism is largely a function of the Embden-Meyerhof pathway. This pathway also regulates the quantity of red blood cell 2,3-DPG within the cell. The pentose phosphate pathway has, among other functions, a vital role in the production of reducing substances such as reduced nicotinamide adenine dinucleotide phosphate (NADPH). Box 144-1 lists the various metabolic characteristics of neonatal erythrocytes. A few of the variations in these cells from adult cells are clinically significant in that they affect the life span of the neonatal cell.

Glycolysis

Red blood cells need a constant supply of carbohydrate to maintain adequate levels of ATP. Although glucose is the preferred carbohydrate, the red blood cell metabolizes fructose or mannose almost as readily. Galactose is metabolized more slowly. Intracellular glucose concentrations equilibrate immediately with changes in plasma glucose concentrations. Glucose enters the human erythrocyte by facilitated transfer, and it is either converted to glucose-6-phosphate or reduced to its polyol derivative, sorbitol, which is then converted to fructose[127] (Figure 144-6). Once formed, glucose-6-phosphate is metabolized by one of three pathways. The *Embden-Meyerhof pathway* converts glucose-6-phosphate to lactate or pyruvate and in the process generates ATP. Metabolism by way of the *pentose phosphate pathway* produces reduced intermediates and a phosphorylated pentose sugar (ribulose-5-phosphate). This sugar ultimately returns to the Embden-Meyerhof pathway. Finally, *glucose-6-phosphate* may be converted to glucose-1-phosphate and then to glycogen, although less than 1% of glucose is metabolized to glycogen within the red blood cell.[128]

BOX 144-1

Metabolic Characteristics of Erythrocytes in the Newborn

Carbohydrate Metabolism
- Glucose consumption increased
- Galactose more completely utilized as substrate both under normal circumstances and for methemoglobin reduction*
- Decreased activity of sorbitol pathway*
- Decreased triokinase activity*

Glycolytic Enzymes
- Increased activity of hexokinase, phosphoglucose isomerase,* aldolase, glyceraldehyde-3-phosphate dehydrogenase,* phosphoglycerate kinase,* phosphoglycerate mutase, enolase,* pyruvate kinase, lactate dehydrogenase, glucose-6-phosphate dehydrogenase, 6 phosphogluconic dehydrogenase, galactokinase, and galactose 1-phosphate uridyltransferase
- Decreased activity of phosphofructokinase*
- Distribution of hexokinase isoenzymes differs from that of adults*

Nonglycolytic Enzymes
- Increased activity of glutamic oxaloacetic transaminase and glutathione reductase
- Decreased activity of NADP-dependent methemoglobin reductase,* catalase,* glutathione peroxidase, carbonic anhydrase,* adenylate kinase,* and glutathione synthetase
- Presence of α-glycerol-3-phosphate dehydrogenase*

Adenosine Triphosphate (ATP) and Phosphate Metabolism
- Decreased phosphate uptake,* slower incorporation into ATP and 2,3-diphosphoglycerate*
- Accelerated decline of 2,3-diphosphoglycerate during red blood cell incubation*
- Increased ATP levels
- Accelerated decline of ATP during brief incubation

Storage Characteristics
- Increased potassium efflux and greater degree of hemolysis during short periods of storage
- More rapid assumption of altered morphologic forms on storage or incubation*

Membrane
- Decreased ouabain-sensitive ATPase*
- Decreased potassium influx*
- Decreased permeability to glycerol and thiourea*
- Decreased membrane filterability*
- Increased sphingomyelin and decreased lecithin content of stromal phospholipids*
- Decreased content of linoleic acid*
- Increase in lipid phosphorus and cholesterol per cell
- Greater affinity for glucose*

Other
- Increased methemoglobin content*
- Increased affinity of hemoglobin for oxygen*
- Glutathione instability*
- Increased tendency for Heinz body formation in presence of oxidant compounds*

*Appears to be a unique characteristic of the newborn's erythrocytes and not merely a function of the presence of young red cells.
NADP, Nicotinamide adenine dinucleotide phosphate.

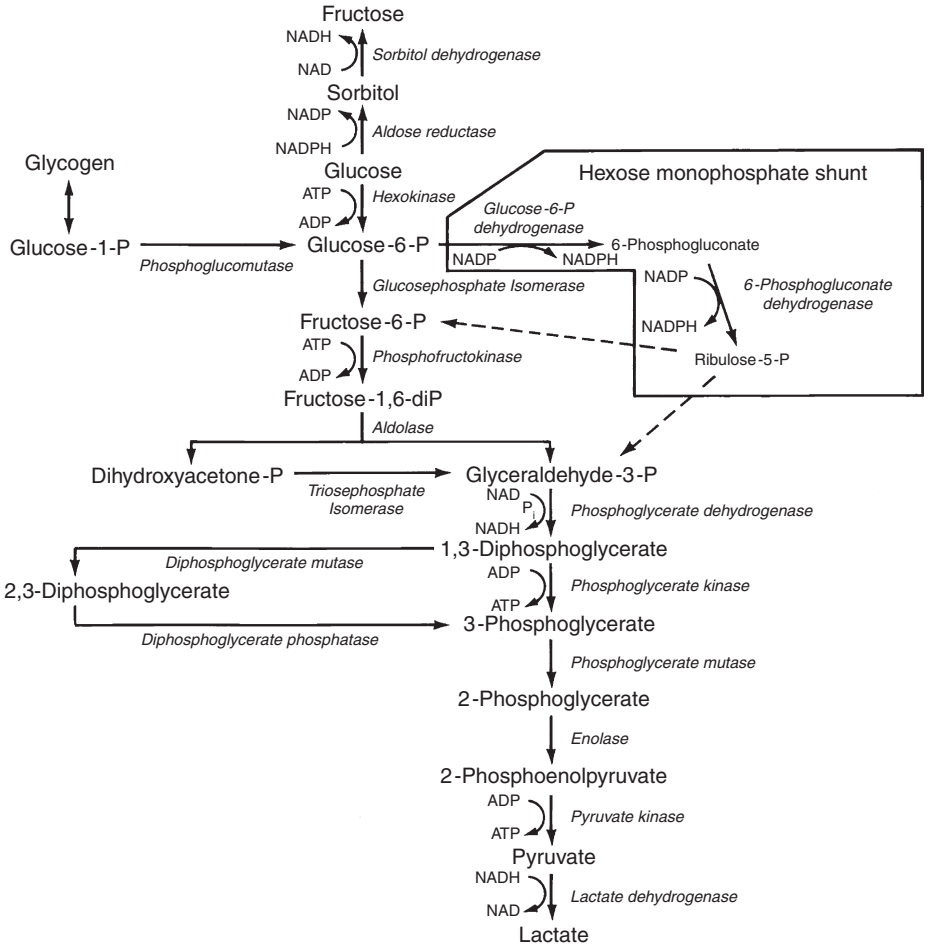

Figure 144-6 Pathways of red blood cell glucose metabolism.

Embden-Meyerhof Pathway

At least 90% of glucose is metabolized by way of the Embden-Meyerhof pathway.[129,130] Two moles of ATP are produced for every mole of glucose catabolized, yielding two moles of lactic acid. This potential for the production of ATP is not fully achieved, because approximately 20% of metabolized glucose traverses the 2,3-DPG cycle, thereby bypassing one of the kinase steps, which is a site of ATP generation.[131]

The Embden-Meyerhof pathway has several unique characteristics with respect to fetal and newborn cells. These cells consume greater quantities of glucose than do the red blood cells of adults.[132] Galactose metabolism in the newborn red blood cell also differs.[133] Galactokinase activity is three times greater in the erythrocytes of newborns, and these cells consume galactose more rapidly than do those of the adult. The glycolytic enzymes phosphoglycerate kinase and enolase are much more active in the cells of the fetus and newborn infant than would be anticipated from their young cell age.[134,135] By contrast, the activity of phosphofructokinase (a rate-controlling enzyme in glycolysis) is lower than normal in the erythrocytes from newborn infants.[134,136,137] Developmental changes in the activities of these three enzymes toward normal adult values during the first year of life appear to be independent of red blood cell age and reflect a transition from fetal to adult erythropoiesis. The decreased phosphofructokinase activity of fetal cells may be a consequence of accelerated decay of an unstable enzyme. The relative deficiency of this enzyme appears to result in alterations in glucose metabolism, and it could be functionally significant. Several of the other enzymes of the Embden-Meyerhof pathway have shown differences in the staining intensity of certain isoenzyme zones as compared with adult controls, although the significance of this observation is not known.

The ATP generated by the Embden-Meyerhof pathway is necessary for the maintenance of the normal biconcave shape of the erythrocyte.[138] It also is necessary for pyrimidine nucleotide synthesis, completion of purine nucleotide synthesis and glutathione synthesis,[139] incorporation of fatty acids into membrane phospholipids,[140] active cation transport,[137] and the initial step in the phosphorylation of glucose by the hexokinase enzyme. Not all of these synthesizing functions are important in the mature red blood cell, which lacks a nucleus. However, loss of red cell ATP produces a marked decrease in cell deformability. As the cell ages, ATP levels fall, and older cells exhibit lower glucose utilization, greater osmotic fragility on incubation, lower membrane lipid content, lower potassium concentration, and greater sodium concentration. They are less deformable and have a shorter life span. The red blood cells of term and preterm infants, when studied in the first several days of life, contain higher levels of ATP than do cells from adults.[141,142] The small premature infant has even higher ATP levels.[141]

Newborn red blood cells seem to demonstrate a transient immaturity in their metabolism. This results in a slower uptake of phosphorus, a delayed incorporation into 2,3-DPG, and a marked decline in 2,3-DPG, as well as ATP, during short periods of incubation in vitro. The precise reason for this relatively transient immaturity is not known, but it may explain why the newborn red blood cell loses potassium at an accelerated rate and undergoes marked morphologic alteration during short incubations in vitro.

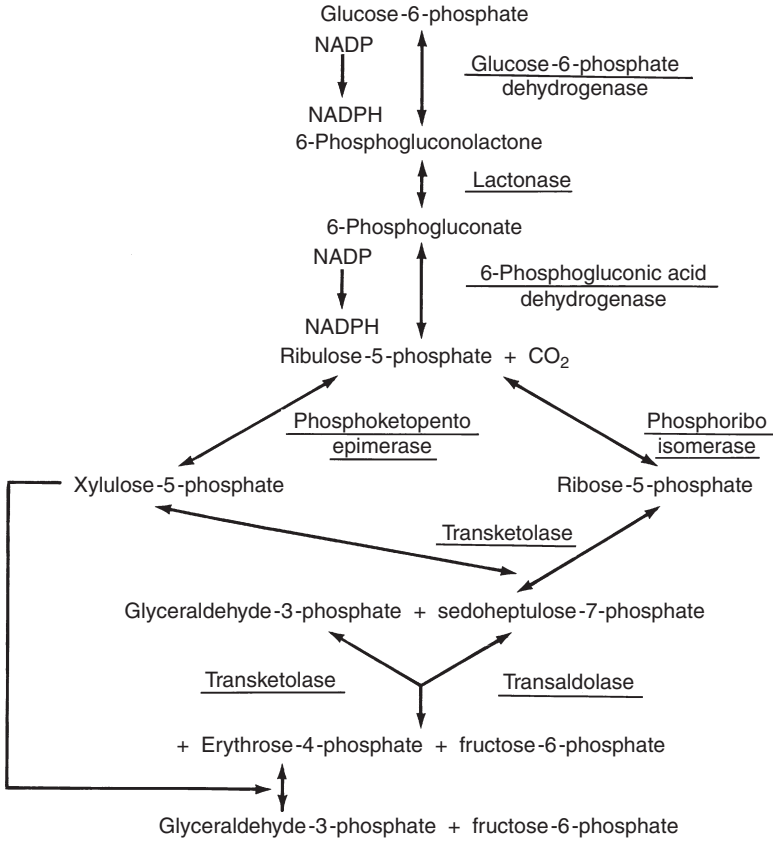

Figure 144-7 The pentose phosphate pathway.

Pentose Phosphate Pathway

Glucose-6-phosphate undergoes oxidative decarboxylation through the pentose phosphate pathway (Figure 144-7), consuming oxygen and producing carbon dioxide. The pentose pathway requires NADP as a cofactor. In the first step, oxidation of glucose-6-phosphate to 6-phosphogluconolactone is catabolized by glucose-6-phosphate dehydrogenase, generating $NADPH_2$. This step is followed by enzymatic hydrolysis of 6-phosphogluconolactone to 6-phosphogluconate, which is then oxidized in the presence of 6-phosphogluconic dehydrogenase to ribulose-5-phosphate with the production of carbon dioxide. Approximately 3% to 10% of all glucose metabolized by the cell is cycled through the pentose pathway. Hypoxia and acidosis increase the proportion of glucose metabolism shunted through this pathway.

The pentose phosphate shunt results in the production of two important products, ribose-5-phosphate and $NADPH_2$. Ribose-5-phosphate is a vital constituent of the pyridine nucleotides, NAD and NADP, and the purine nucleotides adenosine diphosphate (ADP) and ATP. No pathway exists for de novo purine formation inside the red blood cell; however, the mature red blood cell does retain the ability for pyridine nucleotide formation. $NADPH_2$ is critical for preservation of cell integrity because it is necessary for methemoglobin reduction, the reduction of glutathione, and the stabilization of certain enzymes.[143] $NADPH_2$ serves as a hydrogen donor in the presence of the enzyme glutathione reductase, resulting in reduction of glutathione. Reduced glutathione ultimately serves as a substrate for the enzyme glutathione peroxidase, which is responsible for the detoxification of hydrogen peroxide. Hydrogen peroxide is a byproduct of the conversion of oxyhemoglobin to methemoglobin, which is a naturally occurring reaction inside the red blood cell in the presence of oxidative stress. The absence of $NADPH_2$ (or anything that interferes with the production of reduced glutathione), the synthesis of glutathione, or the inability to detoxify hydrogen peroxide will severely impair the viability of the red blood cell.

The pentose phosphate pathway in the newborn red cell differs from that in the adult red blood cell. Two enzymes of the pentose pathway, glucose-6-phosphate dehydrogenase and 6-phosphogluconic acid dehydrogenase, are active at levels higher than those seen in adult red blood cells.[144] Carbon dioxide production by erythrocytes of term and preterm infants is equal to or greater than that seen in red blood cells of adults.

Although some studies suggest that the pentose phosphate pathway activity in the newborn may be normal, additional evidence indicates that newborn infants are more susceptible to oxidant-induced injury, leading to glutathione instability, Heinz body formation, and the development of methemoglobinemia.[145,146] This oxidant vulnerability may be caused by factors unrelated to the pentose phosphate pathway. For example, the red blood cell membrane in the fetus and newborn may have a decreased number of membrane sulfhydryl groups, making these cells more susceptible than mature red cells to Heinz body formation.[146] Additionally, NADPH-methemoglobin reductase activity is decreased in neonatal red cells, and the plasma of newborn infants appears to have a diminished antioxidant capacity.[147]

The precise mechanisms underlying the newborn red blood cell vulnerability to oxidant injury are not known. Fetal and newborn red blood cells have diminished glutathione peroxidase, which may render the cells more vulnerable to hydrogen peroxide–induced oxidant injury. In addition, the newborn red blood cell may have a diminished capacity for handling other activated oxygen radicals, such as singlet oxygen and the superoxide radical.[148] The latter is converted to hydrogen peroxide in the presence of the enzyme superoxide dismutase. Superoxide dismutase levels vary widely between infants. Diminished activity of the superoxide dismutase enzyme could result in

accumulation of superoxide radicals. Free radicals generally are detoxified by antioxidants such as α-tocopherol (vitamin E). If, however, superoxide dismutase levels are increased (as has been described in some infants), the hydrogen peroxide presented to reduced glutathione may not be adequately detoxified.[149] Therefore a delicate balance appears to exist between enzymes involved in production and detoxification of free radicals and oxidative intermediates. The use of inhaled nitric oxide for treatment of pulmonary hypertension in sick neonates may affect this balance, and further studies are required to determine its impact on oxidant injury beyond an increase in methemoglobin formation.

2,3-Diphosphoglycerate Metabolism

The affinity of a hemoglobin solution for oxygen can be decreased by interaction with certain organic phosphates.[150] Among the organic phosphates tested, 2,3-DPG and ATP are the most effective in lowering oxygen affinity. The highly charged anion 2,3-DPG binds to deoxyhemoglobin but not to oxyhemoglobin. Various conditions increase the amount of 2,3-DPG present within the red blood cell, as regulated in the Embden-Meyerhof pathway. Once formed, 2,3-DPG binds reversibly to 1 mole of deoxyhemoglobin tetramer in a 1:1 ratio under physiologic conditions of solute concentration and pH. Fetal deoxyhemoglobin does not possess as great an affinity for 2,3-DPG as that of adult deoxyhemoglobin, so it cannot bind 2,3-DPG to the same degree as for adult hemoglobin. Thus the fetal leftward-shifted hemoglobin oxygen dissociation curve is not easily modulated in the presence of 2,3-DPG. The half-saturation pressure (P_{50}) value for fetal blood is 19 to 21 mm Hg, some 6 to 8 mm Hg lower than that of adult blood. As the fetal hemoglobin concentration declines, however, a marked rightward shift is seen in the hemoglobin oxygen equilibrium curve (Figure 144-8). The percentage of adult hemoglobin and the red cell 2,3-DPG content alter the position of the hemoglobin oxygen dissociation curve. Infants with a greater proportion of adult hemoglobin but less 2,3-DPG may have the same P_{50} as that for infants with increased quantities of fetal hemoglobin but a high red cell 2,3-DPG content.

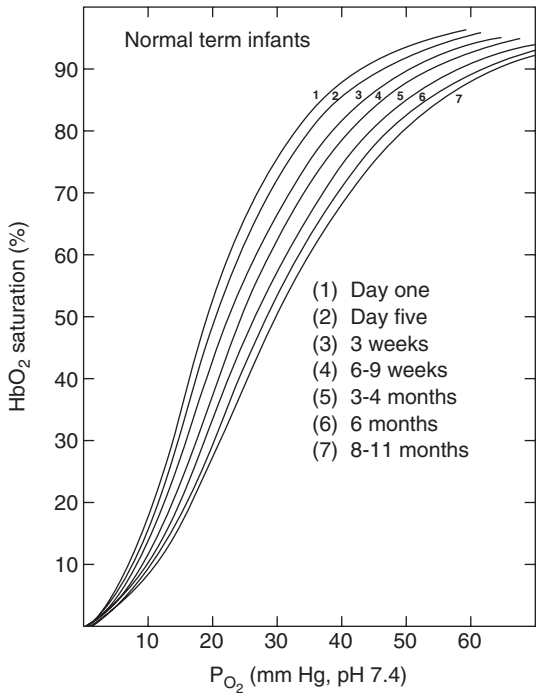

Figure 144-8 Oxygen equilibrium curve of blood from full-term infants at different postnatal ages. The oxygen half-saturation pressure of hemoglobin (P_{50}) on day 1 is 19.4 ± 1.8 mm Hg and has shifted to 30.3. ± 0.7 at age 11 months (normal adult value, 27.0 ± 1.1 mm Hg). *(From Oski FA, Naiman JL:* Hematologic Problems in the Newborn, *ed 3, Philadelphia, 1989, WB Saunders, p 250.)*

ERYTHROCYTE PHYSIOLOGY

Physical Properties of Neonatal Erythrocytes

The fetal and neonatal red blood cell differs from the mature red blood cell of the older infant, child, and adult in various ways. Specific characteristics of fetal red blood cells include a shortened life span, macrocytosis, high fetal hemoglobin content with a $^{G}\gamma/^{A}\gamma$ ratio of 3:1, the presence of i antigen,[151] and low carbonic anhydrase enzyme activity.[152]

Life Span

The differences in physical properties of red blood cells derived from term and preterm infants may in part account for the decreased life span of neonatal red blood cells within the circulation. The average life span for a neonatal red blood cell is 60 to 90 days,[153] approximately one-half to two-thirds that for an adult red blood cell. When neonatal red blood cells are transfused into adults, they exhibit a shortened life span, owing to alterations intrinsic to the neonatal red blood cell.[154] By contrast, cells transfused from adult donors appear to survive normally in newborns.[154] With increasing degrees of prematurity, remarkably shorter red cell life spans (35 to 50 days) are found. Fetal studies using [^{14}C]cyanate-labeled red cells in sheep revealed an average red cell life span of 63.6 ± 5.8 days.[155] The mean red cell life span increased linearly from 35 to 107 days as the fetal age increased from 97 days (midgestation) to 136 days (term).

The shortened red blood cell life span of the preterm and term neonate may be explained by some of the characteristics specific to newborn cells—namely, a rapid decline in intracellular enzyme activity and ATP,[156] loss of membrane surface area by internalization of membrane lipids, decreased levels of intracellular carnitine,[157] increased susceptibility of membrane lipids and protein to peroxidation,[158] and increased mechanical fragility resulting from increased membrane deformability.[159]

Size

Red blood cell dimensions change markedly during fetal and neonatal development. Early in embryogenesis, cell diameters range from 20 to 25 μm, and the MCV averages 150 to 180 fL.[1] During fetal development, red cells gradually decrease in size and volume (see Table 144-3); at birth, the average cell is 8 to 10 μm in diameter, with an MCV between 108 and 118 fL. Over the first year of life, red blood cells continue to diminish in size, and at 1 year of life, they resemble adult red blood cells (see Table 144-5).

Shape and Deformability

Just as with variation in the size of newborn red blood cells, variation in shape occurs as well. Irregularly shaped cells are present in much greater numbers in the peripheral blood of newborn infants than in that of adults.[160] Target cells, acanthocytes, puckered immature erythrocytes, and other irregular projections normally may be found. For example, a greater percentage of neonatal red blood cells have membrane surface pits, which probably are the sites of formation of endocytic vacuoles. In normal adults, 2.6% of erythrocytes appear to have surface pits or craters ranging in size from 0.2 to 0.5 μm in diameter, demonstrated by interference contrast microscopy.[161] By contrast, pits can be found in almost half of the erythrocytes of preterm infants and in one fourth of the erythrocytes of term infants.

Red blood cell deformability is governed principally by three factors: the surface area–volume relationship of the red blood

cell, the viscosity of the cytoplasm of the cell, and intrinsic red blood cell membrane rigidity.[159] The deformability of erythrocytes is important for several reasons. First, this deformability appears to be an important determinant of red blood cell life span in vivo. The removal of a red blood cell from the circulation is thought to be a consequence of declining deformability, making the cell susceptible to sequestration in the spleen and other organs, where it must negotiate extraordinarily narrow passages. Second, red blood cell deformability directly influences blood flow in the peripheral circulation. Third, red blood cell deformability affects whole blood viscosity, which in turn affects peripheral vascular resistance and cardiac workload.[162]

Neonatal red blood cells with the greatest density (representing the oldest cells in the circulation) lose more volume in comparison with adult red blood cells, have a higher mean corpuscular hemoglobin concentration, and are less deformable than the oldest red blood cells seen in adults. These observations suggest an accelerated decrease in deformability of aging red blood cells related to a more pronounced increase in the mean corpuscular hemoglobin concentration, the principal determinant of the internal viscosity of the red blood cell. Neonatal red blood cell membranes deform more readily to a given shear force than do adult red blood cell membranes, resulting in greater susceptibility of neonatal cell membranes to fragment.[162] These mechanical properties may lead to accelerated membrane loss and a decreased life span. A study evaluating the red cell deformability of preterm infants receiving recombinant Epo reported that erythrocyte deformability was significantly related to the reticulocyte count, indicating that the improvement of erythrocyte deformability with recombinant Epo therapy was due to the formation of well-deformable young erythrocytes.[163]

Surface Charge

The surface charge of newborn red blood cells is more negative than that of adult red blood cells. The negative charge at the red blood cell surface is largely responsible for the electrophoretic mobility of the cell, and it appears to reflect the sialic acid content of the red blood cell membrane.[164,165] Proteases expose more negative sites on neonatal red blood cells than on adult red blood cells and increase the electrophoretic mobility to a greater degree.[166] The sialic acid content of the newborn infant's erythrocyte membrane shows a gradual but significant decrease in the first several weeks of life.[167] Most studies, however, have shown that the electrophoretic mobility of the neonatal cell is similar to that of the adult cell.[165] The more negative surface charge of the neonatal red blood cell membrane is one of the many characteristics that results in a decreased sedimentation rate in newborns.[168]

Osmotic Fragility

The osmotic fragility of red blood cells is a composite index of their shape, hydration, and, within certain limitations, vulnerability to in vivo destruction.[159,169] Preterm and term infants have an increased osmotic resistance.[170,171] The osmotic fragility of neonatal cells begins to revert toward adult values shortly after birth, and osmotic resistance reaches adult values by 4 to 6 weeks of age. No advantage has been recognized for the increased osmotic resistance seen in the neonatal red blood cell. However, studies of osmotic fragility in neonates have practical implications. It has been suggested that the diagnostic criteria for hereditary spherocytosis used in adults and older children are unreliable in newborn infants. For example, spherocytes are not regularly seen in all infants with hereditary spherocytosis. Indeed, spherocytes may be a frequent finding in ABO incompatibility. In performing an osmotic fragility test, a neonatal osmotic fragility curve must be used, rather than an adult curve.[172] This underscores the need for calculating an osmotic fragility curve for newborn infants in whom a diagnosis of hereditary spherocytosis is considered.

Surface Receptors and Antigens

The neonatal red blood cell differs from the adult red blood cell in its ability to bind various substances. For example, neonatal red blood cells bind more insulin than that bound by adult red blood cells because of the presence of greater numbers of insulin receptors per cell.[173,174] Newborn red blood cells also have approximately 2.5 times the number of digoxin receptors in adult red blood cells,[175] and as a consequence neonates exhibit erythrocyte-to-plasma digoxin ratios three times those in adults. This finding may explain the greater tolerance of newborns who are receiving maintenance digoxin therapy.

Another unique characteristic of the fetal red blood cell is the expression of the i antigen on the cell surface (adult red blood cells express I antigen). Membrane i antigen is a carbohydrate moiety located on protein membrane band 3, which, during development, is converted from a linear polylactosamine to a branched carbohydrate chain of *N*-acetyl lactosamine units.[151] Red blood cells bearing the i antigen usually are not detectable by the first year of age. It has been suggested that the switch from fetal to adult hemoglobin and the transformation of i antigen expression that occur during the first year of life are governed by a common control mechanism; therefore the presence of i antigen can serve as a marker of fetal hematopoiesis.

Red blood cell antigens in the ABO, MN, Rh, Kell, Duffy, and Vel systems are well developed in early intrauterine life.[176] Antigen expression on the fetal red cell can be detected by 5 to 7 weeks gestation, and expression remains constant for the remainder of intrauterine development. Other antigens, such as the Lutheran and XgA systems, develop more slowly but are present at birth. Lewis antigens are lacking in the newborn. By approximately 2 years of age, the child's red blood cell and plasma antigens have developed a pattern that is seen throughout the remainder of life.[177]

Although A and B antigens are present early in utero, production of A and B isoagglutinins occurs much later.[178] By 30 to 34 weeks gestation, however, approximately 50% of infants have some measurable anti-A or anti-B antibodies. The fetal production of such antibodies is not related to maternal ABO blood type. Intrauterine exposure to gram-negative organisms, whose antigens are chemically related to those of blood groups A and B, is a potent stimulus for the development of these antibodies. Isohemagglutinin antibodies ultimately are demonstrable in normal infants by 6 months of age and approach adult values at 2 years of age. Low to absent titers after this time are suggestive of immune deficiency.[179]

Oxygen Transport

At no other time of life are the mechanisms controlling oxygen transport more complicated than during development in utero and in the immediate postnatal period. During prenatal life, the fetal arterial oxygen tension (Po_2) is approximately 30 mm Hg, and the venous Po_2 is approximately 15 mm Hg (Figure 144-9). This low Po_2 contributes to the development of relative polycythemia in the fetus. After birth, numerous factors affect oxygenation, including the inspired gas mixture, pulmonary function, the arterial oxygen dissociation curve, and the ability to extract oxygen at the tissue level.[180,181] It has been speculated that the actual amount of oxygen released to tissues may be greater in utero, in keeping with the characteristics of the hemoglobin oxygen dissociation curve (Figure 144-10).

If pulmonary function is normal, a rise in the Po_2 of pulmonary blood in adults and neonates, from the 40 mm Hg of pulmonary arterial blood to the 100 mm Hg of pulmonary venous blood, will occur. Because of the shape of the hemoglobin oxygen dissociation curve, these Po_2 values permit 95% saturation of hemoglobin by oxygen. Further increases in Po_2 produce little additional rise in saturation. In the normal adult (see Figure 144-9), approximately 50% of hemoglobin will be saturated with oxygen when the Po_2 has fallen to 27 mm Hg (P_{50} = 27). In situations in which the hemoglobin-oxygen dissociation curve has shifted to the

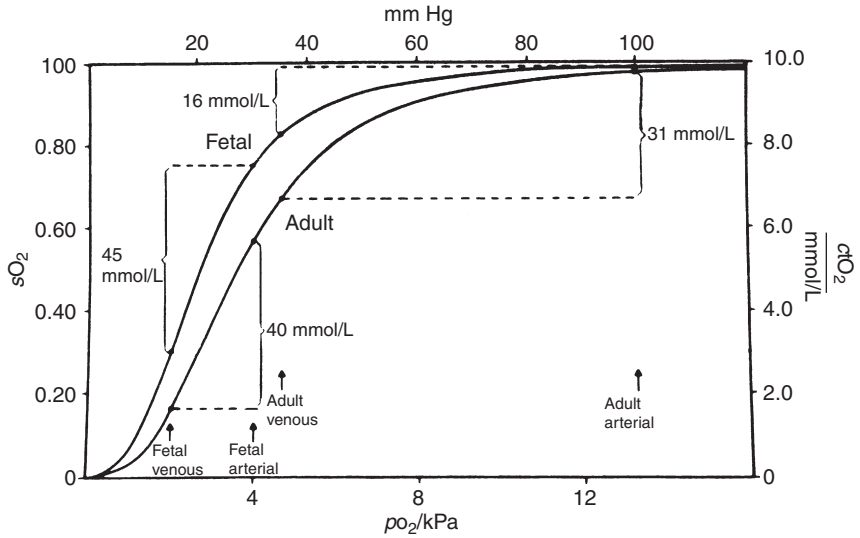

Figure 144-9 Differences in the hemoglobin oxygen dissociation curve between the newborn and the adult. This diagram demonstrates the effects of these differences on oxygen tension (ctO_2) and oxygen saturation (sO_2). *(From Stockman JA: Fetal hematology. In Eden RD, Boehm J, editors:* Assessment and Care of the Fetus, *Norwalk, Conn., 1989, Appleton & Lange, p 124.)*

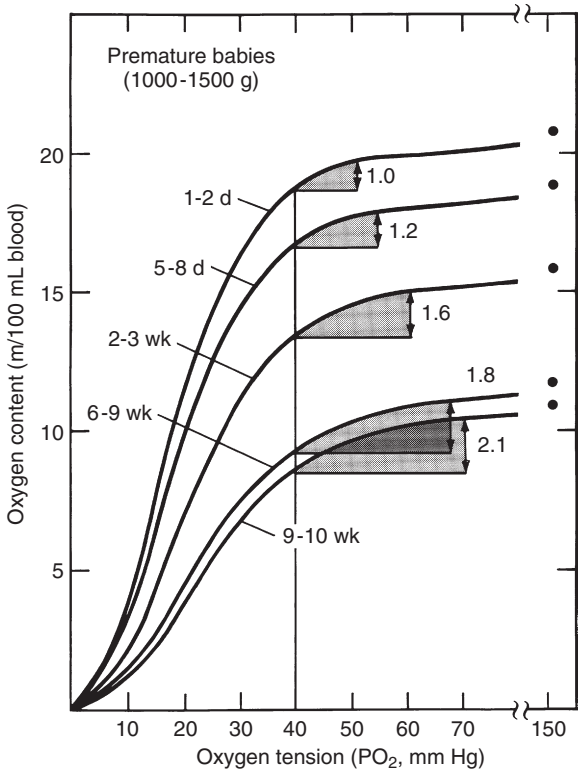

Figure 144-10 Oxygen equilibrium curves for blood from premature infants (1001 to 1500 g) at different postnatal ages. *Double arrows* represent the oxygen unloading capacity between a given arterial and venous Po_2. Points corresponding to 150 mm Hg on the *abscissa* are the oxygen capacities. Each *curve* represents the mean value for the infants studied in each group. *(From Delivoria-Papadopoulos M, et al: Postnatal changes in oxygen transport of term, preterm and sick infants: the role of red cell 2,3 diphosphoglycerate in adult hemoglobin,* Pediatr Res *5:235, 1971.)*

right, the affinity of hemoglobin for oxygen is reduced. Thus, at any given Po_2, more oxygen is released to tissues. Conversely, if the curve is shifted to the left, the affinity of hemoglobin for oxygen is increased, so that at any given Po_2, less oxygen is released to the tissues.

Certain factors are known to alter hemoglobin's affinity for oxygen (Box 144-2). The most important of these are the fetal hemoglobin concentration and the red cell 2,3-DPG content. The level of red cell 2,3-DPG gradually increases with gestation. At term, the concentration of red cell 2,3-DPG is similar to that in adults. By the end of the first week of life, the 2,3-DPG levels are considerably higher than they are at birth. After the first week, red cell 2,3-DPG levels remain relatively unchanged for the next 6 months. In term infants, the hemoglobin oxygen dissociation curve gradually shifts to the right, and by 4 to 6 months of age, the P_{50} values approximate those in the adult.

The situation is somewhat different in preterm infants. Fetal hemoglobin synthesis is still quite active; therefore increases in P_{50}, as seen in term infants consequent to the switch from fetal to adult hemoglobin, do not occur. The red cell 2,3-DPG concentrations are slightly lower in preterm infants as well.[89] These concentrations can be increased with the use of Epo, thereby shifting the oxygen dissociation curve to the right.[182]

A precise relationship between the decrease in oxygen affinity of a neonate's blood and the progressive decline in the concentration of fetal hemoglobin does not exist.[181] Rather, changes in P_{50} reflect the interplay between the levels of red cell 2,3-DPG, the decline in fetal hemoglobin, and the subsequent increase in hemoglobin A. A unifying concept has emerged consisting of a "functioning 2,3-DPG fraction,"[89] which determines how well hemoglobin is able to release oxygen to tissues. The functioning 2,3-DPG fraction (expressed as mμmol/mL of red blood cells) is calculated by multiplying the red cell 2,3-DPG content by the percent adult hemoglobin[86]:

$$[2,3\text{-DPG}]_{\text{functional}} = [2,3\text{-DPG}]_{\text{observed}} \times [100 - \%\ \text{hemoglobin F}]$$

If P_{50} cannot be measured directly, it may be calculated from the following equation[86] after the functioning 2,3-DPG fraction has been determined:

$$P_{50} = 18.4 + 0.0016\,[2,3\text{-DPG}]_{\text{functional}}$$

BOX 144-2

Factors Affecting Hemoglobin-Oxygen Affinity

Increased Red Cell 2,3-DPG, Increased P_{50}
- Adaptation to high altitude
- Hypoxemia associated with chronic pulmonary disease
- Hypoxemia associated with cyanotic heart disease
- Anemia
  - Secondary to iron deficiency
  - Secondary to chronic renal disease
  - Associated with sickle cell anemia
- Decreased red blood cell mass
- Chronic liver disease
- Hyperthyroidism
- Red cell pyruvate kinase deficiency

Decreased Red Cell 2,3-DPG, Decreased P_{50}
- Septic shock
- Severe acidosis
- After massive transfusions of stored blood
- Neonatal respiratory distress syndrome

Increased P_{50}, No Consistent Alteration in Red Cell 2,3-DPG
- Abnormal hemoglobins (Kansas, Seattle, Hammersmith, Tacoma, E)
- Vigorous exercise

Decreased P_{50}, No Consistent Alteration in Red Cell 2,3-DPG
- Abnormal hemoglobins (Kempsey, Chesapeake, J. Capetown, Yakima, Rainier)

2,3-DPG, 2,3-Diphosphoglycerate; *P_{50},* oxygen half-saturation pressure of hemoglobin.

Table 144-6 illustrates the expected changes in hemoglobin concentration, 2,3-DPG, functional 2,3-DPG fraction, and P_{50} during the first 3 months of life in low-birth-weight infants.[89] In low-birth-weight infants, the amount of oxygen released by hemoglobin can be determined on the basis of unloading from a normal arterial Po_2 adjusted for age to an arbitrary central venous Po_2 of 40 mm Hg.[86] Although oxygen-carrying capacity (hemoglobin concentration × percent oxygen saturation × 1.36 mL of oxygen/g of hemoglobin) decreases over the first few months of life as a consequence of a decline in hemoglobin concentration, the amount of oxygen capable of being delivered to tissues actually increases. For example, in a newborn weighing 1000 g with a hemoglobin concentration of 15 g/dL, a P_{50} of 19, and a central venous Po_2 of 40 mm Hg, 1 mL of oxygen will be unloaded to tissues for every 100 mL of blood that passes through the capillary bed. By 10 weeks of age, the P_{50} has shifted to the right and is now 24 mm Hg. In this same infant, 2.1 mL of oxygen will now be delivered per 100 mL of blood, even though the hemoglobin has declined to 8 g/dL (see Figure 144-10).

These calculations emphasize the importance of understanding a particular infant's ability to deliver oxygen to tissues in determining whether to administer an erythrocyte transfusion. The decision to transfuse should not be based on hemoglobin concentration alone. Transfusions will significantly affect the infant's endogenous erythropoiesis. For infants who undergo exchange transfusion or multiple transfusions, both Epo concentrations and reticulocyte counts are lower at any given hemoglobin concentration[86,183] (Figure 144-11).

It often is assumed that oxygen delivery is decreased in newborns because of the presence of high-affinity hemoglobin. In fact, a leftward shift in the hemoglobin-oxygen dissociation curve resulting from high levels of fetal hemoglobin may better maintain oxygen delivery during episodes of severe hypoxemia. Figure 144-12 illustrates the arterial Po_2 below which shifts to the right in the neonatal oxygen dissociation curve are no longer advantageous. The gas tension at which this occurs is known as the *cross-over Po_2*.[184] The cross-over Po_2 is dependent on how low the venous Po_2 falls before oxygen delivery ceases. Wimberley[185] calculated that if the arterial Po_2 fell to less than 32 mm Hg and if the venous Po_2 fell to 10 mm Hg (a value found in the cerebral venous blood of some sick newborns), the infant would achieve better oxygen delivery with a fetal oxygen dissociation curve than with an adult curve. Conversely, if arterial Po_2 can be maintained at a higher value, better oxygen delivery would exist if the oxygen dissociation curve were shifted to the right.

In neonates with hypoxemia (e.g., infants with cyanotic congenital heart disease), a shift to the right (a higher P_{50}) in the hemoglobin-oxygen dissociation curve tends to lower the arterial and venous oxygen saturation at any given Po_2. It has been documented that if arterial hypoxemia results from right-to-left shunting, shifts to the right in the oxygen dissociation curve always tend to increase the arterial-venous oxygen difference, thereby improving oxygen delivery.[186]

After intrauterine transfusion, oxygen-unloading properties of blood in the newborn are characteristic of those of adult blood. Despite the decrease in oxygen affinity that accompanies intrauterine transfusion, no deleterious effects of this procedure with respect to oxygen uptake by the fetus have been documented.[187] The physiologic significance of manipulating the hemoglobin oxygen affinity of fetuses and extremely preterm infants remains to be determined.

HYPOPROLIFERATIVE ANEMIAS

Physiologic and Pathologic Anemia in Neonates

A gradual decrease in hemoglobin concentration occurs over the first 2 to 3 months of life in term and preterm infants. The hemoglobin concentration remains stable over the next several weeks and then slowly rises. In term infants, the fall in red cell production after birth is the result of improved oxygenation and occurs as a natural adaptation to extrauterine life. Accordingly, the decrease in hemoglobin concentration has been recognized as a *physiologic nadir,* rather than representing true anemia. In preterm infants, however, adaptive mechanisms may not be complete. Preterm infants generally exhibit a drop in hemoglobin to lower values than those seen in term infants, and the nadir varies with the degree of prematurity. Table 144-4 illustrates the decline in hemoglobin concentration based on birth weight and gestational age. Hemoglobin values as low as 7 g/dL are common in preterm infants who have not undergone phlebotomies.[87,188]

Assessing the factors that characterize oxygen supply and oxygen demand has provided insight into the adaptive changes occurring in preterm infants in response to low hemoglobin concentrations. In preterm infants, a low central venous Po_2 correlates with a mild increase in Epo production[189] (Figure 144-13). The decline in central venous Po_2 appears to be a sensitive indicator of the presence of anemia, representing the integration of variables that determine oxygen supply and demand: hemoglobin concentration, red cell oxygen affinity, intravascular volume, oxygen consumption, heart rate, cardiac stroke volume, and arterial oxygenation. The hemoglobin concentration is only one of many important variables ensuring adequate oxygen delivery in both term and preterm infants.[181]

Anemia of Prematurity

Characteristics

Despite the slight increase in Epo production that occurs in response to declining central venous Po_2 values, Epo concentrations in preterm infants are still significantly low, in view of the

Reprinted by permission of* The New England Journal of Medicine.*)*

degree of anemia.[73,189-191] This anemia, termed the *anemia of prematurity,* affects infants born at less than 32 weeks gestation, and it is the most common anemia encountered in the neonatal period. It is a normocytic, normochromic anemia, generally associated with hemoglobin concentrations less than 10 g/dL and low reticulocyte counts. Some infants may be asymptomatic, whereas others demonstrate signs of anemia that are alleviated by transfusion. These signs traditionally include tachycardia, increased episodes of apnea and bradycardia, poor weight gain, an increased oxygen requirement, and elevated serum lactate concentrations that decrease after transfusion.[192-195]

Anemia of prematurity was first described by Schulman,[196] who divided the anemia into three phases. *Early anemia* was marked by an initial fall in hemoglobin concentration. The second, or *intermediate*, phase was characterized by maintenance of low hemoglobin concentrations. The third phase, *late anemia of prematurity,* resulted in hemoglobin concentrations that continued to fall despite unequivocal evidence of anemia, which failed to induce appropriate adaptive changes. The anemia of prematurity usually resolved spontaneously by 3 to 6 months of life.

Although much information has accumulated since the 1970s, the mechanisms responsible for the anemia of prematurity remain poorly defined. Shortened erythrocyte survival,[197] hemodilution associated with a rapidly increasing body mass,[198] and the transition from fetal to adult hemoglobin[89] all have been implicated. Despite diminished available oxygen to tissues[86] and the appearance of signs of anemia,[191] serum Epo concentrations remain low.[191] However, erythroid progenitors are highly sensitive to

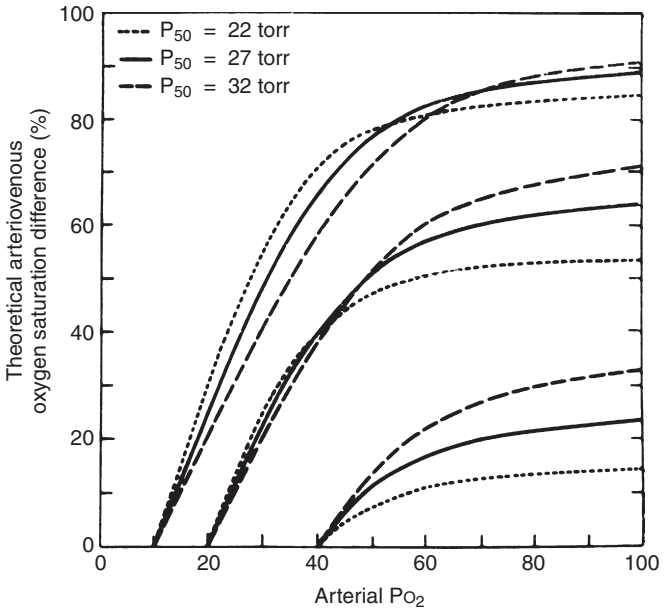

Figure 144-12 The effect of arterial partial pressure of oxygen (Po_2) on theoretical arteriovenous oxygen content difference when venous Po_2 is 40 mm Hg *(lower set of curves),* 20 mm Hg *(middle set of curves),* or 10 mm Hg *(upper set of curves)* at various P_{50} values. *P_{50},* Oxygen half-saturation pressure of hemoglobin. *(From Woodson RD: Physiological significance of oxygen dissociation curve shifts,* Crit Care Med *7:368, 1979. © by Williams & Wilkins, 1979.)*

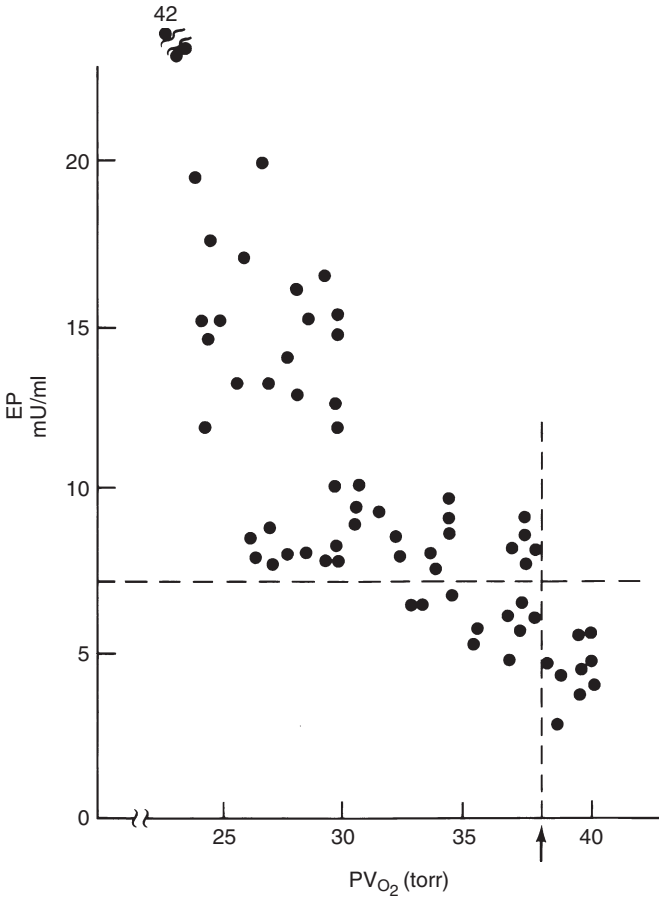

Figure 144-13 Changes in plasma erythropoietin concentrations in response to declines in central venous oxygen tension (PVo_2) in preterm neonates. *Arrow* indicates the position of 38 mm Hg, which for the purposes of this figure is the lower limit of normal for PVo_2. The *horizontal dashed line* is the upper limit of normal for erythropoietin taking PVo_2 ≥38 mm Hg as normal. *EP,* Erythropoietin production. *(From Stockman JA, et al: Anemia of prematurity: determinants of the erythropoietin response,* J Pediatr *105:786, 1984.)*

Epo,[199,200] and concentrations of other erythropoietic growth factors, including IL-3 and GM-CSF, appear to be normal.[201]

Infants born prematurely lack a normal response to anemia, so that Epo production does not increase despite an apparent need for improved tissue oxygenation.[202] This failure to respond has been documented regardless of the cause of anemia, whether it is the early anemia of phlebotomy loss or the later anemia of prematurity. Possible molecular and cellular mechanisms responsible for this lack of responsiveness include defects in transferring the hypoxic signal to the nucleus, diminished or defective binding of transcription factors to the promoter or enhancer regions of the gene, decreased production or stability of the transcriptional factors, decreased production or stability of Epo mRNA, diminished or unstable protein production, and increased production of counterregulatory proteins such as IL-1 or tumor necrosis factor. The inability of the kidney or liver in the premature infant to produce Epo mRNA with magnitude equal to that seen in the fetus also may involve a developmental delay in expression of transcriptional factors responsible for increasing Epo production, or in persistence of fetal Epo gene methylation patterns. Because Epo produced by the liver is indistinguishable from that produced by the kidney, it is unknown whether preterm infants rely on Epo produced by the liver or the kidney, or a combination of the two. However, macrophages from preterm infants generate Epo mRNA and protein as effectively as do those from term infants and adults.[203] The anemia of prematurity thus may involve a delay in activation of Epo gene expression, from prenatal (liver) to postnatal (kidney) sites of production.

Clinical Trials

Multiple clinical studies have been performed evaluating Epo administration administered to preterm infants.[204] Randomized, controlled studies using weekly Epo doses of more than 500 U/kg are summarized in Table 144-7.[205-219] In the first randomized multicenter trial published, Maier and the European Epo Study Group[205] evaluated the effect of Epo on the need for transfusions in preterm infants weighing 750 to 1499 g. Infants who were not receiving mechanical ventilation were randomized on day 3 of life to receive Epo or no treatment. A total of 241 infants were evaluated, 177 of whom completed the study according to protocol. Epo recipients received fewer transfusions (1.2 versus 0.8) and demonstrated a greater success rate (defined as maintaining hematocrit of more than 32% without transfusions) compared with placebo recipients.

Shannon and the United States Study Group[207] evaluated Epo to treat the anemia of prematurity. Infants born at a weight of 1250 g or less and before 31 weeks gestation were randomized to receive Epo (100 U/kg) or placebo, administered subcutaneously (SC), 5 days a week, for a total of 6 weeks. All infants were receiving enteral feedings of at least 60 kcal/kg/day; at the time of study entry, hematocrit values were lower than 40%, and phlebotomy losses were minimal. Infants in both groups received oral iron and vitamin E supplementation, and uniform transfusion criteria were followed by all participating centers. Infants were 24 days of age at the beginning of the study, and they had

received an average of 3.5 transfusions before study entry. Epo recipients required a lower number (1.1 versus 1.6) and smaller volume of transfusions (16 mL/patient versus 24 mL/patient) compared with placebo recipients, and no adverse effects were noted.

Our own laboratory evaluated the efficacy and cost-effectiveness of treating very low-birth-weight infants with Epo for 2 weeks, starting in the first 2 days of life.[208] Epo recipients received a lower number of transfusions than that required by the placebo recipients (0.2 versus 1.4 transfusions per patient), as well as smaller-volume transfusions. When the analysis was extended to include other infants in the intensive care unit who met all study eligibility criteria, the transfusion rate for the placebo recipients was lower (at 2.8 transfusions per patient during the same period) than for infants who were not in the study. This difference in frequency of transfusion also was noted by Bifano and colleagues,[220] who observed that instituting standardized transfusion guidelines decreased the transfusion requirements of very low-birth-weight infants.

In the Argentina multicenter trial, Donato and colleagues[211] randomized infants weighing less than 1250 g to receive either early (250 U/kg five times a week intravenously [IV] for 2 weeks, then 250 U/kg three times a week SC for 6 weeks) or late Epo (placebo for 2 weeks, then 250 U/kg three times a week SC for 6 weeks). These investigators concluded that despite the lack of difference in total number of transfusions between the early and late treatment groups, infants weighing less than 800 g with a phlebotomy loss of more than 30 mL/kg (the early Epo group) appeared to benefit; however, the benefit was noted only after 2 weeks of therapy. A similar delay in response was seen in extremely low-birth-weight infants in the National Institute of Child Health and Human Development Network study,[212] which showed a benefit for Epo treatment after 8 weeks.

Maier and colleagues[213] also compared early administration of Epo (from the first week for 9 weeks) with late Epo (from the fourth week for 6 weeks) in infants weighing less than 1000 g. A control group of infants did not receive Epo. As in their previous studies, these investigators measured the rate of "success," defined by no transfusions and a hematocrit value that never fell to less than 30%. The success rate in the early Epo group was three times greater than that in control subjects: 13% in the early Epo group, 11% in the late Epo group, and 4% in control infants. The investigators reported more than twice the "success" rate (27.6%) for that in same-size infants obtained using a similar dose, dosing schedule, transfusion criteria, and study protocol in one of their previous studies.[210]

Pharmacokinetics

Pharmacokinetic studies in newborn monkeys and sheep indicate that neonates have a larger volume of distribution and a faster elimination of Epo,[221,222] necessitating the use of higher doses than those required for adults.[223] These pharmacokinetic differences apply to preterm infants as well.[224,225] Although various Epo doses and dosing schedules have been evaluated in preterm infants (see Table 144-7), the erythrokinetics of Epo (the interaction between erythroid progenitors and their growth factors) in preterm infants are unknown. Brown and associates[226] compared two dosing schedules in preterm infants: 100 U/kg five times a week versus 250 U/kg twice a week. These workers reported that the more frequent dosing schedule appeared to be more effective in stimulating erythropoiesis, although no differences in transfusion requirements were observed between the two dosing schedules. In a study during which Epo was given continuously over 24 hours to preterm infants for 10 days (versus a daily subcutaneous injection), Epo concentrations and reticulocyte responses were similar in both groups.[225] Peak concentrations in both groups declined from day 3 to day 10.

The route of administration also influences the effectiveness of Epo. Rapid intravenous administration of Epo generates peak serum concentrations that far exceed physiologic concentrations.[227] This may result in wasting of drug through increased renal excretion or binding to nonerythropoietic receptors. Dosing strategies that achieve lower peak serum concentrations over a more prolonged period may be more effective. It appears that doses in the range of 500 to 1400 U/kg/week, administered SC every day or every other day, result in an adequate clinical response. Newer, long-acting erythropoiesis–stimulating agents (ESAs) such as darbepoetin are currently being studied.[228-230] A similar pharmacokinetic relationship in preterm infants is likely in that half-life, clearance, and volume of distribution of these agents suggest that higher doses will be required; however, a decrease in dosing frequency to only once every 2 to 3 weeks may be possible—a great benefit over thrice-weekly subcutaneous dosing.

Side Effects of Treatment

Side effects in neonates receiving Epo have been rare. A side effect unique to neonates, transient neutropenia, was noted in early studies.[231-233] The neutropenia was not associated with depletion of either neutrophil reserves or colony-forming unit–granulocyte-macrophage (CFU-GM) concentrations, but

it appeared to involve reduced production of neutrophils from granulocytic progenitors.[234,235] This disturbance resolved after discontinuation of the Epo. The pathomechanism may involve depletion of the total number of progenitors in slightly older preterm infants or possibly down-modulation of granulocyte-CSF receptors on pluripotent progenitors. In animal studies, neutropenia was documented to occur in newborns after administration of very high doses of recombinant Epo as a result of decreased production of neutrophils from progenitors.[234]

Neutropenia was not reported in any of the trials evaluating administration of Epo to preterm infants starting in the first days of life. In addition, Epo recipients did not experience any increase in morbidity or adverse outcome measures when compared with the placebo recipients. Early studies reported a decreased incidence of symptomatic patent ductus arteriosus,[206,208] possibly as a result of interactions between Epo and endothelin production.[236] Later studies have not shown a statistical effect of Epo on the incidence of symptomatic patent ductus arteriosus.[211-213] In the clinical trial by Emmerson and colleagues,[237] two infants in the Epo-treated group died of sudden infant death syndrome. Meyer and associates[206] also reported one late death ascribed to this syndrome. No other studies reported this association, and follow-up studies did not reveal an association between sudden infant death syndrome and Epo administration.[238]

Overall, the side effects of Epo administration in preterm infants have been minimal compared with those reported in adults—specifically, hypertension, bone pain, rash, and, rarely, seizures. None of these effects were reported in preterm infants involved in clinical trials. Moreover, no studies have reported differences between placebo and Epo recipients in the incidence of neonatal comorbid illnesses such as chronic lung disease, intraventricular hemorrhage, necrotizing enterocolitis, retinopathy of prematurity (ROP), or late-onset sepsis. In a summary report, Romagnoli and colleagues[239] reported an increased incidence of ROP in preterm infants receiving Epo and supplemental iron, compared with a group of control infants. These findings have not been duplicated in any randomized trial, and Epo is still administered to preterm infants cared for by this group. Owing to the inclusion of this report in a recent meta-analysis, the authors of the meta-analysis suggested a relationship between Epo administration and increased incidence of ROP[240]; however, this relationship has not been reported in any of the randomized placebo-controlled trials published in peer-reviewed journals.

Although long-term follow-up studies are few, it appears that the administration of Epo has no adverse effect on developmental outcome or growth, measured at 18 to 22 months.[238] As with many new therapies, however, reports of adverse effects invariably surface as use of the drug increases. Initial concerns regarding red cell aplasia[242] resolved when use of a specific brand of Epo in prefilled syringes was determined to be the primary cause. A report from the U.S. Food and Drug Administration (FDA) raised other concerns over the use of ESAs in adults with cancer.[241] Because of the increased incidence of adverse events documented in cancer patients in remission, new hemoglobin limits have been set for use of ESAs in adults. None of those side effects (stroke, increased thrombosis) have been reported in preterm infants, but careful observation continues.

Nutritional Supplementation

Iron has been administered both parenterally and enterally in published studies. Carnielli and colleagues reported no adverse effects of intravenous iron[243] given at doses of 20 mg/kg once a week. The infants in their study also received vitamin E, 10 mg/kg, intramuscularly twice a week. This iron supplementation regimen, although not using the standard dose or typical route of administration in the United States, may be associated with improved iron availability; it resulted in a greater and more prolonged erythropoietic response than that seen in other studies. Friel and colleagues[244] reported iron accretion rates of preterm infants (not receiving Epo) of 1000 μg/kg/day. Multicenter trials using intravenous iron at doses of 1 to 5 mg/kg/week have shown no adverse effects while producing adequate iron status,[209,212,245] and no long-term oxidant effects have been reported after low-dose parenteral iron infusion.[246]

Oral iron supplementation rates have ranged from 2 to 40 mg/kg/day. Studies evaluating the oxidant effects of infant formulas and oral iron[188] showed increased erythrocyte lysis associated with formulas containing greater amounts of iron and polyunsaturated fatty acids. This effect resolved with the addition of vitamin E. Functional iron deficiency frequently has been reported in pediatric and adult patients receiving Epo, and such deficiency probably limited the success of some of the early Epo trials in preterm infants. Studies evaluating iron stores in Epo recipients[205,206] noted increased iron requirements in infants receiving Epo, as evidenced by diminished ferritin concentrations and elevated numbers of hypochromic red blood cells, despite iron doses of 6 mg/kg/day. Infants receiving Epo probably are at greater risk for iron deficiency than for iron overload and increased oxidant stress. Further evaluation is required to determine the optimal dose and most effective route of administration of iron in preterm infants receiving Epo.

Vitamin E is an antioxidant, inhibiting peroxidation of polyunsaturated fatty acids in the lipid bilayers of all cell membranes. Vitamin E requirements may be increased as a consequence of iron supplementation, because iron promotes oxidation of polyunsaturated fatty acids. Pathak and colleagues[214] evaluated high-dose vitamin E in preterm infants receiving Epo and showed no benefit from doses of 50 IU/kg/day. Further study is needed to determine the optimal dose of vitamin E in preterm infants receiving Epo.

More recently, folate and vitamin B_{12} have been evaluated in combination with Epo and iron, and results have shown significant promise.[218,219] In a study in preterm infants with birth weights less than 800 g, Haiden and colleagues[223] achieved significantly greater success (38% of infants not transfused) when vitamin B_{12} at a dose of 21 mg/kg/week SC was added to a regimen of Epo, iron, vitamin E, and folate. When combined with limited phlebotomy losses, this therapy shows great promise in extremely low-birth-weight infants.

Other Erythropoietin-Responsive Anemias in the Newborn Period

Late Anemia of Rh Disease

Infants with Rh hemolytic disease often exhibit an "early" (congenital) anemia caused by ongoing, antibody-mediated hemolysis, and late-onset anemia (at the age of 1 to 3 months) may develop as a consequence of diminished erythrocyte production. The incidence of late anemia appears to be much higher in infants who receive intrauterine transfusions.[247,248] This anemia is characterized by low serum concentrations of Epo, but erythroid progenitors remain highly responsive to recombinant Epo in vitro.[249] Infants with the late anemia of Rh hemolytic disease routinely receive transfusions until their anemia spontaneously resolves, generally by the third or fourth month of life. During the period of decreased circulating antibody synthesis and delayed endogenous Epo production, administration of exogenous Epo may serve as an alternative to erythrocyte transfusion. In centers in which infants requiring transfusions are hospitalized, Epo administration also may diminish or eliminate the need for hospitalization, because this agent can be given in an outpatient setting. Preliminary studies evaluating the use of recombinant Epo for treatment of the late anemia of Rh hemolytic disease have shown it to be effective in stimulating reticulocyte production and increasing hematocrit.[249,250]

Anemia of Bronchopulmonary Dysplasia

Alverson and associates[251] observed the development of anemia in patients with bronchopulmonary dysplasia (BPD) and reported that repeat transfusions generally are required for management of anemia. Christensen and colleagues[252] subsequently characterized the anemia of BPD as normocytic, normochromic, hyporegenerative anemia, with marrow normoblast iron stains that are distinct from those observed in both the anemia of chronic disorders and the anemia of prematurity. Patients with the anemia of BPD differed from infants with the anemia of prematurity in that not all of the patients with the anemia of BPD were born prematurely, and their average age was older than that typical for infants with anemia of prematurity. Preliminary results show Epo to be effective for treatment for the anemia of BPD.[253] Further study is ongoing to determine the explanation for reduced Epo production in patients with BPD, including the evaluation of factors that could create a relatively Epo-resistant environment, such as IL-1, tumor necrosis factor, and interferon-γ.

Anemia in Neonates with Congenital Heart Disease

In an attempt to decrease transfusion requirements and possibly decrease the incidence of graft rejection, infants with congenital heart disease awaiting transplantation received daily Epo (200 U/kg/day).[254] These infants showed a significant increase in hematocrit and decreased transfusion requirements. Although case reports of infants undergoing open heart surgery have been published,[255] randomized controlled trials evaluating the use of Epo to decrease transfusion requirements of newborns with congenital heart disease should be completed before its widespread use in this population.

Anemia in Neonates Requiring Surgery

Many studies in adults have been performed evaluating the use of Epo as an adjuvant to transfusion before surgery. Pediatric studies are limited. Neonates who are born with problems that require surgical repair, such as omphalocele, gastroschisis, meningomyelocele, congenital diaphragmatic hernias, and craniofacial abnormalities, often undergo surgery during the period of physiologic anemia. These infants are hospitalized and sustain blood loss through phlebotomy, the surgery itself, and postoperative care. As a result, the physiologic anemia is exacerbated, and hemoglobin concentrations may drop to such a low level that transfusions are given. Pilot studies on the use of Epo in these populations have shown promise,[256] but randomized studies are required to determine whether these infants will respond to Epo administration by increasing erythropoiesis.

In addition to neonates who require surgery, other neonatal populations may benefit from Epo therapy. As in adults, Epo has been used successfully to treat anemia in newborns with end-stage renal disease.[257] In addition, infants with ABO incompatibility,[258] hemolytic disease from Kell antibody,[259] and hereditary spherocytosis[260] have shown increased erythropoiesis when treated with Epo. Further studies are required in these populations to determine whether treatment with Epo is beneficial and does not cause further harm through increased hemolysis and hyperbilirubinemia.

In view of transfusion-associated risks such as transmission of hepatitis or *Trypanosoma cruzi,* West Nile virus, or human immunodeficiency virus infection,[261-263] as well as the possible development of graft-versus-host disease,[264] treatment of anemic neonates using recombinant Epo may potentially be cost-effective. Thus Epo administration, in combination with the development of more rigorous and standardized transfusion criteria and the decrease in blood loss through phlebotomy, is likely to have the greatest impact in decreasing transfusion requirements in term and preterm infants. Regardless of treatment strategy, a critical understanding of the physiologic influences affecting oxygen delivery in term and preterm infants is required before attempts at altering the hematocrit through an erythrocyte transfusion or by the administration of Epo or another ESA.

Developmental Megakaryocytopoiesis

BACKGROUND

Megakaryocytes, among the rarest and most unusual hematopoietic cells in the human bone marrow, comprise 0.02% to 0.1% of the total nucleated marrow cells.[1,2] Over the past decades, the study of these cells lagged behind that of other hematopoietic lineages, partly because of the rarity and fragility of megakaryocytes in the bone marrow, and partly because of the lack of a potent thrombopoietic factor to stimulate the growth of these cells in culture.The cloning of thrombopoietin (Tpo) in 1994, the development of better culture systems, and the ability to employ flow cytometry to study megakaryocytes broke many of these barriers and led to major advances in our understanding of megakaryocytopoiesis. This chapter first summarizes these advances and our current knowledge about the biologic processes leading to platelet production and then focuses on what is known about fetal and neonatal megakaryocytopoiesis. Although many questions in this field remain unanswered, a mounting body of evidence suggests that fetal and neonatal megakaryocytes represent

a distinct lineage, with biologic features clearly different from those of their adult counterparts. The implications of these differences are widespread and expand beyond neonatal hematology into the field of cord blood transplantation, a therapy frequently complicated by delayed platelet engraftment.

MEGAKARYOCYTOPOIESIS

In a very schematic fashion, the complex process of platelet production can be represented as consisting of four main steps (Figure 145-1): (1) the production of thrombopoietic factors (mainly Tpo), (2) the proliferation of megakaryocyte progenitors, (3) the differentiation and maturation of megakaryocytes through a unique process of endomitosis, and finally (4) the production and release of platelets into the circulation. The first part of this chapter is dedicated to reviewing the biology of megakaryocyte progenitors, the differentiation and maturation of megakaryocytes, and the effects of thrombopoietic cytokines (particularly Tpo) on the different steps of the process. The second part summarizes our current understanding of neonatal thrombocytopenia, with an emphasis on the factors underlying the predisposition of ill neonates to develop severe and prolonged thrombocytopenia.

Megakaryocyte Progenitors

The development of the megakaryocytic lineage from pluripotent hematopoietic stem cells is not clearly understood. The classical model states that hematopoietic stem cells give rise to a common lymphoid progenitor, which produces lymphocytes, and a common myeloid progenitor, which gives rise to the myeloid, macrophage, eosinophil, erythroid, and megakaryocytic lineages.[3] In adults, erythroid and megakaryocyte lineages arise from a common megakaryocyte-erythroid progenitor (MEP),[4] and recent evidence indicates that the same is true in embryonic and fetal development.[5] However, this classical pathway of hematopoiesis has been questioned by recent findings suggesting that MEPs can arise directly from hematopoietic stem cells.[6] The specific signals that regulate the separation into the different lineages are not well understood and are the subject of active research efforts.

The first cells fully committed to the megakaryocyte lineage are the megakaryocyte progenitors. By definition, these cells have proliferative potential and are characterized by their ability to form clusters of pure megakaryocytes (megakaryocyte colonies) when cultured. Two different types of megakaryocyte progenitors have been identified. The most primitive megakaryocyte progenitor is the burst-forming unit–megakaryocyte (BFU-MK). A later, more mature progenitor has been designated colony-forming unit–megakaryocyte (CFU-MK). These two progenitor types can be differentiated on the basis of their immunologic markers and the characteristics of the colonies that they form in vitro (Table 145-1). Overall, CFU-MK-derived colonies appear in vitro sooner than BFU-MK-derived colonies. They are also smaller (usually <50 cells) and unifocal, compared with the large and multifocal appearance of BFU-MK colonies. CFU-MK progenitors are also the predominant MK progenitor type in the bone marrow, whereas BFU-MK progenitors predominate in the blood. Finally, although both progenitors express CD34, only CFU-MKs express the human leukocyte antigen (HLA)-DR.

Unlike megakaryocyte progenitors, which possess a high proliferative potential, megakaryocytes are cells that have lost the ability to proliferate but instead undergo a unique process known as *endomitosis*. The transition from megakaryocyte progenitors to mature megakaryocytes is characterized by a significant level of overlap, which gives rise to a population of cells known as *transitional cells*, *megakaryocyte precursors*, or *promegakaryoblasts*, which have increasing ploidy (4 to 8 N) and decreasing proliferative potential. These cells are thought to represent the intermediate step between progenitors and megakaryocytes and are difficult to identify morphologically. Immunologic

TABLE 145-1

Comparison of Primitive Megakaryocyte Progenitors (BFU-MK) and Differentiated Megakaryocyte Progenitors (CFU-MK)

Characteristic	BFU-MK	CFU-MK
Appearance in culture	Later	Earlier
Cells/colony	>50	3-50
Foci of development	≥2	1
Immunologic phenotype	$CD34^+$, $HLA\text{-}DR^-$	$CD34^+$, $HLA\text{-}DR^+$
Site of predominance	Peripheral blood and bone marrow	Bone marrow

From Sola MC. Fetal megakaryocytopoiesis. In Christensen R (ed): *Hematologic Problems of the Neonate,* Philadelphia, 2000, WB Saunders.

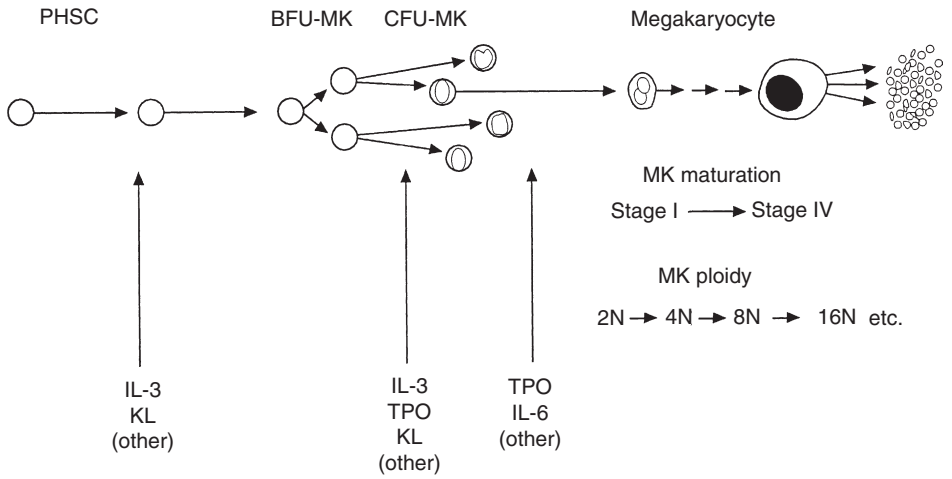

Figure 145-1 Simplified scheme of megakaryocyte (MK) development. Many growth factors probably influence megakaryocytopoiesis at each stage. In some studies, the synergistic effect of interleukin-3 (IL-3) and thrombopoietin (TPO) was demonstrated. IL-3 seems to be essential for early megakaryocyte proliferation (especially fetal) from pluripotent hematopoietic stem cell (PHSC) through colony-forming unit, megakaryocyte (CFU-MK). Although many factors affect megakaryocyte maturation, TPO is probably the primary stimulant. *BFU,* Burst-forming unit.

studies have suggested that transitional cells express both CD34 and CD61 (GPIIIa).[7] One transitional cell may also be the megakaryoblast, the earliest cell of the megakaryocyte lineage that can be identified with the platelet peroxidase reaction.[8] During this phase, the cells begin to accumulate various α-granule proteins: platelet factor 4 (PF4), thrombospondin, β-thromboglobulin, von Willebrand factor, and surface markers such as platelet GPIb and the von Willebrand factor receptor,[9] which can later be detected on megakaryocytes (Figure 145-2).[10-14]

Megakaryocytes

Megakaryocytes are cells that have lost their proliferative abilities and undergo a complex process of maturation. Through this process, they evolve from small, mononuclear cells that are indistinguishable from those of other lineages, to very large, polyploid cells that are easily recognized as megakaryocytes. The process of maturation involves both nuclear and cytoplasmic changes as well as a corresponding increase in size. At the nuclear level, maturation involves a process known as *endoreduplication* or *endomitosis*, by which the ploidy of the cells increases. The ploidy level of megakaryocytes can be measured on stained individual cells in a cytospin, in a colony, or by flow cytometry. Using the latter technique, the modal ploidy in adult marrow has been shown to be 16 N. Recently, it has also been demonstrated that increasing ploidy levels directly correlate with increased platelet production by megakaryocytes.[15] Eventually, as platelets are released, the megakaryocytes become smaller, and multiple nuclear lobes coalesce into a compact nucleus.[16]

Based on a combination of size and nuclear and cytoplasmic features, the maturational stages of the megakaryocytes have been classified as stages I to IV (Table 145-2). This morphologic classification is often difficult, however, particularly because megakaryoblasts and stage I and II megakaryocytes can easily be missed on microscopic examination. For these reasons, other criteria have been established for megakaryocyte differentiation and to define various maturational stages, including the development of surface glycoproteins and the appearance of specific granules.[10,12] For example, GPIIIa and GPIIb/IIIa are present in very early megakaryocytes, whereas GPIb (CD42b) and GPIV (CD36) appear later during megakaryocyte maturation (see Figure 145-2).[11,17,18] The GPIb-V-IX (CD42) complex has also been identified on late megakaryocytes.[19] The development of the demarcation system and of α-granules has been documented by electron microscopy. Contents of the α-granules, such as fibrinogen, thrombospondin, and von Willebrand factor, also correlate with megakaryocyte maturation.[11,12,14] Fibrinogen appears late in megakaryocyte maturation.

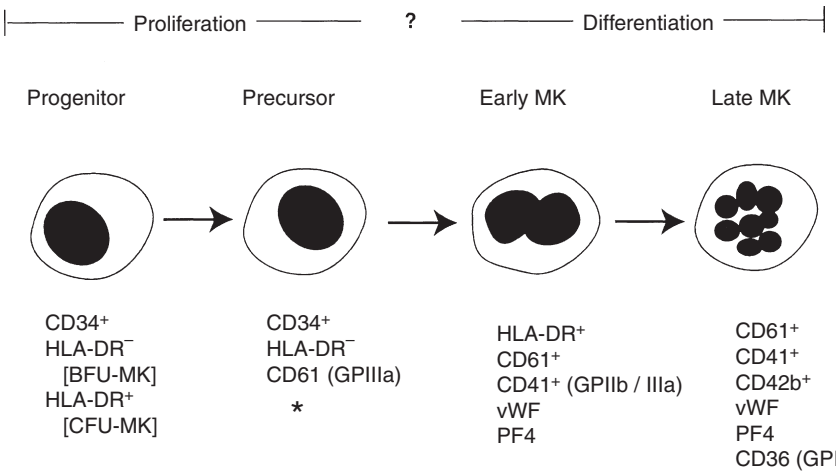

Figure 145-2 Immunologic classification of megakaryocyte (MK) development. Burst-forming unit, megakaryocyte (BFU-MK), and colony-forming unit, megakaryocyte (CFU-MK), are considered progenitor cells. CFU-MK may transition into a precursor cell that still retains proliferative potential. Fragmentary data on various stages of megakaryocyte differentiation suggest a chronologic appearance of specific platelet glycoproteins (GP) and other platelet antigens such as von Willebrand factor (vWf) and platelet factor 4 (PF4). The *asterisk* indicates that megakaryocyte antigens CD41 (GPIIb/IIIa) and CD41a (GPIIb) may be expressed on an earlier cell of the megakaryocyte lineage that retains proliferative capacity.

TABLE 145-2

Cytologic Characteristics of Megakaryocyte Maturation States and Nuclear-Cytoplasmic Ratios at Each State*

Stage	Nuclear Morphology	Cytoplasmic Staining (Wright-Giemsa)	Approximate Size Range	Demarcation Membranes	Granules	Suggested Name
I	Compact (lobed)	Basophilic	6-24 μm	Present by electron microscopy	Few present by electron microscopy	Megakaryoblast
II	Horseshoe	Pink center	10-30 μm	Proliferating to center of cell	Starting to increase	Promegakaryocyte
III	Multilobed	Increasingly more pink than blue	16-56 μm	Extensive but asymmetric	Great numbers	Granular megakaryocyte
IV	Compact but highly lobulated	Eosinophilic	20-50 μm	Evenly distributed	Organized into platelet fields	Mature megakaryocyte

Modified from Williams N, Levine RF: The origin, development and regulation of megakaryocytes. *Br J Haematol* 52:173-180, 1982.
*Much of the size variation for each stage is related to ploidy level.

Transcriptional Regulation of Megakaryocytopoiesis

The process of megakaryocytopoiesis is carefully coordinated by a number of transcription factors responsible for regulating the expression of megakaryocyte-specific genes. Some of the best understood transcription factors that play a role in megakaryocytopoiesis are summarized here.

The GATA family of transcription factors plays key roles in normal hematopoiesis. GATA-1, a 47-kDa protein with the corresponding DNA sequence mapped to the X-chromosome, is required for terminal differentiation of both erythroid and megakaryocytic cell lines. GATA-1 contains three functional domains: two zinc fingers (N- and C-) and an N-terminal activating domain. The C-finger binds to GATA-1 binding sites.The N-finger provides stability during DNA binding, and recruits the cofactor Friend of GATA-1 (FOG-1). Interaction with FOG-1 is necessary for normal hematopoiesis, as demonstrated by the presence of anemia and thrombocytopenia in individuals with *GATA1* mutations that interfere with the binding of FOG-1.[20] The N-terminal activating domain confers transcriptional activity.[21]

Specific GATA1 knockout mice models have demonstrated the necessity of GATA1 in normal hematopoiesis. GATA1-null mice die during gestation from severe anemia. GATA1 mice have normal GATA1 expression in erythroid cells but decreased expression in megakaryocytes. These mutants have thrombocytopenia without anemia, with platelet counts approximately 15% of normal. Morphologically, GATA1-deficient megakaryocytes are also abnormal: small size, large segmented nuclei, scant cytoplasm, and decreased ploidy compared with wild-type cells.[21-22] Several *GATA1* mutations have been described in patients with thrombocytopenia, usually characterized by the presence of large platelets (macrothrombocytopenia).

Calligaris and colleagues first described a short isoform of GATA-1, termed GATA-1 short (GATA-1s).[23] This isoform is 40 kDa in size, compared with the 47-kDa full-length protein, and is produced by the initiation of translation of the GATA-1 transcript at amino acid 84.The resultant protein lacks the N-terminal transactivation domain.The authors demonstrated both transcripts in K-562 cells, a human erythroleukemia cell line with the ability to differentiate into erythroid and megakaryocytic cells, and in murine fetal liver. GATA-1s plays an important role in the pathogenesis of transient myeloproliferative disorder (TMD) and acute megakaryoblastic leukemia (AMKL) seen in Down syndrome. Multiple mutations in the *GATA1* gene have been described in these patients, all of which reside within exon 2 of the GATA-1 transcript and result in the exclusive production of GATA-1s. The megakaryocyte phenotype of these patients is characterized by increased proliferation and maturational arrest of erythromegakaryocytic cells.[24]

FOG-1 is an essential cofactor for proper megakaryocytopoiesis. Single point mutations (V205M, D218G D218Y, G208S) have been described, which result in reduced GATA-1 and FOG-1 interaction and a phenotype of macrothrombocytopenia with anemia.[21] Mice engineered with complete absence of FOG-1 have a complete absence of megakaryocyte progenitors. PF4 and GPIIB (early megakaryocyte transcripts) are detectable in these models, implying an impaired differentiation and replication of early megakaryocyte lineage cells. These data taken together suggest that FOG-1 plays multiple roles in megakaryopoiesis at both early and later stages.[21,25]

NF-E2 is a transcription factor found in erythroid, megakaryocytic, and mast cells. In megakaryocytes, NF-E2 regulates B-tubulin, a major component of microtubulin. Microtubulin formation is required for proplatelet formation and subsequent release of platelets from the megakaryocyte. Loss of NF-E2 results in increased numbers of megakaryocytes with a disorganized internal membrane and impaired release of proplatelets, leading to thrombocytopenia and a lethal coagulopathy in the neonatal period with only a mild decrease in erythropoiesis.[25,26]

Friend Leukemia Integration-1 (Fli-1) is a member of the Ets family of transcription factors. It is expressed in hematopoietic cell lines as well as vascular endothelial cell lines and regulates expression of multiple megakaryocyte proteins, including GATA-1, GPIb, IIb, VI, and XI, and c-mpl. In K-562 cells, expression of Fli-1 results in increased CD-41 and CD-61 expression. In murine knockout models, loss of Fli-1 results in embryonic death due to hemorrhage (related to a state of defective vasculature) as well as dysmegakaryocytopoiesis with immature-appearing megakaryocytes that express early genes (αIIB and cMpl) but diminished expression of late genes (GPIX). Disruption of Fli-1 expression caused by a terminal deletion in chromosome 11 underlies Paris-Trousseau syndrome, which is characterized by thrombocytopenia with platelets that display large α-granules. This clinical phenotype can occur independently or as part of Jacobsen syndrome (platelet defects with cardiac anomalies, facial anomalies, mental retardation). In both instances, megakaryocytes are increased in number but have a diminished number of α-granules as well as a disorganized internal membrane.[25,27]

The Ets family of transcription factors is characterized by the presence of a highly conserved winged helix-turn-helix DNA binding domain (ETS domain) that allows recognition of purine-rich DNA sequences with a core GGA(A/T) consensus, designated EBS (Ets binding sequence). Ets-1 is up-regulated in megakaryocytopoiesis, and Ets binding sites (EBS) have been identified in many megakaryocyte-specific gene promoters. Overexpression of Ets-1 in cultured megakaryocyte cells results in a state of increased proliferation with larger megakaryocytes that have an increased number of nuclear lobes. Gene expression studies in these same cells reveals increased GATA-2, GPIIb, and PF4, indicating that Ets-1 promotes megakaryocyte differentiation.[28,29]

Cytokine Effects on Megakaryocytopoiesis

Before the cloning of Tpo, the prevalent theory was that two different growth factors were responsible for the proliferation of megakaryocyte progenitors and for the maturation of megakaryocytes. These putative factors, although not isolated, were called megakaryocyte colony-stimulating factor (MK-CSF) and Tpo. MK-CSF was thought to be the primary stimulant of proliferation, whereas Tpo was thought to stimulate the maturation of megakaryocytes, leading to increased platelet production.

CFU-MK proliferation was noted in the presence of serum from patients or animals with aplastic anemia, or when hematopoietic progenitor cells were cultured in media from human embryonic kidney cell cultures.[30,31] These therefore became widely used biologic sources of thrombopoietic factors. However, all attempts to isolate and purify MK-CSF or Tpo from these sources failed, until the fortuitous discovery in the early 1990s of a viral myeloproliferative leukemia virus oncogene *(v-mpl)*, whose structure suggested that it was a member of the hematopoietic growth factor superfamily.[32] Surprisingly, the cellular homologue of this viral oncogene (termed cellular myeloproliferative leukemia virus, or *c-mpl*) was found to be expressed almost exclusively in $CD34^+$ cells, megakaryocytes, and platelets.[33-36] These discoveries led to the hypothesis that *c-mpl* was likely the orphan receptor for Tpo, and triggered an active search for its ligand. The search culminated in 1994 with the almost simultaneous isolation of the new thrombopoietic growth factor by four different groups, each one of which assigned the protein a different name: MPL ligand,[37] Tpo,[38] megakaryocyte growth and development factor (MGDF),[39] and megapoietin.[40] Except for species-related differences, all groups sequenced the same protein: the elusive Tpo had finally been found.

Using fluorescence in situ hybridization, the gene that encodes Tpo was localized to the long arm of human chromosome 3,[41,42] and specifically to 3q26-27, an area that has been linked with thrombocytosis in acute nonlymphocytic leukemia.[43-45] The *THPO* gene

is composed of five coding exons, similar to the five erythropoietin exons.[46] The protein is composed of 332 amino acids, divided into two domains: an active amino-terminal half (153 amino acids) with marked homology to erythropoietin, and a carboxyl-terminal domain with 179 aminoacids.[41] At all stages of development (i.e., during fetal, neonatal, and adult life), the main site of Tpo production is the liver,[38,47,48] although Tpo expression has also been identified in the kidneys, spleen, and bone marrow.[47,49] In response to severe thrombocytopenia, however, the usually low level of Tpo messenger RNA (mRNA) expression in bone marrow stromal cells increases greatly.[49] One study has shown that platelet-derived growth factor (PDGF) and fibroblast growth factor-2 (FGF-2), both platelet α-granule proteins, might mediate this increase.[50]

The regulation of Tpo production has also been the object of extensive research. Early studies by several investigators demonstrated that, in steady-state and in noninflammatory conditions (i.e., idiopathic thrombocytopenia [ITP], aplastic anemia), hepatic Tpo production was constitutive; circulating Tpo levels were inversely related to the concentration of available c-mpl receptors and therefore to the platelet and megakaryocyte mass.[51-54] Although this model seems to apply to most conditions, it was challenged by the finding of elevated Tpo levels in patients with thrombocytosis associated with inflammatory conditions, such as infections or Kawasaki disease.[55] Indeed, more recent studies demonstrated that hepatic Tpo expression is up-regulated in response to interleukin-6 (IL-6) both in vitro and in vivo.[56,57] Because an anti-Tpo antibody neutralizes the thrombopoietic effect of IL-6, it is now evident that this is the pathway responsible for inflammation-induced thrombocytosis[55] (Figure 145-3).

Defects in the Tpo/c-mpl axis have also been recognized as the etiology of several human disorders. Specifically, c-mpl mutations causing frameshifts and early termination cause congenital amegakaryocytic thrombocytopenia, a disorder typically characterized by severe thrombocytopenia and absence of megakaryocytes beginning in infancy.[58,59] In contrast, activating mutations in the Tpo gene promoter[60] or in the c-mpl receptor[61] have been found in a subset of patients with familial essential thrombocythemia.

In the years following the isolation of Tpo, multiple in vitro and in vivo studies were conducted to characterize the role of this cytokine. It quickly became evident that Tpo acted both as a potent proliferative factor (MK-CSF) and as a maturational factor,[62,63] at least on murine and *adult* human megakaryocytes (see later). Initial reports that Tpo did not stimulate the maturation of human megakaryocytes likely were due to the use of *cord blood* CD34$^+$ cells in a number of studies,[64] which (unlike *adult* progenitor cells) do not generate high-ploidy megakaryocytes in response to Tpo.[65] The role of Tpo on the terminal stages of megakaryocyte maturation and proplatelet formation has been less clearly established, and it is currently believed that this cytokine does not play a major role on those processes.[66,67] In vitro studies also have suggested that Tpo plays a role in platelet activation, mostly priming the platelets to the effects of other agonists.[68] However, these effects have not been confirmed in vivo.[69,70] Tpo and *c-mpl* knockout mice exhibit platelet counts equivalent to 10% to 15% of wild-type mice and greatly decreased marrow megakaryocytes,[71,72] but the mice are otherwise healthy and viable. This suggests that Tpo is the primary regulator of platelet production, but that alternative pathways exist for megakaryocytopoiesis. Further studies also have shown that the Tpo/c-mpl axis functions in early hematopoietic progenitors (including hematopoietic stem cells), disclosing an important role for Tpo in hematopoiesis in general, in addition to its megakaryopoietic functions.[73,74] These findings have significant clinical implications for patients with disorders affecting this axis, such as individuals with congenital amegakaryocytic thrombocytopenia, who frequently progress to aplastic anemia.

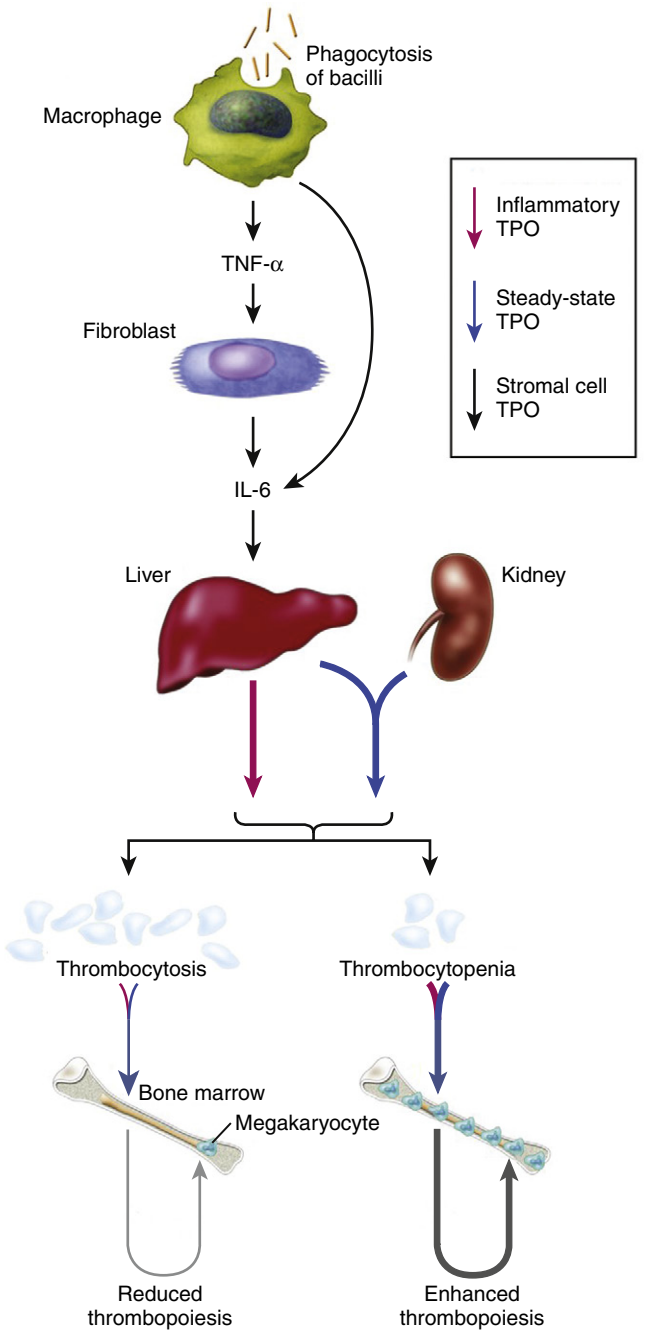

Figure 145-3 The regulation of thrombopoietin levels. A steady-state amount of hepatic thrombopoietin (TPO) is regulated by platelet c-Mpl receptor-mediated uptake and destruction of the hormone. Hepatic production of the hormone is depicted. Upon binding to platelet c-Mpl receptors, the hormone is removed from the circulation and destroyed, which reduces blood levels. In the presence of inflammation, interleukin-6 (IL-6) is released from macrophages and, through tumor necrosis factor-α (TNF-α) stimulation, from fibroblasts and circulates to the liver to enhance TPO production. Thrombocytopenia also leads to enhanced marrow stromal cell production of TPO, although the molecular mediator of this effect is not yet completely understood. *(From Kaushansky K: The molecular mechanisms that control thrombopoiesis,* J Clin Invest *115:3339-3347, 2005.)*

The cloning of Tpo in 1996 led to a flurry of studies that quickly progressed from bench research to animal studies and then to clinical trials, mostly using the full-length recombinant Tpo (rTpo) molecule or a recombinant human polypeptide that contains the receptor-binding N-terminal domain of Tpo (termed *megakaryocyte growth and development factor*, or rhMGDF). When injected into normal animals, rTpo or rhMGDF induced significant thrombocytosis, with peak mean platelet counts up to 670% of baseline.[69,75-78] When administered to animals exposed to myelosuppressive chemotherapy, rhMGDF ameliorated or completely prevented the associated thrombocytopenia[75] and also accelerated red blood cell and neutrophil recovery.[79,80] Most human studies were conducted using a pegylated form of rhMGDF (PEG-rhMGDF, a molecule 5 to 10 times more potent in vivo than the unconjugated polypeptide).[69] In phase I and II clinical trials, rTpo and PEG-rhMGDF potently stimulated platelet production in nonthrombocytopenic adults[81,82] and in patients with chemotherapy-induced thrombocytopenia.[83,84] However, trials showed limited efficacy in the setting of thrombocytopenia associated with myeloablation and stem cell transplantation.[85] In addition, a number of subjects treated with PEG-rhMGDF developed neutralizing antibodies against endogenous Tpo, which resulted in severe thrombocytopenia and aplastic anemia.[86] Ultimately, these complications led to the discontinuation of clinical trials involving any of these forms of recombinant Tpo.

As an alternative, much interest was directed to the development of thrombopoietin-mimetic molecules. These are small molecules that have no sequence homology to Tpo but bind to the Tpo receptor and have biologically comparable effects. The lack of homology represents a significant advantage over recombinant forms of Tpo because it should preclude the development of cross-reactive neutralizing antibodies against endogenous Tpo. At least five different thrombopoietin receptor agonists have been described,[85-87] and three have been studied in human subjects.[88-91] In 2006, Bussel and colleagues published a phases I and II trial of AMG 531 for the treatment of patients with ITP.[89] AMG 531 is an engineered peptibody composed of a recombinant protein carrier FC domain linked to multiple c-mpl binding domains. Forty-five thrombocytopenic patients who had received at least one previous treatment for ITP were enrolled in a phase I or II trial of AMG 531 therapy (24 and 21 patients, respectively). The phase I study demonstrated a dose-dependent increase in platelet counts in response to AMG 531. Overall, a platelet count of at least 50×10^9/L was achieved in 7 of 12 patients given two doses of 3, 6, or 10 μg of AMG 531. In the phase II study, 12 of 16 patients treated with six weekly doses of 1 or 3 μg/kg of AMG 531 reached or exceeded the targeted platelet range (50 to 450×10^9/L). None of the patients had neutralizing antibodies to AMG 531 or thrombopoietin, and the only adverse events attributable to the study drug were headache and transient posttreatment worsening of the thrombocytopenia. Similar results were reported by Newland and co-workers,[90] who performed a phases I and II multicenter trial in Europe in which 16 patients received escalating doses of AMG 531 (30, 100, 300, or 500 μg administered subcutaneously on days 1 and 15 of study). Platelet counts increased to or above the targeted range in 8 of 11 patients who received a dose equivalent to 1 μg/kg or more. The most frequently reported adverse event was headache, and one patient experienced a transient increase in lactic dehydrogenase. No anti–AMG 531 or anti-Tpo antibodies were detected. In 2007, Jenkins and associates[88] also published a phase I placebo-controlled clinical study involving Eltrombopag (SB-497115), an oral, nonpeptide thrombopoietin receptor agonist. In this trial, 73 healthy male subjects received eltrombopag as once-daily oral capsules for 10 days, at doses of 5, 10, 25, 30, 50, and 75 mg/day. Eltrombopag increased platelet counts in a dose-dependent manner, without adverse events attributable to the study drug. In 2008, both AMG 531 (romiplostim) and eltrombopag were approved by the Food and Drug Administration for the treatment of adults with chronic ITP.

Many other growth factors affect megakaryocyte colony growth in vitro. IL-11 also increases megakaryocyte proliferation in vitro, but not in the absence of other thrombopoietic stimulants.[92] Recombinant IL-11 (rIL-11) has been released for clinical use and is approved by the U.S. Food and Drug Administration as a thrombopoietic agent. Studies have shown that rIL-11 stimulates megakaryocytopoiesis in adults and children.[93,94] However, it is also associated with significant flulike symptoms and fluid retention. In addition, at least in one study involving patients with refractory ITP, rIL11 administration resulted in significant side effects combined with a lack of efficacy, leading to early termination of the trial.[95]

Granulocyte-macrophage CSF (GM-CSF) and IL-3 stimulate megakaryocytopoiesis, alone or in combination.[96,97] A synergistic effect of IL-3 and GM-CSF has also been documented.[97] IL-6 affects megakaryocytopoiesis *in vitro*, and megakaryocyte maturation in particular.[98-100] IL-6 also promotes CFU-MK proliferation of in vitro human marrow cultures, although the effect is less than that seen with IL-3 or GM-CSF.[101] The IL-6 receptor has been identified on megakaryocytes by in situ hybridization techniques, and the administration of IL-6 to suspension cultures increases ploidy.[102] In nonhuman primates, recombinant human IL-6 has been shown to affect megakaryocytopoiesis in vivo.[103-105] Recombinant IL-6 (5 to 80 μg/kg/day), injected twice daily for 14 days, caused dose-related increases in platelets and a shift to larger megakaryocytes in the bone marrow, indicating a maturational effect.[103] In a clinical phases I and II study, recombinant human IL-6 was administered to 20 patients with cancer.[106] Doses of 0.5 to 20 μg/kg/day were used. Increases in platelet counts were noted at doses higher than 1 μg/kg/day. Side effects included fever, headache, myalgia, and erythema. At doses higher than 2.5 μg/kg, nausea, elevated liver enzymes, and anemia were noted.

Numerous additional growth factors participate in the process of megakaryocytopoiesis, although their roles have been less extensively studied. These include erythropoietin,[107] stem cell factor,[108-109] vascular endothelial growth factor (VEGF),[110,111] IL-1,[112] stromal cell–derived factor (SDF),[113,114] basic FGF,[114,115] interferon-γ,[116] PDGF,[117] and nicotinamide.[118] Some factors have been shown to be potent inhibitors of thrombopoiesis, including transforming growth factor-TGF-β[119] and platelet factor 4 (PF4).[120,121]

FETAL AND NEONATAL MEGAKARYOCYTOPOIESIS

Fetal Megakaryocyte Progenitors

The study of fetal megakaryocytopoiesis is intrinsically difficult because of the low frequency of megakaryocytes in fetal bone marrow and the limited availability of neonatal bone marrow specimens. Because of that, most studies have been performed using umbilical cord blood, from which large quantities of megakaryocyte progenitors can be readily obtained. Olson and associates[122] found a significantly higher concentration of CFU-MK progenitors in term and preterm cord blood than in adult peripheral blood. Furthermore, when stimulated with previously irradiated aplastic canine serum, cord blood CFU-MK-derived colonies contained significantly more megakaryocytes than adult colonies. Zauli and co-workers[123] compared fetal blood– and adult bone marrow–derived megakaryocyte colonies. Hematopoietic progenitors ($CD34^+$ cells) were obtained from the blood of fetuses between 18 and 22 weeks gestation or from adult bone marrow and were cultured in a fibrin clot assay. They found that, as in adult blood, BFU-MKs predominate in fetal blood, with a CFU-MK–BFU-MK ratio of 0.4:1. Fetal and adult megakaryocyte progenitors had similar immunologic profiles with regard to the expression of CD34 and HLA-DR. However, there were significant differences in the morphology and size of the BFU-MK-derived colonies: the fetal BFU-MK-derived colonies were significantly larger than the adult colonies and were

usually composed of only one or two foci of development, whereas the adult BFU-MK-derived colonies were always multifocal.

Other investigators also reported the existence of a megakaryocyte progenitor with an unusually high proliferative potential in the human fetal bone marrow. Bruno and colleagues[124] described a high proliferative potential cell–megakaryocyte (HPPC-MK) in fetal bone marrow that gives rise to large, unifocal colonies with more than 300 cells. This cell, not observed in adult bone marrow cultures, may represent a more primitive megakaryocyte progenitor. Nishihira and associates[125] cultured cord blood hematopoietic progenitors (26 to 41 weeks gestation) with optimal concentrations of rTpo and found that all colonies consisted of more than 50 cells and that 50% had more than 500 cells. It is unclear whether these colonies should be classified as BFU-MK- or HPPC-MK-derived colonies.

The development of miniaturized assay systems to study megakaryocyte progenitors made it possible to study these cells in the peripheral blood of neonates. Using such a technique, Murray and collaborators[126] showed that preterm neonates (24 to 36 weeks gestation) in the first day of life had higher circulating concentrations of all megakaryocyte progenitors than term neonates. This finding was in concordance with the previously described gestational age-related decrease in the concentration of other committed hematopoietic progenitors.[127] Saxonhouse and associates[128] also observed an inverse relationship between the concentration of circulating megakaryocyte progenitors and the postconceptional age (gestational age + weeks of life) of growing preterm infants being cared for in the neonatal intensive care unit, suggesting that the gestational age–dependent decrease in circulating megakaryocyte progenitors is a process that continues after birth in infants born prematurely.

Based on the premise that circulating megakaryocyte progenitors are a reflection of bone marrow megakaryocytopoiesis, investigators applied these assays to the evaluation of thrombocytopenic neonates. Murray and Roberts[129] quantified circulating megakaryocyte progenitors in preterm neonates with early thrombocytopenia secondary to maternal preeclampsia or intrauterine growth restriction. They observed that the concentration of circulating progenitors in those neonates was significantly lower than in nonthrombocytopenic preterm neonates, and increased as the thrombocytopenia resolved, suggesting that decreased platelet production underlies this variety of thrombocytopenia. Other investigators have used the concentration of circulating megakaryocyte progenitors in combination with other tests to evaluate the mechanisms of thrombocytopenia in neonates with congenital HIV infection[130] and congenital amegakaryocytic thrombocytopenia.[131]

Fetal and Neonatal Megakaryocytes

The yolk sac appears to be the first hematopoietic site.[132] Megakaryocytes have been observed in the yolk sac by 5 weeks gestation,[133] and the first platelets appear in the circulation at 8 to 9 weeks.[134] The transition to hepatic hematopoiesis is thought to involve migration of stem cells from the yolk sac to the liver.[135] Bleyer and colleagues documented that megakaryocytes were present in liver and spleen tissue by 10 weeks gestation.[136] Every stage of megakaryocyte development could be found in the liver phase, although megakaryocytes at every stage were smaller than their adult counterparts.[137-139] Fetal bone marrow hematopoiesis has been documented as early as 11 weeks gestation, when megakaryocytes constitute 0.58% of the nucleated cells (this percentage increases to 1.2% by week 22).[140] By 18 weeks gestation, hematopoiesis is well established in the fetal bone marrow.[139,141-143]

Using different cell sources and techniques, several investigators evaluated the size and ploidy of megakaryocytes in fetuses and neonates. Allen Graeve and de Alarcon[143] studied the size and maturational stage of fetal bone marrow megakaryocytes from 20 human fetuses with 12 to 21 weeks gestation. They reported that, at all stages of maturation, fetal megakaryocytes were substantially smaller than adult megakaryocytes (Table 145-3). There were also less stage IV megakaryocytes in fetal bone marrow compared with adult marrow, reflecting a shift toward less mature megakaryocytes during fetal life (Table 145-4). These investigators[143] also reported lower megakaryocyte ploidy levels in fetal bone marrow biopsy specimens compared with adult bone marrow megakaryocytes.

Hegyi and co-workers[144] cultured megakaryocytes from livers obtained from 8- to 20-week fetuses and from cord blood and compared their size, maturity, and ploidy with that of cultured adult bone marrow megakaryocytes. These investigators found a progressive shift to higher ploidy classes and to larger megakaryocytes during development. Using ultrastructural techniques, they also evaluated the maturity stage of the very small liver megakaryocytes and found that they had all the cytoplasmic components of a mature cell, with multiple granules and a well-developed demarcation system. These findings supported previous observations by Kelemen and associates, who stated that "megakaryocytes with only one to four nuclei produce the platelets of the fetus."[145] Later studies by Ma and co-workers[146] also reported a developmentally regulated shift toward larger and more mature megakaryocytes during gestation. Despite this shift, however, 78% of megakaryocytes in the bone marrow of fetuses with 7 to 8 months gestation had a ploidy of 8 N or less, compared with only 33% of the megakaryocytes in adult bone marrow.

Similar results to those evaluating cultured megakaryocytes or fetal necropsy specimens (which can be associated with artifacts) were also obtained when megakaryocytes elutriated from term cord blood were examined. Levine and associates[147] reported that cord blood contained significantly larger numbers of circulating megakaryocytes than adult blood. As in the fetus, cord blood megakaryocytes were significantly smaller and had less nuclear lobulations than adult megakaryocytes but were otherwise mature cells. These investigators suggested that these small but mature cells were the result of a left shift in the megakaryocyte ploidy.

In summary, megakaryocytes of fetuses and neonates are smaller and of lower ploidy than those of adults. In 2002, Mattia

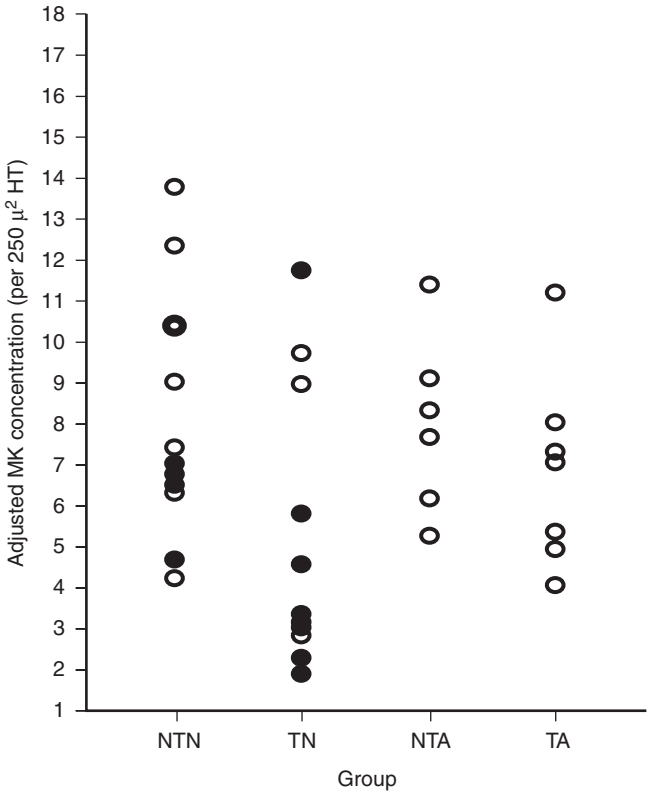

Figure 145-4 Megakaryocyte concentration (per 250 μm² of hematopoietic tissue), after correcting for differences in cellularity, in nonthrombocytopenic neonates (NTN), thrombocytopenic neonates (TN), nonthrombocytopenic adults (NTA), and thrombocytopenic adults (TA) (chronic idiopathic thrombocytopenia [ITP]). Bone marrow megakaryocytes were immunohistochemically stained with an anti-CD61 antibody and quantified using an eyepiece reticle that measured 250 μm² in nine small squares. After adjusting for differences in cellularity between the samples (particularly between neonatal and adult samples), the megakaryocyte concentration was expressed as megakaryocytes per 250 μm² of hematopoietic tissue. As evident in the figure, thrombocytopenic neonates had decreased, normal, or increased concentrations of megakaryocytes, likely reflecting the different etiologies of the thrombocytopenia. *(Modified from Sola-Visner M, Christensen RD, Hutson AD, Rimsza LM: Megakaryocyte size and concentration in the bone marrow of thrombocytopenic and nonthrombocytopenic neonates,* Pediatr Res *61:481, 2007.)*

and associates demonstrated that decreased ploidy levels are associated with decreased levels of platelet production.[15] Thus it is reasonable to assume that megakaryocytes of neonates produce fewer platelets than their adult counterparts and that the normal platelet counts found in *healthy* fetuses and neonates are maintained by the increased proliferative rate of fetal and neonatal megakaryocyte progenitors. To determine whether (and how) these developmental differences affect the ability of neonates to increase platelet production in response to thrombocytopenia, our group examined the megakaryocyte concentration and size in the bone marrow of 13 thrombocytopenic and 13 nonthrombocytopenic neonates, using a combination of immunohistochemistry and image analysis. We observed significant variability in marrow megakaryocyte concentration among thrombocytopenic neonates, with some neonates having less, some similar, and some increased megakaryocytes compared with their nonthrombocytopenic counterparts (Figure 145-4). In regard to the megakaryocyte diameter, we confirmed that megakaryocytes were smaller in neonates than in adults and observed that thrombocytopenic neonates (unlike adults) did not exhibit an increased percentage of large megakaryocytes, compared with nonthrombocytopenic neonates (Figure 145-5). These findings suggested that adult megakaryocytes respond to thrombocytopenia by increasing cell size, whereas neonatal megakaryocytes do not. The mechanisms underlying the small size of neonatal megakaryocytes are not clearly understood but likely involve a combination of cell-intrinsic factors and factors in the fetal and neonatal microenvironment. This was demonstrated in 2005 by Slayton and associates,[148] who transplanted neonatal liver cells or adult bone marrow cells from green fluorescent protein (GFP) transgenic mice into wild-type adult recipients and evaluated the size and ploidy of the donor-derived (GFP^+) megakaryocytes. Megakaryocytes derived from neonatal stem and progenitor cells, placed in an adult environment, were significantly larger and of higher ploidy than neonatal megakaryocytes in their original environment (fetal liver). However, they were still smaller than posttransplantation megakaryocytes derived from adult bone marrow cells. In vitro studies culturing cord blood $CD34^+$ cells in adult bone marrow stromal cell–conditioned media also yielded megakaryocytes with higher ploidy levels than those cultured in fetal bone marrow stromal cell–conditioned or in unconditioned serum-free media.[65] Taken together, these findings suggest that the environment influences the size and ploidy of megakaryocytes (with the adult environment being more conducive to megakaryocyte maturation) but that cell-intrinsic factors limit the ultimate size and ploidy that neonatal megakaryocytes achieve. Adult-size megakaryocytes have been found by 2 years of age, although insufficient data exist on children from birth to 1 year of age, owing to the lack of normal marrow specimens.

Thrombopoietin in Neonates

After the identification of Tpo as the primary regulator of megakaryocytopoiesis, several investigators evaluated Tpo concentrations in cord blood and in the blood of neonates.[47,149-154] Overall, median Tpo concentrations in neonates ranged between 76 and 191 pg/mL and were slightly higher in serum than in plasma. With the exception of the study by Albert and collaborators,[154] which reported higher Tpo concentration in preterm compared with term neonates, these studies found no obvious gestational age–related changes in plasma or serum Tpo concentrations and no correlation with platelet counts. However, all studies reported Tpo concentrations in neonates that were threefold to fourfold higher than in healthy adults. The reasons underlying this finding are unclear and might involve an increased rate of Tpo production, decreased Tpo clearance, alternative mechanisms of Tpo regulation, or a reduced number of *c-mpl* receptors.[155] In support of the last hypothesis, Kuwaki and associates described a significantly lower number of *c-mpl* receptors in megakaryocytes derived from cord blood cells than in those derived from adult bone marrow cells.[156] To determine when Tpo levels transitioned from normal neonatal to adult concentrations, Ishiguro and collaborators[153] measured Tpo concentrations in healthy neonates, children, and adults. In this study, Tpo concentrations increased shortly after birth, reached a peak on the second day of life, and returned to cord blood levels by the end of the first month. They then decreased gradually until adult levels were reached (Figure 145-6).

Several investigators also evaluated Tpo concentrations in neonates with different varieties of thrombocytopenia,[130,131,154,157-159] and some correlated those with other measures of thrombopoiesis, such as marrow megakaryocytes[130,131,152] or circulating megakaryocyte progenitors.[130,131,149,150] Overall, these investigators found great variability in Tpo concentrations among thrombocytopenic neonates and no strong correlation with platelet counts, probably reflecting the different mechanisms underlying

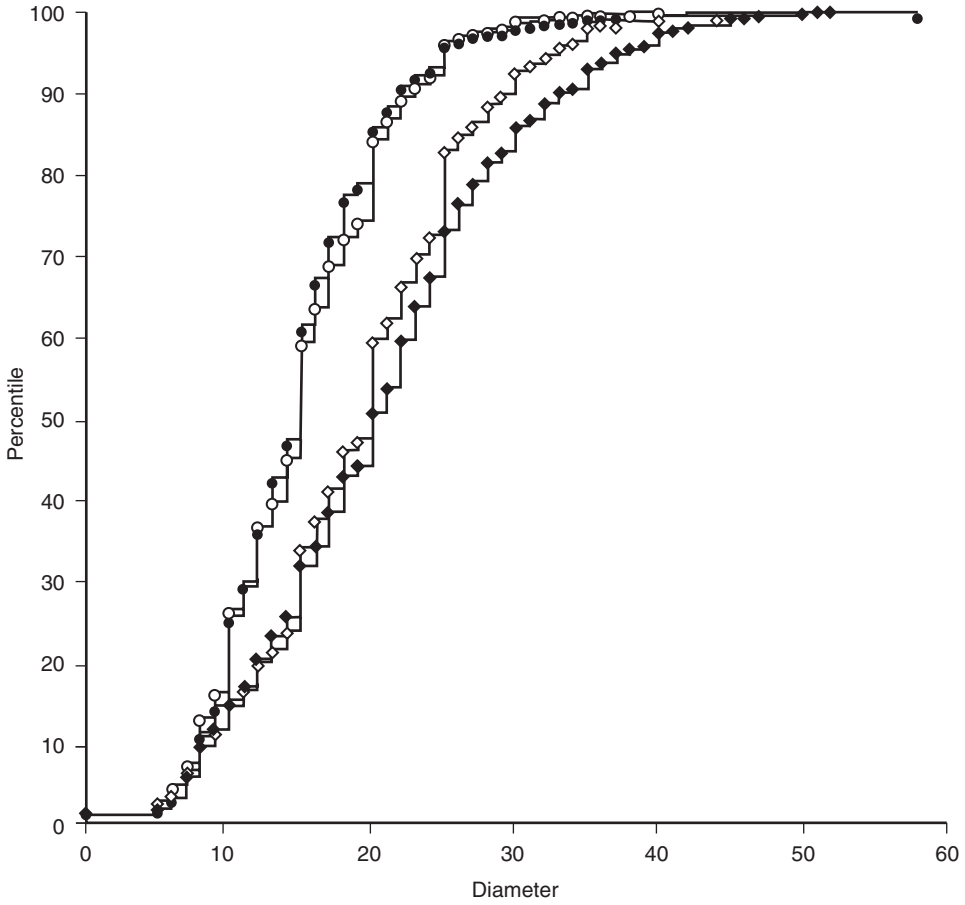

Figure 145-5 Cumulative distribution plots of megakaryocyte diameters in the bone marrow of thrombocytopenic neonates *(filled circles)*, nonthrombocytopenic neonates *(open circles)*, thrombocytopenic adults *(filled diamonds)*, and nonthrombocytopenic adults *(open diamonds)*. Megakaryocytes in marrow histologic sections were immunohistochemically stained with an anti-CD61 antibody and measured with an automated image analysis system. The megakaryocyte diameters are displayed on the *x* axis and their cumulative distribution on the *y* axis. Both adult curves are shifted to the right compared with the neonatal curves, indicating the predominance of larger megakaryocytes in these samples. Furthermore, the curve for the thrombocytopenic adults is also shifted to the right compared with that for the nonthrombocytopenic adults, indicating a higher percentage of large megakaryocytes. In contrast, there is no difference in the megakaryocyte size distribution of thrombocytopenic compared to non-thrombocytopenic neonates. *(Modified from Sola-Visner M, Christensen RD, Hutson AD, Rimsza LM: Megakaryocyte size and concentration in the bone marrow of thrombocytopenic and nonthrombocytopenic neonates,* Pediatr Res *61:482, 2007.)*

the different varieties of thrombocytopenia. In studies in which hyporegenerative thrombocytopenia was suspected on the basis of decreased marrow megakaryocytes or circulating megakaryocyte progenitors, however, Tpo concentrations were less elevated than those reported in adults with thrombocytopenia owing to decreased platelet production.[149,152]

The sites of Tpo production, as detected by reverse transcriptase polymerase chain reaction, were similar in fetuses, neonates, and adults, with the liver accounting for more than 90% of the total Tpo mRNA expression among liver, kidneys, and spleen.[47,48] The response to Tpo, however, has been shown to be substantially different in neonates than in adults. First, studies by several investigators demonstrated that neonatal megakaryocyte progenitors generated significantly larger colonies with more megakaryocytes than adult bone marrow cells.[125,160] Furthermore, when the effects of Tpo on neonatal versus adult bone marrow light-density mononuclear cells were compared, marrow cultures from either thrombocytopenic or nonthrombocytopenic neonates yielded three times more megakaryocyte colonies that adult marrow cultures.[161] These neonatal colonies also contained more megakaryocytes and were more sensitive to Tpo (i.e., the highest number of colonies was reached at a Tpo concentration of 10 ng/mL, compared with 50 ng/mL for adult cultures). These findings were consistent with the pronounced increase in platelet counts observed in newborn rhesus monkeys treated with even low doses of PEG-rHuMGDF.[162]

Pastos and associates[65] also evaluated the effects of Tpo on the ploidy of adult and neonatal megakaryocytes cultured in either serum-free media or adult bone marrow stromal cell–conditioned media with increasing concentrations of Tpo. This study disclosed opposite effects of Tpo on the ploidy of neonatal compared with adult megakaryocytes. Although adult megakaryocytes reached highest ploidy levels when cultured in serum-free medium with maximal concentrations of rTpo, neonatal megakaryocytes reached their highest ploidy when cultured in marrow stromal cell–conditioned media in the absence of rTpo; the addition of supraphysiologic concentrations of rTpo (≥0.1 ng/mL) inhibited their polyploidization (Figure 145-7). This study provided the first evidence that human neonatal and adult megakaryocytes have substantially different biologic responses to Tpo, and potentially to other cytokines. These differences will have to be taken into account when considering the use of thrombopoietic growth factors in the clinical setting of neonatal thrombocytopenia.

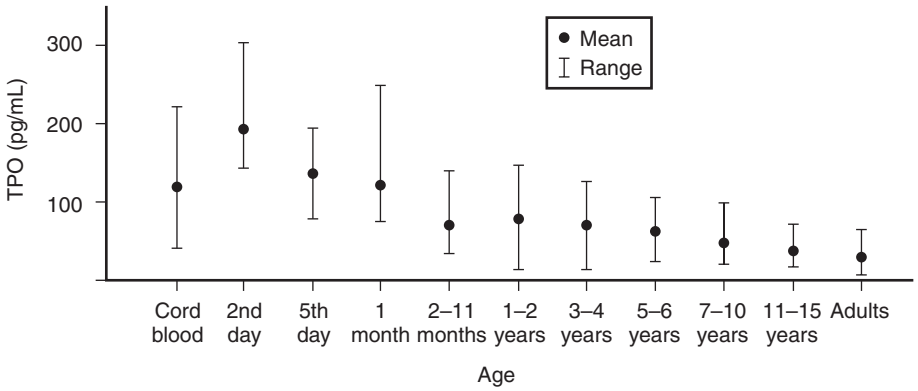

Figure 145-6 Age-related changes in serum thrombopoietin (TPO) levels in disease-free children. TPO concentrations were measured in 254 serum samples, collected from 25 cord blood samples, 200 healthy children, and 29 healthy adults. *Filled circles* indicate the means; *bars* represent the ranges. *(Modified from Ishiguro A, Nakahata T, Matsubara K, et al. Age-related changes in thrombopoietin in children: reference interval for serum thrombopoietin levels.* Br J Haematol *106:884-888, 1999; and from Dame C: Thrombopoiefin in thrombocy to penias of childhood,* Semin Thromb Hemost *27:219, 2001.)*

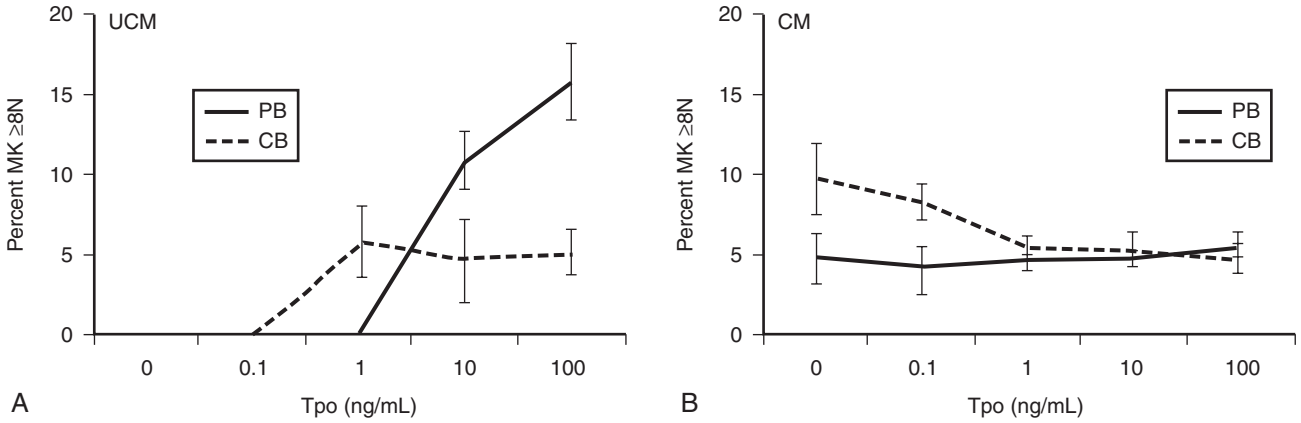

Figure 145-7 The percentage of megakaryocytes (MKs) that were 8 N or greater in PB and CB cultures differed depending on media source and recombinant thrombopoietin (rTpo) concentration. PB- and CB-CD34$^+$ cells were cultured for 14 days in unconditional media (UCM) **(A)** and conditional media (CM) **(B)**, with varying rTpo concentrations. PB-derived MKs *(solid lines)* cultured in UCM **(A)** exhibited a rTpo dose-dependent increase in ploidy levels, an effect inhibited by the presence of CM **(B)**. CB-derived MKs *(dashed lines)* reached highest ploidy levels when cultured in CM with no rTpo, an effect that was reversed by rTpo concentrations of 1 ng/mL or greater **(B)**. Data shown represent the means and standard error of the mean (SEM) of four separate experiments. *(Modified from Pastos, K, et al.,* Blood *108:3361, 2006.)*

More recently, Liu and collaborators[163] demonstrated that neonatal megakaryocytes generated in the presence of Tpo only are fully cytoplasmically mature, despite their small size and ploidy, indicating that neonatal megakaryocytes exhibit diffrent maturational patterns compared to adult magakaryocytes.

NEONATAL THROMBOCYTOPENIA

Platelet Counts

Platelets are produced very early in the fetus, and platelet counts rise in a linear fashion throughout gestation.[164] Premature infants, on average, have a slightly lower platelet count than term infants, but it remains within the same range observed in healthy older children and adults (i.e., 150,000 to 450,000/μL).[165] Appleyard and Brinton[166] evaluated platelet counts in low-birth-weight infants during the first 4 weeks of life (Table 145-5). In this study, platelet counts lower than 100,000/mm^3 were uncommon, and counts less than 50,000/mm^3 were usually associated with some clinical abnormality. As evident in Table 145-5, and described by other investigators, platelet counts rose for several weeks after delivery.[167,168] In term infants, platelet counts are equivalent to those in older children and adults.[166,169]

The incidence of thrombocytopenia in neonates is extremely variable, depending on the population examined. Large studies evaluating platelet counts in thousands of unselected cord blood samples reported an incidence of neonatal thrombocytopenia of 0.7% to 0.9%, depending on the definition of the thrombocytopenia.[170,171] Severe thrombocytopenia (platelet count < 50,000/μL) was present at birth in approximately 0.1% of neonates, but the incidence increased to 0.28% if infants whose platelet counts dropped below that threshold during the first few days of life were included.[171,172]

The relatively low frequency of thrombocytopenia in the general population of neonates is in marked contrast with its high incidence among sick neonates. Mehta and co-workers[173] reported an incidence of 35% among neonates admitted to the neonatal intensive care unit (NICU). Castle and colleagues evaluated platelet counts in 807 consecutive infants admitted to a regional NICU and found thrombocytopenia in 22%. Twenty percent of those infants had platelet counts below 50,000/μL.[174] In

14	33	408,000	262-670	17	343,000	147-460
21	31	403,000	259-720	16	384,000	201-470
28	23	357,000	212-625	17	421,000	278-600

From Appleyard WJ, Brinton A: Venous platelet counts in low birth weight infants. *Biol Neonate* 17:30-34, 1971.

a somewhat smaller study, Oren and associates observed an incidence of 18.2% among preterm neonates and 0.8% among term neonates.[175]

CAUSES OF THROMBOCYTOPENIA IN NEONATES

Thrombocytopenia in the neonatal period can be caused by a large number of disease processes. Several different systems to classify neonatal thrombocytopenia have been proposed, some based on the suspected kinetic mechanism (increased platelet consumption versus decreased production),[176,177] and others based on the time of onset (early versus late thrombocytopenia).[178-180] Our group recently published recommendations for the evaluation of thrombocytopenic neonates based on recognizing typical patterns of thrombocytopenia, which incorporate factors such as time of onset, severity, duration of thrombocytopenia, and suspected mechanism (Table 145-6).[181] These patterns are associated with specific pathophysiologic processes that can cause thrombocytopenia: immune, infectious, genetic, drug-induced, disseminated intravascular coagulation (DIC), placental insufficiency, and miscellaneous causes. Although not all-inclusive, this classification encompasses most causes of neonatal thrombocytopenia.

Immune-mediated Thrombocytopenia

In 1953, Harrington and co-workers[182] described a variety of thrombocytopenia that affects healthy neonates who have no other evidence of disease. The pathogenesis of this type of thrombocytopenia, now known as *neonatal alloimmune thrombocytopenia* (NAIT), resembles that of erythroblastosis fetalis in that it is mediated by maternal antibodies directed against antigens on fetal platelets. When incompatibility between parental platelet antigens exists, the mother can become sensitized to an antigen (inherited from the father) expressed on the fetal platelets. These antibodies can then cross the placenta and coat the fetal platelets, which are then removed from the circulation by the fetal reticuloendothelial system. Unlike neonatal Rh disease, however, the first pregnancy can produce an affected fetus.

The study of NAIT has been complicated by the multiple antigens expressed on platelets and by the fact that the nomenclature for these antigens has undergone multiple changes during the past few decades. To standardize the nomenclature, platelet antigens have been now designated human platelet antigens (HPAs). Different allelic forms are distinguished by an "a" or "b" suffix, with "a" indicating the most common and "b" indicating the uncommon allele[176] (Table 145-7). The most common cause of NAIT is alloantibodies against HPA-1a, formerly known as PLA-1, which accounts for 75% to 90% of all cases of NAIT. However, the frequency with which a particular antigen is responsible for cases of NAIT depends on the relative frequency of this antigen in that population. For example, although HPA-1a is the most common antigen responsible for NAIT in the white population (in which 68.9% of the population has the genotype HPA-1a/HPA-1a), HPA-4 is most frequently implicated among Asian subjects.[176] Cases mediated by antibodies against HPA-5,[183] HPA-3,[184] HPA-2,[185] and HPA-6[186] have also been described, although with much lower frequency. In addition, immunization against "low frequency" or "private" platelet alloantigens might account for a higher percentage of NAIT than previously recognized.[187]

TABLE 145-6

Classification of Etiologies of Thrombocytopenia, Including Severity, Onset, Time to Resolution, and Likely Mechanism

Categories	Subtypes	Severity	On	Time to Resolution	Mechanism
Immune	Alloimmune	Severe	Early	Days to weeks	↑ Consumption
	Autoimmune	Moderate	Early	Weeks to months	↑ Consumption
Infections	Bacterial	Variable	Variable	1-7 days	Mixed
	Viral	Variable	Early	Variable	Mixed
	Fungal	Severe	Late	2-7 days	Mixed
Genetic Disorders	Chromosomal	Moderate	Early	Days to weeks	↓ Production
	Bone marrow failure	Severe	Early*	Variable†	↓ Production
	Familial thrombocytopenias	Mild to moderate	Early	Never	↓ Production
Drugs		Moderate to severe	Late	Median, 8 days‡	Variable
DIC		Severe	Variable	Variable	↑ Consumption
PIH and IUGR		Mild to moderate	Early	7-10 days	↓ Production
NEC		Moderate to severe	Late	7-10 days	↑ Consumption

Sola MC: Evaluation and treatment of severe and prolonged thrombocytopenia in neonates. *Clin Perinatol* 31:1-14, 2004.

*Most congenital bone marrow failure syndromes are present at birth (i.e., congenital amegakaryocytic thrombocytopenia or thrombocytopenia-absent radii). However, the hematologic manifestations of Fanconi anemia usually do not appear until childhood.

†Thrombocytopenia associated with TAR syndrome usually resolves before school age. Other thrombocytopenias associated with bone marrow failure do not improve.

‡After discontinuation of the offending agent.

DIC, Disseminated intravascular coagulation; *IUGR,* intrauterine growth restriction; *NEC,* necrotizing enterocolitis; *PIH,* pregnancy-induced hypertension.

Platelet antigens appear in the fetus early in gestation, and the maternal antibodies can cross the placenta early in the second trimester, thereby inducing severe fetal thrombocytopenia. Bussel and co-workers[188] studied 107 fetuses who had siblings with NAIT, at a mean gestational age of 25 ± 4 weeks. Fifty percent of them had initial platelet counts of 50,000/μL or less, including 21 fetuses evaluated before 24 weeks gestation. The only good predictive factor for severe thrombocytopenia was a history of antenatal intracranial hemorrhage in the sibling.

Overall, NAIT should be suspected in any neonate without obvious clinical illness or malformations, who presents with thrombocytopenia, which is typically severe. Intracranial hemorrhage is the most perilous complication and occurs in 10% to

TABLE 145-7

Classification of Human Platelet Antigens, including Original Name, Associated Glycoprotein, and Cell Surface Marker

System	Antigen	Original Names	Glycoprotein	CD
HPA-1	HPA-1a	Zw^a, PI^{A1}	GPIIIa	CD61
	HPA-1b	Zw^b, PI^{A2}		
HPA-2	HPA-2a	Ko^b	GPIba	CD42b

30% of cases.[189-191] For that reason, neonates with NAIT and platelet counts lower than 50,000/μL should be treated and should have a cranial ultrasonographic examination before hospital discharge. Typically, infants with NAIT do not respond well to random donor platelet transfusions, and the treatment of choice is transfusion with antigen-negative platelets (obtained either from known HPA-1b platelet donors or from the mother). However, recent evidence suggests that a significant percentage of neonates with NAIT respond to random donor platelet concentrates with a substantial increase in platelet counts, suggesting that transfusion of platelet concentrates from random donors is an appropriate strategy in the initial management of severe NAIT, pending the availability of antigen-compatible platelets.[192] High-dose intravenous immune globulin (IVIG, 1 g/kg/day for up to 2 days) has been reported to raise platelet counts to at least twice the baseline level in 48 hours.[193] Methylprednisolone (1 mg/kg/BID for 3 to 5 days) has also been used, although antigen-negative platelet transfusions or IVIG, or both, constitute the first lines of therapy. Retreatment is occasionally required.[194] Subsequent pregnancies can also be managed to limit the risk for fetal bleeding.[195,196] Treatment options include (1) administration of high-dose IVIG or steroids to mothers and (2) intrauterine platelet transfusions, although the latter are associated with high fetal morbidity and mortality.

Neonatal autoimmune thrombocytopenia is similar to NAIT in that it is mediated by the transplacental passage of maternal antiplatelet antibodies. In contrast to NAIT, however, the antibody responsible for these cases binds both maternal and fetal platelets, causing thrombocytopenia in both the mother and neonate. In most cases, the underlying maternal disease is ITP, although other disorders (i.e., systemic lupus erythematosus) can also produce this syndrome. Thrombocytopenia (platelet count <150,000/mm^3) is found in 13% to 64% of infants born to mothers with ITP.[197-203] Unlike in NAIT, however, the incidence of severe neonatal thrombocytopenia (platelet count <50,000/μL) is relatively low, varying from 5% to 20% in different studies. These infants also have a very low rate of significant bleeding complications, particularly intracranial hemorrhages. In an analysis of 474 infants born to mothers with ITP, Cook and colleagues[204] found an incidence of intracranial hemorrhage of 3% among infants with moderate or severe thrombocytopenia. Several subsequent studies have confirmed a very low fetal morbidity associated with maternal ITP.

Infection

Most of the infants with immune platelet disorders appear well. Sick infants should be investigated for an underlying cause. Infections constitute the most common cause of thrombocytopenia among sick NICU patients. Platelet counts less than 150,000/mm^3 were noted in 77% of patients with gram-positive septicemia and in 55% of the patients with gram-negative septicemia.[205] In a small series of neonates with septicemia, 16 of 21 culture-positive neonates had platelet counts lower than 100,000/mm^3.[206] In a larger retrospective review, Guida and associates evaluated neonates with culture-proven sepsis.[207] In this cohort, infants with gram-negative or fungal sepsis had a higher incidence of thrombocytopenia (approximately 80%) compared with gram-positive sepsis (approximately 40%). Furthermore, the duration of thrombocytopenia was also longer in the infants with gram-negative and fungal sepsis (2 versus 0.4 days), and they had lower initial platelet counts and lower platelet nadirs.[207] Increased platelet-associated immunoglobulin G (PAIgG) has been observed in both bacterial and viral neonatal infections.[208,209] Although some septic neonates develop thrombocytopenia on the basis of DIC, most have thrombocytopenia without laboratory evidence of DIC. In a study of septic adults, Neame and collaborators[210] found thrombocytopenia in 75% of patients, but only a small minority had DIC. The principal mechanism responsible for thrombocytopenia in infected neonates is thought to be accelerated platelet destruction, probably secondary to endothelial damage with subsequent platelet adhesion and aggregation, or to platelet lysis or removal by the reticuloendothelial system.[205,211] Decreased platelet production has also been proposed as a contributing mechanism.[149,212] In all cases, treatment should be directed at the underlying infection; platelet transfusions should be administered as needed.

Congenital infections are also associated with neonatal thrombocytopenia.[213,214] Typically, thrombocytopenia is present in both congenital and acquired cytomegalovirus (CMV) infections.[215,216] In murine CMV infections, thrombocytopenia may be caused by direct marrow suppression.[217,218] Chesney and associates documented CMV inclusion bodies in the marrow megakaryocytes of a boy congenitally infected with CMV.[217] The megakaryocyte numbers appeared normal, but megakaryocytes were vacuolated, a finding indicating a direct effect on marrow megakaryocytes. Fetal blood sampling has been used to detect severe thrombocytopenia in the fetuses of mothers with active CMV infections.[217] In mothers infected with *Toxoplasmosis gondii* during pregnancy, 12 of 39 infected infants had low platelet counts.[219] Severe thrombocytopenia caused by ineffective platelet production has also been reported in a neonate with congenital HIV infection.[130]

Genetic Causes of Thrombocytopenia

A variety of syndromes and congenital disorders are associated with neonatal thrombocytopenia. In some of these cases, there are associated features that are easily identified in the neonatal period, such as shortened or absent radii in the thrombocytopenia and absent radii (TAR) syndrome, or more subtle physical findings, such as decreased ability to rotate the forearm due to radioulnar synostosis in the syndrome known as amegakaryocytic thrombocytopenia and radioulnar synostosis (ATRUS).[131] In many congenital thrombocytopenias, there are

no physical findings evident in the neonatal period, but the platelets are either abnormally small (microthrombocytopenias; mean platelet volume [MPV] less than 7 fL) or abnormally large (macrothrombocytopenias, MPV greater than 11 fL). Drachman published an excellent review of congenital thrombocytopenias[220] and classified them according to platelet size (Table 145-8), genetic mutations, associated findings (Table 145-9), and inheritance pattern (Table 145-10). In addition, several chromosomal anomalies are associated with fetal and neonatal thrombocytopenia, including trisomies 13, 18, and 21 and Turner syndrome. Certain inherited metabolic disorders also present with thrombocytopenia, including methylmalonic acidemia, isovaleric acidemia, ketoglycinemia, and holocarboxylase synthetase deficiency.

TABLE 145-8

Inherited Thrombocytopenias Classified by Platelet Size

Small Platelets; MPV < 7 fL	Normal Platelets; MPV 7-11 fL	Large/Giant Platelets; MPV > 11 fL
Wiskott-Aldrich syndrome	Familial platelet disorder/acute myeloid leukemia	May-Hegglin anomaly
X-linked thrombocytopenia	Chromosome 10/THC2	Fechtner syndrome
	Congenital amegakaryocytic thrombocytopenia	Epstein syndrome
	Thrombocytopenia and absent radii	Sebastian syndrome
		Mediterranean thrombocytopenia
		Bernard-Soulier syndrome
		Velocardiofacial/ DiGeorge syndrome
		GATA1 mutation
		Gray platelet syndrome
		Paris-Trousseau thrombocytopenia/ Jacobsen syndrome

MPV, Mean platelet volume.

Pregnancy-Induced Hypertension and Intrauterine Growth Restriction

Thrombocytopenia is common among neonates delivered to women with pregnancy-induced hypertension (PIH) or intrauterine growth restriction (IUGR).[129,221] The mechanism responsible for this thrombocytopenia is thought to be decreased platelet production, based on the finding of decreased concentrations of circulating megakaryocyte progenitors in affected neonates compared to controls.[129] Interestingly, serum Tpo concentrations in these neonates are not as elevated as those found in adult patients with hyporegenerative thrombocytopenia,[149,152] suggesting that a decreased ability to up-regulate Tpo production might contribute to thrombocytopenia. The thrombocytopenia associated with PIH or IUGR is usually mild to moderate (platelet counts between 50,000 and 150,000/μL) and follows a predictable pattern. It usually presents at birth or in the first few days of life, reaches a nadir on days 2 to 4, and resolves by days 7 to 10. Severe thrombocytopenias or thrombocytopenias that persist beyond 10 days of life deserve further evaluation for other potential causes.

Necrotizing Enterocolitis

Thrombocytopenia occurs frequently in neonates with necrotizing enterocolitis (NEC) and is thought to be caused by increased platelet destruction, based on the short half-life of transfused platelets. The inflammatory mediator platelet-activating factor

TABLE 145-9

Inherited Thrombocytopenias Classified by Genetic Mutations and Associated Findings

Syndrome	Gene Mutation	Chromosome Location	Associated Findings
MYH9-related thrombocytopenia			
May-Hegglin anomaly	MYH9	22q11	Neutrophil inclusions, sensorineural hearing loss, nephritis, cataracts
Fechtner syndrome	MYH9	22q11	
Epstein syndrome	MYH9	22q11	
Sebastian syndrome	MYH9	22q11	
Mediterranean thrombocytopenia/ Bernard-Soulier carrier	GP1BB, ? others	17pter-p12	None
Bernard-Soulier syndrome	GP1BA, GP1BB	17pter-p12	None
Velocardiofacial/DiGeorge syndrome	? GP1BB	22q11	Cardiac, facial, parathyroid, thymus anomalies; cognitive and learning impairment
Familial platelet disorder/ acute myeloid leukemia (AML)	AML1	21q22.2	Myelodysplasia, AML
Chromosome 10/THC2	? FLJ14813	10p12-11.2	None
Paris-Trousseau thrombocytopenia/ Jacobsen syndrome	? FLI1	11q23	Psychomotor retardation, facial anomalies (Jacobsen syndrome)
Gray platelet syndrome	Unknown	Unknown	None
Congenital amegakaryocytic thrombocytopenia	MPL	1p34	Marrow failure during second decade
Thrombocytopenia and absent radii syndrome	Unknown	Unknown	Bilateral short/absent radii
Thrombocytopenia and radioulnar synostosis	HOXA11	7p15-p14.2	Fused radius, incomplete range of motion
Wiskott-Aldrich syndrome	WAS	Xp11.23-p11.22	Immunodeficiency, eczema, lymphoma
X-linked thrombocytopenia	WAS	Xp11.23-p11.22	None
GATA1 mutation	GATA-1	Xp11.23	Anemia, dyserythropoiesis, thalassemia

From Drachman JG: Inherited thrombocytopenia: When a low platelet count does not mean ITP. *Blood* 103:390-398, 2004.

(PAF) has been found by multiple investigators to play a role in the pathogenesis of NEC.[222-224] Administration of a PAF receptor antagonist or of the PAF-degrading enzyme acetylhydrolase can significantly attenuate or prevent NEC in several animal models.[225] PAF has also been causally associated to the thrombocytopenia and neutropenia in dogs with endotoxemia[226] and has been found to be inversely associated with platelet counts in infected patients with DIC,[227] suggesting that it might also contribute to the pathophysiology of the thrombocytopenia in neonates with NEC.

Asphyxia

Several studies have reported that birth asphyxia is significantly more frequent among thrombocytopenic neonates than among nonthrombocytopenic neonates.[174,175,228] The reasons underlying this association are unclear, as is the mechanism responsible for the thrombocytopenia. Saxonhouse and collaborators[229] evaluated the effects of 24 hours of exposure to anoxia on the survival and proliferative potential of cord blood–derived megakaryocyte progenitors. He found that megakaryocyte progenitors did not undergo necrosis or apoptosis under these conditions and subsequently proliferated in a manner similar to normoxic controls. These observations suggest that the thrombocytopenia observed in neonates with asphyxia is not due to a direct deleterious effect of severe hypoxia on the megakaryocyte progenitors.

Miscellaneous Causes of Thrombocytopenia in Neonates and Adults

Numerous drugs have been reported to cause thrombocytopenia in adults. When administered to neonates, these medications are equally capable of causing drug-induced thrombocytopenia through a variety of mechanisms. DIC also complicates several disease processes, usually characterized by severe illness. Finally, thrombocytopenia can also occur in neonates with thrombosis and has been reported in neonates with thrombosis of the sagittal sinus,[230] the right atrium,[231] and the renal vein.

TABLE 145-10

Classification of Congenital Thrombocytopenia Based on Inheritance Pattern

Autosomal Dominant	Autosomal Recessive	X-linked
May-Hegglin anomaly	Congenital amegakaryocytic Thrombocytopenia (CAMT)	Wiskott-Aldrich syndrome
Fechtner syndrome	Thrombocytopenia and absent radii (TAR)	X-linked thrombocytopenia
Epstein syndrome	Bernard-Soulier syndrome	*GATA1* mutation
Sebastian syndrome		
Mediterranean thrombocytopenia/ Bernard-Soulier carrier		
Velocardiofacial/DiGeorge syndrome

SECTION XIX

Hemostasis

146 Developmental Hemostasis

*Paul Monagle** *and J. Nathan Hagstrom*

Hemostasis is a dynamic, evolving process that is age dependent and begins in utero. Although evolving, the hemostatic system in healthy fetuses and infants must be considered physiologic. Because the hemostatic system is dynamic, multiple reference ranges reflecting the gestational age and postnatal age of infants are necessary.[1] The evaluation of newborn infants for hemorrhagic or thrombotic complications presents unique problems that are not encountered in older children and adults.[2,3] For example, physiologic levels of many coagulation proteins in neonates are low, which makes the diagnoses of some inherited and acquired hemostatic problems difficult to establish. An understanding of developmental hemostasis in the broadest sense optimizes the prevention, diagnosis, and treatment of hemostatic problems during childhood and undoubtedly provides new insights into the pathophysiology of hemorrhagic and thrombotic complications for all ages.

THE COAGULATION SYSTEM

The understanding of hemostatic physiology in neonates and infants is deficient compared with knowledge of this subject in adults. This deficit is from several factors: in neonates and infants, multiple reference ranges are required because these patients have rapidly evolving systems[1,4-6]; blood sampling in the young is technically difficult; only small blood samples can be obtained; microtechniques are required[7]; and greater variability in plasma concentrations of coagulation proteins necessitates the use of large patient numbers to establish normative data.

Coagulation proteins are independently synthesized by the fetus and do not cross the placenta.[8-20] By 10 weeks gestational age, plasma concentrations of most coagulation proteins are measurable, and they continue to increase gradually in parallel with the gestational age. Samples obtained during fetoscopy provide the best assessment of normal values for fetuses, and by extrapolation, very premature infants (Tables 146-1 and 146-2).[21] True reference ranges for extremely premature infants are not available because the majority of these infants have postnatal complications. Tables 146-3 to 146-6 provide reference ranges for coagulation proteins, inhibitors of coagulation, and components of the fibrinolytic system for premature (30 to 36 weeks gestational age) and full-term infants on day 1 of life, as well as longitudinally during the first 6 months of life.[1,4,5] Tables 146-7 to 146-9 provide similar data for older children.[22]

The variable results for coagulation screening tests reflect the use of cord blood samples rather than samples from infants or differing ethnic populations or the use of different reagents.[23,24,25] Variation in prothrombin time results can be minimized by reporting the prothrombin time as an international normalized ratio.[26] The international normalized ratio is calculated as the patient prothrombin time divided by control prothrombin time to the power of the international sensitivity index. The international sensitivity index corrects for the large variation in sensitivity of thromboplastin reagents to plasma concentrations of coagulation proteins. Unfortunately, no such standardization exists for activated partial thromboplastin times. Reference ranges for activated partial thromboplastin times will differ with each different reagent and analyzer system, often significantly. Table 146-10 shows the variability in activated partial thromboplastin time reference ranges using the same patient samples, but with different activated partial thromboplastin time reagents.[25,27] The thrombin-clotting time performed in the absence of calcium is prolonged because of the presence of the "fetal" form of fibrinogen at birth.[1,4,5] For Tables 146-3 and 146-4, the thrombin-clotting time was measured in the presence of calcium so that abnormal values secondary to the presence of heparin, as well as low levels of fibrinogen, could be detected.

Coagulant Proteins

The vitamin K–dependent factors are the most extensively studied group of factors in infants, reflecting the clinical significance of hemorrhagic disease of the newborn.[28-30] Physiologically low levels of factors (F) II, FVII, FIX, and FX in Tables 146-3 and 146-4 are similar to those in other reports[1,4,5,31-41] and were measured in infants who received vitamin K prophylaxis at birth. The levels of the vitamin K–dependent factors and the contact factors (FXI, FXII, prekallikrein, and high molecular weight kininogen) gradually increase to values approaching adult levels by 6 months of life.[1,4,5] Recently, low prothrombin levels have been found to be associated with increased rates of intraventricular hemorrhage in very preterm infants. The prolonged activated partial thromboplastin time during the first months of life is in large part due to the low levels of the contact factors.[42]

Plasma levels of fibrinogen, FV, FVIII, and FXIII, and von Willebrand factor (vWf) are not decreased at birth (see Tables 146-3 and 146-4). Fibrinogen levels continue to increase after birth.[43] Plasma levels of FVIII are skewed toward the high measurements, necessitating an adjustment of the lower limit of normal (see Tables 146-3 and 146-4). Levels of both vWf and high molecular weight multimers are increased at birth and for the first 3 months of life.[1]

One potential mechanism for the developmental differences in plasma protein levels is reduced production of coagulation factors. Messenger ribonucleic acid (mRNA) levels have been measured for FVII, FVIII, FIX, and FX, fibrinogen, antithrombin (AT), and protein C in hepatocytes from 5- to 10-week-old human embryos and fetuses and in those from adults. Embryonic-fetal transcripts and adult mRNAs are similar in size; the nucleotide sequences of mRNA for factors IX and X are identical.[44,45] However, the expression of mRNA was variable, with adult values existing for some coagulation proteins, but decreased for others.

*Prof. Monagle is supported by a NHMRC project grant (#454385).

Similar concentrations of prothrombin mRNA were found in the livers of newborn and adult rabbits;[46] however, another study reported lower prothrombin mRNA concentrations in sheep. In addition, increased clearance of plasma proteins may account for developmental differences in plasma proteins. Fibrinogen, whether of fetal or adult origin, is cleared more rapidly in newborn lambs than it is in sheep.[47] Similarly, clearance of fibrinogen is accelerated in premature infants with or without respiratory distress syndrome.[48] An increased basal metabolic rate in the young probably contributes to the accelerated clearance of proteins.[49]

Differences in function and structure of fetal versus adult fibrinogen have been recognized for a number of years.[50] These differences have been primarily attributed to an increased sialic acid content of the fetal fibrinogen.[51] Preliminary data suggest that posttranslational modification differences may be present in a number of coagulation proteins in neonates compared with adults. The functional and developmental significance of these changes remain to be determined.

Regulation of Thrombin

Thrombin regulation is both delayed and decreased in newborn plasma compared with adult plasma and is similar to plasmas from adults receiving therapeutic doses of warfarin or heparin.[52] Thrombin generation in newborn plasma is further decreased in the presence of endothelial cell surfaces, but not to the same extent as adult plasma.[53] The amount of thrombin generated is directly proportional to the prothrombin concentration,[54] whereas the rate of thrombin generation reflects the concentration of other procoagulants.

Thrombin is directly inhibited by AT, heparin cofactor II, and α_2-macroglobulin. In addition, a circulating physiologic anticoagulant in cord blood has properties similar to those of dermatan

From Andrew M, Paes B, Milner R, et al: Development of the human coagulation system in the healthy premature infant. *Blood* 72:1651, 1988.

All factors except fibrinogen are expressed as units per milliliter (U/mL) in which pooled plasma contains 1.0 U/mL. All values are given as a mean *(M)* followed by the lower and upper boundaries encompassing 95% of the population *(B)*. Between 40 and 96 samples were assayed for each value for the neonate. Some measurements were skewed due to a disproportionate number of high values. The lower limit, which excludes the lower 2.5% of the population, has been given (B).

From Andrew M, Paes B, Milner R, et al: Development of the human coagulation system in the full-term infant. *Blood* 70:165, 1987.

All factors except fibrinogen are expressed as units per milliliter (U/mL) where pooled plasma contains 1.0 U/mL. All values are expressed as mean *(M)* followed by the lower and upper boundaries encompassing 95% of the population *(B)*. Between 40 and 77 samples were assayed for each value for the neonate. Some measurements were skewed due to a disproportionate number of high values. The lower limit, which excludes the lower 2.5% of the population, has been given.

*Values that are indistinguishable from those of the adult.

Abbreviations given in Table 146-3.

sulfate.[55] The fetal proteoglycan is present in plasma in concentrations of 0.29 μg/mL, has a molecular weight of 150,000 kd, and catalyzes thrombin inhibition by means of the natural inhibitor heparin cofactor II. The fetal anticoagulant also is present in plasmas from pregnant women and is produced by the placenta.[56] The length of time that the fetal anticoagulant circulates in neonates is not known. α_2-Macroglobulin is a more important inhibitor of thrombin in plasmas from neonates than it is in plasmas from adults.[57,58] α_2-Macroglobulin compensates, in part, for the low levels of AT in neonates, even in the presence of endothelial cell surfaces. The elimination half-life of AT is shorter in healthy infants than in adults.[59] Despite these differences, the

From Andrew M, Paes B, Johnston M: Development of the hemostatic system in the neonate and young infant. *Am J Pediatr Hematol Oncol* 12:95, 1990.

For 2AP, values are expressed as units per milliliter (U/mL) in which pooled plasma contains 1.0 U/mL. Plasminogen units are those recommended by the Committee on Thrombolytic Agents. Values for TPA are given as nanograms per milliliter. Values for PAI-1 are given as units per mL where one unit of PAI-1 activity is defined as the amount of PAI-1 that inhibits one international unit of human single-chain TPA. All values are given as a mean *(M)* followed by the lower and upper boundaries encompassing 95% of the population *(B)*.

*Values that are indistinguishable from those of the adult.

†Values that are different from those of the full-term infant.

2AP, 2-Antiplasmin; *PAI-1,* plasminogen activator inhibitor-1; *TPA,* tissue plasminogen activator.

rate of inhibition of thrombin is still slower in newborn infants than it is in adults.

Whether the overall activity of the protein C/protein S system varies with age is unknown. However, at birth, plasma concentrations of protein C are very low, and they remain decreased during the first 6 months of life.[1,4] Protein C in neonatal plasma has a two-fold increase in single-chain form compared with the double-chain form that is prominent in adults.[60,61] Animal data suggest that fetal protein C has increased glycosylation compared with that of adults. Despite these changes, no evidence that protein C is functionally different in neonates is available. Although total amounts of protein S are decreased at birth, functional activity is similar to that in the adult because protein S is completely present in the free, active form due to the absence of C4 binding protein.[62,63] Furthermore, the interaction of protein S with activated protein C in newborn plasma may be regulated by the increased levels of α_2-macroglobulin.[64] Plasma concentrations of thrombomodulin are increased in early childhood, decreasing to

All values are expressed in units per milliliter (U/mL), in which for all factors pooled plasma contains 1.0 U/mL, with the exception of free protein S, which contains a mean of 0.4 U/mL. All values are given as a mean *(M)* followed by the lower and upper boundaries encompassing 95% of the population *(B)*. Between 20 and 30 samples were assayed for each value for each age-group. Some measurements were skewed due to a disproportionate number of high values. The lower limits, which exclude the lower 2.5% of the population, have been given.

*Values that are significantly different from those of adults.

Abbreviations given in Table 146-5.

adult values by the late teenage years; however, the influence of age on endothelial cell expression of thrombomodulin has not been determined.[65-69]

Total tissue factor pathway inhibitor levels in newborn infants are reported as being similar to levels in older children or adults. However, free tissue factor pathway inhibitor is reported as being significantly lower in neonates.[70]

The capacity of newborn fibrin clots to bind thrombin has been assessed through the measurement of fibrinopeptide A production. Cord plasma clots generate significantly less fibrinopeptide A than do adult plasma clots because of the decreased plasma concentrations of prothrombin in cord plasma.[71] This observation suggests that thrombi in newborn infants may not have the same propensity to propagate as do thrombi in adult patients.

THE FIBRINOLYTIC SYSTEM

Although plasmin is generated and inhibited similarly in infants and adults, important differences do exist.[4] In neonates, plasminogen levels are only 50% of adult values, α_2-antiplasmin levels are 80% of adult values, and plasma concentrations of plasminogen activator inhibitor-1 (PAI-1) and tissue plasminogen activator (TPA) are significantly greater than adult levels.[1,4-5,31-39,41,72-74] Increased levels of TPA and PAI-1 on day 1 of life are in marked contrast to values from cord blood, in which concentrations of these two proteins are significantly lower than they are in adults.[41,71,72] The discrepancy between newborn and cord plasma concentrations of TPA and PAI-1 can be explained by the enhanced release of TPA and PAI-1 from the endothelium shortly after birth. PAI-2

Values expressed as mean ± 95% confidence interval. Analyzed by one-way analysis of variance.

*Not significant.

†Adolescents had significantly longer euglobulin lysis time (ELS) postocclusion results compared with adults. Sex demonstrated no effect.

levels are detectable in cord blood, but are significantly lower than they are in pregnant women.[75] Plasminogen, like fibrinogen, has a fetal form. Fetal plasminogen exists in two glycoforms that have increased amounts of mannose and sialic acid.[76] The enzymatic activity of "fetal plasmin," as well as its binding to cellular receptors for fetal plasminogen, are decreased.

Short whole-blood clotting times, short euglobulin lysis times, and increased plasma concentrations of the Bβ15-42 fibrin-related peptides suggest that the fibrinolytic system is activated at birth.[1,74] At the same time, the capacity of the fetal fibrinolytic system to generate plasmin in response to stimulation by a thrombolytic agent is decreased compared with that of adults; this reflects low levels of plasminogen.[77]

The fibrinolytic response to venous occlusion stress testing in healthy adolescents (13 to 18 years) has been compared with the response in healthy adults.[78,79] Adolescents had significantly decreased TPA antigen levels and increased PAI-1 activity levels after venous occlusion, resulting in significantly prolonged euglobulin lysis times (Table 146-11). The age-related differences in fibrinolytic responses to venous occlusion of younger children, and the significance of these differences on the pathophysiology of clinical hemostatic disorders in children, require further studies.

PLATELETS

Classic platelet studies in newborn infants are inhibited by sample volume requirements. Flow cytometry is useful because of the small sample volume required for extensive platelet function studies. Differences in sample timing, method of collection, and concentrations and compositions of platelet agonists likely contribute to apparently conflicting reports on platelet function in the newborn infant.

Megakaryocytopoiesis has been difficult to study in the fetus and neonate because of the intrinsic low level of megakaryocyte production in the marrow and the lack of availability of marrow samples to study. Using microassay techniques, Murray and Roberts[79] have shown that megakaryocytopoiesis is likely increased at 24 to 36 weeks gestation versus term gestation. Platelets appear at 5 weeks postconception, and megakaryocytes appear in the liver at 8 weeks. Fetal and neonatal megakaryocytes are smaller than adult megakaryocytes.[80]

Megakaryocytes

The cord blood of preterm babies has increased numbers of all megakaryocyte precursors compared with term infants. Furthermore, term infants have increased circulating megakaryocyte

progenitor numbers at birth compared with adults.[81] The magnitude of cord blood megakaryocyte progenitors' proliferative and maturational responses to cytokines is related to developmental age.[79] Reticulated platelet counts are reported as similar to adult levels in healthy neonates greater than 30 weeks gestational age but increased in neonates younger than 30 weeks gestational age.[82] However, a study by Joseph and colleagues[83] reported reduced reticulated platelet counts in neonates of all gestational ages compared with adults. No information on developmental differences of megakaryocyte and platelet precursors during childhood is available.

Platelets in Cord Blood

Platelet counts and mean platelet volumes in neonates are similar to those in adults, with values of 150 to 450 × 10^9/L and 7 to 9 femtolitre (platelet volume), respectively.[84-92] Platelet counts in fetuses between 18 and 30 weeks gestational age also fall within the adult range, with the average value being 250 × 10^9/L.[93] Platelet survival has not been measured in healthy infants. Electron microscopy studies on cord platelets have demonstrated normal numbers of granules; however, serotonin and adenosine diphosphate, which are stored in dense granules, are present at concentrations that are less than 50% of adult values. Flow cytometry studies in whole blood without added agonists show that differences between neonates and adults in platelet binding of monoclonal antibodies for glycoprotein Ib or P-selectin are not significant; however, glycoprotein IIb/IIIa is significantly reduced.[94,95] Platelet adhesion at birth has not been assessed with sensitive and reproducible assays; this may explain the conflicting in vitro results.[96,97] Glycoprotein Ib is present on fetal platelet membranes in adult quantities.[98]

Both the plasma concentrations of vWF and the proportion of high-molecular-weight multimers (and therefore more active forms) of vWF are increased in neonates.[99,100] The cord multimeric pattern of vWF appears similar to the forms released by endothelial cells. This may be explained by the recent finding that newborn plasma has little if any detectable vWF cleaving protease.[99,101] The quantitative and qualitative differences in vWF at birth are likely responsible for the enhanced cord platelet agglutination to low concentrations of ristocetin[100,102] and contribute to the short bleeding time in neonates.[103-105] Glycoprotein IIb/IIIa complexes are expressed on platelet membranes early in gestation;[106] however, the capacity of cord platelets to aggregate following exposure to a variety of agonists has been variable, with some observations being more consistent than others. Recently, differences between the cord blood of premature and full-term infants have been described, with reduced aggregation in preterm infants.[107]

Epinephrine-induced aggregation of cord platelets is consistently decreased compared with that of adult platelets because of the decreased availability of α-adrenergic receptors.[108-115] Ristocetin-induced agglutination of cord platelets is consistently increased compared with that of adult platelets, likely because of quantitative and qualitative increases in the level of vWF. Aggregation of cord platelets induced by adenosine diphosphate, collagen, thrombin, and arachidonic acid is variable and may be moderately decreased or similar to that of adult platelets.[116-118] Thromboxane A_2 production is reduced in neonates, despite normal receptor binding, suggesting a postreceptor signal transduction problem.[119]

Inositol phosphate production and protein phosphorylation are normal, as is production of arachidonic acid and its metabolites.[118] In fact, cord platelets release more arachidonic acid than adult platelets in response to stimulation by thrombin.[120] This increased release may be due to the greater reactivity of platelet membranes induced by low levels of vitamin E.[121,122] Agonist receptors, with the exception of the α-adrenergic receptor discussed previously, do not appear to be decreased in number. Despite a poor response to collagen stimulation, cord platelets have normal numbers of the collagen receptor glycoprotein Ia/IIa present in platelet membranes.[123] Coupling of agonist receptors to phospholipases may be the site of this transient activation defect in response to collagen.[124]

Platelet Function in Neonates

A few studies have assessed aggregation of newborn platelets obtained during the first few days of life; other studies have evaluated platelets of older neonates.[125] Improved platelet aggregation was seen in newborn platelets drawn 2 hours after birth, with normalization of platelet aggregation at 48 hours. Studies using whole-blood flow cytometry show that, compared with adult platelets, neonatal platelets are hyporeactive to thrombin, a combination of adenosine diphosphate and epinephrine, and a thromboxane A_2 analogue.[114,121,126,127] The clinical significance of these observations remains unknown.

Bleeding Time

Measurement of the bleeding time is currently the best in vivo test of platelet interaction with the vessel wall.[128] Bleeding times in infants during the first week of life are significantly shorter than those in adults.[129] Several mechanisms contribute to this enhanced platelet/vessel wall interaction, including higher plasma concentrations of vWF,[1,4,5] enhanced function of vWF due to a disproportional increase in the high molecular weight multimeric forms,[130,131] active multimers, large red cells, and high hematocrits.[132,133] The significance of mild platelet aggregation defects in platelets derived from cord blood is uncertain when bleeding times in neonates are shorter than those in adults. Although automated bleeding time devices modified for newborn infants and children are available and have been standardized, the test remains difficult to reproduce in clinical laboratories.[134]

The platelet function analyzer (PFA)-100 system (Siemens Healthcare Diagnostics, Washington DC) provides an in vitro method of assessing primary platelet-related hemostasis by measuring the time, the closure time, taken for a platelet plug to occlude a microscopic aperture cut into a membrane coated with collagen and either adrenaline or adenosine diphosphate. The PFA-100 system is ideal for neonates because of the small volume required and the rapidity of testing. Normal ranges for the closure time of children are similar to those of adults. Newborn infants have shorter closure times that are not influenced by red or white blood cells.[135-139] The ease of the PFA-100 system and the associated difficulties in performing skin bleeding times have reduced the clinical utility of skin bleeding times. Further studies are required to determine the optimal method of assessing primary hemostasis in neonates and children.

Activation During the Birth Process

There is strong evidence that platelets are activated during the birth process. Cord plasma levels of thromboxane B_2, β-thromboglobulin, and platelet factor-4 are increased, the granular content of cord platelets is decreased, and epinephrine receptor availability is reduced, perhaps secondary to occupation.[140-142] The mechanisms of activation are likely multifactorial and include thermal changes, hypoxia, acidosis, adrenergic stimulation, and the thrombogenic effects of amniotic fluid. Activation of the coagulation system may provide an explanation for the paradox that one-stage coagulation times are prolonged in the neonate, but that various measures of whole-blood clotting duration are shortened compared with those in the adult.[143]

BLOOD VESSEL WALL

The vessel wall profoundly influences hemostasis due to the procoagulant and anticoagulant properties of endothelial cells and extracellular matrix components. Each of these properties is

significantly influenced by age. One of the anticoagulant properties of endothelial cell surfaces is mediated by lipoxygenase and cyclooxygenase metabolites of unsaturated fatty acids. Prostaglandin I_2 production from cord vessels exceeds that of vessels from adults.[144] In a rabbit venous model, increase is significant in glycosaminoglycans by mass in inferior vena cavas from pups compared with adult rabbits. The AT-mediated anticoagulant activity of inferior vena cava glycosaminoglycans, especially heparin sulfate, is increased in pups compared with adult rabbits.[145] In a rabbit arterial model, total proteoglycan, chrondroitin sulfate, and heparin sulfate content are increased in the intima and media of aortas from pups compared with adult rabbits. AT activity in aortas of pups, due to heparin sulfate glycosaminoglycans, is also increased.[146] The increased glycosaminoglycan-mediated vessel wall AT activity in pups compared with adult rabbits suggests that young blood vessels may have greater antithrombotic potential.

When measured directly, thrombin generation in cord plasma is decreased in the presence of human umbilical endothelial cells compared with plastic owing to cell surface promotion of AT inhibition of thrombin.[147] Soluble levels of endothelial cell adhesion molecules and selectins are also age dependent, suggesting developmental differences in endothelial cell expression and secretion of these molecules.[148]

Nitric oxide is a labile humeral agent that modulates vascular tone in fetal and postnatal lungs and contributes to the normal decline in pulmonary vascular resistance at birth. Nitric oxide is a potent inhibitor of platelet adhesion and aggregation and stimulates disaggregation of platelet aggregates. Nitric oxide likely interacts with prostaglandin I_2 and other metabolites of the lipoxygenase pathway to modulate platelet function in a synergistic manner.[149]

It has been observed in sheep that vessel wall thickness increases in the perinatal period.[150] This is likely in response to increases in stress per vessel internal diameter. Contractility also increases with fetal development.[151] The endothelial cells of fetal vessels are larger and less uniform and protrude into the lumen.[152]

SUMMARY

The vascular and hemostatic systems of the fetus and neonate are continually evolving. One must take this into consideration when evaluating these systems for dysfunction. Adult normative data do not apply to the fetus or neonate. Although different in content and structure, these systems should be considered physiologically in the fetus and neonate. This is an important consideration when determining and monitoring therapeutic intervention.

Thomas G. Diacovo

Platelet–Vessel Wall Interactions

Although an essential step in our evolution as a species, the development of a complex circulatory system has rendered human beings susceptible to physical and biochemical injuries that can result in hemorrhage and ultimately death. To meet these challenges, the body has developed a unique surveillance and repair system that relies in part on the ability of platelets to recognize and adhere to sites of vascular damage. The importance of this interaction is underscored by bleeding sequelae that result from a reduction in platelet numbers or function associated not only with various disease states but also as a complication from advances in critical care medicine. Such is the case with newborns admitted to the neonatal intensive care unit in which a quarter of them will have thrombocytopenia. To complicate matters, previous studies suggest that neonatal platelet function may be impaired, which would put them at further risk for bleeding. To understand both the mechanism(s) that may predispose the sick neonate to bleeding and the clinical relevance of the reported reduction in function of their platelets, it is necessary to have a broad overview of mechanisms that limit, as well as promote, platelet–vessel wall interactions.

ENDOTHELIUM

Anticoagulant Properties

In the absence of injury, platelets do not interact with the blood vessel wall because of the antithrombogenic nature of healthy endothelium. To prevent inappropriate platelet deposition, endothelial cells generate several substances that directly interfere

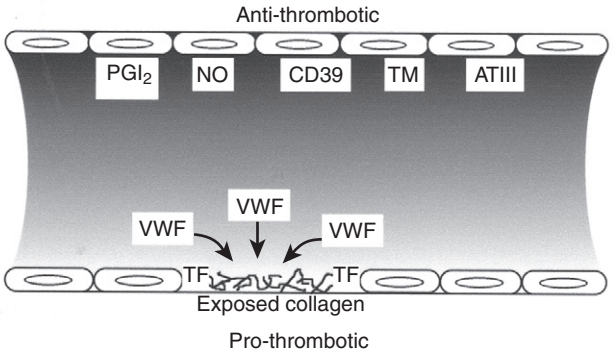

Figure 147-1 Antithrombotic and prothrombotic properties of vascular endothelium. *Top,* Molecules that limit the activation of platelets and the coagulation cascade. *Bottom,* Consequences of disrupting the endothelial cell barrier, which include exposure of tissue factor *(TF)* and collagen, the latter serving as a binding surface for von Willebrand factor*(VWF).*

with platelet function (Figure 147-1).[1] One such product is prostacyclin, which is a major metabolite of arachidonic acid and is produced by the cyclooxygenase system in endothelium.[2] Prostacyclin is released into the circulation where it can bind to a G protein–coupled receptor (GPCR) on platelets, which in turn activates intracellular adenylyl cyclase. GPCRs are transmembrane proteins that interact with the environment both outside and inside the cell. As such, they play a crucial role in receiving chemical signals from other cells and in activating certain cellular responses.[3] Consequently, this results in an increase in levels of cyclic adenosine monophosphate, which ultimately leads to activation of protein kinase A and direct inhibition of Ca^{2+} mobilization and granule release.[4] These events limit the ability of platelets to respond to procoagulant stimuli, thereby preventing interactions with the vessel wall. Because newborns tend to have higher levels of prostacyclin than adults, which are thought to aid in the reduction of pulmonary vascular resistance, these levels may also contribute to the reported hyporesponsive state of their platelets.[5-7]

Nitric oxide (NO) is another important molecule produced by endothelial cells that can prevent platelet activation and aggregation, processes that are part of the sequence of events leading to the formation of a hemostatic plug. It is short-lived (with a half-life of a few seconds), is highly reactive, and is produced by a group of enzymes known as nitric oxide synthases (NOS). Vascular endothelium possesses a type that is constitutively expressed (eNOS). In addition, production of NO can be enhanced by endothelial cell activation or in response to the application of fluid shear stress.[8] Once produced, NO is able to diffuse rapidly into platelets, where it binds to and activates guanylyl cyclase. As a result, levels of 3,5-cyclic guanosine monophosphate are increased, which prevents intracellular calcium release, the critical step in the signal transduction pathway that leads to full platelet activation.[9,10] NO has been shown to blunt the response of neonatal platelets to agonist-induced activation, suggesting that it can play a role in preventing inappropriate platelet–vessel wall interactions in newborns.[11]

Adenosine diphosphate (ADP) is also known to be a potent platelet activator that is released from damaged cells and activated platelets. To limit this possibility, vascular endothelium expresses CD39/ecto-adenosine diphosphatase, a membrane-bound glycoprotein that can hydrolyze ADP.[12] This is supported by the ability of recombinant soluble CD39 to both inhibit ADP-induced platelet activation and significantly reduce the degree of ischemia-induced cerebral infarction in CD39-null mice.[13] Although the role of this ecto–adenosine diphosphatase in contributing to thromboregulation in neonates is not known, human umbilical vein cells do express a functional form of CD39.[14]

Activation of the coagulation cascade in response to vascular injury results in the generation of thrombin, a potent stimulator of platelets. Thrombomodulin (TM) is a membrane-bound protein that modulates the substrate specificity of thrombin so that it preferentially promotes the activation of the protein C anticoagulant system. It is expressed in abundance on all endothelial cells but has no intrinsic enzymatic activity. This pathway is initiated when thrombin binds to the TM, permitting it to convert protein C from an inactive to active state so that it can form a complex with protein S, which leads to inactivation of clotting factors VIIIa and Va. In addition, thrombin bound to TM loses its procoagulant activities such as the ability to convert fibrinogen to fibrin, activates factors V and XIII, inactivates protein S, and mediates platelet aggregation.[15,16] TM can also interact with factor Xa, which prevents the generation of thrombin from prothrombin.[17] Although the TM deficiency in mice is lethal during the early stages of development, it is not known whether differences in function exist between neonates and adults.[18]

Antithrombin III (ATIII) is a protein in blood that prevents activation of the coagulation cascade. It does so by inhibiting thrombin and factors Xa and IXa. ATIII activity is markedly potentiated by heparin and is the principal mechanism by which heparin administration promotes anticoagulation in patients.[19,20] In neonates, ATIII activity has been reported to be 50% to 60% of that found in adults but does not appear to increase their risk of thrombosis.[21] The importance of this protease in preventing inappropriate clot formation is exemplified in patients with congenital ATIII deficiency. It is a rare autosomal disorder that is classified into two major types and results in an increased risk of venous and arterial thrombosis. Type I deficiency is characterized by reduced antithrombin level and function, both at approximately 50% of normal. Type II deficiency results from the presence of a functionally inactive protein with almost normal antigen levels. More than half of all patients with type I disease will likely have a clotting event in their lifetime.[22,23]

Procoagulant Properties

Physical or biochemical disruption of the endothelial cell barrier that exists between extracellular matrix (ECM) components and flowing blood initiates the coagulation cascade and deposition of platelets. Collagen fibers are the most thrombogenic macromolecular components of the ECM.[24] Platelet interaction with collagen occurs as a two-step procedure: (1) indirect contact mediated by von Willebrand factor (VWF) followed by (2) direct contact resulting in platelet activation and firm adhesion to the site of injury (see Figure 147-1).

VWF is a large glycoprotein of complex multimeric structure. It is synthesized exclusively by vascular endothelium and megakaryocytes and is stored and secreted by these cell types, as well as by circulating platelets. In blood, it not only serves as a carrier for factor VIII, protecting it from proteolysis, but also plays a critical role in hemostasis by promoting platelet deposition at sites of endothelial cell injury. To accomplish this task, VWF is able to adhere to components of the subendothelial matrix such as collagen and receptors on the surface of platelets, forming a bridge between them.[25] One remarkable feature of this plasma glycoprotein is its ability to support significant interactions with platelets only on surface immobilization and under specific hemodynamic conditions as encountered on the arterial side of the circulation.[26,27] This avoids the disastrous consequences of platelet–VWF aggregate formation in flowing blood.

VWF production by endothelium occurs through constitutive and inducible mechanisms, with the latter relying on storage

and subsequent release from an intracellular, membrane-bound organelle known as a Weibel-Palade body in response to vascular injury. The inducible pathway is most efficacious in terms of platelet recruitment because it results in the release of the majority of high-molecular-weight multimers of VWF, which possess the greatest hemostatic properties.[28] VWF storage, however, is not limited to endothelial cells because megakaryocytes and platelets also possess this capability (stored in organelles known as α-granules); however, this source of VWF contributes minimally to plasma levels but does play a role in promoting platelet-platelet interactions at sites of vascular injury.

In addition to promoting the deposition of VWF, vascular injury also results in the activation of the coagulation pathway that relies in part on tissue factor (TF).[29] TF is a glycoprotein that usually remains separate from circulating clotting factors in blood and is expressed by multiple cell types including smooth muscle cells in and surrounding blood vessels. On disruption of the endothelial barrier, TF is exposed to blood and can trigger the coagulation cascade, which ultimately results in the generation of thrombin. Thrombin has multiple biologic actions including (1) stimulation of the release of VWF from surrounding endothelium; (2) conversion of fibrinogen to fibrin, the solid component of the clot; and (3) down-regulation of the TM–protein C and S systems. Although deletion of TF in mice is embryonic lethal, no reports of its deficiency in humans have appeared.[30] These results suggest that TF is essential for life, most likely because of its central role in hemostasis.

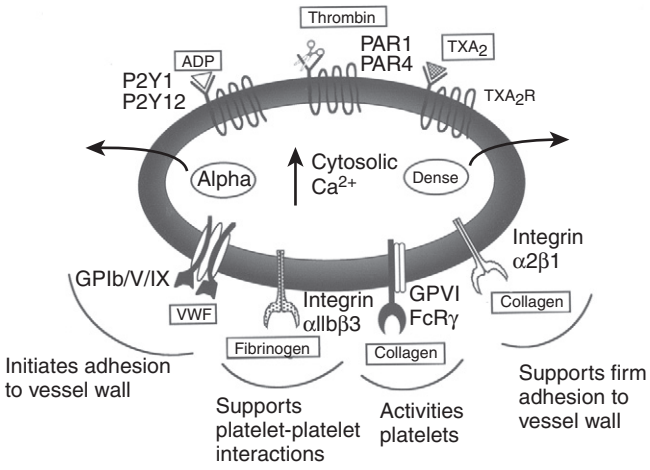

Figure 147-2 Receptors critical for platelet adhesion and activation. The ability of platelets to initiate contact and subsequently adhere with the injured vessel wall relies on the adhesion receptors GPIb-IX-V and α2β1, whereas platelet-platelet interactions are dependent on αIIbβ3. Receptors that support signal transduction include P2Y1/P2Y12, PAR1/PAR4, TxA_2R, and GPVI, which contribute to the mobilization of intracellular calcium stores. Ligands or agonists that bind to platelet receptors are boxed.

PLATELETS

Platelets are small, disk-shaped objects that circulate in the blood for a period of 10 days.[31] They are produced by fragmentation of megakaryocytes located within the bone marrow, and, although platelets do not possess a nucleus, they can synthesize protein products from constitutive or postranscriptionally processed messenger RNAs through a process termed signal-dependent translation.[32,33] In addition, platelets store growth factors, coagulation proteins, adhesion molecules, cytokines, cell-activating agents, and angiogenic factors in secretory organelles known as alpha (α) and dense granules[34]; these play a major role in promoting hemostasis and thrombus formation. In the developing fetus, platelet production by mid–second trimester is sufficient to achieve and maintain counts between 150 and 450 × 10^9/L, which is within the adult range.[35,36] Despite this similarity, it is believed that functional differences exist between newborn and adult platelets that may reduce the capacity of the former to maintain adequate hemostasis especially in the context of increased blood vessel fragility as is the case in premature infants or as a consequence of asphyxia or infection. To better understand the relevance of these observations, it is first necessary to have a basic knowledge of the adhesive and signaling pathways that promote platelet deposition at sites of vascular injury.

Adhesion

Platelets are poised to rapidly adhere to sites where the integrity of the vasculature has been compromised as their unique shape enables them to be pushed against the vessel wall in response to the hydrodynamic forces generated by flowing blood.[37] That said, these same forces would also tend to disrupt thrombus growth, especially on the arterial side of the circulation where the amount of force generated at the vessel wall (termed wall shear stress) is considerable. To overcome this formidable obstacle, platelets rely on several families of cell surface adhesion molecules that have distinct roles in the initiation and stabilization of interactions at sites of vascular injury (Figure 147-2). For instance, the ability of platelets to rapidly attach to the injured vessel wall requires the participation of a constitutively expressed and active glycoprotein complex (GP) known as GPIb-IX-V.[38,39] Each component of the complex is a member of the leucine-rich repeat family and includes GPIbα, GPIbβ, GPIX, and GPV. However, it is GPIbα that plays the predominant role in initiating contact between circulating platelets and the site of injury. The importance of this complex in hemostasis is demonstrated in the autosomal recessive bleeding disorder known as Bernard-Soulier syndrome that results from the absence or decreased expression of these glycoproteins on platelets.[40] The ability of GPIbα to initiate platelet adhesion requires the participation of the plasma protein VWF. As mentioned earlier, VWF serves as a bridge between platelets and components of the damaged vessel wall. It is the role of a specialized region within VWF known as the A1 domain that serves as a ligand-binding site for GPIbα. This interaction, however, is extremely labile in nature and does not permit platelets to remain firmly bound at the site of injury.[26] A role for A1 domain in this process is suggested by the perturbation in hemostasis that can occur in a subclass of patients with von Willebrand disease known as type 2M. Bleeding is believed to occur because of point mutations within this domain that prevent or significantly reduce its interaction with GPIbα.[41] Compared with those of adults, platelets from neonates have been reported to have an enhanced interaction to ECM proteins in the presence of VWF and under flow conditions, which may result from higher amounts of large multimers of VWF in their plasma.[42,43]

For platelets to be retained at sites of vascular injury, a second family of adhesion receptors expressed on their surface must engage counter ligands that are exposed or deposited in such areas. Once such receptor is the integrin $\alpha_2\beta_1$ that permits platelets to firmly adhere to collagen. As with other members of the integrin family, it exists in an inactive form on resting platelets and can only significantly interact with this ECM protein once platelets become activated in response to various agonists. In particular, it is thought that another collagen-binding molecule on platelets known as GPVI plays a supporting role in the activation process. Once engaged, $\alpha_2\beta_1$-collagen interactions are thought to stabilize the formation of the initial layer of platelets covering the injured area. Although an abnormality in collagen-induced platelet activation in solution has been reported in neonates, it

is not clear whether any significant differences in $\alpha_2\beta_1$ function or structure are present.[44] In addition, it appears that absence of this integrin receptor in humans yields only a mild bleeding phenotype, suggesting that it plays a significant but not essential role in hemostasis.[45]

A key step in the formation of a hemostatic plug is the ability of platelets to stick to one another in a process termed aggregation. This is the role of the integrin αIIbβ3, the most abundant glycoprotein expressed on the surface of platelets.[46] The major ligands for this receptor are fibrinogen, fibronectin, and VWF, which on interacting with this adhesion molecule on activated platelets permit aggregation to occur, an event essential for sealing off vascular leaks. Absence or dysfunction of this integrin receptor as occurs in the autosomal recessive disorder known as Glanzmann thrombasthenia results in an inability of platelets to adhere to one another, leading to a severe bleeding phenotype.[40] Alterations in αIIbβ3 function and possibly expression have been implicated as a potential mechanism for neonatal platelet hyporesponsiveness, but results are conflicting. That said, the reported defects in aggregation may have more to do with intracellular signaling events that convert this integrin to an activated state than the actual numbers of receptors present on neonatal platelets.[47-52] However, the mechanisms proposed to contribute to clot strength such as fibrin binding and actin-myosin interactions appear to be intact in neonatal platelets.[53]

Signaling

The formation of a stable hemostatic plug relies not only on adhesion molecules but also on a series of progressive and overlapping biochemical events in platelets. This results from substances generated or exposed at the site of injury and by the platelet itself. Substances that induce platelet activation are called agonists, and each interacts with a specific receptor on the platelet surface, causing a series of intracellular reactions. This process involves both G protein– independent (initial phase of platelet-vessel wall interactions) and –dependent (thrombus growth and stability) signaling.[54] G proteins, short for guanine nucleotide–binding proteins, are a family of proteins involved in second messenger cascades.[3] Regardless of the activating stimulus, a major event that contributes to platelet activation is a rise in cytosolic calcium concentration, which is a widely used mechanism for regulating cell function.[55,56] It appears that the previously documented abnormalities in neonatal platelet function are mainly due to the impaired mobilization of this important intracellular mediator.[57] Ultimately, platelet activation results in changes in the cytoskeleton, release of granule contents, and an increased adhesiveness of integrin receptors, all of which are essential for stabilizing platelet-ECM and platelet-platelet interactions. Platelets express several receptors that convert external environmental cues into biochemical signals in response to interactions with agonists such as collagen, thrombin, ADP, or thromboxane A_2 (TxA_2) (see Figure 147-2). A brief description follows.

The formation of the initial layer of adherent platelets at sites where disruption of the endothelial lining of blood vessels occurs requires activation through the collagen receptor GPVI. It is a member of the immunoglobulin superfamily and is noncovalently associated with a small, immunoreceptor tyrosine-based activation motif (ITAM)–containing subunit, the FcRγ chain.[58] Although GPVI expression relies entirely on its association with the FcRγ chain, signaling can occur by Fc receptor–dependent or –independent pathways. In either case, engagement of GPVI results in increased adhesiveness of the integrins α2β1 and αIIbβ3, enabling platelets to firmly attach to collagen and to one another.[59] It also results in release of storage granule contents that are critical for augmenting and maintaining platelet activation. GPVI deficiency has been reported in humans, causing a mild bleeding diathesis.[60] However, its role in the observed hyporesponsiveness of neonatal platelets remains controversial because of conflicting results concerning the ability of collagen to induce GPVI-mediated platelet aggregation in solution-based assays.[44,61,62] Of interest, neonatal platelets have been reported to have a greater propensity to form aggregates on a surface coated with subendothelial ECM than those from adults, suggesting that this signaling pathway is intact.[42]

ADP also plays an essential role in hemostasis by supporting thrombus growth because of its ability to function in an autocrine and paracrine fashion. It is stored in platelets in organelles known as dense granules and is released in response to agonists such as collagen. ADP binding to the G protein–coupled receptors (GPCR) P2Y1 and P2Y12 on the surface of platelets is required for a full response to this agonist.[54,63] Evidence to support a role for ADP as a positive-feedback mediator required for sustained platelet activation is the reduced response of platelets to thrombin in the absence of these receptors, as well as the observations that patients with deficiencies in either dense granules or P2Y12 have an increased propensity to bleed.[54] Although it is not known whether the number or function of ADP receptors expressed on platelets differs from those of adults, neonatal platelets have been shown to be less responsive to ADP and have impaired dense granule release in response to various agonists.[47,64,65]

As in the case of ADP, TxA_2 is a powerful activator of platelets that also functions in an autocrine and a paracrine manner, permitting the recruitment of platelets into the growing thrombus.[66] TxA_2 is a biologically active lipid mediator that is produced by the metabolism of arachidonic acid through the cyclooxygenase pathway. Its effects on platelets, and on other target cells, are mediated via interaction with G protein–coupled thromboxane–prostanoid receptors. Consistent with the important role of TxA_2 signaling in platelet function and hemostasis is the ability of aspirin, a potent cyclooxygenase inhibitor, to reduce pathologic thrombus formation in patients and the prolonged bleeding times in mice lacking the thromboxane–prostanoid receptor.[67] In the case of neonatal platelets, not only do they have an impaired response to this agonist, but they also produce less of this cyclooxygenase product as compared with their adult counterparts because of a decreased conversion of arachidonic acid to TxA_2.[44,68-70] As no differences in thromboxane–prostanoid receptor binding characteristics have been reported between neonatal and adult platelets, it appears that the reduced responsiveness of the former is mediated by impairment in postreceptor signaling.[69]

As mentioned, thrombin is the major protease of the hemostatic system and is an effective activator of platelets. Although it is not stored in or secreted by platelets, it is generated on the surface of activated platelets where it can further stimulate the coagulation process.[71-73] This includes activating surrounding platelets through GPCRs known as protease-activated receptors (PARs). Of the four known thrombin receptors, only PAR1 and PAR4 are expressed on human platelets, the former shown to mediate platelet activation at low concentrations of thrombin and the latter in the presence of high concentrations of the agonist.[74] As with the majority of platelet agonists, thrombin can trigger shape change, release of granule contents, and increased adhesiveness of integrin receptors. No reported bleeding disorders have been attributed to loss or dysfunction of PAR1 or PAR4 in humans, although inherited disorders in clotting factors demonstrate the requirement for thrombin in promoting effective hemostasis. Reports on neonatal platelet responsiveness to thrombin are conflicting, as well as the ability of plasma from newborns to generate this procoagulant substance.[57,64,75-77]

SUMMARY

The ability of platelets to interact with the vessel wall requires the exposure and generation of agonists that promote adhesion, as well as the activation of the clotting cascade. On the basis of

previous in vitro studies suggesting that neonatal platelets are hyporesponsive to physiologic activators that promote hemostasis, it would appear that they would be at increased risk for bleeding. Despite these findings, the hemostatic system of healthy newborns appears to be effective, because they do not have complications of spontaneous hemorrhage.[78] Thus standardized testing and better methodologies are needed to assess platelet function in neonates before the clinical relevance of these observations can be fully ascertained. What may be of greater importance is the number of platelets in the circulation, as these anucleate cells can release proangiogenic cytokines and growth factors that are essential for enabling vascular endothelium to maintain an antithrombotic barrier in the absence of injury.[79] This is evidenced by the spontaneous extravasation of erythrocytes into surrounding tissues when platelet counts fall below a critical value as a result of the failure of the integrity of the endothelial cell barrier. A better understanding of the role that platelets play in stabilizing the vessel wall is needed to aid clinicians in their decision as to when to transfuse the neonate with thrombocytopenia in the absence of overt bleeding.

SECTION XX

Developmental Immunobiology

148 Host Defense Mechanisms Against Bacteria

Timothy R. La Pine and Harry R. Hill

Bacterial sepsis is a major contributor to neonatal mortality and morbidity. The incidence of sepsis in the first month of life ranges from 1 to as high as 10 cases per 1000 live births.[1,2] In certain geographic areas, this rate may be significantly higher.[3,4] Bacterial sepsis occurs more frequently in preterm infants and when maternal complications have occurred, such as premature rupture of membranes or intrapartum infections.[1,3] Although advancements in maternal medical management and neonatal intensive care have decreased infant mortality and morbidity, prolonged hospitalization and invasive procedures have contributed to an increased incidence of certain bacterial infections. In spite of the development of potent antimicrobial agents, the mortality rate associated with neonatal bacterial sepsis ranges from 5% to 15%.[1,3,5] Furthermore, the compromised nature of a developing neonate's host defense system allows for bacterial dissemination from intravascular to extravascular sites, including the meninges, lungs, and bones. The morbidity from these secondary infections is high.[6,7]

The unique predisposition of the human neonate to bacterial infections is attributed to defects in both innate and acquired immune responses. The innate, or natural, immune response is nonspecific and not influenced by prior antigen interactions. Various physical (e.g., skin, cilia, mucus) and biochemical barriers (e.g., gastric acid, lysozyme, surfactant proteins), as well as phagocytic cells (e.g., granulocytes and macrophages) and the plasma factors (e.g., acute-phase reactants, the complement system, the coagulation cascade, and pattern recognition receptors) comprise innate immune responses. The acquired, or adaptive, immune response is specific. It is characterized by direct immune responsiveness as a result of an initial antigen exposure, with a memory, or anamnestic, response on antigen reexposure. Acquired immune responses include humoral immunity involving immunoglobulin production by B lymphocytes and cellular immunity mediated by T lymphocytes and associated factors (e.g., natural killer [NK] cells, cytokines, and interleukins). Neonatal immune development is discussed in depth in other chapters in this section; here we highlight deficiencies of this development in host defense against bacterial infections.

THE CHANGING NATURE OF NEONATAL BACTERIAL INFECTIONS

Group A streptococci and other gram-positive organisms often were the etiologic agents of newborn bacterial sepsis before the introduction of antibiotics. Later, after penicillins and sulfonamides were introduced in the 1940s, gram-negative organisms such as *Escherichia coli*, *Klebsiella pneumoniae*, and *Pseudomonas aeruginosa* became prominent.[8] Since the mid-1960s, group B streptococcal infections have become the most common infections in neonates throughout the United States and in other developed countries.[1,9] It is interesting that this organism has not played a major role in neonatal sepsis in many developing countries such as Mexico, India, and Thailand, where *Klebsiella* and *E. coli* are still the predominant pathogens.[3] The reasons for this are not clear. Infants generally acquire group B streptococcal infections by vertical transmission from the birth canal of a colonized mother. The low rates of invasive neonatal group B streptococcal disease in developing countries may reflect low maternal colonization rates, less virulent strains of group B streptococci (GBS) bacteria, or high levels of transplacental acquired antibody.

Although GBS and *E. coli* together account for more than 70% of serious bacterial infections in neonates, their distribution is changing.[3] Antibiotics are increasingly used in the perinatal period to reduce the risk for neonatal group B streptococcal infection during premature labor and premature rupture of the membranes. Concern exists that this increased use of antibiotics may result in a change in the spectrum of organisms and their susceptibility to antibiotics. Stoll and associates,[10,11] in a multicenter trial evaluating the etiology of early-onset neonatal sepsis among infants weighing less than 1500 g, found an increased prevalence of *E. coli* sepsis and a marked reduction in group B streptococcal sepsis between 1998 and 2000 when compared with an earlier cohort born between 1991 and 1993. Furthermore, 85% of the *E. coli* isolates were resistant to ampicillin. The mothers who received intrapartum ampicillin for group B streptococcal carriage were more likely to have infants with ampicillin-resistant *E. coli* infections. Antibiotic use can change the spectrum of neonatal bacterial infections and increase the prevalence of antibiotic-resistant organisms.[11]

Staphylococci are a major cause of nosocomial neonatal bacteremia and sepsis in intensive care nurseries. Noel and Edelson[12] identified 23 cases of clinically significant neonatal intensive care unit *Staphylococcus epidermidis* infections during a 17-month period. Ten of these episodes were associated with colonized indwelling catheters. Staphylococci have surface proteins that mediate their attachment to intravascular devices and other foreign bodies in addition to damaged endothelial cells. Once this surface attachment takes place, phagocytosis by neutrophils is inhibited, as is antibiotic penetration, and a nidus for infection is established. Infections with staphylococcal species are of particular concern in the extremely low-birth-weight infants requiring indwelling catheters.

Other organisms such as *Listeria monocytogenes*, *Haemophilus influenzae*, *Neisseria meningitidis*, and groups C, D, and G streptococci also can cause serious neonatal infection.[6] Anaerobic organisms additionally may be isolated alone or in combination with aerobes from septic neonates.

Campylobacter fetus, jejuni, and *coli* also have been implicated in premature delivery and associated with fetal and neonatal infection and mortality.[13]

THE COMPONENTS OF INNATE HOST DEFENSE

The innate, or natural, immune system provides host protection against microbial invasion without the need for prior exposure to that microbe. The innate immune system developed first

phylogenetically, appearing in all multicellular organisms, including plants, insects, and animals, and is the first line of defense against invasive pathogens.[14,15] It is active before the acquired immune responses and does not change or amplify on pathogen reexposure. The activities of innate immunity are both rapid, to prevent early microbial invasion, and nonspecific, to protect against multiple pathogens of diverse nature. Cells of the innate immune system contribute to antigen processing and presentation as well.[14]

Epithelial Cells, Normal Bacterial Flora, and Mucosal Barriers

Integrity of the skin and the epithelial surfaces of the respiratory and gastrointestinal tracts serves to impede microbe ingress physically. Premature infants with incomplete skin epithelization who require indwelling catheters are predisposed to bacterial infections, particularly with staphylococcal species. Damage to the respiratory epithelium with ventilation and oxygenation can predispose neonates to pneumonias. Similarly, immaturity of innate immune responses in the developing gastrointestinal tract predisposes preterm infants to necrotizing enterocolitis and other intestinal infections, all of which can lead to invasive bacterial infections.

Normal microbial flora contribute to innate host defense at epithelial and mucosal surfaces. Humans are colonized with a variety of microorganisms that suppress the overgrowth of pathogenic microbes. Normal flora produce bacteriocins and other antimicrobial agents that suppress the growth of invasive pathogens.[16] Alteration of the flora by antimicrobial therapy may result in the emergence of invasive pathogens.

The moisture content or type of epithelial cell surface may predispose the host to colonization with pathogens. Circumcision decreases the incidence of urinary tract infections.[17,18] Uncircumcised infants are more likely to harbor *E. coli* and *Proteus mirabilis* in the urethral meatus and periurethral area than circumcised boys.[19,20] Fimbriated *E. coli* adhere better to the moist inner surface of the foreskin than to the outer keratinized surface.[21] Vernix caseosa is a product of sebaceous secretions that provides an epidermal barrier and functions to "waterproof" a newborn's skin. Although a direct immunologic effect of vernix has not been described, it possesses growth factors that may promote lung and intestinal development.[22,23]

To produce invasive infection, GBS must first broach the mucosal barrier. Adherence of GBS to mucosal epithelial cells is a critical step for both maternal colonization and invasion of the neonatal respiratory tract. Adhesins are surface molecules on bacteria that facilitate binding to host eukaryotic cells. Lipoteichoic acid and surface proteins facilitate GBS binding to epithelial cells.[24-27] The greater adherence of type III GBS to neonatal respiratory epithelium facilitates their colonization and predominance in early onset neonatal sepsis. The physical disruption of the epithelial cell surface, however, may not be required for GBS invasion. GBS can transgress intact cultured respiratory epithelial cells via actin microfilament–dependent processes.[28]

Innate immunity in the respiratory tract includes the cilia of the nasal mucosa and the passageways of the upper airways, bronchi, and bronchioles. Cilia present on respiratory epithelium serve to impede respiratory invasion of microbial pathogens and remove or expel them.[29] Abnormalities, such as those seen in Kartagener syndrome, underscore the role of cilia in innate host defense. These patients have chronic bronchitis and bronchiectasis because of a defect in ciliary rods that results in immotile cilia. Patients with tracheotomies, or requiring prolonged ventilation, are predisposed to pulmonary infections as a result of the breakdown of epithelial immune integrity in the nasopharynx, glottis, trachea, and lung.

Mucin glycoproteins contribute to airway surface fluid. They provide viscosity and physically impede microbe invasion.[30,31] The genes for the mucin glycoproteins, MUC2 and MUC5A, are up-regulated by lipopolysaccharide (LPS) and by gram-positive and gram-negative bacteria.[32] These glycoproteins do not possess antimicrobial activity but provide a milieu for immune defense. The airway surface fluid contains a variety of antimicrobial proteins, such as lysozyme, lactoferrin, and defensins, as well as reactive oxygen and nitrogen species.[31,33,34] Other inflammatory cells of the respiratory tract include macrophages, neutrophils, mast cells, and NK cells. The cytokines produced by these cells and the respiratory epithelium also contribute to the antimicrobial activity of airway surface fluid.

The salt or fluid content at the airway surface may protect against microbial invasion. The high salt content or the decreased airway fluid observed in patients with cystic fibrosis may inhibit normal airway antibacterial activities and contribute to the persistent bacterial colonization and chronic infections seen in these patients.[33,35]

Growth factors and cytokines within the amniotic fluid contribute to fetal gastric immune development. Pregnancies complicated by oligohydramnios, whether caused by premature membrane rupture or by congenital abnormalities, are at higher risk for intestinal infections.[36] Transplacentally acquired immunoglobulins and hormones also influence the development of the enteric immune system. Immunoglobulins (Ig), particularly IgA, present in breast milk, both promote and provide intestinal mucosal immunity.[37] Within hours after birth, the neonate's intestinal tract is colonized by multiple species of bacteria and some viruses. Premature delivery, systemic infection, diet, and antibiotic exposure can alter enteric flora, resulting in local inflammation or invasive infection.[36]

Cells Involved in Innate Host Defense

The innate immune response involves neutrophils, monocytes, macrophages, and dendritic cells capable of phagocytosis. These cells, along with mast cells, also produce a number of inflammatory mediators, including colony-stimulating factors (CSFs) and a variety of cytokines that have roles in both innate and acquired immune responses.

Neutrophils

Neutrophils are central to neonatal host defense against bacteria.[38] Neutrophils appear after macrophages appear in the human fetus. Scattered neutrophil precursors occur in the liver as early as 5 weeks gestation. Bone marrow neutrophils are first present around 10 to 11 weeks.[39-41] Neutrophils are the first cells to migrate into a local area of microbial invasion and are important components of early innate defense.[42] Activated neutrophils must adhere to and migrate through capillary endothelial cell surfaces, then engulf and destroy invading pathogens.[43] Neonatal neutrophils have profound deficiencies in their ability to perform these functions, which contribute to the neonate's increased susceptibility to infection. Bone marrow neutrophil storage pools are also low in neonates, further predisposing them to bacterial infections.[42,44]

Neutrophils possess individual receptors for complement fragments such as C5a, formylated peptides, leukotriene B_4, and chemokines such as interleukin (IL)-8 (IL-8). These receptors initiate intracellular responses through α, β, and γ and guanosine triphosphate–binding proteins, leading to the activation of protein kinase C and the release of intracellular calcium. Activation of these signaling pathways and the binding of inflammatory mediators induce changes in the neutrophil surface charge, membrane potential, ion flux, and membrane fluidity. This interaction up-regulates the surface expression of adhesive glycoproteins, such as leukocyte selectin, sialyl-Lewis X, and the integrins

CD11/CD18.[42,45] Sialyl-Lewis X promotes neutrophil–endothelial cell selectin interactions, resulting in the rolling along and tethering to activated endothelial cell surfaces. The integrins Mac-1 (CD11b/18) bind to endothelial cell intracellular adhesion molecule 1 (ICAM-1), contributing to tight neutrophil adhesion at the site of microbial inoculation. Stimulated neonatal neutrophils have defective membrane potential changes, decreased fluidity, and an associated decreased intracellular calcium flux when compared with adult neutrophils.[42,45] Their ability to adhere to endothelial cell surfaces in vitro is also reduced when compared with adult cells.[46]

Neutrophil movement is initiated through G-proteins and calcium binding to calmodulin, which activates the contraction of cytoskeleton actin and myosin filaments. This leads to diapedesis through the epithelial cell surface and chemotaxis toward the inflammatory focus. Movement is partially dependent on interactions between Mac-1 (CD11b/18), as well as the other integrins and the extracellular matrix.[47,48] When neutrophils arrive at sites of microbial invasion, the cells spread out and up-regulate several phagocytic cell surface receptors. These include receptors for the Fc fragment of immunoglobulin; the complement receptors, C3b and iC3b; fibronectin; and other nonspecific receptors of innate immunity.[45] Neonatal neutrophils show impaired directed movement. The possible mechanisms for this include decreased complement receptors, defects in signal transduction resulting in low intracellular calcium responses, impaired cytoskeletal regulation, incomplete receptor up-regulation, and reduced energy metabolism.[46]

Neutrophils ingest pathogens opsonized with natural antibodies, specific antibodies, complement fragments, or nonspecific opsonins such as fibronectin.[49] Pathogens are killed by oxygen-dependent or -independent processes and antimicrobial factors. Phagolysosome fusion permits entry of granule contents into phagocytic vacuoles. Myeloperoxidase from primary or azurophilic granules catalyzes the production of hypochlorite ion from chloride and hydrogen peroxide, which can react with amines to produce toxic chloramines.[29] Neutrophils from stressed or infected neonates have decreased respiratory burst activity on exposure to GBS, *E. coli*, and *S. aureus* when compared with adults.[50,51] Other components of azurophilic granules include the antibacterial activities of the defensins, lysozyme, and bacterial permeability–increasing protein.[52] Neutrophils also produce a number of proinflammatory cytokines, including tumor necrosis factor (TNF) α, IL-1β, and IL-6, further activating innate and acquired immune responses.[53]

A newly recognized activity of neutrophils from adults was reported in which neutrophil extracellular traps (NETs) are generated for bacteria.[54] NETs are lattices of DNA, histones, granule enzymes, and antimicrobial proteins that capture and kill extracellular bacteria and fungi.[43] Yost and colleagues[55] found that neutrophils from both term and preterm infants fail to form NETs when activated by inflammatory agonists. This work suggests that the increased susceptibility of human neonates to both gram-negative and gram-positive bacteria may, in part, be related to defective NET production. Extracellular trap function has not been described in mononuclear leukocytes[56] but has been described in mast cells from adults.[57]

Monocytes, Macrophages, and Dendritic Cells

Mononuclear phagocytes, monocytes and macrophages, like neutrophils, are recruited to sites of infection. Neonates have diminished influx of monocytes to areas of inflammation. The adhesion of fetal and newborn monocytes is comparable to that of adult monocytes, but they have reduced chemotactic ability.[58-60] Monocytes exhibit considerably less respiratory burst production of hydrogen peroxide and other toxic reactive molecules compared with neutrophils.[61,62] The ability of fetal and neonatal monocytes to kill pathogens including *S. aureus*, *S. epidermidis, E. coli*, GBS, and *Candida albicans* is equal to that of adult monocytes.[63,64]

Monocytes synthesize and secrete numerous products involved in the inflammatory process. These include polypeptide hormones, complement components, cytokines, coagulation factors, enzymes, extracellular matrix proteins, and bioactive oligopeptides and lipids.[65] Certain products, such as the polypeptides IL-1, interferon (IFN) α, and TNF-α, are synthesized in similar concentrations by newborn and adult monocytes.[66-68] Other molecules, including polypeptides such as IFN-γ, IL-8, IL-10, and granulocyte colony-stimulating factor (G-CSF); extracellular matrix proteins such as fibronectin; and bioreactive lipids, such as leukotriene B_4, are synthesized in reduced concentrations by neonatal monocytes.[69-73] The principal function of monocytes in neonatal host defense may be their production of inflammatory mediators. The significance of these differences in host defense is currently under investigation.

Monocytes from developing bone marrow stores are released into the bloodstream where they may circulate for extended periods of time. These monocytes may then enter into tissues and differentiate into macrophages.[39-41] Macrophages have been described in the developing yolk sac, lung, and liver long before monocyte bone marrow development has been established. Fetal liver and lung macrophages are capable of self-proliferation.[74-76] Macrophages line the vascular sinusoids of the spleen, liver, and lymph nodes. This strategic placement allows for host defense of pathogens just below the epithelial barriers of the skin and respiratory and gastrointestinal tracts, and at blood-filtering sites. Macrophages alert cells of both innate and acquired immunity to microbial invasion through the release of cytokines and other inflammatory mediators.

Macrophages are avidly phagocytic and can readily kill most pathogens such as *S. pneumoniae, H. influenzae,* and *S. aureus*.[29] Some intracellular bacteria, such as *Mycobacteria, Nocardia,* and *Legionella* can survive within macrophages. Cytokine stimulation of infected macrophages (e.g., IFN-γ, IL-12, IL-18, and CSFs), is required to kill these pathogens. Deficiency of these cytokines or their receptors can result in infections with these intracellular bacteria.[29]

Macrophages generate several mediators and proteins that contribute to microbial killing. The ligands include arachidonic acid pathway–derived components such as leukotriene B_4. The proteins include lysozyme, lactoferrin, transferrin, and the defensins.[29] Macrophage-derived mediators initiate the inflammatory response and recruit neutrophils. These include the cytokines, TNF-α, IL-1, IL-12, IFN-γ, granulocyte-macrophage colony-stimulating factor (GM-CSF), G-CSF; the chemokines, chemotactic peptides, IL-8, macrophage inflammatory proteins, macrophage chemotactic peptide; and other related chemokines.[29,77,78]

Dendritic cells are macrophage-like cells that are less phagocytic and less adherent than macrophages. They are notable for their irregular shape with numerous membrane processes. These cells may leave the skin and migrate to afferent lymphatics and regional lymph nodes. Dendritic cells are present throughout the lungs and most organs except the brain. These cells, which ultimately initiate acquired immune responses via T cells, have the ability to migrate through tissues and ingest extracellular microbes by endocytosis.[79,80]

Mast Cells

Mast cells can be activated by IgE or by microbial pathogens.[81] Mast cell interaction with microbes such as *Salmonella typhimurium* and *Schistosoma mansoni* may be opsonin dependent or mediated by complement fragments including C3b and iC3b.[82,83] Bacteria such as *E. coli* and *K. pneumoniae* may associate with mast cells in an opsonin-independent manner through mast cell pattern receptors.[84-86] The pattern recognition receptor on mast cells for mannose-binding lectin on *E. coli*

and other enterobacteria appears to be a mannose-containing receptor molecule.[87] In addition, gram-positive bacteria such as *S. aureus* and streptococci are able to induce mast cell–mediated cytokine release.[84]

Mast cell degranulation can initiate leukocyte recruitment and enhance host defense against microbial invasion.[88,89] Leukocyte recruitment is mediated, in part, by TNF-α stimulation of vascular and bronchial ICAM-1 leading to leukocyte adherence. Histamine up-regulates selectins, which promote leukocyte rolling along and tethering to the endothelial cell surface. Platelet-activating factor may enhance CD-18–dependent leukocyte adhesion.[90] Mast cells may release IL-8, which stimulates neutrophil migration. Mast cells can phagocytize and kill both gram-positive and gram-negative bacteria.[84,85,91] Mast cells can present antigen, in the context of class I or II HLA molecules, to cells of the acquired immune system.[92] Mast cells or their products also play an important role in the defense against parasitic infections.[93]

Recent studies on mast cells from adults have shown that they are able to provide extracellular antimicrobial activity through the production of extracellular structures similar to the reported NETs. The major components of mast cell extracellular traps are DNA, histones, and granule proteins such as tryptase and the antimicrobial peptide LL-37.[57] To our knowledge studies on neonatal mast cell extracellular trap formation have not been conducted.

γδ *T Lymphocytes and B-1 Lymphocytes*

The late innate response to bacterial, viral, and parasitic infections includes γδ T-lymphocyte infiltration and B-1–lymphocyte activation.[94] The γδ T-cell receptors recognize glycolipid antigens present on many microbes.[95] Located in the epithelial linings of the skin and gastrointestinal and respiratory tracts, where they proliferate and release cytokines, they are also termed *intraepithelial T lymphocytes*.[96-98] The peritoneal cavity contains B lymphocytes termed B-1 cells.[99] The antigen receptors of these cells, like intraepithelial γδ T cells, have limited diversity.[95-100] B-1–lymphocyte cell receptors bind immunoglobulins, mainly IgM, which are reactive with common microbial antigens, such as LPS and phosphorylcholine. B-1 lymphocytes produce natural antibodies specific for a variety of microbes present at epithelial cell surfaces.

Natural Opsonins

Nonspecific opsonins contribute to the innate immune responses before specific opsonic antibody can be generated. These natural opsonins include natural antibodies, complement fragments, and fibronectin.

Natural Antibodies

Natural antibodies are antibodies present in normal sera; they are not the result of antigen stimulation.[101] They may be self-reactive or autoreactive, or reactive against a variety of bacterial, viral, and fungal pathogens.[102,103] Natural antibodies are mainly the products of B-1 lymphocytes that develop in the fetus and neonate.[99] Natural antibodies serve as a second line of defense, after an organism has breached the epithelial or mucosal barrier. Most natural antibodies are IgM and activate the complement system, but they may be IgG and IgA. They bind to repeating moieties of polysaccharides.[104,105] Because many microorganisms share structural polysaccharides and phospholipids, natural antibodies protect against a wide variety of pathogens. Mice lacking natural antibody have enhanced susceptibility to bacterial peritonitis, reduced cytokine expression, particularly TNF-α, and higher mortality rates from infection.[103,106,107]

Complement

The complement system is part of the innate immune system that defends against initial pathogen invasion. Complement is composed of two pathways: the classic pathway and the alternative pathway. It has three main physiologic effects: (1) bridging the innate and acquired immune responses, (2) defense against pyogenic bacterial infections, and (3) disposing of immune complexes and the products of inflammatory injury. The complement system is made up of a series of more than 30 plasma and regulatory membrane proteins. Genes for several of the complement components are found within the major histocompatibility complex class III region on chromosome 6. Complement functions include (1) amplification of leukocyte-associated inflammatory responses, (2) anaphylactoid responses through stimulation of histamine release, (3) chemoattraction and activation of neutrophils and macrophages, (4) opsonization of foreign microbes and antigens, and (5) cytolysis of target cell membranes.[108]

The classic complement pathway is triggered primarily by antigen-antibody complexes or aggregated IgM or IgG. Natural IgM and IgG antibodies can trigger the complement system, resulting in classic pathway activation and formation of the inflammatory components C3a and C5a, and opsonic fragments C3b and iC3b.[109] Mannose-binding protein activates the classic complement pathway.[110]

The alternative complement pathway is triggered by complex polysaccharides, LPSs, bacterial cell wall components, aggregated IgA and IgE, and yeast. Phagocytic cells have receptors for C3b (CR1) and iC3b (CR3 and CR4) that allow them to ingest, process, and kill pathogens.[95] C1q-coated particles can be ingested by macrophages. The terminal complement components C5 to C9 can lyse some bacteria, notably *Neisseria* species and *E. coli*.[108,111]

The major effects of complement components include anaphylatoxic (C3a and C5a), opsonic (C3bi and C3b), chemotactic (C5a), and cytolytic activity (membrane attack complex, C5 to C9). Deficiency of the early components of the classic pathway results in a high incidence of collagen vascular–like and lupus-like disease, including arthritis, skin rash, and glomerulonephritis (C1q, C1r, C1s, C4, or C2 deficiency), and some patients may have recurrent infection, usually with *S. pneumoniae*.[108,111] Patients with deficiency of C3 usually have pyogenic infections because both the classic and alternative pathways are impaired. Patients with late complement deficiencies have recurrent infections with *N. meningitidis* or *N. gonorrhoeae*.[111]

The production and function of complement proteins are quantitatively and qualitatively different in the neonate compared with adults. Complement protein synthesis in the developing human fetus occurs between 8 and 19 weeks gestational age. The synthesis of C4, C2, and C3 occurs in the liver between 8 and 14 weeks, and functionally active C5 can be detected in fetal lungs and liver as early as 8 to 9 gestational weeks. Complement proteins are produced in decreased quantity with decreased functional activity, depending on the gestational age of the fetus.[108] Few, if any, of the maternal complement components cross the placenta to the developing fetus. Results of studies done in preterm and term infants compared with adults show that preterm and term infants are markedly deficient in complement components, especially C9 and factor B of the alternative pathway.[112,113] Neonatal serum complement opsonic activity and/or chemotactic activity has been studied with strains of *E. coli*, staphylococcus, and group B streptococcus. Neonates and especially preterm infants have deficiencies in complement opsonic activity critical to bacterial host defense.[108] In addition, the cellular and humoral factors required for the activation of complement are also deficient in neonates. Most neonates have low levels of IgM because maternal passage of this immunoglobulin does not occur and little production occurs in the developing fetus. Because many antibodies against bacteria are of the IgM class, opsonization and subsequent bacterial killing are reduced in newborn infants because of insufficient IgM to activate the classic pathway of complement.[108]

Fibronectin

Fibronectin (Fn) is a high-molecular-weight glycoprotein (440 kDa), which participates in a number of complex processes, including hemostasis, wound healing, cell migration and differentiation, and phagocytosis.[114]

Fn binds to organisms such as *S. aureus*, *S. epidermidis*, and *Streptococcus pyogenes* to promote their interactions with phagocytic cells, including macrophages and neutrophils.[115-117] Fn enhances the binding of *S. aureus* to neutrophils and their subsequent ingestion when activated by inflammatory mediators.[118] Fn increases the uptake of antibody-coated GBS by human neutrophils and enhances survival of neonatal rats infected with these organisms.[119] Similar observations have been made with use of macrophages.[120] Yang and associates[117] also found that Fn increases the respiratory burst activity, phagocytosis, and intracellular killing of *S. aureus* and *S. epidermidis* by human neutrophils in the absence of antibody, probably through functional binding of organisms to Fn receptors on phagocytic cells. In contrast, GBS and *E. coli* uptake and killing are enhanced by Fn but only in the presence of opsonic antibody.[119] Binding of Fn to its receptor on neutrophils, monocytes, or macrophages enhances the respiratory burst activity, alters actin polymerization, and promotes the release of TNF-α.[121,122] Reduced levels of plasma Fn are seen in normal newborn infants; neonates with respiratory distress, perinatal asphyxia, and sepsis; and patients with severe trauma, septic shock, or severe burns.[114,119,123-130]

Pathogen-associated Receptors

Pattern recognition receptors are expressed on most effector cells of the innate immune system, including mast cells, macrophages, dendritic cells, and B-1 cells. They recognize specific pathogen-associated molecular patterns present on many microbes. They are secreted into the plasma or tissue fluid or contained intracellularly as cytoplasmic proteins.[14,131]

Toll-like Receptors

Toll-like receptors (TLRs) are a family of type 1 integral membrane glycoproteins that initiate innate immune responses via ligand recognition of pathogen-associated molecular patterns.[132-135] Ligands recognized by TLRs consist of a wide range of microbial products including diacyl and triacyl lipopeptides, lipopolysaccharide (LPS), lipoteichoic acid, peptidoglycan, flagellin, zymosan, and both single- and double-stranded RNA.[132-135] Ligand recognition initiates TLR dimerization, resulting in signal transduction through one of two pathways: the myeloid differentiation protein 88 (MyD88)–dependent pathway or the MyD88–independent pathway.[132-134] TLR signaling through the MyD88–dependent pathway leads to activation of nuclear factor κB (NF-κB) or activator protein 1 (AP-1), and subsequent cytokine and chemokine production.[132-135] MyD88-independent signaling can activate either NF-κB or interferon regulatory factors (IRFs), leading to the production of type 1 interferons.[132-134]

TLRs may contribute to the increased risk of human neonates for bacterial infections. TNF-α production in response to LPS stimulation of TLR-4 has been shown to be diminished in human neonates compared with adults.[136-138] In addition, TLR-4–stimulated IL-10 release is also decreased in neonates when compared with adults.[139] TLR-4 signaling has also been implicated in defective neonatal mouse neutrophil migration and may contribute to the defective chemotaxis observed in human neonatal neutrophils.[140] Diminished concentrations of MyD88 have been associated with decreased LPS-stimulated TNF-α concentrations in human neonates.[137] The deficiency of IL-1 receptor–associated kinase-4 (IRAK-4), a downstream adapter molecule in the MyD88-dependent pathway for activation of NF-κB leading to transcription of inflammatory genes, has been shown to cause severe pyogenic bacterial infections in children.[141] The role of IRAK-4 in human neonates, to our knowledge, has yet to be defined.

Non-TLR pattern-recognition receptors (PRRs) also remain to be fully described in human neonates. Two recently described PRRs include the NOD-1–like receptors NOD-1 and NOD-2. NOD-1 and NOD-2 are cytosolic PRRs that initiate proinflammatory signaling through the NF-κB and mitogen-activated protein kinase pathways, on the detection of bacterial peptidoglycan degradation products.[142] NOD-1 and NOD-2 have been shown to contribute to sepsis and sepsis-related syndromes.[143-145] NOD-1 and/or NOD-2 may play an important role in the neonatal response to bacterial infections. Caron and colleagues[146] have shown a decrease in the production of TNF-α, IL-1β, and TNF-γ by cord blood mononuclear cells compared with cells of adults in response to NOD-1 and NOD-2 stimulation. The role of NOD-1 and NOD-2 in neonatal inflammatory responses is currently under investigation.

Collectins

The collectins are a family of PRRs, including mannose-binding protein and surfactant proteins A and D, which contain collagen and lectin domains and share biologic activities.[14,147,148]

Mannose-binding protein (MBP) is probably the best characterized of the PRR collectins.[149] It binds to carbohydrate structures on gram-positive and gram-negative bacteria, yeast, parasites, and some viruses.[150] MBP is encoded on chromosome 10.[149] Microbial pathogens bound by MBP in the blood or tissue fluid are then opsonized and phagocytized or lysed by the complement system.[14] Deficiency of MBP is a disorder associated with increased susceptibility to bacterial, fungal, and viral infections, usually beginning early in life before the maturation of acquired immune responses.[149,151,152] These patients usually have recurrent upper respiratory tract infections, otitis media, chronic diarrhea of infancy, and failure to thrive within the first year of life.[151,152] Deficiency of MBP also may contribute to the severity and progression of infection beyond infancy because of abnormal interaction of MBP with the complement system.[151]

Surfactant is a mixture of proteins and lipids that promotes normal respiratory function and enhances lung host defense.[147,153] Two surfactant proteins, SP-A and SP-D, belong to the collectin family of pattern recognition receptors. These are products of alveolar type II cells during the latter stages of pregnancy.

LaForce and colleagues[154] initially reported that surfactant improves macrophage killing of *S. aureus*. SP-A and SP-D bind to certain bacteria, viruses, yeast, and fungi to promote their attachment to phagocytic cells via Fc receptors of immunoglobulin and complement receptors, which facilitates their elimination.[147,155] SP-A and SP-D bind to gram-positive and gram-negative bacteria, *Pneumocystis carinii*, fungi such as *Aspergillus*, yeast including *Cryptococcus neoformans*, bacteria such as *H. influenzae*, as well as herpes simplex virus, *Mycobacterium tuberculosis*, and *Mycoplasma pulmonis*.[156-166] SP-A and especially SP-D promote the formation of microbe aggregates that may enhance their mucociliary clearance.[153]

The surfactant collectins stimulate neutrophil and macrophage chemotaxis, actin polymerization, respiratory burst activity, and nitric oxide production. SP-A knockout mice cannot kill mycoplasma via nitric oxide–dependent mechanisms. They also have abnormalities in neutrophil recruitment, production of toxic oxygen and nitrogen intermediates, and defective phagocytosis.[147] These knockout mice develop disseminated GBS infection after intratracheal inoculation and have diminished clearance of *S. aureus* and *P. aeruginosa*.[167-170]

SP-A and SP-D bind LPS from organisms such as *E. coli*, *K. pneumoniae*, and *P. aeruginosa;* SP-A and LPS subsequently bind to macrophages via CD14-dependent and -independent mechanisms, increasing TNF-α release.[156,170] SP-A and SP-D function by clumping pathogens and promoting adherence to inflammatory

cells.[147,171] Furthermore, they may down-regulate T cells and their cytokine responses and suppress the response to inhaled allergens.[172,173]

Deficiencies of surfactant are observed in premature infants and patients with cystic fibrosis, respiratory syncytial virus infection, and adult respiratory distress syndrome. Reduced SP-D opsonization has been observed in diabetic mice because of competition by free glucose for SP-D–binding sites.[147]

Selectins

Selectins are a family of adhesion molecules that facilitate neutrophil rolling along and tethering to the vascular endothelium. Selectins include leukocyte selectin (L-selectin), endothelial selectin (E-selectin), and platelet selectin (P-selectin), which have lectin-like domains.[174] L-selectin binds lipid-linked galactose with sulfate residues. P-selectin binds sulfotyrosine, and E-selectin binds fuco-oligosaccharides present on leukocytes, epithelial cells, and some tumor cells.[148] Deficiency of L-selectin results in leukocyte adhesion deficiency type II and is associated with decreased leukocyte infiltration, resulting in a poor inflammatory response along with associated neurologic and developmental abnormalities caused by impaired fucose metabolism.[175] P-selectin expression by endothelial cells is decreased in human preterm infants.[176]

Bacterial Lipopolysaccharide

Bacterial LPS is a virulence factor of gram-negative bacteria. It is a powerful cellular activator and promotes cytokine release from neutrophils, macrophages, and other cells of the innate immune response. The polysaccharide groups of LPS vary considerably from species to species, and even between strains of the same species, permitting bacteria such as *E. coli* to be serotyped. The lipid moiety of LPS is generally highly conserved.[14,95]

The primary cellular receptor for LPS is CD14, a glycosylphosphatidylinositol-linked protein.[31] CD14 was first identified on phagocytic cells but also occurs on many other cells. Binding of LPS to CD14 is markedly potentiated by LPS-binding protein (LBP), a normal component of the serum. Binding of LPS to LBP enhances effector cell responsiveness to LPS, promoting cellular activation and cytokine release.[14]

Bacterial Permeability–increasing Factor

Bacterial permeability–increasing factor (BPI) is a 55-kDa pattern recognition receptor present in neutrophil granules, which contain two domains, one of which binds with LPS to increase membrane permeability and lysis of gram-negative bacteria, whereas the other promotes opsonization.[14] Neutrophil BPI functions in concert with defensins and the membrane attack complex of complement to cause bacterial lysis. Neonates have reduced release and activity of BPI, perhaps contributing to their enhanced susceptibility to gram-negative bacterial infections.[177]

Natural Antimicrobial Agents

Antimicrobial peptides, first described in insects in 1981,[178] have now been found in all multicellular organisms, including, plants, insects, and humans.[14] Important antimicrobial peptides in humans are the α and β defensins. They are contained in the primary, or azurophilic, granules and in secondary, or specific, granules of phagocytic cells.

Defensins

The defensins are strongly cationic, single-chain peptides with molecular weights of between 3 and 4.5 kDa. Defensins make up 50% of the protein content of the neutrophil primary granules.[29,179] These are divided into α and β defensins. These peptides possess antimicrobial activity against gram-positive and gram-negative bacteria, fungi, mycobacteria, and some viruses. The defensins create voltage-sensitive pores in microbial membranes, resulting in lysis. Humans have six human α defensins (HD1 to 6) and two human β defensins (HBD-1 and HBD-2).[179]

The α defensins, HD 1 to 6, are made primarily by neutrophils and compose 30% to 50% of the primary granule content.[180] Defensins are present after neutrophil degranulation induced by LPS, IL-8, C5a, and other stimuli. They are also found on the epithelial surfaces of the bronchi and in bronchial lavage fluid of patients with various types of inflammatory lung injury. The antimicrobial activity of defensins is inhibited by high salt content, which may contribute to the decreased microbial activity of lung surface fluid in patients with cystic fibrosis.[181]

The β defensins are produced by epithelial cells of the respiratory and gastrointestinal tracts.[16,182] HBD-1 is expressed constitutively by epithelial cells in the bronchi and intestine, whereas HBD-2 synthesis is up-regulated by inflammatory stimuli, including LPS, TNF-α bacterial infection, and injury. Thus HBD-1 acts to kill organisms in the absence of inflammation, whereas HBD-2 acts primarily as part of the inflammatory process. In inflammatory lung disease both α HD 1 to 6 defensins and β HBD-2 may be increased significantly, perhaps contributing to airway inflammation.[29]

Lysozyme and Myeloperoxidase

Lysozyme, present in primary and secondary granules of neutrophils, is an antimicrobial component present in inflammatory exudates, nasal secretions, and alveolar surface fluid.[31] Lysozyme is a small cationic enzyme that hydrolyzes glycosidic bonds that disrupt the peptidoglycan structural components of some gram-positive bacterial cell walls. Lysozyme can be present in airway surface fluid, where it may be an important component of the innate defense system.[33,34]

Myeloperoxidase is the most abundant enzyme in the primary granules of phagocytes. It catalyzes the reaction between chloride and hydrogen peroxide to form hypochlorite ion, a potent microbicidal agent of the respiratory burst. Bacterial killing takes almost twice as long if this enzyme is missing.[42]

THE COMPONENTS OF ADAPTIVE HOST DEFENSE

The hallmark of acquired, or adaptive, immunity is its specificity for structurally distinct antigens and memory of prior exposure. T and B lymphocytes orchestrate the cellular and humoral immune responses of acquired host defense. Acquired immune responses are the last to develop phylogenetically and the last to mature developmentally; they require close cooperation between cellular elements of the innate immune system and the T and B lymphocytes.[14,183]

T Lymphocytes

The major functions of the T-lymphocyte system are in host defense against intracellular pathogens (fungus, viruses, protozoa, and intracellular bacteria such as mycobacteria and *Listeria* species). T lymphocytes play a limited protective role against pyogenic bacteria such as GBS. The T-lymphocyte system also functions in tumor surveillance, delayed hypersensitivity reactions, and graft-versus-host disease.[184-186]

Thymus-dependent T cells are derived from pluripotent lymphopoietic stem cells residing in developing bone marrow stores. As early as the eighth gestational week, immature T cells infiltrate the thymus, where they differentiate and mature under the influences of thymic humoral factors, before migrating to specific lymphoid tissues. During their intrathymic migration, T cells develop specific outer membrane–bound glycoproteins at different stages. Most of the mature T cells express T-cell antigen receptors, as well as CD3 membrane glycoproteins. Nearly 70%

of the T cells also express the CD4 membrane glycoproteins, the helper-inducer T-cell marker. The remaining 30% express the CD8 membrane glycoproteins, the cytotoxic-suppressor T-cell marker. The CD4 and CD8 membrane glycoproteins typically are not presented on the same mature T cell and serve as functional markers of helper-inducer and cytotoxic-suppressor T-cell populations in the peripheral blood or tissues.

The T-lymphocyte system orchestrates pathogen annihilation through antigen-dependent cellular interaction. Antigen-presenting cells, mainly the monocytes and macrophages, produce soluble antigen and present it in combination with HLA class II antigens on their cell surfaces. Thymus-dependent CD4 helper-inducer T cells recognize and bind to this altered antigen HLA class II complex through the antigen-specific T-cell receptors. During this process, the cytokines IL-1 and TNF-α are released from the antigen-presenting cells. The binding of free IL-1 to its receptor on helper-inducer T-cell surfaces initiates T-cell activation. Once activated, the CD4 helper-inducer T cells produce IL-2, which functions as a T-cell promoter causing the T cells to proliferate and release a number of other cytokines. This initiates a cascade of events that serves to amplify and regulate the immune response with the cooperation and recruitment of many other cell types. IL-2 also interacts directly with CD8 cytotoxic-suppressor T cells that bind viral antigens present on the surface of infected cells, resulting in cellular destruction.[184]

At birth, T-cell immunity is immature compared with that of the adult, in part because of the lack of exposure of the fetal immune system to foreign antigens and decreased cytokine production. Neonatal T cells provide ineffective signals to B cells as a result of developmental defects in local cytokine production and cell-cell interaction. Any defect in T-cell immunity is also associated with variable degrees of B-cell deficiency because most of the maturation, differentiation, and activation processes of B cells require T-cell help.[184,185] The most severe form of immunodeficiency is the syndrome of severe combined immunodeficiency. This immunodeficiency category includes a spectrum of X-linked, autosomal recessive, and sporadic genetic defects characterized by the inability to mount a normal T-lymphocyte and B-lymphocyte immunity. Patients usually have failure to thrive, persistent oral candidiasis, recurrent diarrhea, and pneumonia, usually interstitial and often caused by *P. carinii*, in the first months of life.[186]

In response to microbial invasion, most cells of the innate and acquired immune system produce cytokines, which function in autocrine, paracrine, and endocrine fashions. Macrophages, NK cells, neutrophils, mast cells, and γδ T cells produce cytokines critical in the early response to microbial invasion. Antigen-activated T and B lymphocytes also produce cytokines that can activate, or recruit, effector cells of the innate immune system. Lymphocytes, macrophages, and stromal cells of the bone marrow produce CSFs that promote the growth and differentiation of immature leukocytes.[95,187] The placenta also produces cytokines in response to infection. Levels of cytokines, including G-CSF, GM-CSF, TNF-α, IL-1, IL-6, and IL-8, are increased 10-fold in the amniotic fluid of mothers with chorioamnionitis.[188] We will consider select cytokines that mediate host defense to bacteria—notably, TNF, ILs (IL-1, IL-6, IL-8, IL-11, IL-12, and IL-18), IFNs (IFN-α and IFN-γ), and CSFs (G-CSF, macrophage CSF [M-CSF], and GM-CSF).

Tumor Necrosis Factor

TNF-α and TNF-β are structurally related. They bind to the same receptors with equal affinity and elicit similar biologic effects.[95] TNF-α is primarily the product of macrophages and other antigen presenting cells, NK cells, and activated mast cells of the innate immune system, but it can also be produced by antigen-activated T cells. TNF-β is synthesized by T lymphocytes.[189-193]

TNF-α is the cytokine responsible for the host response to gram-negative bacterial infections and specifically to LPS, as well as to gram-positive bacteria.[192,194-196] Along with IL-1, TNF-α is a principal mediator of septic shock. TNF-α activates neutrophils, stimulates their adhesion to vascular endothelial cells, and induces their production of toxic oxygen products.[29,197-200] If TNF-α production is excessive, these toxic oxygen products damage endothelial cells and cause fluid leak, hypovolemia, and depressed cardiac contractility leading to septic shock. TNF-α production is primarily induced by (1) gram-positive bacteria and their products, including peptidoglycans, lipoteichoic acids, and pyogenic exotoxins[201-204]; (2) nonspecific mediators such as fibronectin, C5a, and surfactant proteins[122,205-207]; and (3) lactic acid, which is elevated in septic shock.[208]

TNF-α knockout mice, or normal mice pretreated with anti–TNF-α monoclonal antibody, have increased susceptibility to bacterial infection and a decreased occurrence of septic shock. In vitro, human mononuclear cells stimulated by GBS first generate TNF-α followed by IL-1, IL-6, IL-8, and IFN-γ.[204,209] In experimental models of GBS, anti–TNF-α monoclonal antibody therapy, administered early during infection, improves survival, probably by limiting cytokine-mediated septic shock.[210]

Interleukins

Interleukin-1

IL-1 is produced predominantly by macrophages and macrophage-like cells but also by endothelial and epithelial cells. IL-1 has two forms, IL-α and IL-β, encoded by two separate genes, which bind to the same IL-1 receptors. Two IL-1 receptors bind to the two forms of IL-1 with different affinities. They are distributed on a variety of cells in different concentrations throughout the body.[95]

During development, IL-1 production by fetal macrophages in response to LPS up-regulates G-CSF production by monocytes from the bone marrow and liver of human fetuses.[211] During inflammation, IL-1 up-regulates the expression of endothelial adhesive glycoproteins, such as ICAM-1, promoting neutrophil attachment.[212] IL-1 also promotes IL-6, IL-8, and other chemokine production by macrophages. IL-1, along with TNF-α, induces prostaglandin E_2 production in the hypothalamus, raising the body's temperature. IL-1, TNF-α, and IL-6 cause production and release of acute-phase reactants by the liver, including α_1-antitrypsin, haptoglobin, C-reactive protein, serum amyloid A protein, complement components, and fibrinogen.[213]

Interleukin-6

IL-6 supports hematopoietic progenitor growth, promotes T- and B-cell function, and mediates some acute-phase responses of inflammation. IL-6 is produced mainly by macrophages and mononuclear cells, but also by fibroblasts and endothelial cells. IL-6 is secreted in response to both TNF-α and IL-1, as well as microbes and their products.[95,187] After cellular activation, IL-1 and TNF-α production occurs, followed by IL-6 synthesis. IL-6 does not activate neutrophils or induce cytotoxicity, but it does increase the production of acute-phase reactants. IL-6 promotes the growth of B cells, stimulates antibody production, and enhances T-cell proliferation. IL-6 also enhances the activity of hematopoietic growth factors such as granulocyte and macrophage CSFs, thus playing a role in both innate and acquired immunity.[214] IL-6–deficient mice have increased mortality associated with bacterial infections because of impairment of neutrophil and macrophage responses.[215]

Interleukin-8

IL-8 is a member of the chemokine family that attracts neutrophils to sites of inflammation and plays an important role in host defense against bacterial infections.[216] IL-8 is produced by fetal

thymic epithelial cells, and its in vitro production is increased by IL-1. IL-8 is present in the cord blood of babies born with chorioamnionitis. Its expression is decreased in babies of mothers receiving steroids to induce fetal lung maturation.[217] IL-8 is a major factor in recruitment of neutrophils to the lung in bacterial pneumonia.[77,218]

Interleukin-11

IL-11 was initially characterized as a hematopoietic cytokine with thrombopoietic activity. It is expressed in the central nervous system and the gastrointestinal tract. The hematopoietic actions of IL-11 include the stimulation and proliferation of primitive stem cells. It acts in synergy with other cytokines to support the proliferation and differentiation of all lineages of hematopoietic stem cells.[219-221]

IL-11 has been used effectively in animal models of sepsis and septic shock. Neonatal rats pretreated with IL-11 and then exposed to GBS demonstrated a significant reduction in mortality.[222] Gastrointestinal protective effects of IL-11 exist as well. IL-11 administration in animal models of chemical-induced acute colitis and ischemic bowel disease results in significant increases in survival.[223-225] Decreased translocation of enteric bacteria is observed in the IL-11–treated animals. IL-11 has been used in patients with Crohn disease, and studies of IL-11 administration for the prevention or treatment of necrotizing enterocolitis in neonates is under consideration.[226]

Interleukin-12

Mononuclear cell production of IL-12 is an important component of the early response to microbial infection.[227] Although monocytes and macrophages are the main source of IL-12, other cells, including B cells, also can produce IL-12.[228,229] IL-12 induces IFN-γ production by T cells and NK cells and promotes cellular cytotoxicity and lymphocyte proliferation. It is down-regulated by IL-10.[200] IL-12 can be induced by exposure of mononuclear cells to microbes or their products, including *S. aureus*, GBS, and LPS.[230-234] The IL-12 receptor, composed of β1 and β2 subunits, binds IL-12 with high affinity.[234]

Decreased transcription and secretion of IL-12 and decreased IFN-γ production by newborn mononuclear cells suggest an abnormality within the IL-12–IFN-γ pathway. In vitro studies suggest that IL-12 can partially correct the IFN-γ deficiency.[231] IL-12 administration to neonatal mice with group B streptococcal infection significantly improves their survival.[235] The IL-12–IFN-γ pathway is also suppressed in older patients with critical infections.[236] Patients with hyper-IgE syndrome have defective synthesis of IFN-γ in response to exposure to staphylococci and candida, suggesting an abnormality in the IL-12–IFN-γ pathway in these patients as well.[237]

Interleukin-18

IL-18 is produced by monocytes, macrophages, osteoclasts, and keratinocytes and stimulates the production of IFN-γ. Its structure is similar to that of IL-1, and its receptor is also closely related to the IL-1 receptor.[238] IL-18 stimulates IFN-γ production using a different transcription promoter than that used by IL-12, but IL-12 and IL-18 act synergistically to enhance IFN-γ production in response to microbes and their products. IL-18 knockout mice do not have a complete deficiency of IFN-γ.[239-241]

Stimulation of NK cells with IL-18 markedly enhances their cytotoxic activity.[242,243] IL-18 knockout mice have decreased but not eliminated NK activity.[239] IL-18 stimulates $CD4^+$ T cells and B cells to produce cytokines and antibodies. It also stimulates IL-8 production by mononuclear cells and IFN-γ production by NK cells.[244] Decreased IL-18 production in cord blood mononuclear cells exposed to GBS, along with their deficiency in IL-12 production, contributes to inadequate IFN-γ production and increased susceptibility to GBS and other infections.[245]

Interferons

The IFNs are cytokines between 18 and 20 kDa produced by a variety of cells that function in both innate and acquired immunity. Interferons are divided into type I interferons, which include IFN-α and IFN-β, and type II, or immune, IFN-γ. The type I interferons share a common receptor, induce similar responses, and are encoded on chromosome 9p21 by a cluster of intronless genes. Type II interferon, IFN-γ, has a distinct receptor separate from that of IFN-α and β. IFN-γ is also structurally distinct from the type I interferons and is encoded on chromosome 12p24.[95,187]

IFN-α is the product of mononuclear phagocytes and has been known as leukocyte IFN, whereas IFN-β is produced by fibroblasts and is known as fibroblast IFN. The major stimulus for type I IFN production is a viral infection. In addition, both type I IFNs are stimulated by the acquired immune response to antigens, in response to T cell–derived factors.[95]

Interferon-γ is a 20- to 25-kDa glycoprotein encoded by a single gene on chromosome 12p24.[246,247] It is produced by $CD4^+$ and $CD8^+$ T cells and by NK cells and is a component of both the acquired and innate immune systems. T-cell IFN-γ production occurs after antigen stimulation in the presence of IL-2, IL-12, and IL-18. IFN-γ also has antiviral and antiproliferative activity and up-regulates both class I and class II HLA molecule expression.[247]

Activated macrophages can generate cytokines (IL-12, IL-15, and IL-18) that induce NK cell activation and IFN-γ production, and enhance macrophage antibacterial activity. IFN-γ activates mononuclear phagocytes and neutrophils, resulting in enhanced killing of phagocytized microbes and intracellular pathogens, such as *Mycobacteria* and *Listeria*. Patients with defects in IFN-γ receptors have severe infections with *Mycobacteria* and related pathogens.[248,249]

Neonates have a deficiency in the transcription and production of IFN-γ.[69,231,250] In vitro administration of IFN-γ enhances the chemotactic activity of newborn neutrophils.[246,247] IFN-γ is also decreased in the hyper-IgE syndrome.[251,252] Borges and associates[237] showed that mononuclear cells of these patients have decreased IFN-γ responses to staphylococci. In vitro incubation of their neutrophils with recombinant human IFN-γ significantly improves their chemotactic responsiveness.[247,253] IFN-γ administration to patients with hyper-IgE increased neutrophil responsiveness, improved eczema, and decreased respiratory symptoms.[254] IFN-γ lowers the incidence of serious infections in patients with chronic granulomatous disease without demonstrating an effect on their neutrophil respiratory burst.[255]

Colony-stimulating Factors

The production and function of neutrophils and macrophages are regulated, in part, by CSFs.[256,257] GM-CSF is a 14- to 35-kDa glycoprotein encoded on chromosome 5q23-31 that stimulates production of neutrophils, macrophages, and eosinophils.[187,258] G-CSF is an 18- to 22-kDa glycoprotein encoded on chromosome 17q11-21 that stimulates neutrophil production. M-CSF is a 21-to 40-kDa glycoprotein encoded on chromosome 5q23-31 that stimulates monocyte production.[187]

GM-CSF is produced by activated T cells and mononuclear phagocytes, vascular endothelial cells, and fibroblasts. It promotes the growth and differentiation of monocytes, macrophages, and neutrophils and, to a lesser extent, platelets and progenitor red blood cells. It activates macrophages in much the same fashion as IFN-γ. GM-CSF is produced by macrophages, fibroblasts, and endothelial cells at inflammatory focuses but is not present in the circulation.[187]

G-CSF is also produced by macrophages, fibroblasts, and endothelial cells and is present in low concentrations in the bloodstream. Microbes and their products and cytokines, such as TNF-α and IL-1β, stimulate the production of G-CSF.[29] G-CSF

acts on neutrophil progenitors to produce neutrophil maturation and release from the marrow. It also activates and enhances the function of neutrophils and macrophages.[187,259-261] G-CSF regulates neutrophil adhesion molecule expression, and also neutrophil adhesion, chemotaxis, respiratory burst activity, phagocytosis, and intracellular microbial killing.[262-264] Pulmonary or systemic infection stimulates the production of G-CSF in the blood, with resultant neutrophilia and enhanced inflammatory response.[265,266]

Monocytes and mononuclear cells from human neonates produce G-CSF and GM-CSF in reduced amounts, compared with adults, in response to inflammatory agents in vitro. Preterm infants have even further reduction in G-CSF and GM-CSF production than do term infants. These deficiencies contribute to the diminished neonatal neutrophil storage pool. Plasma concentrations of G-CSF are low in the preterm infant and in newborns with neutropenia and sepsis.[46]

Natural Killer Cells

NK cells are non-B, non-T cells lacking surface immunoglobulins and T-cell antigen receptors that are essential components of the acquired immune system.[267] NK cells appear in the human liver as early as 5 weeks after conception and increase in numbers and functional ability as development progresses. At birth, however, NK function is low compared with that in adult cells.[267,268]

NK cells release a variety of cytokines, including TNF-α, TNF-β, IFN-γ, GM-CSF, and CSF-1.[269] Several cytokines enhance NK activity, notably IL-2, IL-12, IL-15, IFN-α, IFN-β, and IFN-γ. NK cells also appear to be important in protection against intracellular infections such as *L. monocytogenes* and *Toxoplasma gondii*.[270-272] These pathogens induce macrophages to secrete the NK cell–activating cytokines IL-12 and IL-15, which induce NK cells to produce IFN-γ. This NK cell–derived IFN-γ then stimulates macrophages to kill these intracellular pathogens. The newborn infant has depressed NK cell activity, which might contribute to the susceptibility to these pathogens, as well as to other bacteria and viruses.[273,274]

B Lymphocytes

The neonatal ability to produce antibodies is quantitatively and qualitatively different from that of adults. The B-lymphocytic system is derived from stem cells residing in bone marrow stores. These stem cells produce cytoplasmic IgM heavy chains and become pre-B cells as early as 10 weeks gestation. Pre-B cells continue to differentiate to become mature surface IgM, or IgM- and IgD-bearing B cells, which seed peripheral lymphoid tissues via the circulation. On stimulation, IgM-bearing B cells may undergo class switching to IgG-, IgA-, or IgE-bearing B cells. These B cells can then differentiate into immunoglobulin-secreting plasma cells with the help of T cells and T cell–derived cytokines. Some of the B cells further differentiate into small memory B cells.[275]

The major function of B lymphocytes is to produce antibodies to the protein and carbohydrate antigens present on microorganisms, toxins, or other potentially harmful antigenic substances. These antibodies are classified into nine different immunoglobulin isotypes, including IgM, IgG1, IgG2, IgG3, IgG4, and IgA1, IgA2, IgE, and IgD. The IgM antibodies are made first and are the most effective and efficient in activating the classic complement system. IgM antibodies do not cross the placenta; thus the presence of IgM in the newborn infant may suggest congenital infection.[275,276]

The IgG antibodies, which represent 75% of serum immunoglobulin, are the only immunoglobulin class maternal antibodies that are transplacentally passed; they provide the developing infant with passive immunity. Passively acquired IgG has a half-life of approximately 20 days. All IgG subclasses cross the placenta. At birth, newborn IgG concentrations actually exceed maternal IgG levels, but they immediately begin to decrease until a nadir (400 mg/dL) is reached at 3 to 4 months of age in term infants. The IgG1 subclass represents approximately 70% of IgG and usually contains antiprotein antibody that also activates complement. The IgG2 subclass represents 20% of IgG and usually contains an antipolysaccharide antibody. The ability to produce antibodies to protein and carbohydrate antigens is different during the first 2 years of life. An infant's ability to produce IgG1 protein antibodies in the first few months of life is similar to that of adults. The infant's ability to produce IgG2 antibodies to polysaccharide antigens, however, is much lower, and effective antibody concentrations are not reached until after 2 years of age. Thus children younger than 2 years of age are predisposed to infections by polysaccharide-coated organisms (e.g., *H. influenzae*, pneumococcus, meningococcus). The IgG3 subclass represents 6% of IgG and usually contains antiviral protein antibody.[275,276]

Decreased passage of maternal antibody is suspected to be a major determinant in neonatal infections with GBS and *E. coli*, especially in premature infants. Before 32 weeks of gestation, the developing neonate's IgG concentrations are less than 50% of maternal values. Neonates with deficiency of type-specific antibody to the type III polysaccharide of GBS or the K-1 capsule of *E. coli*, whether because of inadequate maternal stores or decreased maternal antibody transport, are predisposed to GBS and *E. coli* infections.[277]

IgA antibodies are selectively transported across mucous membranes by secretory piece. These IgA antibodies prevent the attachment of microorganisms, absorb harmful antigens from mucous membranes, and are present in human breast milk. Secretory IgA is undetectable in the mucosal secretions at birth and first appears between 1 week and 2 months of age. It has been suggested that decreased levels of secretory IgA may predispose the developing neonate to colonization with pathogenic type III GBS.[278,279]

The IgE antibodies are found on mast cells and basophils and are primarily responsible for allergic reactions, protection against parasites, and anaphylaxis. The IgD antibodies serve as early antigen receptors on B cells; their role in host defense is currently under investigation.[246]

Host-Fungal Interactions Relevant to the Newborn Infant

Fungal infections are commonly classified as either endemic or opportunistic.[1] An endemic fungal infection may occur in any individual living in a geographic area that is the natural habitat of that fungus. Histoplasmosis, coccidioidomycosis, and blastomycosis, which are usually acquired by inhalation, are examples. Although exposure to endemic fungi might be possible in the newborn period, it is unlikely under normal circumstances. Therefore we do not discuss mechanisms of resisting these organisms but, rather, focus on resistance to opportunistic fungi.

Opportunistic fungal infections occur primarily in immunocompromised individuals.[2] Extensive investigation of host defense mechanisms in the newborn has indicated that multiple systems are partially compromised, or blunted, and it is probably this combination of partial deficiencies that places the newborn at risk.[3-5] Among the opportunistic fungi, *Candida* species stand out as particularly threatening to the newly born baby, especially the very-low-birth-weight and extremely low-birth-weight infant.[6-10] Although understanding of how the host resists fungal infection is incomplete, host-candida interactions have been relatively well studied. For these reasons, this chapter focuses primarily on candida, what is known about how humans resist its infection, and what mechanisms of host defense might be expected, on the basis of current knowledge, to be involved in defending the newborn against candidal infection.

Perineal and oral thrush caused by *Candida* species is common in otherwise normal neonates. In neonatal intensive care units, all newborns are at risk for more serious systemic candidal disease, even those with birth weights >2500 g.[9-12] *Candida albicans* remains the most common fungal species isolated in neonatal surveillance cultures[13] and the most common cause of neonatal candidiasis, but nonalbicans species such as *Candida parapsilosis* and *Candida glabrata* are also frequent causes of invasive neonatal infection, especially in low-birth-weight infants.[9,12,14-16] The frequency of serious candidal disease in newborns may be attributed to technical improvement of medical practices and intensive care measures on a backdrop of the newborn's blunted capacity to fight infection.[10,17,18] The prominence of neonatal candidal infections and the difficulties in diagnosis and treatment of invasive candidiasis emphasize the importance of acquiring a better understanding of the mechanisms by which this species causes infection in newborns.

We divide this chapter into discussion of antifungal defense mechanisms thought to be active at body surfaces and how these may be related to mucocutaneous candidiasis and a review of those expected to defend the newborn against invasive candidal infection. In discussing both forms of candidiasis, we use the experience of individuals with primary or acquired immunodeficiency diseases with fungal infections as a guide to understanding basic host-fungal interactions and how these might be expressed in newborn babies.

DEFENSE AGAINST MUCOCUTANEOUS CANDIDIASIS

Candida Virulence Factors and Surface Host Defense

Candida species cause a broad range of mucocutaneous infections involving the skin and mucous membranes.[19,20] *C. albicans* is part of the common commensal microbial flora of the oral cavity and the gastrointestinal and genitourinary tracts of healthy humans. Candidal vulvovaginitis occurs commonly in most women during pregnancy, and the body surfaces of newborns are colonized at birth. Overgrowth of these colonizing candida may lead to mucosal or cutaneous candidiasis characterized by local signs of infection and, in the mouth, visible white patches.

Transformation from the yeast phase to the filamentous form (pseudohyphae, hyphae, and germ tubes) appears to be essential for candidal pathogenicity.[21] Adhesins on blastospores and hyphae of *C. albicans*, like integrins on human leukocytes, can recognize arginine-glycine-aspartic acid (RGD) sequences on epithelial cells and several extracellular matrix proteins.[22,23] The candida gene *INT1* encodes an adhesin, INT1p, that recognizes the RGD-containing proteins and promotes the growth of filaments. This candidal adhesin is homologous to mammalian

integrins and itself contains an RGD site that may be recognized by integrins on human cells, facilitating further the adhesion of candida to the cell surface.[22] These findings provide at least a partial explanation for the symbiosis of candida with humans and the tropism of these fungi to intestinal and mucosal epithelium.

On the host side, secretory antibody, especially of the immunoglobulin (Ig) A class, the mucous layer, and cilia act to prevent adhesion to mucosal surfaces, and a variety of antimicrobial peptides protect both the skin and mucosae. These have the potential to prevent the penetration of commensal fungi such as candida. Demonstration that peptides with broad and potent antimicrobial properties—the magainins—exist in frog skin proved the principle.[24] These cationic peptides bind to anionic components of the microbial membrane and form pores that permeabilize the cell.Two major classes of cationic antimicrobial polypeptides have been described in human skin and epithelia, the β-defensins and the cathelicidins.[25] Both polypeptides can kill fungi. An additional peptide, dermcidin, which is secreted in sweat, can also kill fungi.[26] Nasal and lung secretions contain the antimicrobial polypeptide constituents lysozyme, lactoferrin, and secretory leukoprotease inhibitor, as well as neutrophil and epithelial defensins.[27] Absent function of these proteins across all epithelial surfaces has not been detected, and their precise role in defense against fungal (or any) infection is not yet fully defined. However, in the familial disorder Kostmann congenital neutropenia, patients' neutrophils are markedly deficient in antimicrobial peptides.[28] Normalizing neutrophil counts by treating with colony-stimulating factor prevents systemic infections, but destructive periodontitis continues until the patient's neutrophils are replaced with normal myeloid cells through bone marrow transplantation.[28]

Lessons From Primary and Acquired Immunodeficiency Disorders

Neonatal deficiency of T cell–mediated immunity may play a part in the frequent mucocutaneous candidal infections in newborns. Persistent mucosal candidiasis and oropharyngeal thrush are common complications of primary T-cell deficiencies such as DiGeorge syndrome and severe combined immunodeficiency disease.[5] Patients with autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy syndrome, chronic mucocutaneous candidiasis, and hyper-IgE syndrome, all of which are characterized by subtle, nonlethal defects in T lymphocytes, have protracted candidal infections of the mucous membranes, nails, and skin.[5,19,29] These patients, however, are no more susceptible to life-threatening, generalized candidiasis than immunocompetent individuals.

Oral and gastrointestinal candidiasis is a common manifestation of human immunodeficiency virus infection, and esophageal candidiasis is one of the diagnostic criteria of the acquired immunodeficiency syndrome (AIDS).[30] Disseminated candidiasis is much less frequent in patients with AIDS than in immunosuppressed patients without AIDS and occurs only in end-stage disease when other immune functions are also severely impaired. Oral or esophageal candidiasis associated with AIDS is likely the consequence of a defect in T cell–mediated host defense.[30] An adequate number of functioning T cells are required for the development of a normal secretory immune response to candida, and T cells play an essential role in stimulating differentiation of IgA+ B lymphocytes into plasma cells that produce secretory IgA.[5]

Taken together, these observations support the concept that partial (selective) T-cell deficiency is responsible for the development of mucosal candidiasis in a variety of conditions, including chronic mucocutaneous candidiasis, secretory IgA deficiency, and AIDS, and, perhaps, in newborn infants. This concept is further supported by the observation in mice that recovery from oropharyngeal infection with *C. albicans* depends largely on $CD4^+$ T-cell augmentation of monocyte and neutrophil functions through activity of Th1-type cytokines such as interleukin (IL)-12, and interferon (IFN)-γ.[31]

Deficient T Cell–Mediated Immunity in Newborns

Neonatal T-cell responses are compromised at several steps including deficient production of cytokines by $CD4^+$ T cells. Deficiency in IFN-γ production by neonatal T cells has been well documented.[5,32] IFN-γ deficiency in neonates may be attributed to lymphocyte immaturity and also to decreased production of IL-12 by cord blood mixed mononuclear cells.[5,33-35] In addition, diminished production of IL-12 by cord-derived dendritic cells has been reported.[36] These studies suggest that neonatal T cells, mononuclear phagocytes, and dendritic cells do not mount a normally vigorous Th1 response. This apparent down-regulation of Th1 responses in human neonates[37] may play a part in the developmental immaturity of the immune system on mucosal surfaces and the susceptibility of newborns to oropharyngeal candidiasis.

DEFENSE AGAINST INVASIVE CANDIDIASIS

Invasive candidal disease may arise from translocation of the gut flora, and it may be propagated by the ability of candida to adhere to nonbiologic materials such as IV catheters.[20,38,39] Electron microscopy has shown that candida can burrow into the catheter and form a surrounding biofilm.[20] The use of heparin to prevent blood clot formation in newborns with intravascular catheters may accidentally promote invasive candidal disease. It has been proposed that heparin might facilitate the cleavage of the *C. albicans* surface adhesion protein INT1p, with release of the fungi from the catheter and generation of a cleavage product that stimulates release of inflammatory cytokines.[40]

Once in the bloodstream, candida are able to adhere to the vascular endothelium. Adherence of *C. albicans* exceeds that of less virulent species, and germinated *C. albicans* adheres better than do yeast-phase organisms.[39] INT1p appears to play an essential role in both adhesion and development of filamentous forms.[22] In mice, administration of broad-spectrum antibiotics and glucocorticoids, known risk factors for disseminated candidiasis in newborns,[10,16,18] accentuated the pathogenesis of *C. albicans* infection through an INT1p-influenced mechanism.[41]

Pulmonary surfactant protein-D (SP-D) has been implicated in host defense against *C. albicans* in alveolar compartments of the lung.[42] SP-D may facilitate mucociliary clearance by agglutinating *C. albicans* into large complexes and may decrease hyphal outgrowth. Decreased concentration of SP-D in neonates or alteration in levels of this protein because of lung disease and mechanical ventilation could disrupt local host defense and contribute to the development of pulmonary candidal infection.

Pseudomonas aeruginosa can form a dense biofilm on *C. albicans* filaments and kill the fungi.[43] This example of a bacterial antifungal suppressive mechanism emphasizes the risk for candida infection posed by giving an individual, particularly a newborn baby, broad-spectrum antibiotic therapy.[16,18]

Role of Phagocytes in Protection Against Invasive Candidiasis

Phagocytic cells are an essential defense against infections by candida and other fungi. Patients with chronic granulomatous disease, whose phagocytes cannot convert oxygen to toxic oxidants, and patients with primary or secondary neutropenia have increased susceptibility to infections by *C. albicans* and other fungi. This predisposition exists in the absence of antibiotic or corticosteroid therapy, depressed cell-mediated immunity, or IV lines.[44,45] A few individuals with complete deficiency of myeloperoxidase (MPO), which combines with hydrogen peroxide

to generate microbicidal oxidants, and diabetes mellitus have sustained systemic candidiasis,[46] and phagocytes from patients with MPO deficiency have an impaired ability to kill ingested *C. albicans*.[47] An important role for MPO-derived oxidants in the killing of candida is supported by the in vitro findings that MPO-rich human monocytes killed *C. albicans* significantly better than monocyte-derived macrophages, which have little MPO,[48] and that recombinant human MPO significantly enhanced the killing of *C. albicans* by macrophages in a concentration-dependent manner.[49] Relative resistance to MPO-derived oxidants appears to at least partially explain the greater pathogenicity of *C. albicans* compared with other *Candida* species.[48,50]

In vitro studies have suggested that antibody-mediated immunity can protect against invasive candidal disease.[51-53] We have found that optimal phagocytosis of *Candida* species by human mononuclear phagocytes requires opsonization by human serum, which supports this hypothesis.[50] However, no clinical observation suggests that patients with immunodeficiency disorders other than quantitative or functional phagocytic cell defects have increased susceptibility to invasive candidiasis. It is notable that patients with X-linked agammaglobulinemia or other severe hypogammaglobulinemia do not exhibit an increased susceptibility to either mucocutaneous or invasive candidal infections.

In patients with hypogammaglobulinemia, T cells, natural killer cells, and antimicrobial peptides may suppress candida at the surface, and macrophages and keratinocytes, which phagocytize and kill candidal yeasts through the mannose receptor,[50,54,55] might protect without the need for antibody opsonization. Mouse macrophages can mediate nonopsonic recognition of *C. albicans* and consequent release of cytokines through a complex of Toll-like receptor (TLR)-2 and dectin-1, the receptor for binding fungal-derived β-glucan, which comprises an inner skeletal layer of the candidal cell wall.[56] *C. albicans* cell-wall mannan can mediate binding to macrophages and release of cytokines through TLR-4 and its MyD88-dependent signaling pathway, as well as through the mannose receptor.[57] Neonatal monocytes and mononuclear leukocytes have been reported to have blunted TLR-4 responses to endotoxin and decreased MyD88 levels,[58,59] and cord blood mononuclear cells produced significantly less IFN-γ, IL-12, and IL-18 than adult cells on exposure to group B streptococci.[35] These abnormalities would be expected to predispose newborns to disseminated candidiasis.

Deficient Anticandidal Activities of Neonatal Monocytes and Macrophages

The extent of phagocytosis and killing of serum-opsonized candida by resident monocytes and monocyte-derived macrophages has been reported to be comparable in newborns and adults.[60] In the absence of serum, ingestion and killing by cord and adult cells were reduced by half but still equivalent. Mannan inhibited ingestion of unopsonized candida by macrophages in a concentration-dependent manner, indicating a role for the mannose receptor. However, exposure of cord and adult macrophages to IFN-γ gave quantitatively different results in candida killing, as well as in release of superoxide anion. Maximal increase in these functions with adult macrophages was achieved with 100 U/mL IFN-γ. No enhancement with cord macrophages could be detected after treatment with 100 U/mL, and at 500 U/mL killing and superoxide release by cord macrophages were still significantly lower compared with adult cells.[60] A similar blunted response of cord macrophages to IFN-γ–induced activation and increased killing was found by using group B streptococci as the target organism.[61] The number and binding capacity of IFN-γ receptors were greater on newborn than adult mononuclear phagocytes.[60] These data suggest that neonatal macrophages have a normal capacity to ingest and kill both opsonized and unopsonized candida but cannot be fully activated by IFN-γ, a finding that could not be attributed to lower expression of IFN-γ receptors on neonatal cells.[60]

Could the decreased activation of cord macrophages by IFN-γ be due to defective signal transduction? In response to IFN-γ, phosphorylation of signal transducer and activator of transcription (STAT)-1 was significantly decreased in neonatal monocytes and macrophages.[62] The STAT family are a group of key signaling molecules linking cytokine binding to the macrophage proinflammatory responses. These proteins are phosphorylated by Janus kinases that are activated by the binding of IFN-γ to its receptors. Expression of STAT-1 protein was equivalent in cord and adult monocytes and macrophages, but STAT-1 phosphorylation was deficient in cord cells.[62] Thus it is possible that the decreased capacity of cord macrophages to be activated is the result of defective signal transduction; this defect remains to be defined.

Intracellular parasites have evolved a variety of mechanisms to evade phagocytic killing by macrophages. Candida yeasts have a thick glycoprotein cell wall composed of mannoprotein and covalently linked chitin-glucan components that is highly resistant to lysosomal enzymes.[63] Phagocytosis of *C. albicans* by mouse macrophages reportedly induces rapid fusion of the phagolysosome membrane with late endosomes and lysosomes.[64] The ensuing acidification of the phagolysosome promotes germ tube formation, which can lead to distention of the phagocyte's membranes and eventual escape of the organism.

Ingestion of candida by macrophages can induce genes of the organism's glyoxylate cycle, a metabolic pathway by which two-carbon compounds are assimilated into the tricarboxylic acid cycle.[65] In *C. albicans* isolated from phagolysosomes of macrophages, the principal enzymes of the glyoxylate cycle, isocitrate lyase and malate synthase, were up-regulated. *C. albicans* mutants lacking isocitrate lyase were markedly less virulent in mice than wild-type *Candida*.[65] These findings demonstrate the significance of the glyoxylate cycle to candidal virulence and point to the complexity of the host-parasite interactions that have the potential to influence the outcome of invasive candidal disease.

150 Host Defense Mechanisms Against Viruses

M. Brad Guffey and David Winston Kimberlin

OVERVIEW OF INNATE AND ADAPTIVE ANTIVIRAL IMMUNITY

Viral host defense mechanisms of vertebrates depend on a combination of innate and adaptive immune mechanisms that are tightly interlinked. Key innate immune mechanisms include antiviral and proinflammatory cytokines, such as type I interferon (IFN), IFN-γ, and tumor necrosis factor (TNF)-α, which have pleiotropic immunoregulatory effects and multiple potential cellular sources, including mononuclear phagocytes, dendritic cells, and natural killer (NK) cells. Dendritic cells are key for initiating the adaptive immune response and efficiently take up viral material in various forms, such as necrotic or apoptotic cellular debris. With some viral pathogens, such as human immunodeficiency virus (HIV), dendritic cells also may be directly infected. Dendritic cells process viral proteins and present these in the form of peptides bound to class I (human leukocyte antigen [HLA]-A, -B, and -C in humans) and class II (HLA-DR, -DP, and -DQ in humans) major histocompatibility complex (MHC) molecules for activation of $CD8^+$ and $CD4^+$ T cells, respectively.[1]

As a result of clonal expansion and differentiation, virus-specific $CD8^+$ and $CD4^+$ effector T cells are generated that carry out direct and indirect antiviral immune functions. $CD4^+$ T cells provide key help to B cells for the production of antiviral antibodies, and to $CD8^+$ T cells, which are a major source of cytokines with antiviral activity, and in some cases may also play a role in cell-mediated cytotoxicity. Effector $CD8^+$ T cells are the key cells involved with the clearance of virally infected cells from infected tissues by cell-mediated cytotoxicity, which is triggered when their T cell receptors (TCRs) recognize viral peptide–class I MHC complexes on the surfaces of target cells. B cells provide antiviral antibody that can neutralize viral attachment and entry into cells. Viruses, particularly herpesviruses, can block antigen presentation and may down-regulate the overall level of class I MHC expression on the cell, potentially thwarting $CD8^+$ T cell recognition. As a countermeasure, NK cells recognize and immediately kill cells with reduced class I MHC expression, providing innate and early protection against viral infection before the appearance of differentiated T cells and B cells. NK cell–mediated killing also is augmented by virus-specific antibody produced by B cells, a further example of the linkage of innate and adaptive immunity (Table 150-1). Unlike innate immune mechanisms, T cell– and B cell–specific viral immunity persists for years or for a lifetime.

TABLE 150-1

Innate and Adaptive Immunity

Property	Innate Immunity	Adaptive Immunity
Receptors	Fixed in genome (no rearrangement necessary)	Gene segments (rearrangement necessary)
Distribution	Nonclonal	Clonal
Recognition	Conserved motifs/ patterns	Specific structure
Self-nonself discrimination	Perfect	Imperfect
Timing	Immediate	Delayed
Response	Co-stimulatory molecules Cytokines (IL-1, IL-6) Chemokines (IL-8)	Clonal expansion or anergy IL-2 Effector cytokines (IL-4, IFN-γ)

The neonate is at risk for severe or rapidly progressive infection with certain viruses, most notably herpes simplex virus (HSV) type 1 and type 2 (HSV-1 and HSV-2), HIV, and enteroviruses. Another herpesvirus, human cytomegalovirus (HCMV), often causes severe disease in the premature neonate and is the major viral cause of congenital sensorineural deafness. Because viruses replicate intracellularly, mechanisms that control or block infection within cells, spread of virus from cell to cell, or both, are the most critical for effective host defense. Antibody and complement may also modify viral expression, especially by preventing spread of virus into the central nervous system (CNS), but cellular immune responses are the most central for control of viral replication and the elimination of virally infected cells.

This chapter presents a systematic review of the key components of human innate and adaptive antiviral immunity against viruses such as HSV, HCMV, HIV, respiratory syncytial virus (RSV), and enterovirus, including considerations specific to lack or failure of these components in the neonate. In addition to being "unprimed" as a consequence of lack of previous exposure to antigen, the neonatal immune system has functional deficiencies in both speed and magnitude of its innate and adaptive immunity.

HOST DEFENSE AGAINST HERPES SIMPLEX VIRUS AS A PROTOTYPE OF NEONATAL ANTIVIRAL MECHANISMS

HSV infection is severe in term infants if it is acquired at the time of parturition, as well as in the uncommon cases in which it is acquired *in utero*.[2] Similarly, enterovirus infections also are severe and may be fatal when acquired in the perinatal period. Both HSV and enteroviral infections have a similar propensity for dissemination and for causing CNS disease. Both infections, however, usually are effectively controlled when acquired after 4 weeks of age, suggesting that common developmental limitations in antiviral immunity may be responsible for neonatal vulnerability. The example of neonatal herpes infection illustrates well both the strengths and weaknesses of the neonatal immune system.

Herpesvirus Biology

HSV-1 and HSV-2 are two of eight herpesviruses that have been isolated to date from humans (the others include HCMV, varicella-zoster virus [VZV], Epstein-Barr virus [EBV], and human herpes viruses 6 to 8 [HHS-6 to HHV-8]).The HSV virion is composed of a 150–kilobase pair DNA genome, a capsid shell surrounded by a protein tegument and an outer lipid bilayer derived from the host embedded with a number of viral membrane proteins and glycoproteins.

Cellular targets of HSV include, but are not limited to, epithelial cells of skin and mucosa, neurons, and cells of the immune

system. The virus is capable of infecting other differentiated cell types, however, as is evident from disseminated disease that can occur in neonates and in immunocompromised individuals. Although humans are the only natural host for HSV-1 and HSV-2, a variety of laboratory animals and cultured cells from many vertebrate tissues also are susceptible.[3]

The initial interaction of HSV with the host cell surface usually is by binding of viral glycoprotein gB or gC to heparan sulfate chains on cell surface proteoglycans.[4] This is a reversible step and is not strictly required for viral entry. Entry depends on the binding of gD to one of its cell surface receptors.[5] These include HveA (herpesvirus entry protein A), also known as HVEM (herpesvirus entry mediator), which is a member of the TNF receptor family. Other receptors include nectin-1 (i.e., herpes immunoglobulin-like receptor [HIgR]) and nectin-2, cell adhesion molecules belonging to the immunoglobulin superfamily. These proteins also are known as herpesvirus entry (Hve) proteins C and B, respectively. Additionally, modified heparan sulfate (3-*O*-S HS) generated by cellular D-glucosaminyl 3-*O*-sulfotransferase can serve as the receptor for gD-mediated entry, in the absence of any known protein receptors.[4]

The final step in cell entry involves fusion with the host cell plasma membrane and involves the HSV glycoproteins gD, gB, and the gH-gL heterodimer. Although the key molecules involved in this process have been known for years, the exact mechanisms of membrane fusion are poorly understood. Analysis of amino acid residues 377 to 397 within the ectodomain of HSV-1 gH has identified a predicted membrane α-helix with attributes of a fusion peptide. Disruption of this α-helix abolishes HSV infectivity, and its replacement with other known fusion peptides restores fusion and infectivity.[6] Because the trio of gH, gL, and gB is conserved throughout the Herpesviridae family and is essential for infectivity in all examined herpesviruses, it is likely that gH serves as the principal fusion glycoprotein for the other herpesviruses as well and is part of a conserved mechanism of action.

Additionally, the protein encoded by a recently characterized human gene designated human fetal lung cDNA B5 (*hfl*-B5) has met criteria, when expressed in a model system, suggesting its function as a new class of HSV receptor or possibly a co-receptor.[7] With heptad repeat motifs and a proposed coiled-coil structure, the protein encoded by *hfl*-B5 is thought to function naturally in fusion as a cellular SNARE-like protein. Its HSV viral ligand currently remains unproved; however, because of its α-helix and peptide fusion motif, it is now postulated that gH is possibly the B5 receptor ligand as well.[6,8]

After entry, synthesis of the HSV DNA genome, as well as its assembly with capsid proteins, occurs in the nucleus. The production of HSV progeny results in the irreversible destruction of the host cell and subsequent viral release. Despite this lytic effect, a substantial proportion of both primary HSV-1 and HSV-2 infections are asymptomatic.[9] The hallmark of HSV gene expression is the regulated and coordinated expression of approximately 80 viral genes. This regulation occurs largely through modulation of RNA polymerase II transcription. Two viral proteins, VP16 and ICP4, function to activate transcription of the five immediate early genes and the rest of the HSV genome, respectively. Of the 80 or so genes within the HSV genome, fewer than one half are essential for replication. These essential genes encode functions related to entry of virus into cells, as noted previously, regulation of gene expression and replication, and packaging of viral DNA into virions. A large number of enzymes are involved in nucleic acid metabolism, some of which are targets for antiviral therapy (e.g., with thymidine kinase). The genes that are not essential for replication in culture play a key role in multiplication of the virus and its transfer from cell to cell. Additionally, they serve to complement cellular functions lost as a consequence of viral replication, fine-tuning viral gene expression, and overcoming the host's response to infection.

Upon entering the cell, HSV can enter either a lytic program in which ultimately the host cell is killed, or it can enter a latent state and reside silently for long periods, indeed a lifetime, in sensory neurons such as the trigeminal and sacral ganglia.[10] Mechanisms regulating these pathways are being elucidated and recently have been reviewed.[11] A key player in progression to productive infection is the HSV structural protein VP16, which is important in the initiation of the lytic program through the assembly of a multiprotein transcriptional regulatory complex involving two cellular proteins, octamer binding protein (Oct-1) and host cell factor-1 (HCF-1). This VP16-induced complex represents a regulatory switch. When "on," it promotes immediate early (IE) gene expression and lytic infection. When it is "off," IE-gene transcription is limited, favoring latent infection. Additional mechanisms involved in the establishment and maintainance of latency include maintainance of the viral genome itself, taking on a more stable circular DNA configuration, and posttranslational modifications of cellular histones. Here, for example, hyperacetylation of histones (enhanced by VP16) is associated with an "open chromatin" conformation and transcriptional activity,[12] but histone hypoacetylation is associated with condensed chromatin and gene silencing of IE genes and perhaps enrichment of the latency-associated promoter.[13]

The latency-reactivation cycle can be divided into three major steps: latency establishment, latency maintenance, and reactivation.[14] The latency period is characterized by prominent expression of a single viral gene, the latency-associated transcript (LAT). LAT appears to be important but not absolutely required for establishment of latency, as well as for maintaining the viability of HSV-infected neurons by inhibiting apoptosis[15,16] and by limiting entry into a lytic program. It remains controversial whether the regulatory effects of LAT on latency are mediated solely at the RNA level or require LAT messenger RNA (mRNA) translation into protein. No virally encoded functions are required for establishment of the latency, but a full complement of viral genes (including LAT) is essential for efficient reactivation of the virus from the latent state.

INNATE ANTIVIRAL IMMUNITY

The antiviral immune response generally can be divided into an early, nonspecific phase (typically the first 5 to 7 days in HSV infection) involving innate immune mechanisms, followed by a later, antigen-specific phase involving adaptive immunity by T and B cells.[17] The early phase is critical, because infection either may be successfully contained or, alternatively, may disseminate throughout the host. A closer look at the neonatal antiviral response is provided in the following discussion, which describes host recognition of viral infection, identifies the inflammatory mediators produced in response, and summarizesthe cells participating in these processes.

After recognition of pathogens (principally by dendritic cells), mediators such as interferons, cytokines, chemokines, and surfactant proteins are necessary in signaling the anti-viral state within the cell and activating and attracting other immune cells such as neutrophils, macrophages, and NK cells to orchestrate an effective antimicrobial response at the site of infection. The induction of the innate immune mechanisms is not pathogen specific but is dependent on interactions between pathogenic factors and host cell determinants. The aim of this early innate response is to either eliminate the pathogen or to avoid spread of the infection until elimination is achieved through the adaptive immune response. Additionally, the innate immune system serves to shape and regulate the developing immune response by promoting or inhibiting development of specific downstream effector mechanisms. This is exemplified by the ability of innate cytokines to improve the efficiency of antigen-presenting cells (APCs) and to direct the development of naive T cells into different subtypes expressing

distinct immune responses. Overall, regulation is important to a successful immune response, because many immune mechanisms can cause disease if they are left unregulated or are left in activated status inappropriately.

Pattern Recognition Receptors

Before mounting an antiviral response, the host must first recognize the infection. Unlike in adaptive immunity, which uses remarkably specific receptors and circulating factors to recognize highly variable antigens such as proteins, the receptors and factors of innate immunity react more broadly to less variable structures. The task of innate immune recognition is to identify key molecular signatures borne by pathogens, termed pathogen-associated molecular patterns (PAMPs),[18] by pathogen-recognition receptors (PRRs), leading to a cascade of intracellular signaling and ultimately the mobilization of soluble defense molecules, killing of infected cells, acquisition of specialized functions by sentinel cells, and priming of the adaptive immune response. This process starts with the identification of virions or viral products by extracellular and intracellular receptors. Several of the PRRs have been identified, including Toll-like receptors (TLRs), macrophage scavenger receptor (MSR), retinoic acid–inducible gene protein-1 (RIG-1), nucleotide-binding oligomerization domains (NODs), double-stranded RNA-activated protein kinase (PKR), and the 2′-5′oligoadenylate (2-5A) synthetase system (Table 150-2).

TLR3, TLR7, TLR8, TLR9, and to a lesser extent TLR2 and TLR4[19-21] have been associated with viral recognition by the innate immune system and subsequently acquired antiviral properties such as IFN production (Figure 150-1). Plasmacytoid dendritic cells (pDCs) recognize HSV, for example, by TLR9, expressed on endosomes to sense viral material. TLR9 identifies the HSV DNA because it contains abundant, unmethylated deoxycytidylate-phosphate-deoxyguanylate (CpG) motifs. These CpG motifs are underrepresented in mammalian DNA, where they generally are methylated. In response, pDCs secretes high levels of IFN-α and represent the so-called natural interferon–producing cells of the body.[22] Consistent with this recognition mechanism for HSV, human pDCs express very high levels of TLR9 compared with other dendritic cell populations, such as most myeloid dendritic cells.[23] The secretion of high levels of IFN-α by pDCs probably results in a systemic antiviral state, because receptors for type I interferons are essentially ubiquitous. Exposure of secondary lymphoid tissue to IFN-α also may enhance local adaptive immune responses.[24] TLR9 signaling of pDCs primarily involves the adapter protein myeloid differentiation primary response protein 88 (MyD88) and ultimately activates interferon regulatory factor-7 (IRF-7), which is constitutively expressed by pDCs and serves as a master regulator of IFN-α/β gene expression.[25] Although *in vitro* studies of pDCs in knock-out mice deficient in TLR9 and MyD88 demonstrate poor IFN response, no significant differences in morbidity or mortality were noted after HSV infection in these mice *in vivo*. This observation demonstrates that the presence of TLR9- and MyD88-independent pathways in cells other than pDCs can effectively compensate for defective interferon production by pDCs in response to HSV.[26] TLR8 in humans (TLR7 in mice) also is present on pDCs and serves as a PRR in recognition of single-stranded RNA (ssRNA) oligonucleotides rich in guanisine or uridine derived from ssRNA viruses such as HIV, influenza virus, and vesicular stomatitis virus. TLR7 signaling is also mediated through MyD88 pathways and, in pDCs, has high expression of IRF-7 with subsequent type I IFN production.

TLR3 also functions to recognize viral infection. TLR3, a known ligand for double-stranded RNA (dsRNA), also has been shown to initiate IFN production after viral infection in a MyD88-independent manner through an adapter protein named Toll/IL-1 receptor domain–containing adapter–inducing interferon (TRIF) by activation of IFN transcription regulatory factor-3 (IRF-3). IRF-3 is produced constituitively in most cell types and, in the absence of activation, is present in the cytoplasm in an inactive form. Activation occurs by means of two kinases: IκB kinase-ε (IKK-ε) and TANK-binding kinase-1 (TBK-1). Upon phosphorylation, IRF-3 dimerizes and translocates to the nucleus, where it interacts with coactivators CAAT-binding protein and p300. This complex serves as an enhanceosome complex that transactivates IFN-β gene expression in cooperation with activator protein-1 (AP-1) and NFκB. Infected cells secrete mainly IFN-β as an initial response to infection then switch to IFN-α during subsequent amplification of the IFN response.[27,28] It is not known if TLR3 binds only extracellularly derived dsRNA, for example, from lysed cells, or if dsRNA produced in the cell can be exported to the endosome and trigger TLR3.[29] In studies of mice deficient in TLR9 or TLR3 challenged with murine cytomegalovirus (MCMV), a significant abrogation in IFN production was demonstrated in both, and the mice were susceptible to MCMV infection.[30]

Besides TLRs, other extracellular receptors exist to identify pathogens within the innate immune system. Mannan-binding lectin (MBL) (which activates the complement system), C-reactive protein (CRP), serum amyloid protein (SAP), and the macrophage mannin receptor (MMR) are pattern recognition molecules that mediate phagocytosis of microorganisms, primarily bacteria and fungi. Another phagocytic pattern recognition receptor expressed on macrophages, macrophage scavenger receptor (MSR), has a broader role in host defense including recognition of viruses. Belonging to the scavenger receptor family (type A), it has specificity for a variety of polyanionic ligands, including dsRNA, lipopolysaccharide (LPS), lipotechoic acid (LTA), and acetylated low-density lipoproteins (LDLs). MSR-deficient mice have an increased susceptibility to HSV infection (as well as to other infections such as listeriosis and malaria).[18]

Extracellular receptors and TLRs are not the sole receptors controlling the innate immune response. Recognition of other families of molecules that play a key role in the sensing of infectious microorganisms are emerging. The existence of specific innate immunity receptors in the cytosol illustrates the topological problem

TABLE 150-2

Innate Recognition Receptors and Their Viral Ligands

PRR	Viral PAMP	Pathway/ Mechanism	Outcome
TLR-2	Envelope, lipopeptide	MyD88/Mal	INF-β, IL-6
TLR-3	dsRNA	TRIF/IRF-3	↑ type I IFN
TLR-4	Envelope	TRIF/IRF-3	↑ type I IFN
TLR-8	ssRNA	MyD88/IRF-7	↑ type I IFN
TLR-9	CpG	MyD88/IRF-7	↑ type I IFN
MSR	dsDNA	Phagosomal localization	Degradation/ apoptosis
RIG-1/MDA-5	dsRNA	NFκβ/IRF-3	↑TRAIL/apoptosis/↑ IFN
PKR	dsRNA	eIF-2α	↓ host translation/↑ IFN
OAS	dsRNA	2-5A–dependent RNase ligand	Cleaves viral RNA; ↓ transcription
Mx	ssRNA	GTPases	↓ viral transcription

dsRNA, Double-stranded RNA: *eIF-2α,* eukaryotic translation initiation factor 2 subunit α; *IL,* interleukin; *IFN,* interferon; *IRF,* interferon regulation factor; *Mal,* MyD88 adapter-like protein; *MDA-5,* melanoma-differentiation-associated gene 5; *MSR,* macrophage scavenger protein; *MyD88,* myeloid differentiation primary response protein-88; *NFκβ,* nuclear factor kappa-β; *OAS,* oligoadenylate synthetase; *PAMP,* pathogen-associated molecular pattern; *PKR,* dsRNA-dependent protein kinase; *PRR,* pattern recognition receptor; *RIG-1,* retinoic acid–inducible gene 1; *TLR,* Toll-like receptor; *TRAIL,* tumor necrosis factor–related apoptosis–inducing ligand; *TRIF,* Toll/IL-1 receptor domain–containing adapter–inducing interferon.

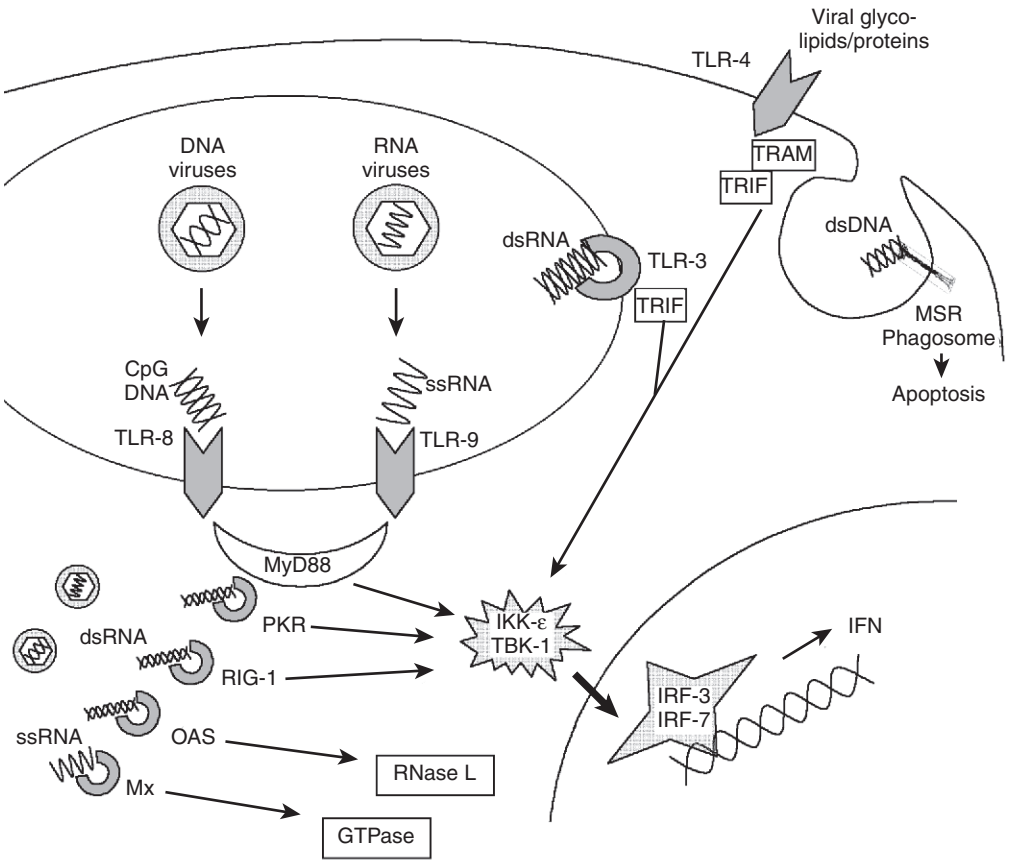

Figure 150-1 Examples of viral pattern recognition receptors and downstream signaling. *IFN*, Interferon; *IKK-ε*, IκB kinase-ε; *IRF,* interferon regulatory factor; *MyD88*, myeloid differentiation primary response protein 88; *OAS*, oligoadenylate synthetase; *PKR*, double-stranded RNA–dependent protein kinase; *RIG-1*, retinoic acid inducible gene-1; *TBK-1*, TANK-binding kinase; *TLR*, Toll-like receptor; *TRAM*, TRIF-related adapter molecule; *TRIF*, Toll/IL-1 receptor domain–containing adapter–inducing interferon.

posed by the cellular location of TLRs: These transmembrane receptors have access only to ligands that are either extracellular or are in the lumen of endosomes. TLRs are blind to microorganisms or their products that have penetrated the cytosol. Two such cytoplasmic receptors of dsRNA have been identified as members of a family of DExD/H box RNA helicases: RIG-1 and MDA5 (Helicard). The DExD/H box RNA helicases are defined by their ability to unwind dsRNA with intrinsic ATPase activity, and both RIG-I and MDA5 contain a caspase recruitment domain (CARD), which serves to activate NFκB and IRF-3, critical regulators of innate immune responses, in response to cytoplasmic dsRNA.

Other well-described cytosolic sensors of viruses include PKR, the 2-5A system, and the Mx proteins. PKR normally is inactive, but on binding dsRNA it undergoes autophosphorylation and subsequent dsRNA-dependent phosphorylation of substrates, including the α subunit of eukaryotic initiation factor 2 (eIF2-α), leading to rapid inhibition of translation.[31] The oligoadenylate synthetase (OAS) system is a multienzyme pathway in which IFN-inducible oligoadenylate synthetases are stimulated by viral dsRNAs to produce a series of short 2′,5′-oligoadenylates ("2-5A") that activate the 2-5A–dependent RNase ligand, which cleaves ssRNA halting viral and cellular processes. Similarly, the Mx proteins are IFN-inducible GTPases in the dynamin superfamily that interfere with viral transcription on encountering a wide range of ssRNA virus targets.

A large new family of cytosolic receptors is the nucleotide-binding oligomerization domain proteins (NODs), now designated nucleotide-binding domain, leucine-rich repeat–containing proteins (NLRs) (formerly called CATERPILLER).[32] They have been shown to be active in recognition of bacterial products such as peptidoglycans, modulated through a family of receptor-interacting (RIP) proteins.[33,34] Although preliminary data demonstrate possible activation of IFN-β through NOD recognition of *Listeria* and *Bacillus,* future studies will show whether NODs are able to recognize viruses and through which pathways they produce inflammatory mediators such as IFN.[35]

Interferons

The IFN system is indispensable for vertebrates to control viral infections. Knock-out mice with deletions in IFN receptors quickly succumb to viral infections despite having a normal adaptive immune system.[36] Likewise, children with genetic defects in the IFN-α/β system have been shown to die in infancy from viral infection, such as with HSV.[37] Animal studies modeling specific knock-out genes of effector molecules within this pathway also have revealed extreme susceptibility to various viral infections, demonstrating the significant power of this antiviral system.[36,38-43]

During viral infections, IFNs are some of the most prominent cytokines produced.[44] Named for their ability to interfere with viral replication,[45] IFNs are a large family of multifunctional secreted proteins involved in antiviral defense, cell growth regulation, and immune activation. They are classified into two types: *Type I* IFNs (IFN-α and IFN-β) are produced in direct response to viral infection and consist of the products of the IFN-α multigene family (14 genes), which are synthesized predominantly by leukocytes, and the product of the IFN-β gene, which is synthesized

by most cell types but especially fibroblasts. *Type II* IFN consists of the products of the IFN-γ gene and, rather than being induced directly by viral infection, is synthesized in response to the recognition of infected cells by activated T lymphocytes ($CD4^+$ T helper 1 cells and $CD8^+$ cytotoxic T cells) and NK cells.[46]

Both types of IFNs stimulate an antiviral state in target cells, whereby the replication of virus is blocked or impaired owing to IFN receptor signaling and the subsequent synthesis of a number of enzymes that interfere with cellular and viral processes. Additionally, IFNs make cells more susceptible to apoptosis, further limiting spread of virus. Finally, both types of IFN have profound immunomodulatory effects and stimulate the adaptive response. However, although both IFN-α/β and IFN-γ influence immune effector cells, they show significant differences, and it is these extended cytokine functions that probably account for the different spectrums of antiviral activities of the two types of IFN.

The signaling pathways for IFNs are well characterized, and the pathways involved in this interferon response circuit have been recently reviewed.[28,29,38,46,47] The biologic activities of IFNs are initiated by the binding of IFN-α/β and IFN-γ to their cognate receptors on the surface of cells, which results in the activation of distinct but related signaling pathways, known as the Janus kinase/signal transducer and transcriptional activator (Jak/STAT) pathways. The ultimate outcome of this signaling is the transcription of target genes that previously were quiescent or being expressed at low levels. The regulatory sequences of IFN-α/β genes contain a variation of the upstream consensus sequence called the Interferon-stimulated response element (IRSE), whereas IFN-γ–inducible genes contain the upstream IFN-γ activation sequence (GAS). The Stats are latent transcription factors that become tyrosine phosphorylated by the Jaks. After binding to their receptor (IFNAR), type I IFNs activate intracellular signaling including Jak1, Tyk2, STAT1, STAT2, and STAT3. The Jaks activate (phosphorylate) the STATs which dimerize, translocate to the nucleus, and induce IFN-simulated genes (ISGs). STAT1-STAT2 heterodimers complex with cofactor nuclear protein p48 forming a heterotrimeric complex known as ISGF3 and binds the ISRE sequence in the promotors of ISGs, influencing the transcription of a distinct group of genes.[48] These include the gene for IRF-7, which amplifies type I IFN production if viruses infect cells that previously have been exposed to type I IFN.[49] STAT1 homodimers and STAT1-STAT3 heterodimers activate GAS sequences.[50] Because STAT-1 but not other STATs is tyrosine-phosphorylated by IFN-γ binding to its specific receptor,[50] the potential exists for type I IFN to induce genes that are characteristic of IFN-γ responses, but not vice versa.

Patients who have genetic defects in STAT-1 that compromise the GAS pathway but not the interferon-stimulated response element (ISRE) pathway of gene regulation, are not prone to severe viral infections.[51] This point argues that the regulation of the GAS pathway by type I interferons, and the induction of certain gene products such as IRF-1,[52] are dispensable for antiviral immunity in humans. By contrast, complete lack of STAT-1 function and, as a result, loss of the ISRE-mediated pathway of signal transduction in humans resulted in recurrent HSV-1 encephalitis and death.[36] The critical importance of the ISRE pathway also is supported by the observation that mice genetically deficient in the type I interferon receptor are highly susceptible to HSV.[53]

IFNs can induce more than 300 cellular proteins.[54] However, the exact pattern of induction varies by cell type and type of IFN. The IFN-induced proteins include enzymes, signaling proteins, chemokines, antigen presentation proteins, transcription factors, heat shock proteins, and apoptotic proteins. Several of the cellular systems already discussed in the detection of viruses (PKR, Mx proteins, and the 2-5A system) also are IFN-driven, allowing for a positive reinforcement of these antiviral systems. Moreover, studies in mice have demonstrated that loss of any of these three systems as examples leads to increased susceptibility to viral infection.[55,56] Interestingly, despite their potency, knock-out mice lacking PKR, Mx, and OAS still exhibit a limited IFN-induced antiviral state, indicating additional pathways exist.[57]

Of note, ISG56 encodes P56, which is one of the most strongly induced genes among all of the IFN-stimulated genes. P56 binds to the large multimeric complex of eIF-3 through p48 and blocks its function in initiating protein synthesis. Of interest, ISG56 also is strongly induced by non-IFN pathways after viral infection (dsRNA).[58]

Interferons also have a profound effect on cells of the immune system that mediate innate and adaptive immunity. Members of the P200 family of structurally related proteins are strongly induced by type I IFNs and encoded by a gene cluster. The P202 protein impairs cell proliferation by inhibiting the functions of many cellular factors, including NFκB, E2F, TP53, c-Fos, c-Jun, MyoD, myogenin, c-Myc, and Rb.[59]

Interferon-γ is the major immunomodulator and activator of macrophages. Consequentally, mice defective in IFN-γ, IFN-γ receptor, or STAT1 genes are highly susceptible to infection with *Listeria, Toxoplasma, Leishmania,* and *Mycobacterium.*[60] IFN-γ has an important role in the development of $CD4^+$ helper T cells: It directs $CD4^+$ T cells toward the T_H1 direction and, by blocking IL-4 production, away from T_H2. This shift is facilitated by enhancing the synthesis of IL-12 in APCs, an effect that also helps develop T_H1 cells. IFN-γ also up-regulates $CD4^+$ T cell expression of IL-12 receptors.

Both type I and II IFNs promote the expression of MHC class I molecules and the development of $CD8^+$ T cell responses.[44] MHC class II induction occurs in mononuclear phagocytes, endothelial cells, epithelial cells, and T cells where it enhances $CD4^+$ responses. The positive role of IFNs in enhancing antigen presentation (besides up-regulating MHC molecules) is augmented by regulating the expression of many proteins responsible for generating antigenic peptides. This is accomplished through IFN-γ induction of three proteosome subunits—LMP2, LMP7, and MECL1. IFN-γ also induces the expression of PA28, the nonenzymatic subunit of the proteosome, and TAP1 and TAP2 (transporter associated with antigen-processing proteins), which transfer the proteosome-mediated peptides to the endoplasmic reticulum, where they bind nascent MHC class I proteins.[44]

In an early study, type I IFN production by neonatal lymphocytes and monocytes was equivalent to that in adult cells for a variety of inducers, including HSV and other viruses.[61] A more recent study,[217] however, found that type I IFN production by peripheral blood mononuclear cells and the frequency of IFN-α–producing cells (assayed by the ELISPOT technique) in response to fixed HSV were diminished in neonatal cells compared with adult cells, particularly for cells from prematurely born infants.

Interfering With Interferons

Shortly after the recognition that heat-inactivated influenza viruses would induce IFN, it was discovered that infection of cells with live virus inhibited the subsequent induction of IFN by an inactivated virus—"inverse interference."[45] The key role of both type I (α and β) and II (γ) IFNs as one of the first antiviral defense mechanisms is highlighted by the fact that anti-IFN strategies are present in most viruses.[46,62] Viruses have been reported to block nearly all aspects of the IFN regulatory pathway, the details of which are available in several reviews[46,63-65]; some of the medically relevant viral interactions with the neonatal host are summarized here. Viruses counteract the host IFN response in a number of ways including by inhibiting IFN production and signaling, and by circumventing IFN-induced antiviral effector molecules.

Substantial amounts of type I IFN are found in the tissues of HSV-infected animals and humans.[66,67] Although HSV efficiently induces the secretion of type I IFN, the virus is relatively resistant

to their antiviral effects. HSV attempts to block synthesis and function of type I IFN in infected cells by several mechanisms. In cells infected with HSV, viral DNA replication leads to the activation of another cytoplasmic receptor, PKR, that phosphorylates the α subunit of translation initiation factor 2 (eIF-2α) and thereby inhibits translation initiation.[31] As a countermeasure, the ICP34.5 protein is expressed by HSV to prevent the shutoff of protein synthesis. ICP34.5 interacts with cellular protein phosphatase 1 and redirects its activity to dephosphorylate eIF-2α.[68] Recent data demonstrate that in HSV-infected cells, eIF-2α dephosphorylation mediated by the ICP34.5 protein is tightly coupled with viral resistance to interferon.[69] As expected, ICP34.5-minus recombinant HSVs are attenuated in the host. Interestingly, the phenotype can be re-established by extragenic mutations in the herpes genome resulting in earlier expression of US11 protein. If the US11 protein binds PKR before its phosphorylation, US11 is able to fully compensate, demonstrating that HSV has utilized at least two ways to overcome PKR.[70]

ICP34.5 and US11 protein effectively negate a major effect of the type I IFNs. Second, HSV blocks the phosphorylation of Stat1, Stat2, and Janus kinases induced by interferons.[71] This may account for the limited ability of type I interferons to treat recurrences of established HSV infections, such as of the eye. A combination of IFN types I and II are effective in the control of HSV infection, at least in mice,[72] suggesting that cellular sources of IFN-γ *in vivo* (T_H1 $CD4^+$ T cells, $CD8^+$ T cells, γδ T cells, NK cells, or NK T cells) play an important role in host defense against HSV by acting in concert with type I IFN.

The OAS (2-5A RNase L) pathway also is inhibited by HSV-infected cells by generation of substituting 2′,5′-oligoadenylate derivatives that inhibit RNase L.[73] HCMV, another herpesvirus, has been shown to have complex interactions with the IFN system of the host. HCMV binding of the cell by its gB glycoprotein activates type I IFN; at the same time, however, the virus disarms downstream effectors involved in the induction of the antiviral state. It does this by reducing the expression of Jak1 and IRF-9, thereby disrupting IFN signaling.[74]

Adenoviruses are another class of DNA viruses that are known to encode several mechanisms to antagonize IFNs. Adenovirus-infected cells express VAI viral RNA, which, like dsRNA, binds to PKR but, unlike dsRNA, does not activates PKR but in fact inhibits it. Additionally, adenovirus produces E1A protein, which inhibits ISGF3 complex by down-regulating the expression of STAT1 and IRF-9 and by directly binding to STAT1.[75] Influenza viruses are segmented negative-strand RNA viruses and counteract IFNs through production of a nonstructural protein, NS1. NS1 binds to dsRNA, prevents dsRNA-mediated activation of PKR and OAS, and prevents synthesis of IFN. The mechanisms by which NS1 achieves this inhibitory effect is through disruption of dsRNA-stimulated IFN gene transcription of IRF-3, IRF-7, and NFκB and activation of cellular protein (p58IPK), which inhibits PKR. NS1 also binds another IFN-induced protein, ISG15, and blocks its action.[76] The nonsegmented negative-strand RNA parainfluenza viruses encode proteins that inhibit IFN signaling by degradation of the Jak/STAT pathway.[77]

Hepatitis B capsid protein specifically inhibits MxA gene expression through an unknown mechanism.[46] Its open-reading frame C product and the viral terminal protein inhibit IFN production at the transcription level by sequestering dsRNA.[78] The sequestration of dsRNA by viral proteins probably has a wider role in protecting the virus from antiviral mechanisms, because dsRNA-activated PKR can activate NFκB and induce synthesis of immunomodulary genes, in addition to IFN.

HIV type I (HIV-1) RNA transcripts contain stem bulge loop structures, called transactivating response (TAR) elements, in their 5′-untranslated region, which are readily detected by PKR.[79] Its transcriptional transactivation protein (Tat) is able to compete with PKR for binding to eIF2-α, allowing protein synthesis and viral replication to proceed.[80] Of interest, the utilization of PKR-phosphorylated Tat by HIV-1 has been shown to increase the interation with its TAR-containing RNAs, thereby enhancing transcription.[81] HIV down-regulates RNase L (OAS) by inducing the expression of the RNase L inhibitor, which antagonizes 2-5A binding to RNase L, preventing its activation.[82]

Cytokines

Interleukin-1 and Interleukin-18

Interleukin (IL)-1 ligands (IL-1α and IL-1β, collectively referred to as IL-1) are pluripotent, proinflammatory cytokines that orchestrate inflammatory and host defense responses in the body. IL-1 augments T cell responses to mitogens (and indirectly activates B cells), increases expression of vascular adhesion molecules, and induces a number of other proinflammatory cytokines, chemokines, and inflammation-associated molecules that form an amplifying cascade to stimulate an immune response.[83] IL-1 affects nearly all cell types and often operates in concert with other cytokines and mediator molecules. IL-1 is a highly inflammatory cytokine, and the margin between benefit and unacceptable toxicity is quite narrow. Thus its gene expression, synthesis, secretion, and regulation are tightly controlled.[84] In fact, IL-1 actually has two receptors: one that transmits a signal (IL-1RI) and one that does not—a "decoy" receptor (IL-1RII) that serves as an IL-1 sink and is somewhat unique to cytokine biology.

Many viruses induce IL-1 production. IL-1 is induced at sites of HSV infection-induced inflammation, such as the cornea, and may contribute to pathogenic inflammation.[85] It is produced by many cell sources, including activated mononuclear phagocytes. Recombinant IL-1α administered to neonatal mice also can enhance survival,[86] but the role of endogenously produced IL-1 in the control of HSV infections is unclear. Some viruses have adapted ways to counteract IL-1, such as the generation of inhibitors to IL-1–converting enzyme (ICE), which blocks the post-translational activation of IL-1. Other viruses produce proteins that bind to and block the IL-1 receptor.[87,88]

The most salient property of IL-18 that separates it from IL-1 is its ability to induce IFN-γ in the presence of IL-12. Besides its IFN-γ–inducing activity, IL-18 enhances the Fas ligand and perforin-mediated T cell and NK cell cytotoxicity, stimulates T_H1 cell development, up-regulates granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-2 receptor-α (IL-2α), decreases IL-10–expression in T cells, and modulates immunoglobulin secretion from B cells. The proinflammatory activity of IL-18 is mediated by the production of nitric oxide (NO), prostaglandins, and inflammatory cytokines such as TNF-α, IL-1β, and IL-13. The IL-18–induced chemokines IL-8, macrophage inflammatory proteins (MIP)-1α and MIP-1β, and monocyte chemotactic protein-1 (MCP-1) recruit monocytes and macrophages to the site of infection.[89,90]

IL-18 binds its receptor (IL18R) in a two-stage manner, first to its α-chain IL-18Rα; then, it forms a tricomplex with its IL-18Rα chain. Subsequently, MyD88 is recruited, followed by activation of IL-1 receptor–activating kinases (IRAKs), TNF receptor–associated factor-6 (TRAF6), and NFκB-inducing kinase (NIK). NIK phosphorylates the IκB kinase, which then degrades, liberating NFκB, which translocates to the nucleus to initiate gene transcription. Its functional regulation is principally by control over its post-translational processing. The ability of INF-γ to increase the synthesis of inducible nitric oxide is essential for killing intracellular organisms. In that regard, IL-18 as an IFN-κ–inducing factor plays a key role in controlling infections due to *Salmonella, Cryptococcus*, *Toxoplasma, Candida,* and *Mycobacterium.* Additionally, IL-18, through IFN-γ, helps to induce endothelial adhesion molecules intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1), which facilitate the emigration of neutrophils and lymphocytes to the nidus of infection.[91]

It also functions in an antiviral capacity.[92] IL-18 administration to mice, including those lacking both T and B cell immunity, provides substantial protection against systemic HSV infection.[93] In wild-type mice, this protective effect depends largely on IFN-γ but not on NK cells.[93] Mice genetically deficient in IL-18 also die earlier and demonstrate an increased viral load compared with wild-type mice after a lethal intravaginal challenge with HSV.[94] The production of IL-18 during human HSV infection remains to be fully characterized.

Interleukin-12 and Interleukin-23

IL-12 is structurally related to several other cytokines, including IL-6, IL-23, and IL-27. IL-12 and IL-23 share a common p40 subunit and have distinct p35 and p19 subunits, respectively. The IL-12 receptor on cells consists of an IL-12Rβ1 and IL-12Rβ2 chain, whereas the IL-23 receptor consists of an IL-12Rβ1 and IL-23R subunit. IL-12 was first described for its ability to stimulate IFN-γ production by NK cells and enhance $CD8^+$ T cell cytotoxicity.[95] It also has been described as a key initiator of cell-mediated immune responses as well as playing a central role in promoting the differentiation of $CD4^+$ T cells into mature T_H1 effector cells. IL-12 does not induce proliferation of resting-blood T cells or NK cells, although it augments proliferation induced by mitogenic lectins, alloantigens, and CD3-specific antibodies, and it has a direct proliferative effect on preactivated T cells and NK cells. Stimulation through CD28 is synergistic with IL-12 for inducing proliferation of resting T cells and does not require the presence of specific antigens. Additionally, because the ligands for CD28 are surface molecules and IL-12 is a secreted product of APCs, their synergy also facilitates T cell proliferation and IFN-γ production after antigen presentation to T cells by APCs. Although IL-12 presumably may affect B cell proliferation, differentiation, and IFN-γ production directly, some of the reported effects of IL-12 on B cell activation and particular immunoglobulin isotypes are mediated indirectly by IL-12–induced T_H1 cells or their products (IFN-γ). IL-12 also induces T cells and NK cells to produce several other cytokines, including GM-CSF and TNF, but particularly IFN-γ.

Initially, this family of interleukins—IL-12, IL-23, and IL-27—was thought to be quite similar from a functional status as well as structural one. They respond to microbial and host immune stimuli such as TLRs and IFNs[96] and are tightly regulated, and each activates members of the Jak/STAT pathway. More recently, their unique functions have become more apparent. The finding that stimulation of activated and memory T cells in the presence of IL-23 (but not IL-12) led to the production of IL-17, but not IFN-γ or IL-4, provided the first evidence of unique role for IL-23 in the regulation of T cell effector function. IL-23 does not have the same ability as that of IL-12 to develop the T_H1 response. Instead, IL-23 induces a subset of T cells with a unique expression pattern—IL-6, IL-17A, IL-17F, and TNF. IL-17, for example, is implicated primarily in the regulation of local inflammation at multiple sites but predominantly in the intestines, lungs, and joints. IL-17 alone, or combined with TNF, can stimulate endothelial cells and macrophages to produce factors including chemokines, granulocyte colony-stimulating factor (G-CSF) and GM-CSF, IL-1, IL-6, and TNF.

The virus-targeted effects of IL-12 and IL-23 include their ability to promote $CD4^+$ and $CD8^+$ T cell proliferation and cytolytic function, and in augmenting NK cell activity. IL-12 is produced by myeloid dendritic cells and by plasmacytoid dendritic cells, after their exposure to HSV. Mononuclear phagocytes also produce IL-12 in response to HSV infection *in vitro*, and this appears to require intermediary synthesis of viral and host proteins and transcriptional activation by NFκB/Rel proteins.[97] HSV corneal infection also has been reported to induce IL-12 p40 mRNA by neutrophils,[98] but it is unclear whether these cells produce functional IL-12 or IL-23 protein. IL-23 transcripts have been detected in the ganglia of HSV-1 infected mice, but the cellular source has not been defined.[99]

IL-12 and IL-23 are important for directing the differentiation of naive $CD4^+$ T cells into T_H1 immune effectors that secrete high levels of IFN-γ in response to TCR stimulation.[100,101] They also can directly induce NK cells and effector T cells to produce IFN-γ. The production of IL-12 by plasmacytoid dendritic cells after their exposure to HSV may skew the immune response to HSV toward a T_H1 outcome. In addition, type I IFN also favors T_H1 differentiation, probably by increasing expression of the IL-12Rβ2 receptor on activated T cells.[102] Together, these mechanisms may account for the predominance of IFN-γ–producing effector and memory $CD4^+$ T cells after most viral infections, such as with herpesviruses.[103,104]

Nevertheless, the role of IL-12 and IL-23 in the control of HSV infection and other herpesviruses remains unclear. Mice lacking both IL-12 and IL-23 as a result of a gene disruption of the common p40 subunit die more rapidly than wild-type mice do after a lethal challenge with HSV.[94] Cellular, or T_H1, immunity has been suggested to play a vital role in the defense against intracellular pathogens such as viruses and a number of bacteria, parasites, and fungi. This view was supported largely by animal knock-out studies in mice lacking IL-12 or IL-12 receptor.[100] The description of human patients with inherited IL-12 or IL-12 receptor deficiency challenges the mouse model. IL-12 in humans was found to be redundant in defense against intracellular microorganisms other than *Mycobacteria* and *Salmonella.* In other studies, IL-12 also was found to be redundant even in defense against primary infection by *Mycobacteria* and *Salmonella.*[105] In fact, viruses almost ubiquitous in distribution—HSV, VSV, EBV, HCMV, influenzavirus and parainfluenza viruses, papillomavirus, molluscum contagiosum virus, rotavirus, enterovirus, parvovirus, adenovirus, RSV, calicivirus, and others—that are classic opportunistic organisms in immunocompromised patients do not cause severe disease in the IL-12 axis–deficient patients. It is therefore possible that human IL-12 alone is entirely redundant in protective immunity. Regardless of their role in primary control of HSV, IL-12 and IL-23 may contribute to inflammatory corneal scarring in HSV infection,[106] suggesting a deleterious impact in cases of established infection.

Interleukin-2 and Interleukin-15

IL-2 and IL-15 are structurally similar members of the short-chain four-helix bundle of cytokines and both utilize the β- and γ-chains of the IL-2 receptor for binding and signal transduction. IL-2 and IL-15 both are involved in adaptive immunity (especially in proliferation and maturation of both $CD4^+$ and $CD8^+$ T cells, the development of memoryphenotypic $CD8^-$ T cells, and the prevention of automimmunity).[107-109] However, these two cytokines, more than any others, are involved in the development, survival, proliferation, apoptosis, and effector functions of NK cells, including the stimulation of NK-derived cytokines such as TNF-α, IFN-γ, and GM-CSF. In contrast with IL-2, IL-15 is produced not by T cells but by other cell types, especially bone marrow stromal cells and activated mononuclear phagocytes. IL-15 also is a potent activator of NK cells for enhanced cytotoxicity against most herpesviruses, including HSV.[110] Exposure of human peripheral blood mononuclear cells to HSV also up-regulates NK cytotoxic activity by an IL-15–dependent mechanism.[111] Infection of mice results in a rapid and substantial increase in serum levels of IL-15, peaking at approximately 3 days after infection[112]—suggesting a role in the early innate immune response. IL-15 administration also is protective to wild-type mice given an otherwise lethal dose of HSV.[112]

IL-12 and IL-15 production by mononuclear cells (presumably mainly monocytes) from term neonates after stimulation with LPS was approximately 25% of that typical for adult cells.[113,114] Although this limited production could contribute to the observed reduced HSV-specific T_H1 response *in vivo* of neonates, such reduced responses are highly stimulus-dependent. For example, neonatal and adult blood mononuclear cells stimulated

with *Staphylococcus aureus* or meningococcal outer membrane proteins produce equivalent amounts of IL-12.[113-116] The production of cytokines that enhance defenses against intracellular pathogens by monocytes derived from newborn infants, such as TNF-α, also is modestly reduced.

Chemokines

Chemokines secreted by mononuclear phagocytes and dendritic cells, as well as nonhematopoietic cells, play an important role in the recruitment of NK cells and subsequently T cells to sites of infection and in maintaining inflammation. In the case of herpes keratitis, the production of the CC chemokine MIP-1α contributes to inflammatory disease but does not influence viral replication.[117] The CXC chemokine IL-8, which is a potent neutrophil chemoattractant, is produced by corneal keratocytes[52] and possibly by corneal epithelial cells,[118] and this property is likely to account for the prominence of neutrophils in HSV keratitis.

Elevated CSF levels of the CC chemokines, MCP-1, MIP-1α, and RANTES, and of IL-8 also have been documented in cases of human HSV encephalitis,[119] suggesting their role in CNS inflammation. Cerebrospinal fluid mononuclear phagocytes, such as macrophages or microglial cells, are likely sources of at least a portion of these chemokines—an idea supported by the ability of microglial cells or macrophages infected by HSV to produce chemokines such as RANTES.[120,121] In addition to their proinflammatory role, certain chemokines potentially may skew the outcome of the adaptive immune response to viral infection. For example, MCP-1 is produced in the cerebrospinal fluid of mice experimentally infected with HSV-2. This effect appears to result in decreased survival compared with that in mice in which this chemokine is neutralized.[122] MCP-1 appears to skew the $CD4^+$ T cell response toward a nonprotective T_H2 (IL-4, IL-5, and IL-13 predominant) response, rather than a protective T_H1 response. This observation is consistent with earlier studies in which administration of relatively small doses of IL-4 in an HSV-1 encephalitis mouse model was found to increase disease severity.[123]

Surfactant Proteins

Surfactant proteins SP-A and SP-D are members of the collectin family of lectins and are synthesized by type II alveolar epithelial cells, lung epithelial Clara cells, and certain extrapulmonary cell types.[124] SP-A and SP-D contribute significantly to pulmonary immunity by involvement in viral neutralization, clearance of bacteria, fungi, and apoptotic cells, and regulation of inflammation.[125] Their carboxyl-terminal (C-terminal) carbohydrate recognition domain can recognize carbohydrates or charge patterns on a wide variety of microbes, whereas the triple helical collagen region interacts with receptors on a variety of immune cells in order to initiate clearance mechanisms. Studies involving gene knock-out mice, murine models of lung hypersensitivity and infection, and functional characterization of cell surface receptors have revealed diverse roles for SP-A and SP-D[126]: They affect agglutination, opsonization, chemotaxis, and enhanced phagocytosis.[125] In mice lacking SP-A, viral load is increased after challenge with RSV, in association with increased neutrophil inflammation of the lung and production of proinflammatory cytokines.[127] SP-D has been shown to bind RSV proteins G and F and to reduce macrophage and neutrophil production of oxygen radicals.[128] SP-D binds *in vitro* to influenza A virus through its hemagglutinin molecule and can promote internalization of the virus by neutrophils. Mice lacking SP-D demonstrate reduced influenza A virus clearance, diminished myeloperoxidase activity, and excessive IFN-γ and IL-2 production in bronchial lavage fluid.[129] SP-A and SP-D both bind LPS from bacteria such as *Klebsiella pneumoniae* and *Pseudomonas aeruginosa,* although by different mechanisms. SP-A, for example, binds the lipid A region of LPS and CD14 and initiates TNF-α signaling. SP-A also has been shown to engage TLR4 and accessory protein MD-2 in an immunomodulatory role.[130] Many of the conditions that predispose to severe respiratory infection, including prematurity and bronchopulmonary dysplasia, are associated with decreased SP expression by the lung, and it is plausible that these decreases could contribute to disease severity. Of note, neither SP-A or SP-D is utilized in the artificial surfactant replacement therapies routinely given for infantile respiratory distress syndrome, although some experimental evidence supports the utility of SP-A and SP-D for antimicrobial therapy and to restore inflammation.[131]

Innate Cellular Mechanisms

Mononuclear Phagocytes and Inducible Nitric Oxide Synthase

Mononuclear phagocytes are widely distributed in the tissues as macrophages and are likely to play an important role in the local containment of viral infections such as HSV before activation of the adaptive immune response. In murine studies with intraperitoneal HSV or MCMV and HSV corneal infections, macrophages have been identified as the predominant cell type involved and demonstrate HSV-instigated production of TNF-α. TNF-α has direct anti-HSV effects, particularly in combination with IFN-γ,[132] and these two cytokines also may synergize to increase expression of leukocyte adhesion molecules and inducible nitric oxide synthase (iNOS) expression by mononuclear phagocytes. HSV infection of mononuclear phagocytes also synergizes with IFN-γ for promoting expression of iNOS,[133] which has anti-HSV effects *in vitro*,[134] and for production of TNF-α.[135] Systemic depletion of mononuclear phagocytes (by administration of liposomes containing dichloromethylene diphosphonate) or of γδ T cells (which produce IFN-γ), or inhibition of TNF-α, IFN-γ, or iNOS activity in the HSV corneal infection model, results in increased HSV-1 replication within the ganglion.[136,137] Specific inhibition of iNOS in mice challenged with intranasal aminoguanidine causes a dose-dependent increase in pneumonitis compared with that in control animals.[138] These complex interactions illustrate the importance of these cellular and cytokine components in local antiviral host defense. An antiviral role for iNOS also is suggested by the increased susceptibility of mice with complete genetic deficiency of iNOS to HSV infection from footpad injection. These mice also demonstrate exaggerated T_H1 responses, indicating that iNOS may have key antiviral effects, as well as inhibitory effects on T_H1 differentiation.[139]

However, innate antiviral immune mechanisms mediated by mononuclear phagocytes, such as iNOS induction, may not necessarily be beneficial in all contexts of HSV infection. In a murine model of HSV pneumonia, inhibition of iNOS activity markedly reduced pulmonary inflammation and improved survival, despite increases in the lung tissue HSV viral titer.[140] Inhibition of iNOS activity also was of clinical benefit in experimental HSV-1 encephalitis in rats and was not associated with increased viral load.[141]

Dendritic Cells

Dendritic cells form a network of immune sentinels throughout the body. Their function is to detect and capture foreign antigens, process them, and carry them to the lymph nodes, where the antigen can be presented to T cells in association with surface MHC molecules.[142] Immature dendritic cells residing in the peripheral tissues have relatively weak T cell stimulatory capacity and express low levels of MHC molecules and co-stimulatory molecules. Dendritic cells mature in response to a pathogen recognized by pattern recognition receptors or danger signals such as IL-1β or TNF-α secreted by surrounding cells. They migrate to a lymph node (in response to chemokine CCR7),[143] where they undergo a series of functional and phenotypic changes necessary for effective antigen loading and priming of naive T cells. Dendritic cell maturation is characterized by an increase in antigen

processing efficiency as well as increased surfaced expression of CD40, CD80, CD83, and CD86.

Most dendritic cells are found in one of three compartments. Epidermal Langerhans cells and the underlying dermal and interstitial dendritic cells constitute the first group and the predominant population within the skin and mucosa. Within peripheral blood, two additional populations of dendritic cells can be identified: myeloid and plasmacytoid.[142] Plasmacytoid dendritic cells ($CD11c^{-}CD123^{+}$) are involved in the production of high levels of type I IFNs (after TLR-9 signaling after endocytosis of antigen, for example) in response to invaders such as HSV, HIV, and influenzavirus. Myeloid dendritic cells ($CD11c^{+}CD123^{lo}$) in the blood are a circulating group of precursors of tissue-resident dendritic cells. Dendritic cells are able to capture antigen from infected cells or from direct contact with virions and present it for recognition by naive T cells. Dendritic cells play a pivotal role in the immune response to a variety of viral infections; thus successfully overcoming this obstacle by the attacking virus will allow persistence of viral infection within its host. Direct infection of dendritic cells is one such strategy and has been used by a number of viruses including influenzavirus, HIV, and HSV-1 and -2 to block the amplification of the immune response by dendritic cells. Indeed, myeloid dendritic cells generated from peripheral blood monocytes express HSV entry receptors Hve-A and Hve-B. Although attack of mature dendritic cells by HSV-1 generally results in a nonproductive or aborted infection, the mature cells generally are not found at the sites of HSV infection. Immature dendritic cells are, however, readily infected by HSV and subsequently down-regulate their co-stimulatory and adhesion molecules, but the expression of MHC molecules is largely unaffected.[144] The inability of HSV ICP47 to interfere with MHC class I expression probably is the consequence of innately high levels of the "transporter associated with antigen processing" (TAP) protein in dendritic cells. Down-regulation of other molecules does have an impact on its stimulatory ability; for example, down-regulation of CD40 expresison on HSV-infected dendritic cells may lead to decreased production of IL-12 on contact with T cells. Observed down-regulation of CD54 on the surface of immature dendritic cells may also effect generation of anti-HSV immunity. CD54/ICAM-1 is a surface glycoprotein that binds leukocyte function antigen-1 (LFA-1), facilitating a number of cellular events including antigen-specific T cell activation and leukocyte transendothelial migration. Binding of CD54 to LFA-1 appears to be of critical importance for the activation of naive T lymphocytes, especially at low antigen concentrations.[145] Infected dendritic cells subsequently are compromised in their ability to carry out their function in stimulating effector cells and may undergo rapid apoptosis. Although this destructive process removes a pool of cells that present antigen, thereby potentially giving a "head start" to viral infection, neighboring uninfected dendritic cells readily take up apoptotic cell debris for antigen presentation through MHC class I (an example of cross-presentation of antigen) and stimulate effector cells such as HSV-specific $CD8^{+}$ T cells. Transfer of viral peptide antigens from infected cells to neighboring bystanders through gap junctions also has been proposed.[146]

In neonatal herpes simplex, the diminished competence of dendritic cell function may explain in part why HSV infection is such a devastating disease in this population. Inherent defects in the ability of human and murine neonatal dendritic cells to mature, produce cytokines, and activate effector cells, in comparison with adult cells, are well recognized. Dendritic cells isolated from human newborn cord blood have reduced expression of accessory molecules and produce less IL-12 owing to reduced IL-12 p35 gene transcription, and less IFN-γ than those from adults. Growing evidence supports an association between HSV infection and suboptimal maturation and activation of the neonatal dendritic cell as well.[147] Treatment of neonatal mice with Flt-3 ligand and growth factors that increase the number and maturation of peripheral dendritic cells increases resistance of neonatal mice to HSV infection, however.

Studies using dendritic cell–enriched fractions that contain both myeloid and plasmacytoid dendritic cells suggest that neonatal dendritic cells overall are less able to activate $CD4^{+}$ T cells.[148,149] However, plasmacytoid dendritic cells make up a greater fraction of circulating dendritic cells in neonates than in adults, and plasmacytoid dendritic cells are relatively poor at activating T cells.[150] Therefore further investigation of myeloid dendritic cell function in neonates and in adults is needed for accurate assessment of developmental limitations in this cell population.

Myeloid dendritic cells derived from immature precursors in neonatal or adult blood can be primed for efficient antigen presentation by engagement of their CD40 molecule by CD154 expressed by activated T cells, or by their exposure to microbial products or inflammatory cytokines induced by these products. Experimental observations support the idea that overall myeloid dendritic cell maturity is increased after exposure to microbial products, such as from endogenous bacterial flora. Myeloid dendritic cells from adult mice lacking functional TLR4, which recognizes LPS and other bacterial products, have reduced levels of expression of co-stimulatory molecules and a decreased capacity to direct T cell activation.[151] Thus it is possible that the lack of previous exposure to microbes (which occurs in a cumulative manner after birth) could contribute to diminished dendritic cell function and the slow rate at which antigen-specific T cells develop.

Natural Killer Cells

NK cells are bone marrow–derived lymphocytes that lack the antigen-specific TCRs and immunoglobulins that are characteristic of T and B cells, respectively. They make up approximately 5% to 20% of lymphocytes in the spleen, liver, and peripheral blood and are present in lower frequencies in the thymus, lymph nodes, and bone marrow.[152] In humans, a minority population of $CD56^{hi}$ NK cells are primarily involved in producing large amounts of cytokines such as IFN-γ, GM-CSF, G-CSF, macrophage-CSF, TNF-α, IL-5, IL-10, and IL-13 and chemokines; $CD56^{low}$ NK cells express high levels of low-affinity Fc receptor for immunoglobulin G (IgG) (FcγRIII) (also known as CD16) that are powerfully cytotoxic, accounting for 90% of the NK population.[153] Activation of NK cells is mediated by cell surface interactions as well as cytokine signals, and in response to these stimuli, NK cells produce further cytokines and lyse target cells. NK function is tightly regulated by a balance of positive and negative signals. Unlike cytotoxic T lymphocytes (CTLs), NK cells do not require antigen-specific recognition to kill their targets.[154] They are activated by the differential engagement of cell surface receptors in combination with activities mediated by proinflammatory cytokines.

The two major groups of inhibitory NK receptors are the killer inhibitory receptors (KIRs) and CD94/NKG2A. The KIRs bind to portions of HLA-B and HLA-C molecules located outside the peptide-binding groove recognized by the TCR, whereas CD94/NKG2A binds to HLA-E, a nonclassic and nonvariable MHC molecule that requires hydrophobic leader peptides from HLA-A,-B, and -C for its surface expression. These NK cell receptors help counteract the ability of viruses to decrease surface expression of class I MHC molecules, thereby limiting $CD8^{+}$ T cell–mediated viral clearance. For example, the down-regulation of HLA-C by HSV results in killing by an NK cell clone by its release from inhibition of KIRs.[155]

NK cells also express positive activating receptors,[156] such as 2B4 (CD244), NKG2D, NKp30, NKp44, NKp46, and NKR-P1A (CD161), that are important for killing. NKG2D may be activated by binding to MHC class I chain A (MICA) or chain B (MICB) or UL-16–binding proteins (ULBPs) on target cells. These molecules are induced by cell stress. Direct activation by viral products

also is possible. For example, the Ly49H-activating receptor of murine NK cells specifically recognizes a MCMV-encoded protein, m157.[157] Viruses, including herpesviruses, use a wide variety of strategies to inhibit NK cell–mediated cytotoxicity (Figure 150-2), indicating the importance of this antiviral mechanism *in vivo*.[158,159] HCMVs interfere at multiple steps of cellular MHC-I production. For example, they cause sequestration of MHC-I before they reach the surface by interfering with peptide chaperones. Then they produce their own MHC-I viral homologues (HCMV UL18).

NK cells are a particularly important restraint on viral replication and dissemination prior to the appearance of adaptive immune responses mediated by T cells and B cells. This has been demonstrated most clearly in the severity of primary infections with herpesviruses, including HSV, HCMV, and VZV, in patients with a selective lack of NK cells.[160] Although the initial disease is severe, these patients are able eventually to clear virus, presumably by means of T cell–mediated immunity.[160,161] NK cells may contribute to the control of viral infection by the direct lysis of virally infected cells, as described earlier, or by lysis of virally infected cells through antibody-dependent cellular cytotoxicity (ADCC). In the case of ADCC, antibody that recognizes viral proteins on the surface of the infected cell can bind to the NK cell through surface Fc receptors and enhance NK cell recognition and lysis of infected target cells. NK cells also produce proinflammatory cytokines that increase intrinsic antiviral resistance (e.g., type I IFN) and promote the development of antigen-specific T_H1 cell immunity (both type I IFN and IFN-γ). Thus the NK cell may contribute both to the innate immunity phase and the late phase of control of herpesvirus infections and be of particular importance in settings in which class I MHC expression is down-regulated and $CD8^+$ T cell recognition of infected target cells is hampered.

Infection of mice with HSV also demonstrates the importance of NK cells in the early control of viral infection. If NK cells are eliminated by injection with specific antiserum concurrent with the administration of virus, the titers of HSV in internal organs and the mortality rate both are markedly increased, but this treatment has no significant effect if started 5 days after viral challenge.[162] Adoptive transfer studies in immunosuppressed mice demonstrate that significant protection against HSV is provided by NK cells.[163] A more detailed study found that after HSV inoculation into the anterior ocular chamber, NK cells accumulated within the eye by day 5 after inoculation and that depletion of these cells by specific antiserum resulted in spread of the infection to the retina.[164]

Studies with MCMV also suggest that NK cells are important in the early control of herpesvirus infection,[165] and that IFN-γ produced by NK cells is more important for this protection than is NK cell–mediated cytolytic activity.[166] The production of IFN-γ by NK cells *in vivo* during the early phase of MCMV infection uses IL-12 and is enhanced by TNF-α, but not type I IFN. By contrast, endogenously produced type I IFN, but not IL-12 or TNF-α, greatly enhances NK cell–mediated cytotoxicity and proliferation.[167] How IFN-γ is protective in early viral infection remains unclear, but it could act directly to limit productive viral infection in cells that are otherwise permissive for infection, such as hepatocytes. Some evidence points to a noncytolytic mechanism of protection of hepatocytes in hepatitis B and hepatitis C infections, particularly through effects mediated by IFN-γ or TNF-α .[168–170]

IFN-γ produced by NK cells also increases class II MHC expression on mononuclear phagocytes *in vivo* and probably other cell types in response to HSV or MCMV infection,[171] an effect that facilitates antigen presentation to $CD4^+$ T cells. Increased IFN-γ

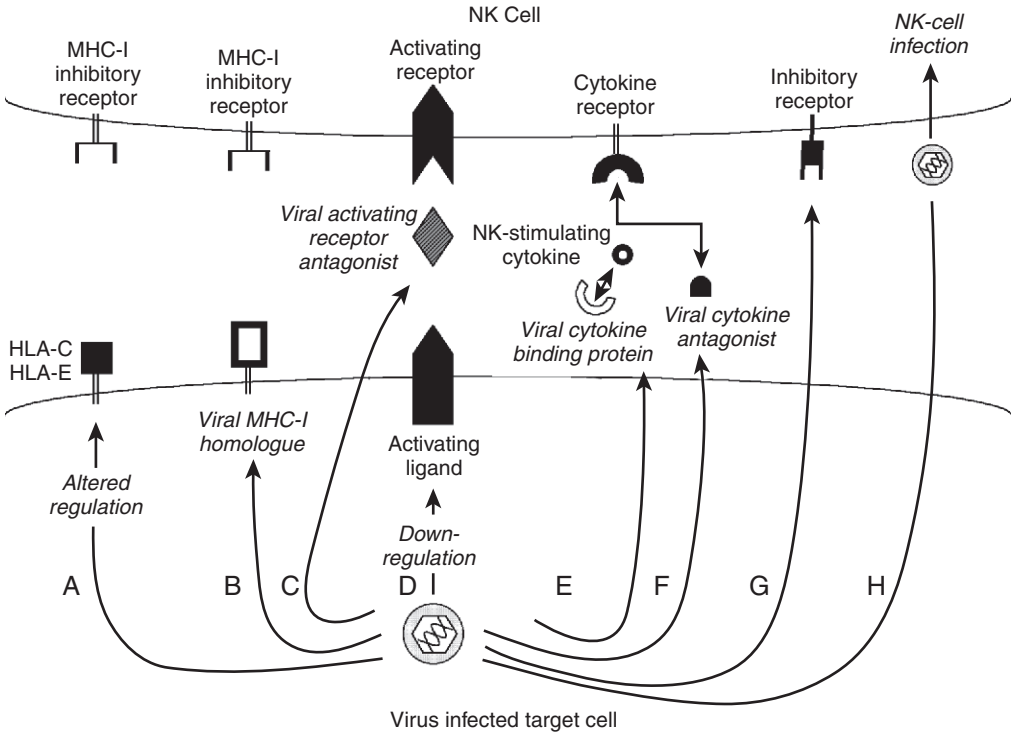

Figure 150-2 Viral mechanisms for evading a natural killer (NK) cell. NK function is tightly regulated by a balance of positive and negative signals. Viruses manipulate expression of native major histocompatibility complex (MHC)-I molecules **A,** express virally encoded MHC-I homologues **B** and generate activating receptor antagonists **C** to mimic "self." Additionally they down regulate target cell activating ligands **D** and block NK-activating cytokines with cytokine binding proteins **E** or NK cytokine receptor blockade **F.** Additionally viral proteins can act directly on NK inhibitory receptors **G,** or the virus can directly infect the NK cell **H.**

during the early phases of T cell activation and differentiation also may favor the development of T cells with an enriched capacity to secrete T_H1-type cytokines. This effect may be mediated by the ability of IFN-γ rapidly to increase expression by T cell T-bet, a key regulatory transcription factor that directs T_H1 development.[172]

More recently, NK cells have been observed to interact with dendritic cells in a number of experimental and *in vivo* settings including studies with herpesviruses and in fact have been shown to share some functional and phenotypic characteristics, such as NK-presenting antigens with MHC II and co-stimulatory molecules. Likewise, antigen-presenting dendritic cells with cytotoxic functions termed NK dendritic cells also have been described in mice.[173]

The cytolytic function of NK cells increases progressively during fetal life to reach values approximately 50% (range, 15% to 60% in various studies) of those for adult cells at term.[174-184] NK cells from the premature infant also have reduced cytotoxic function compared with those from the term neonate. An important point is that decreased cytotoxic activity by neonatal NK cells compared with adult cells also is consistently observed with HSV-infected[185-187] and HCMV-infected target cells,[188] but not with HIV-1 infected cells.[189,190]

Unlike adult NK cells, which are predominantly $CD56^{high}$, most neonatal NK cells are $CD56^{low}$. This $CD56^{low}$ subset, which is phenotypically immature, has relatively low NK cell activity compared with $CD56^{high}$ cells. However, the molecular basis for reduced activity of the $CD56^{low}$ subset remains poorly defined, as does the mechanism responsible for pathogen-specific differences in neonatal NK cell function.[1] It is clear that reduced neonatal NK cell activity is not determined at the level of the hematopoietic stem cell or later precursor cells of the NK cell lineage, because donor-derived NK cells appear early after cord blood transplantation and mediate robust cytotoxicity by way of the perforin/granzyme and Fas/Fas ligand cytotoxic pathways.[191]

As with their effects on adult NK cells, cytokines such as IL-2, IL-12, IL-15, type I IFN, and IFN-γ can augment the cytolytic activity of neonatal NK cells within a few hours[192-194]—an observation consistent with normal levels of expression of surface receptors for these cytokines.[195] However, neonatal NK cells are less responsive to activation by the combination of IL-12 and IL-15 than are adult NK cells, as reflected in the induction of CD69 surface expression.[196]

Reduced NK cell cytolytic activity and cytokine production may be an important contributor to the pathogenesis of neonatal HSV infection. In the murine neonatal model in which human cells are adoptively transferred, the age-related maturation of NK cell function parallels the development of resistance to HSV.[16,197] Neonatal mice, which like human neonates are more susceptible to HSV infection, can be protected by adoptive transfer of human blood mononuclear cells from adults but not those from neonates. Addition of IL-2 augments protection mediated by cells from adults but not cells from neonates, and protection depends on IFN-γ production by the transferred cells. The failure of human neonatal cells to transfer resistance in this model also can be corrected by the addition of IFN-γ, a cytokine produced poorly by neonatal T cells. This set of findings suggests that lack of IFN-γ production may be one important difference between adult and neonatal cells.

ADAPTIVE ANTIVIRAL IMMUNITY

Adaptive immune responses mediated by HSV antigen–specific T cells and B cells are first detected 5 to 7 days after the onset of primary HSV infection in adult humans, and the peak response is achieved approximately 2 to 3 weeks after infection.[198-200] In virtually all affected persons, antigen-specific immunity does not eradicate infection—that is, does not achieve sterile immunity—but rather terminates active viral replication and the acute infection. HSV is able to persist in the form of latent virus in neurons, leaving it potentially capable of causing recurrent localized disease. Recurrent viral replication may be frequent and, in many cases, asymptomatic.

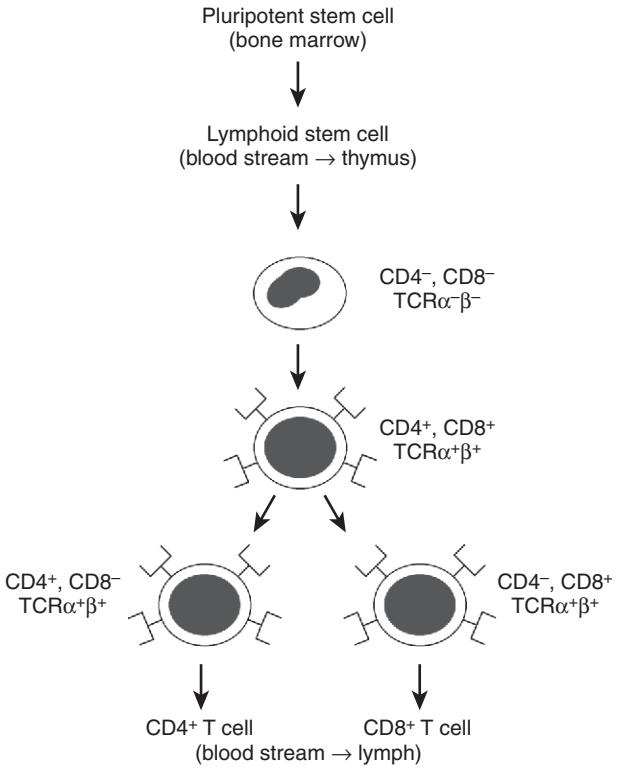

Figure 150-3 T cell maturation. T lymphocytes develop in the thymus where cells that recognize self-antigens are removed and TCRs that recognize foreign antigens in association with self–major histocompatibility complex (MHC) are selected. TCR expression commences in the double-positive $CD4^+CD8^+$ stage, beginning with low numbers of receptors on each cell and increasing as maturation proceeds. Single-positive, that is, $CD4^+$ or $CD8^+$ TCR-αβ–expressing, mature cells are selected from this population. A small population (approximately 5%) of double-negative T cells bearing TCR-γδ also leave the thymus[374] *(not shown).*

Antiviral T Cell Immunity: An Overview

The lymphoid stem cell derives from the pluripotent hematopoietic stem cell and differentiates into three types of cells—the T lymphocyte, the B lymphocyte, and the non-T, non-B NK cell progenitor, discussed previously. The lymphoid stem cells destined to be T lymphocytes (Figure 150-3) undergo positive and negative selection principally within the thymus and undergo development into descendant cells with rearranged α and β (or γ and δ) genes of its TCR. T cell surface expression of the TCR depends on coexpression with the CD3 molecule, which is a cluster of γ-, δ-, ε-, and ζ-chains. Together the TCR and CD3 molecules form the *TCR complex.* These early T cells are capable of distinguishing between self and nonself antigens in the context of self-MHC molecules and circulate within the bloodstream, the lymphatic system, and tissues. For the most part, three populations of T cells leave the thymus: TCR-αβ/$CD4^+$ T cells, TCR-αβ/$CD8^+$ T cells, and (as a minority) TCR-γδ T cells, which are predominantly

$CD4^-/CD8^-$. All bear the TCR complex; thus CD3 represents a universal T cell marker.

Although $CD4^+$ T cells are referred to as helper T cells and $CD8^+$ T cells as cytotoxic T cells or CTLs, they can have diverse functions and should be understood on the basis of their respective phenotypes and their response to MHC molecules. $CD8^+$ T cells recognize peptides in the context of class I MHC (displayed on virtually all nucleated cells), and $CD4^+$ T cells recognize antigens as presented in the context of class II MHC molecules, found on APCs such as monocytes, macrophages, B cells, and dendritic cells.

T cells play the critical role in resolution of active HSV infection and the maintenance of viral latency.[201,202] Adoptive transfer studies and T cell depletion studies using $CD4^+$ or $CD8^+$ monoclonal antibodies indicate that both $CD4^+$ and $CD8^+$ T cells contribute to clearance of HSV after acute infection in mice, acting, in large part, through the production of IFN-γ[203]; by contrast, B cells are not able to provide full protection in the absence of T cells.[200,204-206] The importance of T cells in the control of human HSV and other herpesvirus infections is indicated by the increased susceptibility of those with quantitative (purine nucleoside phosphorylase deficiency,[207] late HIV infection) or qualitative T cell and antigen presentation defects (Wiskott-Aldrich syndrome). Murine studies also suggest that $CD4^+$ T cells are more important than $CD8^+$ T cells in the control of HSV infections of the skin and peripheral nervous system,[204] suggesting that the relative importance of $CD4^+$ versus $CD8^+$ T cells in antiviral control is tissue-specific.

Comparison of newborn and adult T lymphocyte function explains some of the increased susceptibility to viral infections such as HSV infection in neonates. Although the mean T lymphocyte count is higher in neonates, neonatal T cells do not proliferate well in response to antigen, do not function efficiently as B cell helpers, and produce cytokines (such as IFN- and IL-4) in significantly lesser amounts.[208] Additionally, neonatal T cell cytotoxicity is limited in comparison with that of adult T cells. The specific role of T cell immaturity in severe clinical HSV infection in neonates is further suggested by the observation that neonates infected with HSV showed decreased antigen-specific cellular responses (including decreased proliferation and IFN-γ production) compared with adults who had primary HSV infection.[198]

$CD4^+$ T Cell–Mediated Antiviral Immunity

$CD4^+$ T cells appear to play a key role in protection from HSV and have been identified in the circulation[209] and from multiple sites of recurrent human HSV infection, such as the skin,[210,211] cervix,[212] cornea,[213] and retina.[214] Natural infection results in $CD4^+$ T cell recognition of peptide epitopes from a variety of HSV proteins, including those of the envelope, tegument, and capsid.[215,216] A number of mechanisms are likely to be important, reflecting the central and diverse roles of $CD4^+$ T cells in mediating and regulating antigen-specific immunity in HSV infection[1] (Box 150-1).

BOX 150-1

CD4 Anti–Herpes Simplex Virus (HSV) Mechanisms

- CD4 expression of IFN-γ, TNF-α, CD40 ligand[175,176,208]
- CD4 helper stimulation of anti-HSV effector $CD8^+$ CTLs[203,177,178]
- CD4 priming of dendritic cells (CD40 ligand)[179,180]
- CD4-expressed IL-2 expansion and differentiation of $CD8^+$ CTLs[202]
- CD4-expressed IFN-γ interference with ICP47-mediated MHC-I inhibition[202,181]
- CD4 cytolytic activity against cells expressing MHC-II–bound HSV[210,182,183]

CTLs, Cytotoxic T lymphocytes; *IFN-γ,* interferon-γ; *IL-2,* interleukin-2; *MHC-I, -II,* major histocompatibility complex class I, II; *TNF-α,* tumor necrosis factor-α.

T Cell Activation and T_H1/T_H2 Differentiation

In response to microbial pathogens, $CD4^+$ T cells differentiate into T_H1 or T_H2 phenotype. On the one hand, T_H1 cells principally produce IFN-γ and induce B cells to release IgG2 isotype antibodies, which are responsible for phagocyte activation of ADDC, and defense against intracellular pathogens. On the other hand, T_H2 cells produce IL-4, IL-5, and IL10 and induce immunoglobulin E (IgE) antibodies, which are responsible for immunity against parasitic infections.

As discussed previously, TLRs are important for innate immunity and activation of many cell types in response to recognition of pathogens through pattern recognition receptors. For example, the uptake of microorganisms by dendritic cells through TLRs induces the up-regulation of co-stimulatory and MHC molecules, the expression of chemokines, and migration of the dendritic cell to draining lymph node. There they prime and activate the adaptive immune response through interaction with T cells. The activation of T cells by APCs results from (1) T cell recognition of MHC class II–bound pathogen peptide, (2) activation of co-stimulatory molecules (such as CD28/CD80/86 or CD154/CD40), and (3) an initiation signal from specific cytokines, such IL-12 driving a T_H1-type response or IL-4/IL-10 driving a T_H2-type response.

After activation of T cells, a crucial step in tailoring adaptive immunity is determining T_H1 versus T_H2 phenotype.[217,218] Factors such as the density of peptides presented, types of co-stimulatory molecules expressed, and the state of APC activation influence whether the $CD4^+$ T cells differentiate into either T_H1 or T_H2 phenotype. However, the most important signal is the cytokine milieu present at the time of T cell stimulation, with either a T_H1-inducing profile represented by IL-12 family members and IFN-α or T_H2-inducing profile represented by IL-4 and IL-10.

Because presentation of antigen in the absence of co-stimulatory signals leads to anergy instead of activation, the stimulation of CD80 or CD86 by TLR-mediated signals is an important step in the activation of adaptive immunity.[219] In this way, TLRs participate in the translation of nonspecific information contained in conserved pathogen-associated molecular patterns into antigen-specific information and clonal expansion of T cells.

In vitro models of activation have shown that neonatal $CD4^+$ T cells differ from adult $CD4^+$ T cells in tending to become anergic (permanently nonresponsive to antigenic stimuli) unless antigen is presented by primed or mature dendritic cells expressing co-stimulatory molecules and cytokines.[220-223] This anergic tendency may apply to $CD4^+$ T cells that are expanded in instances in which neonates are infected with bacteria that express superantigen toxins, such as toxic shock syndrome toxin-1.[223]

Limitations in dendritic cell antigen presentation or co-stimulatory function could promote such T cell anergy or a failure of expanded $CD4^+$ T cells to acquire T_H1 effector activity. Of note, infants between 6 and 12 months of age exhibit lower $CD4^+$ T cell–derived IL-2 production in response to tetanus toxoid than that typical for older children and adults.[224] This observation supports the idea that either antigen-specific memory $CD4^+$ T cell generation or function is decreased not only for HSV but more generally during early infancy. *In vitro* studies suggest that reduced class II MHC antigen presentation could contribute to this outcome.[224]

T_H1 Cytokine Production

The HSV-specific $CD4^+$ T cell response of humans is characterized by a predominant T_H1 response.[184] The differentiation of naive $CD4^+$ T cells into T_H1 effector cells is favored by production of cytokines, such as IL-12, IL-23, and IL-27,[100] which are induced as part of HSV infection *in vivo*. These cytokines also can directly induce differentiated T_H1 cells to produce IFN-γ. HSV infection also may promote T_H1 immunity by inducing the production of osteopontin by T cells at an early stage of activation and differentiation. This cytokine may act on APCs by interacting with β3 integrins to maintain IL-12 production and with CD44 to inhibit IL-10 production, thereby favoring a T_H1 adaptive immune response.[225] Osteopontin is required for the development of delayed-type hypersensitivity responses (characteristic of T_H1 immunity) to HSV, and of HSV-induced corneal inflammation, which is T_H1-dependent.[225]

IFN-γ is a key immunoregulatory cytokine that is produced in substantial amounts by $CD4^+$ T cells of the T_H1 subset, $CD8^+$ T cells, γδ T cells, and NK cells. It is a key component in appropriately regulating adaptive and innate cellular mechanisms of antiviral control. The potential cellular sources of this cytokine and their temporal appearance (e.g., NK and γδ T cell–derived IFN-γ production preceding $CD4^+$ and $CD8^+$ T cell–mediated production), as well as their location, need to be considered when evaluating the importance of IFN-γ *in vivo*. IFN-γ acts to increase the antiviral state of many cell types, such as mononuclear phagocytes. In addition, this cytokine enhances the expression of the class I heavy chain, β_2-microglobulin, and TAP transporter. These effects help counteract the negative effects of HSV on class I MHC antigen presentation, and increase the ability of infected cells to be lysed.[181] CD40 ligand expression by $CD4^+$ T cells also is key for the antibody production by B cells and isotype switching.

Administration of neutralizing antibodies to IFN-γ increases the severity of HSV-1 infection in mice.[203] Likewise, knock-out mice lacking IFN-γ or its receptor are impaired in their ability to control HSV infection, as measured by higher mortality, prolonged infection, and more frequent reactivations. IFN-γ is a poor inhibitor of HSV replication *in vitro*; this is not a biologically relevant situation, however, because T_H1 cells do not secrete IFN-γ in environments devoid of other cytokines. *In vivo*, the secretion of other proinflammatory cytokines and chemokines occurs before and during the recruitment of T cells into sites of viral infection. In addition, IFN-γ has been found to act in concert with other cytokines such type I IFNs to effect potent inhibition of HSV *in vitro*.[72]

Virus-specific T_H1 cells also are major sources of TNF-α.[102] TNF-α has direct antiviral effects, particularly in conjunction with IFN-γ, and also proinflammatory effects (e.g., by increasing adhesion molecule expression by nonhematopoietic cells, such as endothelium, and production of chemokines). In human corneal infection with HSV, the combination of TNF-α and IFN-γ exerts a synergistic antiherpes effect within the corneal fibroblasts, chiefly attributed to the induction of IFN-β.[226] In the case of MCMV infection, some of these antiviral effects mediated by IFN-γ may be cell type–specific—for example, they may be operative for mononuclear phagocytes but not fibroblasts—and involve novel mechanisms that are shared with type I IFN.[227] Some of these T_H1 cells also are a rich source of IL-17, which is found at sites of HSV infection, such as the cornea. IL-17 may contribute to local inflammation by increasing the production of proinflammatory cytokines and neutrophil chemotactic proteins, such as chemokines.[228]

Some of the best-documented limitations in neonatal adaptive immunity come from two studies comparing T cell responses in neonates and in adults with primary HSV infection.[198,229] HSV-specific proliferation of peripheral blood mononuclear cells and production of both IFN-γ and TNF-α were diminished and delayed in the neonates compared with the adults. The neonates did not achieve adult levels of these responses for 3 to 6 weeks after clinical presentation, whereas the adults all exhibited robust responses by 2 weeks. These studies used ultraviolet light–irradiated viral preparations to stimulate peripheral blood mononuclear cells, in which viral proteins are processed mainly by the class II rather than the class I MHC antigen presentation pathway. Therefore they assayed mainly $CD4^+$ and not $CD8^+$ T cell function.

These results suggest a profound lag in the development of adaptive immunity to the HSV in normal neonates, during which viral replication and cell lysis could continue. Because, as discussed earlier, $CD4^+$ T cells provide multiple critical effector mechanisms that may be important for the resolution of HSV infection (including direct antiviral cytokine production and providing help for $CD8^+$ T cell and B cell responses), these findings suggest that a lag in T cell immunity may be a key contributor to the tendency of HSV infection to disseminate and to cause prolonged disease in neonates.

Studies of the responses of neonates and infants to viral vaccines also support the idea that $CD4^+$ T cell immunity to viruses may be blunted early in life. Peripheral blood mononuclear cells from neonates given oral poliovirus vaccine (OPV) at birth and at 1, 2, and 3 months of age exhibited decreased OPV-specific proliferation, IFN-γ production, and IFN-γ–positive cells in comparison with cells from immunized (but not reimmunized) adults.[230] By contrast, their antibody titers were higher than those for adults.

Antigenically naive $CD4^+$ T cells initially show a very limited capacity to express cytokines other than IL-2, whereas distinct subsets of memory $CD4^+$ T cells express particular cytokines. T_H1 and T_H2 cells produce IFN-γ and IL-4, respectively.[231] Thus the essential absence of memory $CD4^+$ T cells in the circulation of neonates accounts for the limited ability of neonatal $CD4^+$ T cells to produce IFN-γ compared with adult $CD4^+$ T cells.[232] If naive $CD4^+$ T cells are activated *in vitro*, they differentiate into effector-like cells that acquire the capacity to produce IFN-γ (T_H1 effectors) or IL-4 (T_H2 effectors), depending on the conditions used in terms of cytokine milieu and APC populations.[101,233-235] As mentioned earlier, however, studies suggest that neonatal naive $CD4^+$ T cells have a decreased capacity to become IFN-γ–producing cells compared with adult naive $CD4^+$ T cells in response to short-term (i.e., for 24 to 48 hours) stimulation by allogeneic dendritic cells.[1]

This decreased expression of IFN-γ by neonatal $CD4^+$ T cells is likely to be due to several factors. First, neonatal $CD4^+$ T cells are less effective than adult naive cells at inducing the co-cultured adult dendritic cells to produce IL-12, a key cytokine for promoting IFN-γ production.[1] Second, as discussed earlier, neonatal APCs, such as dendritic cells, may have a decreased capacity to produce IL-12 and related cytokines that are key for T_H1 differentiation.[236] It is interesting that this decreased capacity for IL-12 production by mononuclear cells may continue into early childhood, at least for certain stimuli, such as LPS.[237] Third, neonatal naive $CD4^+$ T cells exhibit a decreased expression of certain transcription factors that may play a role in the induction of IFN-γ gene expression, such as the NFATc2 protein.[238,239] Fourth, the greater methylation of DNA of the IFN-γ genetic locus in neonatal T cells also may contribute to a reduced and delayed acquisition of IFN-γ production after activation *in vitro*.[240] Some or all of these mechanisms are likely to contribute to the delay in the appearance of IFN-γ production by antigen-specific $CD4^+$ T cells after viral infections in the neonatal period.

CD154/CD40 Interactions

CD154 (CD40 ligand) is a member of the TNF ligand superfamily and is expressed abundantly on the surface of activated but not resting $CD4^+$ T cells (Figure 150-4). CD154 engages CD40, a molecule expressed by "professional" APCs,[241] including dendritic cells, mononuclear phagocytes, B cells, and possibly $CD8^+$

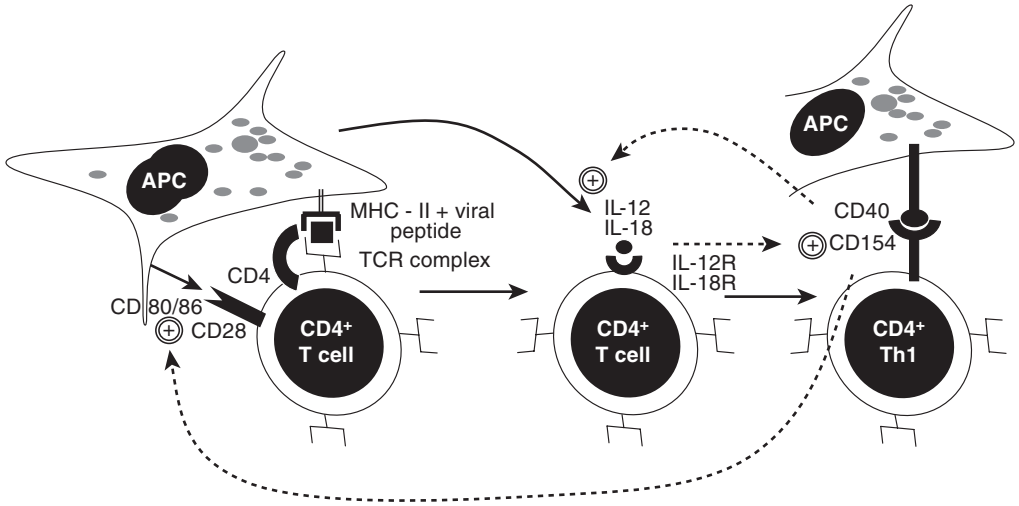

Figure 150-4 Helper T cell (T_H1) differentiation. The ligation of the T cell receptor on naive T cells by an immunogenic major histocompatibility complex (MHC)–peptide complex typically does not provide an adequate signal to induce their proliferation and differentiation. However, when antigen-presenting cells (APCs) such as dendritic cells (DCs) acquire antigens at sites of infection, they mature and express co-stimulatory molecules and cytokines that trigger the additional intracellular signaling required for $CD4^+$ T cell proliferation and differentiation. For instance, CD80 and CD86 expressed on a mature DC induce signaling through CD28 on naive $CD4^+$ T cells, and the interleukins IL-12 and IL-18 secreted by the mature DC induce signaling through IL-12 and IL-18 receptors. Such signaling transiently activates the maturing T cell, which then expresses a number of surface molecules including CD154 (a tumor necrosis factor [TNF] receptor family member) that binds CD40 (a TNF family member) on the DC, which leads to increased expression of CD80/CD86 and increased IL-12/IL-18. This reciprocal activation produces the robust T_H1 $CD4^+$ T cell response that is required to eradicate many viral infections. CD154 also appears to be important for the establishment of B cell and $CD8^+$ T cell memory.[245]

T cells.[242] Engagement of CD40 on dendritic cells is a potent maturation signal and an inducer of IL-12. This engagement also counteracts the inhibitory effect of other cytokines, such as IL-10.[243] The CD154/CD40 interaction is essential for many events in adaptive immunity, including the generation of memory $CD4^+$ T cells of the T_H1 phenotype and memory B cells, as well as most immunoglobulin isotope switching.[244]

The role of CD154 in viral host defense appears to vary with different pathogens but in general correlates with the particular requirement for $CD4^+$ T cells, indicating that $CD4^+$ T cells and CD154 are linked in mediating such help. CD154 deficiency in mice results in decreased $CD4^+$ and $CD8^+$ T cell responses to viral antigens and increased mortality after HSV-1 footpad infection. In studies of HSV corneal infection, the numbers of $CD4^+$ and $CD8^+$ T cells and B cells within draining lymph nodes dramatically expand within the first 7 days. However, no IFN-γ–secreting $CD4^+$ cells can be seen immediately. IFN-γ and a full T_H1 response do not appear until after 7 days after expression of CD154. These findings suggest that CD154 is not required for the initial expansion of HSV-1–specific $CD4^+$ T cells in the draining lymph node, but it is important for their differentiation into mature T_H1 effector cells. Exogenous IL-12 can at least partially relieve the requirement for CD154 in the T_H1 differentiation of HSV-1-specific T cells, consistent with the known capacity of CD40 signaling to induce IL-12 production in dendritic cells.[245]

Mice lacking CD154 as a result of selective gene disruption, or in which CD154/CD40 interactions were neutralized by monoclonal antibody, demonstrated an increased frequency of CNS infection and paralysis compared with wild-type mice after footpad inoculation with HSV.[228] These abnormalities correlated with reductions in $CD4^+$ but not $CD8^+$ T cell responses. The absence of CD154/CD40 interactions eliminates most antiviral antibodies and results in severe disease in viral infections in which antibody plays a critical role, such as in the dissemination of vesicular stomatitis virus to the CNS. In humans, CD154 also appears to play an important role in the expansion of $CD8^+$ T cell recognizing viral peptide antigens, such as from influenza A virus and HIV-1, based on an *ex vivo* assay using monocyte-derived dendritic cells as APCs.[246]

Freshly isolated monocytes from neonates or adults express low levels of CD40,[247] but whether they have similar capacity to produce cytokines in response to CD154 (CD40 ligand) engagement remains unclear. Using more physiologically relevant stimulation, neonatal $CD4^+$ T cells co-cultured with dendritic cells increase their expression of CD154[248] and induce IL-12 production by dendritic cells.[249] CD154 expression by purified neonatal naive $CD4^+$ T cells co-cultured with adult allogeneic dendritic cells was substantially less than by adult naive $CD4^+$ T cells after 24 to 48 hours of stimulation. This reduced CD154 production was accompanied by reduced IL-12 production (by monocyte-derived dendritic cells) and IFN-γ production (by naive $CD4^+$ T cells).[236] These observations suggest that CD154 surface expression is at least initially more limited for neonatal T cells, but that with continued priming *in vitro*, this limitation can be overcome. A likely consequence is that the differentiation of naive $CD4^+$ T cells into T_H1 effector cells by an IL-12–dependent and dendritic cell–dependent process may be delayed.

The generation of $CD4^+$ T effector cells is a complex process, involving antigen presentation by dendritic cells to naive $CD4^+$ T cells and multiple steps of T cell clonal expansion and differentiation; compromise of any of these steps could result in limited T_H1 immunity. Myeloid dendritic cells are essential to the differentiation of naive $CD4^+$ T cells to T_H1 effector and memory T cells. Key events promoting T_H1 differentiation include the elaboration by dendritic cells of cytokines, such as IL-12, IL-23, and IL-27, and their binding to specific receptors on $CD4^+$ T cells.[100] CD154 is expressed by naive $CD4^+$ T cells after the T cell recognizes peptide antigen/MHC complexes through the αβ-TCR and receives co-stimulation through CD28 binding to CD80 and CD86. The engagement of CD40 on the dendritic cell by CD154 on the T cell enhances the dendritic cell production of these T_H1-promoting cytokines and also increases the expression of CD80 and CD86, which helps sustain T cell activation. In persons who are

genetically deficient in CD40 ligand[250] or in the ability to respond to IL-12 and IL-23,[251] antigen-specific T_H1 responses are absent or severely depresssed, supporting the validity of this model.

The basis for the delayed development of HSV antigen-specific $CD4^+$ T cells in neonates is not known; it could reflect limitations at one or more of the steps just described. Neonates have been reported to have a lower frequency of precursor T cells capable of responding to HSV and HCMV.[252] This finding is unlikely to be due to a limitation in the diversity of the αβ-TCR repertoire[253-255] and is more likely to reflect intrinsic limitations in T cell function.

Cytolytic $CD4^+$ T Cell–Mediated Mechanisms

CTLs use two main pathways in executing cytotoxicity: (1) exocytosis of perforin and granzyme granules and (2) death receptor signaling through Fas/Fas ligand (CD95/CD95L) or TNF/TNF-R signaling. Both pathways trigger the apoptotic cascade and programmed cell death involving activation of caspase-3 and the cleavage of apoptotic substrates. Gene knock-out studies in mice defective in key elements of these pathways revealed that MHC-restricted cytolysis by murine $CD4^+$ T cells is mediated predominantly by the death receptor system, whereas MHC-I–restricted cytolysis by $CD8^+$ CTLs relies on perforins and granzymes. Human $CD4^+$ CTLs are able to utilize both pathways.[256]

$CD4^+$ CTLs make up a sizable minority of $CD4^+$ T cells in murine HSV infection (around 30%) and recognize HSV-specific antigens presented on MHC class II molecules.[257] In fact, early efforts to clone CTL specific for HSV resulted in $CD4^+$ instead of $CD8^+$ CTL clones.[258] Studies evaluating the $CD4^+$ CTL response suggest that activated $CD4^+$ T cells express perforin and granzyme A and B, in a fashion similar to that for $CD8^+$ cells; however, $CD4^+$ T cells express substantially lower amounts of perforin and granzymes in both cell numbers and amounts per cell, compared with $CD8^+$ T cells.[259] Human $CD4^+$ cytotoxic cells can recognize peptides derived from viral glycoproteins found in the HSV lipid envelope,[201,260,261] such as gB, gC, and gD,[152] and it is likely that these viral glycoproteins enter into the class II antigen-processing endocytic pathway by first fusing with the host cell membrane.

Although class II MHC normally is expressed by APCs, such as B cells, mononuclear phagocytes, and dendritic cells, a wide variety of cell types can express class II MHC and, in most cases, present antigen, after exposure to IFN-γ, GM-CSF, or TNF-α. These cell types, which include endothelial cells, enterocytes, renal epithelial cells, thyroid epithelial cells, microglial cells, epidermal keratinocytes, myoblasts, eosinophils, NK cells, and T cells themselves,[2] might then become potential targets for cytotoxic $CD4^+$ T cells. However, the importance of $CD4^+$ T cell–mediated cytotoxicity in the control of infection has been questioned, given that substantial $CD8^+$ T cell responses to HSV are generated in humans, and that HSV-specific $CD8^+$ T cells constitute a prominent part of the viral response in tissues such as the skin and cervix. Additionally, HSV-1 renders infected cells resistant to CTL-induced apoptosis[262] by mechanisms such as the down-regulation of MHC class II through the virion host shutoff protein (vhs) and the viral protein encoded by the $\gamma_1$34.5 gene.[263]

An expanded target cell range is possible, however, because class II MHC expression is up-regulated on many non-APC types in response to cytokines, such as IFN-γ. Thus it is plausible that $CD4^+$ cytolytic T cells play an important role in the resolution of HSV infection in humans. No studies have examined the degree of cytolytic activity mediated by neonatal $CD4^+$ T cells for HSV or other infections.

$CD8^+$ T Cell–Mediated Antiviral Immunity

$CD8^+$ CTLs are important in effective clearance of viral infections, including HSV infection,[210,264,265] and are found at sites of local recurrence of such infection such as the skin adjacent to the genital tract,[210,266] cervix,[212] and cornea.[267] $CD8^+$ T cells, when first activated by antigen, are not effective killers but subsequently, under the influence of cytokines such as IL-2 and IL-15, proliferate and differentiate into an effector cell lymphoblast population that efficiently kills. They kill target cells by exocytosing cytotoxic molecules such as perforin, granzymes, or granulysin.[268] Fas/Fas ligand and TRAIL/DR interactions also may play a part in this killing. This differentiation includes increased expression of molecules involved in cytotoxicity, such as perforin, granzymes, Fas ligand, and granulysin, as well as an increased capacity to produce cytokines, such as IFN-γ and TNF-α. The mature virus-specific $CD8^+$ CTL looks conspicuously different from the unprimed, naive $CD8^+$ T cell.

TABLE 150-3

Properties of $CD8^+$ T Cell Subsets

Expression Marker	Naive	Memory	Effector
CD45RA	+	−	+

IFN-γ	−	++	++
TNF-α	−	++	++
Perforin/granzyme B	−	±	++

Compared with naive $CD8^+$ T cells, two discrete primed subpopulations can be found within the human $CD8^+$ lymphocyte compartment. First, the $CD45RA^{neg}$ $CD45R0^+$cells are similar to *memory-type* $CD8^+$ T cells in that they express CD95 (Fas) and integrin family members CD11a, CD18, CD29, CD49d, and CD49e and are able to secrete not only IL-2 but also IFN-γ, TNF-α, and IL-4. This subset does not exert cytolytic activity without previous stimulation but does contain virus-specific CTL precursors. A second primed population is characterized by $CD45RA^{pos}$ $CD27^{neg}$ $CD28^{neg}$ and contains T cells expressing CD11a, CD11b, CD18, and CD49d. These T cells do not excrete IL-2 or IL-15 but can produce IFN-γ and TNF-α. These *effector-type* $CD8^+$ T cells abundantly express Fas ligand and contain perforin and granzyme B and have high cytolytic activity as is.[375]

CTL, Cytotoxic T lymphocyte; *HSV,* herpes simplex virus; *IFN-γ,* interferon-γ; *IL,* interleukin; *TNF-α,* tumor necrosis factor-α.

$CD8^+$ T cell differentiation also is recognized by cell surface changes that reflect the stage of maturation and nomenclature of this population (Table 150-3). For example, in contrast with naive $CD8^+$ T cells that uniformly express CD45RA, HCMV-specific $CD8^+$ T cells early in infection exhibit CD45R0 surface expression. CD45 is a transmembrane phosphatase that regulates signaling through TCR CD3, and distinct isoforms of the molecule are generated through alternative splicing of amino-terminal (N-terminal) exons A, B, and C. The high-molecular-weight form (CD45RA) contains A, B, or C (or all three), whereas CD45R0 does not. Similarly, patterns of CCR7 expression change, indicating activated CTL homing signals. Chemokine receptor CCR7 binds CCL19 and CCL21 and directs the migration of lymphocytes to the lymph node. CD127 (IL7R-α) is expressed by naive T cells, disappears for the most part during active infection but reappears in a subset of virus-specific $CD8^+$ cells within the memory pool with the ability to respond to cytokine IL-7, enabling reactivation.

Studies using class I MHC/viral peptide tetramers, which allow direct detection of $CD8^+$ T cells based on their TCR specificity, have documented that virus-specific $CD8^+$ T cells undergo a dramatic expansion *in vivo* during viral infection. In some instances, such as with primary EBV infection, more than 40% of circulating $CD8^+$ T cells may be reactive with a single viral peptide epitope.[269] Most $CD8^+$ effector T cells have a relatively short life span and probably are eliminated by apoptosis after antigen clearance. $CD4^+$ T cells may aid directly in the generation of $CD8^+$

cytolytic T cells by the production of several cytokines, including IL-2 and IFN-γ. In addition, $CD4^+$ T cells may indirectly influence this process by enhancing dendritic cell function through a CD154/CD40 interaction; dendritic cells, in turn, may then help promote $CD8^+$ cytolytic T cell generation by secreting cytokines and engaging co-stimulatory molecules. In animal models, $CD8^+$ T cells also appear to be key in resolving HSV lytic infection of ganglion during primary infection,[270,251] and in preventing reactivation of virus from latency in sensory neurons[271]; this latter function may involve an IFN-γ–dependent mechanism.[272] Direct recognition of infected ganglion cells by $CD8^+$ T cells is likely, because HSV infection induces detectable class I MHC expression by sensory neurons.[273] Noncytolytic mechanisms,[274] such as the production of cytokines with antiviral activity (e.g., IFN-γ)[275] or the secretion of granzyme A,[276] may be key for $CD8^+$ T cells to maintain latency and to prevent viral spread. By contrast, cytolytic mechanisms, such as those mediated by perforin, may not be necessary for control of HSV infection at particular tissue sites, such as the cornea or brain, and may even contribute to inflammatory disease.[277,278]

Viral Inhibition of Antigen Presentation and Effect on the T Cell Immune Response

In view of the importance of class I MHC–restricted cytotoxicity in the control of viral infection, it is perhaps not surprising that a number of viruses, including HSV and HCMV,[278] have developed mechanisms to inhibit class I MHC antigen presentation. First, the virus can establish latency in sensory ganglia, an immunoprivileged site in which viral proteins are not expressed. During lytic replication, however, the HSV ICP47 protein (gene Us12) inhibits the MHC class I antigen presentation pathway by inhibiting the transporter associated with antigen presentation (i.e., TAP), which translocates peptides across the endoplasmic reticulum membrane.[226,279-282] The virion host shutoff protein, vhs, degrades host cell mRNA preventing synthesis of new HLA class I.[170] The combination of these two proteins is responsible for poor recognition of infected cells by $CD8^+$ CTLs; however, CTL toxicity is restored somewhat by exposure of those cells to IFN-γ, which up-regulates class I antigen processing and presentation. Certainly, the high levels of IFN-γ isolated from clinical lesions suggest that this effect occurs *in vivo* in addition to *in vitro*.[283]

CTL cytotoxicity also is inhibited by HSV products Us3 kinase, ICP22, ICP27, ICP4, gJ, and gD, which confer apoptosis resistance to infected cells.[262] When IFN-γ is present and the effects of ICP47 are not as evident, the second-line defense effects of Us3 (Us3 kinase) and Us5 (gJ) become more apparent. They both partially block CTL-induced chromium release. Us3 kinase blocks the cleavage of Bid by granzyme B. In addition, gJ prevents the activation of caspase-3 by granzyme B (Figure 150-5).

Despite these inhibitory mechanisms, class I MHC–restricted human $CD8^+$ T cells that can lyse HSV-infected targets can be isolated from HSV-2 lesions of patients with genital disease[132,202] or from the blood of HSV-immune donors.[284,285] The $CD8^+$ T cell response in humans appears to be dominated by recognition of HSV proteins that are internal structural components of the virion, such as those of the tegument and nucleocapsid, or those that are rapidly induced upon viral entry, such as certain immediate early genes.[286,287] These proteins apparently can be processed into peptides and presented on class I MHC molecules before the inhibitory effect of either the virion host shut-off or TAP inhibitor proteins. Similarly, immediate-early gene products and tegument and nucleocapsid proteins also may be important targets of the human $CD8^+$ T cell response against HCMV by being presented to $CD8^+$ T cells before the onset of multiple mechanisms that interfere with class I MHC antigen presentation. By contrast, viral glycoproteins that are found in the HSV lipid envelope do not appear to be important antigens for class I MHC–restricted responses, probably because they fuse with the host cell membrane and do not enter in the cytoplasm in substantial amounts.[226]

Inhibition of viral replication also can occur without killing of the infected cell. Studies using fibroblasts preinfected with HSV for 2 hours before exposure to CTLs, under conditions in which less than 10% lysis was observed, resulted in a 50% decrease in production of infectious virus.[288] Similarly, control of viral replication and reactivation from latency in infected neurons is controlled by nonlytic mechanisms.[289] Studies using Us12-deleted HSV ($ICP47^-$) led to a decrease in virus yield, especially when CTL attack occurred at early stages of viral replication. *In vivo*, the effect of ICP47 probably serves to open a short window of time in which infected cells are spared from recognition and attack by CTLs. ICP47 is not present in the virions but is one of the first proteins to be made in infected cells. Therefore, early on, before sufficient ICP47 is present, antigen is presented on the surface of the cells, permitting recognition by CTLs. At intermediate time points, the effect of ICP47 prevents recognition of infected cells, but once IFN-γ is up-regulated within lesions, recognition of infected cells is restored. At that time, the second lines of defense, such as inhibition of apoptosis, come to the fore.

HCMV also encodes proteins that inhibit class II MHC antigen presentation,[290] and the same has been found to be true of HSV, with vhs and $\gamma_1 34.5$.[263] Infection of mice with virulent HSV strains results in CNS lesions in which class II MHC expression remains intracellular, thereby avoiding any chance of detection by $CD4^+$ T cells.[291]

$CD8^+$ T cells can be sensitized *in vitro* for cytotoxicity using allogeneic (MHC other than self) stimulator cells, followed by testing for cytotoxic activity against allogeneic target cells. With this approach, most studies have found that neonatal T cells are moderately less effective than adult T cells as cytotoxic effector cells.[292-295] More substantial defects in T cell–mediated cytotoxicity by neonatal T cells after allogeneic priming are observed when no exogenous cytokines, such as IL-2, are added.[296,297] This finding suggests that such decreased cytolytic activity could be of physiologic significance *in vivo* if $CD4^+$ T cell help also was limited. The capacity of neonatal $CD8^+$ T cells to become cytolytic effector cells when primed using optimal APCs such as dendritic cells, remains to be determined.

The mechanism for reduced neonatal T cell–mediated cytotoxicity remains poorly understood. Two studies have found that only a low percentage of neonatal $CD8^+$ T cells constitutively express perforin, whereas approximately 30% of adult $CD8^+$ T cells contain this protein.[298,299] By contrast, another study found that approximately 30% of neonatal T cells expressed perforin—a frequency similar to that for adult T cells.[300] The capacity of neonatal $CD8^+$ T cells to express Fas ligand (CD95L) and to mediate Fas ligand–dependent cytotoxicity in response to priming by alloantigen also is not known.

Much of the studies of antigen-specific cytotoxicity to date have focused on congenital and perinatal HIV-1 infection. In congenital HIV-1 infection, an expansion of HIV-specific cytotoxic T cells was detected at birth, indicating that fetal T cells were activated by viral antigens.[301] In another case of *in utero* HIV infection, HIV-specific T cell–mediated cytotoxicity was detected at 4 months of age and persisted for several years despite a high HIV viral load.[302] Cytotoxic responses to HIV in perinatally infected infants suggest that, although $CD8^+$ T cells capable of mediating cytotoxicity have undergone clonal expansion *in vivo* as early as 4 months of age,[303] their cytotoxicity may be reduced and delayed in appearance compared with that of adults.[304] In many cases, HIV-1–specific cytotoxic lymphocyte responses were not detectable during the first few months of life.[301,304] When evaluated beyond infancy, cytolytic activity directed to HIV envelope proteins was commonly detected, but that directed against *gag* or *pol* proteins was rarely detected.[305] Also noted was decreased HIV-specific $CD8^+$ T cell production of IFN-γ by young infants

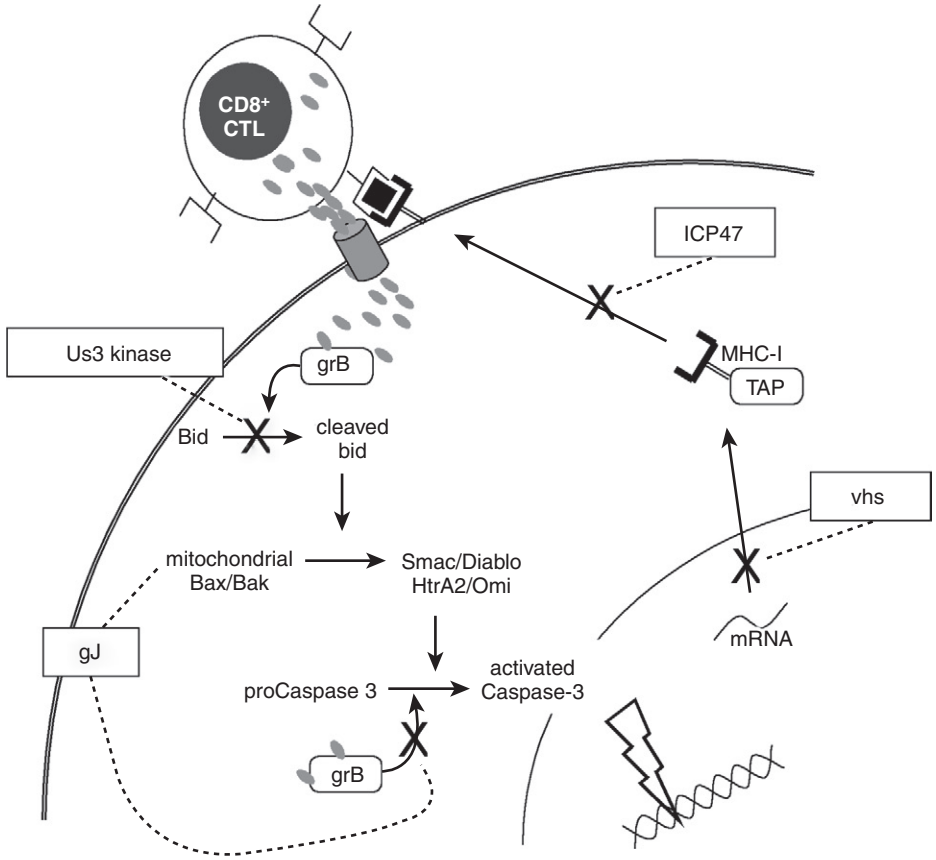

Figure 150-5 Herpes simplex virus (HSV) blocks cytotoxic lymphocyte (CTL)-driven apoptosis. On recognition of viral infection by major histocompatibility complex class I (MHC-I) bound viral antigen, $CD8^+$ CTL releases cytotoxic molecules including granzyme B (grB). grB cleaves proapoptotic molecule Bid, which then associates with proapoptotic protein Bax/Bak at the mitochondria to induce the release of Smac/Diablo, HtrA2/Omi, and cytochrome *c*. In turn, those molecules permit the activation of caspase 3. An additional cleavage of procaspase-3 occurs directly by grB but alone is insufficient for activation of caspase-3. Activated caspase-3 drives apoptosis by stopping translation and DNA repair and by damaging the genomic DNA through DNA fragmentation factor (DFF) and caspase-activated DNase (CAD). HSV proteins circumvent this process. ICP47 blocks TAP transport of MHC-I molecules to the cell surface. Virion host shutoff (vhs) protein cleaves host messenger RNA, blocking new protein synthesis and also effectively down-regulating MHC-I antigen presentation. Us3 kinase blocks grB cleavage of Bid, and gJ stabilizes the mitochondria and blocks grB activation of caspase-3.

with perinatal HIV infection,[306] along with an inability to generate HIV-specific cytotoxic T cells after antiretroviral therapy.[307] Together, these results point to the possibility of a delay in the development of $CD8^+$ T cell–mediated responses in comparison with that in adults and suggest that the nature of the target antigens recognized by neonatal $CD8^+$ T cells may be more limited. These developmental limitations in $CD8^+$ T cell function may not necessarily be limited to HIV-1, at least in early infancy, because one study of RSV-specific cytotoxicity found that it was more pronounced and frequent in infants 6 to 24 months of age than in younger infants.[308]

HIV-1 infection is characterized by a number of severely immunosuppressive features that may not apply to most other viral infections. These include impairment of antigen presentation,[309] decreasing thymic T cell output,[310] and promotion of T cell apoptosis.[311] Of note, these suppressive effects of HIV-1 on cytotoxic responses may be relatively specific for HIV-1, because HIV-infected infants who lack HIV-specific cytotoxic T cells may maintain $CD8^+$ T cell responses against EBV and CMV.[306,307] Whether a lag occurs in the acquisition of herpesvirus-specific $CD8^+$ T cell responses in neonates and infants (either HIV-infected or uninfected) compared with those in adults with primary infection remains unclear.

CD28/CD80–86 Co-Stimulation

In addition to engagement of the αβ-TCR by peptide/class II MHC antigen, full naive T cell activation is thought to require co-stimulation, such as by engagement of CD28 on the T cell by CD80 or CD86 on the APC (see Figure 150-4). Murine studies indicate that such co-stimulation is critical for the development of an effective adaptive immune response to HSV. CD28/CD80–86 interactions appear critical for paralysis-free survival as well as for the generation of both HSV-specific $CD4^+$ and $CD8^+$ T cell responses in the footpad injection model.[228] This was demonstrated using mice with selective genetic disruption of CD28, as well as in normal mice in which CD28/CD80–CD86 interactions were neutralized *in vivo* by administration of CTLA-4–Ig (cytotoxic T lymphocyte antigen-4–immunoglobulin),[228] a soluble fusion molecule that effectively competes with T cell–associated CD28 for CD80–CD86 binding. In an intravaginal HSV murine model, mice lacking both CD80 and CD86 were prone to severe local and disseminated disease and death[312] and, as in the other study, were unable to mount effective $CD4^+$ or $CD8^+$ T cell responses and exhibited more severe disease and increased mortality.[313]

Neonatal T cells express levels of CD28 similar to those in adult T cells and produce IL-2 and proliferate as well as adult T cells do in response to mouse APCs expressing human CD80

or CD86, and to anti-CD3 monoclonal antibody, indicating that CD28-mediated signaling is intact.[314] This finding also is supported by a study showing that anti-CD28 monoclonal antibody treatment of neonatal T cells markedly augments their ability to produce IL-2 and proliferate in response to anti-CD2 monoclonal antibody.[315] These results do not exclude the possibility that neonatal T cell co-stimulation by CD28 could be limited because of decreased expression of CD80 or CD86 by key APCs, such as neonatal myeloid dendritic cells.

Chemotactic and Homing Receptor Expression by Viral Antigen–Specific T Cells

The differential expression of chemokine and homing receptors by T cells is important in their selective trafficking, either to sites at which naive T cells may potentially encounter antigen for the first time, such as the spleen and lymph nodes, or to inflamed tissues for effector functions.[143] The homeostatic chemokines CCL19 and CCL21 have been shown to be essential in the transmigration of lymphocytes across high endothelial venules (HEVs) (highly specialized postcapillary venules within the lymph nodes and Peyer's patches), allowing the passage of lymphocytes bearing their shared receptor CCR7 from the blood compartment into secondary lymphatic organs. CCR7 is uniformly expressed on naive T cells as well as a subset of resting memory T cells known as central memory T cells. CCL21 is constitutively expressed within the lumen of HEVs, whereas CCL19 is produced by other cells within the lymph node, but becomes displayed on the HEV lumen after transcytosis across the endothelial barrier.

Naive T cells also express CCR9 and CXCR4. CCR9 ligand is CCL25 and may help traffic T cells into the gastrointestinal lymphatics. CXCR4's ligand is CXCL12 and is involved in transendothelial migration across HEVs. These are the principal chemokine receptors expressed on naive lymphocytes; this is contrast with the numerous chemokine receptors expressed on effector T cells.

Primed $CD4^+$ T cells briefly express CXCR5, which is a chemokine receptor otherwise expressed principally on B cells. Its ligand CXCL13 is produced within the B cell–rich follicular compartment of secondary lymphoid tissues but is absent from the adjacent T zone. The acquisition of CXCR5 by recently primed $CD4^+$ T cells temporarily relocates these cells to the outer follicle, where they can interact with B cells during antibody production. Accordingly, the $CXCR5^+$ $CD4^+$ T cells also are known as follicular B helper cells (T_{FH}). CXCR5 is rapidly lost during T cell proliferation, indicating that the homing program is an early and transient step in the T cell activation and differentiation process.[316]

Effector T cells are equipped with receptors for inflammatory cytokines and adhesion molecules that are greatly up-regulated during inflammation, so these cells efficiently home to sites of pathogen entry and disease. By contrast, memory T cells are believed to confer rapid and superior protection against pathogens that they have encountered during previous immune responses. They are divided into two subsets based on their different migratory and functional properties. The subset $CCR7^+CD62L^+$ memory T cells, termed central memory T (T_{CM}) cells, far outnumber the memory subset lacking these lymph node–homing receptors termed effector memory T (T_{EM}) cells. The utility of these T_{CM} cells in responding to recurrent herpes infection is unclear, because a recent study did not indicate accelerated proliferation kinetics or tissue infiltration of T_{CM} cells when compared with naive T cells. A more brisk effector (T_{EM}) response was demonstrated.[317]

In established HSV infection, most recurrences of viral replication occur in keratinocytes found at epithelial sites, such as the skin and genitourinary mucosa. Trafficking of T cells into this location is controlled by the expression of cutaneous lymphocyte-associated antigen (CLA), which is a fucose-containing carbohydrate that can decorate P-selectin glycoprotein ligand-1 on T cells. CLA is expressed from most T cells recovered from the skin and is on approximately 5% to 10% of circulating $CD8^+$ T cells. During symptomatic recurrences of virus at these cutaneous sites, virus-specific $CD4^+$ T cells and NK cells may infiltrate within 48 hours after the appearance of lesions. This is followed several days later by infiltration by virus-specific $CD8^+$ T cells, which are associated with viral clearance.[210] Consistent with the importance of $CD8^+$ T cell immunity at these local sites of replication, a majority of $CD8^+$ T cells that recognize a particular HSV peptide express CLA.[211]

It is likely that HSV-specific T cells that enter sites of viral replication, such as the CNS during HSV encephalitis, utilize a distinct combination of homing and chemotactic receptors to achieve selective trafficking. As indicated by studies in mice using other neutrotropic viruses, expression of CXCR3, CCR2 and CCR5 chemokine receptors may regulate $CD8^+$ T cells trafficking into the CNS.[318] Other chemokine and homing receptor combinations are likely to be important for trafficking of HSV-specific T cells to the liver and gastrointestinal tract in cases of disseminated disease.

As discussed earlier, down-regulation of CCR7 and up-regulation of other chemokine receptors by effector T cells probably are important for redirecting these cells from secondary lymphoid tissue to other sites of tissue inflammation, where they can carry out their effector functions. This appears to be true for herpesvirus-specific $CD4^+$ T cell responses, because CMV-specific human memory $CD4^+$ T cells, which are capable of producing antiviral T_H1 cytokines, such as IFN-γ, are essentially all $CCR7^{low}$ cells.[1] This restriction of CMV-specific T_H1 effector function to $CCR7^{low}$ cells has been observed after primary CMV infection in both adults and young children but has not been evaluated in cases of congenital or perinatal CMV infection or in cases of HSV infection.

Human neonatal naive T cells differ from those of adults in that they do not increase CXCR3 expression, which favors trafficking to inflamed tissues that have been exposed to IFN-γ, and they decrease CCR7 expression after activation by way of anti-CD3 and CD28 monoclonal antibodies.[319,320] The CCR7 expressed on neonatal T cells is functional and mediates chemotaxis of these cells in response to CCL19 and CCL21.[321] These findings suggest that activated neonatal T cells may be limited in their capacity to traffic to nonlymphoid tissue sites of inflammation and may recirculate between the blood and peripheral lymphoid organs. Neonatal T cells can increase the surface expression of CCR5 by treatment with either mitogen or IL-2[322] or after differentiation *in vitro* in a cytokine milieu that favors T_H1 development.[323-325] Whether CCR5 expression by T cells, which probably is important for their homing to the CNS, is up-regulated in cases of neonatal or postnatal HSV encephalitis is not known.

γδ T Cells

The γδ T lymphocytes are one of the first T cells to emigrate from the thymus and express a TCR heterodimer consisting of a γ-chain and a δ-chain, in association with CD3. A majority of these γδ T cells take residence in epithelial tissues including the skin, intestines, lung, and reproductive tracts. Their nomenclature is based on their TCR gene rearrangements; for example, the three γ genes are Vγ1 to Vγ3. Vγ3Vδ1 T cells are found principally in the skin and are known as dendritic epidermal T cells (DETCs) and are maintained by expression of zeta (ζ)-chain–associated protein 70 (ZAP-70) signaling molecule within the epidermis.[326] $V\gamma5^+$ γδ T cells, known as intestinal intraepithelial lymphocytes (IELs), are found predominantly in the intestines and are dependent on thymus IL-15 for development. The γδ T cells have multiple functions including tissue homeostasis and wound repair, facilitated by γδ expression of insulin-like growth factor-I (IGF-I) and keratinocyte growth factor-1 (KGF-1), respectively. Total parenteral nutrition

administration, which leads to villus atrophy in the small intestine, is associated with a down-regulation of IEL-derived KGF-1, whereas short bowel syndrome, a model of villus hypertrophy, is associated with up-regulation of IEL-derived KGF.[327] γδ T cells also regulate local inflammation. KGF-1 produced by DETCs, for example, induces expression of hyaluronan by keratinocytes which recruits inflammatory cells such as macrophages. γδ IELs also influence neighboring epithelial cells to produce proinflammatory factors such as chemokine IL-8 and IFN-γ–inducible protein-10.[328] γ δ T cells also are able to recognize and lyse (perforin-mediated) cancerous epithelial cells and lymphoma cells,[329] and they are able to recognize and fight infection. Although some γδ T cells respond to antigens (such as HCMV peptides in the context of MHC class I),[329] little is known about the antigens that stimulate a majority of γδ T cells. These antigens appear to be expressed on stress or transformation of tissues, leading to activation of γδ T cells and their subsequent expression of cytokines and growth factors that aid in tissue repair or lysis of an infected or transformed cell. Some γδ T cells, such as DETCs, have been shown to recognize antigens via TLRs.[330] In the case of herpes simplex infection, the absence of γδ T cells has been shown to lead to increased susceptibility to infection owing to a blunted $CD4^+$ T_H1 and IFN-γ response.[331,332]

Although human neonatal γδ T cells proliferate *in vitro* in response to mycobacterial lipid antigens,[333] they express lower levels of serine esterases than those typical for adult γ δ T cells, suggesting that they are less effective cytotoxic cells.[334] Clones of γδ T cells derived from cord blood also have a markedly reduced capacity to mediate cytotoxicity against tumor cells extracts.[335] Because these neonatal clones also have lower CD45R0 surface expression than the adult clones, their reduced activity may reflect their antigenic naive status.

Natural Killer T Cells

A small population of circulating human T cells express αβ TCRs, lack expression of both CD4 and CD8, and express NKR-P1A, the human orthologue of the mouse NK1.1 protein. These features, as well as others (such as CD56 and CD57 surface expression, along with a dependence on the cytokine IL-15 for their development[336]), are characteristic of NK cells. For this reason, these cells frequently are referred to as NK T cells, or natural T cells. Like murine T cells expressing NK1.1, human NK T cells have a restricted TCR repertoire and mainly recognize antigens presented by the nonclassic MHC molecule CD1d, rather than by class I or class II MHC molecules. These CD1d-restricted antigens that can be recognized by NK T cells include certain lipid molecules as well as hydrophobic peptides. NK T cells also have the ability to secrete high levels of IL-4 and IFN-γ and to express death-inducing ligands (Fas ligand and TNF-related apoptosis–inducing ligand [TRAIL]) on their cell surface on primary stimulation—a capacity not observed with most antigenically naive αβ T cells,[337,338] suggesting that they could play a role in the early stages of the immune response. Additionally, NK T cells have been shown to help B cells produce antibody. This interaction has been shown to require CD40-CD154 co-receptor interaction but not IL-4 or IFN-γ. This role does include augmenting $CD4^+$ T cell response (related to an increased availability of MHC-II–restricted T cell help to B cells), although in the absence of $CD4^+$ T cells, NK T cells have been shown to replace, at least in part, conventional $CD4^+$ T helper functions.[339] Murine NK T cells have been implicated in the control of zosteriform HSV infection,[194] but the antiviral mechanisms involved remain to be defined.[340]

Limitations in NK T cell–mediated immunity in neonates could contribute to the severity of HSV infection. At first, only a small number of NK T cells (accounting for less than 1% of circulating T cells) are present in the neonatal circulation, but this number subsequently increases with age. Neonatal NK T cells differ from adult NK T cells in producing only limited amounts of IFN-γ on primary stimulation, indicating functional immaturity.[341]

B Cells, Antibody, Antibody-Dependent Cellular Cytotoxicity, and Complement

In animal models, evidence points to a protective role of antibody against HSV infection and spread within the nervous system, acting by neutralization directed against glycoprotein B (gB), and gD or by ADCC (discussed further on) against gB, gD, and gC. ADCC in the presence of competent effector cells (NK cells) may be more effective against higher challenge doses of virus than neutralizing antibodies. In humans the role for antibody has been suggested by studies of vertical transmission resulting in neonatal herpes, where passive transmission of neutralizing antibody or antibody titers associated with ADCC have been reported to correlate with protection against disease.[342,343] The risk of neonatal herpes after primary infection is more than 10 times greater than that after recurrent infection, which may be related to the higher titers and longer duration of viral shedding within the genital tract associated with primary infection. Infants born to seronegative mothers with primary HSV infection are at much higher risk for the development of neonatal HSV compared with those born to mothers with recurrent disease (3% versus 30% to 50%).[344] This relatively low occurrence of neonatal HSV compared with those associated with primary maternal infection suggests that the transfer of preexisting HSV-specific antibody at our near the time of birth mediates protection.[345]

Children with agammaglobulinemia, however, do not exhibit an increased susceptibility to primary HSV infection.[346] In immunocompromised patients (such as transplant recipients or persons with acquired immunodeficiency syndrome [AIDS] or leukemia), chronic herpetic lesions are not associated with diminished specific antibodies. In fact, clinical recurrences of HSV often are associated with higher antibody titers in immunocompetent patients than in seropositive asymptomatic control subjects, and antibody titers do not change significantly after dermal recurrences. Nevertheless, it remains a matter of debate whether or not humoral immunity plays a significant part in the prevention of recurrent HSV infection.[347] Either way, antibody certainly may serve an auxiliary role in host defense against herpesvirus infection, and this capability may be especially important when cellular components of the response are deficient, such as in the human neonate. Antibody also has been shown to be important in the prevention of dissemination of viral infections to the CNS. This is quite evident in the case of enteroviral infections, in which echoviruses or coxsackieviruses have been associated with the development of paralytic poliomyelitis or severe chronic encephalitis in agammaglobulinemic or hypogammaglobulinemic patients.[348]

Murine models of HSV support the importance of humoral immunity in controlling HSV infection. Classic murine studies have convincingly demonstrated that both prenatal and postnatal transmission of HSV-specific antibody in neonatal mice will afford protection against severe HSV infection and death.[349] Prenatal transfer of HSV-specific antibody from repeatedly immunized females protects neonatal mice in a dose-dependent manner against HSV-associated mortality. Partial protection is afforded by both transplacental and transmammary transfer of HSV-specific IgG. Such antibody confers protection by both viral neutralization and ADCC.[350,351] In the cutaneous HSV model, mice lacking B cells as a result of selective gene targeting have been reported to be markedly more susceptible to infection and to exhibit impaired T_H1 responses.[352] The finding of decreased T_H1 responses is surprising in view of the normal T cell immunity observed in humans with X-linked agammaglobulinemia. B cell–deficient mice also exhibit more pronounced local inflammation and viremia than that seen in wild-type mice when challenged intravaginally with an attenuated strain.[353] It is interesting

that serum from nonimmune, wild-type mice transferred into B cell–deficient mice was found to decrease vaginal HSV shedding, suggesting that natural antibody may inhibit viral replication.[353] Whether such antibody activity is found in the human circulation is unknown.

Human HSV infection results in the induction of antibodies against a diverse set of proteins, including the surface glycoproteins involved in cell attachment and entry.[354] The production of HSV-specific antibodies by B cells is T cell–dependent and also requires the C3 and C4 complement components, as well as the CD21 complement receptor on B cells,[355] which acts as a co-stimulatory molecule. However, if antibody is passively acquired, as in the case of maternal-to-fetal transfer, humoral immunity may exist independently of T cell immunity. Although enveloped viruses, such as herpesviruses, can be lysed by antibody and complement *in vitro*, this is unlikely to be an important mechanism *in vivo* because of the high concentrations of antibody required.[356] Under relatively physiologic conditions, IgG and alternative pathway complement components can coat the surfaces of many viruses, including HSV, and effectively neutralize their infectivity, possibly by preventing their attachment or fusion with cell membranes.[356,357] Antibodies also can react with viral proteins found on the surface of infected cells. IgG and complement components can lyse human cells infected *in vitro* with a number of different viruses, including HSV and influenza, parainfluenza, measles, and mumps viruses.[358-360] The importance of complement in viral host defense is uncertain, however, because serious viral infection is not a feature of patients with inherited complement deficiencies[361] or of animals made acutely hypocomplementemic.[362]

A potentially more effective system for the elimination of virus-infected cells by specific antibody is by ADCC.[363] In this system, the killer cell is a nonspecific immune effector, such as a mononuclear phagocyte, an NK cell, or a polymorphonuclear neutrophil (PMN), which has surface receptors for IgG. NK cells probably are the most efficient effector cells for ADCC.[364] The specificity of cytotoxicity is due to the specific recognition by antibody of viral antigens present on the infected cell surface. *In vitro* ADCC requires relatively low concentrations of antibody[365] and occurs rapidly (within hours),[207] making it less likely that the virus will have had sufficient time to produce infectious particles. ADCC mediated by all types of effectors is up-regulated by cytokines, such as IFN-γ, type I IFN, IL-12, and IL-15.[366-368] Although *in vitro* ADCC activity correlates (in some cases) with protection against serious viral infections in humans and in animal models, the extent to which this occurs *in vivo* remains uncertain.

Paralleling the reduction in natural cytotoxic activity of neonatal cells, ADCC of neonatal mononuclear cells is approximately 50% of that by adult mononuclear cells, including against HSV-infected targets.[190] Decreased ADCC mediated by purified neonatal NK cells appears to be caused in part by a defect in adherence of NK cells to target cells.[369]

Part of the apparent limited impact of antibody and complement on HSV infection in humans may reflect viral immunoevasion mechanisms that have hampered antibody effector functions. For example, the HSV gC protein is an inhibitor of the complement cascade, especially by way of the alternative pathway,[370] and acts by directly binding C3.[371] The gE-gI heterodimer also binds the Fc portion of antibody molecules and ablates their neutralization activity.[372] It is possible that these or other HSV-encoded inhibitory mechanisms that block viral neutralization may not be as effective in mice as in humans, analogous with ICP47 inhibition of TAP. This might account for the striking differences in the effects of genetic ablation of B cells on HSV infection in humans versus mice.

The immunoglobulin M (IgM) response to most protein antigens in the neonate is intact; IgG responses to certain vaccines, such as hepatitis B surface antigen are only slightly limited. Nevertheless, clear differences are recognized between neonates and older infants in the magnitude of the antibody response to most protein neoantigens, but this response differential rapidly resolves after birth. Abnormalities may be more pronounced in those born prematurely, but, again, it resolves rapidly after the neonatal period. Thus chronologic (i.e., postnatal) age is more of a determinant of antibody responses to T cell–dependent antigens than is gestational age. Isotype expression by B cells after immunization with T cell–dependent antigens is limited by T cell function, such as reduced CD40 ligand production, and intrinsic limitations of B cell maturation and function.[1] These limitations are exaggerated in the fetus.

These limitations in response to T cell–dependent antigens also may apply to neonatal HSV infection. Proceeding from the assumption that neutralizing or ADCC HSV-specific antibody contributes to the control of primary HSV infection in humans, it is possible that limitations in isotype switching from IgM to IgG or a slower rate of somatic hypermutation of IgG responses could contribute to the severity of neonatal infection. The neonate also is unable to produce antibodies in response to T cell–independent type II antigens, such as the capsular polysaccharides of bacteria. This limitation, however, is unlikely to be an important factor in the severity of neonatal HSV infection, because no T cell–independent type II HSV antigen-specific responses by human B cells have been described.

The neonate also is partially protected from infection by passive maternal IgG antibody, transferred predominantly during the latter third of pregnancy. Fetal IgG concentrations are equal to or higher than maternal concentrations after 34 weeks gestation, reflecting active transport mechanisms. In newborn infants with gestational age less than 38 weeks, a greater fraction of this maternally derived HSV-specific IgG may enter into the CNS,[373] reflecting a generally less effective blood-brain barrier. Whether this IgG fraction enters in sufficient amounts to provide protection from CNS disease is unknown. Kohl[16] also has shown that among HSV-infected infants, those with greater concentrations of ADCC antibody had less severe disease. Of note, healthy adults and older children with primary HSV infection, who by definition lack antibody to HSV, do not develop severe disease, as do neonates with primary infection. This observation indicates that the deficits intrinsic to the neonate are the important factors predisposing the neonate to infection. Nevertheless, passively acquired antibody may play a role in decreasing transmission or ameliorating disease severity.

151 T-Cell Development

László Maródi and Luigi D. Notarangelo

Hematopoetic stem cells (HSCs) give rise to committed progenitors of multiple lineages. Whereas maturation along myeloid, erythroid, and megakaryocytic cell lineages occurs within the bone marrow, differentiation into B lymphocytes initiates in the bone marrow and is completed in the periphery. By contrast, T lymphocyte development occurs within the thymus, where bone marow–derived common lymphoid progenitors migrate. In particular, interaction of lymphoid progenitors with thymic stromal cells permits differentiation of $CD4^-$ and $CD8^+$, double-negative (DN) cells into $CD4^-$ $CD8^+$, double-positive (DP) thymocytes within the thymus cortex. Subsequently, DP cells lose expression of either CD4 or CD8, becoming functionally active single-positive (SP) cells that populate the thymic medulla (Figure 151-1).

Although the thymus is particularly active early in life, it ensures lifelong generation of a pool of newly generated T cells. Of importance, the thymus also plays a critical role in purging self-reactive T lymphocytes. Therefore T cells produced in the thymus carry a seemingly unrestricted antigen receptor repertoire, whose reactivity is largely restricted to foreign antigens and is tolerant to self-antigens.[1]

THE THYMUS AND THE EMBRYOLOGY OF T CELLS

The human thymus originates as an epithelial outgrowth from the third and fourth pharyngeal pouches between the sixth and seventh weeks of gestation. It grows caudally into the mediastinum as two elongated structures that fuse at midlevel around week 8 of gestation.[2] In mice, the epithelial component of the thymus completes migration by day 10 of the 19- to 21-day gestation period, and lymphoid cells appear on day 11.[3] By days 12 to 13, these T lymphocyte precursors are proliferating, and by day 14, their surface phenotype shows that they have committed to the T-cell lineage. Further maturation of these precursors occurs over the following week, resulting in the development of distinct corticomedullary demarcation by the time of birth. The first wave of differentiation from precursors to mature T cells requires approximately 7 days in humans as well.

HSCs are present in the yolk sac during early embryonic life. They subsequently are found in the fetal liver and ultimately locate in the marrow, where they continue to seed the thymus. HSCs have high levels of CD34 on the cell surface, but they lack lineage-specific antigens such as the lymphocyte-specific CD52 molecule and the CD3, CD4, and CD8 molecules, which are restricted in expression primarily to thymocytes and mature T cells. Table 151-1 summarizes the relevant CD antigen designations. The least mature precursor cells in the marrow normally are resting and are triggered to divide by stem cell factor (SCF) and interleukin (IL)-3.[4] These and other cytokines important in T-cell development are listed in Table 151-2.

A family of Ikaros proteins, required for the differentiation of lymphoid precursors[5] in the bone marrow and thymus, regulates chromatin remodeling in preparation for commitment to lymphoid lineages. Subsequently, stromal cell–derived cytokines such as IL-7 and thymic stromal lymphopoietin (TSLP) signal through the IL-7 receptor complex to enhance proliferation of T-cell precursors and promote rearrangement of the T-cell receptor γ-chain locus (see later).[6] Another subpopulation of thymocytes, which does not rearrange T-cell receptor (TCR) genes, differentiates into natural killer cells after the binding of IL-15 to the combined IL-2–IL-15 receptor, signaling by way of the common γ-chain.[7,8] Many of these cytokine signals are transmitted through common pathways involving Janus kinases[9] (particularly JAK1 and JAK3) and their target signal transducers and activators of transcription (STAT3 and STAT5), suggesting that other growth and differentiation factors must modulate the responsiveness of developing precursors to these stereotypical signaling pathways.[10]

A functional thymic epithelium is required for the development of mature T cells.[11] Mice and humans with defects in the gene encoding the transcription factor FOXN1 (forkhead box protein N1), required for thymic epithelial development, have few T cells and an impaired ability to reject grafts.[12] In these circumstances, differentiation of hair follicles is also affected (hence the *Foxn1* mouse mutant also is known as *nude* mouse). Moreover, in humans, defects in thymic development (as observed in patients with DiGeorge syndrome) are associated with a variable degree of T-cell deficiency.[13] Actual cell-cell contact between lymphocytes and epithelial cells (and Notch-mediated signaling in particular) appears to be required for T lineage antigens to be expressed, because soluble factors derived from thymic epithelial cultures are unable to promote continued T-cell development. Functional T cells, however, also are required for inducing and maintaining the epithelial cells characteristic of the thymic cortex and medulla. Without continued contact between epithelium and developing T cells, the thymus may lose the ability to support full T-cell maturation with time.[14,15]

COMMITMENT TO THE T-CELL LINEAGE

Mouse T-cell precursors begin to express adhesion molecules common to hematopoietic lineages 2 to 3 days after their first appearance in the thymus. The adhesion molecule CD18/CD11a (also known as leukocyte function associated antigen-1 [LFA-1]) regulates the entry of mature leukocyte populations into sites of infiammation and enhances T-cell activation after antigen stimulation. LFA-1 is expressed on lymphoid precursors shortly after their entry into the thymus and is likely to mediate intercellular interactions that are required for subsequent steps in thymocyte development.[16] Receptors for growth and differentiation factors common to all hematopoietic precursors found in the bone marrow (e.g., c-Kit [CD117], which binds SCF) are still detectable at this stage as well. Commitment to the lymphoid lineage is demonstrated on a fraction of thymocytes by expression of CD25[17] as well as of the enzyme complex (recombinase) that generates functional lymphocyte antigen receptors (see later). Cells from this subset rapidly and selectively begin to activate and express the T cell–specific antigen receptors. They can efficiently repopulate a recipient thymus with developing T cells in cell transfer experiments. The interactions of IL-2, IL-7, and other growth factors with their receptors on thymocytes at this stage of development are likely to be important for the subsequent differentiation of

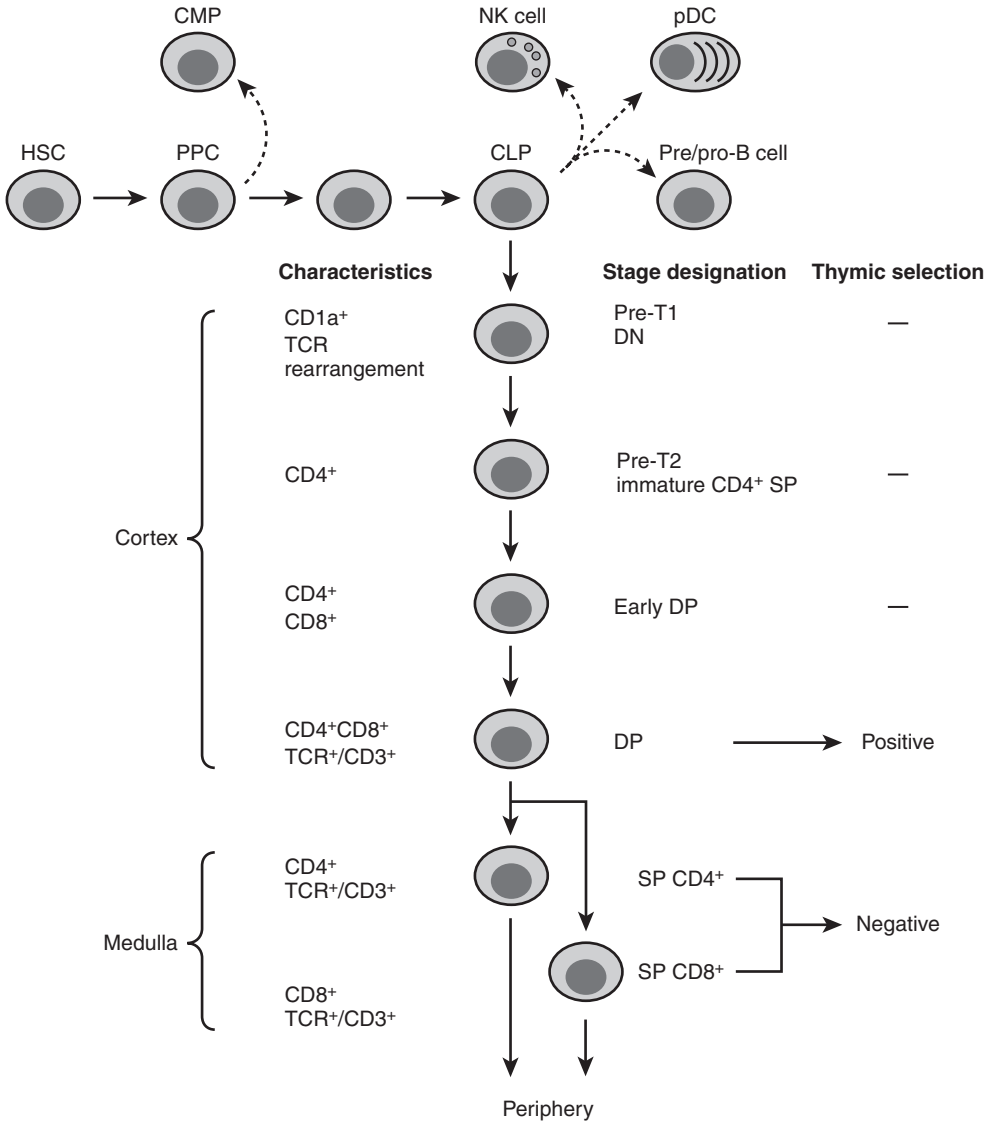

Figure 151-1 T-cell development and selection in the thymus. Hematopoietic stem cells *(HSCs)* with self-renewing capacity give rise to pluripotent progenitor cells *(PPCs)* that may differentiate to common myeloid progenitors *(CMPs)* or common lymphoid progenitors *(CLPs)*. CLPs in turn differentiate into T cell–restricted precursors (indicated in *green*), in addition to giving rise to natural killer *(NK)* cells, plasmacytoid dendritic cells *(pDCs),* and B cells. T cell lineage–restricted cells then pass through pre-T1, pre-T2, early double-positive *(DP),* DP, and single-positive *(SP)* stages in the thymic cortex and medulla. T cells at the pre-T1 differentiation stage express CD1a and initiate T-cell receptor *(TCR)* rearrangement. Next, they express CD4 but not CD8 and are referred to as $CD4^+$ immature cells. Further maturation gives rise to cells expressing both CD4 and CD8 markers, in addition to TCR/CD3. These cells are subjected to positive selection in the thymic cortex. DP thymocytes then differentiate into $CD4^+$ or $CD8^+$ SP cells. After post-selection maturation in the medulla, T cells are exported to the periphery.

mature T cells and may be the target of pharmacologic intervention (as shown by suppression of mature T-cell production by cyclosporine[18]).

Generation of Antigen Receptors

T cells are characterized by their specific cell–surface receptors for antigens (TCRs). Each antigen receptor is composed of two polypeptide chains with two internal disulfide-linked domains. The α-chains generally pair with β-chains, and δ-chains with γ-chains, defining two different populations of T cells in the mature animal.[19] Carboxyl-terminal domains include the peptides spanning the cell membrane. Each has 138 to 179 amino acids of relatively invariant sequence, which includes a hydrophobic transmembrane section and a short cytoplasmic tail. These are known as the constant (C) regions.

In a process called *rearrangement,* selected variable sequences are moved into close proximity to the C region–coding sequences by enzyme-catalyzed excision of the intervening loop of DNA, thereby creating a complete gene sequence for each polypeptide chain. This process is very similar to the rearrangement of immunoglobulin genes that occurs during B-cell development, and is accomplished by activation of a multicomponent recombinase complex that includes recombinase-activating genes 1 and 2 *(RAG1, RAG2)*.[20] The RAG-1 and RAG-2 proteins introduce DNA double-strand breaks that are eventually resolved by means of a

TABLE 151-1

CD Antigens and T-Cell Development

CD Antigen	Common Name	Present on	Function
CD1		Most nucleated hematopoietic cells	Antigen presentation
CD2			Adhesion, co-stimulation of TCR signals
CD3		T cells	TCR-mediated signal transducer
CD4		MHC class II–restricted T cells	Adhesion, co-stimulation of TCR signals
CD7		Most hematopoietic cells; high on immature cells	Co-stimulation of TCR signals
CD8		MHC class I–restricted T cells	Adhesion, co-stimulation of TCR signals
CD11a	LFA-1 α-chain	Most nucleated hematopoietic cells	Adhesion, co-stimulation of TCR signals
CD18	LFA-1 β-chain	Most nucleated hematopoietic cells	Adhesion, co-stimulation of TCR signals
CD25	High-affinity IL-2 receptor	Immature ($CD4^-CD8^-$) thymocytes, activated mature T cells	Supports proliferation, differentiation
CD28		Mature, activated T cells	Co-stimulation of TCR signals
CD34	Sialomucin	Multipotent bone marrow stem cells	Adhesion
CD40		B cells, monocytes, dendritic cells, endothelial cells	B-cell proliferation, Ig class switching
CD45	Leukocyte common antigen	Most hematopoietic cells	Co-stimulation of TCR signals
CD45RA		High levels of expression on naive T cells	Co-stimulation of TCR signals
CD45R0		High levels of expression on memory T cells	Co-stimulation of TCR signals
CD52		Most hematopoietic cells	Unknown
CD80	B7-1	Activated B cells, macrophages	CD28 ligand
CD86	B7-2	Activated B cells, macrophages	CD28 ligand
CD117	c-Kit	T-cell precursors	Proliferation of precursors
CD154	CD40 ligand (CD40L)	Activated T cells	Adhesion, transmission of signal to B cells

LFA-1, Lymphocyte function–associated antigen-1; *MHC,* major histocompatibility complex; *TCR,* T-cell receptor.

TABLE 151-2

Cytokines and T-Cell Development

Cytokine	Common Name	Produced by	Function
IL-1β	Interleukin-1β	Monocytes, macrophages	Enhanced inflammation; thymocyte proliferation
IL-2	Interleukin-2	Activated $CD4^+$ T cells	T-cell proliferation; thymocyte differentiation
IL-3	Interleukin-3	Stromal cells in bone marrow and thymus	TCR-mediated signal transducer
IL-4	Interleukin-4	Activated T_H2 cells	B-cell proliferation and antigen presentation; Ig production; switch to IgE
IL-7	Interleukin-7	Stromal cells: bone marrow, thymus; intestinal epithelium	Expansion of lymphoid precursors
IL-10	Interleukin-10	Activated T_H2 cells	Suppression of macrophage activation; B-cell proliferation
IL-12	Interleukin-12	Activated macrophages	IFN-γ production; macrophage activation
IL-13	Interleukin-13	Activated T_H2 cells, activated $CD8^+$ T cells	Similar to IL-4 with additional proinflammatory signals for fibroblasts and tissue granulocytes
IL-15	Interleukin-15	Many cell types	Differentiation and proliferation of NK cells, $CD8^+$ T cells
IFNγ	γ-Interferon, type II interferon	Activated T cells, NK cells	Enhanced antigen presentation, inflammation
SCF	Stem cell factor	Stromal cells: bone marrow, thymus; intestinal epithelium	Proliferation, differentiation of precursor cells
TGF-β	Transforming growth factor-β	Activated regulatory T cells	Suppression of mature T-cell activation; accelerated T-cell development
TSLP	Thymic stromal lymphopoietin	Stromal cells: thymus	Expansion of T-cell precursors; TCR γ-chain rearrangement

NK, Natural killer; *TCR,* T-cell receptor.

series of proteins belonging to the nonhomologous end-joining and DNA repair pathway. Mutations in the recombinase and DNA repair genes impair cell-mediated immunity by inhibiting productive rearrangements in lymphocyte receptor genes as well as repair of radiation-induced DNA strand breaks.[21]

Recombination of TCR genes, similar to that of immunoglobulin genes, follows a well-regulated sequence in the presence of a normal recombinase complex. In the generation of a functional β-chain, gene sequences coding for variable (V), diversity (D), and joining (J) segments, 18 to 20 amino acids long, are used. In this process, a D region segment is first brought into close proximity to the J region by looping out and deleting much of the intervening DNA. The excised DNA persists as a circle in the cell and is known as a *T-cell receptor excision circle* (TREC). The TREC does not replicate in parallel with nuclear DNA, so counting TRECs in blood T cells gives an indirect estimate of T-cell production from the thymus that also is affected by cell division.[22] Indeed, measurement of TRECs on dried blood spots at birth has been introduced in pilot programs of newborn screening for severe combined immunodeficiency in Wisconsin and

in Massachusetts. The rearrangement process that generates the TREC allows for transcriptional activity at the site as well as a commitment to express 1 of 12 potential J regions. A V segment is then selected and moved closer to the rearranged D-J segment by a similar process. δ-Chains resemble β-chains in having V, D, J, and C segments. α-Chains and γ-chains are somewhat simpler in structure and lack D regions. The rearranged V(D)J segments of TCR chains achieve additional diversity by addition or subtraction of nucleotides at the joints between the V, D, and J segments. This phenomenon appears to result from the properties of the recombinase enzymes acting in conjunction with an enzyme designated terminal deoxytransferase (Tdt) and is known as *N segment diversity.*

The thymocytes of fetal mice rearrange their β-, γ-, and δ-chain genes[18] at approximately 13 to 14 days gestation, and α-chain rearrangement follows 1 to 2 days later. Messenger RNA (mRNA) for α-chains is detectable on days 16 to 17 of gestation, and α-chains are present on the surface of fetal thymocytes on days 17 to 18, so that the appearance of complete γδ heterodimers precedes that of αβ heterodimers by 1 to 2 days. Expression of a rearranged β-chain suppresses further rearrangements of β-chain loci by means of signaling through a receptor-related tyrosine kinase, $p56^{lck}$, in a process known as *allelic exclusion.*[23] α-, γ-, and δ-chain gene rearrangements also are largely suppressed after the binding of mature TCR to MHC molecules on the surface of thymic macrophages or epithelial cells. However, a subset of $CD8^+$ cells appears to rearrange both α-chain loci, creating a small population of potentially bispecific cells.

When either pair of receptor genes (αβ or γδ) has been rearranged and transcribed, it is associated on the cell surface with the five polypeptides of the CD3 complex. The cytoplasmic tail of each TCR chain is small, and intracellular signaling leading to the activation of T-cell signaling cascades is actually mediated through the CD3 complex.[24]

Extrathymic T-Cell Development

Most lymphocytes carrying αβ or γδ antigen-specific receptors develop in the thymus and are exported to peripheral lymphoid organs. However, a small number of lymphocytes carrying T-cell surface markers may develop extrathymically. In particular, lymphoid cells may appear within the epithelium of the small and large intestine in the absence of a functioning thymus. Intraepithelial lymphocytes (IELs) in normal adult individuals are composed of both αβ and γδ $CD3^+$ cells. In contrast with their representation in the thymus, γδ cells are more frequent than αβ cells in the intestinal epithelium. Precursors for the γδ subset appear to begin differentiating within lymphoid aggregates associated with epithelial crypts in the small intestine. Cells in these *cryptopatches* express the recombinase-activating genes RAG-1 and RAG-2, as well as the c-Kit ligand and the IL-7 receptor.[25] Loss of these early-lineage determinants is coincident with expression of TCR and CD3 signaling molecules on lymphoid cells in these aggregates, suggesting that active T cell–like differentiation is occurring in situ. These cells can develop in athymic nude mice, albeit more slowly than in immunologically normal animals, suggesting that thymus-derived factors are not absolutely required for local development of T-like lymphocytes in the gut.

Intestinal immune responses are critical as a first line of defense against intestinal flora and have also been shown to be important in generating tolerance to ubiquitous environmental antigens. However, the importance of local extrathymic T-cell development in performing these functions is unknown. γδ Subsets found in other epithelial compartments (skin, alveolar and bronchial epithelium) seem to be dependent on thymic output, and evidence is lacking for significant extrathymic differentiation of the αβ subset.

CONTROL OF THE T-CELL REPERTOIRE FOR ANTIGEN RECOGNITION

Role of T Cell Receptor–Major Histocompatibility Complex Interactions in T-Cell Development

B and T cells, despite the similarities in the mechanisms of assembly of their antigen-specific receptors, interact with antigen in different ways. In generating a response from B cells, immunoglobulin carried on the B-cell surface binds directly to antigen, whether this is free in blood or tissues or expressed at the surface of a cell or microbe. By contrast, the TCR recognizes antigen in the groove of self major histocompatibility complex (MHC) molecules. The random selection of variable regions and the N region diversification described previously generate a diverse repertoire of antigen specificities. Estimates of the potential diversity of TCRs that can be achieved by the processes of V(D)J recombination and N region diversification exceed 10^{15} for both αβ and γδ heterodimers.[27] This repertoire is subjected to important selection steps in the thymus. Although the pool of T cells in an animal must have broad diversity to recognize a wide array of foreign antigens, for efficiency it must also be limited to those cells bearing TCR capable of binding to self-MHC.

Positive selection has been shown to occur through TCR interactions with MHC molecules expressed on thymic cortical epithelial cells during the $CD4^+CD8^+$ (DP) stage in thymocyte maturation; the large numbers of developing thymocytes that do not bind self-MHC die in the thymus. TCR-MHC interactions that exceed a threshold level, however, result in additional cell death. This negative selection step is the first level of protection against autoimmunity. Negative selection can be initiated by thymocyte contact with virtually any MHC^+ cell in the thymus, suggesting that positive and negative selection may be distinguished not only by the affinity of the TCR-MHC interaction but also by the requirement for epithelium-derived signals in positive selection.[28] The display of self-antigens by thymic epithelial cells is key to inducing tolerance of the T-cell compartment, a process enhanced by the autoimmune regulator (AIRE) gene, which is expressed by a subset of terminally differentiated medullary thymic epithelial cells (mTECs).[29] AIRE, as a transcriptional regulator of tolerance induction, promotes central tolerance by inducing the ectopic expression of a large number of self-antigens by mTECs. This mechanism permits that mTECs (which constitutively express MHC class II molecules) may present self-antigens to nascent thymocytes. Recognition of these antigens by self-reactive thymocytes leads to clonal deletion, thus representing a key mechanism of central tolerance to prevent autoimmunity.[30] Mutations of *AIRE* cause autoimmune polyendocrine syndrome type I, also known as autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED).

Expression of Other T Lineage–Specific Molecules

Although antigen specificity and activation signals are determined by the TCR complex, the CD4 and CD8 co-receptors on T cells play a significant role in thymocyte differentiation as well as in the postthymic activation of mature T cells. These molecules bind to MHC molecules at sites distant from binding sites for the T-cell antigen receptor. CD4 molecules bind to MHC class II molecules (HLA-DP, -DQ, and -DR in humans), which are expressed primarily on cells of hematopoietic origin and participate in generating an immune response. CD8 molecules bind to the MHC

class I molecules found on nearly every nucleated cell in the body (HLA-A, -B, and -C). The cells that first arrive in the thymus are negative for CD4 and CD8 cell-surface antigens. Expression of CD4 and CD8 molecules during thymocyte development is finely regulated. Maturation of early T-cell progenitors (which are CD4–CD8– [DN]) is marked by sequential expression of both CD4 and CD8, along with appearance of a functional TCR,[31] thereby enhancing the likelihood of TCR-MHC interactions during the critical steps of positive selection.

As thymocytes mature, expression of the CD4 molecules and that of CD8 molecules generally become mutually exclusive. CD4 and CD8 molecules potentiate TCR-mediated intracellular signaling because they are associated with the intracytoplasmic protein tyrosine kinase $p56^{lck}$. The switch from $CD4^-CD8^-$ cells to $CD4^+CD8^+$ thymocytes probably occurs by way of an immature thymocyte, which has low levels of surface CD3,[32] and a signaling molecule composed of the rearranged TCR β-chain and an invariant α-chain known as *pre-Tα,* which supports proliferation of T-cell precursors that have successfully rearranged a β-chain allele. In mice, this complex is first detectable at 16 days gestation. $CD4^+CD8^+$ cells first appear 1 day later, and in vivo labeling studies indicate that CD25 is lost immediately before CD4 and CD8 are expressed. Commitment to the CD8 pathway appears to require a specific signal, presumably mediated by binding to a class I MHC molecule. If this signal cannot be transduced, as, for example, in children who lack the Zap70 kinase, no CD8 cells appear in the blood.[33] $CD4^+CD8^+$ DP cells that survive positive and negative selection and that do not become $CD8^+$ cells appear to enter a default pathway, becoming $CD4^+$ SP cells in the blood.[34]

OBSERVATIONS IN HUMANS

T-Cell Phenotypes and Antigen Receptors

T-cell development in the human thymus starts at approximately 7 weeks of gestation[35] with the entry of precursors with the leukocyte antigens CD7 and CD45 on their surface. These cells mature to express first the CD2[36] co-stimulatory molecule and then, around 8.5 weeks gestation, CD3. By 9.5 weeks, 32% of the $CD3^+$ cells have the β-chain of the TCR in the cytoplasm, and at 10 weeks, many of the cells have α-chain in addition to β-chain in the cytoplasm. The proportion of cells expressing the δ-chain of the γδ TCR is highest at 9.5 weeks gestation (11%) and rapidly diminishes (to 4% at 10 weeks and 1% at 12 weeks). CD1a, CD4, and CD8 appear on lymphocytes in the thymus by 10 weeks gestation, and the high-density CD3 phenotype (associated with mature antigen receptor expression) appears on these cells at approximately 12 weeks. A population of immature $CD7^+$ cells with potential for multiple differentiation pathways is present in cord blood.[37]

The biochemistry of the human T cell–antigen receptor resembles that of mice. The αβ heterodimer has a molecular mass of approximately 90 kDa. The α- and δ-chain genes are on chromosome 14, and the β-chain genes are on chromosome 7. The complete αβ or γδ heterodimer is expressed on the T-cell surface in association with five invariant chains, which constitute the CD3 complex.

TABLE 151-3

Summary of T Lymphopoiesis in Human Fetuses

Age (weeks)	Developmental Step
7	Precursors in fetal liver
10	Thymus becomes lymphoid
12	Hassall's corpuscles in thymus
12+	T cells appear in blood

Some estimate of the time and rate of T-cell export from the human fetal thymus comes from measurement of T cells in the blood and spleen. Occasional $CD3^+$ cells are present in blood from the end of week 12 of gestation, their proportion rising from 20% to 30% at 14 weeks to 50% or more by 22 weeks (Table 151-3). Studies suggest that the range of VDJ recombinations that can be made before 14 weeks gestation is limited.[38,39] The mechanism for limited diversity during fetal life may relate to a limited use of N region diversification, secondary to low levels of the TdT enzyme in the thymus. It is interesting that the diversity of the fetal B-cell repertoire also limited, although a selective preference for certain VH genes appears to be the explanation in this case.[40] Because the T-cell diversity is limited, the fetus may have much less ability to respond to antigens (or to reject foreign grafts) than might be predicted from the presence of CD3 cells in the blood. Much remains to be learned about the range of TCR gene recombinations that can be made at different gestational ages.[41]

Of fetal $CD3^+$ cells in blood and spleen, 90% to 96% use αβ heterodimers, and the proportion of γδ receptor-positive cells is between 2% and 8% at 20 to 40 weeks of gestation; this subunit distribution is similar to that found in adults.[42] Fetal T cells resemble adult lymphocytes in expressing either CD4 or CD8 but not both. T cells also appear in the intestinal epithelium and lamina propria by 14 weeks gestation.[43] Cells carrying γδ TCRs populate the epithelium more slowly than do αβ TCR^+ cells and may arise in part through local differentiation, rather than exclusively from thymic sources. Gut-associated γδ lymphocytes increase rapidly in the fed neonate,[44] suggesting that local antigenic stimulation may be responsible for the expansion of this population.

By analogy with studies in animals, it seems likely that T cells accumulate in the blood and lymph nodes of fetuses during the second half of gestation, principally as a result of thymic emigration. This view is supported by studies of CD45 isoforms, which distinguish between naive and memory T cells. More than 99% of the lymphocytes in the cord blood of neonates express high-molecular-weight isoforms of CD45 ($CD45RA^+$ and $CD45RB^+$),[45] in association with the low levels of LFA-1 (CD11a/CD18) and other integrins; this expression pattern is characteristic of the naive T-cell phenotype (Table 151-4). When stimulated, naive cells of newborn infants switch to express the $CD45R0^-$ isoform of CD45. This isoform is present on the surface of adult circulating T cells that respond to recall antigens. The low number of $CD45R0^-$ cells in the blood of healthy term neonates suggests that little antigen-driven expansion of T cells occurs before birth. The minor population of memory phenotype cells that does appear during fetal life may be related to autoantigen stimuli (see later).

TABLE 151-4

Summary of Differences Between Naive and Memory T Cells

Characteristic	Naive T Cells	Memory T Cells
Definition	Cell that has not yet been triggered by antigen	Product of antigen-driven clonal expansion
CD45 phenotype	$CD45RA^+$, $CD45RB^+$, $CD45R0^-$	$CD45R0^+$
Other cell surface antigens	$LFA\text{-}1^{low}$	$CD2^{high}$, $LFA\text{-}1^{high}$, $LFA\text{-}3^{high}$
Cytokine response to stimulation	IL-2	IL-2, IL-4, IL-10, IL-12, γ-IFN
CD40L response to stimulation	Low	High

CD40L, CD40 ligand; *IFN,* interferon; *IL,* interleukin; *LFA,* leukocyte function–associated antigen.

Functional Responses of Fetal T Cells

In vitro tests indicate that several components of a T-cell response (proliferation to mitogens or to alloantigen in mixed lymphocyte culture, IL-2 production, and the expression of IL-2 receptors) exist from approximately 12 weeks gestation. In addition to these ligand-driven proliferative responses, T cells of neonates also can be maintained in culture using a combination of IL-4 and IL-2, or IL-4 and IL-12.[46] Evidence that fetal T cells can make antigen-specific responses comes from their proliferation in mixed lymphocyte culture, together with the generation of antigen-specific cytotoxic cells.[47] Other stimuli, such as *Staphylococcus* enterotoxins and anti-TCR antibodies, tend to elicit lesser responses by neonatal than by adult cells.[48] This difference is accounted for, at least in part, by the lower proportion of CD45R0 cells in neonates than in adults.[49]

The maturation of naive cells to the memory cell-phenotype most likely follows encounter with antigen presented on a specialized antigen-presenting cell, such as B lymphocytes or dendritic cells (DCs) in the lymph nodes. Several studies suggest that naive T cells that encounter antigen in the absence of co-stimulation enter a pathway that leads to unresponsiveness, also known as *anergy,* which may be temporary or permanent.[50] A polyclonal population of $CD4^+$ and $CD8^+$ T cells with a memory ($CD45R0^+$) phenotype makes up 25% of human fetal spleen cells; these T cells express high-affinity IL-2 receptors and proliferate in response to exogenous IL-2 but not to anti-CD2 or anti-CD3 antibodies.[51] Some of these cells may be autoreactive T cells destined to become unresponsive. Finally, umbilical cord blood contains a population of T cells with reduced in vivo responsiveness following ligation of cell surface CD47.[52]

The production of soluble mediators, or cytokines, by T cells that respond to antigen stimulation is essential for host defense.[53] Naive and memory T cells make similar amounts of IL-2, which is required for T-cell proliferation, whereas other cytokines, including IL-4, IL-10, IL-12 and γ-interferon (γ-IFN), are made largely by memory T cells. Consequently, T cells of newborns make little γ-IFN or IL-4 unless they first undergo several cycles of proliferation and maturation[54] or are cultured with stimulation that persists for several days.[55] These differences are likely to be important because T cells show functional specialization regarding their predominant cytokine production.[56] The cells making IL-4 and IL-10 are described as type 2 helper T (T_H2) cells. These cells have an essential role in promoting B-cell replication and increasing the production of immunoglobulin E (IgE) isotype antibodies. T_H1 cells make mainly γ-IFN, and they promote local inflammatory responses, as well as stimulating B cells to make IgG. A third class of T_H0 cells can make both γ-IFN and IL-4. The specialization of cells into a T_H1 or T_H2 phenotype from T_H0 cells is determined in part by the cytokine environment in which stimulation occurs. The presence of γ-IFN, for example, biases responses toward a T_H1 phenotype, whereas IL-4 tends to suppress γ-IFN production and to promote differentiation toward a T_H2 phenotype. Human newborn naive cells can mature into those making IL-4 apparently in the absence of preexisting IL-4.[57] IL-13, an important cytokine in the T_H2 pathway, is produced by newborns' $CD8^+$ T cells even when production of IL-4, IL-10, and γ-IFN remains low.[58] Different specificities of cytokine receptors on the surface of T_H1 and T_H2 cells cause them to have different homing patterns in intact animals. Responses to immunization can be markedly altered by deliberate manipulation of the cytokine milieu in which immunizing antigens are presented to the immune system. This strategy may be useful in the design of future vaccines.[59]

The extent of signaling through the TCR-CD3 complex can be modified also by simultaneous interactions of receptor-ligand pairs of *co-stimulatory molecules* on the surface of T cells and antigen-presenting cells. Interaction of CD28 molecules on the T-cell surface with its ligands B7-1 and B7-2 on B cells, macrophages, and dendritic cells markedly enhances the proliferation and cytokine production of "naive" T cells in response to specific antigen-MHC complexes. Other surface molecules with co-stimulatory function include LFA-1, the inducible costimulator ICOS (another CD28/B7 family member), and tumor necrosis factor (TNF) family members such as OX40. These membrane-bound receptors carry amino acid residues in their cytoplasmic tails that allow recruitment of activating kinases that can amplify intracellular signaling. On the other hand, other members of the CD28 family of molecules, such as CTLA-4, contain intracytoplasmic inhibitory sequences that can activate a series of intracellular phosphatases with opposite function. CTLA-4 also can bind B7-1 and B7-2 molecules on the surface of antigen-presenting cells, and its affinity for these molecules is higher than that of CD28; accordingly, interaction of CTLA with B7-1 (or with B7-2) actively suppresses intracellular TCR signaling. The balance of positive and negative *co-stimulation* shapes the final T-cell repertoire by regulating both clonal expansion and differential cytokine production of the responding T cells. Interruption of these co-stimulatory and regulatory interactions can markedly alter the development of antigen-specific T-cell responses. The effectiveness of blocking CD28 interactions with B7-1 and B7-2 in limiting or reversing rejection of allogeneic tissue grafts is currently being explored.[60]

Postnatal Development of Memory T Cells

Approximately 70% of naive T cells—the predominant population in human newborn infants—contain TRECs that identify recent thymic emigrants.[61] Recirculation of naive T cells through the specialized venules of lymph nodes and other lymphoid tissues allows them to migrate to the T cell–dependent areas of lymph nodes. T cells that do not encounter antigen leave the node in the efferent lymph and return to the bloodstream through the thoracic duct. By contrast, naive T cells, whose surface antigen receptors are cross-linked by antigen in the context of self-MHC molecules, enter a response cycle that is accompanied by expression of a surface receptor for IL-2. In the presence of a co-stimulator signal (such as binding of B7-1 or B7-2 to CD28), the T cells themselves release IL-2. This autocrine loop permits cell division of IL-2–dependent T cells for as long as the antigen stimulus persists. The development of a useful repertoire of T cells in the circulation is therefore best thought of as a consequence of antigenic experience stimulating T-cell proliferation. Specialized DCs play a key role in capturing antigens in tissues and at body surfaces and in transporting them through lymphatics to the draining lymph nodes. The migration of DCs is regulated by chemokine gradients (particularly that for CCR7), and their handling of antigen is affected by receptors for bacterial products such as lipopolysaccharides and certain unmethylated dinucleotides.[62] DCs are likely to contribute to the specialization of T cells along T_H1 or T_H2 pathways (described earlier). B lymphocytes also can present antigens, albeit at low concentrations, and hence may participate in T-cell activation.

The response of naive T cells to antigen stimulation depends largely on the co-stimulatory environment.[63] Stimulation results in an increase in the proportion of $CD45R0^+$ cells from less than 5% at birth to 35% to 45% by age 16 years. This increase occurs mainly during the first years of life,[49] and one attribute of memory cells, the production of γ-IFN, is mature around the age of 2 years. The expansion of populations with defined specificities has been documented for only a few antigens. For example, the frequency of lymphocytes in blood responding to varicella-zoster virus (VZV) antigen is less than 1 in 10^6 before immunization or infection.[64] After a varicella infection, VZV-responsive cells do not appear in the blood for approximately 10 days. At 1 month into convalescence, the responder-cell frequency is

approximately 1:20,000 cells, rising to 1:10,000 after 3 months.[65] VZV is latent and responder-cell frequencies in the range of 1:10,000 to 1:20,000 are maintained through the age of 50 years, when they start to decline. The frequency of T cells with specificity for a nonreplicating antigen, tetanus toxoid, fluctuates directly in relationship to immunization. Before infants receive tetanus toxoid, they have fewer than $1:10^5$ cells that respond to this antigen. Six weeks after the first immunization, the responder-cell frequency is still less than 1:40,000. With completion of the course of three injections by the age of 6 months, the frequency of responder cells increases to 1:10,000 cells, and this falls to less than 1:40,000 one year later.

Novel Subsets of CD4+ T Cells

A recently described effector population of CD4 cells is defined as T_H17 T cells, because they secrete several IL-17 cytokines. The generation of these T-cell subsets requires IL-6 and IL-1 in humans, and differentiation is amplified by IL-21 and IL-23.[66] Severe depletion of T_H17 cells was found in patients with STAT-3 deficiency and clinical manifestations of autosomal dominant and sporadic hyper-IgE syndrome.[67]

Negative selection in the thymic medulla delete many self-reactive T lymphocyte as potential sources of autoimmunity. However, self-reactive T cells slipping past negative selection require a different strategy to restore their naive status. This strategy involves $CD4^+CD25^+$ regulatory T cells (T_{reg} cells), which express the transcription factor Foxp3. Scurfy mice lack detectable T_{reg} function as a consequence of mutations of the *Foxp3* gene.[68] In humans, immune dysregulation–polyendocrinopathy–enteropathy X-linked (IPEX) syndrome is a primary immunodeficiency disease characterized by defective Treg function secondary to mutation in the *FOXP3* gene.[69]

IL-22–producing helper T cells (T_H22 cells) have been the latest addition to the $CD4^+$ T lymphocyte subsets.[70] T_H22 cells are characterized not only by producing IL-22 but also by their propensity to express skin-homing chemokine receptors.

HELP FOR B LYMPHOCYTES

B cells, which that bind antigen through their surface immunoglobulin receptors enter a pathway that leads either to self-destruction by apoptosis[71] or, if a T-cell signal is received, to proliferation and differentiation. The T-cell signal for B-cell proliferation is supplied by cytokines and is delivered mostly at the T cell–B cell interface in lymph nodes. T cells control the switch from IgM to IgG (isotype switching) as well as proliferation. The switch signal is supplied by binding a 39,000-kDa glycoprotein, termed CD40 ligand (CD40L), to the CD40 receptor, which is constitutively expressed on the B-cell surface. Resting memory T cells express CD40L within a few hours of a response to antigen, whereas naive T cells take longer to become CD40L-positive. In vitro experiments suggest that delay in CD40L expression on naive T cells is an important factor limiting the ability of human newborn infants to make antibody responses.[72] T_H1 cells help certain IgG responses, and IL-4 from T_H2-type cells promotes IgA and IgE responses. As noted previously, T_H2 cells are most efficiently generated in an environment already containing IL-4 and IL-13. IL-21 is a very important T cell–derived cytokine that is secreted by helper T cells in the lymph node follicles (the so-called follicular helper T cells) and promotes B-cell maturation and immunoglobulin secretion.

SUMMARY

T-cell development occurs in multiple discrete steps, beginning with lineage commitment by hematopoietic stem cells (HSCs) in the specialized environment of the thymus. Progression through the developmental pathway in the thymus is controlled by soluble cytokine growth factors and cellular interactions between the maturing thymocytes and the local stromal-cell compartment. The repertoire of antigen-specific TCRs expressed on mature thymocytes before export to the periphery results from both positive and negative selection of receptor specificities generated by random association of variable regions for TCR heterodimers and the addition of N region diversity through random nucleotide deletions or additions during the recombination events. After export from the thymus, the mature T-cell pool is further shaped by antigen exposure and the local production of cytokines during initial activation and clonal expansion in lymph nodes, spleen, and epithelial structures such as skin and intestine. Although mature T cells are present in significant numbers by midgestation in humans, a fully mature T-cell population develops slowly after birth in response to antigen exposure.

ACKNOWLEDGMENT

The authors wish to thank Marcia McDuffie, MD, and Anthony R. Hayward, MD, PhD, whose chapter on this topic in the third edition of *Fetal and Neonatal Physiology* provided the foundation upon which this updated chapter is based.

152 B-Cell Development

Sonja E. Johnson and Tucker W. LeBien

B-CELL DEVELOPMENT: OVERVIEW

Mammalian B-cell development represents a series of sequential developmental transitions that culminates in the establishment of an antibody repertoire essential for host immunity. Mutations in genes critical for the development and function of B cells can result in immune deficiency. This chapter focuses on the developmental biology of human B-lineage cells and perturbations in development that give rise to several antibody deficiency states.

SITES OF HUMAN B-CELL DEVELOPMENT

Like all blood cells that appear in the periphery, B cells (also called B lymphocytes) are derived from hematopoietic stem cells. The liver and omentum are the initial sites of B lymphopoiesis in the human fetus, where a detectable population of cytoplasmic μ heavy chain+ pre-B cells first appears at approximately 8 weeks gestation.[1,2] This population differentiates into immature surface immunoglobulin (Ig) M+ (IgM) cells by 8 to 10 weeks gestation, constituting the first wave of B-cell development.[1,3] Between 12 to 15 weeks gestation hematopoietic stem cells begin to home to the marrow, at which time multiple stages of B-lineage cells emerge.[4,5] Human B-cell development continues in the marrow from the midtrimester of fetal development through the eighth decade of life.[6,7]

STAGES OF MARROW B-CELL DEVELOPMENT

The stages of mammalian B-cell development have historically been defined by the rearrangement and expression of Ig gene segments. However, because detection of Ig rearrangements requires destruction of the cell, monoclonal antibodies recognizing cell surface antigens have been useful to define the developmental stages of intact B-lineage cells.[8]

Lymphoid cells committed to the B-lineage are derived from common lymphoid progenitors that develop from hematopoietic stem cells. Common lymphoid progenitors are a heterogeneous population with the potential to develop into B, T, natural killer, or lymphoid dendritic cells.[9-11] Initial rearrangements between diversity (D) and joining (J) gene segments occur in CD34+/CD10+/CD19− common lymphoid progenitors and CD34+/CD10+/CD22+/CD19− precursor-progenitor-B (pre-pro-B) cells.[12,13] Pre-pro-B cells with D to J rearrangements on both alleles then undergo further differentiation by completing variable (V) to DJ rearrangements and expressing the B lineage-specific cell surface antigen CD19. At this stage CD34 and CD10 expression is sustained and the resulting CD34+/CD10+/CD19+ surface phenotype defines progenitor-B (pro-B) cells. Pro-B cells that fail to produce functional VDJ rearrangements undergo apoptosis and are eliminated from further development. If the VDJ rearrangement on either allele is in-frame (i.e., encodes a μ heavy chain protein), pro-B cells then differentiate into large CD34−/CD10+/CD19+ precursor-B (pre-B) cells, defined by transient cell surface and constitutive cytoplasmic expression of the rearranged μ heavy chain. Cell surface μ heavy chain pairs with the surrogate light chain (a heterodimer of two proteins originally named VpreB and λ5 in the mouse), and the complex is referred to as the pre-B cell receptor (pre-BCR).[14] Pre-BCR expression is required for normal human B-cell development. Those pre-B cells that express cell surface pre-BCR undergo substantial proliferation (estimated to be four to six cell divisions), thereby expanding the number of cells with functional VDJ rearrangements.[15] Large pre-B cells eventually cease expression of the surrogate light chain and exit the cell cycle. At this stage they are designated small pre-B cells and initiate V to J rearrangement at the κ light chain (LC) locus. If the small pre-B cell makes a functional VJ κ rearrangement it expresses cell surface μ/κ Ig. If rearrangement of both κ alleles is out of frame, the pre-B cell can undergo rearrangement at the λ LC locus. Immature B cells harboring functional LC rearrangements express the κ or λ LC in complex with μ heavy chain on the cell surface as the B-cell receptor (BCR). Immature B cells express high levels of several B-lineage restricted cell surface markers, including CD20, CD21, CD22, and CD40.[8]

In addition to sequential rearrangement of Ig heavy chain and LC genes, an ordered expression of genes that mediate recombination and diversification of the Ig loci occurs. Recombination activating genes are required for initiation of Ig rearrangement, and both are involved in generation of DNA strand breaks at recognition signal sequences 5′ or 3′ of Ig gene segments.[15] RAG expression initially occurs in common lymphoid progenitor, is down-regulated in large pre-B cells following functional heavy chain rearrangements, and re-expressed at the small pre-B cell stage during LC rearrangement.[16] The expression of an enzyme that contributes to repertoire diversification, terminal deoxynucleotidyl transferase, is expressed in early B-cell development. Terminal deoxynucleotidyl transferase is a DNA polymerase that adds single nucleotides in a template independent manner to the 3′ overhangs within the CDR3 domain of functional VDJ rearrangements.[17]

A summary of the patterns of gene expression unique to individual stages of B-cell development is shown in Figure 152-1.

POSTMARROW B-CELL DEVELOPMENT

Coincident with or immediately following egress from the marrow, immature B cells co-express cell surface IgM and IgD. Cells at this stage are also designated transitional B cells to reflect the fact that they are transiting between the marrow and secondary lymphoid organs, such as spleen and lymph node. They can be distinguished from the bulk of naïve B cells in peripheral blood by differential expression of a variety of cell surface molecules.[18] *Naïve B cell* is the term applied to those cells that have not yet been activated following contact with foreign antigen. Naïve B cells circulate in peripheral blood or reside in primary follicles in lymph nodes to form the naïve follicular B-cell compartment.

Antigen induced activation of B-cell differentiation in the lymph node encompasses a series of developmental transitions collectively designated the germinal center (GC) reaction.[19,20] These transitions include clonal expansion, class switch recombination (CSR) at the IgH locus, somatic hypermutation of VH genes, and affinity maturation. The GC reaction is initiated when naïve B cells are triggered by antigen-driven BCR cross-linking in the presence of co-stimulatory signals from helper T cells. Naïve

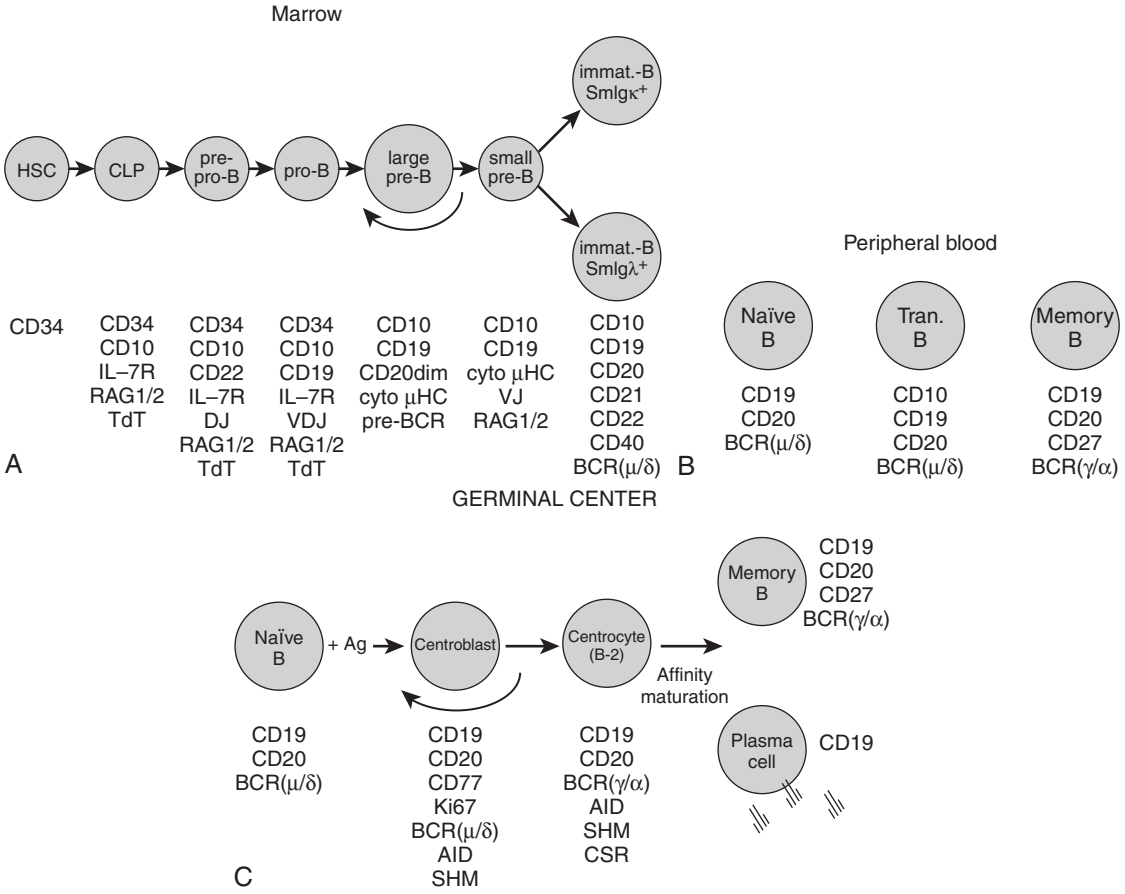

Figure 152-1 Developmental stages of human B cells. Expression of gene products that play a critical role in each B-lineage developmental stage, and/or are useful in characterizing each stage by flow cytometry are shown. **A, B-cell development in the marrow.** Commitment to the lymphoid lineage begins when hematopoietic stem cells *(HSC)* differentiate into the common lymphoid progenitor *(CLP)*. Commitment to the B-lineage is initiated when the IgH locus undergoes D to J *(pre-pro-B)* and then V to DJ *(pro-B)* rearrangement. Large pre-B cells that have successfully rearranged the IgH locus express the μ heavy chain protein paired with the surrogate light chain as the pre-B cell receptor *(pre-BCR)*. Large pre-B cells undergo several rounds of cell division *(curved arrow).* Rearrangement of the immunoglobulin light chain at either the κ or λ loci occurs in small pre-B cells, which then express successfully rearranged IgH and IgL genes as the BCR and become immature B cells. Most immature B cells express IgM and IgD. B-lineage cells that fail to make successful (i.e., functional) IgH and IgL rearrangements undergo apoptosis in the marrow. **B, Peripheral blood B cells.** After egressing from the marrow, IgM+/IgD+ cells circulate in the blood and/or migrate to secondary lymphoid organs such as spleen and lymph nodes. A small fraction of IgM+/IgD+ cells leaving the marrow have been characterized as the putative counterpart of mouse transitional B cells; a population of cells destined to migrate to the spleen and form the marginal zone B-cell compartment. These transitional B cells are rare (<2% of total peripheral blood B cells), and can be distinguished from the naïve and memory B-cell populations by expression of CD10. Memory B cells are identified by CD27 expression, frequently express IgG or IgA, and circulate in the peripheral blood following development in the germinal center reaction. **C, The germinal center reaction.** Naïve B cells encounter antigen in secondary lymphoid organs and, in cooperation with signals from CD4+ helper T cells, up-regulate markers of proliferation (e.g., Ki67) and the cellular machinery (e.g., activation induced cytidine deaminase) necessary for induction of somatic hypermutation. This highly proliferative *(curved arrow)* B-cell population is designated centroblasts. Centroblasts differentiate into centrocytes, which undergo class switch recombination and affinity maturation. During this transition B cells with low-affinity antigen receptors are deleted and those with high affinity receptors further differentiate into either CD27+ memory B cells or antibody-secreting plasma cells. The latter down-regulate all major surface markers with the exception of CD19 and home to the marrow.

B cells undergo robust proliferative expansion and at this stage are referred to as *centroblasts.* Populations of centroblasts can be morphologically identified as the so-called "dark zone" of the GC. Centroblasts are the stage of B-cell development that undergo somatic hypermutation in VH genes (see later discussion). After exiting the cell cycle, centroblasts differentiate into centrocytes, forming the so-called "light zone" of the GC. Multiparameter fluorescence activated cell sorting of tonsillar B-cell subpopulations and subsequent sequencing of VDJ rearrangements was used to demonstrate that somatic hypermutation is initiated in centroblasts.[21] Centroblasts can be distinguished from centrocytes by the expression of CD77 and Ki67 in the former but not the latter.[22] Centrocytes (also called B-2 cells) are highly enriched for mutated VH genes and undergo selection by virtue of binding to cognate antigen presented by follicular dendritic cells and T cells. The affinity of the interaction dictates whether centrocytes will undergo apoptosis (low affinity interaction) or be selected for further differentiation (high affinity interaction) into memory B cells or plasma cells. Some centrocytes also undergo CSR and shift from expression of cell surface IgM and IgD to IgG or IgA.

Multiparameter fluorescence activated cell sorting of peripheral blood B cells has also been used to identify distinct populations of naïve and memory B cells.[22] Expression of the tumor necrosis factor receptor family member CD27 correlates with the presence of somatically hypermutated VH genes. When coupled with analysis of Ig isotype expression, it is now possible to identify four separate CD27+ memory B-cell populations: IgM+/IgD+, IgM+/IgD−, IgM−/IgD+ and IgG+/IgA+. Likewise, CD27− naïve B cells comprise two separate populations: IgM+/IgD+/CD5+ B-1 cells (see below) and IgM+/IgD+/CD5− cells. The collective memory and naïve B-cell populations represent approximately 40% and 60% of peripheral blood B cells, respectively. However, not all memory B cells (i.e., cells with somatic hypermutation) express CD27.[23]

A distinct population of B cells with attributes of both naïve and memory cells are the splenic marginal zone B cells.[24,25] Marginal zone B cells are a first line of defense against encapsulated bacteria in rodents and primates, but there is uncertainty regarding the stage of development and function of marginal zone B cells in humans. This partially reflects the fact that the microscopic anatomy of the human splenic marginal zone differs substantially from rodents.[25] CDR3 spectratyping and gene expression analysis were used to demonstrate that the circulating IgM+/IgD+/CD27+ memory B-cell population is destined to migrate to the spleen to form marginal zone B cells in humans and may be the product of T cell–independent immune responses.[26]

Seminal studies demonstrated that CSR and somatic hypermutation are mediated by an enzyme designated activation-induced cytidine deaminase (AID).[27,28] As might be expected of an enzyme with this function, AID expression is induced in germinal center B cells where CSR and somatic hypermutation occur. There are two somewhat opposing theories on how AID functions to promote antibody diversification. One argument holds that AID subserves an "RNA editing" function; not being the source of hypermutator activity per se, but cooperating with another protein to mediate somatic hypermutation.[29] The prevailing view holds that AID acts directly as a DNA mutator to mutate Ig genes.[30] Interestingly, AID induction also occurs following infection by hepatitis C and the Epstein-Barr virus,[31,32] suggesting that AID plays a role in the innate immune response to viral infection.

As discussed elsewhere in this textbook, neonates are vulnerable to infection with selected pathogens (e.g., encapsulated bacteria) and respond poorly to immunization. In general the neonatal VH repertoire is more restricted than in adults,[33] but this appears to reflect environmental factors (i.e., antigen exposure, hormonal differences) instead of some inherent mechanistic difference in Ig gene rearrangement and VH diversification.

B-1 CELLS

B-1 cells represent a unique population of B cells, originally identified in humans[34] and mice[35] based on the expression of cell surface CD5, a molecule also expressed on most human T lymphocytes. B-1 cells have many developmental and functional attributes that distinguish them from the more conventional follicular-derived B-2 cells that undergo the GC reaction.[36] A wealth of published work in the mouse has revealed an association of B-1 cells with self-reactivity and autoimmunity.[36] Although originally defined by the expression of CD5, it is now known that there are two categories of murine B-1 cells: B-1a (CD5+) and B-1b (CD5−). The former secrete "natural antibodies" critical in the initial response to encapsulated bacteria, whereas the latter have been shown to be important in long-term protection against *Streptococcus pneumoniae.*[37] A long-standing controversy over whether murine B-1 cells originate in a progenitor distinct from B-2 cells may have been resolved by the identification of a B-1 restricted progenitor in murine fetal marrow.[38] Despite considerable knowledge on murine B-1a and B-1b cells, we know less about the identity and function of human B-1 cells. During human fetal development approximately 40% of B cells in the omentum and spleen are CD5+/IgM+, and splenic CD5+ cells reportedly secrete autoreactive IgM.[39] However, if human splenic CD5+ B cells are the counterpart of murine B-1 cells (which are known to play a critical role in immunity to encapsulated bacteria) then it is difficult to explain why infants are so vulnerable to pneumococcal infections.

PLASMA CELL DEVELOPMENT

Plasma cells are terminally differentiated B-lineage cells that secrete copious quantities of antibody central to the humoral immune response. After T cell–dependent or T cell–independent antigen stimulation, plasma cells can develop from all the major mature B-cell compartments, including marginal zone B cells, GC centroblasts, memory B cells, and B-1 cells.[40] Substantial progress has been made in elucidating the identity and function of multiple transcription factors that regulate the potential of an activated B cell to differentiate into a memory B cell or a plasma cell. The basic transcriptional regulatory mechanism comprises distinct genetic programs leading to the development of memory B cells or plasma cells. The transcription factors BCL-6 and PAX5 work in concert to suppress plasma cell development. A prominent target gene of BCL-6 is BLIMP1, a transcription factor the function of which is central to driving activated B cells into plasma cells.[41] PAX5 induces expression of AID[42] and other B-lineage specific genes important for maintenance of a B-cell identity (i.e., CD19 and BLNK).[43] Certain signaling events received at the surface of B-lineage cells may trigger a reduction in BCL-6 levels, which in turn may relieve suppression of BLIMP1. A negative feedback loop then ensues involving BLIMP1 suppression of BCL-6 that, when coupled with the action of two other transcription factors designated XBP1 and IRF4, promotes differentiation to the plasma cell stage.[40] Plasma cells generated in the spleen or lymph nodes during post-GC reactions migrate to the marrow, where they survive for 1 to 2 months. Various integrins and chemokine receptors (e.g., CXCR4) function to promote egress of preplasma cells from spleen/lymph node, followed by migration to and localization in the marrow.

CYTOKINES AND CHEMOKINES IN B-CELL DEVELOPMENT

B-cell development occurs in a complex microenvironment consisting of other lymphohematopoietic cells, stromal cells, and extracellular matrix components such as fibronectin.[44] B-lineage cells develop in the extravascular compartment and, as they differentiate to the immature B-cell stage, migrate to medullary vascular sinuses as a prelude to entering the bloodstream. The term stromal cell is a generic term encompassing multiple cell types, including adipocytes, endothelial cells, osteoblasts, and fibroblastic reticular cells. Marrow stromal cells secrete cytokines and chemokines such as IL-7 and CXCL12 (see later discussion) that mediate development of B-lineage cells. In the mouse, the specific stromal cells that secrete these two molecules may be distinct from one another.[45] In vitro studies using human marrow-derived fibroblastic reticular cells indicated that vascular cell adhesion molecule-1 VCAM-1 plays an important role in the adherence of normal human B-lineage cells.[46,47] A single study to date that examined the physical disposition of human B-lineage cells and marrow stromal cells in situ indicated that B-lineage cells were prominently juxtaposed to CD10+ stromal cells, and that B-cell differentiation was spatially oriented with the most mature cells progressing toward marrow sinusoids.[48] Using gene targeting of cytokines and their receptors, a large number of studies in the mouse have implicated the IL-7 and FMS-related

tyrosine kinase ligand (FLT3-L) as well as the chemokine CXCL12 in the development of murine B-lineage cells.[49] Cytokines such as B cell–activating factor (BAFF), a-proliferation-inducing-ligand (APRIL), and CD40-ligand (CD40L) are expressed by various cell types in the spleen and lymph node and play prominent roles in B-cell survival in the periphery. This section briefly summarizes the effect of these cytokines and chemokines on human B-cell development.

Interleukin-7

The role of interleukin (IL)-7, and its receptor subunits the IL-7Rα chain and the γc chain, have been extensively studied in murine and human lymphopoiesis.[50,51] After its discovery as a B-lineage stimulatory molecule,[52] the physiologic importance of IL-7 was clarified by the demonstration that targeted disruption of the IL-7[53] or IL-7Rα chain[54] genes leads to profound disruption of B-cell development in adult mice. Targeted disruption of the genes encoding the γ_c subunit of the receptors for IL-2, 4, 7, 9, 15, and 21,[55,56] and the JAK3 tyrosine kinase[57,58] also leads to severe disruptions in B-cell development. This is consistent with the now well known structure of the IL-7 receptor and the activation of JAK3 following IL-7 stimulation.[51] Recent studies have clarified the contribution of IL-7 in murine B-cell development. IL-7 deficient mice undergo normal fetal and perinatal B-cell development, culminating in B-1 cell development and a normal-sized marginal zone B-cell compartment.[59] Therefore, B-cell development in fetal and neonatal mice has an element of IL-7 independence. In contrast, mice doubly deficient for FLT3 and the IL-7Rα chain fail to develop fetal and neonatal B-lineage cells.[60] Thus IL-7 and FLT3-L are cytokines that collectively orchestrate fetal and adult murine B-cell development.

Insight into the role of IL-7 in human B-cell development has been gleaned from analysis of patients with congenital and acquired immune deficiency. Patients with severe combined immune deficiency (SCID) with mutations in genes encoding components of the IL-7R signaling pathway often have been cited as evidence that human B-cell development does not have an absolute dependence on IL-7. Similarly, patients with X-linked SCID with γ_c subunit mutations have severe defects in T- and NK-cell development, but have normal or even elevated numbers of peripheral blood B cells.[61] Moreover, patients with autosomal recessive mutations in the JAK3 tyrosine kinase exhibit a lymphocyte developmental phenotype indistinguishable from X-linked SCID,[62,63] including normal numbers of circulating B cells. Further studies have indicated that mutations in the IL-7Rα chain are now the third most common cause of SCID.[64,65] An increase in percentage or absolute number of peripheral blood B cells occurred in essentially all these patients. Thus no doubt exists that circulating B cells in these collective patients with SCID do not have an absolute requirement on IL-7 signaling for their development. However, a normal peripheral blood B cell count does not necessarily equate with normal B-cell development in these patients with SCID. No data are published on the characteristics of marrow B-cell development or the origin and functional capability of circulating B cells in patients with SCID with IL-7R mutations. Furthermore, the requirement for IL-7 signaling could vary in humans as a function of ontogeny, with fetal/neonatal B-cell development being relatively IL-7 independent, as it is in the mouse.

Studies of patients with non-SCID immune deficiency provide a separate perspective on the possible role of IL-7 in human B-cell development. In a clinical study evaluating if in vivo IL-7 administration could restore T-cell numbers in patients with lymphopenic cancer, marrow biopsies performed before and after IL-7 administration revealed a three- to eight-fold increase in the percentage of CD19+/CD10+ B-lineage cells in four of six patients after IL-7 administration.[66] Administration of IL-7 may therefore have induced the expansion of B-cell precursors in the marrow of some patients. Studies in HIV patients[67] and patients with idiopathic CD4+ T lymphocytopenia,[68] the latter being an HIV-independent syndrome, revealed a positive correlation between serum levels of IL-7 and the existence of circulating CD10+/CD27− immature/transitional B cells. In vitro studies have shown that IL-7 transduces a replicative signal to normal human B-lineage cells that is complemented by additional stromal cell–derived signals that cooperate with IL-7 to promote normal human B-cell development.[69] In summary, the precise role of IL-7 in fetal, neonatal, and adult human B-cell development, and the identity of the chemokines that cooperate with and/or compensate for IL-7, remain to be clarified.

FLT3-L

The role of FLT3-L during B-cell development has been facilitated using mouse models, and this signaling pathway may exert an effect at the common lymphoid progenitor stage of development.[70] Similarly, repression of FLT3 expression may be a necessary event for commitment to the B-lineage.[71] Some evidence suggests that FLT3-L can synergize with IL-7 to enhance the proliferation of human pro-B cells isolated from human fetal marrow,[72] and enhance differentiation of cord blood–derived stem cells into B lymphocytes.[73] However, the degree to which FLT3-L plays a role in human B-cell development and whether it can subserve a function distinct from IL-7 signaling is unknown.

CXCL12 (SDF-1)

The chemokine CXCL12 was originally identified as a stromal cell–derived factor that promoted pre-B cell growth in the absence of IL-7.[74] Subsequent studies revealed that CXCR4, one of the receptors used by HIV to gain entry into T lymphocytes, is the receptor mediating CXCL12 effects. CXCL12 has been identified as a chemokine that plays an important role in retention of murine B-cell precursors in the marrow.[75] Studies with human B-lineage cells have indicated that CXCL12 signaling regulates adhesion[76] and migration[77] of early B-lineage cells to stromal cells but plays no role in promoting proliferation.

CD40 ligand (CD154)

The CD40 ligand (CD154) is expressed by T cells and platelets, but not by B cells or monocytes. CD40, a member of the tumor necrosis factor receptor superfamily, is the glycoprotein receptor for CD154.[78,79] CD40 is initially expressed at low level on pro-B cells, is subsequently expressed at high levels on immature and mature B cells, and undergoes down-regulation on plasma cells. B-cell functions that depend on T-cell help often require activation of the CD40/CD154 signaling axis. Engagement of CD40 by CD154 in the presence of cytokines such as IL-4 and IL-13 results in a multitude of functional outcomes specific to the maturational stage of the B cell.[78,79] These range from up-regulation of antiapoptotic genes that promote cell survival, cell cycle entry and proliferation, and CSR and somatic hypermutation during the GC reaction. Thus the differentiation of mature B cells into memory B cells and plasma cells relies heavily on appropriate signals transduced by this axis.[78,79]

BAFF/APRIL

B cell–activation factor of the TNF family (BAFF) and a proliferation inducing ligand (APRIL) are members of the TNF ligand superfamily. Receptors for these molecules include BAFF-R, TACI and BCMA and are differentially expressed initially in transitional B cells. BAFF is secreted by gamma interferon or IL-10 activated macrophages, dendritic cells, and granulocyte colony-stimulating factor–stimulated neutrophils. BAFF/APRIL stimulation leads to

up-regulation of antiapoptotic factors and prolongation of B-cell survival, even in the context of autoreactivity-induced deletion stimuli. Proapoptotic molecules are down-regulated in response to BAFF signaling, further protecting the cell from apoptosis. BAFF signals are also sufficient to induce CSR, although an additional stimulus such as cross-linking of the BCR is needed to induce secretion of class switched immunoglobulin.[80,81]

B-CELL IMMUNODEFICIENCIES

Given the unique and critical role of gene products expressed in early B-cell development, it is no surprise that mutations in some of these genes can have dire consequences on the development and function of human B cells.[82] If a genetic disease affecting B cells deserves the title of a "classic," it would be X-linked agammaglobulinemia. The pediatrician O. C. Bruton[83] originally described an 8-year-old boy with recurrent bacterial infection and no detectable serum gamma globulins. Subsequent studies showed that the disease was inherited in an X-linked pattern[84] and was characterized by an absence of circulating B cells,[85] thus the designation X-linked agammaglobulinemia. Following the characterization of cell surface antigenic maps that define specific stages of B-cell development, it became clear that B-cell development was "arrested" between the pro-B and pre-B stages.[86] Two landmark reports[87,88] then identified the gene mutated in X-linked agammaglobulinemia, and it was christened Bruton tyrosine kinase (Btk). Btk plays a critical role in a variety of biochemical signaling pathways.[89] Notably, after pre-BCR and BCR cross-linking Btk is activated and phosphorylates phospholipase C $\gamma 2$, ultimately culminating in a sustained calcium flux central to proliferation.[89] Hundreds of distinct mutations in Btk have been identified in X-linked agammaglobulinemia, but a relationship between a specific mutation and severity of the disease does not exist. Gammaglobulin is used to treat patients and must be administered throughout life. Rare cases of autosomal recessive agammaglobulinemia have also been described. This heterogeneous cohort includes patients with mutations in the μ heavy chain, the $\lambda 5$ subunit of the surrogate light chain, the pre-BCR/BCR associated signaling molecule Igα, and the adapter signaling molecule BLNK.[82] These patients have similar clinical characteristics to patients with X-linked agammaglobulinemia.

Patients with hyper-IgM syndrome have recurrent infections, elevated serum IgM, a relative paucity of other serum Ig isotypes, and a general failure of B cells to undergo CSR and somatic hypermutation.[90] Mutations in five distinct genes have been found to give rise to this congenital immunodeficiency. The most common is a mutation in CD154 (CD40 ligand) expressed on activated T cells that is inherited as an X-linked mutation. Patients with rare mutations in CD40, IKK-gamma/NEMO, and uracil-DNA glycosylase have also been reported.[90] The critical function of AID in development of a functional Ig repertoire is underscored by the fact that patients with an autosomal recessive form of the hyper-IgM syndrome harbor a deficiency of this enzyme.[91]

Mononuclear Phagocyte System

ORIGIN AND DEVELOPMENT OF MONONUCLEAR PHAGOCYTES

Tissue phagocytes have been recognized as fundamental components of host immune defense. The term *mononuclear phagocyte system* (MPS) identifies a specific lineage of phagocytic hematopoietic cells that share certain morphologic, cytochemical, biochemical, genetic, and functional characteristics.[1,2] In this system, mononuclear phagocytes comprise a cell lineage in which tissue macrophages are derived from circulating monocytes and immature bone marrow precursors. Mononuclear phagocytes share common functional characteristics including: (1) phagocytosis and digestion of invading microorganisms and tissue debris, (2) biosynthesis of numerous secretory products, (3) antigen processing and interaction with lymphocytes in development of the primary immune response, (4) generation of cytoxic response to tumor cells, and (5) performance of specialized tissue functions in concert with functions of other tissue cell types to maintain a homeostatic extracellular environment.[2,3]

Although dendritic cells differ in several morphologic, cytochemical, and functional features from classical cells of the MPS, evidence indicates that at least one population of dendritic cells, the myeloid dendritic cells, are derived from the same bone marrow hematopoietic progenitors as circulating monocytes and macrophages.[4] Because dendritic cells and mononuclear phagocytes share a common progenitor pathway, consideration must be given to including dendritic cells as members of the MPS.[5] Dendritic cells exhibit most characteristics just enumerated. First, dendritic cells are phagocytic cells in which captured material enters endosomes for degradation and antigen processing. Second, they synthesize cytokines that direct actions of innate and adaptive immune cells. Third, dendritic cells are highly effective antigen-presenting cells. Fourth, dendritic cells provide signals for macrophage and T-cell activation. Finally, dendritic cells exhibit specialized functions to maintain homeostasis of the extracellular environment. In this chapter, myeloid dendritic cells are discussed as components of the MPS.

Overview

The mononuclear phagocyte cell lineage originates from a committed progenitor cell present in the bone marrow (Fig. 153-1). Pluripotent stem cells give rise to progenitor cells committed to a program of proliferation and differentiation. Progenitor cells committed to the myeloid lineage, called *colony forming unit–granulocyte macrophages* (CFU-GMs), are supported along various myeloid pathways by actions of glycoproteins called *colony-stimulating factors* (CSFs). CSFs involved in mononuclear phagocyte differentiation include interleukin-3 (IL-3), granulocyte macrophage colony–stimulating factor (GM-CSF), and monocyte colony–stimulating factor (M-CSF or CSF-1). These factors synergize to support differentiation of CFU-GM into macrophages in vitro.[6-8] Addition of M-CSF preferentially induces macrophage differentiation. Inclusion of GM-CSF in combination with IL-4 and tumor necrosis factor–α (TNF-α) generate dendritic cells in vitro.[9-12]

Experiments in which the genes encoding the CSFs have been inactivated in vivo through homologous recombination in mice have increased our understanding of the in vivo role of the CSFs in regulating MPS cell production. Homologous inactivation of the GM-CSF gene did not appear to have a significant effect on fetal, neonatal, or adult growth and did not alter many aspects of granulocyte and macrophage physiology with one notable exception. Affected mice succumbed to alveolar proteinosis as a result of defective alveolar macrophage function.[13,14] Similar results were observed in affected mice when the common β-subunit for the receptors for GM-CSF, IL-3, and IL-5 was inactivated.[15] Shibata and colleagues[16] identified multiple defects in alveolar macrophage function in GM-CSF–deficient mice, including adhesion, phagocytosis, microbicidal activity, surfactant metabolism, and expression of Toll-like receptors (TLRs). Mice suffering from an inherited form of osteopetrosis (op/op) have been shown to have a mutation resulting in M-CSF gene inactivation.[17] Homozygous mutants have a defect in some but not all macrophage populations. The most profound macrophage derangement is in osteoclast numbers leading to severe bone and tooth abnormalities.[18] As op/op mice age, IL-3 expression increases and any of the deficits in the alveolar macrophage population resolve.[19] These studies confirm the importance of CSF function in vivo in MPS development, and, in addition, demonstrate the redundancy in these factors.

The identification and characterization of numerous lineage-restricted transcription factors that regulate the pattern of gene expression in hematopoietic cells suggest that transcription factors may play a key role in regulating hematopoietic progenitor cell proliferation and differentiation.[20] One such transcription factor that plays a significant role in MPS development is designated PU.1 (Fig. 153–2). The importance of this factor is underscored by its developmental expression in alveolar macrophages of GM-CSF knockout mice. Defective PU.1 expression in the alveolar macrophages of GM-CSF–deficient mice leads to impaired host defense functions and surfactant homeostatic mechanisms. These functions are restored using retroviral transduction of the PU.1 gene into alveolar macrophages. Homozygous PU.1-deficient mice also exhibit lack of myeloid dendritic cell development.[21]

Kinetics of Peripheral Blood Monocytes

The normal circulating monocyte count in the healthy human adult is estimated to be between 300 and 450 monocytes/mm^3. Peripheral blood monocyte counts have been observed to vary in a cyclic fashion over a 3- to 6-day period.[22,23]

The production and kinetics of circulating human adult mononuclear phagocytes have been studied by using in vivo pulse labeling of mononuclear phagocytes with tritiated thymidine followed by autotransfusion of radiolabeled leukocytes. The number of promonocytes present in bone marrow has been estimated to be between 3% and 5%, with approximately 40% of the promonocytes actively proliferating.[24] The promonocyte cell cycle rate varies between 30 and 48 hours. These rapidly dividing cells achieve a production rate between 7×10^5 and 7×10^6 monocytes/kg of body weight per hour. After 60 hours of maturation in the bone marrow, mature monocytes move into the intravascular space where they

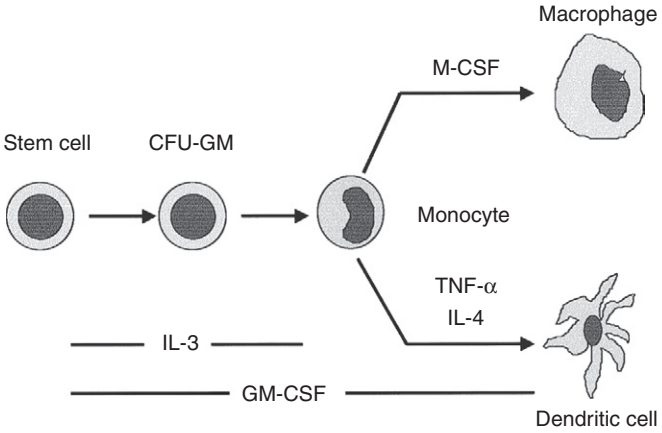

Figure 153-1 Mononuclear phagocyte cell lineage. *CFU-GM,* Colony-forming units granulocyte macrophage; *IL-3*, interleukin-3; *GM-CSF*, granulocyte macrophage colony-stimulating factor; *M-CSF*, macrophage colony–stimulating factor; *TNF-α*, tumor necrosis factor–alpha; *IL-4*, interleukin-4.

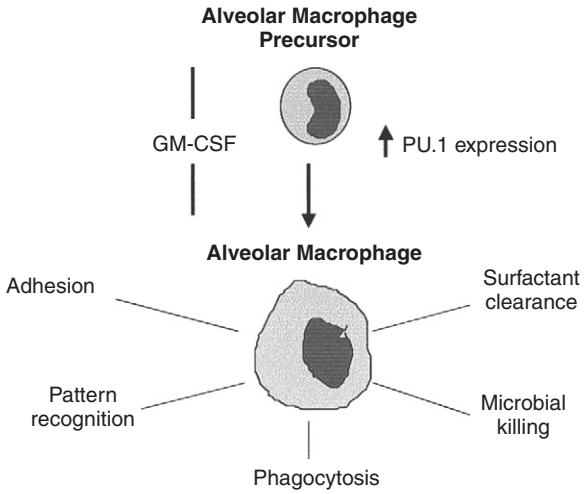

Figure 153-2 Role of granulocyte macrophage colony–stimulating factors (GM-CSF) and PU.1 in regulation of differentiation and function of the alveolar macrophage. GM-CSF induces the transcription factor, PU.1, in macrophage precursors in the lung. PU.1 is required for terminal maturation of alveolar macrophages, and it enables these cells to play critical roles in maintenance of lung homeostasis and innate immune responses.

circulate for approximately 3 days.[24] Van Furth and co-workers[2] calculated that 1.66×10^{10} circulating monocytes leave the intravascular space/hour. Therefore these investigators estimated the turnover of monocytes to be 0.4×10^{9} cells/day. Whitelaw[25] has suggested that the total intravascular monocyte pool is composed of a marginated pool and a circulating pool. He calculated that the marginated pool was 3.3 times greater than the circulating pool. Other investigators have failed to confirm a marginated pool of monocytes in human subjects.[2] Experiments in mice and rats provide evidence for marginated monocyte pools.[26,27]

Kinetics of Macrophages

Analysis of tissue macrophage kinetics is difficult given that the ultimate fate of tissue macrophages is not precisely known. Alveolar macrophages purportedly move from the respiratory tract to the alimentary tract, where they are eventually cleared.[28] The fate of other tissue macrophages has not been determined.

Tissue macrophages are derived from bone marrow precursors. The first evidence for the bone marrow origin of macrophages was obtained in mouse chimeras and rat parabiosis experiments.[29,30,31] Studies in human subjects have confirmed the data observed in animal experiments. In several patients undergoing bone marrow transplantation, isolation and characterization of lung and liver macrophages provided evidence that these cells contained the karyotype of the bone marrow donor.[32,33] Thus terminally differentiated macrophages must have been derived from transplanted bone marrow. Furthermore, after disappearance of the Y-body–containing macrophages from male patients who received female donor marrow, the half-life of the alveolar macrophage was an estimated 81 days.

The size of the tissue macrophage compartment is considerable. By some estimates, the tissue macrophage compartment is 500 to 1000 times larger than the bone marrow compartment. Some organs, such as the lung and liver, may have particularly large macrophage populations that may account for between 20% and 30% of the total cell number. These cells are long lived, and in a number of tissues have been estimated to survive for several months.[28,32,33]

Fetal Period

Embryonic macrophages can be identified early in hematopoietic tissues of the yolk sac. Tissue macrophages present at 3 to 4 weeks gestation do not appear to be associated with mononuclear phagocyte precursors (promonocytes and monocytes). Determination of the origin of these cells challenges the mononuclear phagocyte concept, in which macrophages are believed to be derived from immature precursors. The true origin of these macrophages remains to be clarified, although some investigators believe that these cells differentiate directly from hemocytoblasts.[34] Cline and Moore[35] have demonstrated that murine macrophages develop in vitro from primitive yolk sac precursors. They propose that the macrophage develops from a progenitor in the yolk sac that is proximal to promonocyte and monocyte stages of maturation. Later in gestation when the yolk sac is open to the fetal circulation, promonocytes, monocytes, and macrophages are all readily identifiable.

The liver becomes the predominant hematopoietic organ in the second month of gestation. At 4.5 weeks gestation, approximately 70% of blood cells present in the liver are morphologically identifiable as macrophages.[36] Over the next 6 weeks, macrophages decrease to approximately 1% to 2% of all differentiated blood cells in the liver, with erythroblasts becoming the most numerous blood-cell type in that organ. Primitive hemocytoblasts never account for more than 5% of all hematopoietic cells in the liver.

Although monoblasts and promonocytes may be identified during the period of liver hematopoiesis, true mature monocytes do not appear in the intravascular system of the fetus until the fifth month of gestation.[37] Circulating monocyte numbers remain low until after the sixth month of gestation, at which time bone marrow hematopoiesis predominates. During the first trimester of gestation, monocytes account for 2% to 4% of all hematopoietic cells. At approximately 30 weeks gestation, monocytes constitute 3% to 7% of all hematopoietic cells.[38]

Analysis of mononuclear phagocyte kinetics has not been possible in the fetal tissue examined. Mitotic figures have been seen in 0.1% to 1.2% of all hematopoietic cells in tissues. However, because of the difficulty of adequate preparation of tissues between delivery and the time of analysis, the number of cells in mitosis might actually be higher.[34] Therefore the kinetics of mononuclear phagocyte production and distribution to the tissues during the fetal period remain to be determined.

Neonatal Period

Analysis of the origin and development of mononuclear phagocytes in the neonatal period has been limited by the minimal number of approaches available to sample tissue macrophage populations in these patients. The total cellularity of the bone marrow averages 1.36×10^{11} cells/L on the first day of life but declines to 3.5×10^{10} cells/μL by the ninth day of life.[39] Analysis of bone marrow preparations from premature and term infants suggests that there are no significant differences in the differential counts of marrow elements for these populations of newborn infants.

There is a relative monocytosis present throughout the neonatal period. Peripheral blood monocyte counts are highest during the first 24 hours of life and decline over the remainder of the first month of life. Xanthou[40] reported that the peripheral monocyte counts of newborn infants in the first week of life range from 300 to 2100 cells/mm^3 with a mean of 1000 cells/mm^3. Weinberg and colleagues[41] analyzed the peripheral blood monocyte count in newborn infants and found a range between 0 and 1912, with a median of 600 monocytes/mm^3 in the first 60 hours of life. They also observed a decline in the upper limit of normal during the first month of life, but the median value of 600 cells/mm^3 remained constant. One problem encountered by all of these investigators, which may account for discrepancies in absolute numbers detected, is that mononuclear phagocytes in the newborn period are morphologically heterogeneous. Some monocytes are difficult to differentiate from myelocytes or metamyelocytes belonging to the neutrophil series, whereas other monocytes appear to be morphologically similar to large immature granular lymphocytes.[42]

Analysis of tissue macrophage kinetics in newborn infants has been limited to the examination of pathologic specimens or those gathered at autopsy of cases of stillborn or neonatal death. Alenghat and Esterly,[43] who performed histologic examination on the lungs of 200 consecutive infants who were stillborn or who died during the neonatal period, reported that the lungs of stillborn infants rarely contained alveolar macrophages. The presence of alveolar macrophages was confirmed in only 4 of 100 stillborn infants, and evidence of congenital pneumonia was present in several of these cases. In those babies who survived fewer than 48 hours, alveolar macrophages were observed in 33 of 46 patients. Infants who survived for longer than 48 hours uniformly had alveolar macrophages present in their lungs; however, in most of these cases, pneumonic infections were identified. Alveolar macrophages were detected in infants of all gestations (that is, longer than 30 weeks) who survived longer than 48 hours after birth. These investigators concluded that few alveolar macrophages were present in fetal lungs before birth, but that postnatally, a rapid influx is highly probable.

Experiments in a variety of animal models have confirmed the observation that fetal lung tissue contains few alveolar macrophages.[44-47] Soon after birth in most animal species studied, there are significant increases in the number of alveolar macrophages. Analysis of macrophage kinetics in these studies suggests that macrophage populations in the lungs are replenished both by a continuous monocyte influx and by local proliferation of macrophages.

CHARACTERIZATION OF MONONUCLEAR PHAGOCYTES

Morphology

The morphology of human monocytes and macrophages has been extensively studied at light and electron microscopic levels.[48] The ultrastructure of monocytes is notable for a well-developed Golgi apparatus with a small endoplasmic reticulum containing ribosomes and polysomes. Mitochondria are abundant. Numerous granules containing various lysosomal enzymes are distributed throughout the cytoplasm. The surface membrane of the monocyte includes an extensive system of microvilli. Macrophages are larger than monocytes. The Golgi apparatus, lysosomal granules, and mitochondria are larger than in monocytes. A prominent feature of macrophages is the presence of electron-dense lysosomes along the cell surface. Granules and vacuoles are seen along the periphery of the cell, indicating enhanced pinocytosis. Phagosomes containing ingested material are present at various stages of degradation.

Dendritic cells received their name from their distinctive morphology. They are notable for their irregular shape and numerous membrane processes including spiny dendrites, bulbous pseudopods, and lamellipodia or veils.[49] Distinctive electron microscopic features include prominent mitochondria, endosomes, and lysosomes in the cytoplasm.

Histochemistry

Monocytes and macrophages can be delineated from other leukocytes by cytochemical techniques that detect cellular constituents and biochemical processes. One of the most reliable of these markers is nonspecific esterase, which can be demonstrated using α-naphthyl butyrate as a substrate.[1] Many cell types contain nonspecific esterase, but the isozyme present in monocytes can be identified by inhibition with sodium fluoride.[50] Nonspecific esterase is expressed on the surface of peripheral blood monocytes. As monocytes differentiate into macrophages, additional isozymes of nonspecific esterase are expressed, leading to intense cytoplasmic staining.[51] Cord blood monocytes stain positive for nonspecific esterase, however, the proportion of esterase-positive cells is lower than in adult peripheral blood.[52] Peroxidase activity is also prominent in monocytes and diminishes as they mature into macrophages.[53] No differences are observed in peroxidase activity between monocytes from neonates and adults.

Dendritic cells lack many of the enzymes associated with other members of the MPS. Cytochemical reactions show that dendritic cells lack myeloperoxidase and have low levels of 5-nucleotidase, dipeptidylpeptidase, and cathepsin B activity.[54-57] Other intracellular enzymes, such as nonspecific esterase, acid phosphatase, and lysosomal CD68 may be present in dendritic cells, but their intensity is less than in monocytes or macrophages.[58] Nonspecific esterase decreases with activation of dendritic cells.[59]

Cell Surface Receptors

Numerous cell surface receptors have been identified on human mononuclear phagocytes. Ligands recognized by mononuclear phagocyte receptors include bioactive lipids, carbohydrates, complement components, cytokines, extracellular matrix, growth hormones, pathogen-associated pattern recognition, polypeptide hormones, and lipoproteins.

Fc receptors (FcRs) for immunoglobulin G (IgG) were identified nearly four decades ago with the observation that IgG antibodies could be directly cytophilic for macrophages when opsonized to erythrocytes.[60] Subsequent in vitro studies established the role of these receptors in triggering leukocyte effector functions such as macrophage phagocytosis and neutrophil activation by IgG immune complexes.[61,62] Our current understanding of IgG FcRs has been greatly enhanced by molecular cloning of the murine genes and their human counterparts and by the recently described crystal structures for both receptors.[63-68] Two general classes of FcRs are now recognized: activation receptors characterized by the presence of a cytoplasmic immunoreceptor tyrosine-based activation motif (ITAM) sequence; and an inhibitory receptor, characterized by the presence of an immunoreceptor tyrosine inhibition motif (ITIM) sequence.[69,70] Immunoreceptor activation and inhibitory receptors bind IgG with comparable affinity and specificity; therefore coengagement of both signaling pathways sets the threshold and magnitude for the

effector cell response.[71] The balanced function of these receptors has been comprehended through analysis of mice deficient in either the receptor or signaling pathway component.

Activation FcRs include an ITAM motif either intrinsic to the receptor, as in the case of FcγIIA, or as part of an associated subunit, as in FcγI and FcγRIIIA. Cross linking of the ligand-binding extracellular domain results in tyrosine phosphorylation of the ITAM by members of the src family kinases. This leads to recruitment of SH2-containing signaling molecules that engage phosphorylated ITAM. Depending on the particular cell type activated by FcR, different kinases are involved in these signaling pathways. Early signaling events include activation of phosphatidylinositol-3 kinase (PI3 kinase), the enzymatic activity that leads to production of phosphatidyl-inositol-3,4,5-trisphosphate (PIP3) and recruitment of binding proteins of the pleckstrin homology (PH) domain class such as phosholipase Cγ (PLCγ).[72-74] Ultimately, activation of PLCγ leads to sustained calcium mobilization. The significance of this activity for FcR function has been determined through analysis of PLCγ2-deficient mice.[75] Cellular processes associated with FcγR activation receptors include degranulation, phagocytosis, antibody-dependent cellular cytotoxicity (ADCC), transcription of cytokine genes, and release of inflammatory mediators.[61,62]

Both activation and inhibitory receptors are present on cells of the MPS, notably monocytes, macrophages, and dendritic cells. In general, activation and inhibitory FcγRs are coexpressed on the same cell, a physiologically important means of establishing a threshold for activating stimuli, because the IgG ligands engage both receptors. The ratio of these two opposing signaling systems determines the cellular response. Importantly, these receptors are modulated in their expression during development and differentiation of effector cells by the cytokine activation of these cells.

Microbes display molecular arrays or patterns that are recognized by pattern-recognition molecules. These patterns are shared among groups of pathogens. Representative examples are the lipopolysaccharide (LPS) of gram-negative bacteria, the glycolipids of mycobacteria, peptidoglycans and lipoteichoic acid of gram-positive bacteria, the mannans of yeast, and the double stranded RNA of viruses.[76-78] Important features of these microbial patterns are that they: (1) represent invariant structures shared by large groups of microorganisms, (2) are absolutely essential for the microbe's survival, and (3) are not produced by the host organism.[79] To limit infection the mammalian host uses an array of pattern-recognition molecules. These include complement, the collectins, and a battery of antimicrobial peptides that act with effector cells to combat infectious challenge.

The immune system detects and eliminates invading pathogenic microorganisms by discriminating between self and nonself. In mammals the immune system can be divided into branches: innate immunity and adaptive immunity. Adaptive immunity detects nonself through recognition of peptide antigens using antigen receptors on the surface of B and T lymphocytes. In order to respond to a wide range of potential antigens, B and T lymphocytes rearrange their immunoglobulin and T-cell receptor genes to generate more than 10^{11} different species of antigen receptors. Engagement of antigen receptors by cognate antigens triggers clonal expansion of lymphocytes and further production of antigen-specific antibodies. This sophisticated system is operative only in vertebrates. In contrast, the innate immune system is phylogenetically conserved and is present in almost all multicellular organisms.[80] The mechanisms by which the innate immune system recognizes nonself remained unknown until quite recently. The identification of Toll-like receptors in mammals—and the recognition of their role in detection of specific patterns of microbial components and in regulation of both innate and adaptive immune functions—represents a major advance in our understanding of immunity.

The involvement of Toll receptors in innate immunity was first described in *Drosophila*. The signaling pathway of *Drosophila* Toll shows remarkable similarity to the mammalian IL-1 pathway, which leads to activation of nuclear factor κB (NF-κB), a transcription factor responsible for many aspects of inflammatory and immune responses. The cytoplasmic *Drosophila* Toll and the mammalian IL-1 receptor are highly conserved and are referred to as the *Toll/IL-1 receptor* (TIR) domain. Base on this similarity it was suggested that the Toll pathway might mediate immune responses.[81] This was clearly demonstrated in a study of mutant *Drosophilia* lacking certain components of the Toll pathway.[82] Each mutant was highly susceptible to fungal infection caused by its inability to express the antifungal peptide drosomycin. Subsequent studies indicate that the Toll pathway is required for resistance to gram-negative and gram-positive bacterial infections in addition to fungal infections.

A year after the discovery of the role of *Drosophila* Toll in the host defense against fungal infections, a mammalian homologue of the *Drosophila* Toll was identified.[83] Subsequently, a family of proteins structurally related to *Drosophila* Toll was identified. This family of proteins is collectively referred to as the Toll-like receptors (TLRs), Currently, the TLR family consists of 10 members (TLR1-TLR10) in humans.[83-88] Ectopic expression of TLR4, the first mammalian TLR identified, was shown to induce genes for several inflammatory cytokines.[83] Therefore it was anticipated that the TLRs might be instrumental in immune responses, in particular in the activation of innate immunity. In 1998 it was determined that TLR4 was involved in the recognition of LPS, a major component of gram-negative bacteria. Thereafter, other members of the TLR family were shown to be essential for the recognition of a range of microbial components (Table 153-1). The structural similarity of TLRs seems to reflect their common function in recognition of microbial components.

TABLE 153-1

Toll-Like Receptors and Their Ligands

TLR Family	Ligands (Origin)
TLR1	Triacyl lipopeptides (bacteria, mycobacteria)
	Soluble factors *(Neisseria meningitidis)*
TLR2	Lipoproteins/lipopeptides (variety of pathogens)
	Peptidoglycan (gram-positive bacteria)
	Lipoteichoic acid (gram-positive bacteria)
	Lipoarabinomannan (mycobacteria)
	Porins *(Neisseria)*
	Zymosan (fungi)
	Atypical LPS *(Porphyromonas gingivalis)*
	HSP70 (host)
TLR3	Double-stranded RNA (virus)
TLR4	LPS (gram-negative bacteria)
	Taxol (plant)
	Fusion protein (RSV)
	Envelope protein (MMTV)
	HSP60 *(Chlamydia pneumoniae)*
	HSP60 (host)
	HSP70 (host)
	Type III repeat extra domain A of fibronectin (host)
	Oligosaccharides of hyaluronic acid (host)
	Polysaccharides of heparin sulfate (host)
	Fibrinogen (host)
TLR5	Flagellin (bacteria)
TLR6	Diacyl lipopeptides (mycoplasma)
TLR7	Imidazoquinolone (synthetic compound)
	Loxoribine (synthetic compound)
	Bropirimine (synthetic compound)
TLR8	Unknown
TLR9	CpG DNA (bacteria)
TLR10	Unknown

Recognition of LPS is an important function of innate immunity that can have profound consequences for the host. Failure to contain the infection can result in gram-negative sepsis, shock, and death as a result of LPS release. Two LPS-binding proteins have been characterized in mammals; these are the bactericidal permeability–increasing protein (BPI) and LPS-binding protein (LBP).[89,90,91] Binding of LPS by these molecules results in markedly different functional consequences.[92] BPI is a neutrophil granular pattern–recognition molecule that exhibits selective toxicity against gram-negative bacteria. BPI has two distinct functional domains, one that binds LPS and is antimicrobial and the other that is opsonic.[93] BPI is most effective at the site of infection and acts in synergy with other antimicrobial peptides such as defensins and the membrane attack complex of complement. In contrast, LBP enhances the sensitivity to LPS by binding to the lipid A moiety of LPS thus allowing triggering of circulating effector at subpicomolar concentrations of LPS. LBP plays a significant role in clearance of bacteria from the circulation. This clearance is mediated by activation of NF-κB through the CD14/TLR4 signal transduction pathway. LBP enhances the efficiency of this pathway by binding LPS and shuttling it to the CD14/TLR complex.

Two mouse strains, C3H/HeJ and C57BL10/ScCr, have long been known to be hyporesponsive to LPS. The C3H/HeJ mouse strain was found to have a point mutation in the intracellular region of the *Tlr4* gene leading to replacement of a highly conserved proline with histidine. This mutation results in generation of a dominant negative allele leading to defects in TLR4-mediated signaling and suppression of the response to LPS.[94,95] The C57BL10/ScCr mouse strain was found to have a null mutation in the *Tlr4* gene.[96]

The LPS-LBP complex is subsequently recognized by CD14, a molecule preferentially expressed on monocytes, macrophages, and dendritic cells. LPS stimulation is followed by close physical proximity of CD14 and TLR4. MD-2 was identified as a molecule associated with the extracellular portion of TLR4 whose presence enhances LPS responsiveness.[97,98] Indeed, generation of MD-2–deficient mice demonstrates the essential role of MD-2 in the response to LPS. Macrophages and dendritic cells from MD-2–deficient mice display severely impaired responses to LPS.[99]

The engagement of TLRs by LPS and other TLRs by microbial components triggers the activation of signaling cascades (Fig. 153-3). After binding, TLRs dimerize and undergo conformational changes that enable recruitment of TIR domain–containing adaptor molecules to the TIR domain of the TLR. There are four adaptor molecules: (1) MyD88, (2) TIR-associated protein (TIRAP/MyD88 adaptor-like, or Mal), (3) TIR domain-containing adaptor protein–inducing inerferon (IFN-β) (TRIF)/TIR domain-containing molecule 1 (TICAM1), and (4) TRIF-related adaptor molecule (TRAM).[100-102] The differential responses mediated by distinct TLRs can be explained by selective usage of adaptor molecules. MyD88 and TRIF activate signaling pathways leading to production of proinflammatory cytokines and type I IFNs, respectively.

MyD88 is a critical component for signaling of all TLRs except TLR3. Upon stimulation, MyD88 associates with the cytoplasmic portion of TLRs and then recruits IL-1R–associated kinase 4 (IRAK-4) and IRAK-1 through a homophilic interaction. In TLR2 and TLR4 another adaptor molecule, TIRAP/Mal, is required for MyD88 engagement with the receptor.[103-105] After IRAK-1 associates with MyD88 it is phosphorylated by the activated IRKA-4 and subsequently associates with TNFR-associated factor (TRAF) 6, which acts as a ubiquitin protein ligase (E3).[106] TRAF6, in combination with a ubiquitination E2 enzyme complex consisting of UBC13 and UEV1A, catalyzes the formation of a K63-linked polyubiquitin chain on TRAF6 and on IKK-γ/NF-κB essential modulator (NEMO).[107] A complex including TGF-β-activated kinase 1 (TAK1) and the TAK1 binding proteins TAB1, TAB2, and TAB3 is also recruited to TRAF6.[108] TAK1 phosphorylates IKK-β and mitogen-activated protein (MAP) kinase kinase 6 (MKK6), which in turn modulates the activation of NF-κB and MAP kinases, resulting in induction of genes involved in the inflammatory response. In addition to NF-κB, the transcription interferon regulatory factor (IRF)5 is involved in regulation of cytokine genes.[109] Upon stimulation of the TLR, IFR-5 translocates to the nucleus and binds IFN-stimulated response elements (ISRE) motifs present on the promoter regions of cytokine genes.

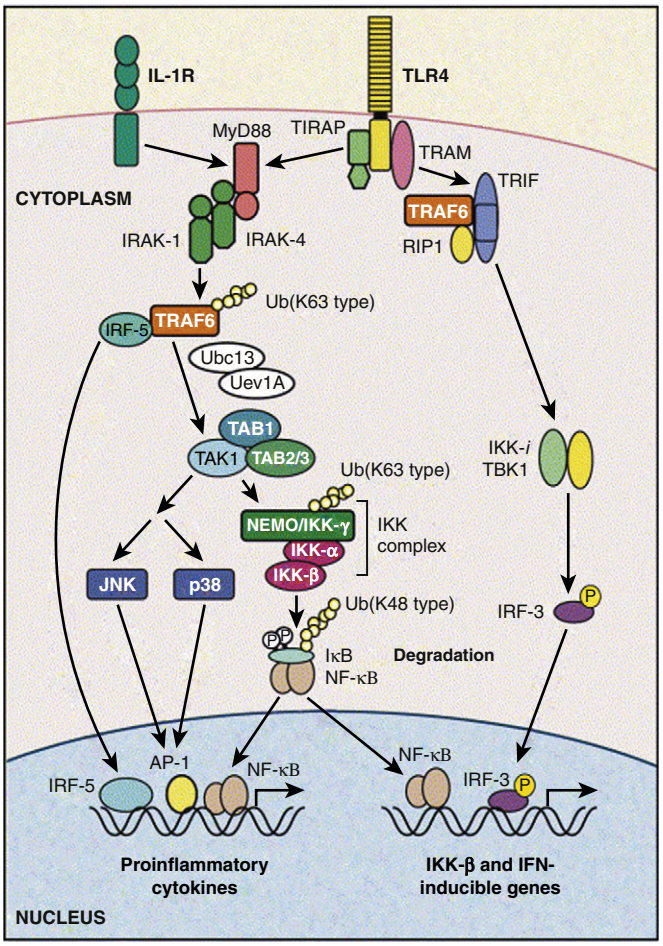

Figure 153-3 The TLR signaling pathway. TLRs and IL-1R share common signaling pathways in general. Stimulation with their ligands recruits TIR domain–containing adaptors including MyD88 and TIRAP to the receptor and the subsequent formation of a complex of IRAKs. TRAF6, and IRF-5 is induced. TRAF6 acts as an E3 ubiquitin ligase and catalyzes the K63-linked polyubiquitin chain on TRAF6 itself and NEMO with E2 ubiquitin ligase complex of UBC13 and EUEV1A. This ubiquitination activates the TAK1 complex, resulting in the phosphorylation of NEMO and activation of IKK complex. Phosphorylated of IκB undergoes K-48-linked ubiquitination and degradation by the proteosome. Freed NF-kB translocates to the nucleus and initiates the expression of proinflammatory cytokine genes. Simultaneously, TAK1 activates the MAP kinase cascades, leading to the activation of AP-1, which is also critical for the induction of cytokine genes. TLR4 triggers the MyD88-independent, TRIF-dependent signaling pathway via TRAM to induce type I Fins. TRIF activates NF-κB and IRF-3, resulting in the induction of proinflammatory cytokine genes and type I IFNs. TRAF6 and RIP1 induce NF-κB activation and TBK1/IKK-I phosphorylates IRK-3, which induces translocation of IRF-3. *(From Akira S, Uematsu S, Takeuchi O. Pathogen recognition and innate immunity,* Cell *124:783-801.)*

Stimulation with TLR3, TLR4, TLR7, and TLR9 ligands induces type I IFN production in addition to proinflammatory cytokine signals. TLR3 and TLR4 have the ability to induce IFN-inducible genes in the absence of MyD88 signaling. The activity of these pathways leads to dendritic cell (DC) maturation, costimulatory molecules, and secretion of IFNα/β.[110] This MyD88 independent pathway is initiated by TIR domain-containing adaptor, TRIF.[111,112] TRAM, another TIR domain-containing adaptor, is specifically associated with TLR4 activation of TRIF. TRIF interacts with receptor-interacting protein 1 (RIP1), which is responsible for the activation of NF-κB.[113] In addition TRIF activates TRAF family member–associated NF-κB activator (TANK) binding kinase 1 (TBK1). TBK1 comprises a family with inducible IκB kinase (IKK-i), and these kinases directly phosphorylate IRF-3 and IRF-7.[114] Phosphorylated IRS-3 and IRF-7 form homodimers, translocate to the nucleus, and bind to the ISREs resulting in expression of a set of IFN inducible genes.

Förster-Waldl and co-workers[115] found reduced TLR4 surface protein and TLR4-specific mRNA in monocytes derived from preterm infants compared with those of mature infants and adults. They found that reduced TLR4 expression paralleled diminished in vitro LPS-stimulated IL-1β, IL-6, and TNF-α secretion. Levy and colleagues[116] reported a striking decrease in sensitivity of monocytes in human neonatal cord blood, compared with monocytes in adult peripheral blood, to the TNF-α–inducing effect of multiple TLR ligands, including bacterial lipopeptides (BLPs), LPS, and the imidazoquinoline compound, imiquimod. In marked contrast, they found that TNF-α release in response to R-848, a TLR ligand that is a congener of imiquimod, was equivalent in newborn and adult blood. Differences in ligand-induced TNF-α release correlated with divergent ligand-induced changes in monocyte TNF-α mRNA levels. Newborn and adult monocytes did not differ in basal mRNA or protein expression of TLRs or mRNA expression of functionally related molecules. However, newborn monocytes demonstrated diminished LPS-induced, but equivalent R-848–induced, phosphorylation of p38 mitogen-activated protein kinase and altered BLP- and LPS-induced acute modulation of cognate receptors, suggesting that the mechanism accounting for the observed differences may be localized proximal to ligand recognition by surface TLRs. Interestingly, newborn plasma substantially reduced BLP-, LPS-, and imiquimod-induced TNF-α release in adult monocytes without any effect on R-848–induced TNF-α release, reflecting differences in a plasma factor(s) distinct from soluble CD14. Impaired response to multiple TLR ligands may significantly contribute to immature neonatal immunity.

Cell Surface Antigens

Morphologic, cytochemical, and enzymatic characteristics have been traditionally used for the identification of mononuclear phagocytes. Monoclonal antibody techniques have provided a more precise description of the mononuclear phagocyte lineage relationships and differentiation sequence.[48] As a result of the large number of monoclonal antibodies generated against cell surface antigens of leukocytes, an international workshop was convened to classify and characterize monoclonal antibodies and their leukocyte cell surface antigens. The Human Leukocyte Differentiation Antigen Workshop has evaluated thousands of antibodies to develop common nomenclature.[117] Monoclonal antibodies having similar reactivity patterns to cellular antigens are given a common cluster of differentiation (CD) designation. Table 153-2 summarizes several CD groupings for the MPS discussed in this chapter. Well-described class I and class II major histocompatibility antigens are not included in the table.

During ontogeny, macrophages in the fetal liver express CD11b as early as 12 weeks gestation.[118] Another antigenic determinant, CD14, appears to be a more mature antigen. Its expression does not appear until 15 to 21 weeks gestation. CD14 expression in cord blood and adult blood monocytes is equivalent.[119] In contrast, CD11a, CD11b, and CD11c are expressed at lower density on cord blood monocytes than on cells from adults. Several investigators have reported that human leukocyte antigen (HLA)-DR, HLA-DP, and HLA-DQ are expressed at lower density on neonatal monocytes than on adult monocytes.[52,120-122] Furthermore, HLA-DR expression is decreased in monocytes from preterm neonates when compared with term neonates.[123,124] Class II histocompatibility antigen density on macrophages has been correlated to antigen presentation capacity in vitro.[125] It remains to be determined whether developmental differences in these antigens account for deficient antibody responses to certain foreign antigens in the newborn period.

Dendritic cells lack expression of surface antigens specific for other leukocytes including T cells (CD3), monocytes (CD14), neutrophils (CD16), B cells (CD19), and natural killer (NK) cells (CD56).[126] Myeloid dendritic cells differentiate directly from CD34+ precursors or indirectly from CD14+ monocytes.[127,128] They express surface markers associated with myeloid cells, such as CD11b and CD11c.

TABLE 153-2

CD Antigens on Mononuclear Phagocyte Cells

CD	Ligand, Receptor, Associated Molecules	Cell Type
CD4	MHC Class II, Gp120, IL-16	DC, Mono
CD11a	ICAM 1,2,3	Mono, Mac, Myeloid
CD11b	iC3b	DC, Mono, Mac, Myeloid
CD11c	iC3b	DC, Mono, Mac
CD14	LPS	Mono, Mac
CD16	Fc	DC, Mac
CD18	CD11a,b,c	Mono, Mac
CD40	CD40L	DC, Mono, Mac
CD80	CD28, CD152 (CTLA-4)	DC, Mono, Mac
CD123	IL-3	DC, Mono, Mac

BIOCHEMISTRY AND METABOLISM OF MONONUCLEAR PHAGOCYTES

Monocyte Metabolism

Metabolic activities of the cells of the MPS vary considerably based on their stage of development, site of origin, and state of activation. Human adult peripheral blood monocytes require an intact glycolytic pathway that is not adversely affected by inhibition of oxidative phosphorylation.[129] Peripheral blood monocytes placed in tissue culture environment demonstrate increased glycolysis with concomitant time-dependent increase in lactate accumulation in the culture media.[130]

Prindull and Prindull[131] compared the glycogen content of mononuclear phagocytes from premature and term newborn infants with that of adult subjects. The glycogen reserves under resting conditions were similar; however, during experimental inflammatory conditions mononuclear phagocytes from adult subjects increased their glycogen content, presumably through pinocytosis of neutrophil glycogen. In contrast, the glycogen content of mononuclear phagocytes from newborn infants decreased. In other studies, the glycolytic activity of cord-blood mononuclear cells (preparations included monocytes and lymphocytes) from preterm and term newborn infants was compared with mononuclear cells from adult peripheral blood.[132] Mononuclear cells from term and premature cord blood cells demonstrated decreased glycolysis and little metabolic activity in response to phytohemagglutinin (PHA) stimulation, whereas cells from adult blood completely converted glucose to lactate and demonstrated a significant increase in glycolysis in response to stimulation with

PHA. In addition, cord blood monocyte pyruvate kinase activity and adenosine triphosphate concentrations were significantly diminished compared with measurements obtained from adult peripheral blood monocytes. These investigators proposed that diminished energy metabolism might contribute to the dysfunction in host defense exhibited by newborn infants.

Macrophage Metabolism

Human adult macrophages are capable of using both glycolytic and oxidative phosphorylase pathways to derive their energy requirements. The operative pathway depends on the site of tissue origin. The pulmonary alveolar macrophage exhibits a high degree of oxygen consumption, whereas peritoneal macrophages depend predominantly on anaerobic glycolysis to provide their energy needs.[133] Analysis of the glycolytic enzymes lactate dehydrogenase and pyruvate kinase and the mitochondrial enzyme glutamate dehydrogenase in macrophages suggests that the metabolic activity of tissue macrophages may be determined by the oxygen tension in the environment. This hypothesis was substantiated by Bar-Eli and colleagues[134] who reported that macrophages derived from a single progenitor cell can develop different metabolic features in response to the oxygen tension in the environment in which they mature. The metabolic state of fetal and neonatal human tissue macrophages has not been determined.

Biosynthesis of Reactive Oxygen Intermediates

Mononuclear phagocytes are capable of either reducing or exciting oxygen molecules to produce highly reactive intermediates, such as superoxide anion, hydrogen peroxide, and the hydroxyl radical. Shortly after the mononuclear phagocyte interacts with stimuli, oxygen consumption increases dramatically. This respiratory burst is associated with enhanced microbicidal activity, particularly in circulating blood monocytes. The respiratory burst and production of reactive oxygen intermediates are discussed in detail in separate studies by Babior[135] and by Nathan and Tsunawaki.[136]

The nitroblue tetrazolium (NBT) dye test is a screening device used to determine deficiencies in oxidative metabolism. The NBT assay is based on the ability of reactive oxygen intermediates to reduce the soluble yellow NBT dye to a blue-black (formazan) insoluble material that precipitates in the cytoplasm and is readily identified by light microscopy.[137] Cells derived from patients with inherited phagocyte deficiencies of oxidative metabolism fail to reduce NBT.[138] Light emission (chemiluminescence) can also be used to detect the respiratory burst when mononuclear phagocytes generate reactive oxygen intermediates in response to external stimuli. This property provides a semiquantitative assay for the formation of oxygen radicals.

Investigators comparing the respiratory burst generated by cord and adult blood monocytes using the quantitative spectrophotometric NBT assay found no differences in the ability of these cells to reduce NBT in vitro.[139] Direct quantitative measurement of oxygen consumption, superoxide anion levels, and hydrogen peroxide production have been performed in parallel studies of cord blood and adult peripheral blood monocytes. These studies suggest that the cord blood monocyte has a respiratory burst that is similar in magnitude to that of adult peripheral blood monocytes.[140]

Macrophages derived from cord blood and adult peripheral blood were found to be equivalent in their capability to generate superoxide in response to soluble stimuli.[140] Treatment of cord blood and adult blood monocyte–derived macrophages with LPS or muramyl dipeptide enhanced production of superoxide anion in response to a soluble stimulus.[141] The superoxide generation by muramyl dipeptide-primed cord blood monocyte–derived macrophages was significantly less than that generated by primed cells from adult blood.[140] These investigators postulated that diminished superoxide generation in response to a priming stimulus indicates that cord blood monocytes may have a diminished capacity to differentiate into activated macrophages.

Biosynthesis of Complement Proteins

The complement (C) system is composed of at least 20 circulating plasma proteins, five membrane-bound proteins that regulate the binding or degradation of complement components, and seven membrane-bound proteins that bind complement components or cleave fragments of components. The complement cascade may be activated through either a classical or an alternative pathway to generate numerous biologically active products. Activation of this cascade through either pathway produces low-molecular-weight inflammatory peptides (termed *anaphylatoxins*) and a final large complex of proteins (termed *the membrane attack complex*) that insert into the target cell membrane, resulting in cell lysis.[142] The anaphylatoxins bind cell surface receptors on many target tissues, which results in release of vasoactive substances, cytokines, arachidonic acid metabolites, and reactive oxygen intermediates. Anaphylatoxins, including opsonic C3b, and chemotactic C5a, stimulate multiple leukocyte functions involved in killing microbial pathogens.[143-145] The significance of the complement system in amplifying the host immune system is demonstrated in animal models and in patients with inherited deficiencies in complement components.[146,147]

The appearance of serum complement components, complement-mediated hemolytic activity, and complement regulatory proteins occurs between 8 and 14 weeks in the human fetus.[148] These components are products of fetal synthesis rather than maternal components acquired transplacentally.[149,150] In the adult human, complement component synthesis (with the exception of C7) occurs predominantly in the liver.[151] In the embryo and fetus, the major sites of synthesis have not been clearly defined, but extrahepatic sites are thought to predominate. The MPS is likely an important source for complement proteins.[152]

In various animal models, serum complement concentrations and complement-mediated hemolytic activity gradually increase over the course of gestation; however, adult serum concentrations are not achieved until several weeks after delivery.[153,154] In newborn infants, serum complement concentrations are diminished compared with findings in adults. Deficiencies in complement components are more pronounced in infants delivered prematurely.[155,156] Serum complement components generally achieve adult levels by 6 to 18 months of age.

Biosynthesis of other Secreted Products

Characterization of mononuclear phagocyte secretory products is a major focus of research. Diverse products synthesized by mononuclear phagocytes include polypeptide hormones, complement components, coagulation factors, enzymes, cytokines, extracellular matrix proteins, other binding proteins, bioactive oligopeptides, bioactive lipids, sterol hormones, purine and pyrimidine products, reactive oxygen intermediates, and reactive nitrogen intermediates.

Production of secretory products by mononuclear phagocytes during fetal and neonatal life is limited. Synthesis of the polypeptide hormones interferon (IFN)-α, IL-1, and TNF by term cord blood monocytes appears to be quantitatively similar to those of adult peripheral blood monocytes.[157-159] However, TNF production by freshly isolated monocytes derived from the cord blood of premature infants is lower than that of term cord blood and adult peripheral blood monocytes.[159] Other investigators described diminished IL-1 and TNF-α synthesis by preterm and term cord blood monocytes stimulated with LPS.[160] Kaufman

and co-workers[161] described a variety of synthetic deficits in LPS-stimulated adherent monocytes from preterm compared with monocytes from full-term infants. These included diminished generation of superoxide, TNF-α, and CD11b/CD18 receptors. They observed no differences in IL-1β or IL-6 production. These investigators postulated that adherence functions such as CD11b/CD18 ligation might be important in modulating subsequent cellular activation and cytokine secretion activities. Synthesis and secretion of several cytokines in vitro including G-CSF, GM-CSF, IL-6, IL-8, IL-10, and IL-12 by stimulated monocytes isolated from preterm and term cord blood monocytes are significantly lower at the protein and mRNA level than those measured from stimulated adult blood monocytes.[162-167] Diminished production of GM-CSF by PHA and phorbol myristate acetate (PMA)-stimulated newborn mononuclear cells has been determined to be secondary to increased levels of AUF1 isoform (RNA binding proteins) that affect mRNA stability.[162,168] Regulation of IL-10 also appears to be developmentally regulated at the post-transcriptional level.[166]

Goriely and colleagues[169] hypothesize that deficits in neonatal dendritic cell function are responsible in part for impaired T-helper 1 (Th1) function in human newborns. Their investigations of neonatal monocyte-derived dendritic cells revealed diminished expression of HLA-DR and costimulatory molecules CD40 and CD80. In addition they observed a selective defect in IL-12 synthesis at the protein and messenger RNA level in response to LPS, CD40 ligation, or poly-deoxy-inosinic acid:poly-deoxy-inosinic-deoxy-cytidylic acid (poly[d(I-C)]). Moreover, they found that neonatal dendritic cells were less effective than adult dendritic cells in promoting IFN-γ production by allogeneic adult T cells. This deficit was corrected with addition of recombinant IL-12.

FUNCTIONAL ASPECTS OF MONONUCLEAR PHAGOCYTES

Morphogenesis

Macrophages are critical during morphogenesis of the fetus. In addition to their role in immunity, macrophages participate in modeling organs, and they engulf debris and apoptotic cells during embryogenesis.[170] For example, they are present in the urogenital ridge, where they clear degenerated cells of the Müllerian duct in the male and the Wolffian duct in the female.[171] They appear to play a similar role in the retina and brain.[172,173] Macrophages have also been observed in close proximity to areas of apoptosis in the developing fetal mouse footplate.[174]

Movement

Mononuclear phagocytes exhibit both random and directed movement.[175] Random or nondirected movement occurs in the absence of attracting substances. Directed movement along a concentration gradient of chemical attractants is essential for the effective localization of mononuclear phagocytes to sites of infection and inflammation. This directional movement, called *chemotaxis*, is governed by chemoattractant molecules that bind to receptors on the cell surface. Chemotactic substances are produced through activation of the complement, fibrinolytic, and kinin systems or are directly produced by microorganisms. These chemoattractants may also accentuate random migration of mononuclear phagocytes in the absence of a concentration gradient. An entire family of proinflammatory molecules called *chemokines* has been identified and many of its members have been characterized.[176] Several members of this family serve as potent chemoattractants for mononuclear phagocytes. Monocyte chemotactic protein 1; macrophage inflammatory protein 1; and regulated upon activation, normal T-cell expressed and secreted (RANTES) are key regulators of monocyte migration. Dendritic cells migrate to lymphoid organs in response to secondary lymphoid chemokine.[177,178]

Mononuclear phagocyte migration in cells derived from cord blood and neonatal peripheral blood has been compared with migration in adult peripheral blood monocytes. In most reports, random movement by cord blood monocytes appears to be equivalent to that of adult peripheral blood monocytes.[179-181] On the contrary, several investigators have reported diminished directed movement by cord blood and neonatal peripheral blood compared with that of adult peripheral blood monocytes. Yegin[182] reported that monocyte chemotaxis increased gradually during childhood and was equivalent to adult chemotactic activity after 5 to 6 years of age. These results are consistent with those of other investigators who reported similar chemotactic activity by cord blood and adult peripheral blood monocytes, but dramatically decreased chemotaxis by neonatal peripheral blood monocytes in the first few days of life.[183] Monocyte chemotaxis gradually increased but remained lower than adult peripheral blood monocyte activity over the first 6 months of life. Other investigators report a slightly increased chemotaxis of cord blood monocytes in response to endotoxin-activated adult serum or activated adult lymphocytes.[184] Differences in methods of measurements applied, patient populations examined, and monocyte isolation used, likely account for the contradictory results reported by these investigators.

Adherence

Adhesion is a requisite function of mononuclear phagocytes for egress from the circulation, movement through interstitial tissues, and interaction with a wide variety of cell and tissue types. In the systemic circulation, movement of monocytes into tissues occurs in three independent steps. First, monocytes rolling along the vascular endothelium have transient low affinity focal interactions with endothelial cells through adhesion molecules called *selectins*.[185] L-selectin is constitutively expressed on the cell surface of blood monocytes and interacts with a variety of endothelial cell surface glycoproteins to promote transient monocyte-endothelium contact.[186] E-selectin and P-selectin are adhesion molecules expressed by vascular endothelium after activation.[187,188] These molecules recognize glycoprotein ligands on the cell surface of monocytes to facilitate monocyte-endothelium adhesion. The second step of monocyte egress from the vascular space involves halting the rolling, shedding of monocyte surface selectins, and firm adhesion of the monocyte to the endothelial cell surface. This firm adhesion is generated by activation of members of the integrin family on the monocyte cell surface. These integrins include CD11a-c and CD18 on monocytes and intercellular adhesion molecule (ICAM-1) or ICAM-2 on the endothelial cell surface.[189] An additional adhesion interaction pathway used by monocytes includes monocyte integrin α4β1 and endothelial vascular cell adhesion molecule-1 (VCAM-1). Both pathways promote firm adhesion of monocytes to endothelium and enable the final step of extravasation to occur. Monocytes migrate through the endothelium in response to a concentration of chemotactic signals to arrive at a focus of infection or inflammation. People who exhibit moderate to severe deficiency of cell surface integrins or selectins are susceptible to recurrent bacterial infections as a result of their inability to recruit neutrophils and monocytes to the site of infection. These defects can be visualized using a Rebuck skin window test.[190-192]

Dendritic cells are involved in a number of adhesive interactions that facilitate their migration and interaction with T cells. The initial tethering and rolling may prove to be mediated by selectins. More firm adherence and migration through the endothelium is likely to involve integrins and ICAMs or other immunoglobulin superfamily members. Integrins and CD44 or syndecans may mediate interstitial tissue interactions. Dendritic cell interactions with epithelium probably involve cadherins.

Adhesive properties of fetal and newborn monocytes have been examined to a limited degree. Boner and colleagues[193] reported equivalent adherenceto glass coverslips in both cord and adult blood neutrophils and monocytes. In others studies, Speer and co-workers[194] isolated mononuclear cells from cord and adult subjects and subjected these cells to a nylon-wool packed column. More than 85% of esterase positive monocytes from cord and adult blood adhered to the column. Other investigators evaluated the capacity of cord blood monocytes to adhere to denatured collagen and fibronectin-coated culture plates.[195] These studies also demonstrated comparable adherence of cord and adult blood monocytes to these substrates. In summary, monocyte adhesiveness appears to be unimpaired in neonatal blood compared with adult blood.

Endocytosis

The ability of mononuclear phagocytes to ingest a variety of materials is crucial to their immunologic function. Endocytosis is important in antimicrobial resistance, removal of old cells, antigen processing, and multiple other functions. Endocytosis is mediated through pinocytosis and phagocytosis. These two processes are believed to use similar mechanisms; however, distinctions have been drawn between them based on size and composition of the particles being ingested. Pinocytosis refers to ingestion of microscopic fluid droplets. Phagocytosis describes ingestion of large particulate matter.[196] Both processes involve internalization of extracellular materials. Phagocytosis is enhanced by opsonization of particulate materials with immunoglobulins or complement components that bind to Fc and C3 receptors on the cell surface of mononuclear phagocytes.

Historically, macrophages and dendritic cells were recognized as separate populations of adherent cells based, in part, on differences in endocytic capabilities. A model of antibody response by mouse spleen cells developed by Mishel and Dutton[197] required cooperation of two populations of cells distinguished by buoyant density and the capacity to adhere to glass or plastic. The high density, nonadherent cells were predominantly lymphocytes, whereas the low density, adherent cells consisted of a macrophage and a nonmacrophage (dendritic cell) population.[49,198] Macrophages had numerous lysosomes and actively internalized any small tracer molecules including microorganisms, antibody-coated particles, soluble horseradish peroxidase, and colloidal carbon. The other adherent cell population called *dendritic cells* based on their morphologic appearance had distinct features, including a paucity of lysosomes, numerous multivesicular vacuoles, and an inability to internalize particulate and fluid phase molecules.[49,198-200] The multivesicular vacuoles were later recognized to be major histocompatibility complex (MHC) class II–rich vesicles. A lack of endocytic activity was reported in many of the initial descriptions of dendritic cells.[200-203] After methods were developed to separate dendritic cells from macrophages, several laboratories found that dendritic cells exhibited two features that had not been previously encountered. They expressed high levels of MHC class II products and exhibited remarkable stimulatory capacity for T-cell–dependent responses (reviewed in Steinman's[126] study). The paucity of lysosomes and weak endocytic activity of dendritic cells, coupled with strong antigen- presenting functions were enigmatic to many investigators. The ability to isolate and culture dendritic cells has allowed resolution of certain aspects of this dichotomy.

Macrophages have the ability to internalize a broad spectrum of substrates in digestive lysosomes. Scavenging is a high capacity form of endocytosis that culminates in complete digestion of substrates. In studies applying fluid phase solutes to macrophages, these cells accumulated 10^5 soluble protein molecules per hour (on average) and substrates were digested to the level of amino acids.[204] Adsorptive uptake using Fc receptors enhances clearance properties of macrophages approximately 1000-fold.[205] In contrast, antigen presentation by dendritic cells requires a relatively small number of MHC-peptide complexes. For example, MHC II-restricted T-T hybrids can respond to presentation of a few hundred specific MHC-peptide complexes.[206,207] Similarly, naive T-cell stimulation can be achieved by presentation of only a few hundred complexes of MHC and superantigen by dendritic cells.[208]

Dendritic cells, like other antigen-presenting cells, have receptors that mediate adsorptive uptake and delivery of peptides to MHC products rather than lysosomes. Dendritic cells can present immune complexes and self-antigens by Fcγ receptors.[209,210] Furthermore, epidermal Langerhans cells (a specialized tissue macrophage) contain Birbeck granules that can be coated and mediate adsorptive uptake.[211,212] Sallusto and colleagues[213] demonstrated that the mannosyl-fucosyl C-type lectin receptor mediates adsorptive uptake of horseradish peroxidase and FITC-labeled dextran. Other C-type lectin domain–containing receptors have been identified and linked to antigen uptake and presentation by dendritic cells.[214,215]

Recycling of internalized membrane is a general feature of endocytosis. Levine and Chain[216] described significant trafficking of endocytic vesicles through endosomes but not lysosomes in dendritic cells. They examined endocytic activity using fluorescent solutes and cytofluorography and concluded that a significant portion of the internalized solute was discharged through the recycling process. On the contrary, Sallusto and coworkers[213] showed accumulation and retention of fluorescent solutes for longer periods of time. Their cell population contained more abundant MHC class II compartment (MIIC) vesicles compared with the cells used by Levine and Chain; thus MIICs might retain internalized substances longer for the purpose of antigen presentation.

Endocytosis of substrates is limited to discrete stages of the dendritic cell life cycle in response to certain signals. Romani and co-workers[217] and Streilein and Grammer[218] reported that dendritic cells isolated from skin efficiently presented protein antigens; however, after 12 hours in culture this capacity is lost. Splenic dendritic cells also capture antigens on isolation, but lose endocytic activity after overnight culture.[213,219] The proposal that macropinocytosis is increased in dendritic cells by growth factors is consistent with cytokine-induced macropinocytosis in other cell types.[220,221]

During the fetal period, macrophages are capable of immune protection of the fetus. In animal models, primitive macrophages are highly mobile and are capable of ingesting latex particles injected into the yolk sac and carrying them to the mesenchymal stroma and loose connective tissue.[222] Fetal Kupffer cells may detoxify circulating endotoxin. Endotoxin that reaches the amniotic cavity is swallowed by the fetus and gains access to the liver through the portal circulation.[223] Macrophages internalize endotoxin through the LPS receptor. This receptor is present on human fetal Kupffer cells and can be up-regulated as early as 8 weeks postconception by IL-3.[224] Later, macrophages contribute to the adaptive immune response as antigen-presenting cells and as producers of a variety of cytokines including TNF-α, IL-1, and IL-6.

The kinetics of phagocytosis by monocytes from cord blood and adult peripheral blood have been studied by Schuit and Powell.[225] These investigators found that monocytes isolated from adult peripheral blood ingested all polystyrene particles within 50 minutes. In comparison only 38% of cord blood monocytes had initiated phagocytosis in the same time period. The cord blood monocytes were able to ingest the particles by 100 minutes. These studies were not influenced by the presence of serum or heat-inactivated serum. Other investigators have reported that opsonized IgG sheep erythrocytes, *Staphylococcus aureus, Escherichia coli, Streptococcus pyogenes, Toxoplasma gondii,* and type II herpes simplex are ingested by cord blood monocytes as effectively as monocytes derived from adult peripheral blood.[194]

Defective phagocytosis of *Streptococcus agalactiae* by cord blood monocytes has been reported by Marodi and colleagues.[226] Monocytes derived from term cord blood ingested fewer group B Streptococci than monocytes isolated from adult blood. Other studies suggested that the phagocytic defect of group B *Streptococcus* by cord blood monocytes could be overcome by inclusion of adhesive glycoprotein fibronectin in the culture.[44] Although fibronectin alone did not enhance phagocytosis, preopsonizing group B *Streptococcus* with IgG preparation in combination with fibronectin enhanced phagocytosis by cord blood monocytes.

The phagocytic activity of cord blood monocyte–derived macrophages has been compared with that of macrophages derived from adult blood monocytes. After a 10-day culture period, Speer and co-workers[227] determined that cord blood–derived macrophages ingested complement opsonized *S. aureus* to the same extent as macrophages derived from adult blood. Other investigations compared the phagocytic activity of alveolar macrophages from intubated newborns with alveolar macrophages from bronchoalveolar lavage of adult subjects. Phagocytosis of *Candida albicans* by newborn and adult alveolar macrophages was determined to be equivalent with respect to rate and number of organisms ingested.[228]

Dendritic cells derived from cord blood monocytes by culture with IL-4 and GM-CSF exhibited decreased endocytic function compared with adult monocyte–derived dendritic cells.[229] Liu and colleagues[229] suggested that decreased mannose receptor expression might contribute to this developmental deficit. Zheng and co-workers[230] reported that after the addition of TNF-α to cultures, monocyte-derived cord blood dendritic cells exhibited equivalent endocytic capacity to adult monocyte–derived dendritic cells. The results of these studies suggest that mononuclear phagocytes in the newborn period have a well-developed endocytic pathway for most microorganisms. Phagocytic activity of mononuclear phagocytes from the fetus and from prematurely born infants has not been reported.

Microbicidal Activity

Several different antimicrobial mechanisms have been identified in mononuclear phagocytes. These are generally divided into oxygen-dependent and oxygen-independent mechanisms. The microbicidal mechanism used by mononuclear phagocytes varies depending on the state of maturation, differentiation, activation, and tissue of origin. The oxygen-dependent mechanism, termed the *respiratory burst*, is initiated with activation of the transmembrane electron transport system involving a reduced nicotinamide adenine dinucleotide, extracellular or phagosomal oxygen, and additional plasma membrane enzymes and cofactors.[135] Superoxide anions are the initial product of the respiratory burst. This molecule is directly toxic to certain proteins and membrane constituents; however, it is often converted to a more powerful antimicrobial agent, hydrogen peroxide, through a reaction catalyzed by superoxide dismutase. Hydrogen peroxide is highly toxic to a number of microorganisms. Hydrogen peroxide toxicity can be further enhanced when it is used as substrate for the oxidation of halides (for example, iodide, bromide, and chloride) to hypohalous acids and other reactive intermediates.[136] This reaction is catalyzed by the phagocytic enzyme myeloperoxidase. Halide oxidation products are themselves powerful oxidants and probably attack bacterial cell wall components leading to microbial killing. Proposed chemical groups involved in these interactions include amino acids, which are decarboxylated and deaminated; lipid membranes, in which polyunsaturated fatty acids are oxidized; and sulfhydryl groups, which are readily oxidized.[231]

Oxygen-independent antimicrobial mechanisms used by mononuclear phagocytes include acidification of the phagosome and the synthesis and secretion of cationic proteins called *defensins, lipid hydrolases*, *proteases*, and *nucleases.*[232] The extent to which these mechanisms contribute to antimicrobial activity in vivo is uncertain. However, in patients with chronic granulomatous disease, despite a deficient oxygen-dependent antimicrobial system, mononuclear phagocytes are capable of killing microbial pathogens.[233]

Nitric oxide (NO) is an additional molecule that plays an important role in oxygen-independent macrophage antimicrobial activity.[234] Initially, NO was identified as an antimicrobial and tumoricidal product of activated macrophages generated from the amino acid L-arginine by the enzymatic activity of inducible nitric oxide synthase (iNOS). NO plays many roles in the immune system as well as in other organ systems. In addition to macrophages, several other immune cells (dendritic cells; NK cells; mast cells; and phagocytic cells, including monocytes, microglia, Kupffer cells, eosinophils, and neutrophils) produce and respond to NO. Three isoforms of NOs are known: iNOS and two constitutive forms collectively called *constitutive NOS* (cNOS). Although the three isoforms catalyze the same reaction, they differ in their regulation, amplitude, and production of NO, and in cellular and tissue distribution.[235] NOS activity is determined by several mechanisms, many influenced by immunologic stimuli. The activity of NO is not restricted to the site of its production. It is a highly diffusible gas and can act locally or can be distributed widely in the body through NO vehicles such as *S*-nitrosothiols, *S*-nitrosylated proteins, and nitrosyl-metal complexes. Unlike cytokines, the interaction of NO is not restricted to a defined receptor. Rather, it can interact with other inorganic molecules (for example, oxygen or superoxide); structures in DNA (for example, pyrimidine bases); prosthetic groups (for example, heme); or proteins leading to *S*-nitrosylation of thiol groups, nitration of tyrosine residues, or disruption of metal-sulfide clusters (for example, zinc-finger domains or iron-sulfide complexes). Considering that many targets of NO are regulatory molecules it is evident that NO exerts diverse effects.

NO has a diverse spectrum of activities against infectious pathogens, including antiviral, antimicrobial, immunostimulatory (proinflammatory), immunosuppressive (antiinflammatory), cytotoxic (cell-damaging), and cytoprotective (tissue-preserving). The analysis of iNOS–/– mice confirms that most of these effects are mediated by iNOS-derived NO.[236-238] Under different circumstances, depending on the species, strain, infective dose, or route of pathogen entry, iNOS was indispensable or helpful in controlling the infection, had no effect, or worsened the disease.[235] The antimicrobial activity of NO results from a variety of mechanisms including mutation of DNA; inhibition of DNA repair or synthesis; inhibition of protein synthesis; alterations of proteins by S-nitrosylation, adenosine diphosphate (ADP)-ribosylation or tyrosine nitration; inactivation of enzymes by disruption of Fe-S clusters, zinc-fingers or heme groups; or peroxidation of lipid membranes.[237,239] These mechanisms likely account for the most actions against infectious agents. Peroxynitrite ($ONOO^-$), a reaction product of NO and O_2^-, is a potent antibacterial effector molecule. The nitrating efficiency and production capacity of peroxynitrite by macrophages have been controversial; however, recent investigations have demonstrated that $ONOO^-$ might be formed within the microbe by host-derived NO and microbe derived O_2^-. The significance of $ONOO^-$ is underscored by the fact that pathogens such as *Mycobacterium tuberculosis* and *Salmonella typhimurium* have developed mechanisms to detoxify $ONOO^-$ to nitrite.[240]

The iNOS-dependent killing of parasites by macrophages can result from depletion of arginine. For certain strains of *Leishmania* it has been shown that L-hydroxyarginine can inhibit arginase activity in the macrophage or parasite promoting parasite killing. Also, arginine is required for polyamine and DNA synthesis in *Leishmania* and African trypanosomes by the ornithine decarboxylase pathway and by *Trypanosoma cruzi* through the arginine decarboxylase pathway.[241]

Cytotoxic Activity

Under some circumstances mononuclear phagocytes are capable of killing other formed elements of the blood, normal cells, and tumor cells. Mononuclear phagocyte cellular toxicity may occur through means of specific antibodies, called antibody-dependent cellular cytotoxicity (ADCC), or it may occur in the absence of specific antibodies to the target cell.[242] Mononuclear phagocyte–mediated ADCC has been studied extensively. Because antibody specificity is the primary determinant of ADCC reactions, this means of cellular killing is used for disposal of both malignant tissue and normal cells. In ADCC, the immunoglobulin-bound target interacts with the Fc receptor on the mononuclear phagocyte. This initial binding is necessary but not sufficient to kill the target. Reactive oxygen intermediates, in particular hydrogen peroxide, are the major secretory products of the mononuclear phagocyte that lyse the target cell.[243] Serine proteases and tumor necrosis factor might also be involved in this lytic mechanism.

Antibody-independent cellular toxicity is highly selective for killing various types of malignant cells of syngeneic, allogeneic, or xenogeneic origin without damaging tissue-matched nonmalignant cells. This cytotoxicity is mediated through cell-cell contact and is usually highly selective and nonphagocytic in nature. Mononuclear phagocytes may have plasma membrane receptors for certain target cells.[242] TNF, reactive oxygen, NO intermediates, and the putative 40-kDa serine protease have been implicated as major secretory products involved in antibody-independent cellular cytotoxicity.[242]

Cord blood monocytes have been reported to exhibit normal ADCC activity to herpes simplex–infected hepatocytes and to antibody-coated human erythrocytes.[244,245] Antibody-independent cytotoxicity in term cord blood monocytes has been reported to be diminished by some investigators but to be normal by others.[244,246] The ontogeny of mononuclear phagocyte cytotoxic functions during fetal development has not been examined.

Antigen Processing and Presentation

The MPS is integral in the establishment of an effective immune system. In addition to the innate immune functions aimed at eradicating invading microorganisms, mononuclear phagocytes are involved in initiating and propagating the adaptive immune response. A complex relationship exists between antigen-presenting cells and antigen-specific T cells. The mechanism by which antigen-presenting mononuclear phagocytes interact with T cells requires internalization, degradation, and display of antigenic fragments on the cells' surface in association with MHC class II molecules. Macrophages and dendritic cells both participate in this function, although their respective roles likely differ.

Mechanisms of antigen uptake might differ between various cell types in the MPS. Macrophages may be more effective than dendritic cells as scavengers as a result of their extensive repertoire of scavenger receptors.[247] Macrophages also appear to be more effective than dendritic cells at ingestion of large antigenic materials and whole cells.[198] For example, colloidal carbon administered intravenously is predominantly ingested by macrophages. Several investigators have observed limited phagocytosis of large particles such as intact cells, bacteria, and synthetic beads in bone marrow–derived murine dendritic cells.[248-250] Macrophages may contribute to antigen uptake by lysing larger particles such as bacteria, viruses, or tumor cells before transferring the degradation products to dendritic cells.[251,252]

Dendritic cells are highly active in endocytosis and pinocytosis. This is the process by which small fluid phase particles, usually smaller than 0.5 μm, are internalized.[253] Mouse and human dendritic cells bind antigen at the cell surface and internalize these along with small portions of their plasma membrane.[254] This activated fluid phase endocytosis explains the low density characteristics acquired by dendritic cells in vitro. Monocyte-derived dendritic cells generated from peripheral blood mononuclear cells treated with GM-CSF and IL-4 take up extracellular fluid, actively processing approximately 100 times their volume per hour.[220]

Nonspecific inflammatory signals may be required to initiate phagocytosis, endocytosis, and expression of antigen capture receptors. Bacteria express complex carbohydrate molecules on their surface, which may bind to pattern recognition receptors, many of which have lectinlike specificity.[255] Mannose-containing residues bind mannose receptors thus facilitating phagocytosis by macrophages. Antigen presentation by dendritic cells has been associated with expression of DEC-205 and BDCA-2. DEC-205 is a membrane protein homologous to the macrophage mannose receptor, and BDCA-2 is a type II C-type lectin.[214,215] Down-regulation of these receptors may reduce the risk of extraneous antigen presentation on egress of antigen-presenting cells from the tissue and reprogramming of dendritic cell machinery toward antigen presentation to T cells.

The MHC gene codes for two families of cell surface glycoproteins (classes I and II). Class I MHC molecules include the classical transplantation antigens and are displayed on all cells in the body. Class II MHC molecules are heterodimeric glycoproteins found on the surface of antigen-presenting cells. The MHC gene is polymorphic, therefore a wide variety of class II molecules can be expressed on the surface of antigen-presenting cells.[256]

Endogenous antigen is degraded by intracellular proteases and peptidases to provide peptides in the cytosol. These peptides bind to transporter (TAP) gene products and are delivered to the class I MHC compartment where they are incorporated into the peptide-binding groove generated by folding of the class I molecule before moving to the surface. This pathway requires intact proteosome and Golgi transport function. In dendritic cells, additional mechanisms are involved in class I antigen processing. First, dendritic cells internalize antigens through macropinocytosis and then release antigens into the cytosol for classical TAP-dependent MHC class I presentation.[257,258] Second, peptides produced in high concentrations may be exchanged with peptides on mature MHC class I molecules. Third, carrier molecules or chaperones capture peptides and deliver them through the dendritic cell surface to the endoplasmic reticulum where they are released, processed, and incorporated into MHC class I molecules.

Exogenous antigens including intact organisms, particulates, and soluble antigens are internalized by the phagocytic or endocytic pathway and must undergo degradation and proteolysis before interacting with the MHC class II compartment where peptide loading occurs. Class II α and β chains are synthesized, combined, and transported in association with HLA-DM to the class II compartment. In this compartment HLA-DM dissociates; the class II molecules are membrane bound with their peptide-binding site protected by class II-associated invariant chain peptide (CLIP). Maturation of these vesicles occurs after fusion with the endocytic lysosome pathway.[259] The invariant chains dissociate allowing the appropriate peptides to bind with MHC.[260,261]

Although expression of class II molecules on antigen-presenting cells is assumed to be a constitutive process in macrophages, studies of antigen processing and presentation in dendritic cells demonstrate the complexity of these mechanisms in this antigen-presenting cell subtype. During the immature stages of dendritic cell development, cell surface expression of MHC class II and costimulatory molecules is low and endocytic activity is high.[262,263] On encountering inflammatory stimuli or microbial products, these cells undergo a maturational process in which class II and costimulatory molecules are up-regulated and endocytosis is reduced. After this programmatic shift, dendritic cells are capable of effective activation of naive T cells.[264]

Increased expression of MHC class II during dendritic cell maturation is believed to be primarily regulated by the rate of invariant chain proteolysis by cathepsin S and the subsequent

binding of antigenic peptides to the newly formed class II αβ dimer in lysosomes.[265,266] In immature dendritic cells, cathepsin S activity is inhibited by cystatin C, preventing invariant chain (Ii) proteolysis. This leads to sequestration of nonfunctional class II αβI complexes in the lysosomes. Activation of dendritic cells promotes down-regulation of cystatin C, thus liberating cathepsin S activity. This permits Ii proteolysis and enhanced trafficking of functional class II MHC molecules to the cell surface.

Although Ii proteolysis is assumed to be the primary regulator of class II trafficking during dendritic cell differentiation, additional levels of regulation have recently been identified. Different rates of macropinocytosis and MHC class II recycling have been observed in immature and mature dendritic cells, suggesting that these factors, rather than Ii proteolysis might control class II MHC surface expression.[267] Macropinocytosis in dendritic cells is controlled by small guanosine triphosphatases such as Rac1 and Cdc42, suggesting molecular mechanisms for regulation of class II transport during dendritic cell maturation.[268] Furthermore, cytokines can modulate class II trafficking in monocytes and can regulate cathepsin activity in dendritic cells.[269,270] It is apparent that antigen-presenting cell function is tightly regulated at the level of MHC class II transport.

The CD4 subset of T cells recognizes antigen presentation by cells expressing the class II MHC antigens. The density of MHC class II molecules appears to correlate with their ability to present antigens to the CD4-positive T cell. Lymphokines such as IFN-γ increase the expression of MHC class II antigens and enhance antigen presentation. In contrast, prostaglandins of the E class and glucocorticoids inhibit MHC class II antigen expression and antigen presentation.

Fetal and Newborn Antigen-Presenting Cell Capabilities

Investigations of antigen presentation and processing by mononuclear phagocytes from fetal blood have not been reported. Antigen-processing capabilities of monocytes derived from term cord blood have been evaluated by Hoffman and co-workers.[271] In their experiments, maternal and neonatal blood samples were paired so that single-haplotype sharing between mother and child was sufficient to allow for T-cell recognition of cord blood mononuclear phagocytes.[271] When cord blood–adherent mononuclear phagocytes were exposed to tetanus toxoid antigen and cultured with tetanus-toxoid–specific T cells, a T-cell proliferative response was observed. This response was equivalent to the response seen when maternal blood adherent mononuclear cells were cocultured with antigen and T cells. These investigators concluded that newborn mononuclear phagocytes were competent in presenting tetanus toxoid antigen, but they cautioned that additional studies would be required to determine whether antigen processing of other microbial products was as efficient.

Zlabinger and colleagues[272] examined the capacity of cord blood mononuclear phagocytes to present *E. coli* or tetanus toxoid antigen to cord or paternal T cells. In these studies, T cells were cocultured with either antigen-pulsed or control-adherent mononuclear phagocytes. When cord blood T cells were cocultured with pulsed-adherent mononuclear phagocytes from cord blood, the proliferative response was significantly less than was seen when paternal T cells were cocultured with adherent mononuclear phagocytes. However, in experiments in which cord blood–adherent mononuclear phagocytes pulsed with *E. coli* were cocultured with paternal T cells, enhanced T-cell proliferation was of similar magnitude as that seen with adult autologous antigen-presenting mononuclear phagocytes. These investigators also reconfirmed the observations by Hoffman and colleagues[271] that cord blood mononuclear phagocytes were fully capable of processing and presenting tetanus toxoid antigen to antigen-specific T cells.

Few studies of dendritic cells have been done in human neonates, and those that exist were done with dendritic cells differentiated in vitro from circulating monocytes with a cocktail of cytokines (that is, IL-4 in combination with GM-CSF). These cord blood monocyte–derived dendritic cells have limited antigen-presenting cell function and defective IL-12 production.[169,229,273] However, it is always difficult to generalize data obtained from these in vitro differentiated cells, because they are derived in a static environment containing high concentrations of cytokines and reduced cellular interactions, which might not mimic the physiologic milieu.

Intrinsic functional defects have been identified in immature dendritic cells derived from cord blood monocytes. Hunt and co-workers[274] described low expression of MHC class I and II molecules and adhesion molecules on cord blood–derived dendritic cells. They postulated that this diminished expression contributed to diminished allostimulatory capacity of these dendritic cells compared with adult monocyte–derived dendritic cells. Investigations by Liu and colleagues[229] concurred with findings that cord blood monocyte–derived dendritic cells exhibited reduced CD1a and MHC II expression. They also demonstrated diminished endocytosis related to low mannose receptor expression and reduced allostimulatory activity by cord blood compared with adult dendritic cells.[229]

Defective antigen-presenting cell function has been hypothesized to contribute to increased infection susceptibility in newborns. Drohan and colleagues[275] characterized antigen-presenting cell subsets in adult peripheral blood and cord blood. Adult peripheral blood had a higher proportion of CD11c+ dendritic cells, whereas cord blood mainly contained CD123+ dendritic cells. Adult blood was enriched in CD16+CD11c+ dendritic cell subset, whereas CD34+CD11c-CD123lo cells were prominent in cord blood. LPS-induced TNF-α production was dampened in myeloid dendritic cells and monocytes from cord blood, whereas IL-1α production was not different. These investigators reasoned that reduction in TNF-α response did not result from reduced surface detection of LPS, because CD14, Toll-like receptor (TLR)-4 and TLR-2 levels were not reduced in cord blood compared with adult antigen-presenting cells. Also, no correlation was observed between TLR-2 or TLR-4 levels and TNF-α production in myeloid dendritic cells and monocytes. Cord blood monocytes had lower surface HLA-DR immediately ex vivo. Both adult blood and cord blood monocytes up-regulated HLA-DR after incubation, but an additional LPS-induced increase in HLA-DR was suggested only in adult blood monocytes.

Mononuclear Phagocyte Activation

The enhanced activity of mononuclear phagocytes against microorganisms and tumor cells requires interaction with sensitized lymphocytes.[276] T lymphocytes stimulated by previous exposure to specific antigens release soluble factors that induce mononuclear phagocytes to enhance microbicidal and tumoricidal activity.[277] Considerable evidence now exists that IFN-γ is the factor produced by T lymphocytes that induces macrophage activation.[276]

IFN-γ is a highly basic heterogeneous glycoprotein with a molecular weight of 40,000 to 70,000 daltons.[277] The biologically active form of the natural protein consists of dimeric aggregates. Recombinant IFN-γ is not glycosylated and has a molecular weight of 17,000 daltons. The effects of IFN-γ on mononuclear phagocytes are initiated by engagement of IFN-γ with specific receptors on the cell surface.[278] Adams and Hamilton[279] have reviewed the signal transduction mechanism through which IFN-γ binding produces immediate and sustained functional responses. These investigators have proposed that mononuclear phagocyte activation should not refer solely to the effects of a stimulus such as IFN-γ thus leading to a proscribed change in morphology or function, but rather activation may be used to describe a composite of multiple specific capacities that enable the mononuclear phagocyte to perform a complex function.[279]

Mononuclear phagocytes play a key role in the interface between innate and adaptive immunity. Both tissue macrophages and dendritic cells recognize pathogens through a variety of receptors, induce potent stimulatory molecules, and initiate microbicidal pathways. Brightbill and colleagues[280] observed production of IL-12 and NO synthase by macrophages in response to microbial lipoproteins recognized through TLRs. Dendritic cells also produce IL-12, which is capable of inducing T lymphocyte activation and subsequent IFN-γ production.[281,282]

Marodi and co-workers[283] examined the mechanisms used by cord blood and adult blood monocyte–derived macrophages to ingest and kill *C. albicans.* They determined phagocytosis and killing of *Candida* sp. to be equivalent between cord blood and adult blood monocyte–derived macrophages both in the presence and the absence of serum. Exposure of cord and adult macrophages to IFN-γ resulted in quantitatively different results. Candidacidal activity and superoxide anion generation was maximal for adult macrophages at 100 units/mL interferon-γ, whereas the magnitude of Candidacidal activity and superoxide production by cord blood–derived macrophages remained low at a dose up to 500 units/mL of interferon-γ. The mechanism accounting for this disparity in macrophage activation was not caused by differences in interferon-γ receptor density. Recent work by Marodi and co-workers[284] analyzed interferon-γ signaling through STAT-1 in cord blood and adult blood monocytes and monocyte-derived macrophages using flow cytometry. They found comparable expression of STAT-1 between cord and adult cells; however, phosphorylation of STAT-1 in response to interferon-γ was significantly decreased in neonatal monocytes and monocyte-derived macrophages compared with findings in adult cells. These data suggest that defective interferon-γ signaling through STAT-1 in neonatal mononuclear phagocytes might contribute to the unique susceptibility of neonates to intracellular pathogens.

Neonatal peritoneal and blood macrophages are known to be ineffective in antigen-presentation functions, and this manifests as inefficient MHC class II expression in response to IFN-γ. The underlying mechanisms responsible for this maturational deficiency have not been completely elucidated. Lee and co-workers[285] reported that MHC class II expression in alveolar macrophages from neonates are refractory to IFN-γ stimulation, and by examining the intracellular pathway leading to MHC class II expression they demonstrated that the site of the impairment is at the level of transcription. Thus expression of mRNA encoding the class II transactivator (CIITA), MHC class II, and Ii was low or undetectable in neonatal alveolar macrophages stimulated with concentrations of IFN-γ that induced adult AM to up-regulate MHC class II expression. The failure of alveolar macrophage from young animals to express MHC class II was not simply the result of deficient IFN-γ receptor function because IFN-γ-responsive genes such as IRF-1, IRF-2, and IP-10 were up-regulated in a dose-dependent manner from animals of all ages investigated. The responsiveness of neonatal alveolar macrophages to IFN-γ, as determined by MHC class II expression, could be modulated to adult levels when pre-cultured in vitro. This suggests that microenvironmental factors operative in vivo may play a role in suppressing the expression of MHC class II in alveolar macrophages from young animals. Type I interferons were not found to be responsible for the inability of alveolar macrophages from juvenile animals to induce MHC class II in response to IFN-γ.[285]

Monocyte Function in the Fetus and Preterm Neonate

The innate immune system of the preterm infant is considered to be immature because multiple host defense proteins are low, immune cell numbers are low, and immune cell functions are low compared with cells from older children or adults.[286] Very little information is available about innate immune responses and their modulation in the fetus, although such responses might be central to a number of injuries associated with preterm birth. Fetal exposure to inflammation might either increase or suppress subsequent immune actions.[286] Immune responsiveness could be decreased by exposure to inflammatory products resulting in the fetal equivalent of endotoxin tolerance. For example, plasma interleukin IL-6 concentrations are strikingly decreased in fetal sheep after repetitive administration of low dose *E. coli* endotoxin.[287] Alternatively, increased responsiveness is characterized by increased production of hydrogen peroxide and augmented phagocytosis by blood monocytes in fetal sheep seven days after maternal glucocorticoid exposure.[288]

The fetus is generally recognized as immunologically naive, but chronic indolent chorioamnionitis caused by commensal or low pathogenic organisms occurs in the majority of pregnancies complicated by preterm labor and delivery before 30 weeks gestation.[289-291] Fetal exposure to infection or a fetal systemic inflammatory response increases neonatal morbidity and mortality.[292-295] Approximately 30% of very-low-birth-weight preterm infants also develop nosocomial infections that have no identifiable source.[296] The role of in utero infection, inflammation, and medication exposure on the developing immune system is complex.

Temporary suppression of innate immune cell response has been referred to as endotoxin tolerance.[297,298] The concepts of endotoxin tolerance have been developed primarily in mice and in adult human. In adult mice, endotoxin exposure decreases TNF–α and IL-1 secretion by monocytes.[297] Mechanisms proposed for endotoxin-induced tolerance include down-regulation of endotoxin receptors, LPS-binding protein, or CD14 and the alteration of signaling pathways to decrease NF-κB nuclear translocation. Alternatively, changes in cytokine expression profiles or in inhibitory pathways in the cells might be operative.

Endotoxin tolerance has been used to describe in vivo models in which normally lethal doses of endotoxin can be tolerated by animals that were previously exposed to sublethal doses of endotoxin.[297] Chronically catheterized preterm sheep respond to intravascular endotoxin with a tolerance response.[287] Preterm infants are extremely susceptible to nosocomial infections several weeks after preterm birth, at a time when they are clinically stable.[299] This susceptibility to infection is consistent with immune tolerance.

The responses of monocytes to endotoxin are complex. In fetal sheep models of intraamniotic endotoxin exposure, suppressed production of hydrogen peroxide and IL-6, and decreased expression of CD14 and MHC II receptors have been observed.[288] These responses are typical of endotoxin tolerance. In contrast, increased hydrogen peroxide and IL-6 production and increased TLR4 expression two weeks after in utero endotoxin exposure indicate an augmented innate immune response. The enhanced response 14 days after endotoxin exposure might represent recovery from endotoxin tolerance or maturation of monocyte function. Unique aspects of studies in which intraamniotic endotoxin was administered include the induction of lung maturation and impaired lung development.[300,301] Despite the use of higher endotoxin doses that would have been lethal if given intravascularly, no impairment of fetal well being or growth was observed. The lung inflammation required direct contact of endotoxin with the fetal lung, presumably by mixing of fetal lung fluid with amniotic fluid as a result of fetal breathing. Provision of intraamniotic endotoxin more than 30 days before preterm delivery resulted in increased monocytes and lymphocytes in the alveolar fluid of preterm lambs. It is noteworthy that intraamniotic endotoxin also modified the systemic monocytes to an immune tolerance phenotype. In a similar manner, repeated exposure to endotoxin at 7-day intervals resulted in profound suppression of hydrogen peroxide production by systemic monocytes from preterm sheep.[288] Clinically, chorioamnionitis is often indolent and persists for weeks or months.[290] Chronic fetal exposure to inflammation could cause a profound and persistent immune tolerance and thus put these infants at risk for nosocomial infection.[302]

have been demonstrated to correlate with the inability of neonatal PMNs to achieve a fully bipolar shape change on stimulation.[15]

Measurement of light-scattering response to FMLP has been used to assess whether defective neonatal neutrophil tubular assembly is a result of impaired signal perception or immature responsiveness of the cytoskeleton. Light-scattering effects are the result of an extremely synchronous and massive rearrangement of organelles in the responding neutrophils. Wolach and colleagues[16] compared the response of neonatal and adult neutrophils with FMLP stimulation. Cell polarization of adult neutrophils and that of neonatal neutrophils were similar when these cells were stimulated with low FMLP concentrations, but with increasing FMLP concentrations, neonatal PMN polarization was reduced compared with adult PMNs. These observations suggest that neonatal neutrophils have a fully functional signal perception, but that their cytoskeleton framework fails to comply with the demands of a strong signal.

Taniuchi and associates[17] confirmed these findings by demonstrating differential actin polymerization in adult and neonatal PMNs after stimulation with FMLP. No difference was found in binding capacity of FMLP receptors between adult and cord neutrophils, but actin polymerization was significantly decreased in cord blood neutrophils compared with adult PMNs.

Merry and associates[18] investigated the role of actin polymerization and its regulation by protein kinase C and by phosphatases in the defective neutrophil chemotaxis of the human newborn. Neutrophils isolated from adult volunteers and healthy term newborns were studied for assessment of chemotaxis by flow cytometry. The neutrophils from neonates demonstrated reduced actin polymerization in response to chemotactic agents that act through cell surface receptors, but not with those that act directly on cytoplasm. This finding suggests that a defect in cell signal transduction may be one of the factors implicated in defective chemotaxis. Phosphatase 1 and 2A inhibitors inhibit chemotaxis but not actin polymerization. Therefore, phosphatase 1 and 2A can be considered chemotaxis regulators, but not through actin polymerization.

ADHERENCE

The events of phagocytosis begin within minutes of tissue damage or pathogenic invasion with the accumulation and adherence of neutrophils to endothelial surfaces at the site of infection. Recruitment of neutrophils to the site of infection involves a coordinated series of events mediated by three families of adhesion receptors: selectins, integrins, and the immunoglobulin G (IgG) gene superfamily. The selectins promote the initial rolling or tethering of the neutrophils to the endothelium under the shear force of blood flow, whereas the integrins induce firm adhesion.[19] This initial process is mediated by three selectins, which have been identified as P- and E-selectins (CD62P, CD62E), induced by inflammatory cytokines on endothelial cells, and L-selectin (CD62L), constitutively expressed on circulating neutrophils. On the neutrophil surface, L-selectin (CD62L) interacts with specific oligosaccharide moieties on endothelial cell surface glycoproteins, whereas on the endothelium, E-selectin (CD62E) and P-selectin (CD62P) similarly recognize specific neutrophil carbohydrate moieties.

Selectins are critical to neutrophil transmigration by virtue of their ability to tether leukocytes in a reversible fashion under conditions of shear flow, a process that mediates their rolling on the endothelium of inflamed vessels. Within minutes of activation with certain agonists (phorbol myristate acetate, histamine, thrombin, C5a, or oxidants) or inflammatory mediators (interleukin-8 or platelet-activating factor), selectins are translocated to the plasma membrane, following which neutrophil attachment is facilitated by β_2-integrins, leukocyte factor antigen-1 (i.e., CD11a/CD18), and macrophage-1 antigen (Mac-1) (i.e., CD11b/CD18).

Thus contact with selectins begins the process of neutrophil adhesion by slowing the velocity of neutrophil flow and increasing the duration of intercellular and membrane contact with the endothelium. Next, firmer attachment is accomplished through the action of the β_2-integrins and intercellular adhesion molecules ICAM-1 and ICAM-2, which mediate neutrophil arrest and transmigration. ICAM-1 (CD54) and ICAM-2 are members of the IgG gene superfamily and are expressed constitutively on endothelial cells, increasing when the endothelium is inflamed. ICAM-1 is the ligand for leukocyte factor antigen-1 and Mac-1 and is required for neutrophil arrest and transmigration.[20] Neutrophil-neutrophil adhesion (aggregation) also involves initial tethering through L-selectin followed by β_2-integrin–dependent firm adhesion.[21]

Neutrophils use various signaling pathways to link receptors for adhesion with effector molecules in the cytoplasm and nucleus. The Rho family of GTPases, members of the Ras superfamily, plays a key role in regulating these responses. The role of the Rho GTPases in phagocyte cell function has been studied. Williams and associates,[22] using a murine model genetically deficient in hematopoietic-specific Rho GTPase, Rac-2, demonstrated that Rac-2 plays an essential and unique role in neutrophil rolling by L-selectin, chemotaxis, and phagocytosis.

Several investigators have reported deficient adhesion of neonatal neutrophils to endothelial cells as a result of decreased expression of integrins, diminished expression of L-selectin, and a rigid cytoskeleton that prevents redistribution of adhesion sites. Lorant and associates[23] demonstrated decreased P-selectin expression in endothelial cells lining mesenteric venules and umbilical veins of premature infants compared with term infants. Reports differ regarding the resting and stimulated expression of Mac-1 on neonatal neutrophils. Several investigative groups have demonstrated that the expression of Mac-1 in neonates is equal to that in adults; however, the total cell content of Mac-1 is decreased.[24] Rebuk and co-workers,[25] however, reported a decrease in baseline expression of neonatal neutrophil Mac-1 and a stimulated expression equal to that in adults. Additional studies have shown that neonatal neutrophils fail to up-regulate Mac-1 surface expression to the same extent as for adult neutrophils in response to chemotactic stimulation. Mariscalco and colleagues[24] demonstrated no significant difference in the stimulated expression of Mac-1 in neonatal and adult neutrophils but showed a significant decrease in the expression of L-selectin in neonatal over than in adult neutrophils and a significant decrease in the interaction of neonatal neutrophils with human umbilical vein endothelial cells compared with those from adult subjects.

HEMATOPOIETIC GROWTH FACTORS IN NEONATAL SEPSIS

Sepsis continues to be an important cause of morbidity and mortality among both full-term and preterm infants, secondary to an immaturity in neonatal host defenses. The dysregulation of the expression and production of hematopoietic cytokines in the neonate contributes to the quantitative and qualitative deficiencies in neonatal myeloid progenitor activity and decreased availability and function of mature effector neutrophils. Two myeloid-stimulating cytokines, granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), have been shown to augment the number of circulating neutrophils, promote their maturation and activation, and extend neutrophil lifespan.

Granulocyte Colony-Stimulating Factor

G-CSF is a lineage-specific hematopoietic growth factor that stimulates the proliferation and differentiation of myeloid progenitor cells in the bone marrow, induces the egress of mature cells from the neutrophil storage pool, and enhances mature neutrophil effector function.[26] G-CSF improves neutrophil function by increasing adhesion and by stimulating chemotaxis and phagocytosis, and it could improve neutrophil functions that are deficient in the neonate. Significant differences between adults and newborns, especially preterm infants, have been reported in GCSF serum levels, mRNA expression, and activity. Laver and colleagues have studied the plasma levels of G-CSF and GM-CSF in the umbilical cord blood of normal term newborns and have reported higher levels than those seen in adults.[27] Ohls and co-workers[28] reported that in term and preterm neonatal neutrophils, G-CSF significantly increased expression of β_2-integrin to a greater extent than levels observed in adult neutrophils. However, L-selectin expression in term and preterm neonatal neutrophils decreased after G-CSF incubation and decreased further after stimulation.[28] Cairo and associates have shown that G-CSF production from stimulated adult mononuclear cells was higher than that from cord blood mononuclear cells ($P < .007$).[29] Additionally, significantly more G-CSF mRNA transcripts were produced from adult than from cord mononuclear cells. No differences were found in affinity, binding, and number of G-CSF receptors between cord and adult peripheral effector cells.[29]

Granulocyte-Monocyte Colony-Stimulating Factor

Bailie and co-workers[30] have reported an inverse linear relationship between maternal GM-CSF levels and gestational age. In neonates, a quadratic (nonlinear) association was found between GM-CSF and gestational age. Furthermore, levels were not related to neutrophil count, perinatal complications, or the presence of infection.

Cairo and associates[31] previously reported the effects of GM-CSF on neonatal neutrophils. In a study of the effect of GM-CSF on neonatal neutrophil function, GM-CSF directly up-regulated the expression of the C3bi (complement receptor) in neonatal neutrophils, which resulted in increased aggregation and adherence. Results of a phase I/II trial using GM-CSF in very low-birthweight neonates demonstrated that a 7-day regimen of GM-CSF in this patient population appears to be safe and well tolerated. Additionally, the use of GM-CSF induced a significant increase in the absolute neutrophil count, absolute monocyte count, platelet count, neutrophil C3bi receptor expression, and bone marrow neutrophil storage pool.[32]

A study by Molloy and colleagues[33] evaluated the effect of G-CSF and GM-CSF on neonatal neutrophil function in both normal mothers and neonates and those at high risk for sepsis. Results indicated that G-CSF enhances neonatal neutrophil survival with no significant impact on neutrophil function (CD11b, reactive oxygen intermedicates (ROI). By contrast, after LPS priming, GM-CSF significantly increased neutrophil respiratory burst and CD11b expression. In summary, Molloy's group showed that GCSF has a greater postsurvival effect in neonatal neutrophils than GM-CSF, even after LPS priming. However, GM-CSF augments neonatal neutrophil function by up-regulating both CD11b expression and ROI activity, either alone or in response to LPS. A recent randomized control trial comparing G-CSF and GM-CSF in neonates found that the absolute neutrophil count was significantly increased in the G-CSF group compared with the placebo or GM-CSF therapy group.[34] G-CSF has the greatest antiapoptotic effect on neonatal neutrophils, and GM-CSF has the greatest effect on function.

DEFORMABILITY

The movement of adherent neutrophils through vessel walls requires the expansion of pseudopods between endothelial cells, opening a passageway for the remaining portion of the leukocyte. The neutrophil subsequently moves freely in the intercellular

spaces under the influence of various chemotactic agents. This movement and diapedesis depend on energy, provided by ATP, and on the neutrophil locomotor apparatus.[11]

Neutrophils from newborn infants, compared with PMNs from adults, have been demonstrated to have significantly decreased deformability,[35,36] especially in immature forms.[37] Immature neutrophils from neonates and adults are both less deformable and larger than with mature PMNs. During stressful conditions, such as neonatal sepsis, up to 100% of the circulating neutrophils may be immature. In addition, evidence suggests that neutrophils activated in vivo or in vitro with chemoattractants are much stiffer than unactivated (basal) neutrophils. In particular, pseudopods, which are formed as a result of polymerization and alignment of actin molecules near the surface membrane, are extremely rigid.[38]

Studies of neutrophil transmigration through endothelial monolayers have shown that term neonatal PMNs display approximately 50% transmigration relative to that in adult PMNs, and antibody-blocking studies have demonstrated that these neonatal PMN abnormalities may be explained, in part, by reduced Mac-1 expression.[39]

Lorant and associates[23] demonstrated that delayed transmigration of neutrophils in the neonatal rat correlates with a defect in the expression of P-selectin on the surface of the endothelial cells. In an animal model of inflammation, radiolabeled neutrophils from adult rats transmigrated into the peritoneum of adult rats five times more efficiently than they did through the peritoneum of neonatal rats. The decreased P-selectin expression was associated with decreased numbers of P-selectin storage granules and decreased P-selectin transcription.

CHEMOTAXIS

The most consistently observed functional abnormality of neonate neutrophils is reduced chemotaxis. *Chemotaxis* is the directed migration of a cell toward a chemoattractant along a concentration gradient. In most assays, neutrophils from newborn infants migrate at approximately half the speed observed for adult cells.[40-42] The ability of neutrophils to undergo chemotaxis implies the possession of a sensory mechanism that must be linked to the locomotor apparatus of the cell. After chemotactic factor-receptor interaction, a complex sequence of events occurs: activation of phospholipases, breakdown of phosphoinositol, activation of protein kinase C, an increase in intracellular calcium, release of eicosanoids, and activation of kinases and phosphatases.[7,43] This sequence of events leads to neutrophil-directed migration. The cells migrate from an area of low concentration (i.e., blood vessel walls) to an area of high concentration (site of infection or inflammation), whereupon the chemotactic factors become potent activators of neutrophils.[44]

Since the 1980s, several investigators have studied neonatal neutrophil responses to chemoattractant agents and have determined that neonatal PMNs have normal random migration, but a decreased ability to move toward defined chemoattractant stimuli in comparison with adult PMNs.[42,45,46]

The neutrophils of clinically stable preterm neonates as immature as 24 weeks gestation appear to be functionally very similar to those of term infants.[47] Expression of both L-selectin and Mac-1, after stimulation, is similar to that in term PMNs.[25,47] However, in a study of preterm neonates, PMN Mac-1 content (both in the cytoplasm and on the cell surface) ranged from 10% of adult levels at 27 weeks gestation to 48% at 36 weeks gestation to 57% in term neonates. This study showed a high correlation between PMN Mac-1 content and gestational age.[48]

Sacchi and colleagues[49] demonstrated that chemotactic responses of PMNs in term neonates mature to those of normal adult PMNs by 2 weeks of postnatal age, and those in preterm neonates (born at 34 to 36 weeks) reach adult values by 40 to 42 weeks of postnatal age. Eisenfeld and co-workers[50] similarly demonstrated improvement in term neonatal PMN chemotaxis in term neonates from 40% of adult values at birth to normal adult values between 10 and 32 days of postnatal age. Carr and associates[47] studied preterm infants (24 to 32 weeks gestational age) over a 2-month period and found that chemotaxis improved during the second month of life but remained abnormal in comparison with that in adults.

Impaired expression and up-regulation of receptors may additionally contribute to defective chemotaxis. Falconer and associates[51] demonstrated that neutrophils from preterm and stressed neonates have significantly fewer receptors for complement factors C3b and iC3b than those from term neonates and adults.

Reddy and co-workers[52] studied CR3 expression in neonatal and adult PMNs. Neonatal neutrophils, on average, expressed less CR3 in comparison with adult PMNs. However, because of the higher concentration of neutrophils in umbilical cord blood versus the adult, the absolute number of neutrophils in cord blood expressing high amounts of CR3 was equivalent to that in adult blood. High proportions of immature PMNs in cord blood may explain the previous findings of deficient CR3 expression. Therefore the typical neutrophilia of cord blood can be considered a compensatory event in providing the adult concentration of mature neutrophils.

Human complement component C5a is an important mediator of the inflammatory response, neutrophil chemotaxis, and activation. Nybo and associates[53] demonstrated that C5a uptake was significantly lower in neonatal neutrophils than in adult PMNs. Using FMLP and C5a as stimuli, less migration was observed in neonatal neutrophils than in adult neutrophils.

Various abnormalities of Mac-1 receptors correlate closely with the reduced chemotaxis observed in neonatal neutrophils. In resting neutrophils, Mac-1 receptors are distributed evenly on the cell surface, but during cell locomotion, these receptors are translocated to the tail of the cell, whereas new receptors are translocated from stores in cytoplasmic granules to the leading edge of the migrating cell. This process in neonatal neutrophils is not up-regulated to the same extent as in adult PMNs. The defect is thought to be caused by both a reduced total PMN content of preformed Mac-1, which in term neonates is approximately 60% of adult PMN Mac-1 levels, and a reduced translocation of preformed new receptors from cytoplasmic storage to the PMN surface. The secondary translocation of these receptors to the uropod is also impaired in the neonatal PMN.[54]

Abnormalities in events that follow initial chemotactic factor-receptor interaction have been suggested to contribute to defective PMN chemotaxis. Changes in membrane potential, in the generation of inositol, and in release of calcium ions from intracellular stores have been reported to be impaired in neonatal neutrophils.[55-57] Specific cytoplasmic granules constitute essential supply for the new membrane receptors required for PMN movement. The number of lactoferrin-containing granules appears to be decreased in neonatal neutrophils.[58] Chemoattractant-induced hexose uptake by neonatal neutrophils[59] and release of leukotriene B_4[60] also are decreased when compared with adult PMNs.

Chemotaxis of neonatal and adult neutrophils was compared after stimulation with two chemoattractants: FMLP and DL1.2, a chemotactic monoclonal antibody that binds to a specific neutrophil antigen.[61] Stimulated neonatal neutrophils demonstrated reduced chemotaxis in comparison with adult PMNs, suggesting an aberration in chemoattractant-induced signaling.[62] FMLP induced a rapid increase in intracellular calcium in both adult and neonatal PMNs, but this response was of lesser magnitude in neonatal PMNs. Moreover, a subpopulation of unresponsive neonatal neutrophils was identified.

Impaired polarization and chemotaxis in neonatal neutrophils may result from insufficient production of hematopoietic growth

factors, such as G-CSF and GM-CSF. The in vitro effects of G-CSF and GM-CSF on neutrophil chemotaxis and polarization were studied in isolated PMNs of neonates compared with adults. Both G-CSF and GM-CSF significantly enhanced the chemotaxis of neonatal neutrophils, thereby normalizing their chemotactic defect. This effect was more pronounced when chemotaxis was severely impaired. The reduced polarization, observed in neonatal neutrophils, was corrected after in vitro incubation with both G-CSF and GM-CSF.[16]

PHAGOCYTOSIS

Neutrophils are the predominant mobile phagocytes of the circulating blood. They move from the circulation by adherence to vascular endothelium and migrate through the walls of small blood vessels to the site of infection, where they kill and ingest foreign organisms. Neutrophils possess a selective ability to recognize foreign antigens and have cell surface receptors for the Fc portion of the IgG molecule as well as the C3b complement component. Humoral factors known as *opsonins* coat the foreign antigen and make it more susceptible to phagocytosis after the specific adherence between the opsonized antigen and the neutrophil cell surface receptors. The best-described opsonins are heat-stabile antibodies, immunoglobulins, and complement, particularly the heat-labile component C3b.[61] Preterm and term neonates have reduced production of immunoglobulins. Because most of the IgG is transferred during the last weeks of gestation, premature infants have decreased levels of circulating IgG. Preterm neonates have significantly lower concentrations of complement components and total hemolytic complement activity compared with term neonates. Thus decreased IgG and complement components in the neonate may result in deficient opsonization.[63]

Both the Fab and Fc portions of the IgG immunoglobulin molecule enhance phagocytosis. The Fab portion adheres to the bacteria, whereas the Fc portion adheres to receptors on the neutrophil. Neutrophils express three different types of receptors for the Fc component of IgG: FcγRI (CD64), FcγRII (CD32), and FcγRIII (CD16). FcγRII and FcγRIII are low-affinity receptors normally expressed on neutrophils, and they bind to polyvalent IgG complexes. FcγRI is a high-affinity receptor for IgG and is absent from resting neutrophils; it is considered to be a marker of activated neutrophils. The interaction of these Fc receptors and immunoglobulin initiates the process of phagocytosis, degranulation, and antibody-dependent cellular cytotoxicity (ADCC). Neutrophils from preterm infants express FcγRII and FcγRIII to a significantly lesser extent than neutrophils from term infants and adults.[64,65] Fjaertoft and associates[66] reported that the expression of FcγRI on neutrophils from preterm infants was similar to that in term infants, older infants, children, and adults. Most neutrophils from patients with sepsis express CD64 (FcγRI), and up-regulation of CD64 on neonatal neutrophils is regarded as an indicator of sepsis.[67] This correlation also has been observed in newborn infants: The expression of FcγRI was significantly higher in neutrophils from neonates with bacterial infection than in both noninfected preterm and term newborn infants.[65] Other investigators demonstrated that FcγRI (CD64) expression also is a very sensitive marker for diagnosing late-onset nosocomial infection in very low-birth-weight infants.[68]

The functional response of the stimulated neutrophil, including the cross-linking of Fcγ receptors, involves a complex cascade of biochemical events. The regulation of phagocytosis has been associated with the cross-linking of Fcγ receptor by the induction of tyrosine phosphorylation of FcγRII itself. After ligand binding, there is a rapid induction of protein phosphorylation of the several nonreceptor proteins by the activation of multiple kinases, including tyrosine kinase, protein kinase C, and mitogen-activated protein (MAP) kinase. Protein kinase C and Raf-1 have been shown to translocate to the plasma membrane during the first minutes of neutrophil phagocytosis, in which Raf-1 initiates the MAP kinase cascade, activating extracellular signal-regulated protein kinases 1 and 2 (ERK1 and ERK2), which are required for the ingestion of IgG-opsonized particles.[69] Ydrenius and associates[70] reported that cyclic adenosine monophosphate (cAMP) and cAMP-dependent protein kinase (cAPK) regulate F-actin reorganization during IgG-FcR receptor–mediated neutrophil phagocytosis.

The γ subunit of the Fc receptor contains a cell activation motif referred to as an immunoreceptor tyrosine-based activation motif (ITAM). ITAM tyrosines are phosphorylated after Fcγ clustering, and the phosphorylated ITAMs create sites for the assembly of Src homology 2 (SH2) domains including the Syk tyrosine kinase.[71] Syk plays a critical role in the phagocytic pathway mediated by the FcγRs. Matsuda and associates,[72] using antisense oligonucleotides, reported that ablation of Syk expression significantly reduced FcγR-mediated phagocytosis in human monocytes. Furthermore, transfection of Syk into COS1 cells has been shown to enhance FcγR-mediated phagocytosis, and Syk-deficient macrophages do not signal for FcγR-mediated phagocytosis.[73] Hunter and co-workers[74] identified the regions of Syk that are critical for interaction with the phagocytic pathway and demonstrated that an intact kinase domain is required for facilitating phagocytic signaling by FcγRs.

Activation of the complement system, resulting in the formation of C3b, can be initiated either by the bacteria itself through the alternate complement pathway or by the interaction of specific antibody with microbial antigen and activation of the classical pathway. The complement receptor 3 (CR3, Mac-1, CD11b/CD18) functions as a nonopsonic receptor and is the specific receptor for the complement fragment C3bi. CR3 (a β_2-integrin) is also a receptor for extracellular proteins and, as a lectin, recognizes many different sugars. CR3 is a heterodimer consisting of CD18, the protein common to the β_2-integrins, and CD11b, which contains the C3bi binding site and recognition domain of matrix proteins. An internal peptide sequence in the fibrinogen γ chain has been shown to function as the high-affinity binding site for C3R on neutrophils. Soluble human fibrinogen has been demonstrated to activate neutrophils through a CD11b-dependent mechanism that results in an up-regulation of CD11b, enhancement of phagocytosis, and increased degranulation.[75]

C3R also is involved in the selective internalization of pathogenic mycobacteria. The phagocytosis of mycobacteria by neutrophils under nonopsonic conditions elicits the production of superoxide (O_2^-) and the release of specific granule proteins. The mechanism of the nonopsonic phagocytosis is reported to involve CR3, which associates with a glycosylphosphatidylinositol-anchored protein (GPI) and relocates to cholesterol-rich domains in the cell membrane where the mycobacteria are internalized. When CR3 is not associated with a GPI, it remains outside these domains and mediates phagocytosis of opsonized particles.[76]

Once the opsonized microbe and neutrophil establish contact, a cohesive force prevents their separation. The microbe binds to specific receptors on the surface of the neutrophil through microbe-bound opsonins (IgG, C3b). The sequential interaction between opsonins and membrane receptors leads to submembranous activation of neutrophil contractile microfilaments, resulting in the flow of pseudopods completely surrounding the microbe. The opposed membranes of the pseudopods fuse and then invaginate the captured microbe, enclosing it in an internalized vacuole called a *phagosome.* Ingestion of the foreign particle is an active process requiring ATP glycolysis, glycogenolysis, and oxidative phosphorylation. After the phagosome is formed, degranulation begins, and cytoplasmic azurophilic and specific granules fuse with the phagosome. The granules rupture and discharge toxic chemicals into the phagosome.

Colony-stimulating factors and cytokines have been reported to enhance neutrophil function. Interferon-γ treatment is associated with a significant increase in the expression of the high-affinity Fcγ receptor (peaking 48 hours after exposure to the cytokine), as well as a significant increase in neutrophil phagocytosis of opsonized *Staphylococcus aureus*. This increased phagocytosis after interferon-γ treatment correlates with FcγRI expression by the neutrophils.[77] Recombinant GM-CSF and G-CSF have been shown to enhance phagocytic activity of mature neutrophils.[78] In vitro studies have demonstrated enhanced neutrophil C3bi expression and bacterial killing in neonatal neutrophils incubated with GM-CSF.[31] In addition, Campbell and associates[79] reported an enhancement of phagocytosis of opsonized type III group B streptococci (III GBS) by neonatal neutrophils after pretreatment with G-CSF and GM-CSF but not tumor necrosis factor-α. These workers also demonstrated the abrogation of the heightened killing of III GBS by blocking FcγRIII receptors and that phagocytosis was further enhanced by the addition of purified IgG containing III GBS–specific antibody to the GM-CSF–treated neutrophils.[79]

DEGRANULATION

Bacterial killing occurs within a matter of minutes after phagocytosis. The neutrophil makes tight contact with its target, and the plasma membrane flows around the surface until the bacterium is completely enclosed, thus forming a phagosome. The formation of a phagosome limits the amount of extracellular fluid, and the exclusion of external medium allows a new environment to be established that will provide favorable conditions for the biochemistry of oxidant production and bacterial killing. Killing is initiated within seconds of ingestion by two interrelated processes: *degranulation,* the release of granule contents into the phagosome, and the *respiratory burst,* which consists of a series of oxidation-reduction reactions. Degranulation begins with the fusion of cytoplasmic azurophilic (or primary) and specific (or secondary and tertiary) granules with the phagosome. The granules then rupture and discharge their contents into the phagosome[80] Figure 154-2). Thus the contents of the cytoplasmic azurophilic and specific granules constitute a significant proportion of the phagosomal volume. These granule contents generally are membrane-active cationic proteins and peptides[79] whose affinity for the negatively charged microbial surface depends not only on electrostatic interactions but also on their tertiary structure[81,82] (Table 154-1).

Azurophil (primary) granules can be distinguished from specific granules by their affinity for the basic dye, azure A, owing to a high content of acid mucopolysaccharide and myeloperoxidase, which are present only in azurophil granules. Azurophil granules are further characterized by their content of hydrolytic and bactericidal proteins such as elastase, bactericidal permeability-increasing protein (BPI), defensins, and myeloperoxidase. The contents of the azurophil granules are released into the phagosome, thereby exposing ingested microorganisms to high concentrations of hydrolytic enzymes, antimicrobial proteins and peptides, and reactive oxygen intermediates.

Myeloperoxidase, a major constituent of the azurophilic granules, is critical for oxidative killing. It is a classic heme peroxidase that uses hydrogen peroxide (H_2O_2) to oxidize a variety of aromatic compounds and is unique in readily oxidizing chloride ions to the strong nonradical oxidant HOCl. HOCl is the most potent bactericidal oxidant known to be produced by the neutrophil, and many species of bacteria are killed by the myeloperoxidase-H_2O_2-chloride process.[82] Bacterial targets include iron-sulfur proteins, membrane transport proteins, ATP-generating systems, and the origin of replication sites for DNA synthesis. Chloramines are generated indirectly through the reaction of HOCl with amines, and these also are bactericidal. Myeloperoxidase can also generate peroxides and hydroxylated derivatives of phenolics, such as salicylate in the oxidative reactions.[82]

BPI is a 55-kDa cationic protein produced only by precursors of neutrophils and stored in the azurophilic granules. BPI plays a dominant role in the bactericidal activity against gram-negative

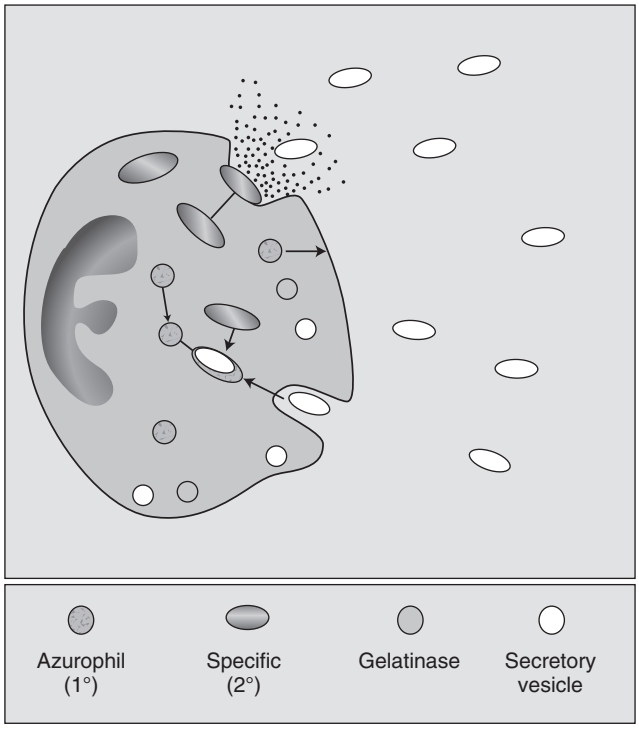

Figure 154-2 Neutrophil degranulation of antibiotic proteins and peptides. An activated neutrophil in the process of phagocytosis of gram-negative bacteria *(open ovals)* is demonstrated. As shown, specific (secondary) granules are more prone to discharge their contents (including lactoferrin and cathelicidins) into the extracellular space. By contrast, with azurophil (primary) granules, containing bactericidal permeability-increasing protein and defensins, degranulation occurs predominantly into the phagolysosome. To a lesser extent, specific granules also release their contents into the phagolysosome, and primary granules into the extracellular space *(arrows).* Neutrophil granule populations, including gelatinase granules and secretory vesicles, are depicted at the *bottom* of the figure. *(From Levy O: Antimicrobial proteins and peptides of blood: templates for novel antimicrobial agents,* Blood *96:2664-2672, 2000.)*

TABLE 154-1

Antimicrobial Proteins and Peptides of Neutrophils

Protein	Size (kDa)	Neutrophil Granule	Mechanism
Lactoferrin	80	Secondary	Iron-binding/ membrane-active
BPI	55	Azurophil	Binds lipid A of lipopolysaccharide
Serprocidins	~30	Azurophil	Proteolysis/membrane-active
Cathelicidins	10-20	Secondary	Release of membrane-active peptides
Lysozyme	14.5	Azurophil and secondary	Lysis of peptidoglycan/ membrane-active
Defensins	4	Azurophil	Formation of voltage-gated multimeric pores

BPI, Bactericidal permeability-increasing protein.

bacteria and is bactericidal in nanomolar concentrations. The biologic effects of BPI are linked to its high-affinity binding to bacterial lipopolysaccharides, which causes immediate growth arrest; actual killing is accomplished by its interaction with lipid phosphate groups and acyl chains of the membrane lipids perturbing the structures, thereby leading to outer and inner membrane lysis. The antibacterial and antiendotoxin activities of BPI are fully expressed by the amino-terminal (N-terminal) half of the molecule.[80,83] Furthermore, activated neutrophils release BPI into inflammatory fluids, where it is potently bactericidal. Levy and colleagues[84] reported that neutrophils of newborns are selectively deficient in BPI. These investigators demonstrated that newborn neutrophils from cord blood contain at least three to four times less BPI per cell than adult neutrophils, and this deficiency correlated with decreased antibacterial activity of newborn neutrophil extracts against serum-resistant *Escherichia coli.*[84] Further studies reported that supplementing newborn cord blood with recombinant BPI potently inhibited the tumor necrosis factor–inducing activity of gram-negative bacteria and in some cases enhanced bactericidal activity. These results suggest that the administration of recombinant BPI may be of clinical benefit to neonates suffering from gram-negative bacterial infection or endotoxemia.[80]

Serprocidins, 25- to 37-kDa serine proteases localized in the azurophil granules, include elastase, cathepsin G, proteinase 3, and azurocidin/CAP37 (heparin-binding protein) and are related to the granzymes of cytotoxic T cells. The serprocidins exert broad cytotoxic activity against gram-negative and gram-positive bacteria through proteolytic action and direct membrane perturbation.[80] Elastase participates in generating antimicrobial activity during inflammatory responses by cleaving cathelicidin proforms to generate active antimicrobial peptides.[85] Proteinase 3 has the ability to degrade extracellular matrix proteins and also plays an important role in myeloid differentiation. Fractionation studies of neutrophils have shown that proteinase 3 could be detected not only in azurophil granules, but also in specific granules and in the plasma membrane–enriched fraction containing secretory vesicles.[86]

Defensins, a family of 4-kDa peptides with broad cytotoxic activity against bacteria, fungi, parasites, and viruses, are found in the azurophil granules. The activity of defensins depends on their cationicity and three-dimensional structure. Defensins form multimeric voltage-dependent pores that permeabilize cellular membranes. α-Defensins are expressed in human neutrophils and are characterized by six invariant cysteine residues forming three disulfide bonds. The activity of defensins is limited by monovalent and divalent cations, a finding suggesting that the action of these peptides is limited to prevent indiscriminate cytotoxicity.[80]

Peroxidase-negative specific granules contain distinct antimicrobial proteins and peptides that are deployed toward the leading edge of the "chemotaxing" neutrophil, thus accomplishing extracellular degranulation.[81] The peroxidase-negative specific granules can be subdivided into secondary granules, defined by the high content of lactoferrin, and tertiary granules, defined by a high concentration of gelatinase. These granules play different functional roles in the process of degranulation. Three novel proteins of specific granules—neutrophil gelatinase-associated lipocalin (NGAL), human cathelicidin (i.e., human cationic antimicrobial protein [hCAP-18]), and SGP28—have been confirmed to contribute significantly to the function of neutrophils. NGAL is a 25-kDa FMLP-binding protein that may play a role in regulating the inflammatory response by binding small lipophilic mediators such as FMLP, platelet-activating factor, leukotriene B_4, and lipopolysaccharide. Synthesis of NGAL has been shown to be induced in peripheral blood neutrophils treated with GM-CSF.[81,87] The only human member of the cathelicidin family of bactericidal peptides, hCAP-18, is a major component of specific granules, in which it is co-localized and co-mobilized with lactoferrin.[88,89] The antibacterial and endotoxin-binding domain resides in the carboxyl terminus (C terminus) of hCAP-18 and is thought to be unleashed by the proteases from the azurophil granules. The 28-kDa glycoprotein SGP is a member of a family of cysteine-rich secretory proteins (CRIPs) and shows high amino acid sequence homology to pathogenesis-related proteins, which are thought to be important for resistance to viral, bacterial, and fungal infections.[81]

Lactoferrin, an 80-kDa member of the transferrin family also localized to the secondary granules, exerts a direct microbicidal effect by membrane disruption. It also has been shown to bind to the lipid A moiety of gram-negative bacterial lipopolysaccharide, thereby neutralizing its endotoxic activity. Lysozyme is a 14-kDa enzyme that degrades bacterial peptidoglycans by cleaving the glycosidic bond of *N*-acetyl glucosamine. This enzyme is stored in both the primary and secondary neutrophil granules. The activity of lysozyme is synergistic with other granular proteins including defensins and lactoferrin.[80]

Stimulation of the bacterial tripeptide receptor FMLP induces the exocytosis of primary and secondary granules and the process of degranulation. FMLP stimulation has been shown to induce a rapid induction of tyrosine phosphorylation of several intracellular proteins including tyrosine kinases and MAP kinases. Studies of adhesion-dependent degranulation demonstrate that the release of lactoferrin is blocked by a selective inhibitor for the Src family kinases. Additional studies with mice deficient in two Src family kinases, Frg and Hck, have demonstrated the essential role these kinases play in degranulation.[90] Mócsai and co-workers,[91] using broad-specificity tyrosine kinase inhibitors, found that FMLP-induced degranulation of primary and secondary granules of neutrophils is mediated by p38 MAP kinase activated by the Src family of tyrosine kinases. Degranulation also involves the rapid activation of p38 MAP kinase and phospholipase D after ligand binding to FMLP receptors. Phospholipase D, found primarily in secretory vesicles, is mobilized to the plasma membrane on stimulation and is activated by small GTPases of the ARF and Rho families. Mansfield and associates[91] reported that neutrophil degranulation is regulated by ceramide, an inhibitor of kinase phosphorylation, through the inhibition of phospholipase D. These investigators demonstrated that phospholipase D activity is significantly increased in neutrophils primed with G-CSF and is stimulated with FMLP; however, the activity was completely inhibited by ceramide.[92]

MICROBICIDAL ACTIVITY

Bacterial killing is initiated by two interrelated processes: oxidative and nonoxidative microbicidal activity. The oxygen-dependent mechanism uses a multicomponent enzyme that is dependent on reduced nicotinamide adenine dinucleotide phosphate (NADPH) to convert molecular oxygen into reactive oxygen-derived species, including (O_2^-) and H_2O_2. These molecules in turn act in concert with PMN-derived granule components such as myeloperoxidase to exert antimicrobial activity.

Oxidative Microbicidal Activity

The *respiratory burst* is characterized by a several-fold increase in oxygen consumption and a 10-fold increase in glucose utilization by activation of the hexose monophosphate shunt. The respiratory burst results in the production of and release of large quantities of O_2^- and H_2O_2 by the phagocytes into their surroundings. The respiratory burst consists of a series of reactions, all of which depend on the activity of the phagocyte oxidase (phox). Current evidence suggests that the phox is a complex multicomponent system that catalyzes the one-electron reduction of oxygen to O_2^- at the expense of NADPH. In the resting phagocyte, the phox system includes a 91-kDa flavoprotein and a

22-kDa heme protein, usually referred to as flavocytochrome b_{558}. Both are plasma membrane–associated, and they act with at least three soluble cytosolic components—$p47^{phox}$, $p67^{phox}$, and rac2.

Defective or absent oxidase activity, manifested clinically as chronic granulomatous disease, can be explained on the molecular level as a disorder of flavocytochrome b_{558}, $p47^{phox}$, or $p67^{phox}$, and full activity can be demonstrated using recombinant forms of these factors with added rac2.[93,94] In unstimulated PMNs, each molecule of flavocytochrome b_{558}, with its two heme groups and flavin adenine dinucleotide and NADPH-binding sites, is located primarily intracellularly, in the membrane of secretory vesicles and specific granules, with a lesser amount in plasma membrane.[81] The segregation of functionally competent components of the oxidase in intracellular compartments allows resting PMNs, cells with limited synthetic activity, to maintain the response in an inactive but ready-to-be-recruited state.[95] The activation of PMNs triggers degranulation and results in increased surface expression of flavocytochrome b_{558}. Biosynthesis and assembly of mature flavocytochrome require coordinated expression of genes encoding each subunit, because they are located in different chromosomes. For example, analysis of the X-linked chronic granulomatous disease PMNs demonstrated a membrane defect consistent with the localization of $gp91^{phox}$ on the X chromosome, whereas $p47^{phox}$ is localized to chromosomal region 7q11.23 and $p67^{phox}$ to 1q25.[96]

The biochemical events of the respiratory burst are summarized as follows:

$$2O_2 + NADPH \xrightarrow[phox]{} 2O_2^- + NADP^+ + H^+$$

Most of the O_2^- is rapidly converted to H_2O_2 by dismutation either occurring spontaneously or mediated enzymatically by superoxide dismutase (SOD):

$$2O_2^- + 2H^+ \xrightarrow[SOD]{} H_2O_2 + O_2$$

NADPH consumption rises because of the O_2^--forming reaction as well as the detoxification of some of the H_2O_2 by NADPH in a glutathione-dependent process:

$$H_2O_2 + NADPH + 2GSH \xrightarrow[glutathione\ peroxidase]{} H_2O_2 + GSSG + NADP^+ + H^+$$

The oxidation of glucose by the hexose monophosphate shunt, involving glucose-6-phosphate dehydrogenase (G6PD), is stimulated by NADPH consumption and leads to the replenishment of NADPH:

$$\text{Glucose-6-phosphate} + NADP^+ \xrightarrow[G6PD]{} \text{5-carbon-P} + CO_2 + NADPH$$

The respiratory burst produces microbicidal agents by the partial reduction of oxygen. However, the most potent of these agents are products from further reactions involving O_2^- and H_2O_2. O_2^- and H_2O_2 react in the presence of iron to form the hydroxyl radical and possibly singlet oxygen.

$$H_2O_2 + O_2^- \xrightarrow[Fe^{3+}]{} HOX + OH^- + O_2$$

In the best-defined microbicidal system, myeloperoxidase derived from the azurophilic granules catalyzes H_2O_2 in combination with chloride, bromide, or other halide to form HOCl or HOBr:

$$H_2O_2 + 2Cl^- \xrightarrow[MPO]{} 2HOCl$$

These reactive species halogenate bacterial cell walls, which lose integrity, resulting in cell death. Oxidizing radicals such as O_2^- also contribute significantly to bacterial killing. Microorganisms vary relatively little in their susceptibility to these oxygen-dependent antimicrobial systems.

Several investigators have explored PMN respiratory burst activity in the newborn. The activities of glutathione peroxidase and catalase, the major enzymes responsible for detoxifying H_2O_2 within the cell, were decreased in neonatal neutrophils in comparison with adult PMNs.[97] Neonatal PMN SOD activity, however, was normal[97] or slightly decreased[98] compared with that in adult PMNs.

Adult neutrophils exposed to low concentrations of gram-negative lipopolysaccharides become primed and exhibit an increased oxidative response to a second stimulus.[99] Bortolussi and co-workers[100] demonstrated lipopolysaccharide-deficient priming activity of neonatal PMNs, and Qing and colleagues[101] identified an association of this reduced priming activity with decreased expression of CD14 on neonatal neutrophils. Subsequently, Bonner and associates[102] investigated the role of ERK1 and ERK2 and found that lipopolysaccharide activated ERK1 and ERK2 in PMNs of adults and newborns, suggesting that the ERK pathway was not responsible for the lack of lipopolysaccharide priming.

In 1986, Allen and associates[103] discovered that activated neutrophils could generate light—the phenomenon of chemiluminescence. Sources of this light emission include singlet oxygen, which releases some of its energy as a photon as it decays to the ground state, and carbonyl compounds in excited states. As a sensitive, noninvasive technique, chemiluminescence has been used extensively to measure respiratory burst activity by neutrophils.

Kallman and colleagues[104] examined the respiratory burst activity of adult and neonatal term and preterm PMNs after activation and opsonization. Term neonate neutrophils exhibited a chemiluminescence response identical to that in adult neutrophils, but preterm (28 to 34 weeks) neutrophils responded with a very much smaller chemiluminescence peak. The normal chemiluminescence response in neutrophils of full-term neonates and the reduced respiratory burst activity in those of preterm infants have been confirmed by other investigators.[105-107]

In contrast with that of adult PMNs,[108] the respiratory burst of term neonatal neutrophils becomes less active when it is challenged by sepsis or other clinical stress.[109] At the time of diagnosis of sepsis, increased levels of cytokines and intensity of oxidative metabolism were found in serum of newborns by Sikora and associates.[110] Over the course of time, however, these findings were further accompanied by prolonged neutrophil stimulation and, eventually, by functional exhaustion and diminished oxidative metabolism in PMNs.

Term neonates with GBS sepsis demonstrated neutrophil chemiluminescence responses of only 50% to 75% those measured in uninfected infants, and this was associated with a 10-fold reduction in ability to kill opsonized GBS in vitro.[111] A similar, although less marked, reduction in chemiluminescence was found in uninfected infants with respiratory distress.[112]

Postnatal maturation of the respiratory burst was studied by Driscoll and co-workers[113] in 57 premature infants over a 2-month period. During the first postnatal week, most preterm infants exhibited a lower chemiluminescence peak. During subsequent maturation, mean PMN chemiluminescence continued to be lower than in adult control subjects. The suppression of the respiratory burst seemed to be more closely associated with clinical stress and prolonged intensive care than with low gestational age. Usmani and associates[107] likewise demonstrated suppression of PMN chemiluminescence at 21 days after preterm birth.

An intriguing aspect of the neonatal respiratory burst is that although the generation of hydroxyl radicals is reduced, the initial phase of the respiratory burst, O_2^- generation, is increased in neonatal neutrophils compared with that in adult PMNs.[114] Measurement of light scattering in neutrophils from 90 healthy neonates and 96 healthy adults demonstrated that O_2^- generation in response to FMLP of neonates exceeds that of adult PMNs.[16] Ambruso and colleagues[115] demonstrated that the

kinetics of the neonatal NADPH oxidase system, which generates O_2^-, was different from that in adult PMNs, and an increase was observed in O_2^- production by cord blood neutrophils collected after labor, in contrast with that observed after cesarean section.[116] The paradoxical findings of reduced bactericidal oxidants and increased generation of O_2^- may be explained by inadequate stores of lactoferrin and myeloperoxidase to catalyze the later stages of the respiratory burst. Lactoferrin, if saturated with iron, enhances the production of hydroxide ions.[117] Neonatal neutrophils contain only half the amount of lactoferrin found in adult cells, and lactoferrin levels in premature neonatal PMNs are even lower.[118] Myeloperoxidase, which is involved in generation of hypochlorous acid from H_2O_2, has been found in normal concentrations in the azurophil granules of term neonatal PMNs,[114] but it is reduced in PMNs from preterm infants.[119]

Reddy and co-workers[52] studied CR3-dependent respiratory burst activity in neonatal and adult leukocytes. Neonatal neutrophils, on average, expressed less CR3 in comparison with that in adult PMNs. Because of the higher neutrophil concentration in cord blood versus in adult blood, the calculated number of neutrophils in cord blood expressing high amounts of CR3 was equivalent to that in adult blood.The size of CR3-dependent respiratory burst correlated with CR3 expression; therefore respiratory burst activities were equivalent in newborn and adult cells. High proportions of immature cells in cord blood may explain in part the deficiency in CR3 expression and neutrophil-dependent killing activities.

Nonoxidative Microbicidal Activity

Neutrophil cytoplasmic granules contain antimicrobial agents that are released into phagolysosomes and do not require the production of oxidants for activity. The granules are extremely heterogeneous in terms of shape, size, and content.

The first granule type produced during neutrophil maturation is the azurophilic granule, which contains myeloperoxidase, defensins, cathepsin G, BPI, hydrolases, elastase, and collagenase.[120] Defensins possess antimicrobial activity through their ability to bind to the negatively charged cell surface of the organism and thereby interfere with growth. Cathepsin G microbicidal activity does not rely on proteolysis but depends on inhibition of macromolecular synthesis (proteins, RNA, and DNA) of the invading bacteria.[121] BPI contributes to the ability of neutrophils to kill gram-negative bacteria.[82,122,123] During microbial ingestion, acid hydrolases have a digestive role against proteins, complex lipids, polysaccharides, and nucleic acids.

PMN secondary and tertiary granules are produced later in development, and they are twice as abundant as azurophilic granules. They include lysozyme, lactoferrin, gelatinase, and β-glucuronidase. Lysozyme can kill some saprophytic bacteria within the phagocytic vacuole by hydrolyzing the mucopolysaccharides of the bacterial cell walls, as well as by digesting the glycopeptide cell wall debris of dead bacteria. Lactoferrin exerts bacteriostatic activity by competitively binding the iron required as an essential nutrient for microbial growth.[124] Lactoferrin also makes the bacteria more accessible to lysozyme, leading to alterations in the bacterial cell wall.[125]

To investigate specific deficits in neutrophil microbicidal activity as a risk for neonatal sepsis, Levy and co-workers[83] compared the relative contents of BPI in the neutrophils of neonates and adults. Newborn and adult PMNs contain nearly identical amounts of myeloperoxidase and defensin peptides in their azurophilic granules, but neonatal neutrophils contain three to four times less BPI than that in adult PMNs.These data suggest a selective deficit of BPI in neonatal neutrophils, which may partly explain the increased incidence of gram-negative sepsis in the neonate.

Studies of bactericidal activity by neonatal neutrophils indicate that phagocytic killing of different microorganisms is normal in most healthy neonates but is reduced in preterm infants.[126,127] The relevance of reduced microbicidal activity to increased sepsis in preterm infants is supported by in vitro studies of bacterial killing. Intracellular killing of *S. aureus* or *E. coli* by neutrophils of term neonates has consistently been demonstrated to be normal,[128-130] whereas killing of staphylococci was impaired in preterm neonates with birth weights less than 2000 g.[57] Various conditions, such as respiratory distress and sepsis, have been associated with decreased bacterial killing.[131] A depression of microbicidal capacity also was demonstrated when neonatal neutrophils were challenged with a large number of *E. coli* organisms.[132] *Candida*-cidal activity has been shown to be normal in neonatal PMNs.[133] In one study, however, neonatal PMNs were unable to kill *Candida albicans* as efficiently as adult PMNs.[134]

ANTIBODY-DEPENDENT CELLULAR CYTOTOXICITY

Neutrophils are the predominant mobile phagocytes of the circulating blood and constitute the first line of defense against infection. They also are active in immunosurveillance against tumor cells.[135-137] The lytic disruption of target cells, cytolysis, is a fundamental immunologic effector function mediated by neutrophils as well as by cytotoxic T cells, natural killer cells, and macrophages. One mechanism of cytolysis is ADCC. Neutrophils exhibit fast recruitment activity in vivo, and rapid, potent neutrophil cytotoxicity toward various tumor targets has been documented.[138,139]

ADCC requires opsonization of a target cell with immunoglobulin and the engagement of effector cell surface receptors for the Fc domains of immunoglobulin molecules. Neutrophils can trigger ADCC by engagement of FcγRI (CD64), FcγRIα (CD32A), and FcαRI (CD89). FcαRI has been identified as the most effective FcR for neutrophil-mediated tumor cell killing. FcαRI is constitutively expressed on neutrophils and has a medium affinity for both IgA1 and IgA2 that is increased on exposure to G-CSF or GM-CSF.[140,141] Neutrophil-mediated GM-CSF/Lym-1 cytotoxicity has been reported to require the intervention of FcγRII and CD11b-CD18 integrins.[142] Furthermore, studies with transgenic mice also have demonstrated the requirement of CD11b/CD18 (CR3) for FcαRI-mediated ADCC.[143] The role of CR3 in neutrophil Fc-mediated lysis of tumor cells was further characterized in the CR3-deficient mouse. ADCC was abrogated in $CR3^{-/-}$ neutrophils and in human neutrophils blocked with anti-CR3 monoclonal antibodies.[138]

Nagarajan and associates[144] reported that affinity modulation of FcγRIIa also is one of the mechanisms by which neutrophils regulate their FcγR-dependent functions. These studies demonstrate that resting neutrophils express FcγRIIa in a low-affinity state, but on activation, FcγRIIa is converted to a high-affinity state that leads to FcγRIIa-dependent ligand binding and signaling for tumor cell cytotoxicity.[144] Membrane-associated CD45, a protein tyrosine phosphatase essential for antigen receptor kinase–mediated signaling in lymphocytes, also has been shown to regulate and enhance the stimulation and function of neutrophils mediated through Fcγ receptors. Gao and associates[145] demonstrated that neutrophils pretreated with anti-CD45 have a reduced ability to perform ADCC compared with untreated neutrophils.

Antibodies against HLA class II or related epitopes are highly effective in recruiting neutrophils. Whole blood from patients during G-CSF therapy exhibits significantly enhanced lysis of breast cancer target cells in the presence of Her-2/neu antibody, and the extent of tumor killing correlated positively to neutrophil blood counts.[146] Furthermore, separation of whole blood into plasma, mononuclear cells, and neutrophils demonstrated that significant cytotoxicity was found in the neutrophil fraction.[146] Bispecific antibodies contain one specificity against a

tumor target and another specificity against selected epitopes of an activating Fc receptor on neutrophils. Preclinical studies of bispecific antibodies and tumor targets have demonstrated that neutrophils are the most active effector cell population in tumor cytolysis. During G-CSF therapy, bispecific antibodies (FcαRI × Her-2/neu) are reported to induce enhanced killing of Her-2/neu$^+$ breast cancer cells.[140] This enhanced cytotoxicity is attributed to the increased neutrophil counts that resulted in higher effector-to-target cell ratios in G-CSF–primed blood.[140] Neutrophils also were found to effectively lyse malignant B cells with an FcαRI × CD20 bispecific antibody.[147]

The particular role of extracellular and intracellular domains of CD19 and Her-2/neu for ADCC by neutrophils was examined by creating Her-2/CD19 and CD19/Her-2 chimeric target molecules. Their ability to trigger ADCC was compared with that for wild-type Her-2/neu and CD19 targets.[148] Neutrophils predictably killed wild-type Her-2/neu but not CD19 targets; however, neutrophils also were effective against chimeric CD19/Her-2–transfected but not Her-2/CD19$^-$ transfected target cells. These results suggest that intracellular domains of target antigens may contribute to effective neutrophil ADCC.[148]

The Complement System of the Fetus and Newborn

Complement is a system of more than 30 soluble proteins, cell surface regulatory factors, and receptors that work together to accomplish a wide variety of functions.[1-4] These are important not only in host defense and inflammatory responses but also in normal physiologic homeostasis. By effecting proper disposal of apoptotic cells and antigens from infectious agents, complement plays an important role in preventing autoimmune and immune complex diseases under normal conditions. In infections, complement fragments rapidly activate and attract leukocytes and macrophages, and complement-derived opsonins facilitate clearance and killing of infectious organisms. Complement also provides two-way bridges between the innate and adaptive immune systems. Besides its traditionally understood roles in amplifying the effector functions of antibody, it also has important influences on antigen presentation and B cell activation, giving it a key role the afferent limb of antibody responses. As expected with a system that ties together so many different physiologic activities, disorders of complement can have wide-ranging effects.

From a biochemical standpoint, it is fascinating to study the processes by which circulating proteins that seem inert when considered individually can transform themselves into complex multisubunit enzymes,[4] form multichain integral membrane proteins that insert into cells from the outside, provide address tags that direct trafficking of a wide variety of cellular and foreign materials, and stimulate vigorous inflammatory responses. These transformations are achieved by two main mechanisms: limited proteolytic cleavage and conformational changes. At each stage of activation, newly revealed conformations are accompanied by new properties, such as enzyme activity and markedly increased binding activity for other components or cell surface receptors. In the first several steps of activation, newly formed enzymes can cleave many molecules of the next component in the sequence, further amplifying the signal. For this reason, the activation pathways are considered "cascades," in analogy with the cascades of the clotting or contact activation (kinin) systems. Understanding the way the complement proteins are activated is the first step toward understanding the functions of this system.

ACTIVATION PATHWAYS

There are three major pathways by which complement activation can be initiated. Because complement was originally discovered as a set of heat labile serum proteins that could cause lysis of erythrocytes sensitized with antibody, the antibody-dependent or "classical" pathway has been best studied. Although it is phylogenetically the newest pathway, its activation is easiest to describe, so it will be presented first (Fig. 155-1, *A*.)

The Classical Pathway

C1, its first component, is composed of 22 peptide chains arranged into three subcomponents termed C1q, r, and s.[5] C1q itself contains six sets of trimers, each of which has a collagen-like stalk and a globular head. Electron micrographs show the six trimers arranged with their stalks together and the globular heads all at the same end, giving the appearance of a bunch of tulips. Around the stalk are wrapped two molecules each of C1r and C1s, which are latent proteases. Classical pathway activation begins when two or more of the six globular immunoglobulin-binding domains of C1q become attached to the Fc regions of antigen-bound immunoglobulin M (IgM) or IgG molecules. This causes internal rearrangements in the complex, leading to activation of latent proteolytic activity of C1r, which then cleaves and activates the C1s molecules.[5,6] Because of the requirement for two or more of the globular heads of C1q to be engaged for activation to begin, IgM, which has five Fc regions attached together, is a very efficient activator of the classical pathway. In contrast, many molecules of IgG must be bound to the surface of a target cell or bacterium in order for two of the IgG molecules to find themselves close enough together to bridge a single C1q. The other classes of immunoglobulins, IgD, IgA, and IgE, do not bind to C1q and hence do not activate the classical pathway. C1s, when activated, also has proteolytic activity. This enzyme can cleave synthetic esters in vitro, in addition to its substrates in the complement system, and it is hence often referred to as *C1 esterase*. Its physiologic role is to carry out limited proteolytic cleavage of the next two components in the reaction sequence: C4 and C2.[5,6] The components were numbered in the order in which they were discovered rather than the order in which they act, hence C4 comes before C2. C1s cleaves the largest of the three chains of C4 at a single site, liberating a 9-kDa peptide (C4a) and leaving the larger fragment (C4b) with a transient ability to form covalent bonds to the target.[7] The C4b fragment also takes on a new conformation in which it can bind a molecule of C2 so that the C2 be cleaved by C1s as well. Again, a small fragment is released and diffuses away, and the conformation and activity of the larger fragment are changed. In this case, the larger fragment is C2a. The newly formed C2a has its own proteolytic active site, and together with C4b, which can also hold onto a C3 molecule, forms an enzyme that can cleave and activate C3. This complex is therefore called *C3 convertase*.[1-4] This classical pathway C3 convertase, composed of one molecule of C4b covalently attached to the target and one molecule of C2a loosely bound to that, is capable of cleaving many molecules of C3. C3 is homologous with C4. On cleavage, the larger fragment also transiently has the ability to bind covalently to the surface or target on which activation is occurring.[7-9] The heavy chain of immunoglobulin molecules provides particularly good "acceptors" for covalent attachment of C3b.[10] Many molecules of C3 can be cleaved by a single convertase, but the convertase eventually loses activity when the C2a subunit diffuses or is pushed away. Some of the newly formed C3b molecules will diffuse away before they can bind to the surface. Many others will bind to the surface at short distances around the convertase; these may serve to "opsonize" (facilitate phagocytosis of) the target. Some of the C3b molecules may deposit in very close proximity to the C4b2a complex and actually join with it. These C3b

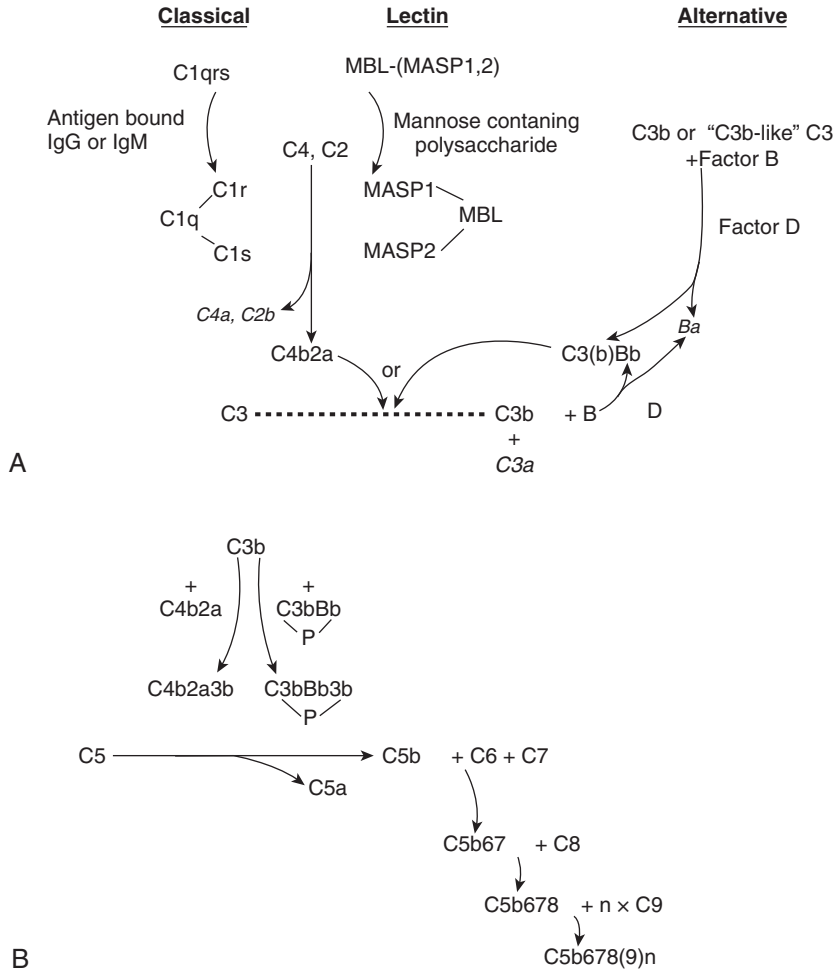

Figure 155-1 A, The early steps of complement activation drawn to emphasize homology between different pathways. The classical pathway is activated when C1q in the C1 complex binds to antigen-bound immunoglobulin Gs (IgGs) or IgM. *C1r* then activates C1s. The lectin pathway is activated when the MBL-MASP complex binds to mannose residues of a polysaccharide. *MASP 1* activates MASP 2. *C1s* and *MASP 2* cleave C4 and C2, which form a C3 convertase, *C4b2a*. The inactive *C4a* and *C2b* fragments *(italics)* diffuse away. The convertase cleaves C3 into *C3a*, an anaphylotoxin that diffuses away, and the major fragment, C3b. C3b can bind a molecule of B, which makes the latter susceptible to cleavage by *D*. *Ba* diffuses away, but Bb binds to C3b and forms the alternative pathway C3 convertase, which is homologous with *C4b2a*. **B,** Activation of C5 and formation of the membrane attack complex. Addition of another molecule of C3b provides a binding site for C5 and changes the C3 convertase into a C5 convertase. C5 can be cleaved by the classical/lectin pathway convertase, *C4b2a3b,* or the alternative pathway convertase, *C3bBb3b* (here shown in the form stabilized by properdin, P). The smaller fragment, *C5a,* is an anaphylotoxin and chemoattractant that diffuses away. The larger fragment binds to C6, forming a lipophilic complex that may insert into cell membranes. C5b6 binds C7 and then C8 without proteolytic cleavage, and this complex activates and binds multiple molecules of C9, forming the complete membrane attack complex.

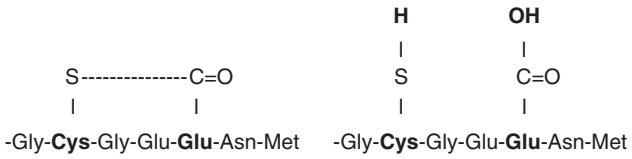
molecules can provide binding sites for C5 molecules, which will be cleaved by the proteolytic active site on the C2a. Thus the complex C4b2a3b serves as the classical pathway C5 convertase.[11] Like C4 and C3, the cleavage of C5 liberates a small fragment (C5a), but unlike C4 and C3, C5 cannot form a covalent bond with the surface. The larger fragment, C5b, however, undergoes a conformational change that allows it to bind C6. This leads toward formation of the lipophilic membrane attack complex (MAC), discussed later.



The Lectin Pathway

Activation by this route begins with the protein mannan binding lectin (MBL), Like C1q, this multichain molecule has collagen-like stalks composed of three protein chains that form a globular binding domain at one end.[12] In the case of MBL, however, the binding sites recognize polysaccharides containing mannose, hence its name. Because MBL, C1q, and other similar molecules have collagen-like regions and binding sites that often have lectin-like activity in recognizing polysaccharides, they are often considered to be members of the same family of collagen-like lectins, or "collectins."[13] Lung surfactant proteins A and D are also members of this collectin family. Different isoforms of MBL may contain between two and eight of the basic trimer subunits. Because many bacteria and fungi are coated with mannose-containing polysaccharides, the MBL pathway of complement activation is considered part of the innate immune system, as is the alternative pathway, which is discussed later. Phylogenetically, the alternative and lectin pathways likely originated earlier than the classical pathway. In a sense, C1q may be

seen as an adaptor protein that allowed this important part of the innate immune system to be used to enhance the activity of antibody produced by the adaptive immune system. The ability of the lectin and alternative pathways to activate complement in the absence of antibody may be particularly important in the neonate, while the adaptive immune system is immature. Similarly, early in the course of infections, before antibody production and other effector mechanisms of the specific immune system are brought to bear, MBL and the lectin and alternative pathways provide an important innate system for distinguishing self from non-self. Like the binding of C1q to the Fc regions of IgG or IgM, the binding of MBL to mannose-containing polysaccharides leads to activation of latent proteases. In this pathway, the proteases that are analogous to C1r and C1s are termed *MBL-associated serine proteases* (MASPs).[14] Two major MASPs have been identified and may circulate in the plasma as a large complex together with MBL and another protein component whose function has not yet been determined. When MBL is engaged with polysaccharides, MASP 1 becomes activated and cleaves MASP 2. Both MASP 1 and MASP 2 have been shown to be capable of cleaving C3,[15] but some studies suggest that they actually act more like C1r and C1s in cleaving C4 and C2. Just as in the classical pathway, the larger fragments of those components go on to form a C3 convertase, and the addition of a molecule of C3b confers C5 convertase activity on the complex. The physiologic importance of the lectin pathway is illustrated by the occurrence of an increased susceptibility to infections and also to autoimmune diseases like lupus in patients with MBL deficiency.[16,17]

The Alternative Pathway

The alternative pathway, also known as the *properdin pathway*, shares with the lectin pathway the ability to activate complement without antibody. Alternative pathway activation is initiated by C3b, which may be formed by one of the other pathways, by nonspecific proteolytic cleavage of C3, or after the spontaneous activation of C3 by water molecules[18] (see later). Most investigators visualize native C3 in the circulation as a kind of coiled spring, which holds a unique structure called a *thioester* in an internal hydrophobic pocket.[7,8] This highly unusual chemical structure is formed by the binding of a thiol on the side chain of one of the protein's cysteine residues with the carboxyl on the side chain of a glutamate three residues away in the polypeptide.[7,8]

C4 and α_2-macroglobulin also contain this internal thioester. Although the cleavage site on the protein chain containing the thioester is distant from that structure, cleavage by a convertase or nonspecific protease causes conformational changes in which the coiled spring is released, the thioester is transiently exposed, and the carbon on the glutamate can transfer one of its bonds from the sulfur of the cysteine to another acceptor.[8,9] It is the ability of these molecules to transfer a carbon bond to hydroxyl or amino groups on other proteins or to sugar molecules that allows C3b and C4b to bind covalently during complement activation. If the transfer to another protein or sugar does not occur within milliseconds, the bond will transfer to the hydroxyl group of a water molecule, whose other hydrogen atom will bind to the sulfur of the cysteine to create a free thiol (−SH). This process of transfer or hydrolysis of the internal thioester is greatly accelerated by the conformational changes that follow cleavage of the protein chain. However, water molecules may occasionally penetrate into the hydrophobic pocket and hydrolyze this bond even in intact molecules of C3. Once that occurs, similar conformational changes in the protein chains will follow, even though no cleavage fragment has been removed. That process goes on constantly at a slow rate, hence there is always some turnover of C3. These C3 molecules with hydrolyzed thioester bonds assume a conformation similar to that of C3b and are thus called "C3b-like" C3 molecules.[18] This constant low-grade turnover of C3 may be thought of as the idling of a car engine: the system is always turned on and ready to accelerate at any time. This allows the alternative pathway of complement to play an important role in recognition of foreign invaders as part of the innate immune system and also allows it to play a role in eliminating dead or damaged body cells. However, it also means that the system must be carefully regulated, as discussed later in the section, Control of Complement Activation.

C3 and C4 are highly homologous proteins, and the alternative pathway C3 convertase is highly homologous to the classical pathway convertase and is formed in an analogous way.[1-4,18] This is initiated when a molecule of C3b-like C3, or C3b itself, which acts like C4b in the classical pathway, binds with a molecule called *factor B*, which is homologous with C2. The B is then cleaved by factor D, a proteolytic enzyme that circulates in its active form all the time but can only act on factor B when it is held in the proper configuration by C3b. Cleavage of factor B is analogous to cleavage of C2, but the large fragment is named Bb. Like C2, factor B has latent protease activity. The Bb fragment that results from cleavage by factor D has its proteolytic active site exposed, and this enzyme can cleave C3 and C5. The C3b or C3b-like C3 molecule that initiated the pathway also serves the same role as the C4b in the classical pathway C3 convertase: holding additional molecules of C3 substrate in place, which are then cleaved by Bb. Just as in the classical pathway, some of the newly cleaved C3b molecules will deposit sufficiently close to the C3bBb enzyme to join with it. This new molecule of C3b can provide a binding site for C5, which will be cleaved by Bb. Thus, the addition of this new C3b molecule changes the C3 convertase *C3bBb* into the alternative pathway C5 convertase, *C3bBb3b*.[11,18]

The alternative pathway contains an additional molecule not found in the classical or lectin pathways, which is called *properdin*, or *factor P*. The discovery of this molecule led to the elucidation of the alternative pathway, and thus it is sometimes referred to as the *properdin pathway*.[19] P is capable of stabilizing the alternative pathway convertases, which might otherwise lose activity when the Bb, which contains the proteolytic active site, diffuses away.[18] This may also occur pathologically in the presence of *C3 nephritic factor*, an autoantibody with properdin-like properties found in some patients with glomerulonephritis.[20]

Activation of C5 and Formation of the Membrane Attack Complex (MAC)

One of the most dramatic features of complement activation is the conversion a series of separate, water-soluble, circulating plasma proteins into a large multisubunit, lipophilic membrane channel that can insert itself into plasma membranes, spanning both leaflets. Insertion of just one of these channels into an erythrocyte allows enough water to rush into the cell to cause explosive lysis. This ability of a heat labile fraction of plasma proteins to lyse erythrocytes sensitized by heat stabile antibodies was recognized more than 100 years ago and led to the elucidation of the complement reaction sequence because the liberated hemoglobin provided a convenient end point for assays. It is arguable, however, that complement-mediated lysis is not the most important function of the complement system in vivo, as discussed in subsequent sections. The transmembrane water channel formed

by the assembly of C5 through C9 is the MAC, and its formation begins with activation of C5 by a proteolytic cleavage.

After C5 has been activated, regardless of which pathway was responsible, the remaining steps of activation of C6 through C9 follow the same sequence. Unlike the early activation pathways, however, activation beyond C5 and formation of the MAC do not involve proteolytic cleavages or other enzymatic activity. C5 does not contain the same internal thioester as its homologues C3 and C4, and C5b cannot form covalent bonds with the target. However, just after cleavage, C5b gains the ability to interact with C6. Interaction with C6 increases the lipophilicity of C5b, and the C5b6 complex can insert into lipid membranes at some distance from the C5 convertase, even on adjacent cells.[21] This phenomenon can lead to "bystander lysis" of normal cells in the vicinity of soluble immune complexes or bacteria that are being attacked. The C5b6 complex can then attract and bind a molecule of C7. The complex of C5b67 is highly lipophilic and, if formed in the fluid phase, will rapidly insert into plasma membranes, where it will serve as a binding site for C8. Binding of C8 to C5b67 creates an active complex, which can disrupt the phospholipids of target cell membranes and can cause lysis of erythrocytes, even without the addition of C9.[22,23] The C5b-8 complex can induce conformational changes in soluble C9 molecules.[24,25] These conformational changes include elongation and unfolding of the C9 molecules, exposing previously protected hydrophobic regions as well as potential sites for disulfide bonding between chains.[25] These changes, in turn, give the C9 molecules the ability to polymerize and cause their addition to the complex. Isolated C9 can also be induced to undergo these conformational changes and polymerize in vitro.[23-25] These polymers may contain up to 12 molecules of C9 linked in dimers by disulfide bonds. Electron micrographs of these C9 polymers look very similar to MACs isolated from cells or artificial membranes that have been attacked by complement. They appear like grommets or donuts, with a top rim 15 to 20 nm in diameter sitting above a slightly narrower cylinder, 15 to 16 nm in length, which spans the plasma membrane.[26] The conformational changes that accompany C9 polymerization are recognized by monoclonal antibodies that do not recognize native, circulating C9 molecules.[27] These antibodies to the C9 "neoantigen" that is formed on activation may be used to identify sites of MAC deposition in tissue sections[27] and are now widely used in enzyme-linked immunosorbent assays of complement activity.

CONTROL OF COMPLEMENT ACTIVATION

Besides the ability to lyse cells, complement activation liberates C3a and C5a, which are potent mediators of inflammation. The deposition of large amounts of C3b can opsonize, or target, our own cells for destruction by macrophages in the reticuloendothelial system, just as it can opsonize invading microorganisms. The apparent dichotomy between complement's role as a part of the innate immune system that is always turned on to detect foreign invaders and its potential for tissue damage and destruction requires that a delicate balance must be maintained at all times. This balance depends on a set of control mechanisms no less intricate than the activation pathways discussed previously.

Control of the Alternative Pathway

The need to control alternative pathway activation becomes apparent when one considers the fact that the alternative pathway can be initiated wherever C3b has been deposited, whether by any one of the activation pathways, by the action of a nonspecific serine protease, or even spontaneously after lysis of the thioester by water.[18] The alternative pathway is often visualized as an amplification loop that can feed forward whenever C3b is formed (Fig. 155-1, *A*). The danger of uncontrolled alternative pathway activation is illustrated by the case of a patient with congenital deficiency of the complement regulatory protein, factor H (see later).[28] This patient lacked detectable C3 activity in his serum, giving him an increased susceptibility to infection; but he did have C3b deposited on his red blood cells, causing mild but chronic hemolytic anemia.[28] In this patient, most of the C3 was being consumed continuously, by nonspecific activation of the alternative pathway, as fast as it was synthesized, and some of the C3b was deposited nonspecifically on his own red blood cells.[28]

First of all, the activity of complement is controlled by maintaining low circulating concentrations of the complement proteins. C3, C4, and other components are "acute phase reactants," whose synthesis by hepatocytes and other types of cells can be increased rapidly in response to cytokines, hormones, and other signals.[29] Thus, local synthesis and changes in vascular permeability are important determinants of the amounts of the components available at any site or time. Activation of the cascades of the early activation pathways discussed previously is also inherently limited by the instability of the multisubunit convertase enzymes. In these bimolecular and trimolecular complexes, the proteolytic active sites are on the C2a and Bb fragments, which are not covalently bound to the target. These proteolytically active subunits have relatively weak, noncovalent interactions with the C4b, C3b, or both subunits, which bind the next component, the substrates C3 or C5. The mechanism by which properdin facilitates activation of the alternative pathway is by holding together the two subunits of the noncovalent *C3bBb* enzyme so that it will maintain activity.[18,19] In contrast, dissociation of the active subunit (C2a or Bb, respectively, in the classical or alternative pathways) causes loss, or "decay," of the convertase activity. This decay may occur spontaneously, or it may be accelerated by proteins that bind to the covalently attached member of the convertase and "push away" the proteolytically active subunit, thereby "accelerating decay" of the complex.[30] Several proteins have this function; some are soluble and some are membrane-bound (Table 155-1). Many of these proteins share homology with each other. This is not unexpected because they all bind to C3, C4, or both, which are themselves homologous. These proteins belong to the regulators of complement activation (RCA) family and are encoded by genes in the RCA gene cluster on chromosome 1.[31,32] Members of this family are all composed of variable numbers of short homologous repeats, each of which has 60 to 65 amino acids and two internal disulfide bonds, which give it a double-looped structure. These are further grouped into long homologous repeats, which form the binding sites for C4b and C3b.[32] A prototypic member of this family is called *decay accelerating factor* (DAF) (CD55).[30,33] DAF is bound to the plasma membrane by a glycolipid anchor, which is believed to give it increased lateral mobility in the membrane, to prevent attack of complement on our own cells.[33] The major function of DAF is to bind to C3b and C4b molecules and push off Bb or C2a. Besides the ability to bind to and push off (or block binding of) active subunits of convertases, some of the regulatory proteins can also facilitate degradation of the C4b or C3b to which they bind. A circulating protease, called *C3b/C4b inactivator* (factor I), can cleave C3b and C4b into forms that will no longer bind other components of the convertases. This factor I can only cleave its substrates when an additional cofactor is present. Soluble cofactors include C4 binding protein (C4bp) and factor H (formerly termed *β-1-H globulin*). Several integral membrane proteins also have this kind of cofactor activity, including complement receptor type 1 (CR1, CD35),[34] commonly considered the C3b receptor, and a separate membrane cofactor protein (MCP) (CD46).[35] DAF and MCP only bind to C3b and C4b that have been deposited on same cell on which they reside, so they are considered important in protecting our own cells from becoming activators or targets of complement. CR1 can also bind C3b on other cells or circulating

TABLE 155-1

Regulators of Complement Activation (RCA) Proteins

Protein*	Abbreviation	Molecular Weight	No. of Short Consensus Repeats (SCRs)	DISSOCIATION OF C3 AND C5 CONVERTASES		FACTOR 1 COFACTOR ACTIVITY ON:	
				Alternative	Classical	C3b	C4b
Factor H, β_{1H}	H	150,000	20	+	−	+	−
C4 binding protein	C4bp	570,000 (Octamer)	8	−	+	−	+
Decay accelerating factor (CD55)	DAF	70,000-80,000	4	+	+	−	−
Membrane cofactor protein (CD46)	MCP	45,000-70,000	4	−	−	+	+
Complement receptor type 1 C3b/C4b receptor (CD35)	CR1	205,000-250,000	22-30	+	+	+	+
Complement receptor type 2 C3d receptor (CD21)	CR2	145,000	15/16	−	−	−	−

*Factor H and C4bp are soluble. All others are membrane proteins indicated by CD number in parentheses.

complexes, so it is important in processing these complexes and in promoting phagocytosis of particles opsonized with C3b or C4b. The enzymatically inactive fragments are termed *iC4b* and *iC3b*, respectively. The latter still serves as an important opsonin, however, by binding to its own receptor, termed *CR3*.

From the viewpoint of a C3b molecule, regulation of the alternative pathway might be seen as a competition between binding of factor B, which would lead to additional activation, and factor H, which would lead to inactivation.[36] The enzymes that execute those actions, factor D and factor I, respectively, are both present in their active forms in the circulation at all times. An important determinant of the fate of any given C3b molecule is the chemical nature of the surface on which it is bound because the surface has an important role in influencing the binding of B compared with H. Surfaces that are rich in sialic acid, like our own cells, favor the binding of H and thus promote the action of I.[36,37] These surfaces are thus poor activators of the alternative pathway. In contrast, many bacteria and cells from some other species of mammals lack sialic acid. On these surfaces, binding of B is favored. Those cells are good activators of the alternative pathway. Thus, the alternative pathway can be considered an important part of the "innate" immune system because it can distinguish self from non-self, even in the absence of antibody or a rearranged T cell receptor. It is interesting in this context that bacteria, such as K12 *Escherichia coli*[38] and type III group B *Streptococcus,*[39] which have terminal sialic acid residues on their surface carbohydrates or capsules, are dangerous pathogens, particularly for newborns who lack specific antibody. Related bacteria, without the sialic acid, are much less virulent. Antibody molecules provide good acceptor sites for C3b deposition, on which B is favored over H and the C3b is "protected" against inactivation.[10] This allows the alternative pathway to amplify initial signals generated by antibody and the classical pathway. Besides their coating with sialic acid, most of our own cells are protected from amplification of the alternative pathway by the presence of DAF and MCP. Some cell types, including erythrocytes, are also similarly protected by CR1.

Control of Early Steps of the Classical and Lectin Pathways

Besides these critical mechanisms of regulation of the activation of the alternative pathway, there is a specific plasma protein, called *C1 inhibitor* (C1 INH), or *C1 esterase inhibitor*, that can complex with C1r and C1s and terminate their activity.[40] This protein has also been shown to inhibit the MASPs.[41] All these enzymes contain serine in their active sites, and C1 INH is a member of the serine protease inhibitor or serpin family of proteins. C1 INH also can also inhibit serine proteases in the clotting and kallikrein-kinin systems. Congenital deficiency of this protein results in the autosomal dominant condition, hereditary angioedema (HAE), which is manifest clinically in repeated episodes of swelling, including attacks of laryngeal edema that can be fatal.[40]

Control of Membrane Attack Complex Formation

Activation of the complement system beyond C5 involves conformational changes in individual soluble protein molecules that expose hydrophobic domains and lead to assembly of a multimeric lipophilic complex. Several circulating molecules are capable of interacting with the newly developing lipophilic sites on C5b-6 and C5-7 and preventing attachment of these intermediate complexes to plasma membranes. Some of these proteins may also interfere with binding of C8 or C9 and may bind to nascent MACs forming on cells, preventing their completion. Proteins with these properties include some of the lipoproteins, a protein called *clusterin* (apolipoprotein J)[42]; a specialized plasma protein called *S-protein* or *vitronectin*,[43,44] which also inhibits the blood clotting system; and others. Besides these plasma proteins that inhibit the formation of MACs before they insert into cells, there are membrane proteins that protect the cells on which they reside.[45-48] These include homologous restriction factor (HRF), also known as *protectin* (CD59), which inhibits polymerization of C9 and its incorporation into complexes containing C8.[47] This blocks formation of the full MAC. Like DAF (CD55), CD59 is not a true transmembrane protein but rather is linked to the cell membrane by phosphatidyl inositol glycolipid anchors.[48] This linkage may give them high mobility in the plasma membrane, facilitating their ability to move to sites of complement activation. Mutations in the enzymes that produce this type of anchor lead to the disease paroxysmal nocturnal hemoglobinuria, in which there can be spontaneous lysis of the unprotected cells.[48]

PHYSIOLOGIC EFFECTS OF COMPLEMENT ACTIVATION AND DEPOSITION

C3a and C5a

C3a is a 9.6-kDa fragment released from the N-terminal of the α chain of C3 when it is cleaved by convertases or other serine proteases. C5a is a similarly released on cleavage of C5, but C5a is heavily glycosylated and has a molecular weight of about 11 kDa.

TABLE 155-2

Properties of Complement Components and Inhibitors

Component	Molecular Weight	Serum Concentration (μg/mL)	Chain Structure
Classical Pathway			
C1q	390,000	190	6 each α, β, γ
C1r	95,000	100	s*
C1s	85,000	80	s
C4	209,000	430	α, β, γ
C2	117,000	30	s
C3	190,000	1400	α, β
C5	206,000	75	α, β
C6	95,000	60	s
C7	120,000	55	s
C8	163,000	80	α, β, γ
C9	79,000	160	s
Alternate Pathway			
P (properdin)	223,000	25	4 identical chains
D	25,000	1-5	s
B	100,000	200	s
Mannan Binding Lectin Pathway			
Mannan Binding Lectin	32,000	0.5 ng-5 μg/mL	3 identical chains per unit circulates as assembly of 2-8 units
MASP 1	90,000	1.6-7.5 μg/mL	s
MASP 2	74,000	0.4 μg/mL	s
Control Proteins			
Soluble Control Proteins			
C1 esterase inhibitor (C1EI, C1 INH)	105,000	180	s
C4 binding protein	570,000	150	6-7 α chains, 1 β chain
I (C3b/C4b inactivator, C3 INA)	100,000	50	α, β
H (β_{1H} globulin)	150,000	520	s
Clusterin (apolipoprotein J)	80,000	50-100	2
S protein (vitronectin)	80,000	600	s
Membrane Bound Control Proteins		**CD Designation**	
Decay accelerating factor (DAF)	70,000-80,000	CD 55	s
Membrane cofactor protein (MCP)	48,000-68,000	CD46	s
Complement receptor type 1 (CR1)	190-220,000	CD35	s
Protectin, homologous restriction factor (HRF)	20,000	CD59	s

CD, Cluster of differentiation; *MASP,* mannose binding lectin-associated serine proteins.
*Single chain.

Both of these peptides can bind to specific receptors on several types of cells, including mast cells, causing non–IgE-mediated degranulation, with release of histamine and other mediators. Thus, the actions of C3a and C5a mimic anaphylaxis, and they are known as *anaphylotoxins*.[49] C4a has only weak anaphylotoxin activity. Expression of the receptors[50] for C3a and C5a on epithelial, gland, and smooth muscle cells in the lung likely contributes to non-histamine-mediated mucus secretion and bronchoconstriction, and there are reports that these anaphylotoxins can induce interleukin-6 (IL-6) production,[51] providing a mechanism by which local complement activation can contribute to the systemic response to infection. All three of these peptides end with a C-terminal arginine. Removal of this residue by the enzyme carboxypeptidase N (an "anaphylotoxin inactivator") markedly decreases the ability of the "des-Arg" forms of the anaphylotoxins to activate their receptors.[49-53]

The carbohydrate moiety is important in the binding of C5a to its receptor (CD88) on myeloid cells, making this peptide one of the most potent known chemoattractants and activators of neutrophils, monocytes, and macrophages.[53] The des-Arg form of C5a has reduced, but still very potent, chemoattractant and proinflammatory activity.[53] Exposure of neutrophils to C5a or C5a des-Arg causes rapid up-regulation and activation of CD11/CD18 on the surface of polymorphonuclear leukocytes (PMNs), which allows the neutrophils to adhere to surfaces or aggregate with each other, or both.[54] In some cases, neutrophil aggregates formed in response to C5a or C5a des-Arg released by intravascular complement activation may plug pulmonary capillaries, which can cause transient pulmonary dysfunction or acute respiratory distress syndrome.[54] This may occur in sepsis as well as in burns and ischemia-reperfusion injury, in which damaged tissues can activate the alternative and lectin pathways. This pathophysiology also occurs when blood comes into contact with artificial membranes in oxygenators and during hemodialysis.[54] It has been hypothesized that part of the pulmonary dysfunction that accompanies amniotic fluid embolism may actually be caused by PMN aggregates induced by C5a produced intravascularly when complement is activated by fetal antigens and intracellular cellular debris from the placenta entering the maternal circulation.[55]

Bound C3 Fragments and Their Receptors

C3 is present in serum at a higher concentration than any other complement protein (approximately 100 mg/dL in normal adults) (Table 155-2). On activation, C3b can become covalently bound to its target, whether that is a bacterium, human cell, or soluble antigen. Subsequent metabolism of bound C3b involves

an orderly sequence of limited proteolytic cleavages, resulting in fragments that bind to distinct receptors on different types of cells.[56,57] The stage of degradation of C3 fragments on any target of complement activation plays a major role in determining the fate of that target and the host's response to it.[58]

When the α chain of C3 is cleaved or when the internal thioester is opened, the resulting C3b or C3b-like C3 molecule undergoes conformational changes that markedly increase its affinity for CR1 (CD35), the C3b receptor.[59,60] Uncleaved, native C3 does not bind to this receptor,[59] but C4b can also bind, so it is often termed the *C3b/C4b receptor*. This receptor is a member of the RCA family, but its cytoplasmic domain is short and cannot activate cells. Hence, its main function is to hold onto C3b-bearing immune complexes and C3b-opsonized bacteria and cells. By itself, it does not actually induce the internalization phase of phagocytosis.[61] That usually requires a "second" signal, such as that generated by binding of IgG to certain Fcγ receptors.[61] The conformational change that accompanies conversion of native C3 to C3b is followed by changes of similar magnitudes if and when the bound C3b is converted to iC3b.[60] That form of the molecule has a greatly reduced affinity for CR1 (CD35) but increased affinity for CR3 (CD11b/CD18). CD11b/CD18 is a multifunctional molecule that is a β2 integrin and serves as the neutrophil's major adhesion protein. Mutations in the CD18 subunit interfere with expression of this class of molecules, resulting in the condition known as leukocyte adherence deficiency (LAD) type 1.[62] Reduced intracellular pools of this molecule likely contribute to decreased chemotactic and phagocytic responses of neonates' neutrophils.[63] Because there are fewer CR3 molecules on neonates' neutrophils, more iC3b must be on the opsonized target to achieve the same number of adherence interactions.[64] Further cleavage of iC3b results in the release of a large soluble fragment termed *C3c*, which contains fragments of the cleaved α chain as well as the entire β chain.[56,57] The smaller fragment of the α chain remains covalently bound to the target. This is termed *C3dg* or *C3d*, depending on whether additional cleavages occur. This fragment binds to another distinct receptor, CR2 (CD21), which is also a member of the RCA family.[57,58] CD21 is most notably expressed on B lymphocytes and follicular dendritic cells. Simultaneous engagement of CR2 by C3d on an antigen or immune complex and the receptor (surface immunoglobulin) for that antigen on B cells markedly enhances the B cells' response to that antigen.[65] Persistence of C3d-bearing antigen complexes on the surface of dendritic cells and costimulation of B cells by additional bound C3d fragments is probably the major mechanism by which complement contributes to the afferent arm of "adaptive" immune responses (see later).[65,66]

C3 and Disposal of Immune Complexes and Apoptotic and Necrotic Cells

Although the proinflammatory activities of complement usually receive the greatest emphasis, it is important to realize that a major physiologic function of the complement system actually limits excessive inflammatory reactions by targeting the stimulus for elimination. Similarly, a major function of complement is to prevent tissue pathology by promoting solubilization and appropriate disposal of antigen-antibody complexes.[67] Activation of the complement cascades can deposit many C4b and C3b molecules onto antigen-antibody precipitates. The covalent binding of these water-soluble polypeptides disrupts the lattice-like structure of the antigen-antibody precipitate, forming smaller, soluble C3b-bearing complexes. The C3b targets these smaller complexes for phagocytosis and digestion by cells in the reticuloendothelial system which are specialized to perform those functions. Thus, C3b deposition can solubilize large antigen-antibody aggregates that might otherwise be trapped in tissues by ionic interactions with basement membranes (e.g., in the kidney). Interestingly, in the circulation, C3b-bearing complexes adhere to CR1 on the surface of erythrocytes (in primates only), and the erythrocytes thus carry the complexes on their surfaces into the narrow sinusoids of the liver and spleen.[68] This "immune adherence" of the C3b-bearing complexes to CR1 on the nonphagocytic erythrocytes slows down transit of the complexes and increases the ability of the macrophages to phagocytose the complexes, by stripping them off the erythrocyte's surface. Studies in patients with deficiencies of C3 or other early complement components demonstrate the importance of these mechanisms in normal immunologic homeostasis. Thus, for example, patients with congenital C3 deficiency have an increased incidence of glomerulonephritis, presumably owing to the failure of their reticuloendothelial macrophages to remove antigen-antibody complexes that result from common infections.[69] The lack of complement to solubilize and opsonize antigen-antibody complexes allows their accumulation in the kidneys, where they induce pathology by other pathways.[69]

Patients with deficiencies of the early components of the classical pathway or MBL have an increased incidence of autoimmune diseases like SLE.[10,69-71] C1q can bind to proteins that are usually intracellular but become exposed when cells undergo apoptosis or necrosis.[72] Such cells can also bind "natural antibodies" and MBL, and they can activate complement by the classical or lectin pathway. C3b deposited on apoptotic cells or their fragments can enhance their phagocytosis in situ by tissue macrophages, thus facilitating "disposal" of this cellular "waste."[3,72,73] It is hypothesized that the failure to efficiently clear cellular debris and proteins that would normally not be seen by the immune system allows potentially antigenic material to accumulate.[3] Epitopes not normally exposed could then stimulate autoimmune responses. Viewed in this way, a properly functioning complement system actually plays an important role in preventing inappropriate inflammatory and immune responses.

Complement in Host Defense Against Infectious Agents

Viruses

Because viruses employ specific proteins to adhere to and enter host cells, binding of antibody or complement directly to these proteins or to nearby sites on the virus surface can block this interaction, neutralizing the infectivity of the virus.[74] With enveloped viruses, insertion of the MAC can disrupt or lyse the envelope.[75] Some viruses can activate the alternative pathway at sites where the complement causes little damage to the virus; in those cases, antibody may play an important role by redirecting the complement to more critical sites. Retroviruses may activate the classical pathway directly by interacting with C1 without requiring antibody.[76] However, this does not usually lead to viral neutralization or lysis of the envelope. C3b fragments deposited by this route may actually facilitate entry of the virus into host macrophages that carry CR1. Other pathogens may also employ similar strategies of subverting host defenses to increase their virulence (see later).

Bacteria

The most important functions of complement in host defense are its contributions to control of bacteria, as evidenced by the increase in bacterial infections in patients with complement deficiencies.[77,78] Gram-positive bacteria have thick cell walls and must be phagocytosed and killed intracellularly to be eradicated.[79] The MAC cannot penetrate the cell wall to reach the cell membrane. Although the cell walls themselves often activate the alternative pathway, with many organisms, a polysaccharide capsule surrounds the cell wall. The capsule is permeable to proteins but holds off other cells at a distance. Thus, with encapsulated gram-positive organisms, C3 fragments can become bound to the

cell wall, but phagocyte receptors cannot reach them.[78-80] Organisms with capsules that lack sialic acid will be good activators of the alternative pathway, and complement will easily limit their pathogenicity. On the other hand, organisms that have terminal sialic acid on their capsular polysaccharides will not activate the alternative pathway. With these types of organisms, which include group B streptococcus, K12 *E. coli*, and others, anticapsular antibody plays a critical role by binding to the capsule, activating the classical pathway, and providing good acceptor sites for C3b.[79] Phagocytes, attracted and activated by the C5a generated during complement activation, will then rapidly phagocytose the C3b-opsonized organisms, especially if the anticapsular antibody is IgG. The roles of antibody and complement in clearance of circulating bacteria from the bloodstream are similar to those in phagocytosis of the bacteria at peripheral sites of tissue invasion.[81] Efficient killing of gram-negative bacteria requires insertion of the C5 through C9 MAC into their cell membranes, which are more accessible than the membranes of gram-positive organisms.[78,79] Patients deficient in components C5 to C9 thus have an increased susceptibility to serious infection with *Neisseria* species,[77,82] but these often do not present until the teenage years.

Protozoans

The cell membranes of protozoans are generally susceptible to attack by the C5 to C9 components of complement, which can lyse the organisms.[83,84] Thus many can be killed by antibody and the classical or the alternative pathways. However, several protozoans have adapted elements of the complement system to their own advantage. For example, *Plasmodium falciparum* has a surface protein that binds to CR1and other mammalian cell surface proteins, allowing it to adhere to erythrocytes and endothelial cells in the microvasculature and avoid destruction in the liver or spleen.[85] There is some evidence suggesting that expression of different allotypes of CR1 correspond with differences in susceptibility to malaria.[85] Some types of leishmanial promastigotes may also be killed by complement, but deposition of C3 fragments on their surfaces allows some of them to be phagocytosed through interactions with complement receptors on macrophages before they are killed.[83] These organisms can then survive intracellularly by altering trafficking of lysosomes and inhibiting microbicidal mechanisms. Other protozoans, including *Trypanosoma cruzi,* can produce complement regulatory proteins that function like DAF.[84,86-88] Many protozoans produce extracellular proteases that may degrade complement proteins, protecting the organisms. In addition,[88] some protozoans and bacteria produce enzymes that can transfer sialic acid onto their surfaces in mammalian hosts.

Molecular Mimicry and Complement Evasion Strategies of Pathogens

Many organisms that are significant pathogens have either adapted elements of the complement system to facilitate invasion of the host or have developed adaptations to evade complement attack to increase their pathogenicity.[86-88] For example, adenovirus, human herpesvirus type 6, measles virus, and other pathogens use CD46 (membrane cofactor protein) and other cell surface proteins as attachment sites to facilitate their entry into a variety of host cell types.[89] The surface protein GP350/220 of Epstein-Barr virus (EBV) contains a nine-residue sequence that is similar to the sequence on C3d that interacts with CR2.[90] This allows EBV to bind to and activate B lymphocytes and is believed to account for the tropism of that virus for those cells and the induction of polyclonal B cell activation during EBV infection.[90] C3d on the surface of HIV serves to hold the virus on CR2 on the surface of follicular dendritic cells in lymph nodes, accounting for a major reservoir of the virus in most infected individuals.[91] Mycobacteria may become coated with complement without being damaged. The mycobacteria then use the complement fragments to induce phagocytosis through the complement receptors on macrophages,[92] in which these intracellular pathogens survive and replicate.

Besides putting sialic acid on their capsules to inhibit alternative pathway activation, many other adaptations help pathogenic bacteria evade complement.[78,88] The side chains of some gram-negative bacterial lipopolysaccharides are able to hold active complement components at a distance from the cell membrane or cause shedding of the nascent MAC as it is being formed. Many gram-positive bacteria have surface proteins that mimic or interact with complement control factors. For example, streptococcal M proteins and other somewhat similar proteins on pneumococci can bind C4 binding protein and factor H from human serum, then these proteins inhibit complement activation on the bacteria.[93] A similar strategy has been developed by *Borrelia burgdorferi,*[94] the spirochete that causes Lyme disease, and is also used by the blood forms of protozoans and parasitic worms. In addition, some bacteria secrete enzymes that can degrade the complement components in their milieu.[95] Viruses also have specific proteins that allow them to evade complement: the surface glycoprotein gC on herpes simplex–type 1 virus binds C3,[96] and orthopoxviruses, including both variola and vaccinia, code for proteins that are homologous with RCA family members and that protect virus-infected cells from attack.[97] In yet another variation, cytomegalovirus infection up-regulates synthesis of CD46 (MCP), protecting infected cells from complement attack and increasing pathogenicity of the virus.[98] The blood phases of treponema, other protozoans, and schistosomes and other parasites also often bind factor H or other complement regulatory proteins, thereby protecting themselves.

Role of Complement in Antibody Responses

Complement plays a major role in localization and persistence of antigen on follicular dendritic cells in germinal centers, most importantly by the interaction of C3d with CR2.[99] Complement-bearing antigens are much more efficient in activating B cells than are non-complement-bearing antigens, and coengagement of CR2 and antigen receptor surface immunoglobulin increases processing and expression of major histocompatibility complex (MHC) class II antigen peptide on the B cells, which probably contributes to T cell activation in vivo.[65,66] Some T cells themselves have complement receptors, and recent studies show that complement may provide costimulation for T cells.[100] These effects, particularly those involving antigen persistence and localization, likely explain the in vivo observations that depletion of complement in mice decreases secondary antibody responses, particularly to T cell–dependent antigens.[101] Similar results are found in humans and guinea pigs congenitally deficient in C4.[102] Primary IgM responses are not affected much, but on reimmunization, the secondary IgG response is markedly diminished, and IgM production resembles the response to the primary immunization.[102] Thus, by directing antigen localization and by increasing B cell activation, bound C3 fragments play a major role in immunologic memory and immunoglobulin class switching.

COMPLEMENT GENES AND THEIR ORGANIZATION

The genes for each of the complement proteins and major receptors and control proteins have all been identified and sequenced.[103] As expected, because many of the proteins are homologous with each other (i.e., C1r with C1s and the MASPs; C2 with factor B; C3, C4, and C5 with each other), studies of the structures and locations of various genes suggest that these homologies have arisen by gene duplication then divergence.The three different polypeptides that make up the trimeric subunits of C1q are all encoded by different genes that are clustered together on the short arm of chromosome 1 and organized similarly.

The homologous genes for MBL, surfactant proteins A and D, and other members of the collectin family are on chromosome 10.[104] C1r and C1s are encoded by separate but adjacent genes on chromosome 12, which share about 40% homology.[105] The homologous MASP genes are on chromosome 3 (*MASP1*) and chromosome 1 (*MASP2*). The genes for C2 and its homologue, factor B, and the gene for C4 are on chromosome 6 and are considered part of the MHC complex,[106] termed MHC class III genes. Although less diverse than MHC class I and II proteins, these and many other complement proteins also have different allotypes, which also correlate with susceptibility to different autoimmune diseases, although the reasons for this have not been clearly elucidated. There are two separate loci for C4, with multiple allotypes at each.[107] The proteins encoded by the different genes have different tendencies to form amide versus ester bonds when they transfer their internal thioesters, and they may have different activities in hemolytic compared with other types of assays. It is possible to have homozygous null mutations at one locus but still produce the other type of C4. The two slightly different gene products are distinguished as the Chido and Rogers blood group antigens when their fragments are displayed on red cells. Like its homologues C3 and C5, C4 is synthesized as a single chain precursor pro-C4, which is cleaved to form the predominant form in plasma, but as much as 5% of the circulating C4 may be the single chain pro-C4 form.[108] Unlike the other multichain components, the three chains of C8 are the products of two separate genes. Most of the genes for the homologous proteins that regulate complement activity by binding to C3 or C4 are found in the RCA gene cluster on chromosome 1(q32).[31] CR1, the C4b/C3b receptor, has structural allotypes as well as genetically determined quantitative differences in expression.[109] Allotypic differences in specific components' functions, as well as in receptor expression and function, may be related to differences in the efficiency of clearance of immune complexes and therefore to the susceptibility to autoimmune and inflammatory diseases.

COMPLEMENT SYNTHESIS

Complement synthesis by fetal tissues has been observed as early as the sixth week of gestation,[110,111] and most of the components are detectable in fetal serum by the 10th to 12th weeks.[110,111] Studies of maternal-fetal pairs that express different allotypes of C3[112] and other components and studies in babies of complement-deficient mothers[113] indicate that complement proteins do not cross the placenta and that fetal synthesis accounts for the complement components easily measurable in cord blood. Complement synthesis has been documented in kidney and other fetal tissues[114-116] in addition to the liver. The liver is the major site of production of most of the complement proteins in adult's plasma.[117] For example, the colon may be the major site of production of C1 in fetal life[118] and continues to be an important site of synthesis in the adult. Various components can also be synthesized by myeloid and other types of cells, and local synthesis may play important roles in inflammatory reactions (i.e., in inflamed joints, lung, and sites of infection). The levels of most components increase with gestational age and reach 50% to 75% of the levels in maternal serum at term.[119-127] However, the levels of most of the complement proteins in maternal serum also increase during pregnancy, so the levels in the term newborn correspond more closely to about 80% of normal adult levels.[120-122] The levels of C8 and C9 in term babies are lower than that, at only about 10% of the level in maternal serum.[122] The addition of normal human C9 in vitro increases the hemolytic activity and the ability of neonatal sera to kill gram-negative organisms.[128] In contrast to the active components, C1 INH reaches the same concentration as in adult serum by the 28th week of gestation.[110]

As expected, because the concentrations of most components increase progressively during gestation, preterm babies have lower levels of complement activity than full-term babies. The concentrations usually climb to within the normal adult range by 3 months of postnatal life. The difference between the actual functional amount of complement at a site of infection in a baby compared with an adult, however, may be greater than the difference in the serum levels because synthesis in the baby may not increase in response to infectious stimuli in the same way as the adult.[129] However, it is not clear whether this difference resides in the regulation of the complement proteins themselves compared with differences in other proteins, such as interferon-γ, which are involved in the response to lipopolysaccharides and other stimuli.[29] The relatively lower levels of C3 and factor B in neonates' sera, together with the decreased levels of CR3 in neonate's neutrophils, likely both contribute to compromise phagocytic defenses,[130] even in term newborns.

COMPLEMENT IN MATERNAL-FETAL MEDICINE

Recent studies suggest that there is ongoing low-level complement activation during pregnancy, as evidenced by increased concentrations of C3a and other split fragments in maternal circulation.[131] Both fetal and maternal complement components are present in the placenta, and alloantibodies in the mother have the potential for activating complement in the placenta. Expression of the complement regulatory proteins DAF (CD55), MCP (CD46), and protectin (CD59) on trophoblasts has been documented[132] and may play an important role in maintaining the fetus. Homozygous deletion in mice of the major complement receptor and control protein, Crry, which is a homologue of CR1 and CR2, causes embryonic lethality,[133] suggesting the importance of restricting complement activation in the placenta. Elegant studies in mice show that passive transfer of antiphospholipid antibodies purified from women with recurrent pregnancy losses or other signs of antiphospholipid antibody syndrome cause fetal loss.[134] Studies of this model in the presence of complement inhibitors and in complement knockout mice strongly suggest that complement can play an important role in damaging the placenta.[134] Even in the absence of antibody, complement activation and generation of C5a can lead to inflammatory infiltrates in the placenta, intrauterine growth retardation, and loss of fetuses.[135] Furthermore, it has been reported that there may be complement-fixing antitrophoblast or antiendothelial cell antibodies in the serum of women with recurrent fetal losses who do not have antiphospholipid antibodies.[136] Complement does not play a major role in Rh(D) hemolytic disease of the newborn because the density of D antigens on erythrocytes are too few and far apart for the IgG antibodies to attach to and activate C1 molecules. Destruction of the fetal red cells in this case is carried out by FcγR-mediated macrophage phagocytosis.

A growing body of evidence suggests that maternal neutrophil activation occurs in, and probably contributes to, the pathophysiology of preeclampsia and eclampsia.[137,138] Some reports suggest that these conditions are associated with activation of complement and liberation of C5a, which activates the neutrophils and may induce formation of aggregates that occlude capillaries. In addition, local production of complement fragments and release of mediators like tumor necrosis factor from complement-activated leukocytes could certainly induce prothrombotic changes in endothelial cells, promoting microthromboses.[139] The resulting restriction of blood flow could contribute to hypertension in the mother and intrauterine growth restriction in the fetus.[138] This process could certainly be initiated by binding of maternal alloantibodies to trophoblasts or by formation of immune complexes in the placental circulation. One report suggests that the risk for preeclampsia is higher in women with the low expressing allele of CR1, whose erythrocytes have less capacity to bind and carry away immune complexes than the erythrocytes of women with medium- or high-level expression of CR1.[140] Meconium has also

recently been shown to be a potent activator of the alternative pathway,[141] and the severity of lung damage or inflammation in an animal model of meconium aspiration correlates with the degree of complement activation induced by instillation of meconium into the lungs.[142]

THERAPEUTIC MANIPULATION OF COMPLEMENT ACTIVITY

In many diseases that involve autoantibodies or alloantibodies formed by the mother against antigens expressed by the fetus but not herself, complement may be physiologically activated after antibody binding. However, because in these situations, the antigen is a normal body constituent, the complement activation causes pathology. This may occur if the mother produces IgG antibodies against fetal antigens because that is the only class that crosses the placenta. Complement activation by the alternative pathway may also occur after ischemia-reperfusion injury.[34] In all those situations, production of C5a may cause local neutrophil activation and aggregate formation, which can plug capillaries; deposition of C3 fragments may lead to attack on cells and interstitial structures, and deposition of MACs may cause endothelial or parenchymal cell damage. It may be thus be desirable to inhibit complement activation as part of the therapy. It is possible that augmentation of normal C1 esterase inhibitor activity may be beneficial because of the broad range of activity of this inhibitor.[40,143] Small molecule inhibitors of the complement convertases are under development, but they have not yet come into use clinically. As noted earlier, by binding to C3b, CR1 can inhibit both the classical and alternative pathways. A recombinant form of soluble CR1 has been prepared, which inhibits both the classical and alternative activation pathways.[34] This molecule impressively limits the extent of myocardial infarction in an animal model of transient ischemia,[34] and some clinical trials have been started. A monoclonal antibody against C5 has been developed, which has shown very promising results in inhibiting lysis of paroxysmal nocturnal hemoglobinuria erythrocytes[144] and may prove useful in other disorders in which MAC formation participates.

As mentioned earlier, IgG antibody molecules provide very good acceptors for the nascent covalent binding site that is exposed during C3 activation.[10] Activating complement in the presence of increased concentrations of IgG results in distraction of some of the C3b molecules from the target to some of the extra IgG molecules in solution.[145] In this way, excess IgG can decrease C3b deposition and can prevent hemolysis of sensitized erythrocytes and other forms of tissue damage.[145-147] Therapeutically, administration of high doses of intravenous immune globulin (IVIG) (1 to 2 g per kg) may have this effect in vivo, and inhibition of complement deposition and reticuloendothelial clearance may be major mechanisms by which IVIG treatment acts in autoantibody- or alloantibody-mediated diseases, such as thrombocytopenia due to maternal alloantibodies. IVIG also exerts additional antiinflammatory effects whose mechanisms are not well defined, and this is the mainstay of treatment for Kawasaki syndrome. Whether IVIG is really effective in preventing fetal loss due to antiphospholipid antibodies or other alloantibodies remains to be proved, and the exact circumstances in which it is most likely to be effective must be defined by additional studies.

CONCLUSION

Complement is an important part of the innate immune system, which may be particularly important in neonates, who have low IgM concentrations and do not produce much of their own IgG. When antibody is present, complement can serve as a major amplification and effector pathway for the adaptive immune system. As with other aspects of complement's activities, its ability to attract and activate leukocytes is a double-edged sword that is necessary for normal host defense but that can cause serious pathology when activated inappropriately. Complement plays important roles in limiting inflammatory responses by removing infectious agents and noxious stimuli and supports normal homeostasis by directing trafficking and disposal of apoptotic cells and immune complexes. However, complement can contribute to local pathology when these mechanisms are overwhelmed or function imperfectly. Fortunately, an elaborate set of soluble and cell surface regulatory molecules keeps this system in delicate balance.

Cytokines and Inflammatory Response in the Fetus and Neonate

CYTOKINE STRUCTURE AND FUNCTION

Inflammation is a protective response to infection or injury. The several different components of this response act to mobilize host defense systems.

The inflammatory response is controlled primarily by cytokines, which are endogenous mediators of the immune system. An understanding of how the inflammatory response is regulated at both local and systemic levels requires an appreciation of the wide range of biologic activities of this set of multifunctional proteins. To provide this background, an overview of the production and physiologic functions of cytokines is presented next.

General Description of Cytokines

Cytokines are produced by various different cell types in response to multiple types of stimuli and have overlapping biologic activity.[1-5] Cytokines are potent endogenous mediators whose synthesis and secretion are under tight regulatory control. These endogenous mediators are not stored as preformed molecules in producer cells; rather, new synthesis is required for secretion.

Once these mediators are released, their half-life is relatively short, further limiting their biologic activity. Cytokines act in minute quantities (10^{-9} to 10^{-12} mole) by binding to specific cellular receptors that are members of distinct structural families. Most cellular responses to cytokines result in an altered pattern of gene expression that leads to alterations in cellular physiology.

An important function of cytokines is cell-to-cell communication. Cytokines are unusual in that they can communicate in autocrine, paracrine, or endocrine mode.[1,2,5] Most cytokine activity occurs on the local level, where these proteins act in paracrine fashion to exert their effects by simple diffusion or by cell-to-cell contact. Some cytokine producer cells also express cytokine receptors, and secreted cytokines can bind to their producer cells, whereby they can modulate cell function. Cytokines also can leave the local environment, enter the circulation, interact with different organ systems, and alter host physiology.

A group of cytokines is produced specifically in response to inflammatory stimuli. The function of these *proinflammatory* cytokines is to communicate to surrounding tissue the presence of infection or injury.[3-5] Principal proinflammatory cytokines are tumor necrosis factor-α (TNF-α); the interleukins IL-1, IL-6, IL-8, IL-12, IL-18; and interferon-γ (IFN-γ). TNF and IL-1 are the principal mediators of the inflammatory response and are thought to have a critical role in orchestrating the local response through cell activation and triggering a cytokine cascade.[3,6] Proinflammatory cytokines also can enter the systemic circulation and can produce immune cell activation and significant alterations in host physiology, such as fever, and the acute phase reaction.

Inflammatory stimuli also trigger the synthesis of *antiinflammatory* cytokines and specific cytokine inhibitors that serve to modify the host inflammatory response.[6-8] Antiinflammatory cytokines limit the inflammatory response by inhibiting proinflammatory cytokine synthesis; key antiinflammatory cytokines include IL-10, IL-13, IL-4, and IL-11.

Naturally occurring proinflammatory cytokine inhibitors neutralize proinflammatory cytokine bioactivity by blocking cytokine: cytokine receptor interactions, by binding to either the proinflammatory cytokine itself or to its specific receptor. These naturally occurring inhibitors include soluble proinflammatory cytokine receptors, decoy receptors, receptor antagonists, and cytokine binding proteins. The interplay among these proinflammatory cytokines, antiinflammatory cytokines, and naturally occurring cytokine inhibitors determines the inflammatory response and its effectiveness.

Proinflammatory Cytokines

Tumor Necrosis Factor

TNF-α is one of the principal mediators of the inflammatory response and has a critical role in orchestrating the local inflammatory response through cell activation and initiation of a cytokine cascade. TNF is synthesized as a 26-kDa transmembrane protein, which is processed to the mature 17-kDa form after cleavage of the residue signal peptide by a matrix metalloproteinase disintegrin.[9,10] TNF can exert activity as a transmembrane cell-associated species as well as in a secreted form.

TNF synthesis is triggered by endotoxin, enterotoxin, toxic shock syndrome toxin-1, viruses, mycobacterial cord factor, C5a, fungal and parasitic antigens, IL-1, and TNF itself.[6,11-13] The primary producer cells of TNF are monocytes and tissue macrophages. TNF also is produced by many other cell types, which include lymphocytes, natural killer (NK) cells, neutrophils, mast cells, endothelial cells, keratinocytes, smooth muscle cells, astrocytes, and microglial cells.

Tumor Necrosis Factor Receptors

The tight regulation of TNF signaling is important in the control of TNF-induced cellular alterations. Most cell types possess two TNF receptors: a 55- to 60-kDa receptor, TNFR-1 (i.e., CD120a), and a 75- to 80-kDa receptor, TNFR-2 (i.e., CD120b).[14,15] These two receptors are structurally related and are members of the tumor necrosis factor (TNF)/tumor necrosis factor receptor (TNFR) family. The extracellular domains of the TNFR-1 and TNFR-2 share 28% homology, but no homology is observed in the cytoplasmic domain.[16] The lack of homology of the two receptors suggests that they mediate discrete signaling pathways.[16]

TNFR-1 is largely responsible for proinflammatory cellular responses.[11,12,17-19] TNFR-1 also is unique in that it regulates signaling pathways linked to both proapoptotic and antiapoptotic responses (as reviewed by Aggarwal,[11] MacEwan,[12] and Wallach[19]). The cellular response to TNF is dependent on numerous environmental factors, including input from other signaling pathways.

TNFR-1 (Figure 156-1) contains a cytoplasmic sequence of approximately 80 amino acids termed the *death domain.* This region regulates apoptosis through its association with effector proteins that activate programmed cell death, but the death domain also is the region in this receptor that mediates the cell's survival or antiapoptotic pathways.[20]

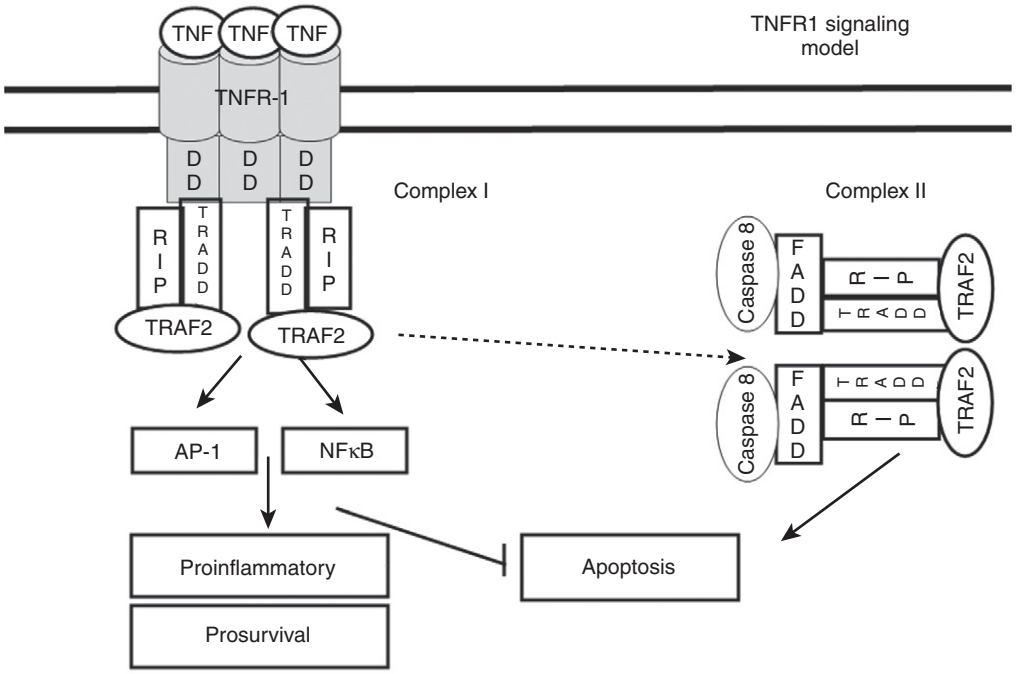

Figure 156-1 The tumor necrosis factor receptor-1 (TNFR-1) signaling complex. Binding of tumor necrosis factor (TNF) to TNFR-1 results in the recruitment and formation of a TNFR-1 signaling complex. TRADD (TNFR-associated death domain) associates with TNFR-1 through death domain (DD) interactions and serves as a platform for the recruitment of other adaptor proteins including TRAF-2 (TNFR-associated factor-2) and RIP (receptor-interacting protein) to form complex I. These adapter proteins recruit additional components necessary for the activation of proinflammatory and antiapoptotic pathways through the activation of transcription factors, such as nuclear factor κ-B (NFκB). Complex II is formed when TRADD:RIP:TRAF2 disassociate from TNFR-1. Subsequent recruitment of FADD (Fas-associated death domain) and caspase-8 to this complex initiate TNF-mediated apoptosis. *(Adapted from Micheau O, Tschopp J: Induction of TNF receptor 1-mediated apoptosis via two sequential signaling complexes,* Cell *114:181, 2003.)*

Additional studies have provided insight into the assembly of the TNFR-1 signaling complex and the regulation of proapoptotic and antiapoptotic signaling.[21] Activation of the TNFR-1 by TNF results in the formation of a receptor trimer through self-association with the death domains. Receptor trimerization leads to recruitment of effector proteins to form a signaling complex at the plasma membrane.[17] The TNFR-1–associated death domain protein (TRADD) associates with TNFR-1 and acts as a scaffold for recruitment of the effector proteins RIP (receptor-interacting protein) and TRAF2 (TNFR-associated factor 2) to form the complex TNFR-1:TRADD:TRAF2:RIP. This complex, termed complex I, controls both antiapoptotic and proinflammatory pathways primarily through activation of mitogen-activated protein (MAP) kinases and transcription factors such as nuclear factor-κB (NFκB) and activator protein-1 (AP-1), leading to the coordinated expression of antiapoptotic proteins, proinflammatory cytokines, chemokines, enzymes, and adhesion molecules.[22-24] Several studies suggest that the complex that signals apoptosis is distinct from complex I.[18,21,25]

A second complex termed complex II can be assembled when TRADD-TRAF2-RIP complex disassociate from TNFR-1 to form a second cytosolic complex with FADD (fas-associated death domain protein). FADD is essential for apoptosis through its association with and activation of caspase-8.[17] Apoptosis is activated by complex II under conditions in which the signal from complex I fails to activate NFκB.

Interleukin-1

IL-1α (or IL-1F1), IL-1β (or IL-1F2), and IL-1 receptor antagonist (IL-1ra)(or IL-1F3) (see the section on proinflammatory inhibitors) are members of the IL-1 ligand superfamily.[26-28] IL-1α and IL-1β are agonists, regulated independently, that are products of distinct genes located on chromosome 2.[27,29] The two molecules share little sequence homology (22% to 26%) but have similar tertiary structures, bind to the same receptors, and share biologic activities.[30]

Both IL-1α and IL-1β are synthesized as large 31-kDa leaderless precursor proteins (proIL-1α and proIL-1β).[27,31] Most of IL-1α remains in the cell cytosol in the pro form, where it can function in an autocrine fashion or be transported to the cell surface and participate in cell-to-cell communication.[27,32] IL-1α also is biologically active when it is cleaved to the 17.5-kDa mature protein by membrane-associated cysteine protease calpains and released from the cell. IL-1α is rarely observed in the circulation and appears systemically only during severe disease.[33] By contrast, IL-1β is active only in its cleaved mature form, and after secretion, it is the principal mediator of the systemic effects of IL-1. Activation and release of the mature biologically active 17-kDa form require the cysteine protease, caspase-1 (also called IL-1β–converting enzyme [ICE]).[34] IL-1β processing and secretion constitute a highly regulated event that involves multiple steps.[35] Initially, the IL-1β precursor and inactive procaspase-1 co-localize in the specialized secretory lysosomes. A molecular scaffold termed the IL-1β inflammasome activates the inactive procaspase-1 through proteolytic cleavage to caspase-1.[36] Caspase-1 in turn cleaves proIL-1β to its active form IL-1β. IL-1β is then secreted via a mechanism that may be linked to the nucleotide P2X7 receptor and activation of phospholipases.[28,31]

IL-1 synthesis is triggered by many of the same stimuli that activate TNF production (i.e., microbial products of inflammation). IL-1 is synthesized by many different cell types, including monocytes, macrophages, neutrophils, epithelial and endothelial cells, fibroblasts, B and T lymphocytes, smooth muscle cells, microglial cells, and astrocytes.[33]

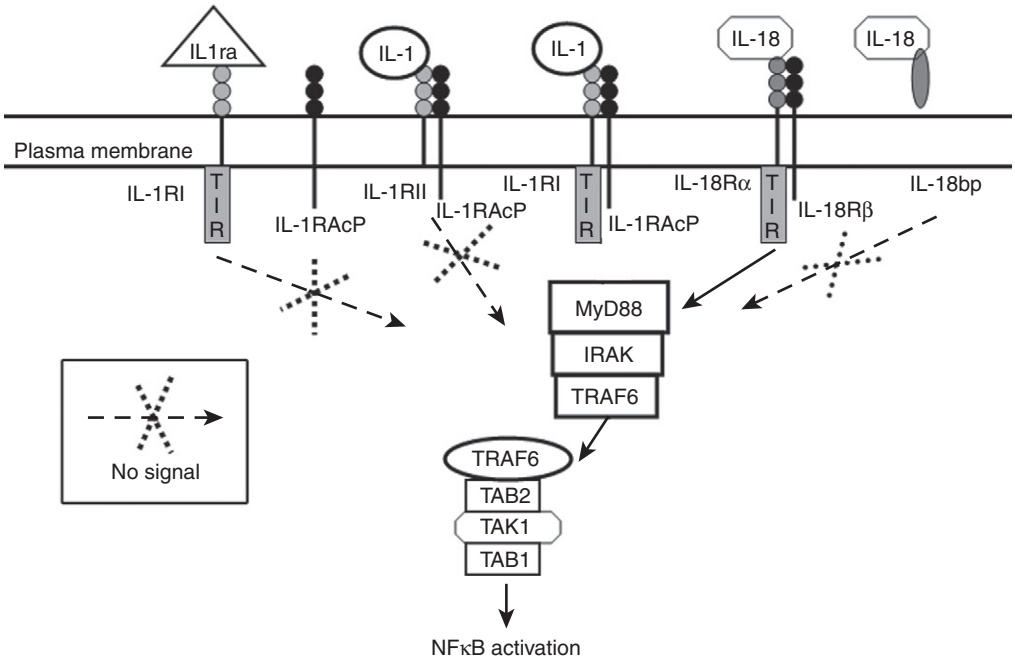

Figure 156-2 Interkeulin-1 (IL-1) and IL-18 receptor family. The IL-1 and IL-18 receptors are members of the interleukin-1/Toll-like receptor family. IL-1 can bind to either the type I IL-1 receptor (IL-1RI) or the type II IL-1R (IL-1RII). IL-1 binding to IL-1RI results in the association of the IL-1R accessory protein (IL-1RAcP) to form a complex that recruits the MyD88 (myeloid differentiation protein 88) to the TIR (Toll/interleukin-1 receptor) domain, activation of MYD88 signaling cascade, and subsequent activation of NFκB and proinflammatory gene transcription. Members of the IL-1RI signaling complex include MyD88, IRAK (IL-1R–associated kinase), TRAF6 (TNFR-associated factor 6), TAK-1 (transforming growth factor-β–activated kinase), and TAB-1 and TAB-2 (TAK-1 binding protein-1 and -2). IL-1 receptor antagonist (IL-1ra) also binds to the IL-1RI but does not trigger the association of IL-1RAcP and activation of the MyD88 signaling cascade. IL-1RII can bind IL-1, but binding does not result in the formation of a signaling complex. IL-1RII lacks the TIR domain and may act as a decoy receptor. IL-18 is also a member of the IL-1/Toll-like receptor family. IL-18 binding to the IL-18Rα triggers the association of IL-18Rβ and activation of the MyD88 signaling cascade. IL-18 also can bind to IL-18bp (IL-18 binding protein), a soluble inhibitor that prevents IL-18 interaction with the IL-18 receptor. *(Adapted from Mantovani A, Locati M, Vecchi A: Decoy receptors: a strategy to regulate inflammatory cytokines and chemokines,* Trends Immunol *22:328, 2001.)*

Interleukin-1 Receptors

Two different receptors bind IL-1: the type I IL-1 receptor (IL-1RI) and the type II IL-1R (IL-1RII). Both receptors are members of the IL-1 receptor/Toll-like receptor (IL-1R/TLR) superfamily[30,37-39] (Figure 156-2). This receptor family also includes receptors for the proinflammatory cytokine IL-18 and receptors for both gram-negative and gram-positive bacterial products. Most members of this family of receptors contain a conserved cytosolic region termed the Toll–IL-1 receptor (TIR) domain.[30,39] The IL-1RI and IL-1RII have similar extracellular characteristics, with three immunoglobulin domains and a high degree of sequence homology.[27,39] IL-1β binding to the IL-1RII, however, does not trigger signal transduction, because it contains a cytoplasmic region of only 29 amino acids that does not contain a TIR domain.[37,39] This receptor may serve as a decoy receptor and may decrease the availability of IL-1β to bind to the functionally active IL-1RI (see the section on cytokine inhibitors). IL-1RI is found on most cell types and is important in transducing the action of IL-1. IL-1 binds to IL-1RI with low affinity and requires the recruitment of the IL-1 receptor accessory protein (IL-1RAcP) to the receptor to form a high-affinity receptor complex, a requirement for optimal signal transduction.[37,39]

IL-1β, similar to TNF, activates the nuclear transcription factors NFκB and AP-1, which trigger the synthesis of numerous proinflammatory mediators[39-41] (see Figure 156-2). IL-1 binding to IL-1RI elicits the formation of a receptor complex with IL-1RAcP. This trimeric complex then recruits the cytosolic protein MyD88 (myeloid differentiation protein 88).[42] MyD88 acts as an adapter protein and mediates the recruitment of members of the IRAK family (serine/threonine IL-1 receptor–associated kinases) with the receptor complex.[43] IRAK-4 is activated and phosphorylates IRAK-1.[44] Phosphorylation of IRAK-1 triggers dissociation from MyD88 and subsequent association with TRAF6 (TNF receptor–associated factor 6). TAB-1 and TAB-2 (transforming growth factor-β–activated kinase-1 (TAK-1)-binding protein-1 and -2) are recruited to the activated TRAF6 complex that, in turn, phosphorylates TAK-1 (transforming growth factor-β–activated kinase 1).[45] TAK-1 initiates signaling, leading to the activation of NFκB and the MAP kinases p38 MAPK and JNK. Although IL-1 and TNF share many of the same postreceptor signaling pathways, they are not entirely redundant cytokines. IL-1, unlike TNF, cannot activate cellular programmed cell death pathways.

Interleukin-6

IL-6 is a pleiotropic cytokine with a wide range of biologic functions and is an important regulator of inflammation, immune responses, oncogenesis, and hematopoiesis.[46-48] IL-6 is a potent inducer of the acute phase response, as well as specific cellular and humoral immune responses including B cell differentiation and T cell activation.[48] IL-6 also is an important regulator of the transition from acute to chronic inflammation and of the shift from neutrophil to mononuclear cell infiltration.[49] IL-6 is not expressed constitutively, and IL-6 production is triggered in response to viral and bacterial infections and other cytokines such as TNF, IL-1β, and IFN-γ. IL-6 is a single-chain 21- to 28-kDa

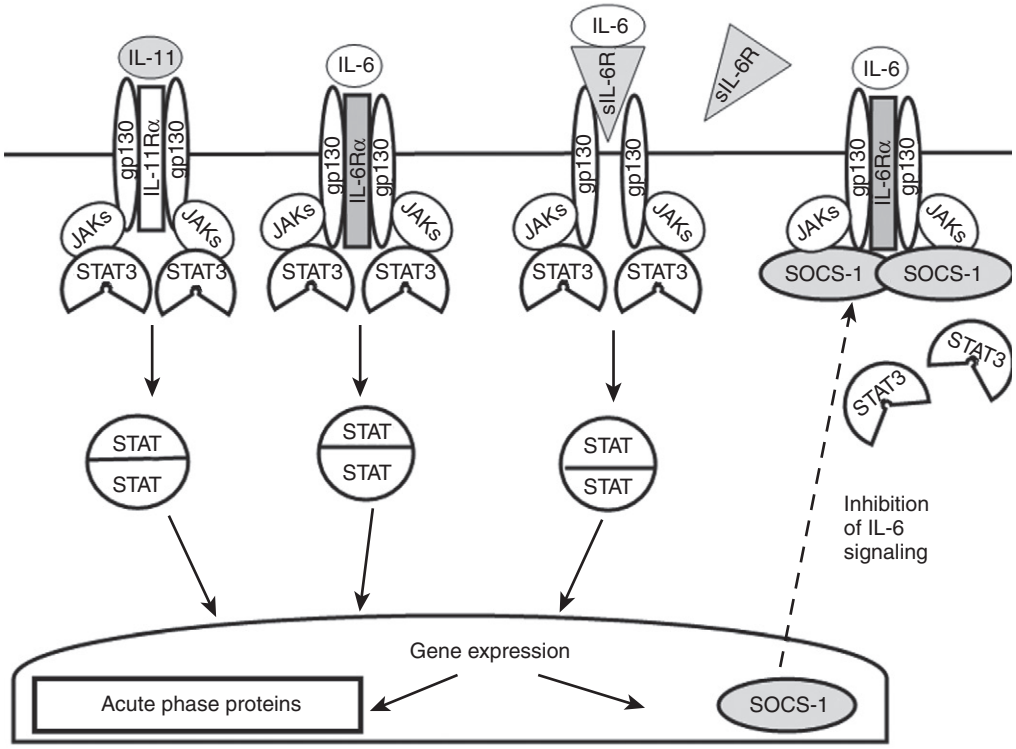

Figure 156-3 Interleukin-6 (IL-6) and IL-11 receptors are members of the IL-6 receptor family and utilize a common signal transducing subunit gp130. IL-6 and IL-11 bind to unique receptor α-chains IL-6Rα and IL-11Rα, respectively. A soluble form of IL-6R (sIL-6R) can also bind IL-6 and this complex can then associate with gp130 and initiate IL-6 signaling through a process termed trans-signaling. Receptor binding triggers association of gp130, activation of JAKs (Janus kinases) and STAT3 (signal transducer and activator of transcription), and the subsequent activation of gene transcription. STAT3 induces transcription of multiple genes including acute phase proteins and SOCS-1 (suppressor of cytokine signaling-1). SOCS-1 acts as a negative feedback regulator of IL-6 signaling by preventing JAK/STAT signaling.

protein produced by a variety of cells including B and T cells, monocytes, fibroblasts, endothelial cells, and some tumor cells.[47,50,51]

Interleukin-6 Receptors

The IL-6 receptor system consists of two components.The ligand-binding molecule, or IL-6R, is an 80-kDa glycoprotein[52] (Figure 156-3). Mutation studies have demonstrated that the cytoplasmic domain of IL-6R is not essential for signal transduction. The second component of the IL-6 receptor system is gp130, a non–ligand binding signal transducer.[53] IL-6 binding to the IL-6R leads to the association of gp130 with the receptor complex. Both IL-6R and gp130 are members of the cytokine receptor family, which is characterized by four conserved cysteine residues and a tryptophan-serine-X-tryptophan-serine motif above the transmembrane domain.[54] The gp130 also is the common signal-transducing subunit for other members of the cytokine receptor family including IL-11, oncostatin-M, ciliary neurotrophic factor, cardiotrophin-1, leukemia inhibitory factor, and the newly discovered interleukins IL-27 and IL-31, leading to redundancy in cytokine activity.[55,56]

Although the membrane IL-6R is expressed on hepatocytes, monocytes, macrophages, neutrophils, and some types of lymphocytes, a naturally occurring soluble form of the IL-6R (sIL-6R) also is present in most body fluids.[56] The sIL-6R is produced by proteolytic cleavage or through translation from alternatively spliced messenger RNA (mRNA). IL-6 binding to sIL-6R triggers the association with the signal-transducing gp130 component in cells that do not express the membrane-bound form of IL-6R.[56,57] Thus, unlike most other soluble cytokine receptors, sIL-6R can act as an agonist and through trans-signaling can activate cell types which do not express the IL-6R. In contrast with sIL-6R, soluble gp130 (sgp130) inhibits IL-6 activity by binding to IL-6/sIL-6R complexes and interfering with IL-6 trans-signaling.[56]

Formation of the IL-6 receptor complex leads to activation of gp130 associated tyrosine kinases of the Janus family (JAK) resulting in tyrosine phosphorylation of the cytoplasmic domain of gp130.[53,58,59] These phosphorylated sites serve as docking sites for the transcription factors STAT 1 (signal transducer and activator of transcription-1) and STAT 3. STAT1 and STAT3 also are kinase substrates, and after phosphorylation, they disassociate from the receptor complex and translocate to the cell nucleus, where they initiate expression of target genes. JAK kinases also activate other tyrosine kinases, which in turn activate MAP kinases and the transcription factors AP-1 and nuclear factor IL-6 (NF-IL6).[53] IL-6 signaling is regulated by feedback inhibition of the JAK-STAT pathway. Activation of STAT3 also induces transcription of SOCS-1 (suppressor of cytokine signaling-1), which binds to JAK and acts as a negative regulator of gp130 signaling.[46,47]

Interleukin-8 and Chemokines

IL-8 is the prototype of a family of cytokines that are chemotactic for leukocytes. Chemotactic cytokines or chemokines are proinflammatory mediators that orchestrate the recruitment of leukocytes to sites of inflammation. IL-8 is synthesized as a precursor form of 99 amino acids.After cleavage of a signal sequence, IL-8 is secreted in the mature form, approximately 8.4 kDa in size.[60] IL-8 is produced by monocytes, macrophages, fibroblasts, endothelial

cells, epithelial cells, hepatocytes, keratinocytes, synovial cells, chondrocytes, and some tumor cells.[60] Endotoxin, TNF, and IL-1, but not IL-6, trigger production of IL-8. IL-3, granulocyte-macrophage colony-stimulating factor (GM-CSF), lectins, phorbol esters, immune complexes, and phagocytosis also stimulate IL-8 production.

IL-8 (also termed CXCL8) is a member of the chemokine supergene family which is composed of close to 50 members.[61-64] Little sequence homology exists between chemokines, but they are remarkably similar in their three-dimensional structure.[63,64] The chemokine family is divided into four structural groups characterized by the number and spacing of conserved cysteine residues: CXC, CC, C, and CX_3C.The CXC chemokine group contains one amino acid between the first two cysteine residues.The CXC chemokine subgroup is further divided into two groups based on the presence or absence of a Glu-Leu-Arg (ELR) motif located before the first cysteine residue and termed ELR^+CXC and ELR^-CXC chemokines.[65] ELR^+CXC chemokines act primarily on neutrophils, whereas ELR^-CXC chemokines interact with mononuclear leukocytes. The ELR^+CXC family includes several chemokines with biologic activity similar to that of CXCL8 (IL-8), such as CXCL1 (GRO-α), CXCL2 (GRO-β), CXCL3 (GRO-γ), CXCL7 (neutrophil-activating peptide-2 [NAP-2]), CXCL5 (epithelial cell–derived neutrophil activating protein-78 [ENA-78]), and CXCL6 (granulocyte chemotactic protein-2 [GCP-2]).[61]

CC chemokines—the second structural group—contain adjacent cysteine residues. CC chemokines act principally on monocytes, basophils, eosinophils, and some lymphocyte subpopulations.[61,66] The best-characterized CC chemokine is CCL2 (monocyte chemotactic protein 1 [MCP-1]). Other members of the CC chemokine family include CCL8 (MCP-2), CCL7 (MCP-3), CCL5 (RANTES), CCL3 (macrophage inflammatory protein [MIP-1α]), and MIP-1β (CCL4).

The C chemokine structural group has a single amino-terminal (N-terminal) cysteine and contains two highly related chemokines, XCL1 (lymphotactin) and XCL2 (SCM-1β).[62] The last subgroup, CX_3C, contains a single member, CX3CL1 (fractalkine), which is characterized by separation of the first two cysteine residues by three amino acids. CX3CL1, as well as CXCL16, is present in two forms: a membrane-bound form, which acts as a leukocyte adhesion receptor, and a cleaved form, which is secreted and acts as a soluble chemoattractant.[61,64] Chemokines also have been classified as constitutive and inducible to differentiate other chemokines involved in homeostatic trafficking and those involved in inflammation.[62,64] However, a number of chemokines have overlapping characteristics, depending on environmental factors.

Chemokine Receptors

Chemokine receptors are a family of G-protein–coupled receptors (GPCRs) composed of at least 10 CC chemokine receptors, 6 CXC chemokine receptors, 1 CX_3C chemokine receptor, and 1 C chemokine receptor[61,67] (Table 156-1).An unusual feature of this receptor family is their ability to bind more than one chemokine within their particular subclass. An exception is the DARC receptor (Duffy antigen receptor for chemokines) located on erythrocytes and endothelial cells, which will bind both CC and CXC chemokines. Engagement of this receptor does not appear to activate signal transduction, and DARC may limit leukocyte activation by serving as a chemokine sink.

Two distinct CXCL8 (IL-8) receptors—CXCR1 and CXCR2—have been cloned and demonstrate 77% sequence homology.[68,69] CXCR1 binds CXCL8 (IL-8) with high affinity and CXCL1 (GRO-α) and CXCL7 (NAP-2) with low affinity, whereas CXCR2 binds most ELR^+CXC chemokines.[67] In neutrophils, CXCL8 (IL-8) binding to CXCR1 or CXCR2 leads to the activation of G-protein–sensitive phospholipase C, which, in turn, results in the formation of inositol triphosphate and elevation of cytosolic calcium.[62,66,67] These receptors also activate other signaling pathways coupled to activation of phosphoinositide 3-kinase, tyrosine kinases, MAP kinase, and low-molecular-weight proteins Rho and Ras. CXCL8 (IL-8) binding also triggers receptor phosphorylation and desensitization, a process thought to be important for continued cellular ability to detect chemotactic gradients.[70]

Interleukin-12

IL-12 is a potent proinflammatory cytokine that plays a major role in linking innate and adaptive immune responses.[71,72] IL-12 is a member of the IL-12 cytokine family comprised of structurally related cytokines including IL-12, IL-23, and IL-27.[73-75] IL-12 is a heterodimer composed of two subunits, an α-chain (p35 subunit) and a β-chain (p40 subunit), which are encoded by separate genes and covalently linked by disulfide bonds.[72,76,77] The p40 subunit of IL-12 contains the receptor binding site,

TABLE 156-1

Chemokine Receptors and Their Ligands

Receptor	Ligand(s)*
CXC Chemokine Receptors	
CXCR1	CXCL6 (GCP-2), CXCL7 (NAP-2), CXCL8 (IL-8)
CXCR2	CXCL1 (GROα), CXCL2 (GROβ), CXCL3 (GROγ), CXCL5 (ENA-78), CXCL6 (GCP-2), CXCL7 (NAP-2), CXCL8 (IL-8)
CXCR3	CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC)
CXCR4	CXCL12 (SDF-1)
CXCR5	CXCL13 (BCA-1)
CXCR6	CXCL16
CC Chemokine Receptors	
CCR1	CCL3 (MIP-1α), CCL5 (RANTES), CCL7 (MCP-3), CCL13 (MCP-4), CCL14 (HCC-1), CCL 15 (HCC-2), CCL16 (HCC-4), CCL23 (MPIF-1)
CCR2	CCL2 (MCP-1), CCL7 (MCP-3), CCL8 (MCP-2), CCL13 (MCP-4), CCL16 (HCC-4)
CCR3	CCL5 (RANTES), CCL7 (MCP-3), CCL11 (eotaxin), CCL 15 (HCC-2), CCL16 (HCC-4), CCL24 (eotaxin-2), CCL26 (eotaxin-3)
CCR4	CCL17 (TARC), CCL22 (MDC)
CCR5	CCL3 (MIP-1α), CCL4 (MIP-1β), CCL5 (RANTES), CCL8 (MCP-2)
CCR6	CCL20 (MIP-β)
CCR7	CCL19 (ELC), CCL21 (SLC)
CCR8	CCL1 (I-309)
CCR9	CCL25 (TECK)
CCR10	CCL27 (CTACK), CCL28 (MEC)
C Chemokine Receptor	
XCR1	XCL1 (lymphotactin), XCL2 (SMC-1β)
CX3C Chemokine Receptor	
CX3CR1	CX3CL1 (fractalkine)

*Ligands are listed under the new nomenclature, with the old name in parentheses.

BCA-1, B cell–attracting chemokine-1; *CTACK,* cutaneous T cell–attracting chemokine; *ELC,* Epstein-Barr virus–induced receptor ligand chemokine; *ENA-78,* epithelial neutrophil-activating protein-78; *GCP-2,* granulocyte chemoattractant protein; *GRO,* growth-related oncogene; *HCC,* hemofiltrate CC chemokine; *IL-8,* interleukin-8; *IP-10,* interferon-γ–inducible protein; *I-TAC,* interferon-inducible T cell α-chemoattractant; *MCP,* monocyte chemotactic protein; *MDC,* macrophage-derived chemoattractant; *MEC,* mammary-enriched chemokine; *MIG,* monokine induced by interferon-γ; *MIP-1,* macrophage inflammatory protein-1; *MPIF,* myeloid progenitor inhibitory factor; *NAP-2,* neutrophil-activating protein-2; *RANTES,* regulated on activation normal T cell expressed and secreted; *SCM,* single C motif; *SDF-1,* stromal cell–derived factor-1; *SLC,* secondary lymphoid tissue chemokine; *TARC,* thymus- and activation-regulated chemokine; *TECK,* thymus-expressed chemokine.

whereas the p30 subunit is required for signal transduction. The two subunits demonstrate little sequence homology, but the p35 subunit shows sequence homology with IL-6 and G-CSF, whereas the p40 shows homology with the extracellular domain of the IL-6 receptor.[77] The p40 chain of IL-12 can also associate with another molecule termed p19 to form a distinctive heterodimeric cytokine, IL-23.[78] A homologue of IL-12p40, Epstein-Barr virus–induced gene 3 (*EBI3*), forms a noncovalent association with another homologue of IL-12p35 (p28) to produce IL-27.[79]

IL-12 is produced principally by phagocytic cells, such as monocytes, macrophages, and neutrophils, and by microglial and dendritic cells, in response to bacteria, bacterial products, intracellular pathogens, and viruses.[72] Similar to IL-12, IL-23 and IL-27 are produced predominantly by macrophages and dendritic cells in response to inflammatory stimuli.[71,75] IL-12 induces production of interferon-γ (IFN-γ) and regulates T helper (T_H1)-type inflammatory responses. IL-27 also promotes T_H1 cell differentiation and IFN-γ production, but preferentially acts on naive $CD4^+$ T cells.[73,74] By contrast, IL-23 acts on several T cell types and promotes synthesis of IL-17, a proinflammatory cytokine involved in neutrophil-mediated inflammation.[75] Both IL-12 and IL-27 act to suppress the development of IL-17–secreting T cells and limiting IL-17–mediated proinflammatory actions.[74,75]

Interleukin-12 Receptors

IL-12 receptors are expressed primarily on NK and T cells. The receptor is composed of two subunits—IL-12Rβ1 and IL-12Rβ2—and is a member of the gp130 cytokine receptor superfamily.[80] IL-12 signaling is through the JAK/STAT family signal transduction pathway.[81] IL-12 binding to the IL-12 receptor leads to tyrosine phosphorylation of JAK2 and TYK2; subsequent phosphorylation of STAT1, STAT3, STAT4, and STAT5; and synthesis of IFN-γ.[72,75] IL-23 binds to a receptor composed of the IL-12Rβ1 subunit and an IL-23R subunit and activates a similar pattern of JAKs and STATS.[72] The IL-27 receptor also is principally located on NK and T cells but is composed of an orphan receptor subunit WSX1/TCCR linked to a gp130 subunit. IL-12 and IL-27 signaling is mediated principally though STAT4, whereas IL-23 signaling is mediated through STAT3.[72,74,75]

Interferon-γ

IFN-γ is a pleiotropic cytokine produced by activated T cells and NK cells in response to IL-12, IL-27, and IL-18.[77,82,83] IFN-γ is a critical mediator of T cell recruitment and phagocyte-mediated clearance of pathogens.[4] In macrophages, IFN-γ triggers cytokine (including TNF) and chemokine synthesis, enhanced oxygen radical generation and nitric oxide (NO) production, and induction of major histocompatibility complex (MHC) class II expression.[4,83] The cellular targets of IFN-γ are numerous because IFN-γ receptors are present on virtually every cell type, and most of the biologic effects mediated by IFN-γ are through transcriptional regulation of approximately 500 genes.[82,83]

Interferon-γ Receptors

Similar to other cytokine receptor systems, the receptor is composed of two subunits, IFN-γR1, which is necessary for ligand binding, and IFN-γR2, which is involved in signal transduction.[77,82,83] IFN-γ binding to the IFN-γR1 subunit leads to receptor dimerization and the association of two accessory chains—the IFN-γR2 subunits. Both IFN-γR1 and IFN-γR2 have specific JAK kinases constitutively associated (JAK1 and JAK2, respectively).[84] The formation of the receptor complex results in transphosphorylation of the JAK kinases and subsequent phosphorylation of the IFN-γR1. Tyrosine phosphorylation of the receptor provides a docking site for the cytosolic factor STAT1, which, after receptor phosphorylation, is also phosphorylated. STAT1 phosphorylation results in the formation of STAT complexes, translocation of these complexes to the nucleus, and the regulation of immunological relevant genes.

Interleukin-18

IL-18 originally was designated the IFN-γ–inducing factor, a factor that stimulated the synthesis of IFN-γ by $CD4^+$ T lymphocytes and had biologic activity similar to that of IL-12.[85] Later studies demonstrated that the IL-18 receptor is a member of the IL-1/Toll-like receptor superfamily, and that IL-18 has structural homology with IL-β[86] Similar to IL-1β, IL-18 is synthesized in a proform with an unusual signal peptide that lacks the amino acid sequence necessary for secretion.[87,88] Unlike that of IL-1β, the precursor form of IL-18 has no biologic activity. ProIL-18 also is cleaved by caspase-1 to an 18-kDa nonglycosylated protein. IL-18 is produced by a wide range of cell types including Kupffer cells, macrophages, monocytes, T and B cells, dendritic cells, epithelial cells, and osteoblasts in response to inflammatory stimuli, such as lipopolysaccharide (LPS), exotoxins from gram-positive bacteria, and a variety of other microbial products.[89,90]

Interleukin-18 Receptors

The IL-18 receptor system is similar to that of the multicomponent IL-1β receptor system and expressed in a variety of cells including macrophages, neutrophils, NK cells, smooth muscle cells, and dendritic cells (see Figure 156-2).[30,91] The IL-18 receptor is composed of two subunits, an IL-18–binding component (IL-18Rα) and a signal-transducing component (IL-18Rβ) that is a homologue of AcP. IL-18 binds to IL-18Rα with low affinity that is significantly enhanced with the recruitment of IL-18Rβ. Similar to IL-1β receptor system, IL-18Rβ does not bind to IL-18; rather, it binds to the IL-18–IL-18Rα complex. IL-18 binding to the IL-18 receptor complex recruits the same adapter proteins as for IL-1β, including MyD88, IRAK, and TRAF-6. These adapter proteins activate the transcription factor NFκB and p38 MAPK. The p38 MAPK in turn activates another transcription factor, C/EBPβ. These transcription factors stimulate the synthesis of several proinflammatory genes including other cytokines and cytokine receptors, chemokine and chemokine receptors, NO synthase, adhesion molecules, and the Fas ligand.[30,90] Although several similarities between the biologic properties of IL-1 and IL-18 have been identified, significant differences are recognized. Unlike IL-1, IL-18 is not able to induce fever but can stimulate IFN-γ synthesis in T cells and NK cells.[90-92]

Antiinflammatory Cytokines

Interleukin-10

IL-10 was first described as a cytokine synthesis-inhibiting factor and a potent inhibitor of IFN-γ.[93] It is now recognized that IL-10 possesses both potent antiinflammatory and immunosuppressive properties. IL-10 inhibits mononuclear cell synthesis of a wide range of proinflammatory cytokines including TNF, IL-1β, IL-1α, IL-6, IFN-γ, IL-12, IL-18, IL-8, and both CXC and CC chemokines.[7,94-97] In addition to inhibiting the production of proinflammatory cytokines, IL-10 also stimulates the production of natural proinflammatory cytokine inhibitors such as IL-1ra and sTNFRs (see the section on inhibitors of proinflammatory cytokines).[7,94,96] IL-10 further modulates the proinflammatory response by down-regulating MHC class II expression, oxygen radical production, NO synthesis, and intercellular adhesion molecule-1 (ICAM-1) expression. These properties make IL-10 a critical factor in the regulation of the magnitude of the inflammatory response and in the prevention of an overwhelming response to inflammation.[94-96,98] IL-10 is synthesized by numerous cell types including monocyte-macrophages, B and T cells, dendritic cells, and epithelial cells in response to bacteria, bacterial products, proinflammatory cytokines, parasites, fungi, and viruses.[94,98]

IL-10 is a 37-kDa homodimer whose tertiary structure resembles IFN-γ, a cytokine whose actions are antagonized by IL-10.[94,96,97,99]

Interleukin-10 Receptors

IL-10 receptors are members of the class II cytokine receptor family and are expressed predominantly on immune cells.[94,100] IL-10R is composed of two subunits, IL-10RI, a ligand-binding subunit, and IL-10RII, an accessory subunit. The accessory subunit associates with the receptor after IL-10 binding and is required for signal transduction. Similar to other members of this cytokine receptor family, the receptor complex interacts with members of the JAK family, specifically JAK1 and TYK2. IL-10 binding triggers tyrosine phosphorylation and activation of the transcription factors STAT3, STAT1, and STAT5.[95,97] Critical to its potent antiinflammatory properties, IL-10 inhibits nuclear translocation of the transcriptional factor NFκB and subsequent synthesis of proinflammatory cytokines, as well as promoting degradation of mRNA of proinflammatory cytokines.[95,96,99] The activation of STAT3 by IL-10 also triggers the synthesis of SOCS-1 and SOCS-2, effector proteins that can interfere directly with proinflammatory signaling.[97]

Interleukin-4 and Interleukin-13

IL-13 and IL-4 are members of the T_H2-type cytokine family and are the products of $CD4^+$ T cells, $CD8^+$ T cells, mast cells, basophils, eosinophils, and NK cells.[101-104] IL-4 is a 20-kDa glycosylated protein, and IL-13 is a 10-kDa nonglycosylated protein.

Although IL-4 and IL-13 have only 20% to 25% amino acid sequence homology, their tertiary structures are highly homologous, and they possess numerous overlapping biologic properties.[7,102,105,106] Both IL-4 and IL-13 are potent antiinflammatory cytokines that are capable of inhibiting monocyte-macrophage production of proinflammatory cytokines and chemokines. Moreover, IL-4 and IL-13 up-regulate the synthesis of antiinflammatory IL-1ra and promote adherence by increasing expression of adherence molecules. The overlapping biologic properties of these two cytokines are the result of a common component in their respective receptor complexes.[107] However, the two cytokines do not share all biologic properties; most notable is that IL-4, but not IL-13, can promote T_H2 lymphocyte differentiation.[106] The functional differences between these two cytokines are the result of cell-dependent differential receptor expression.

Interleukin-4 and Interleukin-13 Receptors

IL-4 can bind to two receptor complexes, type I and type II[106-109] (Figure 156-4). The type I IL-4 receptor consists of a ligand-binding chain (IL-4Rα) and a common γ-signaling chain (γc), which also is an essential component of IL-2, IL-7, IL-9, and IL-15 receptors. The type II IL-4R receptor is composed of IL-4Rα subunit and IL-13Rα1 subunit. Unlike the type I IL-4R, both IL-4 and IL-13 can bind to the type II IL-4R. A second IL-13 binding component has been identified, IL-13Rα2 receptor subunit, which binds IL-13 with high affinity but does not initiate cell signaling.[110] IL-13Rα2 serves as a decoy receptor to down-regulate IL-13 activity. Signaling of both IL-4 and IL-13 is mediated principally through the IL-4Rα chain and involves activation of the transcription factor STAT6.[107-109,111,112] IL-4 binding to type I IL-4R induces the phosphorylation of the JAK1 associated with the IL-4Rα chain and JAK3 associated with the γc chain. These kinases, in turn, phosphorylate the IL-4Rα chain itself, as well as STAT6, resulting in STAT6 translocation to the nucleus and transcription of IL-4 responsive genes. Phosphorylation of IL-4Rα also stimulates recruitment of IRS-2, a member of the insulin substrate family, which activates the phosphoinositide 3-kinase pathway—a pathway critical in IL-4/IL-13 induced cell survival and protection from apoptosis.[107,108] IL-13 also activates similar signaling pathways through interaction with the type II IL-4R.[109] IL-13 binding to the IL-13Rα chain induces heterodimerization with IL-4Rα and stimulates phosphorylation of JAK1 associated with the IL-4Rα chain and another member of the JAK family, TYK2, associated with the IL-13Rα1 chain. The IL-13Rα1 can both amplify IL-4Rα

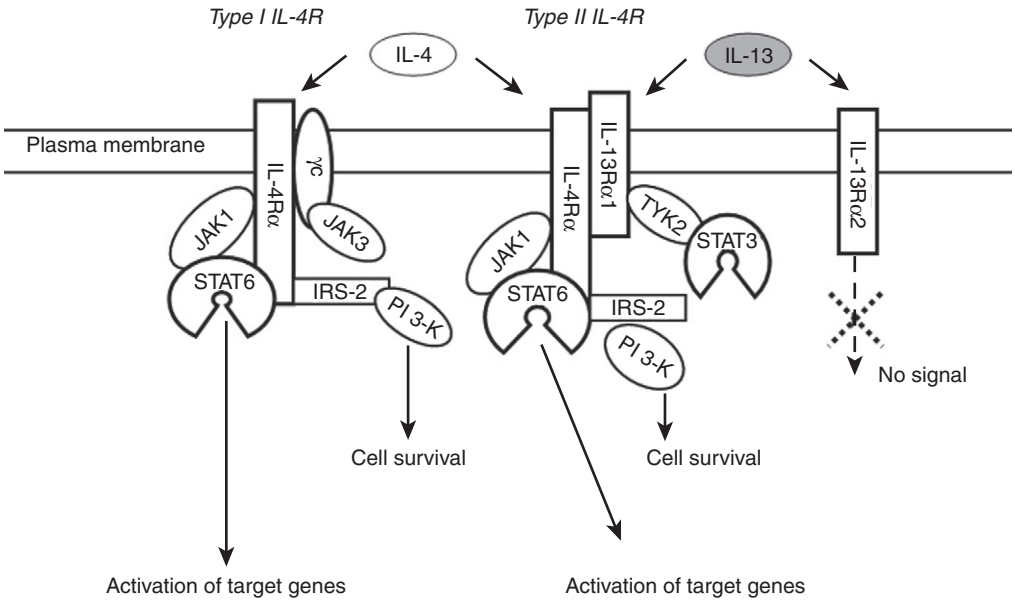

Figure 156-4 Interleukin-4 (IL-4) and IL-13 receptor complexes. IL-4 can bind to two different receptors: type I IL-4R and type II IL-4R. Type I IL-4R is composed of IL-4Rα and the common γ subunit (γc), whereas the type II IL-4R contains both IL-4Rα and IL-13Rα subunits. IL-4 binds to both type I IL-4R and type II IL-4R by way of the common IL-4Rα-chain. By contrast, IL-13 binds only to the type II IL-4R by way of the IL-13Rα1 subunit. Both receptors activate STAT6 and IRS-2 (insulin receptor substrate 2) signaling pathways resulting in the induction of gene expression and cell survival pathways. IL-13 also binds to IL-13Rα2 with high affinity. This receptor does not initiate signaling, however, and may serve as a decoy receptor to suppress IL-13 signaling.

signaling through activation of STAT6 and signal independently through the activation of other STAT proteins such as STAT1 and STAT3.[107]

Interleukin-11

IL-11 is a 23-kDa nonglycosylated protein produced by fibroblasts, epithelial cells, and endothelial cells in response to various stimuli, including IL-1, TGF-β, TNF, parathyroid hormone, respiratory syncytial virus, rhinovirus, and parainfluenza virus.[113-116] IL-11 is a member of the IL-6 family, proteins that share a four-helix bundle fold motif.[114] This pleiotropic antiinflammatory cytokine can stimulate hematopoiesis, regulate T cell function, activate macrophage proliferation and differentiation, and confer mucosa-protective effects.[114,116] Similar to IL-6, IL-11 inhibits production of proinflammatory cytokines and NO, and it is able to induce the acute phase response.[117]

Interleukin-11 Receptor

The IL-11 receptor is similar to other members of the IL-6 family of receptors and is composed of an IL-11–specific α-chain that binds IL-11 and the gp130 subunit, which is the common receptor β-chain subunit and functions as the signal transduction component of this receptor family (see Figure 156-3).[114,118] The binding of IL-11 to the IL-11α receptor triggers homodimerization of the gp130 subunit and formation of an IL-11 receptor complex. Signaling through the gp130 receptor occurs by way of JAK/STAT pathways.[114,115] Activation of this signaling pathway by IL-11 is mediated predominantly by JAK1 and STAT3.[119] Other signaling pathways activated by IL-11 include the Ras/MAP kinase pathway, protein kinase C, and Src families.[115]

Inhibitors of Proinflammatory Cytokines

Soluble Tumor Necrosis Factor Receptors

Soluble cytokine receptors are highly selective inhibitors of proinflammatory cytokines and represent another level of regulation of proinflammatory signaling. Both the TNFR-1 and TNFR-2 receptors are expressed on the surface of most cell types.

In response to various proinflammatory stimuli such as IL-6, IL-1β, IL-2, IFN-γ, and TNF itself, TNFR-1 and TNFR-2 can be proteolytically cleaved and the extracellular cytokine binding domains released from the cell surface.[120,121] TNF-α–converting enzyme (TACE), a member of the ADAM (a disintegrin and metalloprotease) family, has been implicated as the protease involved TNFR cleavage.[122]

A second pathway for the release of soluble TNFRs has been described in which full-length TNFR-1 can be released extracellularly in exosome-like vesicles.[123,124] Both forms of the soluble TNFRs (sTNFRs) retain their ability to bind TNF and compete with membrane-bound TNF receptors, leading to decreased availability of circulating TNF.[2,123,125] The shedding of these receptors from the cell surface also serves to decrease cellular responsiveness to TNF by decreasing the receptor number. The sTNFRs are thought to be a part of a negative feedback loop to regulate TNF bioactivity, to control inflammation, and to restore homeostasis. However, sTNFRs can act as agonists as well as antagonists of TNF bioactivity.[120,122,126] TNF binding to sTNFRs forms a stable complex and enhances the half-life of circulating TNF.[120] The TNF-sTNFR complex may act as a reservoir and may prolong TNF bioactivity. Soluble TNFRs have been detected in the plasma and urine of patients with sepsis, and increased TNF-sTNFR ratios are correlated with increased mortality.[127,128]

Interleukin-1ra and Interleukin-1RII

IL-1ra and IL-1RII are two natural regulators of IL-1 biologic activity. IL-1ra is a member of the IL-1 gene family.[7,32,129,130] Synthesis of IL-1ra is triggered by the same stimuli that trigger IL-1 production, and it is produced by the same cell types. IL-1ra is structurally similar to IL-1α and IL-1β and has a molecular weight similar to that of the mature form of IL-1β. Sequencing studies have shown 26% homology with IL-1β and 19% homology with IL-1α.

IL-1ra is a competitive inhibitor and binds to the IL-1RI with similar affinity as IL-1α and IL-1β, but it has no agonist activity (see Figure 156-2). IL-1ra binding to the IL-1RI does not trigger the association of IL-1RAcP and the formation of a heterodimer.[131] During the inflammatory response, IL-1ra levels tend to increase later than IL-1, suggesting that IL-1ra functions to block further IL-1 activity and have a role in the termination of the inflammatory response.[132] Administration of IL-1ra to animals reduced inflammation in various different diseases.[7,129,130]

IL-1RII is present as both a membrane-bound receptor and, in a truncated form, as a soluble receptor.[37,133] The receptor acts as a decoy receptor for IL-1 and is the principal IL-1 receptor on neutrophils, monocytes, macrophages, and B cells.[134] The extracellular domain of the IL-1RII is similar to that of IL-1RI and has high affinity for IL-1β but much lower binding affinity for IL-1α and IL-1ra. After IL-1 binding, IL-1RII associates with the IL-1AcP. However, IL-1RII lacks the TIR (Toll/IL-1R) region, and without this domain, the receptor cannot interact with MyD88 and initiate signal transduction (see Figure 156-2). Thus the membrane-bound IL-1RII may act as ligand sink by competing for IL-1 binding with the active IL-1RI and by reducing the concentration of available AcP.[32,37,134] IL-1RII also exists in a soluble truncated form, and circulating levels are increased during inflammation.[135,136] The extracellular domain of the IL-1RII is released from the cell surface by proteolytic cleavage by matrix metalloproteases to form a soluble IL-1RII (sIL-1RII).[137] Shedding of the IL-1RII is regulated by two major mechanisms.[39,133] Antiinflammatory agents, such as IL-4, IL-13, and glucocorticoids, increase gene expression of IL-1RII, enhanced cell surface expression, and subsequent extracellular shedding. Alternatively, rapid shedding of the IL-1RII is triggered by reactive oxygen intermediates, LPS, TNF, and chemoattractants. sIL-1RII binds IL-1β but not IL-1α or IL-1ra and may serve to inhibit the systemic effects of IL-1.

In summary, IL-1 activity is modulated by two different modes of regulation. IL-1ra competitively blocks IL-1 binding to the signaling IL-1RI. A second mechanism of regulation is IL-1RII or decoy receptor, which can bind both IL-1 and IL-1AcP and can prevent their interaction with an active receptor (i.e., IL-1RI). Furthermore, cleavage and release of sIL-1RII into the circulation further serve to modulate systemic IL-1 activity.

Interleukin-18–Binding Protein

Another member of the Toll/IL-1R family is IL-18. IL-18, similar to IL-1 and TNF, has a naturally occurring circulating inhibitor.[138] However, unlike sTNFR or IL-1RII, IL-18–binding protein (IL-18bp) is not a truncated form of the extracellular domain of the IL-18 receptor. Rather, IL-18bp is a naturally occurring antagonist of IL-18 that binds to IL-18 with high affinity and prevents binding to the IL-18 receptor (see Figure 156-2).[139,140] IL-18bp is composed of a single immunoglobulin domain and lacks a transmembrane and cytoplasmic domain. IL-18bp is not membrane-associated and is secreted rather than cleaved from the cell surface.[138,140] Circulating IL-18bp is present in healthy individuals and is significantly elevated in sepsis.[139] Additional studies have shown a beneficial protective effect of exogenously administered IL-18bp in sepsis; however the therapeutic benefit correlates with the inflammatory status.[89]

Inflammation

Inflammation is a protective mechanism in response to invasion by exogenous agents (microbial, chemical, or physical) or endogenous factors (immunologic or neurologic).[141] The host

inflammatory response is composed of innate and acquired immunity and cytokines play an important role in both components of the immune system. The inflammatory response is characterized by the accumulation and subsequent activation of leukocytes in affected tissue. The inflammatory response is initiated when immune cells, such as macrophages, dendritic cells, neutrophils, and NK cells, are activated after detection of microbial molecules through specific pattern recognition receptors (PPRs), which recognize specific pathogen-associated molecular patterns (PAMPs).[142-145] Activation of PRRs, such as Toll-like receptors (TLRs), which can recognize specific PAMPs from bacteria, viruses, fungi, and protozoa, leads to the activation of the transcription factor NFκB and the rapid production of early proinflammatory cytokines such as TNF, IL-1, and IL-6. TNF and IL-1 amplify the immune response through activation of the cytokine cascade and the production of other proinflammatory cytokines and chemokines. In addition to cytokines, other proinflammatory mediators such as NO, platelet-activating factor (PAF), prostaglandins, and leukotrienes also are produced.[2,146,147] These cascades are responsible for activating complement, coagulation, and kinin cascades as well. As inflammation progresses, antiinflammatory cytokines and cytokine inhibitors are produced, which serve to contain the inflammatory response, bring about resolution, and limit host tissue damage.

The accumulation of specific subpopulations of leukocytes at the site of inflammation is the result of a series of events: (1) endothelial cell activation and the expression of adhesion molecules; (2) leukocyte expression of adhesion molecules and leukocyte-endothelial cell adhesion; (3) leukocyte transendothelial migration; (4) leukocyte migration along a chemotactic gradient; and (5) the release of reactive oxidants, proteinases, and antimicrobial polypeptides at the site of inflammation.[146] Cytokines are involved at each step of this process and act both locally and systemically to initiate, maintain, and finally resolve the inflammatory response.[4]

Local Effects

At the site of inflammation, the local release of TNF and IL-1 and other cytokines including IL-8, IL-4, IL-13, IL-18, IL-6, and IFN-γ leads to the activation of endothelial cells and the expression or up-regulation of adhesion molecules such as selectins, ICAMs, platelet-endothelial cell adhesion molecule-1 (PECAM-1), and vascular cell adhesion molecule-1 (VCAM-1).[148,149] This event initiates leukocyte endothelial interaction. Increased endothelial cell surface expression of the adhesion molecules E-selectins and P-selectins (in conjunction with the constitutively expressed L-selectin on leukocytes) mediates the initial adhesive interaction resulting in the leukocyte's rolling along the endothelium.[150]

The endothelium also is a source of cytokines such as TNF, IL-1, IL-4, IL-11, IL-8, and IL-18.[151] These cytokines, as well as IFN-γ, promote leukocyte activation, surface expression of the adhesion molecules β-integrins, and the shedding of L-selectins.[67,149,150] The interactions between leukocyte β_2 integrins and endothelial counterligands such as ICAM-1, ICAM-2, and ICAM-3 mediate the firm attachment of the leukocytes to the endothelium and subsequent migration. Activated endothelium also produces CC and CXC chemokines, which are released or localized on the luminal surface of the endothelium to further enhance leukocyte adhesion.[149-151] Transmigration occurs by migration through endothelial junctions (paracellular transmigration) or through the endothelial cell itself (transcellular migration).[150,152-154] Paracellular migration involves the release of endothelium–expressed VE-cadherin (vascular endothelial cadherin) and involves PECAM-1, ICAM-1, ICAM-2, CD99, ESAM (endothelial cell–selective adhesion molecule), and JAMs (junctional adhesion molecules). The specific adhesion molecules involved in transmigration are both stimulus- and cell-dependent.

Movement of leukocytes to the inflammatory site is directed along a chemotactic gradient, where the strongest concentration of chemoattractants is at the site of inflammation. Local production of chemokines by both immune and nonimmune cells serves as a source for long-lasting chemoattractants. The movement of specific populations of leukocytes into the inflammatory site depends on the specific stimuli and the resultant type of chemokines synthesized (i.e., CXC chemokines versus CC chemokines).[150] Thus the movement of leukocytes is a cytokine-mediated process and the result of coordination of endothelial expression of adhesion molecules, leukocyte adherence, and specific chemotactic gradients.[155]

Cytokines also are directly involved in the activation of cells at the inflammatory site. After recruitment of inflammatory cells to the site of inflammation, cytokines can further amplify the inflammatory response through the activation of transcription factors, such as NFκB, which regulate proinflammatory gene expression. Both TNF and IL-1 increase the expression of genes for proinflammatory cytokines, chemokines, adhesion molecules, inducible NO synthase, matrix metalloproteinases, and cyclooxygenase-2 (COX-2).[156] Cytokines and chemokines also can effect the activation of resident and recruited phagocytic cells. Both CXC and CC chemokines are capable of triggering, in their specific target cells, the generation of oxygen radicals. Chemokines also trigger exocytosis of secretory vesicles and specific granules, resulting in release of enzymes and other soluble proteins.[67,157,158] In adherent neutrophils, TNF triggers the release of oxygen radicals and degradative granule enzymes such as elastase and promotes cytoskeleton reorganization.[159,160] IFN-γ also acts directly on phagocytic cells and enhances bactericidal activity, phagocytosis, NO synthesis, and oxygen radical production.[83] Proinflammatory cytokines such as TNF, IL-1, and IFN-γ also stimulate the release of potent lipid mediators such as PAF, leukotrienes, thromboxane, and prostaglandins.[161] IL-18 has a direct role in neutrophil activation and can induce cytokine and chemokine release, increased β_2 integrin expression, and degranulation.[162] Antiinflammatory cytokines also modulate local activation of phagocytic cells. IL-10, IL-11, IL-4, and IL-13 can inhibit proinflammatory cytokine synthesis, suppress oxygen radical production, and down-regulate NO synthesis, thereby further limiting the local inflammatory response, 163.[95-98,105,106,114,116,117,163]

Mature neutrophils are end-stage cells and have a relatively short life span. Once released into the circulation, neutrophils undergo constitutive apoptosis, or programmed cell death. Enhanced neutrophil survival at the site of inflammation promotes increased bactericidal activity but also may play a role in acute inflammatory damage through excessive release of oxygen radicals, proteases, lipid mediators, and cytokines. TNF and other proinflammatory cytokines are important regulators of neutrophil function during the inflammatory response through activation of proinflammatory signaling and suppression of neutrophil apoptosis.[164-167] Thus cytokines are involved both in trafficking specific populations of leukocytes to the site of inflammation and in the activation process once the leukocytes arrive at their destination.

Coagulation

The coagulation system is activated during the inflammatory response and is an essential component of the host response. Coagulation is initiated by the expression of tissue factor (TF) on the surface of endothelium and monocytes.[168] The proinflammatory cytokines TNF, IL-1, and IL-6 promote the expression of TF and activation of the extrinsic pathway of coagulation resulting in thrombin production and ultimately fibrin deposition.[169-171] Studies also have implicated IL-12, IL-8, and the chemokine CCL2 as procoagulation mediators.[8,169,172] TNF and IL-1 further enhance the procoagulation state by also inhibiting key anticoagulation pathways. TNF and IL-1 inhibit the synthesis and release of thrombomodulin, resulting in the impairment of

thrombin-mediated protein C activation and the subsequent inhibition of that anticoagulation pathway.[146,173]

Fibrinolysis is suppressed by TNF through the inhibition of tissue-type plasminogen activator release.[170] Tissue-type plasminogen activator is essential for the conversion of plasminogen to the active protease plasmin. Plasmin can dissolve the fibrin network in thrombi. Fibrinolysis also is limited by TNF and IL-1–mediated release of plasminogen-activator inhibitors (e.g., PAI-1), which further inhibit the conversion of plasminogen to plasmin.[146,174] The stimulation of the extrinsic coagulation pathway, coupled with the inhibition of fibrinolysis, is thought to promote containment and localization of the inflammatory site. However, the activation of the coagulation pathway can further up-regulate the inflammatory response through cross-talk between the two pathways. For example, thrombin binding to its receptor triggers the activation of NFκB, the synthesis of proinflammatory cytokines, and the release of NO.[168,170]

Antiinflammatory cytokines also regulate coagulation. In vivo administration of IL-10 reduced LPS-activation of the coagulation pathway as well as modulated the fibrinolytic system.[170,175] Although the coagulation system is critical for maintaining homeostasis and the containment of inflammatory stimuli, if it is not adequately regulated, it can lead to the development of disseminated intravascular coagulation and multiple organ failure.[171]

Systemic Effects

Proinflammatory cytokines, either acting alone or synergistically, can produce systemic alterations in host physiology. These systemic alterations include induction of fever, stimulation of hepatic acute phase response, and nonspecific activation of host immune systems.

Fever

IL-1 (previously known as endogenous pyrogen), TNF, and IL-6 are able to raise the temperature set point of an organism and cause fever.[176,177] These cytokines stimulate production of inducible cyclooxygenase (i.e., COX-2), which induces the hypothalamic production of prostaglandins, particularly PGE_2. PGE_2 stimulates the release neurotransmitters such as cyclic adenosine monophosphate (cAMP) and increases body temperature.[28,177] Other proinflammatory cytokines, such as IFN-γ, may indirectly cause fever through induction of IL-1 and TNF synthesis. Cytokines that are members of the same receptor families as those of pyrogenic proinflammatory cytokines do not necessarily trigger fever. The IL-18 receptor is a member of the IL-1/Toll-like receptor superfamily, but unlike IL-1 and LPS, IL-18 does not trigger PGE_2 synthesis in vitro or cause fever when it is administered in vivo.[92,177] Similarly, IL-11 and IL-6 both are members of the gp130 cytokine family, and both activate the acute phase response.[48,117] In contrast with IL-6, IL-11 does not produce fever. IL-10 is an endogenous antipyretic cytokine and probably modulates fever through inhibition of proinflammatory cytokine synthesis.[178]

Acute Phase Reaction

The synthesis and release of hepatic acute phase proteins constitute an important mechanism in modulating the inflammatory response and the restoration of homeostasis. Acute phase proteins have diverse biologic activities and include antiproteases, antioxidants, activators of the complement system, blood-clotting agents, and immune response modulators.[48,179]

The hepatic acute phase response is regulated principally by IL-6, but other members of the IL-6 family, including IL-11, also can induce the acute phase response.[48,55] TNF, IL-1, IFN-γ, and possibly IL-8 also induce synthesis of various hepatic acute phase proteins.[48,179-181] The acute phase reaction is terminated indirectly through the inhibition of proinflammatory cytokine synthesis by IL-4, IL-13, and IL-10.[182] Natural inhibitors of TNF, IL-1, and IL-6, including soluble receptors and receptor antagonists, also can remove excess IL-6, IL-1, and TNF. IL-4, in contrast with other antiinflammatory cytokines, can inhibit synthesis of select hepatic acute phase proteins.[183] Acute phase proteins themselves also are capable of modulating the proinflammatory response through the induction of cytokine antagonists such as IL-1ra.[184] Thus cross-talk between cytokines and the hepatic acute phase response contributes to the resolution of the inflammatory response.

Inflammatory Diseases

Proinflammatory cytokines play a central role in inflammatory diseases of infectious or noninfectious origin. TNF triggers a cytokine cascade that initially is composed of the proinflammatory cytokines (IL-1, IL-6, IL-8, IL-12, IFN-γ, IL-18, and TNF itself).[2,6,8,185,186] These cytokines serve to contain and resolve the inflammatory foci through activation of local and systemic inflammatory responses. TNF also triggers a cytokine cascade of the antiinflammatory cytokines that block proinflammatory cytokine synthesis, as well as cytokine inhibitors that block proinflammatory cytokine actions.

In most cases, the inflammatory response is successfully resolved. Overzealous production of cytokines or the inability to shut down proinflammatory cytokine production, however, can lead to increasing concentrations of cytokines in the systemic circulation ("cytokine storm"). This continued cytokine production can have a deleterious effect on the host, with the development of hypotension, intravascular thrombosis, pulmonary edema, and hemorrhage; if this process is left unchecked, it can lead to multiple organ failure and death. This condition often is referred to as the *systemic inflammatory response syndrome* (SIRS).[187] This term describes the clinical manifestations of widespread endothelial inflammation that leads to increased vascular permeability.[170,188-190] This condition is the initiating pathologic process in a group of diverse disorders, such as bacterial sepsis, ischemia, burn injury, trauma and tissue injury, and hemorrhagic shock.

It has become apparent that interactions between proinflammatory and antiinflammatory mediators regulate the inflammatory response.[5,7,8,125] Antiinflammatory cytokines, in particular IL-10, inhibit proinflammatory cytokine synthesis and adhesion molecule expression while increasing the levels of specific cytokine inhibitors. Excess production of antiinflammatory cytokines, however, can compromise the host's ability to clear microorganisms through suppression of immune cell function. If a balance is not maintained, the result is either an excessive proinflammatory response or, alternatively, immunosuppression and increased susceptibility to secondary infection. Thus, although the cytokine cascade triggered by TNF is often beneficial to the host by initiating the inflammatory response, overproduction or underproduction of proinflammatory or antiinflammatory endogenous mediators may actually be deleterious to the host. Studies suggest a genetic predisposition that determines the balance of proinflammatory and antiinflammatory cytokines and, hence, susceptibility to disease.[3,7,191-193] Various polymorphisms have been identified within cytokine and cytokine receptor genes that alter their expression. These cytokine and cytokine receptor polymorphisms may determine the balance of proinflammatory and antiinflammatory cytokines in the inflammatory response.

To date, therapeutic strategies targeting proinflammatory cytokines such as TNF and IL-1β have proved ineffective in the treatment of SIRS.[1,125,194] These cytokines are critical to the initiation of the inflammatory response and may have peaked before the clinical signs and symptoms of SIRS become apparent. Current investigational approaches are now focused on mediators that appear later in disease progression. Two important late

proinflammatory mediators are high-mobility group box protein type 1 (HMGB1) and macrophage inhibitory factor (MIF). HMGB1, originally identified as a DNA-binding protein, is now recognized as a late mediator of sepsis and SIRS.[195] HMGB1 is actively released extracellularly by macrophages and endothelial cells during the inflammatory response as well as passively from necrotic cells. HMGB1 mediates numerous proinflammatory actions both locally and systemically.[196] Administration of recombinant HMGB1 to mice produces the clinical features of SIRS and multiple organ failure. Furthermore, antibodies or antagonists directed against HMGB1 are protective in animal models of sepsis and SIRS.[195,197]

Although the proinflammatory mediator MIF originally was identified as a modulator of macrophage migration, it is now recognized to be a critical regulator of the inflammatory response.[198] Unlike other proinflammatory cytokines, MIF can be induced by glucocorticoids.[143] MIF is released in the periphery by several types of immune cells in response to infection. MIF also can be released centrally from the anterior pituitary gland, and this central release contributes to sustained plasma elevations of MIF in response to inflammation. Furthermore, in animal models of infection and sepsis, anti-MIF therapy significantly improved survival.[143,198,199] Thus these "late" proinflammatory mediators may provide novel therapeutic targets for the treatment of SIRS.[143,186,199,200]

CLINICAL APPLICATION OF CYTOKINE PHYSIOLOGY IN NEWBORN INFANTS

Cytokine Physiology in Newborn Infants

The newborn period represents a time of increased risk for the development of bacterial infection and increased mortality from sepsis.[201,202] Among other factors known to increase this risk is a functional immaturity of newborn immune mechanisms. Both immunoglobulin and complement levels are low, and leukocyte functions, including the secretion of inflammatory mediators, may be deficient.[203-205] Only recently has attention been directed to developmental aspects of the immune response.

The fetus and newborn infant are unique from the standpoint of immunity and infection. The fetus lives in a sterile, immunologically protected environment. However, it is during this time that the development of the immune system is initiated—a highly complex process mediated, at least in part, by the expression of cytokines.[206,207] Fetal cytokines are known to play a role in the regulation of hematopoiesis and to protect the fetus against rejection. Placental and fetal cytokines also protect against infection.[206,207] Evidence suggests that cytokines in the fetus and neonate play a role in the pathophysiology of severe neonatal diseases including sepsis, bronchopulmonary dysplasia (BPD), and necrotizing enterocolitis (NEC).[208-211]

In the past, therapeutic strategies were aimed exclusively at killing the bacteria that caused neonatal infection. It has become evident, however, that many infants die despite the sterilization of blood cultures with antimicrobial agents.[212,213] It is now appreciated that the physiologic derangements that occur during sepsis are secondary to the host response induced by pathogenic microorganisms. During overwhelming sepsis, the host produces proinflammatory cytokines that initiate a cascade of events resulting in tissue injury at distant sites and generalized multiorgan system failure.[213,214] The balance of proinflammatory and antiinflammatory cytokines may ultimately determine the outcome with sepsis in newborn infants. This inflammatory response may have its origins during the fetal period.[206,207] Thus the heightened morbidity and mortality in neonatal sepsis result from physiologic deficiencies in immune function, as well as the pathophysiologic alterations produced by bacterial byproducts.[212,213] This section discusses the development of the inflammatory response in the fetus and neonate, the production of inflammatory mediators, and their role in the inflammatory response to specific disease processes in newborn infants.

Cytokine Production in Newborn Infants

In comparison with adult data, considerably less is known regarding the production and release of cytokines in the fetus and newborn infant. Studies indicate that both proinflammatory and antiinflammatory cytokines mediate many of the pathophysiologic events during bacterial sepsis. Moreover, growing evidence suggests that the fetal inflammatory response plays a major role in the induction of several neonatal diseases. Thus attention has been focused on determining the capability of monocytes from newborn infants to produce these cytokines and the balance of proinflammatory and antiinflammatory mediators in the fetus and neonate.

Tumor Necrosis Factor

TNF, an early proximal mediator in the cytokine cascade,[215,216] is produced by human fetal Kupffer cells as well as placental mononuclear cells in response to stimulation by LPS.[217,218] TNF can be found in amniotic fluid during the second and third trimesters, and TNF levels increase with premature rupture of membranes.[219]

Several (but not all) investigators have demonstrated significantly decreased TNF production by cord blood monocytes.[220-224] In addition, preterm infants born before 30 weeks gestation demonstrated significantly diminished LPS-stimulated TNF secretion when compared with neonates of later gestational ages or adults.[222] Levy and co-workers[225] further demonstrated a specific inhibitory effect of adenosine on TNF production during the perinatal period. When analyzed in culture, monocyte-macrophages derived from newborn infants also secreted diminished amounts of TNF when compared with adult cells.[224,226] Kwak and colleagues[227] examined TNF production by cord blood mononuclear cells in response to several stimuli. In contrast with the immediate response to LPS (in which TNF, IL-1β, IL-6, and IL-8 appeared almost simultaneously), stimulation by group B streptococci resulted in increased TNF production but a delayed appearance of the other cytokines. Thus, abnormalities of TNF production and release, particularly in preterm infants, may increase susceptibility to bacterial infection in this age group.

TNF receptor expression also may be diminished. Using flow cytometry and a human recombinant TNF that binds to the 75- and 55-kDa receptors, Chheda and co-workers[226] demonstrated reduced expression of TNF receptors on cord blood monocytes when compared with that on adult cells. Moreover, these findings suggest a dissociation between the production and release of TNF and other cytokines, such as IL-1 and IL-6.

Interleukin-1

IL-1 also is an integral mediator in the cytokine cascade that is produced by fetal Kupffer cells in response to LPS.[217] IL-1 is present in amniotic fluid and increases with premature rupture of membranes.[219] Production of IL-1 by cord blood monocytes is comparable with that in adult control subjects, even in monocytes obtained from preterm infants.[220,221,228-231] However, in preterm infants with bacterial sepsis, monocyte IL-1 secretion was lower during the acute infectious phase, but improved significantly during the convalescence period.[232] Bry and co-workers[233] found gender differences in the antiinflammatory IL-1ra responses in newborn infants (female > male). Moreover, increased cord IL-1ra levels were associated with neonatal morbidity and adverse outcome in preterm infants.[234]

Although monocytes, endothelial cells, and fibroblasts are thought to be the primary sources of cytokine production, neutrophils also possess that capability, albeit in lesser amounts. After stimulation with LPS or TNF, Contrino and associates[235]

found significantly increased expression of IL-1 by cord blood neutrophils compared with that in cells from adults. Although neutrophils function primarily as rapid effector cells with little immunoregulatory function, IL-1 secretion by neutrophils may be important in the amplification of the early inflammatory response.

Interleukin-6

IL-6 is a pleiotropic cytokine that induces the acute phase response with additional important antiinflammatory properties.[223] After stimulation with LPS, IL-6 is produced by human fetal Kupffer cells as early as 13 weeks after conception.[218] This cytokine also has been detected in the amniotic fluid during infection.[236]

Several studies have evaluated IL-6 production by monocytes from newborn infants.[222,223,228,236-238] Liechty and colleagues[236] demonstrated equivalent IL-6 production by fetal and maternal mononuclear cells after stimulation with IL-1. Angelone and coworkers[223] demonstrated that LPS-stimulated cord blood IL-6 production and IL-6/TNF ratios were higher than in adult peripheral blood. This robust IL-6 production was linked to both cellular (monocyte) and humoral (serum) factors. However, IL-6 production was reduced in cells from preterm neonates, perhaps contributing to their enhanced susceptibility to overwhelming bacterial infection.[236,239] Using flow cytometry and LPS stimulation, Schultz and associates[208] demonstrated that both term and preterm monocytes displayed a higher percentage of IL-6–positive cells than in those from adults, suggesting an enhanced inflammatory response in these infants.

Cord blood lymphocytes express both the gp80 and the gp130 IL-6 receptor, although generally at lower levels than in adult cells.[240] The immunofluorescence staining patterns for IL-6 receptors on monocytes were similar for cord and adult cells; however, the available data are limited.

Interleukin-8

IL-8 is a low-molecular-weight cytokine produced by mononuclear and endothelial cells that attracts and activates neutrophils.[241] Little is known about the expression and function of IL-8 in the fetus. Using cord blood mononuclear cells stimulated with endotoxin, Taniguchi and co-workers[242] found that IL-8 production was significantly greater in neonates born to mothers with chorioamnionitis than in those born to healthy women. Although early studies suggested deficiencies in IL-8 production by neonatal mononuclear cells, more recent literature indicates an intact proinflammatory cytokine pathway.[213,214,243,244] After LPS stimulation of whole blood cultures, IL-8 production by neonates exceeded adult levels.[245] Moreover, IL-8 production was independent of gestational age.[239] Using flow cytometry to analyze cytokine production at the single cell level, Schultz and colleagues[208] also found enhanced IL-8 production by neonatal monocytes after LPS stimulation. In this study, cells from both term and preterm infants displayed a higher percentage of IL-8–positive cells than in adult cells, a finding challenging the existing view of an immature neonatal inflammatory response.[208] IL-8 levels in whole cord blood specimens increased in response to the stress of labor and delivery.[246] Furthermore, elevated IL-8 levels have been found in neonates with diseases including cerebral white matter damage, BPD, and NEC.[208]

Interleukin-10

IL-10 is an antiinflammatory cytokine that decreases the expression and function of proinflammatory cytokines, including TNF, IL-1, and IL-8.[100,102] In addition, IL-10 limits the participation of helper T cells in delayed hypersensitivity and protects against inflammation. During the fetal period, placental production of IL-10 may prevent immune rejection.[207,247] Neonates exhibit decreased IL-10 production.[209,248,249] Both term and preterm infants demonstrate significantly diminished IL-10 mRNA expression and IL-10 production after stimulation.[250] Although IL-10 is less well explored than other cytokines in this respect, diminished production of IL-10 and immaturity of the antiinflammatory response may contribute to the enhanced proinflammatory state in newborn infants.

Interleukin-18

Il-18, a more recently described member of the IL-1 family, is an important regulator of both innate and acquired immune responses. Overall, data for newborn infants are lacking, but a single study found diminished IL-18 production in response to stimulation with group B streptococci.[251] This deficiency may contribute to the notable susceptibility of the neonate to group B streptococci and other pathogens.

Fetal and Neonatal Cytokines in the Inflammatory Response

The fetus and newborn infant are uniquely susceptible to the development of bacterial infection as well as heightened mortality from infectious disease. In adults, cytokines have been implicated as endogenous mediators elaborated during the pathogenesis of sepsis and shock. Work in developmental immunobiology also has suggested that cytokines contribute to the inflammatory response in the fetus and newborn infant with chorioamnionitis, sepsis, NEC, and BPD.

Chorioamnionitis and Brain Injury

Evidence suggests that intrauterine infection is a cause of cerebral palsy in both term and preterm infants. Both clinical and subclinical chorioamnionitis may trigger an inflammatory response in the mother and fetus associated with the elaboration of proinflammatory cytokines. This fetal inflammatory response is thought to contribute to the development of neonatal brain injury and subsequent cerebral palsy.[252-254]

The cytokines TNF, IL-1β, and IL-6 normally are present in amniotic fluid, with levels increasing until term gestation.[252] During the course of intrauterine infection, however, levels of proinflammatory cytokines are significantly increased and have been correlated with the initiation of preterm labor.[255] Although chorioamnionitis traditionally was considered a maternal infection, more recent evidence suggests that the systemic fetal inflammatory response is more important in contributing to neonatal brain injury.[256] Observations by Dammann and Leviton[257] support the hypothesis of a fetal vasculitis as part of the response to perinatal infection.

Exposure to LPS during pregnancy is associated with elevated concentrations of the proinflammatory cytokines TNF, IL-1, IL-6, and IL-8 in both amniotic fluid and neonatal plasma, suggesting both maternal and fetal involvement.[258-260] In turn, elevations of these cytokines are associated with increased risk for neonatal brain injury and cerebral palsy.[255,257,261] Yoon and associates[255,258,259] demonstrated higher levels of TNF, IL-1β, IL-6, and IL-8 in amniotic fluid in infants who subsequently developed periventricular leukomalacia. Other investigators have reported higher umbilical cord plasma IL-6 levels in neonates with white matter damage.[261-263] Shimoya and colleagues[264] found elevated IL-8 levels in cord sera from preterm fetuses with chorioamnionitis, which increased proportionately with the severity of disease as graded histologically. These workers suggested that the measurement of IL-8 may be more sensitive (97%) and specific (89%) for the diagnosis of chorioamnionitis than conventional markers, such as leukocytes, C-reactive protein, and immunoglobulin M. Pacora and associates reported an association between elevations of IL-18 in amniotic fluid and intrauterine infection.[265] Minagawa[266] further suggested a possible correlation between elevations of cord blood IL-18 levels in preterm infants and the

development of periventricular leukomalacia and cerebral palsy. A recent study has also noted the relationship of higher levels of IL-6 and IL-10 in cerebrospinal fluid and magnetic resonance imaging (MRI)-defined cerebral white matter injury.[267] Furthermore, TNF and IL-6 have been demonstrated directly on histopathologic examination of white matter lesions in newborn infants.[255] These findings lend further direct support to the association of an inflammatory process in the central nervous system with neurologic injury in vulnerable infants.

Several mechanisms have been suggested to explain the link between infection/inflammation in pregnancy and cerebral white matter damage.[255,268-270] Intrauterine infection stimulates the fetal production of proinflammatory cytokines, which increase the permeability of the blood-brain barrier, thereby allowing inflammatory products into vulnerable areas of the developing brain.[268,271] Dammann and Leviton[268] proposed that proinflammatory cytokines cross the blood-brain barrier and then cause white matter damage directly, or induce further cytokine production by microglial cells and astrocytes. The brain-derived cytokines exert a direct neurotoxic effect on oligodendrocyte precursors and inhibit their subsequent differentiation into mature myelinating oligodendrocytes.[271,272] Inflammatory cytokines also activate astrogliosis and NO release, producing mitochondrial damage and cellular energy failure.[271,272] The final result is the accumulation of reactive oxygen species and apoptosis of oligodendrocytes.[271] Furthermore, elaboration of inflammatory mediators may increase the susceptibility of the cerebral white matter to other insults, such as hypoxia or ischemia.[256]

Epidemiologic data suggest that preterm infants exposed to an intrauterine infection are more likely to develop cerebral palsy. Positive associations have been reported between cystic periventricular leukomalacia and intraamniotic, brain, and umbilical cord cytokine levels.[252-254,259,270] In a meta-analysis of data for women with histologic and clinical chorioamnionitis, a relative risk of 1.8 (confidence interval, 1.5 to 2.3) was found for cerebral palsy in association with chorioamionitis.[254] Although these data do not establish causality between cytokines and perinatal brain injury, they do provide evidence of the association of cerebral palsy with an inflammatory environment at birth.[254]

Genetic polymorphisms in cytokine expression may influence the host response to chorioamnionitis and the development of cerebral palsy.[252,259] These polymorphisms may, in turn, explain differences in outcome after intrauterine infection and predict which infants will incur brain damage.[252,254,257,273] Using multivariate analysis, Annells and colleagues found an association between polymorphisms in the immunoregulatory genes for TNF and IL-10 and the presence of histologic chorioamnionitis.[274] Gibson and co-workers[275] further demonstrated that carriage of polymorphisms in TNF genes was associated with an increased risk for cerebral palsy, either directly through cytokine-mediated brain damage or indirectly in association with an altered immune response to infection. These associations warrant further investigation.

Bacterial Sepsis

Sepsis and septic shock are important determinants of morbidity and mortality in the neonatal intensive care unit (NICU). Cytokines play a key role in this response in newborn infants. Although the immune system produces cytokines to protect the host when threatened by microbial invasion, overproduction or an imbalance of proinflammatory versus antiinflammatory mediators may sometimes occur, with potentially deleterious effects.[212,214]

Several groups of investigators have examined levels of the proinflammatory cytokines TNF, IL-1, IL-6, and IL-8 during the evolution of bacterial sepsis in newborn infants.[276-280] In an early report, Girardin and associates[277] demonstrated significantly higher TNF levels in infants with systemic infection than in infants in other clinical groups; the highest levels were found in the neonates with circulatory failure, particularly those who died. TNF levels were unrelated to gestational age or to the Gram stain characteristics of the infecting organism. Similarly, Roman and co-workers[281] correlated the degree of TNF elevation with the severity of sepsis, with the infants who died having the highest levels of TNF.

Miller and colleagues[282] prospectively measured levels of TNF, IL-1, and IL-6 in cord blood samples from neonates born after complicated perinatal courses. In this study, IL-1β levels were significantly elevated in the presence of severe perinatal complications, whereas TNF and IL-6 levels did not reflect the type of delivery or severity of the perinatal course. In infants with strictly defined infectious complications, however, cord blood IL-6 levels were markedly elevated.[282] In neonates with herpes simplex virus infection, Kawada and co-workers[283] demonstrated significantly higher IL-6 and sTNF-R1 in disseminated disease than in infection confined to the central nervous system or skin, eyes, and mouth. Furthermore, concentrations of inflammatory cytokines were correlated with viral load.[283]

Numerous studies have demonstrated elevations of IL-6 and IL-8 in infected neonates, although the methodology used to measure cytokine levels has varied, and a group of neonates with "probable" infection sometimes is included.[284-286] Santana and associates found elevated cord blood levels of IL-6 in newborn infants with various infectious and noninfectious conditions, whereas IL-8 was the best predictor of early-onset bacterial infection.[286] Using a chemiluminescence immunoassay that allowed results within 1 to 2 hours, Krueger and co-workers[287] found elevations of IL-6 and IL-8 in preterm infants with culture-proven sepsis. These investigators suggested that this method may allow an immediate diagnosis of infection in preterm infants. Using reverse transcriptase–polymerase chain reaction analysis, Berner and colleagues[288] also found elevations of IL-8 mRNA to be highly sensitive (86%) and specific (96%) for the detection of neonatal infection.

Lehrnbecher and colleagues[289] extended these findings by measuring both proinflammatory mediators (IL-6, IL-8) and sIL-6 receptors in cord blood from infected neonates. Although IL-6 and IL-8 levels were significantly elevated, as predicted from previous studies, sIL-6R levels were significantly reduced in sepsis.[289] This phenomenon has also been described in adults with sepsis, and it is speculated that the reduction of sIL-6R during sepsis may alter the biologic activity of IL-6. Døllner and co-workers[290] found elevated TNF receptors (p55 and p75) as well as IL-1ra in infected neonates. In an experimental mouse model of group B streptococcal sepsis, Cusmano and associates detected significant elevations of IL-18 in infected animals; however, survival was improved after the administration of recombinant IL-18.[291]

A recent study by Harris and colleagues[284] measured levels of IL-8, IL-10 and IL-18 in critically ill infants with bacterial sepsis versus sepsis syndrome. Infants with bacterial sepsis had significantly higher plasma levels of IL-8 and IL-10, but not IL-18, suggesting differential regulation of this cytokine.[284] Plasma IL-8, IL-10 and IL-18 levels were correlated with mortality.[284] Romagnoli and co-workers[292] also demonstrated that persistently high IL-10 levels correlated with death from sepsis. In preterm infants weighing less than 1500 g at birth, Ng and colleagues[279] found elevations of both proinflammatory (TNF, IL-6) and antiinflammatory (IL-10) cytokines in infected infants versus noninfected control infants. Measurements of IL-6 and IL-10 at clinical presentation predicted the development of disseminated intravascular coagulation in infected neonates, with the sickest infants demonstrating higher concentrations of inflammatory cytokines than in those with milder infections.[293] These studies suggest that interactions of both proinflammatory and antiinflammatory cytokines play a critical role in the clinical manifestations of and outcomes with neonatal sepsis.

Several studies also have monitored cytokine levels as a guide to the duration and efficacy of antimicrobial therapy.[294-296] DeBont and associates[294] measured TNF, IL-1, and IL-6 in newborn infants hospitalized for clinically suspected sepsis. Plasma TNF and IL-6 levels were significantly increased in the infants with sepsis, although IL-1 levels were only slightly elevated. After the start of antimicrobial therapy and concomitant clinical improvement, TNF, IL-1, and IL-6 levels decreased and normalized within 2 days. Sikora and colleagues[295] found elevations of both proinflammatory (IL-1, IL-6, IL-8) and antiinflammatory (IL-10, IL-13) cytokines early in the course of sepsis, which decreased after antimicrobial therapy. Levels of cytokine inhibitors (IL-6sR, sTNFR II) also decreased after treatment.[295] Franz and co-workers[297] suggested use of a diagnostic algorithm measuring IL-8 and C-reactive protein to reduce unnecessary antibiotic exposure in newborn infants evaluated for early-onset sepsis. However, infants who were rapidly deteriorating or in septic shock were excluded from this trial.[297] Cytokine elevations also have been demonstrated in newborn infants with nosocomial sepsis. Groll and associates[296] reported elevations of IL-6 in 8 of 10 infants at the onset of proven nosocomial infection; in 7 infants, these values returned to normal on completion of antibiotic therapy.

In view of the excessive morbidity and mortality from bacterial sepsis in newborn infants, several investigators also have addressed the predictive value of cytokine measurements in the early diagnosis of bacterial infection.[290,298-300] In one report, Mehr and Doyle[301] reviewed results of studies published between 1996 and 1999 using TNF, IL-6, and IL-8 as markers of bacterial sepsis in newborn infants. Although the patient populations studied and the cytokines measured varied, several conclusions can be drawn from these data. Of all the cytokines measured, the most consistent results were found using IL-6.[301] Less consistent results were obtained with TNF; however, TNF is an evanescent cytokine whose levels peak early and decline rapidly during sepsis. IL-1 was an unreliable indicator of bacterial infection. Finally, IL-8 may prove most useful for the diagnosis of bacterial infection. More recently, Verboon-Maciolek and colleagues[302] compared levels of IL-6 and IL-8 in bacterial versus viral sepsis in the NICU. Although elevated levels of both cytokines were found in bacterial sepsis, normal values were noted in infants with enterovial disease, suggesting that cytokine measurements may aid in the differentiation of bacterial versus viral infection.[302]

Genetic polymorphisms in cytokine expression may influence neonatal susceptibility to infectious disease as well as host response to infection.[303] The most consistent results to date have been obtained for TNF. TNF-308 is the best-studied polymorphism and has been associated with increased mortality from sepsis in ventilated preterm infants.[304] Other polymorphisms related to IL-6 and IL-10 have been reported to increase the risk of sepsis in adult patients; however, studies in neonates have thus far produced conflicting results.[303,304]

Necrotizing Enterocolitis

NEC is a disease frequently encountered in premature infants in the NICU. Although the manifestations of the illness are quite variable, the development of fulminant sepsis and shock is not uncommon in affected infants.[305] As with the involvement of cytokines in bacterial sepsis, the generation of cytokines in NEC occurs in response to circulating bacteria and their byproducts as well as local mediator release associated with tissue inflammation.[306]

Data from both animal and human studies support the role of PAF and TNF in the pathophysiology of NEC.[307,308] Caplan and associates[308] demonstrated higher circulating levels of PAF and TNF in infants with NEC than in age-matched control patients. Feedings alone increased circulating PAF levels, which preceded the development of NEC. Plasma TNF levels also were elevated in affected infants, thereby augmenting the inflammatory response.[308] Harris and colleagues[309] measured TNF and IL-6 levels in infants with suspected sepsis or NEC at clinical presentation and at 12, 24, and 48 hours thereafter. IL-6 levels were highest (10-fold greater) in infants with bacterial sepsis plus NEC, intermediate in infants with bacterial sepsis alone, and lowest in control infants with negative findings on evaluation for infection. Elevated IL-6 levels also were associated with increased mortality. By contrast, plasma TNF levels did not reliably identify infants with sepsis or NEC.[309] These data suggest that increased plasma IL-6 levels in NEC may reflect the combined effects of bacterial invasion of the bloodstream and the systemic response to severe bowel injury. Morecroft and co-workers[310] also demonstrated elevated TNF levels in a majority of samples (71%) from infants with NEC but found no correlation with severity of disease. By contrast, IL-6 levels were significantly increased in infants with definite (stage II) and advanced (stage III) NEC. These investigators concluded that although TNF may be an early marker of disease, IL-6 correlates best with disease severity. Furthermore, therapy with anti-TNF antibodies in animals reduced the incidence and severity of disease.[311]

Expression of both proinflammatory and antiinflammatory cytokines in NEC has been studied.[211,284] Edelson and colleagues[211] found circulatory levels of both proinflammatory (IL-1, IL-8) and antiinflammatory (IL-1ra, IL-10) cytokines to be elevated at the onset of NEC in infants with severe disease. Moreover, an elevated IL-1ra concentration had a high sensitivity (100%) and specificity (92%) for the presence of severe disease. In a more recent study, Harris and colleagues[284] reported elevations of IL-8 and IL-10 in infants with NEC versus sepsis syndrome controls, reflecting a response to circulating bacteria and their byproducts as well as local mediator release associated with tissue inflammation. Elevated IL-10 levels in preterm infants with NEC versus control infants were reported previously;similar to the findings by Harris' group,[284] these levels were lower than in infants with bacterial sepsis.[292]

More recent evidence suggests that inflammatory mediators produced locally in the intestine may contribute to the pathogenesis of NEC. Viscardi and associates[312] measured TNF, IL-1, IL-6, and IL-8 mRNA in surgical specimens of NEC and normal intestine. Although TNF and IL-1 mRNA levels were higher in intestinal specimens from infants with severe disease, IL-6 and IL-8 mRNA levels did not distinguish between infants with NEC and control infants. By contrast, Nadler and colleagues[313] found up-regulation of intestinal IL-8 mRNA in acute NEC; however, elevations of IL-8 did not correlate with mortality. IL-11 mRNA levels also were increased; this increase may represent a protective response to limit the extent of intestinal damage. Levels of IL-8 and IL-11 returned to baseline at the time of stomal closure. Elevations of ileal IL-18 also have been demonstrated in NEC[313]; however, Harris and co-workers[284] found no significant elevation in plasma IL-18 levels in critically ill infants with NEC versus sepsis syndrome control infants.

A more recent study of HMGB1, a late but potent mediator of intestinal inflammation associated with NEC, found elevated levels in ileal samples from infants undergoing intestinal resection for NEC.[314] Thus investigations of plasma and intestinal mRNA levels suggest elevations of both proinflammatory and counterinflammatory cytokines in NEC.

Bronchopulmonary Dysplasia

Since the mid-1990s, improvement in neonatal respiratory care has enhanced the survival rate of premature infants who develop chronic lung disease. In these infants, the pathogenesis of BPD is complex and probably multifactorial, but evidence suggests the development of an early and persistent inflammatory response in the lung.[209,315,316] This inflammatory response may have its origins during the fetal period after intrauterine infection.[317] As hypothesized separately by Speer[210] and Jobe,[318] antenatal

inflammation may prime the lung so that minimal postnatal injury can produce an excessive inflammatory response.

Yoon and colleagues[319,320] reported elevated levels of TNF, IL-1, IL-6, and IL-8 in amniotic fluid from mothers of infants who subsequently developed BPD. In addition, elevated cord blood IL-6 levels, suggesting a fetal inflammatory response, were shown to be an independent risk factor for the development of BPD.[320] An and co-investigators[321] found elevated IL-6, IL-8, and sTNFR-1 levels in cord blood from infants with subsequent chronic lung disease, whereas IL-1, IL-2, IL-4, IL-10, and IFN-γ were undetectable. IL-6 levels also were higher in the infants who required prolonged oxygen therapy.

The presence of cytokines in bronchoalveolar lavage specimens may also serve as markers of inflammation. Cayabyab and co-workers[322] detected IL-1 in bronchoalveolar lavage (BAL) specimens from preterm infants within the first hour of life, which correlated with the presence of maternal chorioamnionitis, the presence of other proinflammatory cytokines (TNF, IL-6, IL-8), and increased risk for the development of chronic lung disease. In a more recent study of preterm infants in whom BPD developed subsequently, Kakkera and colleagues[323] found higher levels of IL-1ra as well as IL-1 in tracheal aspirates on day 1 of life. By days 5 to 7, increasing IL-1 expression (relative to IL-1ra) favored a proinflammatory response and the development of BPD. Other investigators have reported elevated IL-6 levels in lung lavage samples from infants in whom chronic lung disease developed later on.[324,325]

Jones and associates[209] measured IL-8 levels in BAL supernatants from term and preterm infants. Whereas IL-8 levels declined in term infants, elevations persisted in preterm infants over a 96-hour observation period. In infants with hyaline membrane disease, Kotecha[325] correlated the development of chronic lung disease with increased BAL IL-8 levels. Huang and co-workers[326] measured IL-8, IL-10, and TNF levels on the first day of life in BAL samples from preterm infants intubated for respiratory disease. Levels of IL-8, but not TNF or IL-10, were correlated with the development of BPD. Similarly, De Dooy and associates[327] found high levels of IL-8 (but not TNF, IL-1, IL-6, or IL-10) to be associated with adverse respiratory outcome in infants younger than 28 weeks gestation by multivariate analysis. These results are in accord with those reported by Kwong and colleagues[328] who found the highest IL-8 levels on day 12 of life in preterm infants with diffuse alveolar disease, which then declined to low levels by 28 days of age. Furthermore, tracheal aspirate concentrations of monocyte chemoattractant protein-1, -2, and -3 and macrophage inflammatory protein-1α and -1β were significantly increased in oxygen-dependent preterm infants at 28 days of age.[329]

By contrast, Jones and associates[209] reported undetectable levels of IL-10 mRNA in BAL samples from preterm infants with respiratory distress syndrome but measurable levels in term infants with meconium aspiration syndrome. These investigators speculated that the susceptibility of the preterm infant to chronic lung disease may in part reflect an inability to generate the antiinflammatory cytokine IL-10.[209,210] In a more recent study, Blahnik and colleagues[330] found that whereas TNF expression was nearly identical in term and in preterm neonates, a trend toward diminished levels of IL-10 was evident in the preterm group. In preterm infants born before 27 weeks gestation, a strong inverse relationship was found between constitutive IL-10 production by lung cell cultures and the development of BPD.[331] However, IL-10 production induced by LPS was correlated to gestational age. In contrast with the foregoing studies, McColm and co-workers[315] found that IL-10 was readily detectable in BAL samples from ventilated preterm infants with respiratory failure, most of whom developed chronic lung disease. Overall, however, data are consistent with a proinflammatory-antiinflammatory imbalance that favors the development of chronic inflammation and contributes to the pathogenesis of BPD.[319,331]

Investigations also have focused on genetic polymorphisms that may increase the risk and severity of chronic lung disease. A TNF polymorphism (TNF-α-238) in which lower TNF levels are produced after stimulation has been associated with diminished severity of BPD.[332] However, the IL-10-1082 G/A polymorphism did not influence the development of BPD in ventilated infants weighing less than 1500 g at birth.[333] Future multicenter studies in large populations are needed to address the potential associations of genetic susceptibility to inflammatory states.

Integrins and Cell Adhesion Molecules

Adhesion is of fundamental importance to cell functioning. Besides providing "anchorage," it also provides cues for migration, signals for growth, differentiation, and cell activation. There are two principal types of cell adhesion: cell to extracellular matrix and cell to cell. Embryonic development, maintenance of tissue architecture, wound healing, hemostasis, inflammation, and the immune response all involve the interaction of cells with extracellular matrices or adjacent cells. The seminal role of adhesion molecules in embryogenesis and tissue morphogenesis cannot be overemphasized. Indeed much of the understanding of cell adhesion derives from this prolific area of research.[1] The focus of this chapter will be on the role of cell adhesion necessary for leukocyte and platelet localization in inflammation and the immune process, emphasizing what is known regarding the changes in these mechanisms in the immature host.

With the use of intravital microscopy, several investigators in the 19th century established white cells adhering to the blood vessel lining as the hallmark of the acute inflammatory response. In the absence of inflammatory stimuli and under conditions of flow, leukocyte contact with the endothelium is random and circulating leukocytes do not adhere to the vascular endothelium. With inflammation, leukocytes marginate within the venules where they are only loosely tethered to the endothelial wall and roll along the surface. After rolling, leukocytes become firmly adherent to the endothelium and become "activated," changing shape from a spherical to a flattened configuration. The leukocytes finally crawl along through the endothelium lining of the blood vessel (This process also is known as transendothelial migration or diapedesis). Though the initial observations of this phenomenon were made more than 150 years ago, only in the past several decades with the identification of specific cell adhesion and chemotactic-activator molecules have the molecular mechanisms of what has been termed the *leukocyte-endothelial cascade* been elucidated.[2] It is important to emphasize that this cascade does not necessarily occur in all areas of the body, and that other mechanisms appear to be operative in tissues such as the liver, lung, and kidney.

The susceptibility of human neonates to localized soft tissue infections, as well as systemic infections caused by bacterial or fungal agents, has prompted extensive investigations of neonatal host defense mechanisms. Among the most consistently observed functional abnormalities are those related to leukocyte migration. Compared to adult cells, neonatal neutrophils and monocytes have diminished random and directed migration (chemokinesis and chemotaxis, respectively) and decreased adhesion to substrates.[3-6] Motile function is affected by gestational age in that more severe abnormalities have been recognized in premature infants than in term neonates.[7-9]

In vivo studies employing Rebuck "skin windows" in human neonates provide limited data suggesting that inflammatory

Integrins and Cell Adhesion Molecules

Adhesion is of fundamental importance to cell functioning. Besides providing "anchorage," it also provides cues for migration, signals for growth, differentiation, and cell activation. There are two principal types of cell adhesion: cell to extracellular matrix and cell to cell. Embryonic development, maintenance of tissue architecture, wound healing, hemostasis, inflammation, and the immune response all involve the interaction of cells with extracellular matrices or adjacent cells. The seminal role of adhesion molecules in embryogenesis and tissue morphogenesis cannot be overemphasized. Indeed much of the understanding of cell adhesion derives from this prolific area of research.[1] The focus of this chapter will be on the role of cell adhesion necessary for leukocyte and platelet localization in inflammation and the immune process, emphasizing what is known regarding the changes in these mechanisms in the immature host.

With the use of intravital microscopy, several investigators in the 19th century established white cells adhering to the blood vessel lining as the hallmark of the acute inflammatory response. In the absence of inflammatory stimuli and under conditions of flow, leukocyte contact with the endothelium is random and circulating leukocytes do not adhere to the vascular endothelium. With inflammation, leukocytes marginate within the venules where they are only loosely tethered to the endothelial wall and roll along the surface. After rolling, leukocytes become firmly adherent to the endothelium and become "activated," changing shape from a spherical to a flattened configuration. The leukocytes finally crawl along through the endothelium lining of the blood vessel (This process also is known as transendothelial migration or diapedesis). Though the initial observations of this phenomenon were made more than 150 years ago, only in the past several decades with the identification of specific cell adhesion and chemotactic-activator molecules have the molecular mechanisms of what has been termed the *leukocyte-endothelial cascade* been elucidated.[2] It is important to emphasize that this cascade does not necessarily occur in all areas of the body, and that other mechanisms appear to be operative in tissues such as the liver, lung, and kidney.

The susceptibility of human neonates to localized soft tissue infections, as well as systemic infections caused by bacterial or fungal agents, has prompted extensive investigations of neonatal host defense mechanisms. Among the most consistently observed functional abnormalities are those related to leukocyte migration. Compared to adult cells, neonatal neutrophils and monocytes have diminished random and directed migration (chemokinesis and chemotaxis, respectively) and decreased adhesion to substrates.[3-6] Motile function is affected by gestational age in that more severe abnormalities have been recognized in premature infants than in term neonates.[7-9]

In vivo studies employing Rebuck "skin windows" in human neonates provide limited data suggesting that inflammatory

responses as reflected by leukocyte exudation may differ from those in older children and adults.[10] Neonatal animal studies have provided insight into these differences, revealing diminished localization in response to inflammatory agents to the peritoneum and lung and other organs compared to adult animals. The basis for this defect in neonatal leukocyte motility is likely multifactorial and possibly includes diminished decrease in f-actin polymerization and abnormalities of microtubule assembly, as well as diminished adhesion receptor number and function.[5,11,12,13]

CELL ADHESION MOLECULES

Three families of cell adhesion molecules have been found to play a central role in leukocyte-endothelial interactions: the integrins, the immunoglobulin (Ig) gene superfamily, and the selectins.[2,14] The ligands for selectins constitute a fourth family of adhesion molecules.[15] Newer adhesion molecules identified in the last decade add increasing complexity to this area. These include new members of the Ig gene superfamily, junctional adhesion molecule (JAM) -1, -2, -3, and CD99.[16] Other molecules, such as platelet endothelial cell adhesion molecule 1 (PECAM1), found on the cell surface modulate transendothelial migration. PECAM-1, with a structure that originally placed it in the Ig gene superfamily, appears to have a signaling-inhibitory function as well as an adhesive function.[16] It is beyond the scope of this chapter to cover each of these molecules in detail, but the following will serve as an introduction to the basic elements so that "differences" in neonate, compared to "mature host," adhesive molecule function can be explored.

Integrins

Overview

The integrins are transmembrane cell surface proteins. Unlike the other families of cell adhesion molecules, the integrins are heterodimers, consisting of noncovalently associated α and β subunits of 150 and 100-kDa, respectively. Each subunit crosses the membrane once, with most of each polypeptide in the extracellular space (≥1600 amino acids) and a short cytoplasmic tail (30-50 amino acids). The term *integrin* was originally suggested to describe membrane receptors that "integrate" the extracellular environment (matrix or other cells) with the intracellular cytoskeleton. At present, 18 α- and 8 β-chains have been identified with the formation of 24 distinct integrins. The adhesion molecules also may have a cluster designation (CD) classification (Table 157-1). As seen in Figure 157-1, β subunits define the subfamily of integrin receptors and can associate with more than one α subunit. Several α subunits may associate with more than one β. Phylogenetically ancient integrins recognize the tripeptide sequence arginine (R)-glycine (G)-aspartic acid (D) in fibronectin, fibrinogen, and vitronectin whereas other integrins mediate the adhesion to the basement membrane laminin (Figure 157-1). Collagen receptors have inserted (I) domains, which is discussed in more detail in subsequent paragraphs. A pair of related integrins (α4β1, α9β1) recognizes both extracellular matrix proteins such as fibronectin and an Ig gene superfamily cell surface counterreceptor, vascular cell adhesion molecule (VCAM-1). The β2 and β7 integrins (Figure 157-1) are restricted to leukocytes; their counterreceptors are members of the Ig gene superfamily; they mediate heterotypic cell-cell interactions, and several mediate adhesion to extracellular matrix proteins. Ligand specificity relies on both subunits of the αβ heterodimer pair. Each of the integrins has a specific function that is mostly nonredundant. The phenotypes of genetically altered mice in which the specific integrin is "knocked out" of the genome details the ligand specificity of these molecules and their various roles.[17] The phenotypes range from a complete block in preimplantation development (β1) to defects in leukocyte (αL, αM, αE, β2, β7) or platelet function (αIIbβ3).

Although integrins appear to have a nonredundant function in regard to their roles in adhesion to extracellular matrix ligands or counterreceptors on adjacent cells, they nonetheless share a number of characteristics. On the cytoplasmic side, integrins coordinate the assembly of cytoskeletal proteins and signaling complexes. On the extracellular side, integrins engage either extracellular matrix macromolecules or counterreceptors on adjacent cell surfaces. The adhesiveness of the integrins is regulated through a process known as *inside-out* signaling. In contrast, ligation of the integrin transduces signals from the extracellular integrin domains to downstream cytoplasmic pathways. This is known as *outside-in* signaling.[2] Thus the integrins link signaling and extracellular matrix assembly spatially and bidirectionally thereby "integrating" cells with their microenvironment.

Integrin Structure

Integrins are not constitutively "active" and usually exist in an "off" state. As such, integrins do not bind ligand, and they do not signal. One of the most important mechanisms of integrin function is the rapid transition from a nonadhesive, low-affinity state to an intermediate state which can transition to a very transient high-affinity state and then return to a low affinity state (Figure 157-2). This change in affinity is caused by intracellular signaling, or inside-out signaling. Members of the β2 integrin subfamily, which are expressed on leukocytes, are inactive when the cells are quiescent. However β2 integrins become rapidly activated in response to cell activation with low dose chemokines, cytokines, and with shear stress.[18] The activated β2 integrins may then bind to their ligands on the endothelial surface, other cells, subendothelial matrix, or complement-coated bacteria. Activation of the integrins is quite transient, with rapid return to an inactive state.[19] Clearly this function of integrins is necessary for maintenance of a "nonthrombotic," "noninflamed" state in the host.

At least two mechanisms are proposed to explain how integrin activation increases integrin-ligand interactions.[19,20] These mechanisms include conformational changes in integrins (regulating the affinity of the integrin for the ligand) and clustering of integrins and association with the cytoskeleton (regulating the avidity of integrin-ligand binding). Using crystal structure analysis, electron microscopic images, and electronic magnetic resonance, extensive progress has been made in elucidating conformational regulation of ligand binding by integrins.[19,20] The N-terminal portions of α and β subunit form a globular head containing the ligand-binding region. It is connected to the cell membrane by a stalk approximately 170 Å in length containing C-terminal segments from the both α and β subunits. As seen in Figure 157-2, in the α subunits, there are 7 segments of about 60 amino acids each that have weak homology to each other, but which are predicted to fold into a seven-bladed β propeller domain with Ca^{2+} binding motifs in 4-7. As outlined earlier and demonstrated in Figure 157-1, nine of the integrin α subunits contain an I domain also called a von Willebrand factor (vWF) A domain (A), as it resembles this structure. The I domain is the exclusive ligand binding site in those integrins. Divalent cations are necessary for ligand binding, and the residues coordinating metal binding are referred to as the metal ion-dependant adhesion site (MIDAS). The remaining α subunits are non-αI, and ligand binding involves specific regions of the N-terminal portions of both the α and β subunit. The remainder of the extracellular α subunit is predicted to be three β sandwich domains designated the thigh, calf-1, and calf-2 domains (see Figure 157-2).

The N-terminal cysteine-region of the β subunit is termed the PSI domain—for plexins, semaphorins, and integrins—because it shares sequence homology with these proteins. The first cysteine of the PSI domain forms a long-range disulfide bond to the C-terminal cysteine-rich region further down the β-subunit (see Figure 157-2). Although the β subunit lacks a true I domain, it

does have a region of about 240 residues, which is highly conserved among species. It has been termed the *I-like* domain because it has a metal binding motif similar to that of MIDAS region in the I domain, a weak amino acid sequence homology with the I domain, and similar secondary structure. The I-like domain appears to directly bind ligands in integrins that lack I domains and to indirectly regulate ligand binding by integrins that contain I domains.[19] Mutations in this region result in lack of association—or loss of function—of the integrin β2 subunit with the α, resulting in leukocyte adhesion deficiency (LAD).[21] As seen in Figure 157-2, the hybrid domain is folded with the I-like domain in the middle, with two covalent connections between the I-like and hybrid domains. There is a cysteine rich region with four repeats with structural similarity to epidermal growth factor (integrin-EGF or I-EGF). The cysteine-rich repeats have unique structural properties that make this region rigid and suited for transmission of structural motion in signaling. Many antibodies, which "activate" the integrins or only bind when the integrin is in an activated state, bind to this region.[20]

The most widely accepted model of integrin activation is that of a global change in conformation. Integrins can exist in a number of activation states. The integrin in the "inactive" conformation is "bent over" (see Figure 157-2, *B*). The ligand-binding headpiece is folded back on the tailpiece and thus is unavailable for binding to ligand. This occurs in the presence of Ca^{2+}. With activation, and/or in the presence of Mn^{2+} the integrin straightens like a "switchknife," and the I domain orients away from the membrane for optimal ligand binding. This is an "intermediate" activation state and is described as the extended confirmation. With the straightening and separation of the "legs" of the integrin, there are epitopes in the I-EGF and the PSI regions of the β subunit that are then "unveiled" and are now available to bind to

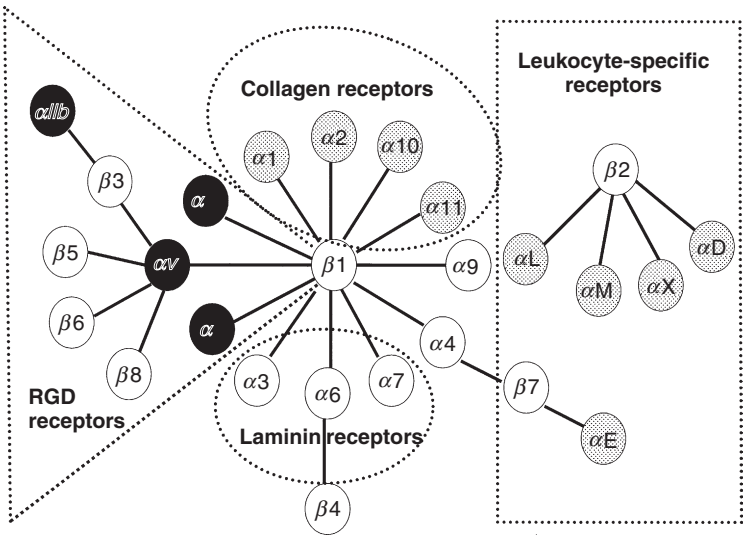

Figure 157-1 The integrin family. Integrins are αβ heterodimers. The figure depicts the mammalian subunits and their αβ associations; eight β subunits can associate with 18 α subunits to form 24 distinct integrins. α Subunits with *gray stippling* have inserted I domains (see text). α Subunits with I domains are found only in chordates, as are α4 and α9 and subunits β2-β8. In contrast, α subunits specific for laminin or RGD (*black spheres*) are found throughout the metazoa. Note that β2 and β7 integrins are restricted to leukocytes only. *(From Hynes RO: Integrins: bidirectional, allosteric signaling machines.* Cell *110:673-687, 2002.)*

antibodies, which bind only when the integrin is activated.[20] In the extended confirmation with high affinity, local conformational changes within the α and β I and I-like domains result in the hybrid domain swinging out and the subunit separating at the genu. This remodeling of the I-domain ligand-binding causes increased affinity for ligand (see Figure 157-2, *C*).

Much of our understanding of integrin physiology has been based on work examining the leukocyte integrins: lymphocyte function-associated antigen-1 (LFA-1 [CD11a/CD18, αLβ2]); Mac-1 (CD11b/CD18, αMβ2); α4β1 (very late antigen [VLA-4])]; and the platelet integrin (GPIIbIIIa [CD41/CD61, αIIbβ3]) individually.[19] Chemokine-receptor signaling leads to extension of the bent "low affinity" form of CD11a/CD18 (LFA-1), and this happens in less than 0.4 seconds. The extended form of LFA-1 is proposed to be in an intermediate state of affinity simply as a result of the greater accessibility of the ligand-binding I domain compared with the bent form. It has been proposed that the interaction of intermediate-affinity LFA-1 with its ligand intercellular adhesion molecule 1 (ICAM-1) leads to the high-affinity conformation that stabilizes adhesion.[20] However, there now is increasing evidence that mechanical forces can result in allosteric alterations of integrin conformation. For leukocytes, the interaction with the endothelial lining of the blood vessel under flowing conditions would be the major supplier of this force.[15]

Bidirectional Signaling and Integrins

Integrins are activated by inside-out signaling. The key target of this pathway is the GTPase Rap1. Agonist activation (such as chemokine stimulation) leads to relocalization of Rap1 to the membrane through several steps. The localization of Rap1 to the plasma membrane results in recruitment of the cytoskeletal protein talin to the β subunit of the integrin cytoplasmic domain. The recruitment is modulated by the cytoskeletal protein Kindeln3. It is the recruitment of talin to the cytoplasmic tail of β subunit which brings about the conversion of the integrin conformation to one of higher affinity.[20,22] Rap1 can be activated by the second messenger Ca^{2+} and diacylglycerol (DAG) and protein kinase C. At least in the case of lymphocytes it appears that there may be several mechanisms to activate Rap1. A fast route occurs with chemokine stimulation, in that Rap1 is activated within seconds and lasts a few minutes. A more sustained activation of Rap1 occurs through the T cell receptor.[20]

Ligand binding by the integrins then results in outside-in signaling (see Figure 157-2, *C*). It appears that high-affinity LFA-1-talin connection favors the formation of stable LFA-1 clusters. Macroclustering of LFA-1 strengthens adhesion to the LFA-1 ligand ICAM-1 (see Table 157-1).[19,20] It is accepted that the successful functioning of all leukocytes depends on cytoskeletal remodeling. Outside-in signaling of integrins causes cell spreading and migration. This implies that cytoskeletal reorganization occurs downstream of integrin-signaling. It is clear that β2 integrins mediate adhesion, spreading, chemotaxis, and production of reactive oxygen species and the release of cytokines from neutrophils and macrophages. At least part of this signaling is through Src kinase, which is constitutively associated with the β2 and β3 cytoplasmic tails.[20] Integrin activation results in Src kinase activation. It in turn phosphorylates adaptor molecules, which ultimately recruit Syk kinase to the integrin β tail.[23] Syk kinase activation results in downstream activation of several key proteins critical for spatio-temporal control of actin polymerization. These proteins include Vav—a guanine exchange factor for the Rho family GTPases—Rac, and Cdc42, all of which are major regulators of the organization of the actin cytoskeleton during leukocyte polarization and migration.[24]

INTEGRIN FUNCTION: ADDITIONAL LEVELS OF CONTROL

Integrin receptor expression can also be modulated at the transcriptional and translational level. During leukocyte differentiation, the levels of β2 integrins are differentially regulated. αLβ2 appears in early progenitor cells, the expression of αMβ2 (Mac-1), and αXβ2 (p150,95) occurs in later maturational stages. Numerous stimuli increase the expression level α4β1on lymphocytes and macrophages through transcriptional control. In contrast, rapid alterations in levels of integrins expressed on the surface of neutrophils and platelets can be achieved by mobilization of intracellular pools of integrins in response to extracellular stimuli and chemotactic factors (Table 157-2). Stimulation of neutrophils or monocytes can increase the αMβ2 and αXβ2surface expression tenfold, as these integrins are stored in secretory and tertiary

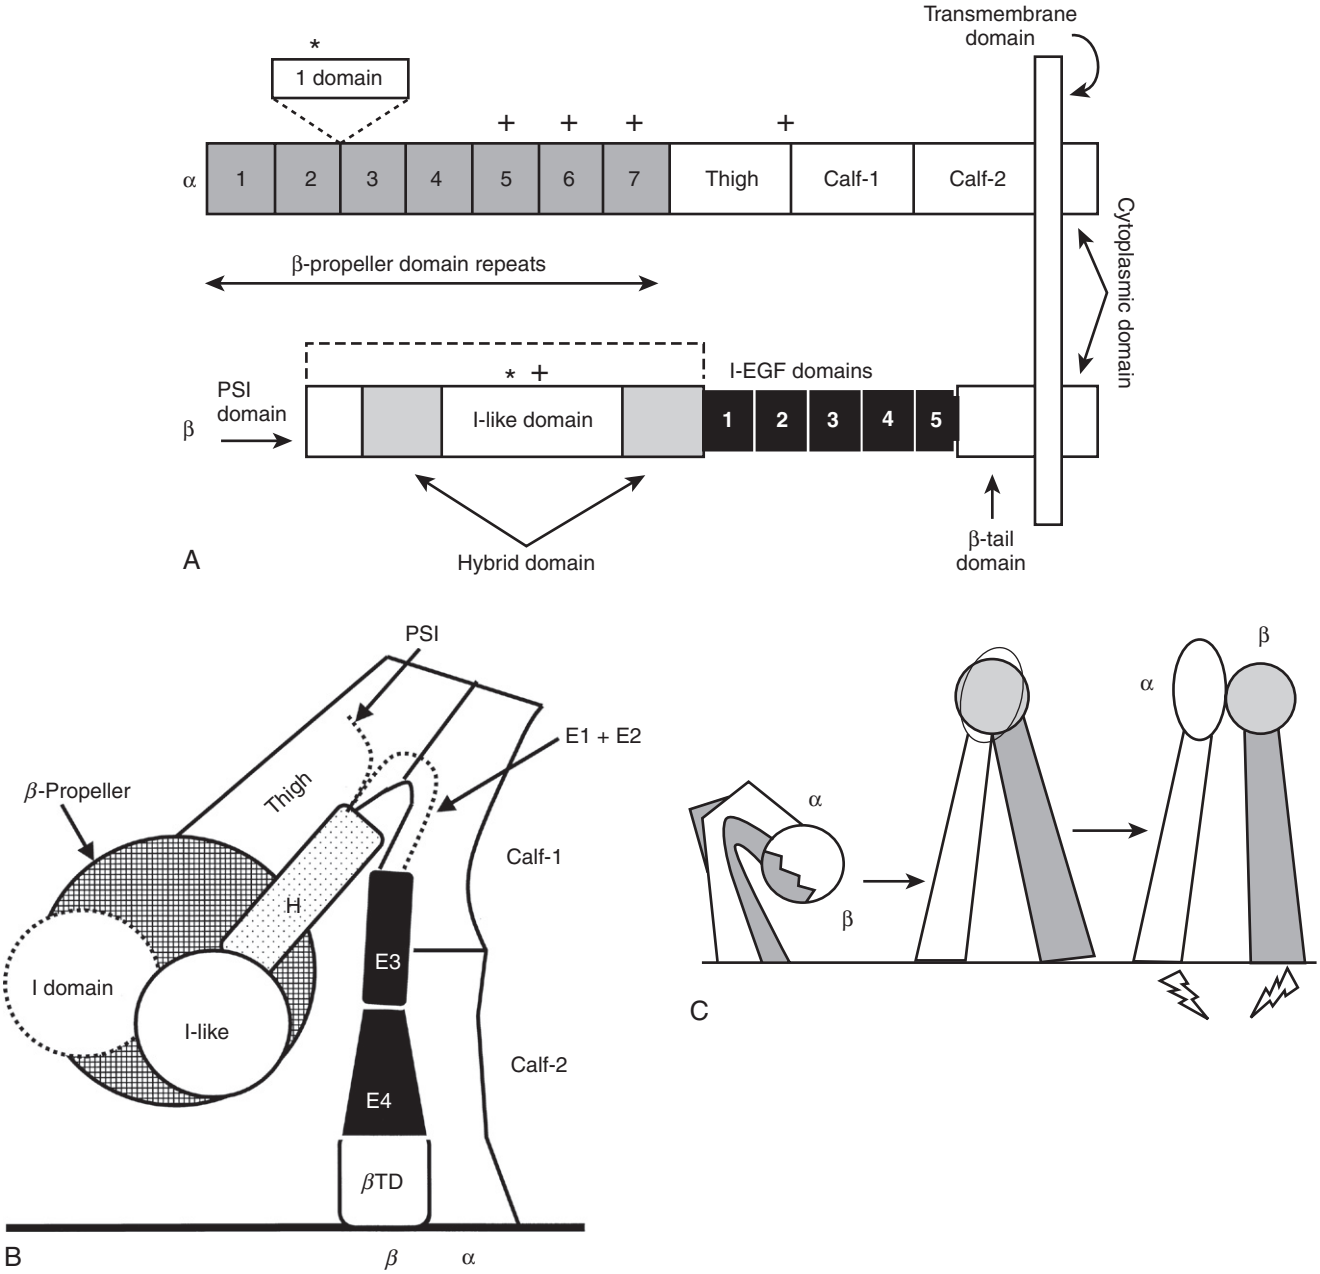

Figure 157-2 Integrin structure. A, General structure of the α and β subunits. Depending on the α subunit, there may also be an inserted I domain as outlined in the text. Mg^{2+} and Ca^{2+} binding sites are shown as asterisks *(*)* and plus signs *(+)* respectively. Only the disulfide bonds within the β chain between the PSI domain and the first I-EGF domain are shown (*dotted line*). Both chains have numerous disulfide bonds that are not included, but which account for the complex tertiary structure. **B,** Arrangement of the domains based upon the three-dimensional structure of αvβ3 with an added I domain. Domains refer to those listed in A. PSI and I-EGF domains 1 & 2 are referenced by a *dotted line* as they are "out of the plane" of the molecule. The transmembrane and cytoplasmic domains are not included. **C,** Hypothetical model for integrin activation. In the inactive state, the integrin is "bent over" with low affinity for ligand *(figure on left)*. In the *central figure*, there is an extended conformation with intermediate ligand affinity and closed headpiece. In the *figure on right*, there is a high ligand affinity conformation with an extended conformation that has open headpiece when bound to ligand, here RGD for αvβ3. The transient high affinity conformation results in "outside-in-signaling," demonstrated in this figure by the *lightning bolts*. *I-EGF,* Integrin-epidermal growth factor-like; *PSI,* plexin, semiphorins, integrins. *(From Shimaoka M, Springer TA: Therapeutic antagonists and the conformational regulation of the β2 integrins.* Curr Top Med Chem *4:1485, 2004.)*

granules.[25] Although not present or present at very low levels under resting conditions, neutrophils that have undergone migration can express large amounts of α2β1, α4β1, α5β1, α6β1, and α9β1, which assist the neutrophil in migrating through extracellular matrix.[26] It is unclear whether all these integrins are present in granules or are synthesized de novo. Platelets contain reserves of αIIbβ3 (GPIIb/IIIa, the receptor for fibrinogen, vWF, Table 157-1) in the α granules. With platelet activation, fusion of α granules with the plasma membrane occurs, effectively doubling the number of αIIbβ3 complexes.

Integrin Ligands

The integrin ligand binding characteristics have been extensively studied, and clusters of integrin-ligand combinations reflecting a structural basis for molecular interactions are being characterized. All five αV integrins, two β1 integrins (α5, α8) and αIIbβ3 share the ability to recognize ligands containing an Arg-Gly-Asp (RGD) tripeptide active site. The Leu-Asp-Val (LDV)-binding integrins bind ligands with an acidic motif similar to LDV. Although fibronectin contains the prototype LDV ligand, other ligands such as VCAM-1 and MAdCAM-1 use similar motifs for binding. LDV-binding integrins include α4β1, α4β7, α9β, the β2 integrins, and α4β7. As seen in Table 157-1, there are extracellular matrix proteins that are dominant ligands for the β1 integrins. These include fibronectin, fibrinogen, laminin, and thrombospondin. Cell surface ligands for integrins include members of the Ig gene superfamily, which are discussed in following sections (see Table 157-1).[2,27]

β2 Integrins

It is the β2 subgroup (CD18), found exclusively on leukocytes, that is the major contributor to leukocyte motility and function. All members share the common β2 (CD18) subunit (Figure 157-1 and Table 157-1), but have unique α (CD11) subunits that primarily confer ligand specificity. αLβ2 (LFA-1,CD11a/CD18) is located on all leukocytes. αMβ2 (Mac-1, CD11b/CD18), and αxβ2 (p150,95, CD11c/CD18) are located on neutrophils, monocytes, macrophages, natural killer (NK) cells, and some lymphocytes. LFA-1 and Mac-1 appear to interact equally with their endothelial ligand, ICAM-1. LFA-1 also binds to both ICAM-2, -3, and JAM-A. Lymphocyte adhesion to the vessel wall involves the interaction of LFA-1 with its endothelial ligands, ICAM-1 and -2. However lymphocyte LFA-1 participates in many other cell-cell interactions such as T cell activation by antigen-presenting cells or the killing of virus-infected cells by cytotoxic T lymphocytes.

Mac-1 and p150,95 are capable of binding to a wide range of ligands including fibrinogen, factor X, denatured albumin, and the complement fragment iC3b. This rather "promiscuous" attachment to a number of native and denatured proteins is of importance during leukocyte migration over a variety of substrata, as well as adhesion to and phagocytosis of foreign particles. Neutrophil and monocyte adhesion to endothelium relies mainly on LFA-1 and Mac-1 with only a minor role for p150,95.

β1 and β7 Integrins

Most integrins are members of the β1 (CD29) or VLA subfamily (see Figure 157-1 and Table 157-1). VLA derives from *very late antigen* because the first ones to be identified (VLA-1 and VLA-2) were expressed only at a late stage after T cell activation. They comprise a series of cellular receptors for extracellular matrix proteins including fibronectin, collagen, and laminin. α4β1 (VLA-4, CD49d/CD29) is expressed at substantial levels on most mononuclear leukocytes including lymphocytes, monocytes, eosinophils, basophils, and NK cells, whether the cells are in circulation, within lymphoid organs, or resident in other tissues. α4β1 is also expressed on transmigrated neutrophils.[28] α4β1 binds to vascular cell adhesion molecules-1 (VCAM-1), mucosal addressin cell adhesion molecule-1 (MAdCAM-1), and to the alternatively spliced connecting segment (CS-1) of fibronectin. The site of α4β1 binding to VCAM-1 is distinct from that involved in fibronectin binding. α4β1 is of critical importance for monocyte and eosinophil trafficking to inflamed tissues and to lymphocyte migration and differentiation. Unlike LFA-1 and Mac-1, α4β1 can function both as a selectin, that is, mediate the initial tether of the leukocyte from the free stream to VCAM-1 and MAdCAM-1, as well as transition to a more stable adhesion.[29]

α1ββ1, α2β1, α3β1, α5β1, α6β1 (see Table 157-1) are expressed on T cell subsets or resting T lymphocytes and generally are of importance to lymphocyte-extracellular matrix interactions. Their ligands include the extracellular matrix proteins collagen, laminin, and fibronectin. Neutrophils also express α2β1, α5αβ1, α6β1 as they infiltrate lungs, joints, peritoneum, and spleen, and adhere to and migrate through interstitial matrix via pathways that are β2 integrin independent.[26,28] α9β1 is abundantly expressed on neutrophils, but not on lymphocytes and modestly on monocytes. Its ligand is VCAM-1. As with α4β1, α9β1 mediates neutrophil transendothelial migration.[26,28]

The α4β7 (CD49d/β7) and αEβ7are expressed primarily on gut-associated T lymphocytes. α4β7 is required for lymphocyte recirculation to specific areas of the gut containing MAdCAM-1, which is expressed on Peyer's patch high endothelial venules and postcapillary venules in the lamina propria. αEβ7 is expressed on T lymphocytes in the intestinal mucosa, genitourinary tract, lymphocytes derived from the lung, and on intraepidermal T cells in some skin disorders. It is also present on 90% of $CD8^+$ T cells. Its primary ligand is epithelial (E) -cadherin.[30]

β3 Integrins

Like Mac-1, αvβ3 (CD51/CD61), also known as the vitronectin receptor, and αIIbβ3 (gpIIb/IIIa) are promiscuous receptors and have overlapping ligands including fibrinogen, vWF, fibronectin, collagen, and vitronectin, though each may bind to different regions of the same molecule. αvβ3 is present on a large number of cell types and has been shown to play a role in tumor invasion, proliferation and metastasis, bone resorption, angiogenesis, differentiation, development, and the immune response. It serves as an accessory molecule for T cell activation and is of importance for complement deposition on platelets and cells. Additionally αvβ3 is expressed on macrophages in a maturationally related process and mediates recognition of apoptotic cells (both neutrophils and lymphocytes). Thus αvβ3 represents a mechanism that limits tissue injury through macrophage clearance of leukocytes at an inflamed site.

Many integrins are found on platelets including α2β1, α5β1, α6β1, and αvβ3and are of importance to either stimulatory or adhesive-cohesive phases of platelet function. αIIbβ3 (gpIIb/IIIa) is found exclusively on platelets and it is largely responsible for the final cohesive phase of platelet activation in vivo, that is, platelet aggregation supported by the binding of adhesive proteins like fibrinogen or vWF.[31] Coincident with platelet activation, surface expression of αIIbβ3 increases through release from α granules. Additionally, αIIbβ3 undergoes profound conformational changes with resultant binding to fibrinogen; resting platelets do not bind fibrinogen. With binding of αIIbβ3 through outside-in signaling, the platelet is stimulated further and can potentiate clot retraction.[31]

Immunoglobulin Gene Superfamily

The Ig gene superfamily encompasses a large group of molecules with multiple Iglike domains in the extracellular portion of the molecule resembling the second domain of the constant region of Ig (Figure 157-3). At least seven members of this family are involved in leukocyte-leukocyte or leukocyte-endothelial interactions. ICAM-1, CD54; ICAM-2 CD102; VCAM-1, CD106; PECAM-1, CD31; MAdCAM-1; and JAM all serve as endothelial ligands for leukocytes. ICAM-3, CD50 is expressed on leukocytes and is of importance for leukocyte-leukocyte adherence and cell signaling.[2,16,32]

ICAM-1, ICAM-2, and ICAM-3 were all initially identified by their ability to interact with LFA-1, and each is the product of distinct though homologous genes (see Figure 157-3). ICAM-1 contains five Ig domains, but ICAM-2 contains two; both domains are highly homologous to the two NH_2-terminal domains of ICAM-1. ICAM-3 also contains five Ig domains that are highly homologous to ICAM-1 and -2. The binding site for LFA-1 has been mapped to the first Ig domain for each of the molecules. In contrast, ICAM-1 has been found to bind to Mac-1 through a distinct site in its third Ig domain. ICAM-1 is constitutively present on endothelial cells as well as on other cell types including lymphocytes, dendritic cells, fibroblasts, hepatocytes, and epithelial cells such as type I pneumocytes. ICAM-1 is expressed on resting endothelium, but its expression increases dramatically after stimulation with a number of cytokines including tumor necrosis-α (TNF-α), interleukin-1(IL-1), and interferon-γ (IFN-γ) (Figure 157-4).

VCAM-1 exists predominantly as a 7 domain transmembrane protein in humans, though an alternatively spliced minor form exists (see Figure 157-3). VCAM-1 binds to αβ41 at its first and fourth domains. It also binds to α4β7 and α9β1 (see Table 157-1). VCAM-1 is expressed constitutively on some nonvascular cells including dendritic cells in lymphoid tissues and skin, epithelial cells, some monocyte-derived cells, and bone marrow stromal cells. VCAM-1 is absent on resting endothelial cells, but is induced in response to IL-1 and TNF with maximal expression reached by 6 to 12 hours (see Figure 157-4). VCAM-1 is required for lymphocyte, eosinophil, and monocyte adherence and emigration and appears critical in the initiation of atherosclerosis. Unlike ICAM, it is able to participate in the tethering and rolling of leukocytes.[29]

PECAM-1, CD31 is a six Ig domain molecule which mediates both leukocyte- and platelet-endothelial adhesion and leukocyte transendothelial migration. PECAM-1 is present on platelets, bone marrow precursor cells, neutrophils, monocytes, and certain subsets of lymphocytes. It is highly expressed on endothelial cells, but much less so on neutrophils. With its Iglike extracellular domains, it was classified initially as a cell adhesion molecule. However recent work has demonstrated that its cytoplasmic domain may be the "work" end of the molecule. PECAM-1 is a member of the Ig immunoreceptor tryosine-based inhibitory motif (Ig-ITIM) family. When members of this family are engaged by their extracellular ligand, their cytoplasmic ITIM domain becomes phosphorylated, which serves as a docking site for intracellular lipid and protein phosphatases. Once these catalytic enzymes become localized to

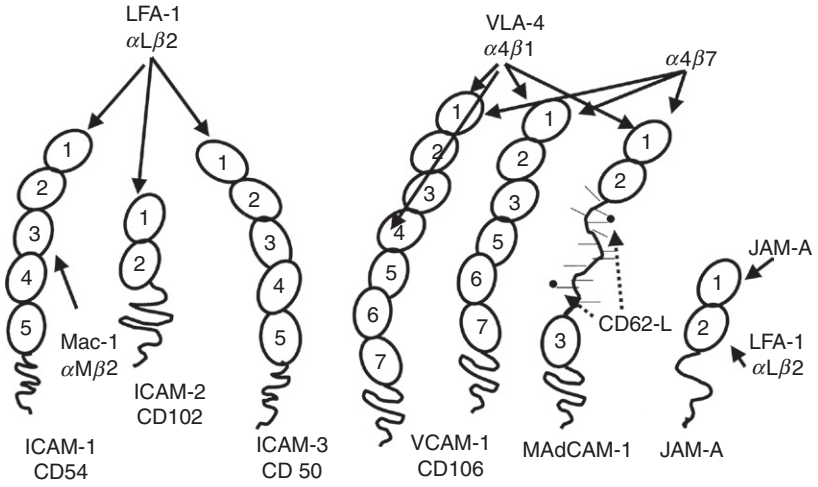

Figure 157-3 Immunoglobulin gene superfamily. The immunoglobulin gene superfamily (IGSF) comprises a large group of molecules, each of which contains multiple extracellular domains resembling the second domain of immunoglobulin *(oval)*, a transmembrane domain, and cytoplasmic tail. Note that there is an alternatively spliced form of VCAM-1 which does not contain domain 4. The *sticks* and *lollipops* on MAdCAM-1 refer to the N-linked and O-linked glycosylation sites, respectively. Included also on the structure diagrams are the domains to which specific adhesion molecules bind. *CD62L,* L-selectin; *ICAM,* intercellular adhesion molecule; *JAM,* junctional adhesion molecule; *MAdCAM,* mucosal addressin cell adhesion molecule; *VCAM,* vascular cell adhesion molecule.

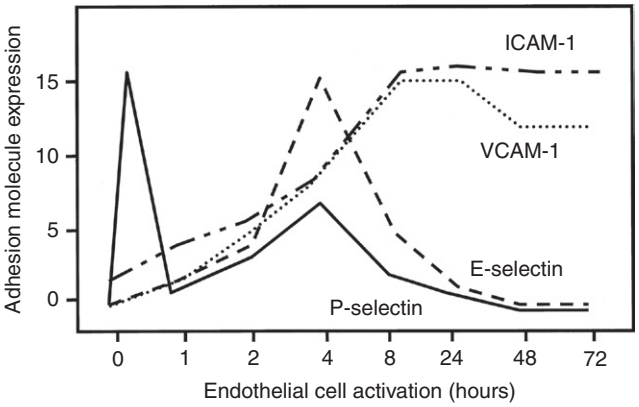

Figure 157-4 Temporal expression of adhesion molecules induced by cytokines. Note that P-selectin has two peaks at 0.5 hour and 4 to 8 hours. The first peak is caused by release of P-selectin from Weibel-Palade bodies; the second is caused by protein synthesis. There is constitutive expression of ICAM-1 (intercellular adhesion molecule). *VCAM,* Vascular cell adhesion molecule. *(From Imhof BA, Dunon D: Leukocyte migration and adhesion.* Adv Immunol *58:345-416, 1995.)*

their cytoplasmic anchors and activated, they affect a wide range of cellular functions including events which inhibit signaling, proliferation, and cellular activation. In particular, PECAM-1 appears to modulate activation of β1, β2, and β3 integrin function on platelets, lymphocytes, and neutrophils. PECAM-1 participates in homophilic (i.e., binds to another PECAM-1 molecule on adjacent cells) and heterophilic (binds to other ligands such as αvβ3) interactions. PECAM-1 is critical for leukocyte transendothelial migration.[16]

An adhesion molecule for lymphocyte recirculation to mucosa is expressed on Peyer's patch high endothelial venules, as well as other venules. Known as MAdCAM-1, this adhesion molecule contains three Iglike domains and a mucinlike region between domain 2 and 3 (see Figure 157-3). Mucins are serine- and threonine-rich proteins that are heavily glycosylated through an O linkage. They are rigid and have an extended structure (see following discussion on selectin-ligands.) MAdCAM-1 binds both α4β7 and α4β1. MAdCAM-1 is unique in that with the presence of a mucinlike domain it is also able to bind L-selectin and mediate lymphocyte rolling.[33]

JAM-A, -B, -C are some of the new members of the Ig family (see Table 157-1).[16] The JAMs have two extracellular Ig domains and are present on endothelial and epithelial cells at the tight junctions. Thus they are critical to maintaining barrier function. With stimulation by proinflammatory cytokines JAMs move away from the borders and appear to mediate permeability.[16] JAMs are also present on neutrophils, lymphocytes, and platelets. Recent studies demonstrate that these molecules may play unique roles in leukocyte transendothelial migration as they are ligands for LFA-1 and α4β1.[16]

CD99 does not belong to the Ig superfamily. It is a heavily glycosylated transmembrane protein present on many hematopoetic cells and has been shown to increase the presence and activity of LFA-1 and α4β1. It has also been found on endothelial cells and is concentrated at the borders between confluent cells. CD99 on monocytes and neutrophils appears to mediate homophilic binding to endothelial CD99 and mediate transendothelial migration.[34,35]

Selectins

There are three members of the selectin (CD62) family of adhesion molecules: E- (CD62-E), P- (CD62-P), and L-selectin (CD62-L). This family mediates the earliest events in leukocyte-endothelial adhesion in that they "capture" leukocytes from the free-flowing blood stream and allow rolling to occur along the blood vessel lining. The name incorporates the term *lectin*, which refers to a wide range of carbohydrate-binding proteins, reflecting the fact that this family of adhesion molecules recognizes carbohydrate ligands. Each is an integral membrane protein with an N-terminal, Ca^{2+}-type lectin domain followed by an EGF-like module, multiple copies of the consensus repeat units characteristic of complement-binding proteins, a transmembrane segment, and a short cytoplasmic domain. The amino acid sequences of the lectin and EGF domain of all three selectins are highly conserved, suggesting that both domains participate in ligand recognition. The lectin domain of P- and E-selectin has a single Ca^{2+}-binding site located on the face of the molecule opposite where the EGF domain is attached. Although there is strong homology between different selectins in the extracellular domains, there is none in

the cytoplasmic tails, suggesting selectin-specific functions for these domains (see Table 157-1).[18,36]

The characteristic feature of selectins is their ability to recognize and bind to specific carbohydrate determinants on selectin ligands in a calcium-dependent manner.[36] Binding takes place under dynamic conditions where continuous shear forces, exerted by the flowing blood, act on leukocytes rolling along the endothelium at rolling velocities ≈100- to 1000-fold slower than the mean blood flow velocity. To achieve controlled and stable leukocyte rolling under these conditions, selectin binding to selectin ligands needs to comply with the following three requirements: (1) rapid bond formation at the leading edge, (2) high tensile strength during binding, and (3) fast dissociation rates. Selectins can adjust to increasing flow rates by locking their bonds with their ligands more tightly. This enables leukocytes to roll even at high shear rates. However, there is a shear rate limitation, and once this is reached the bond properties change toward a slip bond behavior, which eventually leads to breakage of the bond. Thus these critical properties create a breaking system that recruits free flowing leukocytes to the endothelial wall and prepares them (during rolling) for subsequent adhesion and transmigration.

L-selectin functions as the peripheral lymph-node homing receptor on lymphocytes and binds through its lectin domain to carbohydrate-containing ligands on high endothelial venules in peripheral lymph nodes (see Table 157-1). It also serves as an important adhesion molecule for monocyte, neutrophil, and eosinophil trafficking. The cell surface expression of L-selectin is down-regulated after activation of both lymphocytes and myeloid cells. The process involves the shedding of L-selectin rather than the internalization or a conformational change and arises through proteolytic cleavage of the molecule at the extracellular part close to the transmembrane region. L-selectin has been demonstrated to be located at the tips of the surface folds of unstimulated neutrophils. In this position, L-selectin would be in a particularly advantageous position to contact the endothelium in the initial margination of neutrophils. Inhibition of L-selectin shedding in mice results in decreased leukocyte rolling velocity and increased number of arrested and transmigrated leukocytes.[37]

P-selectin is constititutively synthesized by megakaryocytes and endothelial cells, but is sorted into secretory granules (α granules in platelets and Weibel-Palade bodies in endothelial cells). Upon stimulation by thrombin, histamine, hydrogen peroxide, and other secretagogues, P-selectin is rapidly transported to the cell surface by fusion of granule membranes with the plasma membrane (see Table 157-2). Once mobilized, P-selectin usually remains on the cell surface for less than an hour. Lipopolysaccharide (LPS) and other inflammatory cytokines induce P-selectin expression in a manner similar to that of E-selectin. The kinetics for cytokine-induced P-selectin are similar to those occurring after cytokine induced E-selectin expression (see Figure 157-4). P-selectin mediates adhesion between leukocytes and platelets as well as leukocyte-endothelial adhesion (see Table 157-1).

The expression of E-selectin on endothelial cells requires the *de novo* synthesis of both mRNA and protein. Many stimuli—including the cytokines IL-1, TNF-α and lymphotoxin TNF-β, and LPS (see Table 157-2)—are capable of inducing the expression of E-selectin. It is also induced on dermal endothelial cells in delayed type hypersensitivity reactions and in chronically inflamed skin. Maximal expression of E-selectin peaks at 4 to 6 hours and then declines to near basal levels within 24 hours (see Figure 157-4).

Selectin Ligands

All three selectins bind sialylated and fucosylated oligosaccharides, of which sialyl Lewis^X (sLe^X) is the prototype (see Table 157-1).[2] Most but not all of the selectin ligand glycoproteins are mucinlike. Mucins are serine- and threonine-rich proteins, they are heavily O-glycosylated, extended, and rigid. The mucin P-selectin glycoprotein ligand-1 (PSGL-1) is expressed constitutively by most leukocytes (see Table 157-1). It is a disulfide-bonded homodimer with two 120-kd subunits containing functional sialylated O-glycans on its serine and threonine residues. It is modified with α2,3 linked sialic acid and α1,3-linked fucose. It is sulfated on 1 or more of 3 tyrosine residues on the N terminal region.[18,36] PSGL-1 recognizes P-selectin, E-selectin, and L-selectin.[18,36] L-selectin and P-selectin recognize the region containing sulfated tyrosines, and E-selectin recognizes the sialylated and fucosylated core-2 O-glycans. As is the case with L-selectin, PSGL-1 is localized to the tips of the surface folds of unstimulated neutrophils, providing a topographical advantage in the initial interaction of leukocytes with endothelial cells. As with integrin ligands, there are many different selectin ligands. CD44 is present on leukocytes and can function as an E-selectin ligand in vivo.

Lymphocyte L-selectin recognizes mucins synthesized by the high endothelial veins (HEV) of lymph nodes and Peyer's patches: glycosylation-dependent cell adhesion molecule-1 (GlyCAM-1), CD34, and MAdCAM-1 (see Table 157-1). GlyCAM-1 is expressed by the high endothelial venules of peripheral lymph nodes and mesenteric lymph nodes and is secreted. CD34 has a much broader tissue distribution with constitutive expression on endothelial cells in a diversity of blood vessels. GlyCAM-1 and CD34 along with podocalyxin and endomucin are known as peripheral node addressins (PNAds). No one molecule is absolutely required for L-selectin–dependent lymphocyte recruitment, thus there is probably overlapping L-selectin ligand function by all members of the PNAd group.[18,36]

LEUKOCYTE, PLATELET, AND ENDOTHELIAL ACTIVATION

Mobilization of leukocytes to sites of acute inflammation is a critical factor in successful host defense. Because activated leukocytes can damage host tissue, their localization and activation is tightly controlled. A number of factors have been identified that activate leukocytes or the cells to which they bind, resulting in increased cell adhesion molecule expression and/or chemotactic migratory response (see Table 157-2). Chemoattractants are important in integrin activation and in directing the migration of leukocytes. In chemotaxis, cells move in the direction of an increasing concentration gradient. For example, bacterial peptides N-formyl-methionyl-leucyl-phenylalanine (fMLP), anaphylatoxins produced by generation of complement (C5a), lipids such as LTB_4 and platelet activating factor (PAF) all elicit varying leukocyte populations. Leukocytes can sense a chemoattractant concentration difference of 1% across their diameter and therefore migrate in the direction of the attractant. However, the generation of these chemoattractants at sites of inflammation can be rapidly diluted and swept downstream by blood flow unless they are retained at the site of production. PAF is produced by activated endothelial cells when stimulated by histamine, thrombin, and leukotriene C_4. Although other cell types release PAF, endothelial cells express and retain PAF on their surface under the same conditions that P-selectin occurs.[38]

Chemokines are a group of small (8-14 kDa) molecules that regulate cell trafficking of all types of leukocytes. Chemokines interact with a subset of seven transmembrane spanning G-protein coupled receptors (GPCR) on the leukocyte surface. The first chemokines identified were those produced by many cell sources such as IL-8. The more recently identified are much more tissue and cell specific. Table 157-2 includes some of these chemokines. Chemokines are subdivided into two major subfamilies based upon the arrangement of the two N-terminal cysteine residues, CXC and CC, and depending on whether the first two cysteine residues have an amino acid between them (CXC) or are adjacent (CC). Two other groups—the CXC3 (fractalkine) and the XCL (lymphotactin)—exist. *L* in the name refers to the ligand

(i.e., chemokine), and the number is the gene that encodes it. IL-8, one of the first chemokines identified, is CXCL8, as it is in the CXC subfamily and is a ligand (L) encoded on gene 8. The receptors for chemokines are classified by *R*. There may be more than one receptor for a chemokine, for example for IL-8 (CXCL8) the receptors are CXCR1 and CXCR2. Chemokines can also share receptors, that is, CXCR1 also bind CXCL1 (Groα/MGSA-α), CXCL6 (GCP-2), and CXCL7 (NAP-2).[39,40]

Chemokines have a wide range of effects on cell types beyond the immune system, for example in the central nervous system and on the endothelial cells where they result in either angiogenic or angiostatic effects. Their function in the immune system is important in antigen presentation and development of the immune response. Chemokines are also critical for leukocyte activation and localization. They can induce changes in cell shape, release of intracellular enzymes, formation of bioactive lipids, the respiratory burst, and the activation of integrins and chemotactic migration.[14] Chemokines presented on the surface of endothelial cells can participate in the rapid activation of the leukocyte integrin assisting in the "breaking" mechanism of the rolling leukocyte.[15] Chemokines can be "presented" on the surface of endothelial cells by glycosaminoglycans and the Duffy antigen/receptor for chemokines (DARC).[41] In such a manner, chemokine-induced activation of leukocytes can occur.

As previously discussed, cell adhesion molecules may themselves generate biochemical signals within the cells in a process known as outside-in signaling. The cytoplasmic tails of most of the cell adhesion molecules are relatively short and do not appear to have any intrinsic enzymatic activity generally. Any signals that are generated therefore must occur through coupling of the cytoplasmic tail with cytoplasmic proteins that nucleate the formation of large protein complexes containing both cytoskeletal and catalytic signaling proteins (see Figure 157-2, *C*). For neutrophils, ligation of either Mac-1 or LFA-1 results in potentiation of the respiratory burst. TNF-induced degranulation and release of proteases is dependent on Mac-1. On lymphocytes, LFA-1 can cosignal along with antigen to yield an augmented T cell response in vitro, with increased calcium flux, increased cytokine production, and increased proliferation. One of the most exciting areas of integrin adhesion biology has been the observation that adhesion and transmigration of leukocytes in an integrin-dependent manner result in the expression of a large number of genes associated with the inflammatory response termed *immediate-early* (IE) response genes. Many of these genes code for cytokines such as IL-1, TNF, and IL-8.[42] Thus the integrins can not only modulate the response on the adherent cell, but also influence the inflammatory milieu by resulting in production of chemokines. Selectins can also activate leukocyte integrin function and production of oxidative radicals, as well as production of cytokines and chemokines.[18,36]

LEUKOCYTE-PLATELET-VESSEL WALL INTERACTIONS

Leukocyte Localization to Inflammatory Sites

Direct observations of microvascular beds have revealed a consistent pattern of leukocyte endothelial interactions. Leukocytes are seen rolling along the walls of small venules but not arteries.[43] Following introduction of inflammatory stimuli, the number of rolling leukocytes increases, and many leukocytes become firmly adherent to the endothelium and change shape from a spherical to a flattened configuration. Leukocyte-leukocyte and leukocyte-platelet aggregates are often seen. Adherent leukocytes then migrate through the endothelium and into the region between the endothelium and it basement membrane. After pausing briefly in this location, the leukocytes migrate into the surrounding tissue (Figure 157-5).[2,18]

Each member of the selectin family can support leukocyte rolling under conditions of flow. In inflammatory states, endothelial L-selectin ligands E- and P-selectin are up-regulated. Leukocyte L-selectin and PSGL-1 "tether" to their endothelial ligands, which helps capture the leukocyte from the free flowing stream and "slow it down," even under high shear. This occurs through the specific selectin ligand bond characteristics (described previously) (see Table 157-2).[36] Cells then "roll" at a constant shear rate. α4β1, constitutively present on all mononuclear leukocytes (also all mouse neutrophils and some human neutrophils under specific conditions) can also participate in "tethering" to VCAM, itself up-regulated on the inflamed endothelial cell surface.

Selectins are able to slow, but are insufficient to arrest rolling leukocytes. Leukocyte arrest requires the activation of the β2 integrins and α4β1, which then bind to their respective endothelial ligands (see Table 157-1). It requires several signals for the β2 integrins and α4β1 to transition from a low affinity to the transient high affinity state; at least one of these signals is that provided by selectin-selectin ligand interactions. It has been estimated that contact duration of more than 25 msec is needed for β2 integrin bonds to form, and this is provided by the selectin-selectin ligand interaction. Other activating signals, PAF and chemokines, derived in part from the endothelial surface itself, are required. Constitutive endothelial expression of ICAM-1 and ICAM-2 can function as ligands for LFA-1 and Mac-1. Even though high levels are found on resting endothelium, inducible expression of ICAM-1 remains crucial for leukocyte-endothelial interactions. VCAM-1 is present only on inflamed endothelia (see Figure 157-5).

After arrest, leukocytes have been observed in animal models to crawl along the luminal surface to arrive at a point of transendothelial migration. This crawling is dependent on both leukocyte LFA-1 and Mac-1 and the downstream signaling molecule Vav-1. In vivo, leukocytes using "mechanosensing" crawl perpendicular to the flow of blood to the point of transmigration.[44] Passage through the endothelium requires active participation of the leukocyte and the endothelium. The route of transendothelial migration can be between the endothelial cells by penetrating junctions that lie within the intercellular cleft (paracellular route) or across endothelial cell (transcellular route).[45] Although it is not clear what determines the route, it is clear that integrins, particularly β2 and α4 integrins depending on the leukocyte subset, are required. Adhesion molecules toward the apical surface, including E-selectin, VCAM-1, ICAM-1, and PECAM-1 (CD31) are required. CD99, JAM-A, and ICAM-2 located at the interendothelial junctions are also critical (see Figure 157-5).

Leukocytes must then migrate through the extracellular matrix for localization to inflammatory sites.[46] As outlined in Table 157-1, extracellular matrix ligands for integrins include fibrinonectin, laminin, collagen, entactin, tenascin, thrombospondin, and vitronectin. Although Mac-1 and αXβ2 are known to bind fibrinogen after activation, they are not critical for adhesion to and emigration through other extracellular matrix proteins. β2 Integrin-deficient– activated neutrophils adhere to fibronectin, vitronectin, and laminin through α5β1, αvβ3, and α6β1, respectively.[47] Migratory cells use adhesion receptors and proteolytic enzymes, such as the urokinase-urokinase receptor/plasmin system, to regulate the function of each for the other and migrate through the extracellular matrix.[46] Using peptides, which mimic extracellular proteins, Gonzalez and colleagues[48] demonstrated that "naive neutrophils" (i.e. those freshly isolated from whole blood) utilize Mac-1 and α4β1 for migration. In contrast, neutrophils that had migrated across IL-1β–stimulated endothelial cells utilized αvβ3, α5β1, α4β1, and α6β1, while Mac-1 contributed to the speed of migration. Thus transmigration results in a change in the neutrophil adhesion molecules which enhances migration on proteins found in the extracellular matrix.

Leukocyte Localization in Adaptive Immunity

With inflammation, lymphocytes, like neutrophils and monocytes, extravasate to the affected site. However, for the immune response the mechanism is different in lymphoid organs.

Lymphocytes exit the blood stream in the postcapillary venules at specialized postcapillary vascular sites called high endothelial venules (HEV). This is the major route for constitutive extravasation, and most recirculating lymphocytes selectively bind to the endothelial cells of the HEV and do not interact with quiescent vascular endothelium. HEV is found in all secondary lymphoid organs (except the spleen). In chronically inflamed nonlymphoid tissue, HEV-like vessels are observed and support lymphocyte recruitment. HEVs are found in peripheral lymph nodes (PLN), mesenteric lymph nodes (MLN), Peyer's patches, and tonsils.

It is the controlled expression of adhesion molecules on the lymphocyte and the counter ligands on the specialized endothelial

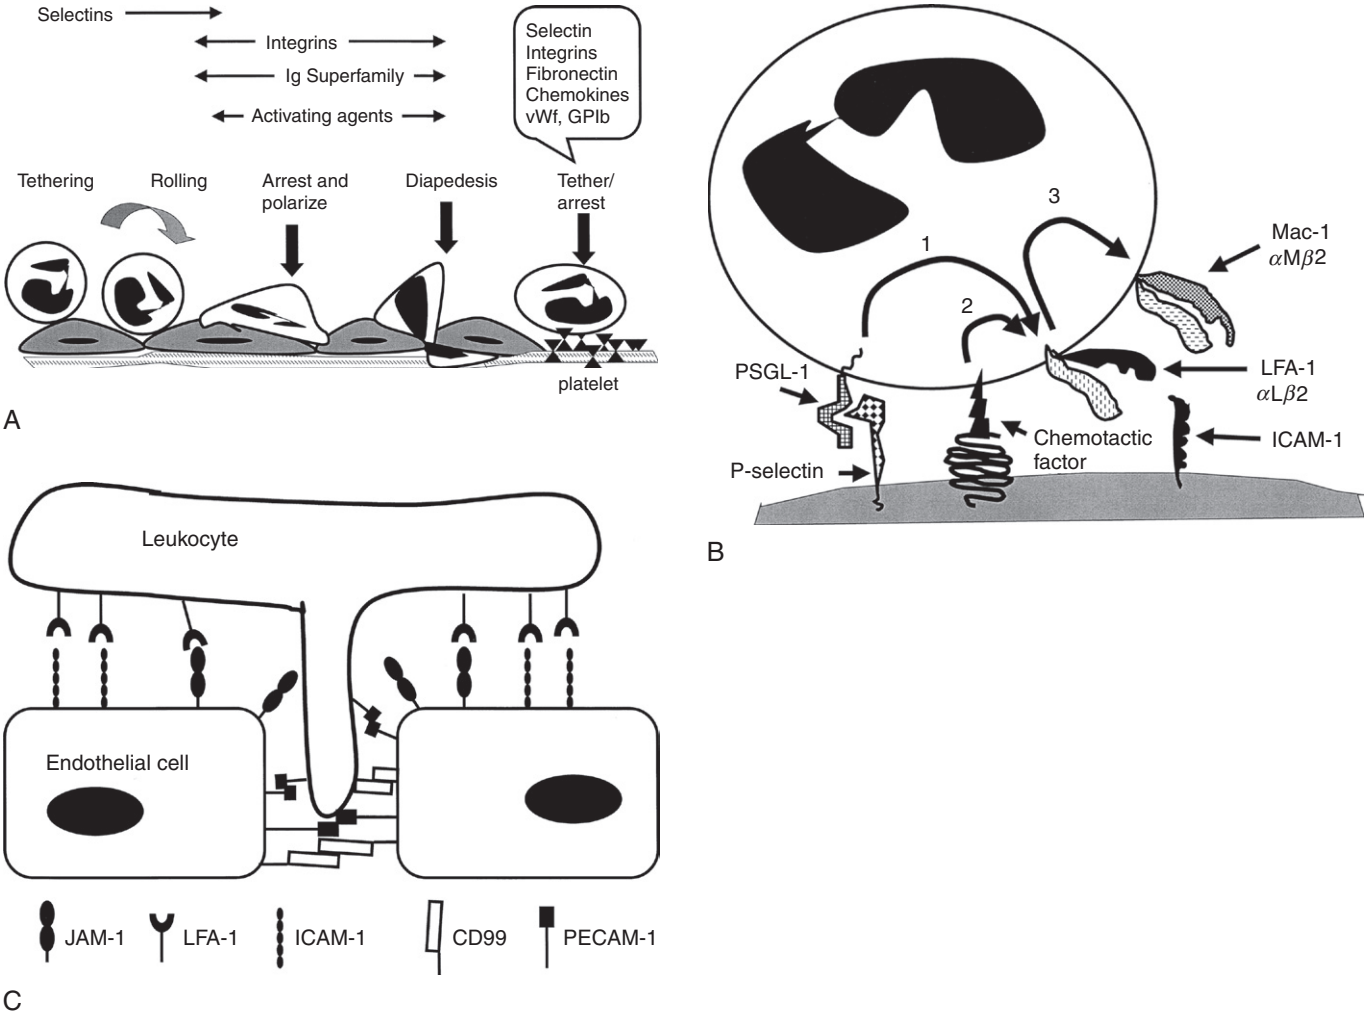

Figure 157-5 Leukocyte localization. A, Leukocytes are captured from the free-flowing stream (tether) and roll on the endothelial lining of the blood vessel. This interaction is mediated by all three members of the selectin family. The leukocyte slows, arrests, and changes shape (polarizes). Activating agents presented on the endothelial cells (or by activated platelets) are necessary for the transition from rolling to arrest. Integrins and their ligands, the Ig superfamily (IGSF), mediate these steps. The cells then "crawl" or diapedese over the surface of the endothelial surface until they migrate through the endothelium. The integrins, members of the IGSF, and CD99 have a role at this point. A leukocyte may also be tethered by adherent platelets *(as shown here)* or adherent leukocytes. Platelets through β3 integrins and GPIb- IX-V can bind directly to collagen or fibronectin on exposed basement membrane, or alternatively to von Willebrand factor bound to basement membrane. They can release chemokines, which can directly activate leukocytes once tethered. Leukocytes can bind to platelets directly through integrins or to fibrinogen which is bound to platelets. **B,** Model of leukocyte activation leading to arrest. Leukocytes tether to endothelial cells expressing P-selectin via P-selectin-glycoprotein ligand 1 (PSGL1). In the presence of shear, P-selectin–PSGL-1 interactions can result in leukocyte (and LFA-1) activation, *(arrow 1).* Chemotactic factors expressed at the endothelial surface can also result in activation of both Mac-1 and LFA-1. Finally LFA-1-ICAM-1 (intercellular adhesion molecule) interactions can augment the adhesivity of Mac-1. **C,** Proposed mechanisms for leukocyte transendothelial migration. With stimulation of the endothelial cell, ICAM-1 is up-regulated; JAM-1, which is localized at the interendothelial cleft, appears to be mobilized away from the cleft. With activation of the leukocytes (see Figure 157-5B) migration across the vascular endothelium can then occur via LFA-1, PECAM-1, JAM-1, and CD99. Leukocyte LFA-1 can bind to JAM-1 and ICAM-1 on the endothelial cell. Leukocytes may then traverse the interendothelial cleft through sequential transhomophilic interactions of PECAM-1 and CD99. Although CD99 is abundant on lymphocytes and monocytes, it does not appear to be so on neutrophils. *Ig,* Immunoglobulin; *JAM,* junctional adhesion molecule; *PECAM,* platelet endothelial adhesion molecule; *vWf,* von Willebrand factor. *(Part **B** from Smith CW: Possible steps involved in the transition to stationary adhesion of rolling neutrophils: a brief review.* Microcirculation *7:385-394, 2000. cells of the HEV of PLNs (draining the skin) and the lymphoid tissues of the mucosa (Peyer's patches, tonsil, and appendix) that ensures this selectivity of lymphocyte homing. Chemokines specific for lymphoid organs are required to activate the lymphocyte integrins for the transition from a rolling to adherent cell capable of transmigration. Although many chemokines specific for lymphocyte integrin activation are produced in inflammatory states, many serve a "housekeeping" function and are constitutively expressed at high levels in the thymus, lymph nodes, and certain lymphoid tissues.[30] L-selectin is present on virtually all lymphocytes and is required for homing to lymph nodes. Naive lymphocytes have abundant L-selectin, while specific activated or memory helper T cells lack L-selectin expression, but regain it when they transform into fully mature memory cells. L-selectin binds to ligands on PLN HEV via PNAd, as discussed above.

Cell-Blood Vessel Interactions in the Absence of the Cascade

There are many instances in which leukocyte and platelet recruitment to the vascular endothelium does not occur in the sequential manner described above. Neutrophils already localized to inflamed endothelium can recruit other neutrophils. In vascular beds where blood flow is diminished either by geometric constraints or by vascular occlusion/vasoconstriction, activation of the β2 integrins alone in the presence of a chemotactic gradient may be sufficient for neutrophil transmigration.[49] In the lung, leukocyte sequestration and transmigration appear to occur primarily in the capillaries. Leukocytes appear to "hop" through the capillaries rather than roll.[50] Neutrophils may spend considerable periods of time in stationary contact with capillary endothelium, and this predisposes to adhesive interactions between the neutrophil and the subjacent endothelium. In inflammatory states such as sepsis, the neutrophils become increasingly less deformable, resulting in increased retention. Though Mac-1 and LFA-1 are not required for the sequestration of neutrophils in the vascular bed of the lungs, they do mediate neutrophil migration. However nonβ2 integrin–dependent mechanisms are also present. The type of stimulus, the site of administration (lung versus peritoneum) or route (intravenous administration versus intratracheal) will affect the mechanisms required for lung recruitment. Leukocyte localization in the liver and kidney likewise is affected by geometric constraints and specialized endothelia.[51,52]

Activated platelets can adhere to endothelial cells, denuded vessel walls, and leukocytes. In response to vessel injury, vWF is exposed. Platelets, which are recruited from the free flowing blood, attach to vWF via the glycoprotein platelet receptor complex GPIbαβ-IX-V primarily through GPIbα. Platelets are recruited into the growing thrombi by release of activating substances from the platelets themselves. However release of P-selectin from the platelet α granules allows tethering under shear conditions to PSGL-1 on leukocytes. Leukocyte activation might then follow as a result of signaling through PSGL-1 or platelet-derived chemokines.[53] Firm adhesion of the leukocyte to the platelet involves leukocyte integrins, such as Mac-1, binding to platelet glycoprotein Ibα. Leukocyte-platelet aggregates are readily seen in human subjects in many inflammatory states. Selective platelet depletion in animal models affects leukocyte accumulation in various organs.[53] Leukocytes are critical to the development and maintenance of the hemostatic plug and thrombus as demonstrated by models in which inhibition of P-selectin function accelerates thrombolysis and prevents reocclusion.[54]

ADHESION MOLECULES AND THE DEVELOPING HOST

As outlined in the beginning of this chapter, several lines of investigation suggest that functional deficits in neonatal leukocyte adhesion increase the infectious susceptibility of the neonate. However, these functional deficits may play a physiologic role in limiting inflammatory responses that are possibly deleterious in immature hosts such as bronchopulmonary dysplasia (BPD). The remainder of this chapter will be devoted to the genetic defects of adhesion molecules, LAD I, LAD II, LAD III and Glanzmann's thrombasthenia (GT), which may present in the neonatal period, as well as our understanding to date of the neonatal developmental deficits of adhesion molecule expression and function.

Genetic Deficiencies of Adhesion Molecules

Leukocyte Adhesion Deficiency I

Leukocyte adhesion deficiency is an autosomal recessive trait of humans, dogs, and cows characterized by recurrent, necrotic bacterial infections, impaired pus formation and wound healing, and abnormalities of many adhesion-dependent functions of granulocytes, monocytes, and lymphoid cells (Table 157-3).[55,56] With the targeted mutation of each of the β2 integrins in mice, we have found both similarities to and disparities with the syndrome as occurs in humans and other animals.[17,57] The affected gene, ITGB2, is located on 21q22.3, which encodes the common β-chain of the β2 integrin family. LAD I results from a decrease or absence of the cell surface expression or function of the entire β2 integrin family, which is, in turn, a result of heterogeneous mutations of the CD18 gene.[58] The α and β subunits are initially assembled in the cytoplasm of the cell, and only then is the complete β2 integrin heterodimer expressed at the membrane. Both subunits are required for expression. Given the diverse functional characteristics of β2 integrins it is not unexpected that patients with LAD I have profound deficits of acute inflammatory function and specific immunologic defects. Clinical and histopathologic features of LAD I are remarkably similar among human, canine, and bovine subjects. Recurrent necrotic and indolent infections of soft tissues primarily involving the skin, mucous membranes, and intestinal tract are the clinical hallmarks of this disease.[59,60] Superficial infections on body surfaces may invade locally or systemically. Typical small, erythematous nonpustular skin lesions often progress to large, well-demarcated ulcerative craters that

heal slowly or with a dysplastic scar. Septicemia progressing from omphalitis associated with delayed umbilical cord severance has been observed in infants from several affected families.[56,61] Perirectal abscess or cellulitis leading to peritonitis and/or septicemia has been reported in multiple patients, and facial or deep neck cellulitis has been observed to progress from ulcerative mucous membrane lesions of the oral cavity. Recurrent invasive candidal esophagitis, erosive gastritis, acute appendicitis, and necrotizing enterocolitis have been reported. Common respiratory infections include severe bacterial laryngotracheitis, recurrent pneumonitis, and sinusitis. Severe gingivitis and/or periodontitis are major features among all patients who survive infancy.

The recurrent infections observed in affected patients reflect the profound impairment of leukocyte mobilization into extravascular inflammatory sites. Skin windows and biopsies of infected tissues demonstrate inflammatory infiltrates devoid of neutrophils. This histopathologic feature is particularly striking considering that marked peripheral granulocytosis (fivefold to twentyfold higher than normal) during episodes of infection is a common finding. Two LAD I phenotypes were originally described. Patients with severe deficiency had essentially undetectable expression of all three complexes on their neutrophils. These patients either died in infancy or demonstrated a susceptibility to severe, life-threatening systemic infections. In contrast, among the six patients with moderate deficiency, life-threatening infections have been infrequently observed. Patients with moderate deficiency expressed 2.5% to 6% of all three β2 complexes. Patients with moderate disease may die in their second to fourth decade of life. In some moderately affected patients skin lesions may disappear after the first few years of life, recurring only with occasional infections.[56,59] Severe gingivitis is always observed in these patients and may be the presenting symptom.[62]

Abnormalities of neutrophil or monocyte antibody-dependent cellular cytotoxicity have also been observed in individuals with LAD I.[63] Most patients have normal and self-limiting courses of varicella and other viral infections. The predominance of recurrent bacterial infections in patients with LAD I implies that the functions of neutrophils and monocytes are more profoundly affected than those of lymphocytes. However T lymphocyte–mediated killing, proliferative responses, natural killing, and antibody-dependent killing by patient's lymphocytes are deficient compared to adult controls. Nonetheless delayed cutaneous hypersensitivity reactions are normal in most patients tested, and most individuals demonstrate normal specific antibody synthesis.[56,59]

The diagnosis of severe LAD I is suspected in the newborn or within the first few months of life when the infant displays extreme prolonged neutrophilia associated with recurrent severe infections (Table 157-3). Delayed separation of the umbilical cord occurs more frequently in patients with the severe phenotype, but is not universally found.[61] Delay in cord separation alone does not indicate a child has LAD I. The mean age of umbilical cord separation in normal neonates is reported to be 15.0 ± 7.2 days, standard deviation, with the range of 3 to 67 days.[64] In patients with the severe form of LAD I, prolonged cord retention was associated with omphalitis and extreme neutrophilia. The diagnosis of LAD I is made by immunophenotyping leukocytes using flow cytometry techniques. With immunophenotyping in classic LAD I there will be a few or no β2 integrins on the neutrophil or lymphocyte surface. The patients who were described as having "moderate" LAD I by clinical course had 2.5% to 6% of Mac-1, LFA-1, and p150,95 compared to normal adults.[64] Infants with this immunophenotype can still have clinically severe disease and succumb to overwhelming infections within the first year of life.[60] Treatment at present for patients with LAD I is limited to surveillance for recurrent infections, prompt institution of antibiotic therapy, and, when indicated, granulocyte transfusions.[65] Bone marrow transplantation has been advocated for these patients. The experience of the European Group for Bone Marrow Transplantation is that LAD I patients have good outcomes after bone marrow transplantation though graft versus host disease is a frequent complication.[66] The introduction of a normal β2 subunit gene (ITGB2) into hematopoietic stem cells has the potential to cure children with LAD I. Successful gene therapy has been reported in canine model of LAD I, implying that this procedure may be beneficial also in humans in the future.[67]

Glanzmann's Thrombasthenia

Glanzmann's thrombasthenia is a relatively rare autosomal recessive disease that is characterized clinically by purpura, epistaxis, gingival hemorrhage, and bleeding resulting from qualitative or quantitative defects of platelet αIIbβ3.[68] The diagnosis is virtually assured when there is absence of platelet aggregation in response to all agonists. Platelet αIIbβ3 binds fibrinogen, and, under shear, vWF. In GT, platelets attach to exposed subendothelium but do not spread, a process dependent on αIIbβ3. Formation of platelet-fibrinogen and platelet-vWF bridges do not occur, and clot retraction is often defective. In addition, prothombin, which can bind directly to platelets, is unable to do so in patients with GT and significantly less thrombin is generated in response to tissue factor. As with LAD I, large series of mutations have been described. However, unlike LAD I in which mutations occur primarily in the β subunit, in GT, mutations have been described in genes encoding either the αIIb or β3 gene. Classic GT occurs when there is insufficient or absent expression of αIIbβ3 on the cell surface. Variant GT occurs when there is quantitatively normal expression of αIIbβ3, but there are functional defects present. As such, patient presentation is heterogeneous. Bleeding difficulties range from severe to mild. Patients with either type of GT may be relatively asymptomatic, though they may have profuse bleeding after minor operative or dental procedures. Alternatively they may present in the newborn period and require frequent blood transfusions.

As many of the integrins share common pathways for activation, it is not surprising that individuals are now being described that have defects in β1, β2, and β3. These individuals have normal or near normal expression of cell surface molecules, but have features of both GT and LAD I (see following discussion regarding LAD III).[69]

Leukocyte Adhesion Deficiency II

An immune deficiency resembling LAD I was first described in 1992. In this syndrome there is a defect in the gene Slc35c1, which leads to the congenital disorder of glycosylation IIc (CDG2c), or CDG IIc. It is characterized by recurrent infections, failure to form pus, gingivitis, and pronounced neutrophilia (see Table 157-3).[70,71] Although the severity of the infectious complications resembles that of the moderate type of LAD I, the patients express normal levels of the β2 integrins and L-selectin. Additionally, these patients exhibit mental and growth retardation and the rare Bombay blood phenotype. LAD II is caused by a congenital defect of endogenous fucose metabolism. These patients demonstrate markedly decreased levels of sLe^x on leukocytes and other fucose-containing structures. Neutrophils from these patients bind minimally or not at all to E-selectin and P-selectin though β2 integrin function is normal. In vivo they have a marked decrease in migration into skin chambers or skin windows.[72] Using fluorescein-labeled cells from LAD I and LAD II patients in intravital microscopy (mouse mesenteric preparation after stimulation with TNF) the following observations were made: (1) LAD I neutrophils demonstrated normal rolling, but were unable to stick and emigrate with chemotactic factor stimulation; and (2) neutrophils from LAD II patients rolled very poorly and failed to stick and emigrate under the shear forces provided by flow. However, once flow was reduced the cells adhered and emigrated in response to LTB_4.[72] Similar to the studies of mice that are deficient in P-selectin and E-selectin, these studies clearly demonstrate the significance in humans of selectin-carbohydrate

ligand interactions in initiating low affinity adhesion manifested by rolling under conditions of flow.[73] When these interactions are not possible, leukocyte emigration cannot occur. Initial studies in infants suggest that high doses of oral fucose supplementation may mitigate some of the clinical effects.[74]

Leukocyte Adhesion Deficiency III

There are an increasing number of patients with an immune deficiency resembling LAD I with abnormal clotting, that is, like GT. These individuals have "normal" expression of Mac-1, LFA-1, α4β1, and αIIbβ3 integrins on the cell surface, but these integrins do not function properly. Although leukocytes from patients with LAD III rolling on endothelial surfaces were normal, these cells failed to arrest on endothelial integrin ligands in response to endothelial displayed chemokines. Their platelets also failed to aggregate, thus these individuals have a defect in β1, β2, and β3 function.[75-78] Studies confirm that this defect arises from an inability of the cell to "signal" integrin activation by chemokine activation, though other functions of the chemokine G-coupled protein receptor (GCPR) appeared to be normal.[79] Although initial work suggested that downstream mediators of GCPR, such as RAP-1, may be affected, recent work supports that Kindlin-3 is defective in most if not all of the kindreds.[80] Kindlin-3 binds the cytoplasmic tails of β1, β2, and β3 integrins at the same protein motif (NPXY) in all three. The evidence suggests that the binding of Kindlin-3 enhances talin binding at the membrane-proximal NPXY site, which causes an increase in integrin affinity. It appears that Kindlin-3 is essential for the generation and/or maintenance of integrin activity on human leukocytes and platelets and that this crucial step is faulty in individuals with LAD III.

Neonatal Integrin Expression and Function

β2 Integrin Function

It has been known for several decades that neutrophils from cord blood do not adhere to matrix proteins and migrate to the same extent as adult neutrophils in response to a chemotactic stimulus.[6,81-83] With the identification of the function of the β2 integrins and description of LAD I, a molecular basis for diminished neonatal neutrophil adhesion and motility was first detailed.[56,59,84] As we have outlined in previous sections, low levels of Mac-1 are present on the adult neutrophil cell surface. During cell activation, outside-in signaling activates Mac-1. This activated Mac-1 engages its ligand(s) and then translocates to the tail (uropod) of the cell. New Mac-1 is released from secretory and secondary granules, which may then be activated, and locomotion continues.[85] Several investigators have demonstrated that neonatal neutrophils when stimulated in vitro do not upregulate Mac-1 to the same extent as adult cells.[7,8,25,84,86] This is likely caused by diminished total cell content of preformed Mac-1, which is approximately 60% of that found in adult cells.[12] In addition, it appears that translocation of receptors to the uropod is also diminished.[82] Delays in chemotaxis appear to reverse by 1 month of age.[87] Stimulated Mac-1 expression remains depressed until about 11 to 12 months of age.[88] That Mac-1 expression on stimulated neonatal neutrophils is diminished compared to adult cells is controversial as others have not found this to be so.[89,90] It is unclear as to why these discrepancies exist though possibilities include large variance in expression for the neonatal population, preparation methods, and potentially larger proportion of "immature cells." In premature infants, Mac-1 expression is also diminished compared to adults, which also appears to correlate with their ability to undergo adhesion and chemotaxis.[8] It appears that the more "premature" the infant, the lower the levels of Mac-1.[91,92] This may be the result of even more marked decreases in the premature total cell content of Mac-1 compared with that in term neonates (30% and 60% of adult values respectively).[93] Using assays of neutrophil adhesion and transmigration through endothelial monolayers, term neonatal cells display about 50% transmigration compared to adults, and this appears to be completely caused by LFA-1. The diminished transmigration can almost entirely be explained by reduced Mac-1 expression.[84] In the preterm neonate, LFA-1 expression (and total cell content) remains less than adult values before 35 weeks gestation.[93]

Complementing the in vitro studies using neonatal or infant leukocytes, delays in leukocyte localization have also been demonstrated consistently in neonatal animals.[94-98] Peritoneal leukocyte accumulation is delayed in neonatal animals in response to a variety of chemotactic agents and bacteria. Leukocyte extravasation into the lung is also delayed in young animals in response to various bacteria and their products and in response to mechanical injury or hyperoxia. Using a rabbit model, we demonstrated that many of the changes in leukocyte integrins observed in the developing rabbit appear to generally model what has been described in neonatal human studies.[99] One-day-old rabbit neutrophils have decreased surface expression of the β2 subunit compared to adult and juvenile rabbits (14 days old), and, with chemotactic factor stimulation, failed to up-regulate Mac-1 (CD11b subunit) to the same extent as adult neutrophils. In addition, neonatal rabbits have diminished neutrophil accumulation in the sterilely inflamed peritoneum compared to adult or juveniles, and their extravasated neutrophils have diminished Mac-1 expression. β2 Integrin–dependent neutrophil accumulation in this model was caused by LFA-1, as an antiMac-1 monoclonal antibody had no effect on blocking leukocyte emigration.[100]

At least in adult humans and in mice, there are distinct roles for Mac-1 and LFA-1 for leukocyte localization in the host response.[101,102] In humans neutrophils, under conditions in which neutrophils can aggregate with cells expressing ICAM-1 under shear conditions, LFA-1 but not Mac-1, mediated the initial interaction as a result of shear alone. Chemotactic factors boosted LFA-1–dependent aggregation fourfold. Under the same conditions, Mac-1–dependent aggregation was only one third as efficient. However, Mac-1 was necessary for aggregate stability particularly at increased shear rates.[102] In assays in which human neutrophils transition from rolling to arrested cells, Mac-1 and LFA each may support the transition independently.[101] Mice deficient in LFA-1 or Mac-1 can use the alternative mechanism to "slow down" the rolling leukocytes, although LFA-1 appears to have a greater role in the transition to firm arrest.[103] Using intravital microscopy, we directly examined leukocyte recruitment in rabbit pup mesenteric vessels 6 hours after intraperitoneal injection of IL-1β.[104] Neonatal animals (≤1 week old) have diminished leukocyte arrest and emigration compared to adult animals.[104] Four-week old pups demonstrated diminished arrest of leukocytes compared to adult animals, though leukocyte emigration was not different. Using antiLFA-1 and antiMac-1 antibodies we demonstrated that in rabbits: (1) LFA-1 in all age animals was primarily responsible for leukocyte arrest and subsequent emigration; (2) Mac-1 dependent arrest and emigration was not present in neonatal animals, and accounted for about 30% of leukocyte arrest and adhesion in adult animals; and (3) leukocyte arrest in 4-week-old animals was not dependent on Mac-1 though Mac-1 accounted for 30% of transmigration.[105] Thus mechanisms for "slowing," "arrest," and subsequent emigration may change with maturation of the host.

The adhesion molecules involved with leukocyte mobility are dependent upon the organ and inflammatory stimulus used in adult animals. β2 Integrins do not appear to be necessary for leukocyte accumulation in the lungs of mice and rabbits infected with streptococcal pneumoniae.[106] This appears to be true also for neonatal animals. Term and preterm neonatal rabbits had increased alveolar neutrophils after infection with group B *Streptococcus*.[107] Anti-β2 monoclonal antibodies (mAbs) failed to inhibit neutrophil influx, though they did inhibit killing of the *Streptococcus*.[107] The age-dependent differences in neutrophil migration appear to be species dependent; neonatal bovine

neutrophils had levels of Mac-1, LFA-1, and p150,95 equal to that of adult bovine neutrophils. There were no delays in adhesion to or migration through stimulated bovine endothelial monolayers.[108]

The β2 integrins modulate a number of other events including phagocytosis of iC3b-coated particles, neutrophil homotypic aggregation, and adhesion-dependent oxidative burst. Phagocytosis of iC3b-coated particles was not different between term or premature neutrophils compared to adults, and the degree of phagocytosis could not be correlated with Mac-1 levels.[109] Neonatal monocyte phagocytosis of iC3b-opsonized *Candida* or unopsonized *Candida* (in which ingestion occurs via Mac-1) was equal to that of adult monocytes.[110] Thus it appears that the neonatal neutrophils utilize LFA-1 for adhesion and emigration. Decreased Mac-1 function and/or amount appears to contribute to the deficits in neonatal neutrophil motility. However, other Mac-1 functions may be intact.

β1 Integrin Function

As described above, neutrophil β1 and β3 integrin expression and function are affected by transendothelial migration. Neutrophil migration in the extracellular matrix is dependent on both β1 and β3 integrin function. Neonatal neutrophils at baseline and after transendothelial migration have equivalent amounts of α4β1, α5β1, α6β1, and β3 compared to their adult counterparts.[111] Using peptide mimetics, in which we could dissect the contribution of each integrin to neutrophil motility, we demonstrated that neonatal neutrophil β1 and β3 was equivalent to that of adult neutrophils, though β2 function remained diminished.[48,111] Thus it is possible that once neonatal neutrophils traverse the endothelial barrier, their motile function is equal to that of adults.

Using flow cytometry, it has been shown that in healthy 1- to 3-day-old infants there are elevated proportions of total T cells (CD3+), helper T cells (CD3/CD4+) with decreased proportions of CD3/CD8+, and NK cells in the blood compared to adults.[112] The newborns have a higher proportion of immature B cells and CD8+ T cells that express the costimulatory molecules CD28 or CD38. Compared to adult blood cells, the neonatal blood contained a lower proportion of activated T cells.[112] Such studies and others support that neonatal lymphocytes are "naive" and prepared to "home" to secondary lymph organs for priming for an immune response, but do not respond to sites of infection. Those CD4+ cells that are CD45RO+ (memory) have concomitantly increased expression of β1, α5, LFA-1, and CD2, but not necessarily α2, α4, and CD44 (another adhesion molecule).[113] Locomotion of T lymphocytes in extracellular matrices are caused both by the expression and function of cell adhesion markers, such as α4β1 and α2β1, and loss of L-selectin.[114] Although T cells from children have decreased β1 and α5 compared to adults, they have comparable levels of α4, (probably as α4β7).[115] In addition, child CD45RA+ lymphocytes are β1 integrin "high," while in adults β1high T cells are CD45R0+.[115] In contrast, lymphocytes from cord blood are uniform for β1 expression; the single peak is between the two peaks usually seen in adult cells.[115] Thus, for cord blood lymphocytes and those from very young infants, α4β1 integrin expression is present at moderate levels and can function as a ligand for VCAM-1.

As with neutrophils, lymphocyte chemotactic responses depend upon chemokine receptor expression. Cord blood lymphocytes in general have diminished chemotactic responses to CCL2 (MCP-1), CCL3 (MIP-1α), CCL5 (RANTES), CXCL9 (MIG), and CXCL10 (IP-10) compared to adult peripheral blood lymphocytes because they lack the respective chemokine receptor.[116] However, cord blood lymphocytes express both CCR7 and CXCR4, and as such they respond robustly to CCL19 (MIP-3β) and CXCL12 (SDF), respectively, in assays of directed migration. We have shown that cord blood lymphocytes can interact (tether and roll) on cytokine-stimulated endothelial cells to the same extent as adult peripheral blood cells, and this is dependent on α4β1.[117] In the presence of shear stress, cord blood and adult lymphocytes roll, arrest, and migrate across stimulated endothelial cells when the vascular endothelium bears apical CXCL12 stromal-derived factor (SDF).[118,119] Thus neonatal cord blood lymphocytes, though naive, maintain the capability to localize to an inflammatory response if the "signals" for localization are present in the microenvironment (i.e. VCAM-1 and chemotactic chemokines for which neonatal cells have receptors).

Neonatal Selectin Function

In assays where L-selectin is known to be operative for the initial tether of flowing neutrophils, neonatal cells are less able to interact with stimulated endothelial cells compared to adult cells.[120] Neonatal cells have diminished surface expression of L-selectin, and antiL-selectin monoclonal antibodies have minimal effect on neonatal cell rolling.[120] In contrast, in the presence of antiL-selectin antibodies, adult cell rolling is decreased to levels comparable to neonatal cells.[120] Thus neonatal cells have a relative L-selectin deficiency. Diminished neutrophil L-selectin has been confirmed in other studies of neutrophils and eosinophils from term and preterm infants.[86,121] In contrast, neonatal monocytes and fetal neutrophils and eosinophils demonstrate "adult" levels of L-selectin.[86,122] As L-selectin can be shed from the cell surface, it remains unclear whether the decrease in neutrophil surface L-selectin in the term and preterm neonate is the result of activation in utero or whether this was caused by maturational changes in neutrophil content of L-selectin. Though diminished total cellular L-selectin is found in cord neutrophils, soluble L-selectin (that which is cleaved from the cell surface) is also decreased in the serum compared to adult.[123] Additionally cord neutrophils demonstrated diminished down-regulation of L-selectin compared to adult neutrophils with chemotactic peptides and granulocyte-macrophage colony stimulating factor (GM-CSF), though the response to IL-8 was equal to that of adult neutrophils.[124]

Neutrophils from 1-day-old rabbit pups have approximately 60% of adult rabbit levels of L-selectin, and, similar to human neonatal neutrophils, failed to show a significant decrease after chemotactic factor stimulation.[99] Neutrophil L-selectin expression remained depressed until about 14 days of age when it was equal to that of adult rabbits. Systemic administration of an antiL-selectin mAb to rabbits with sterile peritonitis resulted in a significant decrease in peritoneal neutrophil accumulation both in adult and 14-day-old animals. In contrast there was no effect in the 1-day-old animals.[99] We examined L-selectin–dependent leukocyte localization in the mesenteric vessels of rabbits in response to IL-1β using intravital microscopy.[104] Inhibition of L-selectin had greater effects on arrest and emigration of leukocytes in adult animals than neonatal animals especially at those stages in which L-selectin serves as a signaling molecule for integrin activation. Inhibition of L-selectin also had less of an effect on leukocyte rolling in neonatal than in adult rabbits.

Human neonatal neutrophils appear to have diminished amounts and function of PSGL-1. Neonatal neutrophils demonstrate decreased rolling and arrest compared to adult neutrophils on either endothelial cells or transfected cell lines expressing E&P selection.[125-128] Neonatal neutrophils also have decreased interaction with platelet monolayers, and this appears to be caused by diminished tether duration of neonatal cell PSGL-1 to platelet P-selectin. As discussed, selectin-ligand interactions have a rapid "on" rate and much longer "off" rate, allowing cells to attach quickly and then remain attached for longer periods thus facilitating the transition to β2 integrin mediated arrest. At least for P-selectin, the "off" rate is much shorter for neonatal cells, thereby requiring these cells to arrest in a shorter period of time than that required by adult cells. As β2 integrin function is depressed in neonatal cells, this puts the neonatal cells at an even greater disadvantage to transition to arrest.

At present there is little understanding of the developmental differences in adhesion molecule expression at the level of the endothelium and other nonleukocytic cells. Human neonatal platelets have decreased up-regulation of P-selectin.[129] However, neonates have increased amounts of larger multimerized vWF, and as such cord blood platelet deposition on subendothelium may be equal to or exceed that of adult blood.[130] In the context of the developmental biology of endothelial cell adhesion molecules it is critical to highlight that much of the in vitro work has been performed on human umbilical vein endothelial cells (HUVEC). However, endothelial cells from umbilical veins in culture may not reflect what occurs in vivo in either the neonate or mature host.The use of cultured human foreskin provides some insight as to the relevance of these molecules in the human neonate, but there is no comparative data with adult tissue samples. Cultured foreskin postcapillary venular endothelium up-regulated ICAM-1 and E-selectin in response to cytokines and growth factors, and the effect was greater than predicted with isolated HUVEC assays.[131] Animal models have also been useful, but again there is uncertainty in extrapolating animal (particularly rodent) findings to humans. In neonatal rats subjected to sterile peritonitis, leukocyte accumulation is diminished compared to adult animals.[13] However this did not appear to be caused by decreased leukocyte responsiveness, as adult cells injected into neonatal animals also demonstrated decreased localization. Furthermore there was diminished P-selectin expression on neonatal mesenteric vessels compared to adult animals.[13] Inflamed endothelial cells cultured from midgestation fetal pigs had diminished P-selectin expression and decreased leukocyte localization compared to cells obtained from adult pigs.[132] Fetal mice that were deficient in P-selectin had diminished leukocyte influx in excisional wounds compared to their wild type controls.[133] That such differences in P-selectin expression in human neonates may also be operative are based upon the following observations: (1) P-selectin expression is diminished on the surface of endothelial cells from human newborn mesentery and expression increases with age. PECAM-1 and ICAM-1 staining was not affected by age; (2) endothelial cell stores of P-selectin and vWF increase with gestational age in humans; and (3) there is diminished mRNA in endothelial cells from premature neonates, and decreased P-selectin in endothelial cells from premature neonates is associated with fewer Weibel-Palade bodies.[13] An examination of healthy term and preterm infants demonstrated no polymorphisms in E- or P-selectin that had an effect on sepsis, development of BPD, or early birth.[134] Carriers of the 213Ser L-selectin allele were found to be more prevalent in low-birth-weight infants, particularly in those with BPD.There was no association between the L-selectin polymorphism and early postnatal sepsis.

Adhesion Molecules in Diagnosis and Therapy

Adhesion Molecules as Markers of Inflammation

In 1985 Arnaout[135] described eight patients who developed neutropenia while undergoing dialysis. The neutropenia was associated with increased surface expression of Mac-1 on circulating neutrophils. Because this first description there has been an explosion of studies quantifying the expression of adhesion molecules either on leukocytes or circulating in the sera as indication of leukocyte activation. An increase in neutrophil Mac-1 has been documented in patients undergoing cardiopulmonary bypass, with sepsis, and at early time points in the adult respiratory distress syndrome (ARDS).

Term infants with early-onset sepsis or suspected sepsis have increased Mac-1 expression on circulating neutrophils compared to those who do not.[92,136] One study did not demonstrate an increased surface expression of Mac-1 in septic premature neonates though other markers of leukocyte activation (CD33 and CD66b) were present.[137] However when premature infants were followed serially, and Mac-1 was determined daily for 3 to 4 weeks, those infants who subsequently developed sepsis had an increase in leukocyte Mac-1 compared with those who did not.[137] It also appears that for preterm infants with respiratory distress syndrome, neutrophil Mac-1 was elevated compared to cord blood from term infants and from preterm infants not requiring mechanical ventilation.[92,138] As has occurred in adult patients, the onset of ventilation in premature infants induced Mac-1 expression on circulating leukocytes.[139] Thus it appears that leukocytes from term and preterm infants with sepsis and those with respiratory distress syndrome have evidence of neutrophil activation, at least as demonstrated by Mac-1 expression. Furthermore the "act" of mechanical ventilation appears to activate neutrophils in premature infants, as demonstrated by increased Mac-1.

L-selectin is shed from the leukocyte cell surface with cell activation and is thought to occur as the leukocyte transitions from rolling to arrest. Neutrophils deficient in L-selectin can not localize to an inflammatory site.[140] L-selectin shedding may be a mechanism to release a slowly rolling, activated cell and inhibit it from interacting at a site distant from the original focus. L-selectin expression has been shown to be decreased in neutrophils and monocytes from the cord blood of infants with acute bacterial infection and in adult patients with surgical sepsis.[141,142] However L-selectin expression decreases in the neutrophils as they are released from the bone marrow and as they age.[143] In addition, inflammatory mediators such as glucocorticoids, IL-6, and granulocyte colony-stimulating factor (G-CSF) all result in decreased L-selectin on circulating cells, likely as a result of shedding of L-selectin during marrow release.[144] As outlined earlier, L-selectin is depressed on circulating newborn neutrophils and does not demonstrate further decrement with cell activation. Although soluble L-selectin is found in the plasma, its significance is unclear though it is present at levels in humans and rodents that can potentially inhibit L-selectin-dependent leukocyte function.[145]

With the observation that there are soluble forms of ICAM-1, VCAM-1, L-, E-, and P-selectin in normal human sera and/or in sera from patients with inflammation, much investigation has explored whether soluble adhesion molecules could be useful monitors of disease activity.What is unclear is whether determining the absolute level of soluble circulating adhesion molecules will have the necessary specificity and sensitivity required to predict disease severity or outcome. In term, infection-free newborns, plasma sL-selectin levels are diminished while sE-selectin levels are increased on the second and fifth day of life compared to adult values.[146] From day 2 to day 5, there is a decrease in plasma sE-selectin.The baseline level of sL-selectin, which is low compared to normal adults, remains unchanged. In a separate large cohort of infants, those neonates with definitive infection and those with possible infection had increased plasma levels of C-reactive protein (CRP), IL-6, sICAM-1, and sE-selectin compared to those neonates without infection.[147] However, using multiple logistic regression modeling, IL-6 in addition to CRP predicted sepsis, and sICAM-1 and sE-selectin did not contribute significantly to the prediction model. In a group of 25 neonates with clinical sepsis followed prospectively, only s-ICAM-1 appeared to correlate with severity of infection.[148] Neither sE-selectin, s-VCAM-1, nor sL-selectin changed during the infection, nor were they significantly different than that found at baseline in healthy newborns.[148]

In premature infants, plasma sL-selectin was not different between those with respiratory distress and those without respiratory distress.[138] However, bronchoalveolar fluid sL-selectin is increased in premature infants at risk for chronic lung disease compared to more mature infants, and those infants who developed chronic lung disease had persistently elevated bronchoalveolar lavage (BAL) sL-selectin.[149] Premature infants had increased plasma sP-selectin in cord blood on the first day of life, regardless of whether they developed chronic lung disease (CLD).[150] In contrast, plasma sE-selectin was increased in cord blood and in serum

samples on day of life 1 and 3 in those infants that developed CLD compared to those who did not.[150,151] Plasma sICAM-1 levels were also increased later in the first week and during the second week of life in those who developed CLD compared to those who do not.[150] Dexamethasone treatment increases the concentration of plasma sL-selectin and decreases sE-selectin.[144,152] Thus it appears that premature infants who develop CLD have evidence of increased inflammation in their early perinatal and neonatal course, as measured by sE-selectin, sL-selectin, and sICAM-1. It also appears that dexamethasone modulates the inflammatory response as measured by circulating adhesion molecules and those present on circulating cells. Platelet P-selectin and activated αIIbβ3, at least early in life, are elevated, most likely secondary to platelet activation at the time of birth.[153,154]

Modulation of Adhesion Molecules as Adjunctive Therapy

A new and exciting era began with the application of antiadhesive strategies to ameliorate tissue injury. Perhaps the most far-reaching has been the use of antiαIIbα3 (platelet glycoprotein IIb/IIIa) "chimeric" antibody in patients who have undergone coronary angioplasty for acute ischemic heart disease. Platelets play a large role in ischemic complications of coronary angioplasty, such as abrupt closure of the coronary vessel during or soon after the procedure. At 30 days and 6 months after coronary angioplasty, patients who received the antibody had markedly reduced rates of reinfarction or repeat urgent interventions compared to patients who did not receive the antibody.[155] The blockade of cell adhesion molecule function with specific murine antibodies is limited in the treatment of human disease because of generation of antimurine antibodies in the recipient. However the development of small molecular peptides that inhibit adhesion molecule function has revolutionized their use.[156] Antiadhesive therapy is used for Crohn's disease, psoriasis, multiple sclerosis, and other chronic inflammatory disorders. A large number of preclinical studies supported the concept that blocking endothelial-leukocyte interactions would be beneficial in models of ischemia/reperfusion injury such as stroke or myocardial infarction, traumatic shock, cardiopulmonary bypass, sepsis, and acute lung injury. However, longer clinical studies did not support these immunologic approaches.[157] Occasionally drugs are developed that appear to have an unexpected antiadhesive effect. Such has occurred with HMG-CoA reductase inhibitors like lovastatin. Some of these drugs "lock" LFA-1 into an inactive conformation close to the I domain, thereby inhibiting its ability to adhere to ICAM-1.[158] Thus, for these patients, inhibition of the inflammatory response in atherosclerosis may have beneficial effects in addition to the treatment of hypercholesterolemia.

The experiments in nature, the genetic deficiencies resulting in LAD I, LAD II, LAD III, and GT, should be a warning to the clinician scientist attempting to manipulate adhesion molecule function without discrimination. For those caring for the premature and term newborn, understanding adhesion molecule biology will be crucial in supporting immune function as well as attempting to modulate the effects of inflammatory-mediated injury such as BPD.

Immunology of Human Milk and Host Immunity

In 1891, it was discovered that immunity could be transmitted through breast-feeding in experimental animals.[1] In the 1920s,[2-4] the incidence and severity of diarrheal diseases were found to be much lower in breast-fed than cow's milk–fed infants. Those clinical observations were confirmed repeatedly,[5-8] and it was ascertained that breast-feeding protected against many bacterial and viral enteric pathogens.[7-13] Three explanations for the protection were advanced. The first explanation: Because human milk is less contaminated with enteropathogens than formula feedings, breast-fed infants are exposed to fewer infectious agents. The second: Increased birth-spacing as a result of the contraceptive effects of lactation decreases the number of children who transmit common contagious agents to susceptible siblings.[14] The third: Breast-fed infants are rarely in group-care facilities and are thus less exposed to communicable infections.

These propositions did not, however, entirely explain the protection provided by breast-feeding, for breast-fed infants are asymptomatic even when they are exposed to bacterial enteropathogens such as *Shigella* that contaminate the mother's nipples, colostrum, and milk.[5] Further, breast-fed infants are more resistant to common respiratory infections.[15-18] Much of the protection is provided by a complex immunologic system in human milk. Furthermore, antimicrobial agents, which were the first parts of the immunological system to be recognized,[19-21] have certain shared features (Box 158-1). The inverse relationship between the quantities of many agents in human milk and the production of these agents by the infant suggested a relationship between the development of the infant's immune system and the ability of the lactating mammary gland to produce the immune factors.[22-24]

After the concept of an immune system in human milk was formed,[19] antiinflammatory[21,25,26] and immunomodulating agents[21,26] were discovered to be part of that system. Thereafter the evolutionary relationships between the immune system in human milk and the development of the immune system in the infant were appreciated.[22-24]

1. Certain postnatal developmental delays in the infant's immune system are compensated by the transmission of the same agents in human milk.
2. Other postnatal delays in components of the immune system in the infant are compensated by dissimilar agents in human milk.
3. Some agents in human milk initiate or augment functions poorly expressed in the infant.
4. Many antimicrobial agents in human milk act synergistically.
5. Some agents in human milk alter the physiological state of the alimentary tract from one suited for fetal life to one that is appropriate for extrauterine life.
6. Antibodies in human milk are produced by plasma cells that transformed from B cells that originate in the maternal intestines and bronchi.
7. Specialized living leukocytes are found in human milk.
8. Defense agents in human milk protect against microbial pathogens without provoking inflammation in the infant.
9. Some agents in human milk inhibit inflammation.
10. Some agents in human milk are immunoregulators.
11. Some agents in human milk are antineoplastic.
12. Defense agents in human milk resist enzymatic digestion and thus function in the recipient's GI tract.
13. Certain defense agents are created in the infant's GI tract by partial digestion of substrates in milk.
14. When defense agents in human milk interact with some pathogens, the infant develops specific adaptive immune responses but no symptomatic infections. Such a sheltered immunization is similar to immunizing with an attenuated microbial pathogen.
15. Agents in human milk augment the growth of commensal enteric bacteria adapted to infants that produce compounds that protect against bacterial pathogens and convey other immunologic benefits.[27,28]
16. There is often a reciprocal relationship between the defense agents that are transmitted in milk and those transmitted during fetal life via the placenta.

BOX 158-1

Features of Antimicrobial Agents in Human Milk

- Heterogeneous array of biochemical agents and live leukocytes
- Agents not well represented in other mammalian milks used to feed human infants
- Common to mucosal sites
- Adapted to persist in the gastrointestinal tract
- Often inhibit or kill microbial pathogens synergistically
- Often multifunctional
- Do not trigger inflammation
- Production often inversely related to the production in the infant

ANTIMICROBIAL FACTORS

The physical features, functions, and quantities of antimicrobial agents in human milk are summarized in Table 158-1. The proteins will first be considered.

Antibodies

IgM, IgG, IgD, and IgA are in human milk. IgM concentrations are much lower in human milk than in serum.[29] IgM molecules in blood and milk are pentamers. However, unlike serum IgM, human milk IgM is bound to secretory component.

The concentrations of IgG in human milk are lower than IgM in human milk and are much less than IgG in human serum.[29] All IgG subclasses are in human milk,[30] but the relative proportion of IgG4 is higher in human milk than serum.[30] Very little IgD is present in human milk.[31] IgE, the immunoglobulin responsible for immediate hypersensitivity, is essentially absent.[32] In contrast, IgA in the form of secretory IgA comprises more than 95% of human milk immunoglobulins.[29] Although some trimers and tetramers of IgA are in human milk, most secretory IgA consists of two identical IgA monomers united by a 15-kD polypeptide called the joining chain and complexed to a 75-kD glycoprotein, the secretory component.[33-35] Secretory IgA is assembled when dimeric IgA produced by plasma cells in the stroma of the mammary gland binds to the first domain of polymeric immunoglobulin

TABLE 158-1

Principal Antimicrobial Agents in Human Milk

Agents	Main Functions
Proteins and peptides	Microbiostatic and microbiocidal
Lactoferrin	Lyses siderophilic pathogens by chelating Fe^{+++}
Lysozyme	Lyses certain bacteria by degrading exposed cell wall peptidoglycans
SIgA	Binds adherence sites, toxins, virulence factors on intestinal and respiratory pathogens
α-Lactalbumin	Kills *Streptococcus pneumoniae*
CCL28	Kills *Candida albicans* and many gram-positive and gram-negative bacteria
MUC1	Blocks binding of S-fimbriated *Escherichia coli* to epithelium
Lactadherin	Blocks attachment of rotavirus to mucosa
C3 and fibronectin	Augment phagocytosis of pathogens
β-Defensin-1 and α-Defensin-1,2, and 3	Lyses bacteria and inhibits HIV-1, respectively
Oligosaccharides	Receptor analogues inhibit binding to epithelium
Glycoconjugates	
GM_1 gangliosides	*Vibrio cholerae* and *E. coli*
Globotriaosylceramide Gb3	Shigatoxin β subunits
Fucosyl oligosaccharides	*E. coli* stable toxin, *Campylobacter jejuni*
G1cNAc(β1-3) Gal-disaccharide	*Streptococcus pneumoniae*
Sulfated glycolipids	HIV-1
Glycoaminoglycans	HIV-1
Lewis X component	HIV-1
Monoglycerides and fatty acids from digested milk lipids	Inactivate enveloped viruses, certain bacteria, *Giardia lamblia* and *Entameoba histolytica*

TABLE 158-2

Antigen-binding Repertoire of SIgA Antibodies in Human Milk

Bacteria and Their Products	Viruses	Fungi	Parasites	Autoantigens
Escherichia coli	Adenoviruses	*Candida* sp	*Giardia lamblia*	DNA
Helicobacter pylori	Cytomegalovirus			RNA
Clostridium botulinum	Polioviruses and other enteroviruses			CCR5
Klebsiella pneumoniae	Rotaviruses			
Campylobacter sp	RSV			
Shigella sp				
Salmonella sp				
Vibrio cholerae				
Streptococcus pneumoniae				
Group B *Streptococcus*				
Haemophilus influenzae				

receptors on the basolateral surface of epithelial cells.[35] The complex is internalized, the original cytoplasmic part of the receptor is cleaved off, and the remaining assembled protein is transported across the cell into milk.

Secretory IgA antibodies in human milk are directed principally against enteric and respiratory pathogens (Table 158-2). The precursors of the cells that generate those antibodies originated at those mucosal sites. In fact, those precursors are released from the maternal mucosal sites because of immunogen-triggered events.[36] Hormonal stimulation during lactation causes antigen-stimulated B cells from Peyer's patches of the lower small intestinal tract to switch from the IgM to the IgA isotype and migrate to the mammary gland.[37,38] A similar B-cell pathway links bronchial lymphoid tissues to the mammary gland.[39] The details are as follows.

After antigenic stimulation, cytokines from mononuclear leukocytes in Peyer's patches induce local B cells to switch from IgM to IgA.[40,41] The IgA^+ B cells then migrate sequentially into local intestinal lymphatic channels and lymph nodes, the cisterna chyli, the thoracic duct, and the vascular circulation. During lactation, they home to the stroma of the mammary gland. Experimental evidence suggests that the chemokine CCL28 and its receptor CCR10 are crucial to this process: (1) CCL28 is up-regulated in the murine mammary gland epithelium during lactation;[42] (2) most IgA^+ B cells in the enteromammary gland pathway display CCR10;[43] and (3) IgA^+ B cells that are $CCR10^+$ move toward CCL28, which is expressed by mammary gland epithelium during lactation.[43]

IgA^+ B cells in the mammary gland differentiate into IgA-producing plasma cells that remain in the lamina propria of the organ. IgA dimers produced by mammary gland plasma cells principally contain λ-light chains, whereas κ-light chains predominate in serum immunoglobulins.[44] IgA dimers released from those plasma cells bind to polymeric immunoglobulin receptors on the basolateral external membranes of mammary gland epithelial cells.[33,34,45,46] The resultant receptor-dimeric IgA complex is transported to the apical side of the cell where the intracytoplasmic portion of the receptor is removed. The remaining molecule, secretory IgA, is secreted into milk. Thus enteromammary and bronchomammary pathways protect the immunologically immature infant against pathogens that the mother encounters (see Table 158-2). This is important since secretory IgA antibodies and the antigen-binding repertoire of immunoglobulins are developmentally delayed during early infancy.[47] Also, some secretory IgA molecules in human milk are antiidiotypic antibodies that function as immunogens.[48]

Certain secretory IgA antibodies in human milk are directed against the autoantigen CCR5, which is not only a chemokine receptor but is also the co-receptor for R5-tropic strains of HIV-1 that permits macrophages and immature dendritic cells to become infected with HIV-1.[49] The antibodies from uninfected as well as HIV-1 infected women bind to the second extracellular loop of CCR5 and thus block infection of macrophages and dendritic cells by HIV-1. In addition, secretory IgA antibodies to DNA enzymatically cleave DNA.[50,51] Therefore the DNA is recognized as an autoantigen and a substrate by the antibody enzyme and may hydrolyze free nucleic acids in the recipient's intestinal and respiratory tracts.

Secretory IgA in human milk also facilitates mucosal immunization against enteric microorganisms.[52] Secretory IgA adheres selectively to cells in Peyer's patches. Subsequently, the antibodies are transported to the underlying lymphoid tissue. There they bind to and are internalized by dendritic cells in the subepithelial dome region of Peyer's patches. If foreign enteric protein antigens are coupled to these antibodies, they will be processed by dendritic cells and then presented to T cells. Once the processed antigens are presented to TcRs on helper T cells, the T cells are activated. The activated T cells secrete cytokines that activate local cytotoxic T cells or stimulate local IgM^+ B cells to proliferate and switch their isotype to IgA. That eventually leads to the production of secretory IgA at mucosal sites.

The quantity of secretory IgA in human milk declines as lactation proceeds, but considerable secretory IgA is transmitted to the infant throughout breast-feeding.[54-57] Concentrations of secretory IgA in human milk are highest in colostrum[50] and gradually plateau later in lactation to about 1 mg/mL.[56] The approximate mean daily intake of secretory IgA in healthy full-term

breast-fed infants is 125 mg/kg/day at 1 month and 75 mg/kg/day by 4 months.[57]

The pattern of immunoglobulins in human milk differs from the pattern in other mammals except closely related primates.[25] For example, the dominant immunoglobulin in bovine colostrum, IgG, is absorbed into the calf's blood. IgG production is developmentally delayed in those newborns. Without colostrum, they remain IgG-deficient and very susceptible to intestinal infections.

Secretory IgA resists intestinal proteases such as pancreatic trypsin.[58] Bacterial proteases attack the hinge region of IgA1,[59] but the second subclass, IgA2, is resistant to those proteases and is disproportionally increased in human milk.[30] Furthermore, secretory IgA antibodies against bacterial IgA proteases are present in human milk.[59] In that respect, the amount of secretory IgA excreted in stools of low birth weight infants fed human milk is about 30 times that in infants fed a cow's milk formula.[60] In addition, urinary excretion of secretory IgA rises in infants fed human milk.[61,62] It is unlikely that the antibodies are from human milk because there is no mechanism for the their transport from the gastrointestinal tract to the blood. Thus human milk may stimulate the infant to produce the antibodies and transport them into the urinary tract.

Free Secretory Component

Free secretory component is also secreted into human milk, and this peptide inhibits the adherence of certain enterobacteria to epithelial cells.[63,64]

Lactoferrin

Lactoferrin is a single-chain glycoprotein with two globular lobes, each of which displays a binding site for ferric iron.[65] In 90% of lactoferrin in human milk,[66] iron-binding sites are available to compete with siderophilic bacteria and fungal enterochelin for ferric iron.[67-69] The iron chelation disrupts the proliferation of those pathogens. Lactoferrin also kills by damaging outer membranes of many gram-positive and gram-negative bacteria.[70-72] This process is conducted by a peptide, lactoferricin, which is usually comprises 18 amino acid residues from the N-terminal region of lactoferrin that are formed by gastric pepsin digestion.[71,72] Furthermore, lactoferrin inhibits certain viruses by a chelation-independent mechanism[73-76] and interferes with the adhesion of *Escherichia coli* to epithelial cells.[68]

The mean concentration of lactoferrin in human colostrum is between 5 and 6 mg/mL.[54] As the volume of milk production increases, the concentration falls to about 1 mg/mL at 2 to 3 months of lactation.[55] The mean intake of milk lactoferrin in healthy breast-fed full-term infants is about 260 mg/kg/day at 1 month and 125 mg/kg/day by 4 months.[57] Because human lactoferrin resists proteolysis[77] and the concentration of lactoferrin is much greater in human than bovine milk,[25] the excretion of lactoferrin in the stools is higher in infants fed human milk than in those fed a cow's milk formula.[60,78] The quantity of lactoferrin excreted in stools of low-birth-weight infants fed human milk is approximately 185 times that excreted by infants fed a cow's milk formula.[60] That estimate, however, may be too high because of immunoreactive fragments of lactoferrin in the stools of human milk-fed infants.[79] There is also a significant increment in urinary excretion of intact and fragmented lactoferrin as a result of human milk feedings.[62,79] Although the transport mechanism is unknown, the increase is a result of absorbed human milk lactoferrin and it fragments.[80]

Lysozyme

Lysozyme, a 15-kD single chain protein, lyses susceptible bacteria by hydrolyzing β-1,4 linkages between N-acetylmuramic acid and 2-acetylamino-2-deoxy-D-glucose residues in cell walls.[81] High concentrations of lysozyme are in human milk throughout lactation.[54-56] Longitudinal changes in lysozyme during lactation are unlike most other immune factors in human milk. The mean concentration of lysozyme is about 70 μg/mL in colostrum,[54] 20 μg/mL at 1 month and 250 μg/mL by 6 months of lactation.[55] The high content of lysozyme in human milk and its resistance to proteolysis lead to an eightfold increase in lysozyme in the stools of low-birth-weight infants fed human milk.[60] The urinary excretion of this protein is not increased in infants fed human milk.[62]

α-Lactalbumin

α-Lactalbumin is expressed only in the lactating mammary gland. A folding variant of the protein kills *Streptococcus pneumoniae* in vitro.[82] Furthermore, a molecular complex consisting of partially unfolded α-lactalbumin and oleic acid kills many types of tumor cells in vitro by several mechanisms including apoptosis and macroautophagy.[83,84] The protein invades tumor cells, depolarizes mitochondrial membranes, releases cytochrome c, exposes phosphatidyl serine, reduces caspase responses, and activates 20S proteasomes. α-Lactalbumin also translocates to tumor cell nuclei to cause chromatin disruption, loss of transcription, and nuclear condensation. The protein also kills certain skin papillomas and bladder cancers in situ. However, the in vivo antineoplastic action of the protein in human milk upon the recipient infant is undetermined.

CCL28

CCL28 is not only a chemokine; it also kills *Candida albicans* and many gram-positive and gram-negative bacteria. The killing is mediated by the 28 amino acid C-terminus of the molecule.[85]

MACROPHAGE MIGRATION INHIBITORY FACTOR

Macrophage inhibitory factor (MIF), a constituent of human milk,[86] is a proinflammatory cytokine that also up-regulates TLR-4[87] and aids in killing *Mycobacterium tuberculosis* in human macrophages.[88]

Fibronectin

Fibronectin facilitates the uptake of many particulates by mononuclear phagocytes. The in vivo effects of this opsonin in human milk[89] are unknown.

Complement

All components of the classical and alternative pathways of complement are in human milk, but their concentrations are much lower than those in serum.[90-92] Based upon in vitro experiments,[93] degradation products of C3 (C3b or C3bi) in human milk may augment phagocytosis of microbial pathogens in the infant's gastrointestinal or respiratory tracts.

Human Milk Mucin

Milk mucins are high-molecular-weight, highly glycosylated proteins.[94] Two thirds of mucin in human milk is bound to milk fat globule membranes. The concentration of mucin in human milk ranges between 50 and 90 mg/mL. Human milk fat globules and mucin from their membranes inhibit the binding of S-fimbriated *E. coli* to human epithelial cells.[94]

The most prominent mucin, MUC1, resists intragastric digestion in preterm infants.[95] Major fragments of MUC1 are in feces of breast-fed infants,[96] and mucins from such feces inhibit the adhesion of S-fimbriated *E. coli* to epithelial cells.[97]

Lactadherin

Human milk mucin was thought to defend against rotavirus in experimental mice,[98] but the protection turned out to be lactadherin,[99] a 49-kDa glycoprotein on milk fat globules that resists intragastric digestion.[95]

A protein analogous to human lactadherin, MFG-E8, is found on murine milk fat globules.[100] MFG-E8 on murine macrophages binds to phosphatidyl serine exposed on the outer membranes of apoptotic cells.[101,102] It also binds to α1β3 and α1β5 integrins on macrophages in the spleen and lymph nodes and elicited peritoneal macrophages via a tripeptide (RDG) motif within the second of its two EGF repeats. Because of the double linkage, apoptotic cells are phagocytized without inducing inflammation. Human lactadherin may have similar effects.

Low-Molecular-Weight Antimicrobial Peptides

In addition to antimicrobial peptides generated by partial digestion of lactoferrin, cysteine-rich, cationic low–molecular-weight peptides are in human milk including β-defensin-1,[103] which disrupts *E. coli,* and the α-defensins -1,-2, and -3 (HNP -1, -2, and -3)[104] and α-defensins, which inhibit HIV-1 replication and may interfere with postpartum transmission of HIV-1.[104]

Oligosaccharides and Glycoconjugates

Oligosaccharides in human milk are produced by mammary gland glycosyltransferases. Their concentrations in colostrum and mature milk are about 20 mg/dL and 12 mg/dL, respectively.[105] Many oligosaccharides are in human milk,[106] and they differ from those found in cow's milk. Although the quantities of total gangliosides in human and bovine milk are similar, the frequencies of each type of ganglioside in the milk of the two species are different. For example, greater amounts of monosialoganglioside 3 and GM_1 are found in human than in bovine milk.[106,107]

Because these agents resist enzymatic digestion, it was predicted that they would have nonnutritional functions. Indeed, some are receptor analogues that inhibit the in vitro binding of certain enteric or respiratory bacterial pathogens and their toxins to epithelial cells.[106,108,109] The chemistry of these compounds dictates the specificity of their binding. For example, GM_1 gangliosides are receptor analogues for *Vibrio cholerae* and *E. coli* toxins,[109] whereas the globotriaosylceramide Gb3 binds to b subunits of shigatoxin.[110] A fucosyloligosaccharide inhibits the stable toxin of *E. coli*,[111] whereas a different one inhibits *Campylobacter jejuni*.[112] Human milk oligosaccharides interfere with the attachment of *Haemophilus influenzae* and *S. pneumoniae* to respiratory epithelium,[113] and G1cNAc(β1-3) Gal-disaccharide subunits block attachment of *S. pneumoniae* to respiratory epithelium.[113]

The severity of *Campylobacter* or calcivirus enteritis in breast-fed infants is inversely proportional to concentrations of oligosaccharides in maternal milk that consist mainly of α-(1→2) oligosaccharides.[114] It is unclear whether the risk to other enteropathogens is related to quantitative variations in other oligosaccharides in human milk.

In addition, sulfated glycolipids, glycosaminoglycans,[115] and Lewis X component[116] in human milk inhibit in vitro infection by HIV-1. Polymers of Lewis X component interact with a dendritic cell–specific ICAM3-grabbing nonintegrin that facilitates the transfer of HIV-1 from dendritic cells to $CD4^+$ T cells. Consequently, gp120 on the envelope of HIV-1 is unable to bind to those T cells.

Animal experiments suggest that oligosaccharides and glycoconjugates in human milk protect against certain enteric bacterial infections.[117] In that regard, certain human milk oligosaccharides survive passage through the alimentary tract[118] and some are absorbed and then excreted into the urinary tract.[119] This may account for some protection by human milk against urinary tract infections.[120] Sugars in the glycoconjugates mucins, lactadherin, and secretory IgA also interfere with binding of bacterial pathogens to epithelial cells.[93,94,121]

In addition to the direct antibacterial effects of the carbohydrates in human milk, nitrogen-containing oligosaccharides, glycoproteins, and glycopeptides in human milk are growth promoters for lactobacilli and bifidobacilli.[122,123] For example, the growth-promoter activity associated with caseins may reside in the oligosaccharide moiety of those complex molecules.[123] These factors are responsible for the predominance of lactobacilli and bifidobacilli in the bacterial flora of the large intestine of breast-fed infants. The commensal bacteria produce large amounts of acetic acid, which suppress the multiplication of enteropathogens. The *Lactobacillus* strain GG may also aid in the recovery from acute rotavirus infections[124] and may enhance the formation of specific circulating antibodies during enteric infections.[29] In addition, enteric commensal bacteria may stimulate the production of IL-12[125] and low-molecular-weight antibacterial peptides such as defensins.[126] These latter defense mechanisms may contribute to the comparative paucity in stools of breast-fed infants of bacterial pathogens most often found in urinary tract infections such as P-fimbriated *E. coli*.[127]

Lipids

Fatty acids and monoglycerides generated by the enzymatic digestion of lipid substrates in human milk disrupt enveloped viruses.[128,129] These antiviral lipids may aid to prevent coronavirus infections of the intestinal tract[130] and defend against intestinal parasites such as *Giardia lamblia* and *Entameoba histolytica*.[131,132] Monoglycerides from milk lipid hydrolysis also inactivate certain gram-positive and gram-negative bacteria.[133] These lipids may act synergistically with one another and with antibacterial peptides.[134] Hydrolysis of milk lipids occurs in infants because of lingual lipase and the activation of human milk bile-salt stimulated lipase in the duodenum. Thus the products of lipid digestion may help defend breast-fed infants against enteric infections in the proximal gastrointestinal tract.

LEUKOCYTES IN HUMAN MILK

Living leukocytes are found in human milk,[135] and virtually all of them are activated.[136,137] In contrast to B cells that transform into plasma cells that remain sessile in the mammary gland, other leukocytes attracted to the site traverse the mammary epithelium and become part of milk secretions. The highest concentrations of leukocytes in human milk occur in the first few days of lactation ($1–3 \times 10^6$/mL). The several types of leukocytes and their major features are as follows.

Lymphocytes

The relative frequencies of T cells and B cells among lymphocytes in early human milk secretions are 83% and 6%, respectively.[136] The small number of natural killer cells in human milk[136] is in keeping with the low cytotoxic activity of human milk leukocytes.[138] The numbers of B cells in human milk are small because most B cells that enter the lamina propria of the mammary gland transform into sessile plasma cells.

Both $CD4^+$ (helper) and $CD8^+$ (cytotoxic/suppressor) T-cell subpopulations are present in human milk.[136] But compared with human blood T cells, the proportion of $CD8^+$ T cells in human milk is greater.[136] $CD4^+$ and $CD8^+$ T cells in human milk bear markers of cellular activation including CD45RO and HLA-DR.[136] Moreover, a greater percentage of human milk $CD8^+$ T cells express the intestinal homing receptor, CD103, and the mucosal homing receptor, CCR9, than those found in blood.[139]

T cells in human milk produce certain cytokines such as interferon-γ.[140] Additional cytokines are produced by human milk leukocytes,[141] but the extent of their production and secretion is undetermined.

Neutrophils and Macrophages

Neutrophils and macrophages are the dominant leukocytes in human milk. Both types of cells are laden with milk fat globules and other membranes that have been phagocytized. Because of

these intracytoplasmic bodies, they are difficult to recognize by common staining methods. They can be identified however by the presence of myeloperoxidase in neutrophils),[141,142] nonspecific esterase in macrophages,[141,142] or CD14 or MHC class II molecules in macrophages.[141] Both types of cells in human milk are phagocytic. A respiratory burst occurs in milk macrophages after stimulation.[142,143] Superoxide anion generation by those cells is more marked after exposure to mannose-receptor ligands.[143] The macrophages also process and present antigens to T cells.[144]

In contrast to blood neutrophils, human milk neutrophils do not increase adherence, polarity, directed migration,[145] or deformability after exposure to chemoattractants.[146] These alterations may be due to agents in human milk. For example, the decreased calcium influx found in human milk neutrophils is duplicated by incubating blood neutrophils in human milk.[147]

Unlike human milk neutrophils, the motility of macrophages in human milk is increased compared with blood monocytes.[148] The features of these cells in human milk are likely due to cellular activation, because they display phenotypic features of activation, including an increased expression of CD11b/CD18 and a decreased expression of CD62L.[137] The activation may be due in part to ingestion of milk fat globules or other membranous materials in human milk.[137]

Potential In Vivo Effects

The in vivo fate and role of human milk leukocytes in the infant are poorly understood. Only a small numbers of memory T cells are detected in infancy[149]; thus maternal memory T cells in milk may compensate for that developmental delay in the infant. There is evidence from experimental animal studies that milk lymphocytes enter tissues of the neonate,[141] but that has not been demonstrated in humans. In addition, cellular immunity may be transferred by breast-feeding.[150]

ANTI-INFLAMMATORY PROPERTIES

Inflammatory agents and systems that give rise to them are poorly represented in human milk.[25,26] These include (1) the coagulation system; (2) the kallikrein-kininogen system; (3) most complement components; (4) IgE; (5) basophils, mast cells, eosinophils; and (6) cytotoxic lymphocytes. Certain proinflammatory cytokines (see subsequent discussion) are found in human milk, but there is no clinical evidence that they generate inflammation in the recipient.

Human milk also contains many antiinflammatory agents[25,26] including (1) factors that promote epithelial growth and thus strengthen mucosal barriers; (2) antioxidants; (3) agents such as lactoferrin that interfere with some complement components[26,151]; (4) enzymes that degrade mediators of inflammation; (5) protease inhibitors[152]; (6) agents that bind to substrates such as lysozyme to elastin[153] and lactoferrin to the toxic moiety of lipopolysaccharide, lipid A[154]; (7) cytoprotective agents such as prostaglandins E_1, E_2, and $F_2\alpha$,[155,156]; and (8) agents that inhibit the functions of inflammatory leukocytes[26] such as binding of LPS to CD14 by lactoferrin[154] and the down-regulation by lactoferrin of LPS-induced cytokine production by mononuclear phagocytes via NFκB[157] (Table 158-3). Furthermore, many antiinflammatory agents in human milk are adapted to survive in the alimentary tract.

The main antioxidants in human milk include an ascorbate-like compound,[158] uric acid,[158] α-tocopherol,[159,160] and β-carotene.[159,160] Blood levels of α-tocopherol and β-carotene are higher in breast-fed than formula-fed infants not supplemented with those agents.[160] The in vivo action of those agents in human milk is unknown.

Mucosal growth factors in human milk include epithelial growth factor,[161] lactoferrin,[162] cortisol,[163] polyamines,[164,165] and peptides produced from α-lactalbumin and lysozyme.[166] Other hormones and growth factors in human milk[167] also affect the growth and differentiation of epithelium and thus limit the penetration of antigens and pathogens into the intestines. In that respect, the biophysical and biochemical organization and functions of mucosal barriers in adults and neonates are different.[168,169] Furthermore, their maturation may be accelerated by human milk.[170,171]

TABLE 158-3

Antiinflammatory Agents in Human Milk

Categories	Examples
Cytoprotectives	Prostaglandins E2, F2α
Epithelial growth factors	EGF, lactoferrin, polyamines
Maturational factors	Cortisol
Enzymes that degrade inflammatory mediators	PAF-acetylhydrolase
Binders of enzymes	α1-Antichymotrypsin
Binders of substrates of enzymes	Lysozyme to elastin
Binders of toxins	Lactoferrin to lipid A of LPS
Modulators of inflammatory leukocytes	IL-10, TGF-β1
Antioxidants	Uric acid, β-carotene, ascorbate

Enzymes in human milk degrade inflammatory mediators. Platelet-activating factor (PAF) plays a role in an intestinal injury in rats induced by endotoxin and hypoxia.[172] Human milk, however, contains an acetylhydrolase that degrades PAF,[173] whereas the production of human PAF-acetylhydrolase is developmentally delayed.[174] As a result of these agents in human milk, intestinal permeability is lessened in breast-fed infants.[175-177]

IMMUNOMODULATING AGENTS

Observations suggest that immunomodulating agents in human milk are important:

1. Epidemiologic investigations suggest that older children who are breast-fed during infancy may be at less risk for developing certain chronic diseases mediated by immunologic, inflammatory, or oncogenic mechanisms. The diseases are type 1 diabetes mellitus,[178-180] type 2 diabetes mellitus,[181] lymphomas,[182,183] acute lymphocytic leukemia,[183,184] and Crohn's disease.[185,186]
2. Increased levels of certain immune factors in breast-fed infants cannot be accounted for by passive transfer of those substances from human milk. Breast-feeding primes the recipient to produce higher blood levels of interferon-α in response to respiratory syncytial virus (RSV) infections.[187] In addition, increments in blood levels of fibronectin achieved by breast-feeding cannot be accounted for by the amounts of that protein in human milk. Moreover, breast-feeding leads to a more rapid development of systemic[188] and secretory[188,189] antibody responses and of secretory IgA in external secretions[60-62] including urine,[61,62] which are far removed from the route of ingestion. There is no evidence that those increments are caused by absorption of those same factors from human milk.
3. Thymic growth,[190] T-cell emigration from the thymus possibly caused by increased IL-7 in human milk,[191] T-cell maturation, and IL-10 production[192] are increased in breast-fed infants compared with infants who are not breast-fed.
4. All leukocytes in human milk are activated.

Cytokines

After it was ascertained that human milk leukocytes were activated, activating agents in human milk were sought. It was found that human milk enhances the movement of blood monocytes in vitro and that much of that motility was abrogated by antibodies to tumor necrosis factor-α (TNF-α).[193] Subsequently, TNF-α

TABLE 158-4

Cytokines in Human Milk

Types	Examples
T-cell production augmentation	IL-7
Cellular immunity enhancement	Interferon-γ, TNF-α, IL-12, and IL-18
Humoral immunity enhancement	TGF-β2, IL-4, IL-10
Macrophage stimulation	IL-1β, IL-6, IL-6, MIF
Chemokine activities	IL-8, RANTES, MIP-1, CCL28
Interferon-inducible proteins	IP-10 and MIG
Antiinflammatory actions	TGF-β1, IL-10
Growth stimulation	EGF, M-CSF, G-CSF, erythropoietin

in human milk was detected immunochemically.[194] Since then, many cytokines have since been found in human milk (Table 158-4). They include the following:

1. IL-7, which promotes intrathymic development of T cells and maintenance of mature T cells in the peripheral lymphoid system.[192]
2. IL-2 with IL-7, which promotes the proliferation of recent thymic immigrants.[195]
3. Th1 (interferon-γ,[196] IL-12,[197] and IL-18[198]) and Th2 (IL-10[199,200] and IL-4[201]) cytokines.
4. Macrophage-stimulating cytokines including IL-1β,[202] IL-6,[203] and MIF.[86]
5. Chemotaxins including IL-8,[204] RANTES,[201] CCL28,[85] and eotaxin.[201]
6. Interferon-inducible proteins IP-10 and MIG.[205]
7. Antiinflammatory agents such as Il-4,[201] TGF-β1,[206] TGF -β2[207] and IL-10[199,200]
8. Growth factors EGF,[161,167] granulocyte colony-stimulating factor,[208] macrophage-CSF,[209] hepatic growth factor,[210] Il-4[196] and erythropoietin.[211]

It should be pointed out that the in vivo fate, action, and interactions of these cytokines in human milk are complex and largely unexplored. For example, IL-2 greatly decreases the expression of IL-7 receptor α-chains (IL-7Rα).[212] Because IL-7Rα is a component of receptors for IL-7 and thymic stromal lymphopoietin, IL-2 may negatively regulate signals by each of these cytokines. It is unclear whether the in vitro actions pertain to the in vivo effects upon the infant.

Other Modulators

Other immunomodulating agents in human milk include β-casomorphins,[213] prolactin,[167,214] antiidiotypic antibodies,[48] α-tocopherol,[159,160] nucleotides that enhance NK-cell, macrophage, and Th1 activities,[215] cell adhesion molecules ICAM-1, VCAM-1, E- and L-selectin,[216] mannan-binding lectin—which activates complement by the lectin pathway after recognizing surface saccharide motifs on microorganisms[217] and soluble CD14, a B-cell mitogen.[218]

Toll-like receptors (TLR) in human milk are being investigated. Soluble TLR-2 is present in human milk.[219] Furthermore, a protein of approximately 80 kD in human milk enhances the response of TLR4 and TLR5 receptors on umbilical cord blood mononuclear leukocytes.[220]

In addition to the antimicrobial and antiinflammatory functions of lactoferrin, this single-chain glycoprotein also promotes the differentiation of dendritic cells from monocytes.[221] It will be important to establish whether lactoferrin in human milk has a similar in vivo effect in the recipient infant.

In addition to their antimicrobial properties, some oligosaccharides are immunomodulatory. Lacto-N-fucopentaose III and lacto-N-neotetraose increase the production of murine IL-10.[222] Furthermore, human milk acidic oligosaccharides increase the number of interferon-producing $CD4^+$ and $CD8^+$ T cells and IL-13 production by $CD8^+$ T cells.[223] In addition, more CD25 is expressed on $CD4^+$ T cells after exposure to those oligosaccharides.[223]

TABLE 158-5

Immune Factors in Human Milk Whose Production Is Delayed in the Recipient

Immune Functions	Representative Agents
Antimicrobial	SIgA
	Lactoferrin
	Lysozyme
Antiinflammatory	IL-10
	PAF-acetylhydrolase
	Lactoferrin
	Lysozyme
Immunomodulatory	Memory T cells
	IL-4
	IL-10
	IL-12
	G-CSF
	TNF-α
	Interferon-γ
	RANTES

IMMUNE SYSTEM IN HUMAN MILK AND THE RECIPIENT INFANT

Several evolutionary outcomes concerning the relationships between the immune status of infants and defense agents in human milk have been recognized. In respect to one of the main evolutionary outcomes, many aspects of the human immune system are incompletely developed at birth, and the immaturity is most marked in very-low-birth-weight infants. They include (1) the mobilization and function of neutrophils,[224-226] (2) the maturation of dendritic cells,[227,228] (3) the recognition by monocytes and macrophages to bacterial agents by toll-like receptors TLR2 and TLR4,[229] (4) the production of lysozyme[230] and secretory IgA,[231] (5) memory T cells that bear CD45RO,[149] (6) the full expression of the antibody repertoire,[232] and (7) the production of certain cytokines including TNF-α,[233-235] IL-4,[236,237] interferon-γ,[237-239] IL-6,[234,240] IL-10,[233,241] IL-12,[242,243] IL-18,[243] G-CSF,[244] GM-CSF,[245] IL-3,[244] and RANTES.[246]

Many developmentally delayed defense agents are present in human milk (Table 158-5). For instance, secretory IgA antibodies in milk compensate for low production of secretory IgA during early infancy.[248] Human milk antibodies are polyclonal and directed against protein and polysaccharide antigens. This is important because infants display a more restricted antibody clonality[248] and do not produce IgG antibodies to polysaccharides.[249] Conjugate vaccines have been introduced, but antibody responses to them are higher in breast-fed than cow's milk-fed infants.[250]

An additional example is the interrelationship between the production of lysozyme by the infant and the mammary gland. High lysozyme levels in human milk[54-56] are coupled to low production of the protein by tracheo-bronchial mucosal cells during infancy.[230] Indeed, normal intraluminal concentrations of lysozyme in infancy may depend on breast-feeding. This is in keeping with higher lysozyme activities in stools of breast-fed infants than in infants who are not breast-fed.[60]

The functions of immune factors in human milk in the recipient infant depend on their survival in the infant. The following are germane: (1) Proteins may affect the epithelium, leukocytes, or other cells of the proximal GI or respiratory tracts where proteolytic enzymes are not produced. (2) Some proteins are inherently resistant to proteolysis. (3) Ingested proteins may escape

digestion because of developmental delays in production of gastric HCl and pancreatic proteases.[251]

This resistance to digestion may be augmented by (1) the buffering capacity of human milk that shields some acid-labile components of milk, (2) antiproteases in human milk,[152] (3) the inherent resistance of many defense agents in human milk to digestive processes, and (4) the compartmentalization of some defense agents in human milk.[86,94,95] In that respect, much of the TNF-α in human milk is bound to soluble receptors.[252]

PROTECTION OF PREMATURE INFANTS BY HUMAN MILK

Maturational delays of the immune system are generally more profound in premature infants. Furthermore, the problem is compounded by the shortened duration of placental transfer of IgG to the fetus,[253] medical problems during the newborn period,[254] nutritional imbalances, and invasive clinical procedures that increase the risks to infections.

Milk from women who deliver prematurely contains many of the same antimicrobial factors that are found in milk from women who have delivered after a full-term pregnancy. These include secretory Ig, lactoferrin, and lysozyme.[255] The concentrations of some defense agents are higher in preterm than term milk. Those higher concentrations may be in large part due to a lower production of milk by women who deliver prematurely. However, that may not be the total explanation for the higher concentrations in that patterns of the concentrations of some antimicrobial agents in preterm and term milk are not the same.[255]

Bacterial Sepsis

In addition to the protection against enteric infections and respiratory infections, there are several indications that human milk feedings protect premature infants against systemic infections that are prone to occur in such infants.[256-258]

Necrotizing Enterocolitis

Human milk protects against necrotizing enterocolitis (NEC).[259] Human and experimental animal studies suggest that IgA,[260] erythropoietin,[261,262] PAF-acetylhydrolase,[172-174] and IL-10[199,200,263,264] protect against NEC. These possibilities are in keeping with two important findings: 1) each of these defense agents is well represented in human milk and not in artificial feedings, and 2) the production of each agent in human infants is developmentally delayed.

One animal model suggests that IL-10 in human milk may prevent intestinal inflammation. Mice homozygous for IL-10 null genes develop a fatal enterocolitis that begins soon after weaning and is dependent on an enteric bacterial flora.[263,264] The enterocolitis had some features of Crohn's disease and NEC. Much of the enterocolitis in those animals is prevented by intraperitoneal injections of IL-10 given at the start of weaning.[263]

One study suggests that variations in the concentrations of IL-10 in human milk may be responsible for some of the risk of NEC in premature infants.[200] Two distinct populations of women were found in respect to the concentrations of IL-10 in their milk—72% were high producers, and 28% were very low producers.[200] In women whose infants developed NEC while receiving their own mother's milk, IL-10 was barely detected or undetected in milk from more than 90% of them.[200] The study awaits verification.

Lung Disease

Although it is unknown whether human milk protects against pulmonary and vascular effects of hyperoxia, α_1-antitrypsin prevents many of the features observed in hyperoxic neonatal rats including elevated pulmonary elastolytic activity.[265] Furthermore, a murine model suggests that TGF-β1 in human milk protects against certain pulmonary inflammatory diseases. Mice homozygous for the TGF-β1 null gene display infiltrations of macrophages and T cells in many organ sites, particularly the lungs, heart, and salivary glands.[266-268] Further, the effects of TGF-β1 deficiency are mitigated by ingestion of TGF-β1 in murine milk.[268] Furthermore, one study suggests that greater exposure to human milk TGF-β1 lessens the risk of asthma in the first year of life.[206]

ATOPIC DISEASE

Some studies suggest that human milk protects against atopic dermatitis[269] and asthma[206,270] and that some of the protection against asthma is mediated by TGF-β1[206] and soluble CD14 in human milk.[270] However, there is no consensus whether as to whether breast-feeding protects against atopic diseases.[271] Much of the disagreement may be due to confounding variables including variations in genetic predisposition to atopic disorders, the sufficiency of breast-feeding, unappreciated dietary exposures, and exposures to inhaled allergens or irritants. Further, increased exposures to infectious diseases facilitate Th1 responses that lead to cellular immunity, whereas lower exposures engender Th2 responses that lead to antibody formation and hence to possible IgE-mediated hypersensitivity. Thus, the effect of breast-feeding on atopic diseases may depend on factors that are not equally represented in all investigated populations.

Moreover, the question is complicated by foreign food antigens in human milk[272] and the triggering of allergic reactions by those antigens in some infants.[273] To test whether a breast-fed infant reacts to a foreign food antigen in human milk, dietary elimination and oral challenge with the food in question in the breast-feeding mother are needed.[273] If the infant reacts to a foreign food antigen in human milk, then the food should be eliminated from the maternal diet. If the allergen is a basic food, the elimination diet should contain the correct types and quantities of nutrients to meet the needs of the mother.[20] If dietary elimination is impractical, breast-feeding may be stopped and a hypoallergenic formula instituted. In addition, allergic disease in breast-fed infants may be due to alterations in fatty acids in human milk.[273-275]

IMMUNOLOGIC TOLERANCE

Evidence for induction of immunologic tolerance by breast-feeding comes from studies of alloreactivity. Maternal renal allografts are better tolerated in children from women who breast-feed transplant recipients than those who do not.[276,277] The difference in alloreactivity is also shown with blood lymphocytes from mothers and their children. Less alloreactivity occurs when lymphocytes from the mother (stimulators) are co-cultured with her breast-fed child's cells (reactors).[278] The tolerance may be induced by HLA-DR antigens on fat globules[279,280] and macrophages[137,141,144] in human milk.

CONCLUSION

Although much has been learned, there is much to be discovered. This includes: 1) other defense agents present in human milk, 2) regulation of production of the agents during lactation, 3) the precise molecular form of each defense agent in human milk, 4) where compartmentalized and soluble-receptor bound agents in human milk are released, 5) whether other defense agents are created in the infant's gastrointestinal tract by partial digestion of substrates in human milk, 6) mechanisms responsible for activating leukocytes in human milk, 7) in vivo fate and action of the

defense agents in human milk, 8) effects of commensal bacterial flora induced by breast-feeding upon the immune system of the recipient, 9) tolerogenic effects of human milk, and 10) long-term effects of antiinflammatory, immunomodulating, and antineoplastic agents in human milk.
