Neonatal Pulmonary Host Defense

Like the skin and gastrointestinal (GI) tract, the lungs are a mucosal organ with a large surface area exposed to the external environment. Unlike the skin and GI tract, the lung is considered to be largely sterile below the glottis whereas the skin and GI tract are colonized with bacteria termed "commensal flora." Despite the lower airway being sterile, the upper airway becomes rapidly colonized with bacteria that can be aspirated into the lower airway, thus the lung has evolved an array of host defense mechanisms to prevent development of infection in the air space. This robust development of pulmonary host defense mechanisms was an essential step in the evolution of air-breathing animals. The major physiologic aspect of the lung is to perform gas exchange, namely the exchange of oxygen and carbon dioxide across the alveolar capillary membrane. To maintain this function, the lungs must have buffering capacity in the airway and alveolar space to neutralize potentially injurious agents including pathogens. In a 3.5-kg neonate with a typical minute ventilation ranging from 100 to 150 mL/(kg•min), the lungs are required to filter approximately 30 L of inhaled air hourly. This is a problematic task in that the alveolar surface area requiring protection is 20 times the average neonatal body surface area.[1] In addition to normal tidal breathing or gas exchange the lung must be able to handle larger insults because of what may occur upon aspiration of oropharyngeal or gastric contents.

Available pulmonary host defenses can be broadly categorized as either structural or immunologic. Examples of structural defenses include the larynx and epiglottis (which are

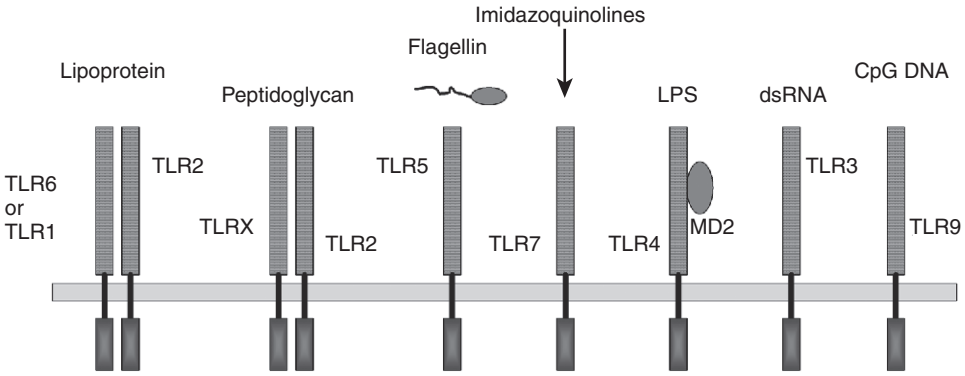

Figure 159-1 Toll-like receptors and their ligands. Toll-like receptors function as molecular recognition receptors with specific ligand recognition motifs encoded by their leucine-rich repeat domains *(horizontal lines)*. The TLR2/6 heterodimer recognizes bacterial lipoproteins, and TLR2 also recognizes peptidoglycans. TLR5 recognizes flagellin whereas TLR7 recognizes molecules such as Imiquimod. TLR4 in conjunction with MD2 recognizes LPS, but TLR4 is critical for signaling induced by LPS stimulation. TLR3 recognizes double stranded RNA, and TLR9 recognizes hypomethylated CpG DNA.

anatomically situated to minimize aspiration of oropharyngeal material), airway angulation, mucus secretion, and mucociliary clearance mechanisms including the cough reflex. These mechanisms result in progressive filtering of about 99% of inhaled particles as they pass through the conducting airways so that overall level of antigen exposure at a given site is inversely related to its depth within the respiratory tree.

Immunologic mechanisms can be divided into innate immune response and adaptive immune response. Innate immunity is highly conserved from lower order species such as worms *(Caenorhabditis elegans)* and fruit flies *(Drosophila melanogaster)*. Innate immunity is rapid (within minutes to hours) and generally lacks specificity toward the pathogen. Adaptive immunity takes longer to develop (days as opposed to minutes to hours), is more pathogen specific, and is characterized by recombination of cell surface receptors to achieve pathogen specificity in both B-lymphocytes and T-lymphocytes. Adaptive immunity is present in higher order eukaryotes such as fish and mammals. Although innate immune responses are thought to be nonspecific, they often rely on host recognition of pathogen-associated molecular patterns or specific molecules such as peptidoglycans, lipopetides, lipopolysaccharides (LPS), flagellin, fungal glucans, or specific nucleic acid structures such as single stranded RNA or unmethylated CpG DNA (Figure 159-1).[2] A major class of molecules that recognizes these specific molecules are the Toll-like receptors (TLR) (see Figure 159-1). These receptors are expressed on both blood-derived cells such as lung dendritic cells and alveolar macrophages and on nonmyeloid cells such as the lung epithelial cell.[3,4] Ligation of TLRs can initiate early alarm cytokines such as TNFα and IL-1β in the lung, and these can, in turn, stimulate lung endothelial expression of adhesion molecules, which augments binding of inflammatory cells to endothelium.[4a] Additionally, TLR signaling and the alarm cytokines can amplify the production of specific chemokines such as C3a, CXCL1, CXCL2, and CXCL8, which can augment neutrophil recruitment into the air space. Mice deficient in CXCR2, which is the receptor for CXCL1, CXCL2, and CXCL5 in the mouse, have significantly attenuated neutrophil recruitment in response to bacteria and hence have markedly reduced survival as a result of an inability to control bacterial growth in the lung.[5]

The lung is unique among mucosal organs in that it expresses surfactant proteins. Although surfactant was originally described as the critical phospholipid component of the alveolar lining fluid that reduces surface tension and allows successful transition from liquid breathing in the fetus to air breathing in the neonate, surfactant also plays critical roles in innate immunity.[6] Specifically, the surfactant proteins (SP) A and D have collagen stalks with lectin-binding domains termed "collections." SP-A and SP-D can act as opsonins and have been shown to be critical for host defense against bacterial, fungal, and viral pathogens.[7,8] These proteins can interact with carbohydrates on pathogens to directly neutralize the pathogen or augment macrophage-mediated uptake of these pathogens. Macrophages express a variety of phagocytic receptors to ingest and kill pathogens including Dectin-1, macrophage mannose receptors, and scavenger receptors.[9] Immature dendritic cells (iDCs) are also capable of ingesting pathogens-antigens, and when activated, iDCs can become mature DCs that express high levels of class II major histocompatibility complex for antigen presentation and costimulatory molecules such as CD80 and CD86. In addition, maturation leads to up-regulation of CCR7, a G-coupled chemokine receptor that is critical for migration of DCs to lymphoid tissue for antigen presentation to CD4+ T cells. Additionally it has recently been shown that cytokines, specifically IL-12p40, are required for DC migration to lymph nodes[10] possibly through the regulation of CCR7.[10] It is partly through these mechanisms that innate immunity can markedly drive adaptive immunity. For example, antigen presentation to CD4+ T cells in the absence of costimulation can lead to anergic T-cell responses that may be a key mechanism of achieving antigen tolerance in the lung. This is important because the delicate lining of the lung cannot afford to have strong immune reactions to all inhaled particles (such as ubiquitous mold spores) because the inflammation could adversely affect gas exchange. Thus the lung comprises macrophages and dendritic cells, which likely respond to specific thresholds of stimulus that are important in regulating decision points of antigen-specific tolerance versus antigen-specific immunity.

In addition to macrophages, dendritic cells, and epithelial cells, the lung also contains cells that are capable of "bridging" immunity. These cells include γδ T cells and natural killer (NK) T cells that often respond to canonical antigens (and cytokines). Thus these cells can secrete cytokines that control mucosal immunity but undergo limited T-cell receptor rearrangement compared with classic αβ T cells, which orchestrate more specific adaptive immunity. The recruitment of αβ T cells and B cells heralds the onset of the adaptive immune response. These cells express T-cell and B-cell receptors that undergo genetic reengagement so that the receptor has high affinity for peptides that are antigen specific. These cells consist of an effector population and a memory population. The latter population is capable of responding much more rapidly than naive cells if the antigen is reencountered by the host. Adaptive immunity thus initiates a targeted response aimed at

containment and clearance of a specific antigen, allowing titration of nonspecific—and potentially host injurious—alveolar inflammation. Although it is convenient to think of innate and adaptive immunity as innate immunity occurring proximal to adaptive immunity, complex pulmonary immune responses, as seen in pneumonia, require interplay between innate and adaptive elements.

STRUCTURAL MECHANISMS OF HOST DEFENSE

Structural defense exists throughout the respiratory tract. During air entry, the nose performs humidification of entrained air and also serves as an important filter. Particle filtration occurs through nasal hairs and through nasal turbinates. The turbulent airflow that exists in the upper airway facilitates particle deposition in the upper airway. These structures can filter particles as small as 10 μm. The next barrier to protect the lower airway is the larynx, which consists of the epiglottis, aryepiglottic folds, and glottis. Nervous innervation into these structures provides a gag and cough reflux which minimizes oropharyngeal aspiration. Particles smaller than 10 μm can be inhaled into the lower respiratory tract, and particle deposition is greatest at areas of airway bifurcation. An important clearance mechanism in the lower airways is cough and mucociliary cleanse, which is coordinated by specialized epithelia cells.

Epithelial Cells

Airway epithelial cells consist of both ciliated and nonciliated cells. The cells in the large airways exist as a pseudostratified epithelium with each cell having contact with the basement membrane. These cells express apical-tight junctions that restrict passive diffusion or pathogen movement across the lateral intracellular space, augmenting local mechanical barriers.[11] The cilia extend apically from the epithelium into the airway surface liquid (ASL) which has been estimated to be 7 to 8 μm in height.[12] On top of this liquid layer there is a mucous layer which is the site of particle deposition. The height of the ASL can markedly affect mucociliary clearance and is regulated by both sodium and chloride transport across the epithelium. Excluding regions of the larynx and pharynx where squamous epithelium predominates, ciliated epithelium is present from the upper respiratory tract to the level of the respiratory bronchioles. In addition to the ciliated epithelium, there are a variety of different nonciliated cell types including mucus-producing goblet cells, serous cells, Clara cells, neuroendocrine cells, and basal cells.[13,14] Ciliated cells are in physical contact at tight junction desmosomes and in physiologic communication via gap junctions.[15] Columnar ciliated cells may carry up to 200 cilia, ranging from 4 μm in the distal airways to 6 μm centrally. Ciliogenesis commences in the upper trachea early in gestation (week 7) and proceeds distally; by week 24 of gestation, the fetal airway epithelium resembles that of the mature trachea.[16] Although fetal cilia are motile, the function of ciliary activity in utero is unknown.

Epithelial cell types responsible for mucus production include the goblet cells, serous cells, and Clara cells. Goblet cells are found predominantly in large airways and are the principal source of mucus. Clara cells are found only in small airways and produce watery secretions; serous cells have similar location and function, but have been identified only in fetal tissues. Clara cells also serve as a likely stem cell for regeneration of ciliated epithelium.[17] Submucosal glands located in the cartilaginous portion of the airways also contribute to overall mucus secretion.

There is hierarchy of cell populations as one travels from the large airways to the alveolar ducts. In the trachea and large airways, ciliated columnar epithelium forms an essentially continuous epithelium, with a ratio of ciliated cells to goblet cells of 5:1.[18] In the lower airways, ciliated and goblet cell numbers are reduced, a ciliated cuboidal epithelium predominates, and Clara cells become the only secretory cells present.[19]

As alluded to above, particle deposition occurs in the mucus layer and the apical situated glycocalyx layer, which consists of mucins tethered to the epithelial cell surface.[20] The epithelium expresses both tethered mucins and nontethered mucins.[20] MUC1 and MUC4 are genes that encode tethered mucins, which are highly glycosylated and extend up to 1500 nm into the airway lumen. These mucins and other glycoproteins in the glycocalyx can bind particles and bacteria, facilitate clearance, and form an anatomic barrier between the particle and the epithelial cell. The glycocalyx has also been shown to be a critical barrier to prevent infection of the epithelium by various respiratory viruses.[21]

Ciliary Function

Human cilia are composed of nine doublet microtubules (subfibers) surrounding two microtubules. The major microtubular axonemal proteins are dynein, an adenosine triphosphatase (ATPase), and tubulin.[22] At the tip of the cilium, the nine subfibers simplify into nine single fibers that insert into a common cytoplasmic extension (Figure 159-2) through which they mechanically engage the overlying mucus sheet during the effective ciliary stroke.[23-25] At the base of the cilium, the nine subfibers end in the basal body, which is anchored to the cytoskeleton.[25] Because all basal bodies of a cell are oriented in approximately the same direction, the effective strokes of all cilia of a given cell have a similar orientation; however, neither the orientation of these structures nor the orientation of the ciliary beats is necessarily identical in adjacent cells.[26,27] During ciliary motion, dynein projections from one subfiber transiently interact with the nondynein-containing subfiber of an adjacent microtubule doublet and, using energy from dynein-mediated adenosine triphosphate (ATP) hydrolysis, induce a conformational change resulting in subfiber movement. Repetition of this process in adjacent doublets, in a unidirectional front circumferentially, causes the sequential movement of fibers that effect cilia motion.[28] From a resting state, a cilium in its recovery stroke swings close to the cell 180 degrees backward, then fully extends and moves through its effective stroke, an arc of approximately 110 degrees in a plane perpendicular to the cell surface.[29] During the effective stroke, the ciliary tip engages the overlying mucus, advancing it in the same direction. Following this, the cilium rests then repeats this sequence. As a cilium swings backward into its recovery stroke, it engages other resting cilia, stimulating them to begin a recovery stroke; this mechanical recruitment is pivotal for the coordinated beating of airway cilia.[30]

Cilia of human nasal, tracheal, and bronchial mucosa beat at 11 to 15 Hz at body temperature, with progressively slower frequencies noted in proximal bronchi and bronchioles.[25] Because the combined surface areas of the distal airways are exponentially greater than those of the central airways, this differential ciliary beat frequency allows efficient handling of the relatively large mucus loads eventually delivered to the trachea. Endogenous mechanisms that allow such local ciliary beat modulation have been described. Local physiologic loads to airway epithelium, such as increased quantities of mucus, can mechanically stimulate increased ciliary beating in vivo; this effect appears to be mediated by increased cytosolic calcium and can be reproduced pharmacologically by agents that modulate intracellular calcium levels.[31,32] Ciliary beat frequency is also exquisitely sensitive to alterations in temperature; cilia of the small airways beat optimally near body temperature, decreasing and increasing their beat frequencies in response to decreased and increased body temperatures, respectively.[32] Increased ciliary beat frequency in response to increased ambient air concentrations of nitric oxide (NO) has been described, suggesting that local cellular production of this bioactive substance may modulate ciliary function.[32] These

observations are consistent with in vitro data demonstrating that ciliated epithelium produces NO, which regulates ciliary beat frequency in an autocrine manner via a cyclic guanosine monophosphate (GMP) signaling pathway.[33] In addition to the dynein ATPase, a cyclic adenosine monophosphate (cAMP)-dependent kinase also facilitates control of ciliary beating.[32] Whether intrinsic neural control of ciliary beat frequency exists is unclear. Although acetylcholine increases ciliary beat frequency in vitro, suggesting a potential role for cholinergic regulation of ciliary "tone," there is no cholinergic efferent innervation of the superficial airway epithelium, making it unlikely that neural mechanisms regulate lung mucus transport.[34] Finally, recent interest has focused on autocrine and paracrine airway epithelial signals generated by local purinergic pathways.[32] In this model, luminal ATP and uridine triphosphate (UTP) induce increased ciliary beat frequency by binding to G protein–coupled purinoreceptors on the epithelial apical membrane. Nucleotide-hydrolyzing enzymes of the airway surface liberate adenosine, which acts through a separate receptor to sustain the ciliostimulatory effects of ATP, while cilia-derived phosphatases hydrolyze ATP and UTP, down-regulating ciliary beat frequency. Nucleotide release by airway epithelia is induced by shear stress and possibly other stimuli so that local mechanical or metabolic perturbations may modulate ciliary activity.[32]

Ciliary function may also be affected by a variety of exogenous substances introduced into the airway. Inhaled β-adrenergic agonists may increase ciliary beat frequency by increasing cellular cAMP.[35] Inhaled NO, via metabolism to S-nitrosothiols, may increase ciliary motility.[36] Conversely, ciliary activity may be diminished by a number of anesthetic gases or by exposure to high concentrations of inspired oxygen.[32] Finally, ciliary function may be impaired by infection. Specific pathogens, including *Pseudomonas aeruginosa*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*, produce soluble products inhibiting ciliary function.[32] These products may induce ciliary beat slowing, ciliary beat disorientation, ciliostasis, or frank ciliary lysis. Some of these substances are directly ciliotoxic, whereas others act by inducing local macrophages to generate hydrogen peroxide, which has a local cilioinhibitory effect.[32] Lipid-derived inflammatory mediators, such as platelet-activating factor (PAF) induce dose-dependent slowing of ciliary beat, whereas proteins released into the airway lumen during inflammation, such as leukocyte elastase and neutral protease, are also ciliotoxic.[32] Although other inflammatory mediators stimulate ciliary beating in vitro, overall mucociliary function is typically diminished during inflammation in vivo.[32]

Airway Surface Liquid

Airway surface liquid (ASL) is a thin, nonviscous secretion lying just between the epithelial cell and overlying mucus, bathing the basal portion of the cilia and providing an environment of low resistance for the cilia to move during the backstroke portion of the movement cycle. The level of the ASL is critical for effective mucociliary function.[12] If the fluid level is too high, the ciliary tips will not be able to engage the overlying mucus and effect its movement. If the fluid level is too low as occurs in cystic fibrosis (CF), the cilia will not be able to disengage from the mucus layer during the recovery stroke and ciliary beating will be impeded.[12]

As mentioned above, ASL is regulated by active ion transport across the epithelial cells with concomitant fluid movement that is either passive or aquaporin regulated.[12] The bulk of fluid transport is regulated by both sodium and chloride transport. The predominant apical sodium channel is the epithelial sodium channel (ENaC), and chloride conductance is regulated by the cystic fibrosis transmembrane conductance regulator (CFTR) and

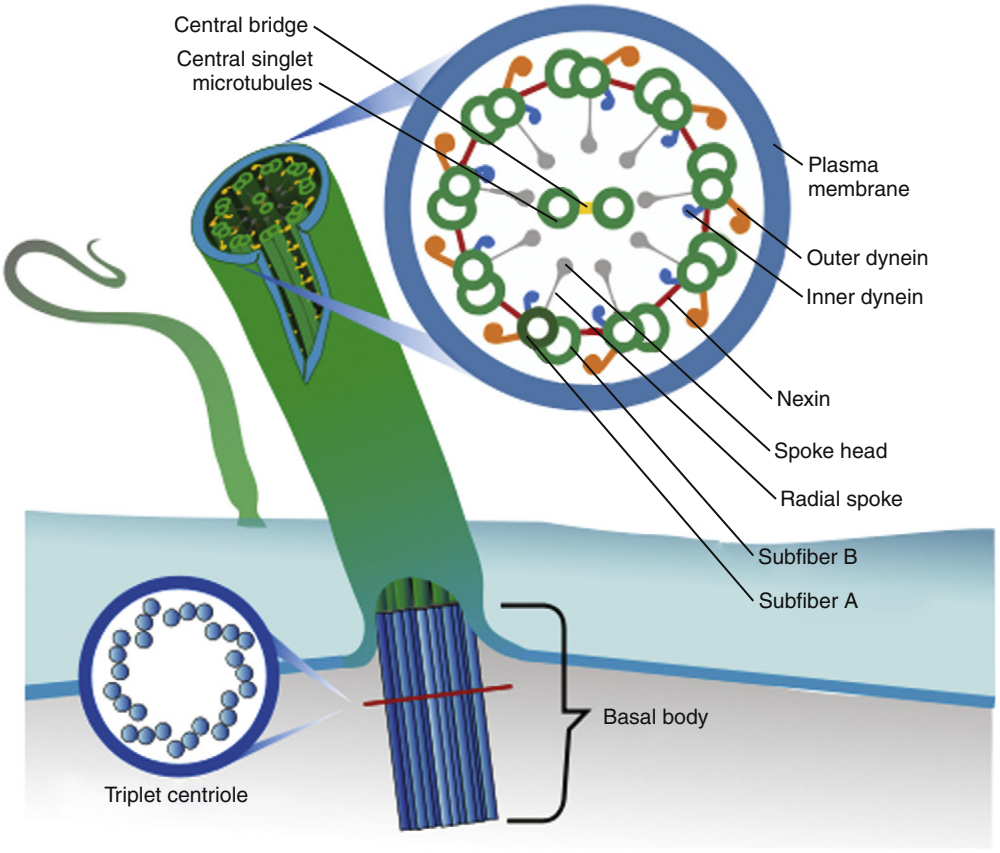

Figure 159-2 Schematic diagram of a cilium. Note the relationship of dynein projections from one subfiber with the adjacent subfiber *(inset)*. ATP hydrolysis results in conformational changes of the dynein arm, inducing subfiber movement and, ultimately, ciliary movement.

calcium-activated chloride channels (Figure 159-3). These channels are subject to precise regulation by environmental stress such as particle deposition or infection. ENaC is regulated by proteases as proteolytic cleavage of ENaC subunits can markedly augment channel activity.[37] CFTR is regulated by cAMP, and thus this channel is subject to influences such as osmotic stress or cytokine stimulation that influence cAMP levels.[38] In addition to these sodium and chloride channels, there are also bicarbonate exchangers that regulate ASL pH.[39] Passive efflux of water across the apical epithelial membrane results in cell shrinkage, triggering release of epithelial-derived mediators, including NO; these mediators increase blood flow and water content of the submucosa. Movement of water from the submucosa across the basolateral epithelial membrane, possibly regulated by aquaporin 4, restores epithelial cell volume.[40] In contrast, fetal lung fluid results from active secretion of Cl^- by all respiratory tract epithelium, with passive cation and fluid transit into the airway lumen.[41] In the distal airways these mechanisms persist, providing a source of periciliary fluid and mucus hydration for the rest of lung. Conversely, tracheobronchial epithelium gradually transitions postnatally from Cl^- secretion to Na^+ absorption, and Na^+ absorption eventually predominates in the larger airways under basal conditions.[12] At the same time, production of mucus components transiently increases. Mucociliary clearance has been shown to be reduced in neonates, presumably the result of increased ASL secretion and impaired ciliary tip engagement of mucus.

Mucins and Mucus

Mucins are high molecular weight, heavily glycosylated proteins that contribute to the gel-like qualities of mucus and are critical for mucosal host defense. Multiple mucin genes are expressed in the airways, but the primary gene products in mucus are MUC5AC and MUC5B.[42] Mucins are formed in the Golgi apparatus, concentrated in vesicles, and released by exocytosis from goblet cells and mucus cells of submucosal glands. Once secreted, condensed mucin polymers are hydrated, increasing their volume exponentially.[43,43a] Mucin proteins typically exhibit several hundred sugar side chains that contribute to their structural and barrier functions. As a result of their extensive glycosylation and their long carbohydrate side chains, mucins are capable of binding virtually any inhaled particle they encounter, facilitating particle entrapment within the mucus layer. Both MUC5AC and MUC5B show extensive regulation by both Th2 cytokines, including IL-9 and IL-13, and Th17 cytokines, namely by IL-17.[44,45] Additionally proinflammatory molecules such as histamine, prostaglandins, leukotrienes (LT), PAF, and tumor necrosis factor-α (TNF-α) can regulate mucin expression.

Mucus also contains proteoglycans, other proteins, lipids, water, and DNA. DNA is found in significant concentrations only during infection or inflammation of the airways originating from dead leukocytes or denuded epithelium; large amounts of DNA markedly increase mucus viscosity.[46,47] DNA is an important component of neutrophil extracellular traps (NETs), which consist of products of degranulated neutrophils such as granular proteases and antimicrobial peptides. NETs have been shown to serve as traps for bacteria and possibly a way to concentrate antimicrobial peptides at the host pathogen interface.[48] Other antimicrobial proteins including lysozyme, lactoferrin, human beta defensin-2 (HB-2), and immunoglobulin A (IgA) are secreted into the ASL-mucus layer.[49] Mucus rheology is determined by mucus hydration and by polyionic interactions between mucin molecules. These factors, in turn, depend on the pH and salt content of the ASL, and this may explain the thick, relatively immobile mucus seen with the impaired transepithelial Cl^- secretion and accelerated Na^+ absorption characteristic of cystic fibrosis.[50]

Mucociliary Function

Optimal mucociliary function depends on complex interactions among cilia, the mucus layer, and the intervening ASL. Both the mucus layer and the ASL are moved unidirectionally along

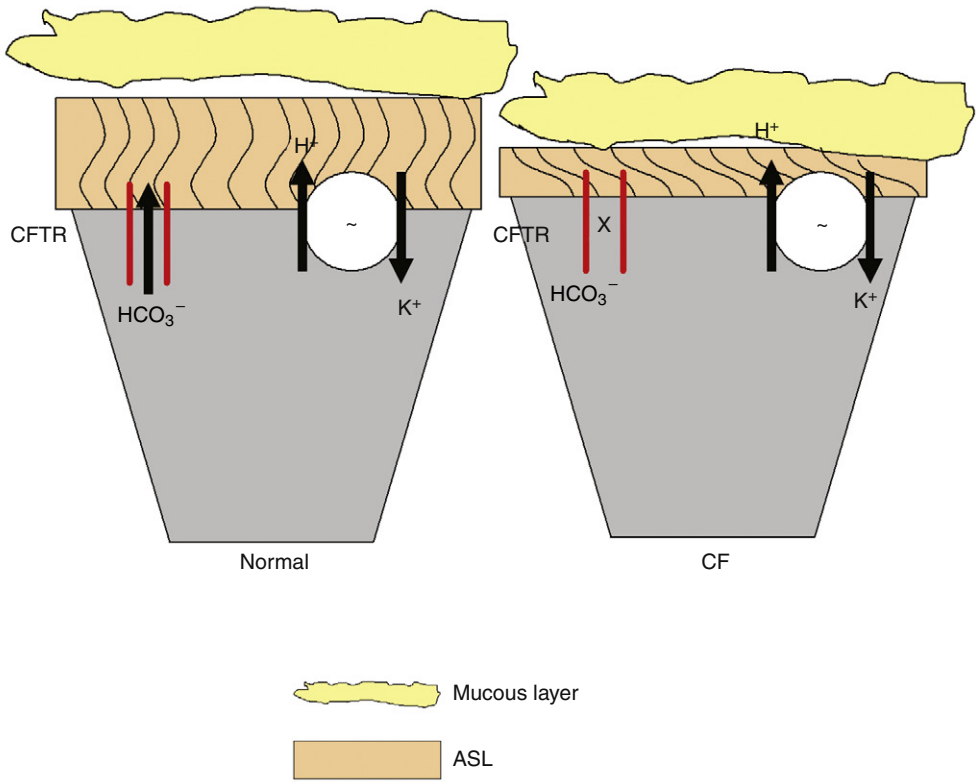

Figure 159-3 Regulation of the ASL by CFTR. The ASL is regulated by active ion transport across the epithelial cells with concomitant fluid movement that is either passive or aquaporin regulated. CFTR regulates both Cl^- and HCO_3^- transport, and, along with the epithelial sodium channel (ENaC), regulates the height of the ASL. Disease-causing mutations of the CFTR result in defective Cl^- and HCO_3^- conductance and reduction of the ASL. This leads to ciliary dysfunction and mucous impaction.

airway surfaces by ciliary action; cilia effect movement of the mucus layer through direct contact while frictional interaction with the mucus layer "drags" periciliary fluid. Beyond their propulsive function, cilia also impart vertical movements within the mucus layer; inhaled particles deposited within the airways are effectively "churned" into the mucus layer, facilitating binding by mucins and retention within the mucus layer until forced removal by mucociliary transport occurs.[51] Using aerosols of technetium-labeled albumin one can measure mucociliary clearance in humans. Mucociliary transport has been estimated to be 4 to 5 mm/min in the trachea, decreasing in the smaller airways to less than 0.4 mm/min in the bronchioles. Overall mucociliary clearance of the lung is achieved in two phases: (1) an initial rapid phase (half-life of about 4 hours) representing mucociliary clearance of the tracheobronchial tree and (2) a simultaneous slow phase lasting weeks to months, which represents alveolar clearance by nonmucociliary transport mechanisms.[52] Humans exhibit a wide range of mucociliary clearance rates, implying some endogenous control of this process. As noted earlier, purinergic regulatory mechanisms have been postulated, given the demonstrated effect of secreted nucleotides on ciliary beat frequency, goblet cell degranulation, and periciliary fluid secretion.[53] Mucociliary function continues to develop postnatally, gradually becoming adultlike over several weeks.

Mucociliary function can be perturbed by alterations in ciliary activity, changes in ASL composition, mucus secretion, or mucociliary interactions. Relevant environmental influences include temperature and humidity. Ciliary beat frequency and mucus transport rates are diminished at conditions below body temperature. Environmental tobacco smoke also reduces mucociliary clearance.[54] Furthermore, high inspired concentrations of oxygen can also damage the respiratory epithelium and impair mucociliary clearance.

Bacterial exotoxins can also perturb mucociliary clearance. Cholinergic agonists increase mucus clearance by increasing rates of mucus secretion and ciliary beat frequency, whereas atropine decreases mucociliary clearance and transport rates.[55] β-Adrenergic agonists increase intracellular cAMP levels, which increase ciliary beating ion and fluid secretion and mucus elaboration, resulting in the expected increase in mucociliary transport rates.[32,55] Methylated xanthines also enhance mucociliary clearance, presumably through similar actions on epithelial cell cAMP levels.

The critical role of cilia in mucosal host defense in humans has been clearly demonstrated by disorders that disrupt ciliogenesis or result in impaired ciliary function. These patients often lose sterility of the lower respiratory tract and suffer from sinusitis, bronchitis, and ultimately bronchiectasis. Primary ciliary dyskinesia (PCD) is a group of genetic disorders that result in congenital ciliary dysmotility state. Some mutations result in an absence of an intermediate chain dynein important in assembly and coordination of heavy chain dyneins of the ciliary shaft.[56] A subgroup of PCD is manifested by the triad sinusitis, bronchiectasis, and situs inversus termed "Kartagener's syndrome."[57] Other structural defects such as abnormal cilia length and orientation have been described in association with bronchiectasis and recurrent pulmonary infection. There is an ongoing effort to establish a better phenotype of these patients to allow better gene association studies to advance the gene-based diagnosis of these disorders. In addition to congenital disorders, many respiratory infections including both viral and bacterial infections can impair ciliary function. Adenovirus infection, particularly serotype 7, has been shown to cause marked damage to lung epithelium resulting in impaired ciliary function and the development of bronchiectasis.[58] As a result of marked decrease in blood flow to the damaged lung, the patient may develop a hyperlucent lung as described by Swyer and James.[59]

Another important cause of acquired ciliary dysfunction is the use of positive pressure ventilation in the neonate. Ventilator-associated lung injury and bronchopulmonary dysplasia (BPD) can impair mucociliary clearance. The airway epithelium is exquisitely sensitive to mechanical injury, and manipulations such as endotracheal intubation and/or the use of suction catheters have been shown to cause flattening or denuding of the epithelium in concert with a local inflammatory response. Prolonged mechanical ventilation has been shown to result in squamous metaplasia of the respiratory epithelium. Additionally, BPD is associated with bronchomalacia, which may further impair regional mucociliary clearance.[60]

AIRWAY REFLEXES

Integration of Breathing and Swallowing

Shared upper pathways for breathing and swallowing require that these functions be closely coordinated to prevent pulmonary contamination with oropharyngeal contents. In the neonate, multiple protective processes functionally separate the respiratory and alimentary tracts during swallowing.[61] The more cranial position of the larynx provides closer approximation of the epiglottis and soft palate, better isolating the oral cavity from the rest of the upper airway. Because newborns have lower resistance across the nasal passage than across the oral passage, owing to deficient control of oropharyngeal musculature, nasal breathing is favored, especially by preterm newborns; this may also facilitate functional separation between the upper tracts. Finally, it is well documented that neonatal breathing is interrupted by airway closure during nutritive sucking.[62]

Swallowing occurs early in fetal life, and three distinct stages have been identified: oral, pharyngeal, and esophageal. In neonates, the oral stage is coincident with nutritive sucking. During the pharyngeal stage, the bolus moves through the pharynx into the esophagus; the larynx is elevated and pulled forward; the epiglottis covers the laryngeal opening, which is further sealed by contraction of the laryngeal adductors; and inhibition of breathing occurs. At the end of the swallow, the airway reopens, and the esophageal phase follows.[63] This transient apneic response is also seen in nonfeeding swallows, which allow the infant to clear the airway of oral secretions or regurgitated materials before resuming breathing.[64,65] Premature infants typically exhibit incomplete integration of swallowing and breathing functions, such that oral feeding may result in pronounced apneic pauses.

When studied, intact cough reflexes were found in only 50% of term infants and only 25% of preterm infants; therefore, when challenged by a swallowing misadventure, neonates are more likely to defend the airway by sustained laryngeal closure than by coughing. Reflex laryngeal closure is mediated by stimulation of receptors in the laryngeal mucosa innervated by branches of the superior laryngeal nerves.[66] Although potentially pathologic, this response is also adaptive because attempts to breathe against an obstructed airway are reduced. Conversely, failure of laryngeal closure and premature termination of the apnea before airway clearance has occurred results in aspiration. As maturation occurs, coughing replaces apnea as the primary response to stimulation of these receptors.[67]

Cough and Forced Exhalation

In addition to mucociliary transport, cough is an important mechanism to accelerate the transport of inhaled or aspirated particulates out of the lung. The accessory muscles of expiration are used for coughing and sneezing. Contraction of the internal intercostal muscles decreases the antero-posterior diameter of the thorax, aiding in expiration. The abdominal muscles aid in forceful expiration (such as coughing) by increasing intraabdominal pressure, which is transmitted through the diaphragm to the pleural space. To move the mucus in the direction of the large airways, the shear force generated by the airflow must overcome

mucus viscosity and gravitational forces. At high airflow velocities (2500 cm/second), mucus is rendered off the surface as droplets, producing the mist flow characteristic of sputum expectoration from the trachea; such airflow velocities can be reached in the small airways during cough or forced exhalation.[67]

For a cough maneuver, there is rapid inhalation of a supranormal tidal volume followed by glottis closure, an intrathoracic pressure increase (50 to 100 mm Hg), and glottis opening with rapid exhalation. Although the cough reflex is quite effective in older children and adults, the cough is not as effective in neonates. This is the result of the markedly enhanced compliance of the chest wall and cartilaginous airways that impairs the ability to transfer pleural pressure to transpulmonary pressure. In addition, as the airways are more compliant, the neonate is subject to more airway collapse during the cough reflex. Coughing is also less effective in settings of respiratory muscle weakness or inability to close the glottis as when endotracheally intubated. A coordinated cough maneuver relies on local chemoreceptors and mechanoreceptors, vagal afferents, signal integration in the dorsal medulla, and efferent innervation to relevant muscles of inspiration and expiration. The receptors inducing cough are poorly characterized, but may be activated by local mediators including histamine, tachykinins, and substance P.[68] Cough can also be induced by stimulation of other vagally innervated sites such as the external auditory canal or esophagus. The afferent limb involves the vagus nerve and vagally innervated structures such as the larynx and conducting airways. Of these, the larynx and upper airways seem more sensitive to mechanical stimulation, whereas the lower airways are more chemosensitive.[68] Vagal afferents from these sites synapse in the nucleus tractus solitarius of the doral medulla, the putative "cough center." Efferent pathways include the recurrent laryngeal nerve, which stimulates glottic closure, and spinal nerves from C3 to S2, which innervate intercostal, abdominal, and pelvic muscles required to achieve sufficient tidal volume and expiratory pressure. As noted earlier, the cough reflex of premature neonates tends to be immature or absent, which is attributed to incomplete myelination of vagal afferents.[43a]

In the absence of effective cough, additional airway protective reflexes exist. Mechanical irritation of the epipharynx via the glossopharyngeal nerve elicits the sniff-like aspiration reflex by which foreign particles can be removed from the back of the nose to be either swallowed or expelled by mucociliary clearance. Mechanical stimulation of the vocal folds by means of the superior laryngeal nerve elicits a brief expiratory effort without preceding inspiration (the expiration reflex).

INNATE IMMUNE MECHANISMS OF HOST DEFENSE

Despite barriers to microbial colonization and invasion discussed earlier, particles of 2 to 10 μm in diameter may still infiltrate the lower airways and alveoli. Furthermore, anatomic barriers may be inadequate in situations of overwhelming pathogen inoculum via the air stream or ineffective in the situation of lung microbial invasion through hematogenous routes. Immune protective mechanisms are therefore frequently employed to contain penetrant microorganisms. Such mechanisms may be broadly characterized as either innate or adaptive. Adaptive immunity relies on specialized antigen-presenting cells to activate T cells and B cells, resulting in clonal expansion of lymphocyte pools unique for a specific antigen. Although advantageous for their specificity and capacity for long-term "memory," such responses are also delayed, owing to the multiple cellular interactions required. This is especially true in the setting of an "immunologically naive" host such as the newborn. Because delay in this setting may be deleterious to survival, capacity for more immediate immune response must also exist. The soluble and cellular components of this immediate host response constitute innate immunity.

Innate immunity is phylogenetically primitive, nonspecific, immediate, and the primary antimicrobial defense of the naive host. Innate immune responses recognize and target structurally conserved molecular sequences shared among groups of pathogens; these include LPS of gram-negative bacteria, lipotechoic acids of gram-positive bacteria, bacterial lipoproteins or peptidoglycans, mycobacterial glycolipids, fungal mannans or beta-glucans, unmethylated bacterial DNA sequences, and double-stranded viral RNAs. These are referred to collectively as "pathogen-associated molecular patterns" (PAMPs) and are recognized and ligated by pattern recognition receptors (PRRs) of the innate immune system. PRRs are nonclonal and do not depend on immunologic memory because they are germline encoded. These receptors are expressed on barrier and effector cells—such as epithelial cells, endothelium, and phagocytes—of innate immunity where binding and activation induce either direct phagocytosis or cellular signals culminating in leukocyte recruitment and nonspecific inflammation.[69] Alternatively, PRRs are also components of soluble or secreted humoral proteins. When present in the airway lining fluid, they constitute an additional "chemical barrier" and complement mucociliary clearance.[70,71]

Soluble Elements of Innate Immunity

As noted earlier, bacterial clearance from peripheral airways by mucus transport may require up to 6 hours; because bacteria can exhibit doubling times of fewer than 20 minutes, forced mucociliary clearance alone is potentially inadequate to maintain alveolar and airway sterility. Therefore concurrent mechanisms to contain bacterial growth must be present. Products of the neonatal lung that may confer innate, or nonspecific, antimicrobial protection include complement, other opsonins such as fibronectin, antimicrobial peptides (defensins, cathelicidins), lysozyme, collectins, and NO.

Complement

The complement system is a sentinel limb of innate immunity because it can be directly activated by component recognition of PAMPs. As such, it is a potentially important neonatal host defense providing a mechanism for direct bacterial lysis in the absence of optimal cellular immune responses. Specific complement components also function as microbial opsonins to facilitate phagocytosis and as chemotaxins to facilitate granulocyte recruitment.[72-75] The complement system consists of more than 20 proteins synthesized by cells of the liver or the reticuloendothelial system. Once activated, most components exhibit a proteolytic function responsible for activation of subsequent components in orderly series. Although normally quiescent, circulating and local complement components may be activated by any one of three major pathways.

The classical complement pathway is initiated by the binding of C1q to the Fc portion of either IgG or immunoglobulin M (IgM) complexed to antigen. This results in an amplified cascade leading sequentially to activation of C4b2a ("C3 convertase"), generation of C3a and C3b, and formation of the C4b2a3b complex that cleaves C5 into its split components C5a and C5b. The MB lectin pathway is mediated by mannan-binding lectin (MBL), an acute phase protein of the collectin family structurally similar to C1q.[76-79] MBL possesses domains that recognize and bind membrane glycoproteins of bacteria, yeast, mycobacteria, and certain viruses.[80,81] Pathogen binding induces an MBL conformational change, exposing two MBL serine proteases that activate C4, ultimately generating classical C3 convertase.[82-85] The alternative pathway is initiated by a number of substances, including endotoxin, complex polysaccharides, immune complexes, and surface components of intact cells such as certain bacteria and fungi.[86-91] Binding of nascent C3b fragments to these substances

protects C3b from inactivation by serum factors H and I. Subsequent cleavage and binding of factor B and the stabilizing protein properdin yield C3bBb, alternative pathway "C3/C5" convertase, which enzymatically cleaves C5 into the active components C5a and C5b. Each pathway ultimately activates terminal components of the complement system to form C5b-9, which inserts into lipid bilayers to form a transmembrane pore, permitting bidirectional solute flow and ultimately cell wall lysis.

Although there is considerable variability in data regarding neonatal complement levels and function, some generalizations can be made. Although many neonates have complement levels within the adult range, the level of components and activity of the alternative pathway are consistently diminished relative to those in the classical pathway. Marked deficiencies of C8 and C9 are seen and appear associated with poor killing of gram-negative bacteria in vitro.[92,93] Poor cross linking of C3 may contribute to decreased lytic and opsonic activity.[94,95] Preterm neonates have more consistent impairment of both pathways.[96,97] Complement levels increase steadily postnatally and reach adult levels by 12 to 18 months of age.[98,99] Finally, whereas MBL serum levels of term neonates approach those of adults, values in preterm neonates are roughly 60% of levels at term; the absence of increased morbidity or infection suggests only an adjunctive role for the MBL pathway in this population.[100,101]

Complement components are found throughout the lower respiratory tract and are produced locally by alveolar macrophages, pulmonary fibroblasts, and type II epithelial cells (Figure 159-4).[102-104] In this milieu, complement activation can be initiated by PAMPs or in the immune host by IgM or IgG microbial binding. Each pathway results in binding of component C3b, which is recognized by specific receptors on neutrophils and macrophages, facilitating phagocytosis. C3a and C5a are potent neutrophil chemoattractants, whereas C5b initiates the membrane attack complex effecting direct, non leukocyte–mediated bacterial killing. Evidence that complement is critical in defending against some pulmonary infections is provided by murine models of acquired and inherited hypocomplementemia, in which pulmonary clearance of *S. pneumoniae* and *P. aeruginosa* is impaired.[105-107]

Fibronectin

Fibronectins are extracellular matrix glycoproteins capable of interacting with a number of macromolecules and cells bearing specific fibronectin receptors.[108] The ability of specific mesenchymal cells such as fibroblasts to elaborate fibronectin during embryogenesis is critical in thoracic development. After birth, basal expression of fibronectin is limited primarily to hepatocytes, which produce circulatory fibronectin, and to the respiratory tract where fibronectin is present in saliva produced by bronchoepithelial cells and constitutively secreted by alveolar macrophages.[109] Serum concentrations of fibronectin are diminished in neonates (particularly in preterm infants), whereas bronchoalveolar lavage (BAL) levels appear inducible in settings of lung injury.[110-112] Enhanced fibronectin production by pulmonary fibroblasts, alveolar macrophages, and epithelial cells is induced by local production of macrophage-derived cytokines associated with acute inflammation, TNF-α, IL-1β, transforming growth factor-β (TGF-β), and platelet-derived growth factor (PDGF).[113] In acute lung injury, fibronectin stimulates fibroblast and epithelial cell recruitment and endothelial cell proliferation to facilitate tissue reparative processes. However, the ability of fibronectin to bind certain bacteria and to augment leukocyte adherence and migration suggests an additional role for this molecule in lung antimicrobial defense.

Fibronectin is bound by a number of pathogenic bacteria (*Staphylococcus aureus*, *Streptococcus pyogenes*, *Escherichia coli*, and *P. aeruginosa*) as well as *Mycobacterium* species, *Pneumocystis,* and fungi.[114-119] Because fibronectin binds multiple microorganisms it was originally thought to promote phagocytosis and destruction of the invasive organism before the onset of a specific immune response; studies demonstrating increased neutrophil and macrophage binding of *S. aureus* supported this theory.[120-122] Opposing studies suggested that fibronectin by itself may possess only weak opsonic activity.[123,124] More recent data indicate that fibronectin-binding proteins (FnBPs) present on the surface of *S. aureus* and streptococcal organisms promote adhesion of the bacteria to host tissue leading to increased

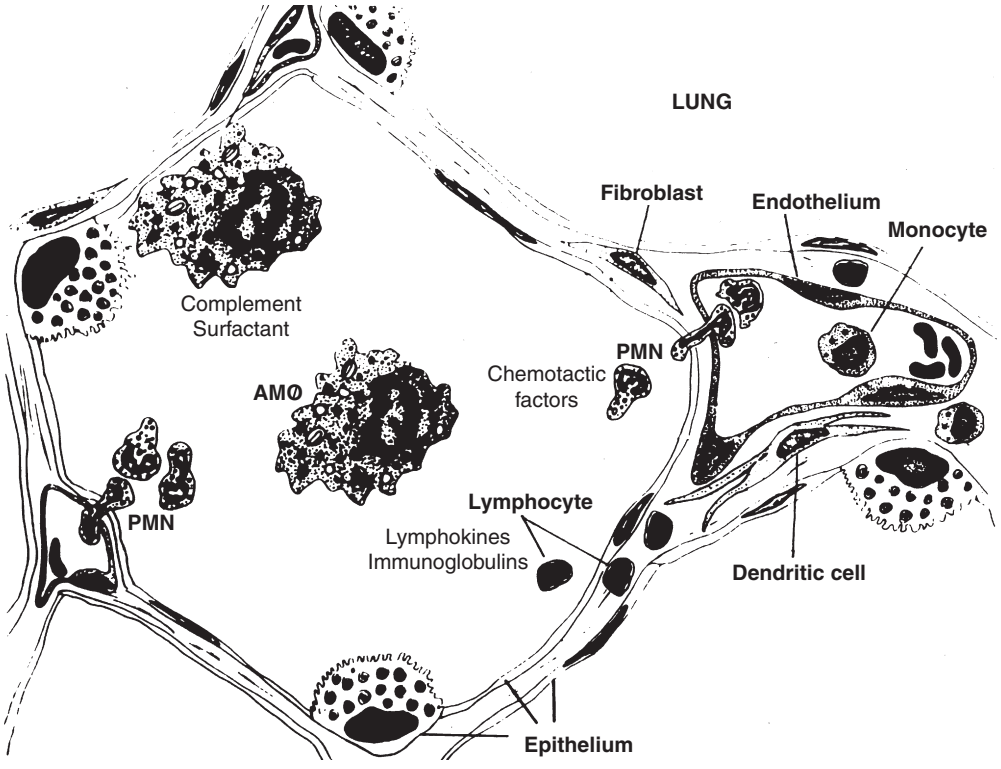

Figure 159-4 Normal alveolar architecture. Note specifically the relative location of structural cells (fibroblasts, epithelial cells, endothelial cells), which may be stimulated to participate in modulating local immune-inflammatory events. As noted in the text, vascular endothelial cells are strategically located to directly facilitate immune cell recruitment to the alveolar space. *(From Toews GB: In Shelhamer JH [moderator]:* Ann Intern Med *117:415, 1992.)*

colonization and infection.[125-127] This would be particularly problematic in cases of impaired mucociliary clearance or epithelial cell damage, yielding a partial explanation of pulmonary microbial tropism in these settings. In vitro studies have demonstrated that *S. aureus* can be internalized by a variety of nonphagocytic cells including epithelial and endothelial cells, fibroblasts, osteoblasts, keratinocytes, and kidney cells.[128-132] Furthermore, recent studies have shed light on a newly discovered mode of internalization through fibronectin-binding proteins, which may avoid fusion with the degrading lysosomes of phagocytic cells.[133-136] In the normal lung, the most important host defense role of fibronectin may be to facilitate binding of, and local colonization by, nonpathogenic organisms.

Iron-Binding Proteins

The availability of iron in the host environment and its effect on bacterial growth is one of the best studied aspects in pathogenicity.[137,138] Iron is an essential element for bacterial growth and survival, thus pathogens have evolved various ways to compete for the host's iron. Some of the strategies developed during the coevolution of host and pathogen include the production of low-molecular-mass iron–chleating compounds (siderophores); expression of transferrin and lactoferrin receptors; proteolytic cleavage of nonbinding glycoprotiens; disruption of iron-binding sites; and reduction of ferric to ferrous complex.[97,139] Host defenses that have evolved to restrict bacterial colonization or invasion include mechanisms to sequester elemental iron either in cells or complexed to transport proteins.[140] There are currently five known iron-binding proteins that have been described in human innate immunity: lipocalin, hepcidin, Nramp, the transferring family of proteins (lactoferrin and transferrin), and ferritin (cytsolic and plasma).[141-155] The primary iron-binding protein in serum is transferrin, whereas lactoferrin predominates in mucosal secretions. Because each of these proteins is present in airway mucosal secretions and airway lining fluid, they may be important local protective factors in containing microbial growth.Transferrin is found in BAL fluid in amounts between 1 and 2 times greater than matched serum; human lactoferrin is stored in specific granules of polymorphonuclear neutrophils (PMNs) from which it is released following activation.[140] It binds with high affinity to lipid A and may play an antibiotic role by depriving invading microorganisms of iron.[146,156] In contrast, lactoferrin is the predominant iron-binding protein of airway secretions and is rarely present in deep alveolar lavage unless inflammation is actively occurring; it is also stored in neutrophil granules in addition to its secretion on mucosal surfaces.

Iron-binding proteins effectively complex free iron available in mucosal secretions and alveolar lining fluid, thereby limiting the growth of most iron-dependent pathogens; notable exceptions include *Moraxella* and *Neisseria* species, which are able to obtain iron from these proteins.[157] In addition to iron binding, human lactoferrin has other antimicrobial activity against specific bacteria, including *E. coli*, *S.pneumoniae*, and *Legionella pneumophilia.*[83,158] Lactoferrin binds to LPS, disrupting gram-negative bacterial membranes, and this effect may be synergistic with the effects of other soluble components of the mucociliary layer such as lysozyme.[159] Lactoferrin also demonstrates antiviral activity, binding to HIV and cytomegalovirus (CMV), preventing their uptake by host cells.[160] Cleavage of lactoferrin by either proteases or pepsin yields a small cationic peptide, lactoferricin, with structure and antimicrobial activity similar to those of the defensins.[161] Finally, recent work suggests a unique role for lactoferrin in prevention of bacterial biofilms. Biofilm formation is a growth mode specialized for long-term bacterial colonization of surfaces, as is seen in chronic *Pseudomonas* infection; once established, organisms within biofilms are notoriously resistant to host eradication.[162] By chelating iron, lactoferrin stimulates "twitching," a pilimediated bacterial motility that deters biofilm formation. Once a biofilm has been established, however, sensitivity to this lactoferrin effect is lost.[147]

Beyond these antimicrobial effects, lactoferrin may also play an important role in modulation of local immune response. As a component of neutrophil secondary granules, lactoferrin is delivered to sites of inflammation. Here, lactoferrin binds LPS, effectively competing with LPS-binding protein and minimizing endotoxin presentation to immune cells.[163] Similarly, lactoferrin also recognizes and binds recurrent "motifs" of bacterial DNA, potentially dampening the broad proinflammatory immune responses that would ordinarily be triggered.[164] Teleologically, this may allow lactoferrin to limit excess immunostimulatory activity at mucosal surfaces with microbial exposure.

In addition to the primary iron-binding proteins, lactoferrin and transferrin, recent studies have provided insight into the antimicrobial roles of lipocalin, hepcidin, and natural resistance-associated macrophage protein (Nramp). Using a mouse model, host lipocalin has been shown to bind bacterial siderophores, thereby preventing iron acquisition by invading pathogens.[141,165] The human analogue of lipocalins was recently renamed siderocalin after demonstrating its dramatic up-regulation following bacterial colonization with *S. pneumoniae* to potentially bacteriostatic levels, stongly indicating its role as a host defense mechanism in the upper respiratory tract.[142]

Hepcidin, first discovered by Park and colleagues,[144] possesses antimicrobial activities. Originally, only hepatocytes were thought to produce this iron regulatory protein. Recent evidence, however, has demonstrated that alveolar macrophages also produce hepcidin in addition to expressing the iron importer divalent metal transport (DMT1) and iron exporter ferroportin1 (FPN1) proteins.[166] Further studies suggest that upon exposure to LPS, iron mobilization by alveolar macrophages is reduced and is mediated by hepcidin-induced degredation of the FPN1; as such, less iron is available to the pathogen.[166]

Nramp was discovered more than 30 years ago to possess antimicrobial properties. It is now widely accepted that the expression of Nramp1 (also called Slc11a1) confers innate immune defense against certain bacterial infections. It is thought to work by sequestering iron from bacteria within the phagosome or through a reaction in which iron catalyzes the production of toxic hydroxyl radicals.[167] Nramp1 has further been shown to play a role in early macrophage activation, and its expression is up-regulated by interferon γ (IFNγ), LPS, and granulocyte–colony stimulating factor (G-CSF).[87,168-171]

Antimicrobial Peptides (Defensins, Cathelicidins, Lysozyme)

One form of host defense, found in both plants and animals and therefore predating the separation of the plant and animal lineages, is the production of antimicrobial peptides. These endogenous peptides complement the activity of the larger opsonizing or nutrient-binding proteins in maintaining airway sterility (Table 159-1). They act by disrupting cell membranes of a wide range of pathogens including bacteria, viruses, and fungi; each peptide manifests a broad but fixed spectrum of activity, underscoring the need for multiple peptide classes within the airway lining fluid.[172-174] Within the respiratory tree they are either produced by epithelial cells, where their expression is both constitutive and inducible, or delivered to vulnerable loci by circulating leukocytes. Apart from their direct antimicrobial activity, which is nearly immediate in onset, these peptides can also activate cellular immunity, amplifying host response as necessary. The major human antimicrobial peptides are lysozyme, cathelicidins, and the defensins.

Defensins are small (3 to 6 kDa, 29-40 amino acids) cationic peptides containing six conserved cysteine residues. They are divided into α and β subclasses on the basis of their secondary

TABLE 159-1

Antimicrobial Products in the Mucosa (Partial Listing)

Product	Relative Concentration	Source
SLPI	μg/mL	Epithelia, Paneth cells, macrophages
Lactoferrin	μg/mL	Epithelia, Paneth cells, neutrophils
SP-A, SP-D	ng-μg/mL	Epithelia, Type II pneumocyte
α-Defensins	ng-mg/mL	Paneth cells, neutrophils
β-Defensins	ng-mg/mL	Epithelia, neutrophils, glands
Reg3γ/Reg3β	ng-mg/mL	Paneth cells
Lipocalin-2	ng/mL	Epithelia, neutrophils
CCL20	ng/mL	Epithelia, neutrophils, macrophages
PGLYRP-1	μg-mg/mL	Neutrophils, M cells
PGLYRP-3, PGLYRP-4	ug/mL	Epithelia, glands
Cathelicidins (LL37)	ug/mL	Epithelia, neutrophils

structure, but their gene locations imply a common evolutionary origin.[175] Structurally they share a β-sheet conformation that spatially segregates their cationic and hydrophobic amino acid clusters into an amphipathic motif.[176] When secreted, defensins are driven into anionic phospholipid bilayer membranes by electromotive forces where they multimerize into channels, disrupt normal membrane function, and induce cell lysis.[176,177] Although host cells are potential "bystander" targets, their lower anionic lipid content and the presence of cholesterol as a membrane stabilizer imbue significant protection.[178,179] Apart from their structural differences, the α and β defensins differ in their sites of expression and roles in airway defense.

The human α-defensins constitute a subclass of six members: four "human neutrophil peptides" (HNP-1 through HNP-4) and two "human defensins" (HD-5 and HD-6). HD-5 and HD-6 are secreted by Paneth cells of the small intestine and epithelia of the female urogenital tract and are presumed to attenuate local commensal burden; respiratory epithelia is not a source of α-defensins.[180,181] HNPs 1 through 4 are abundant (up to 50% of total protein) in primary granules of neutrophils, where they assist in nonoxidative killing, and are also found in NK cells, monocytes, and lymphocytes.[182,183] Individual α-defensins have unique spectra of antibacterial activity against gram-positive and gram-negative species, as well as activity against enveloped viruses (including *herpes* species) and activity against *Candida.*[173,175,184] The α-defensins also exhibit both proinflammatory and antiinflammatory activities. As discussed later, they are chemotactic and induce chemotaxins for a variety of immune cells. They also bind to serine protease inhibitors, amplifying PMN-derived elastase activity.[185] Conversely, they can inhibit complement activation by binding to C1q and participate in local wound repair by stimulating epithelial cell proliferation.[186,187] Extracellular α-defensins are scavenged by α_2-macroglobulin, which minimizes cytotoxicity to host cells and down-regulates defensin concentration at inflammatory sites.[188] Immunohistochemical analysis has demonstrated HNPs on bronchial epithelial surfaces and in mucinous exudate in the air spaces, presumably derived from PMN granule release within the airway.[189] In adults, α-defensins have been found in BAL fluid of patients with pneumonitis, correlating with chemotaxin concentration and PMN counts.[190]

Unlike the α-defensins, the β-defensins are produced by airway epithelium. This subclass contains four identified human β-defensins (HBD-1 through HBD-4), although more than 20 genes are postulated to exist.[191] As a group, these peptides demonstrate antimicrobial activity against several gram-positive and gram-negative organisms, as well as *Candida* and *Aspergillus* species; however, differences in antimicrobial spectra exist between individual peptides.[181,192] Histologically, β-defensins are expressed in the epithelia of airways and lung and in the serous cells of submucosal glands.[192,193] HBD-1 is found in the BAL specimens of healthy adults; its expression in the airways appears to be constitutive and noninducible.[194] In contrast, the remaining β-defensins are all inducible, with HBD-2 the best characterized. Endotoxin, *Pseudomonas,* and the cytokines TNF-α and IL-1β each induce HBD-2 expression, and this induction may be amplified further by concurrent alveolar macrophage stimulation. Apart from this interaction with alveolar macrophages, HBDs further interface with cellular immunity by functioning as chemoattractants, or "microchemokines." HBD-1 and HBD-2 are each chemotactic for immature dendritic cells (DCs), as well as memory T cells by means of ligation of the chemokine receptor CCR6. Sustained β-defensin induction by noncontained microbial stimuli may thus invoke cellular and adaptive immune responses. In vivo, tracheal aspirates of term and preterm newborns demonstrate similar levels of HBD-2 with increased levels seen in local and systemic infections. These data imply that β-defensin responses are intact even in preterm infants and that neonates may up-regulate some facets of pulmonary innate immunity in the context of a systemic inflammatory response.[195] More recent information confirms that HBD-2 is the predominat β-defensin in human neonatal lung; however, its abundance in neonatal tracheal apsirates increases as a function of gestational age. Compared to HBD-2, HBD-1 had a lower level of expression, and HBD-3 expression was absent in neonatal airway epithelial cultures.[196] Although no direct correlations have been made, it is likely that the lower levels of HBD-2 in infants may contribute to the increased susceptibility of premature infants to pulmonary infections.

Cathelicidins are a diverse family of vertebrate antimicrobial proteins found in leukocytes and on epithelial surfaces where they function like defensins. They are produced as preproproteins, stored as inactive proforms, and require enzymatic cleavage for bioactivity. The sole known human cathelicidin is hCAP-18, which requires proteolytic activation by proteinase 3 to liberate the antibacterial peptide LL-37—a 37 amino acid molecule whose amphiphilic α-helical structure facilitates affinity to and disruption of bacterial membranes. Human LL-37 displays a range of antimicrobial activities. It is a broad-spectrum antimicrobial with effects against *Actinobacillus*, *E. coli*, *P. aeruginosa*, *Enterococcus faecalis*, and *S. aureus,* and it demonstrates synergy with the defensins. LL-37 also directly binds endotoxin and is chemotactic for eosinophils, neutrophils, monocytes, and T lymphocytes.[197] LL-37 is found in primary granules of neutrophils and has also been shown in NK cells, lymphocytes, and monocytes. Expression of LL-37 in the lung is seen in cells of the submucosal glands and surface epithelia of the proximal airway, where its elaboration can be induced by up to fiftyfold in states of inflammation. Interferon-γ (IFN-γ) has been shown to induce LL-37 release, but it concurrently down-regulates gene transcription, perhaps balancing antimicrobial effects against host cytotoxicity.[192] At high concentrations, LL-37 can manifest cytotoxicity toward eukaryotic cells, and hosts have scavenging mechanisms as exist for the defensins. In vivo, comparable levels of LL-37 are found in the tracheal aspirates of term and preterm newborns, with increased levels seen in local and systemic infections. A recent study demonstrated that LL-37 is present in the airway secretions of newborns, but there was no association between concentration and gestational age.

Lysozyme is a 14-kDa cationic enzyme that hydrolyzes glycosidic bonds of bacterial cell wall peptidoglycan. This peptide is found in the granules of neutrophils and mononuclear phagocytes and is also secreted by airway epithelial cells of the pulmonary tract where it confers nonspecific antimicrobial protection. Lysozyme is highly active against many streptococci, but resistance to its enzymatic activity is common among other gram-positive organisms and nearly universal among gram-negative organisms. This is likely caused by variable accessibility of

vulnerable glycosidic bonds within the cell wall matrix with the outer membrane of gram-negative bacteria providing an additional barrier to the penetration of lysozyme. However, in the presence of other membrane-targeting substances such as complement or hydrogen peroxide, lysozyme enhances the destruction of *E. coli* and other gram-negative bacteria. Lysozyme is also capable of direct antimicrobial activity toward *Streptococcus sanguinis* and *Steptococcus faecalis* species by virtue of its cationic properties and possesses fungicidal activity against *Candida albicans* by targeting the glycosidic bonds of fungal chitin. Although lysozyme may appear redundant in the presence of other antimicrobial peptides, emerging data suggest otherwise. In vivo, a transgenic murine model of lysozyme overexpression imbued increased resistance to pulmonary infection from either *P. aeruginosa* or group B *Streptococcus*. Furthermore, lysozyme exhibits important antimicrobial synergy with HBD-2, with LL-37, and with lactoferrin. More recently, immunodepletion studies have suggested that lysozyme is a major antibacterial component secreted by submucosal glands within the tracheobronchial airways.[198] Together, these findings suggest a critical contribution by lysozyme to airway defense.

Lipopolysaccharide-Binding Protein

LPS-binding protein (LBP) is a soluble 60-kDa glycoprotein that recognizes and binds the lipid A moiety of LPS, enhancing host immune response to endotoxin. LBP is homologous to other phospholipid transport proteins and functions as a transport protein that disaggregates soluble LPS and presents it to targets on cellular membranes. Membrane bound CD14 is a PRR for LPS; however, it does not contain a cytoplasmic domain and cannot transduce activating signals across the cell membrane.[199] Instead CD14 complexes with Toll-like receptor 4 (TLR4) to form the cellular pattern recognition receptor for LPS, with TLR4 acting as the transmembrane signal-transducing portion of the receptor. LPS-induced signaling through the CD14/TLR4 complex, expressed on inflammatory cells, is distinctly enhanced by the presense of LBP, resulting in the production of "early response" cytokines TNF-α and IL-1β.[200,201] LBP is produced primarily in the liver as an acute phase protein, and its plasma concentration increases exponentially during acute inflammatory responses. LBP is also a normal constituent of lung fluid, with alveolar concentrations estimated at 1 μg/mL; these concentrations also increase exponentially with pulmonary inflammation, likely owing to capillary leak of plasma LBP and enhanced local generation. The relevance of LBP to pulmonary host defense is suggested by murine transgenic models of LBP deficiency; such mice exhibit blunted alveolar bacterial clearance with increased bacteremia and lethality in response to pneumonia. Despite these findings, pulmonary sources of LBP remain a focus of inquiry. Human alveolar type II epithelial cells demonstrate capability ex vivo to up-regulate LPB production in response to mediators (TNF-α, IL-1β, IL-6) that similarly induce hepatic acute phase production of LBP. Additionally, animal models suggest that in the neonate, alveolar macrophages may be a concurrent source of LBP in the lung. Although elevated serum levels of LBP have been reported in neonatal sepsis, pulmonary LBP expression in response to respiratory infection remains unquantified in this population. The most recent studies of infant LBP suggest its use as a viable diagnostic tool for neonatal bacterial infections.[202]

Pulmonary Collectins

Pulmonary surfactant is a bioactive material that bathes the alveolar surfaces and keeps alveoli from collapsing during expiration by reducing surface tension at the air-liquid interface.[203] It is a mixture of lipids and proteins, whereby dipalmitoylphosphatidylcholine (DPCC) functions as the primary lipid for lowering surface tension. The four known surfactant protein are SP-A, SP-B, SP-C, and SP-D. Together, they have several important functions including regulation of surfactant lipid metabolism, lipid membrane organization, and pulmonary host defense.[194] As with the lipid components of pulmonary surfactant, SP-B and SP-C are extremely hydrophobic and function primarily to reduce surface tension and maintain pulmonary homeostasis after birth.[204] The role of pulmonary host defense rests with SP-A and SP-D, which along with mannan-binding lectin make up a family of carbohydrate-binding proteins known as collagenous C-type lectins or collectins. These proteins are characterized by a discrete, four-domain primary structure consisting of a cysteine-containing N-terminus, a subsequent collagen-like region, a coiled neck region, and a C-terminal carbohydrate recognition domain (CRD).[205] Collectins function as soluble scavenger receptors, interacting through their lectin CRDs with microbial carbohydrate and glycolipid PAMPs to enhance phagocytosis and pathogen clearance; through this mechanism, collectins exhibit activity against a broad range of bacterial, viral, and fungal pathogens. Beyond these opsonizing qualities, SP-A and SP-D each exerts specific immunomodulatory effects that titrate the magnitude of inflammation and influence pulmonary immune responses.[93,206]

SP-A and SP-D share many characteristics related to their synthesis and bioactivity. Both collectins are produced by type II alveolar epithelium and Clara cells and are secreted into the alveoli and distal airway. Production and secretion of both proteins increase dramatically during the third trimester of fetal lung development and appear to be further inducible in utero in response to dexamethasone; both proteins are also up-regulated in response to acute lung injury or epithelial activation by microbial products such as LPS. The pulmonary collectins directly interact with a variety of microorganisms.[207-209] Both SP-A and SP-D bind with broad specificity to bacteria including *Klebsiella pneumoniae, P. aeruginosa, H. influenza, S. pneumoniae, S. aureus, E. coli, Mycobacterium tuberculosis,* and *Mycobacterium avium.* Pathogen encounter with lung collectins results in agglutination and/or opsonization. Agglutination impedes microbial invasion and colonization and facilitates clearance by the mucociliary escalator, whereas agglutination of viruses enhances their internalization by neutrophils. Alternatively, SP-A or SP-D may act as opsonins by bridging between PAMPs on the microbial surface and collectin receptors on phagocytes. The pulmonary collectins also enhance specific leukocyte functions. Both SP-A and SP-D are chemotactic for neutrophils and macrophages, although SP-D is more potent in this regard. SP-A and SP-D both enhance alveolar macrophage phagocytic function and oxyradical production. Induction of this latter effect requires the collectin CRD(s) to concurrently engage ligand; this presumably minimizes spurious up-regulation of potentially injurious mediators. Finally, although earlier studies suggested a direct inhibition of T-cell proliferation by SP-A and SP-D, recent evidence demonstrates that this inhibition may be a result of the presence of TGF-β in surfactant protein preparations.[210] Although the relationship between SP-A and TGF-β has not been fully described, it is postulated that SP-A acts as a storage site for latent TGF-β in the lung, thereby indirectly participating in the control of inflammation.[210] Despite their many shared functions, SP-A and SP-D exhibit several biochemical differences that result in distinctive, unshared activities in vivo. Relevant differences include solubility, CRD specificity, length of collagen domain, and affinity for available collectin receptors.

About 30% of the pulmonary collectin pool is made up of SP-D, the product of a single gene. SP-D exists primarily in a cruciform structure: four homotrimeric subunits radiating from a disulfide-linked hub. Unlike SP-A, it is relatively impervious to proteolytic or elastase degradation. Its up-regulation secondary to LPS-induced cytokines confirms its role in innate host defense. SP-D binds specifically to carbohydrates containing glucopyranosides, resulting

in affinity for the core oligosaccharides of LPS, the mannose-rich oligosaccharides of influenza A hemagglutinin, and fungal cell wall glycoconjugates of *Candida* and *Pneumocystis carinii*. SP-D binds to the putative collectin opsonin receptor, gp-340, a macrophage scavenger receptor, and CD14 via interactions between the CRD and the N-linked oligosaccharides on CD14; SP-D inhibits the interactions between CD14 and LPS.[211,212] Attempts to further clarify the role of SP-D in host defense have led to the development of transgenic murine models of SP-D deficiency. Such mice exhibit a phenotype of pulmonary alveolar proteinosis, with foamy activated macrophages, hypertrophy of alveolar type II cells, and increased inducible inflammatory responses.[213] SP-D-deficient mice show impaired functions of host defense against *H. influenza,* group B *Streptococcus* (GBS), influenza type A virus, and respiratory syncytial virus (RSV), but lack of SP-D does not affect newborn survival from infection.[214-216]

In contrast, about 70% of the pulmonary collectin pool is made up of SP-A, the product of two genes, SP-A1 and SP-A2, each producing different chain types. The SP-A subunit can therefore exist as a homotrimer or heterotrimer, introducing heterogeneity to this protein. Differential tissue expression has been reported, with SP-A1 expressed in the lower respiratory tract and SP-A2 expressed in the tracheal and bronchial epithelium and submucosal glands. Its production is up-regulated by interferon-γ (IFN-γ) and other LPS-induced cytokines. Its short collagen domain and preferred hexameric structure result in a "flower bouquet" pattern, and this clustering of CRDs influences ligand selectivity. SP-A binds specifically to carbohydrates including fungal wall glycoconjugates and some capsular polysaccharides. It also binds a variety of lipids including the lipid A moiety of LPS. Leukocyte receptors for SP-A include the C1q receptor, SPR210, the 210-kDa receptor specific for SP-A, the gp-340 receptor, and CD14. Multiple studies suggest that SP-A influences LPS-CD14 binding; however, reports disagree on whether SP-A promotes or inhibits this interaction.[212,217,218] SP-A–deficient mice exhibit increased susceptibility to many pathogens including GBS, *H. influenza,* RSV, *P. aeruginosa,* and *Pneumocystis jirovecii.*[214, 219-221]

SP-A exhibits a variety of immunoregulatory activities within the alveolus. It suppresses IFN-γ, an activator of leukocyte and macrophage inflammatory activity and an essential mediator for transition to a lymphocyte-mediated adaptive immune response. SP-A may also dampen LPS-dependent cellular activation by competing with LBP. Taken together with the reported SP-A/TGF-β inhibition of T-cell proliferation, these functions suggest that SP-A acts, at least in part, by tempering inflammation that might induce alveolar injury. Such a host-protective role would be consistent with transgenic models of SP-A deficiency, where microbial challenge results in delayed pathogen clearance, increased pathogen dissemination, and enhanced inflammation with increased production of TNF-α, IL-1β, and IL-6. This paradigm, however, is complicated by contradictory data regarding SP-A induction of proinflammatory cytokines and up-regulation of inducible NO synthase (iNOS). These disparate findings are reconciled by recent observations that the response to SP-A is determined by the state of cell activation and concurrent stimuli. Thus SP-A up-regulates iNOS in alveolar macrophages primed by IFN-α and stimulated by LPS, but conversely inhibits LPS-induced iNOS if IFN-γ priming has not occurred. SP-A, therefore, augments an inflammatory response already under way but dampens similar responses evolving de novo. In this context, SP-A induction of iNOS also exerts host protective effects. In a murine model of tuberculosis, exogenous SP-A enhances pathogen entry into alveolar macrophages by almost fivefold. This enhanced entry resulted from SP-A ligation of the SPR210 receptor with increased endocytosis of the SP-A:BCG complex; SP-A–mediated up-regulation of NO; and TNF-α production, achieving increased mycobacterial killing. SP-A similarly enhances *Mycoplasma* killing through analogous NO-dependent mechanisms.

SP-A and SP-D exhibit only partial redundancy of their bacterial specificities, owing to their distinct structures and their differing affinities for specific carbohydrates and lipids. These differences may result in complementary functions that enhance the antimicrobial activity of surfactant in toto. One example of such synergy is illustrated by collectin interactions with *Klebsiella,* a pulmonary pathogen that can reversibly switch between encapsulated and unencapsulated phenotypes. Unencapsulated forms of this organism allow optimal adhesion to the epithelial surface, facilitating colonization; these forms predominate early in infection. As noted earlier, SP-A binds to lipid A of LPS whereas SP-D preferentially binds to the LPS core sugars. Because lipid A is embedded within the bacterial cell wall and inaccessible to SP-A, SP-D is the primary collectin ligand for LPS expressed on the surface of unencapsulated forms. Encapsulation limits interaction of SP-D with the underlying LPS but invokes significant binding by SP-A, which recognizes the capsular polysaccharides expressed by this pathogen. In this scenario, SP-A and SP-D thus fulfill distinct but complementary opsonizing roles in the innate host response, as depicted in Figure 159-5. Similar complementary function is illustrated by collectin interaction with influenza A virus (IAV). SP-D binds viral envelope glycoproteins (hemagglutinin and neuraminidase) through its CRD and induces massive agglutination of IAV particles; this agglutination is facilitated by higher-order oligomerization, most achievable by SP-D by virtue of its longer collagen domain. Such agglutination generates particle size sufficient for mucociliary clearance and also directly enhances neutrophil uptake and respiratory burst. Alternatively, SP-A activity results from IAV recognition and binding of sialic acid residues on this collectin. SP-A has much less agglutinating capacity, but interacts with a broader range of IAV strains including those that are highly resistant to inhibition by SP-D or serum collectins. SP-A forms much smaller aggregates, resulting in less augmented neutrophil uptake but enhanced uptake by alveolar macrophages. As before, the differing collectin structures and binding affinities result in a broader range of antimicrobial activity and immune cell activation, which ultimately prove to be beneficial to the host.

Immunomodulating Role of Surfactant

Apart from the specific actions of its collectins, surfactant also exerts a host of immunomodulatory effects within the alveolus. Surfactant enhances phagocytosis by means of a mechanism separate from the actions of SP-A. Interestingly, this prophagocytic effect is more pronounced for resident alveolar macrophages than for recruited peripheral blood monocytes. Whole surfactant reportedly suppresses mononuclear cell oxyradical production by inhibiting the intracellular assembly of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, impairing hydrogen peroxide generation. However, specific lipid components of surfactant may exert different modulatory effects. Therefore, although macrophage oxidative burst is blunted by phosphatidylglycerol moieties, it is enhanced by phosphatidylcholine components. Enhanced microbicidal function of phagocytes and down-regulation of Fc receptors have each been reported and attributed to the lysophospholipid and free fatty acid components of surfactant. Whole surfactant also modulates phagocyte chemotaxis. Macrophage movement into the alveolus postnatally coincides with increased surfactant synthesis, suggesting a chemotactic effect, possibly SP-A mediated. Conversely, DPCC treatment of alveolar macrophages in vitro decreases their migration in response to serum chemotaxins; this is consistent with a teleologically preferred "default" attenuation of inflammatory

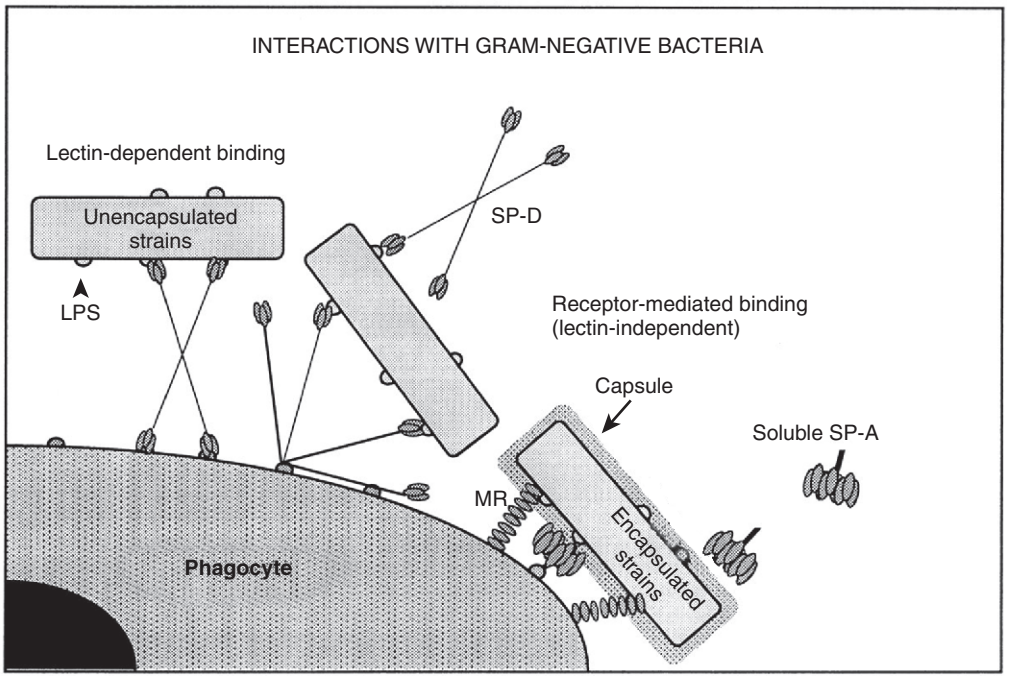

Figure 159-5 SP-A and SP-D are complementary opsonins for gram-negative bacteria. SP-D binds to LPS core sugars exposed by nonencapsulated variants, the phenotype required for colonization and invasion. Encapsulation increases pathogenicity and limits SP-D binding, but allows SP-A recognition and binding of capsular polysaccharides. Subsequent phagocytosis may occur through SP binding to phagocyte surface carbohydrates (lectin-dependent) or may be receptor mediated (lectin-independent), as depicted by SP-A engagement of mannose receptors. *(From Crouch EC:* Am J Respir Cell Mol Biol *19:177–201, 1997.)*

response designed to preserve alveolar function. Lastly, surfactant reportedly modulates lymphocyte function as well. Lymphocytes exposed in vitro to surfactant are less responsive to mitogens and exhibit depressed function; under similar conditions, cytotoxic T cells, B cells, and NK cells are all inhibited to various degrees. As discussed earlier, however, some lipid components (DPCC, phosphatidylglycerol) are more suppressive, whereas less abundant components (cholesterol, sphingomyelin) stimulate lymphocyte proliferation; this suggests that conditions that alter these phospholipids ratios may alter adaptive immune responses. Additionally, the differing effects of SP-A and surfactant lipids on lymphocyte proliferation are consistent with the hypothesis that, in some scenarios, surfactant lipids and proteins may be counterregulatory.

In contrast to whole surfactant, conventional surfactant analogues (Exosurf, Survanta) contain neither SP-A nor SP-D. Consequently, collectin-mediated immune effects are not provided by exogenous replacement therapies. Moreover, the surfactant replacements are generally immunosuppressive, presumably owing to their nonphysiologic lipid/protein ratios. Both Exosurf and Survanta have been shown to inhibit production of the early response cytokines TNF-α, IL-1β, and IL-6 by stimulated alveolar macrophages, putatively by depressing activation of the nuclear transcription factor NF-κB. Similar suppression of fibroblast-derived IL-6 and prostaglandin E_2 (PGE_2) has also been described, suggesting impairment of those inflammatory responses up-regulated by alveolar cytokine networks. Additionally, Survanta has been shown to blunt lymphocyte proliferation, killer cell cytotoxicity, and adhesion molecule expression, possibly through down-regulation of lymphocyte receptors for IL-2. Much of this is in vitro data and must therefore be interpreted cautiously; however, it suggests that available surfactant replacement therapies, although efficacious in normalizing pulmonary compliance, may concomitantly attenuate normal alveolar immune cell responses.

Nitric Oxide

NO is a short-lived, oxyradical-related bioactive mediator with potent vasodilatory actions. It mediates and modulates pulmonary transition from fetal to postnatal life and plays a role in both immune regulation and innate host defense. NO is synthesized by 3 nitric oxide synthase isoforms (NOS-1, -2, and -3), all of which are expressed in the airway epithelium from the bronchus to the distal air space[222]; thus NO is produced along the entire length of the human airway and is present in airway lining fluid at concentrations of about 15 μm.[222] NO isoforms exist in either constitutive (NOS-1, NOS-3) or inducible (NOS-2) forms; cells with constitutive NOS include neurons, vascular endothelium, neutrophils, and platelets. Cells with inducible NOS (iNOS; NOS-2) are recruitable to generate NO and include mononuclear phagocytes, alveolar macrophages, vascular smooth muscle cells, epithelial cells, type II pneumocytes, and hepatocytes.[223-228] All NOS isoforms are detected early in lung development and ontogeny shows no significant changes in abundance or distribution with advancing gestational age.[222]

NO exerts potent cytotoxic and inflammatory effects, which support its role as an antimicrobial molecule during host response to infection. NO production from cells containing iNOS is induced by microbial products such as lipoteichoic acid, endotoxin, and bacterial DNA. Locally produced NO inhibits sodium uptake from the apical surface of airway epithelial cells, increasing airway hydration and enhancing mucociliary clearance. Specific NO products such as nitrosylated thiols exert antimicrobial activity by killing the pathogen directly or by inhibiting the pathogens' replication. NO inhibits the growth of a wide variety of organisms including viruses, bacteria, parasites, and fungi, presumably by targeting microbial DNA and cysteine proteases, which are critical for virulence or replication of these pathogens.[229-231] NO appears to be particularly important in the innate immune response to intracellular organisms such

as *Listeria monocytogenes, Salmonella,* and *Mycobacterium tuberculosis.*[232] NO products also inhibit viral RNA synthesis, inactivate a broad range of microbial proteins by S-nitrosylation, and induce membrane damage through lipid peroxidation. By up-regulating inflammatory cell function; NO augments macrophage motility, up-regulates surface expression of complement and immunoglobulin Fc receptors, and stimulates leukocyte respiratory burst. Concurrent synthesis of NO increases microbicidal activity of the leukocyte respiratory burst by generating additional cytotoxic radicals such as peroxynitrite, which possesses potent activity against bacteria and *Candida.* In vitro, phagocytes demonstrate diminished microbicidal activity after NOS inhibition, and this correlates with in vivo models in which diminished NOS activity impairs microbial clearance.

The role of NO in pulmonary microbial clearance is consistent with recent neonatal data. BAL specimens from preterm (≤32 weeks estimated gestational age) infants exposed to intrauterine infection demonstrated a strong association between inability to express iNOS or up-regulate NO and subsequent development of fulminant pneumonia. Conversely, newborns of similar age and risk that did not develop pneumonia exhibited iNOS up-regulation and increased NO products on BAL analysis, relative to either their pneumonic cohorts or noninfected controls. A separate retrospective analysis of lung tissue from neonatal autopsies yielded similar findings; alveolar macrophage–derived iNOS could not be detected in specimens from fulminant pneumonia patients but was demonstrable in controls. Taken together, these data suggest that delayed or diminished macrophage–derived NO in the setting of neonatal pulmonary infection correlates with increased morbidity. Etiology of this impaired response is speculative, but may result from a paucity of mediators (TNF, IFN-γ) known to up-regulate iNOS expression. Based on the important antimicrobial function of NO, recent studies have evaluated the role of inhaled NO on pulmonary infections in humans. These studies have gerenated mixed results to inhaled NO therapy, however it is likely that infections caused by intracellular organisms will be more likely to benefit from inhaled NO therapy.[233-236]

In general, NO exerts antimicrobial effects; however, not all pathogens are inhibited by NO and in some instances may contribute to infectious disease pathogenesis. In an influenza pneumonia mouse model, targeted deletion of iNOS or treatment with NOS inhibitors led to less severe disease compared with control mice.[237] Similar observations were made in mouse models of *M. avium* pneumonia and herpes simplex virus encephalitis.[238,239] It is postulated that in these disease processes, cytotoxic effects of NO on host cells may contribute to pathogenesis.

Beyond the functions just detailed, NO exhibits additional immunomodulatory activities relevant to pulmonary host defense, which is demonstrated through its up-regulation by immune activating cytokines such as IFN-γ, TNF-α, IL-1, and IL-2. NO has been shown to reduce T helper 1 (Th1) proliferation and IL-2 synthesis while increasing IL-4 synthesis by T helper 2 (Th2) cells.[240-242] Th1 cells produce IFNγ, which is an essential cytokine in viral cell–mediated immune responses. Alternatively, Th2 cells selectively produce IL-4 and IL-5 that participate in the development of humoral immunity. NO-induced imbalance in the Th2/Th1 ratio may promote inflammation in allergic diseases like asthma while inhibiting the inflammatory response to viral and bacterial pathogens.[243] RSV is a common pulmonary infection in infants, which has been linked to a large Th2/Th1 cytokine immune response; it has been associated with the pathogenesis of RSV bronchiolitis and severity of infection in infants.[244-246]

NK cells are specialized cytotoxic lymphocytes and a primary source of IFN-γ within the alveolus; they are normally activated by IL-12. Transgenic iNOS deficiency reportedly induces a phenotype of IL-12 deficiency despite normal IL-12 levels. This phenotype is characterized by diminished IFN-γ and increased transforming growth factor-β (TGF-β), a cytokine milieu suppressing local macrophage function. Analysis of these data subsequently identified iNOS-derived NO as an essential "cosignal" for IL-12 signal transduction and activation of NK cells. In this model, the signaling role of NO was therefore critical in maintaining a cytokine microenvironment that allowed normal immune cell function. NO exerts a biphasic effect on NF-κB activity, which is dependent on local NO concentrations; as such, NO is able to both up-regulate and down-regulate the expression of a number of inflammatory mediators. In this paradigm, immune activation up-regulates iNOS, generating increased NO. Initial NO activation of NF-κB promotes expression of adhesion molecules and proinflammatory cytokines, facilitating immune cell recruitment. NF-κB up-regulation of iNOS amplifies NO production, eventually generating local NO concentrations sufficient to inhibit NF-κB activity. At this point, both inflammatory cytokine and adhesion molecule expression down-regulate, effectively dampening the component of inflammation sensitive to modulation by NO. In summary, the putative actions of NO in immune cell signal transduction suggest a sentinel role for this molecule in both the initiation and suppression of cellular immunity.

Carbon Monoxide

As with NO, evolving data suggest a potential role for carbon monoxide (CO) in pulmonary host defense. Endogenous CO derives from degradation of hemoglobin, myoglobin, NOS, and cytochromes by the enzyme heme oxygenase (HO). HO immunoreactivity is found throughout the airway in respiratory epithelium, alveolar macrophages, seromucous glands, and nose and paranasal sinuses. Like NOS, HO exists in constitutive (HO-2) and inducible (HO-1) isoforms. Whereas HO-2 is basally expressed in most tissues, HO-1 is identified as a heat shock protein inducible by a variety of stimuli including microbial toxins, proinflammatory cytokines, and reactive oxygen or nitrogen species; both isoforms are substantially expressed in human lungs. HO-1 is a cryoprotective and antiinflammatory enzyme that plays a critical role in defending the body against oxidant-induced injury during inflammatory processes.[247] It catalyzes the first and rate-limiting step in the oxidative degradation of heme to CO and two other molecules, biliverdin and ferrous iron, with cytoprotective properties.[248-250] The antiinflammatory properties of HO-1 are related to inhibition of adhesion molecule expression and reduction of oxidative stress, while exogenous CO gas treatment decreases the production of inflammatory mediators such as cytokines and NO.[251] Like iNOS, HO is induced by many infectious agents, and levels of carboxyhemoglobin and/or exhaled CO are reportedly elevated in patients with viral or bacterial respiratory tract infections. Unlike NO, however, the direct effects of CO appear less microbicidal and more antiinflammatory, or host cytoprotective. In vitro and in vivo, CO has been shown to inhibit endotoxin-induced proinflammatory cytokines, including TNF, IL-1β, and macrophage inflammatory protein-1β (MIP-1β) while concurrently up-regulating the antiinflammatory IL-10. Furthermore, in a murine model of influenza A pneumonitis, overexpression of HO-1 resulted in diminished respiratory epithelial cell apoptosis and decreased lung inflammation. Interestingly, HO appears to counteract the cytotoxicity caused by excessive production of NO.[252-255] The up-regulation of iNOS in inducible pulmonary cells upon exposure to LPS results in a burst of NO generation that is essential for bactericidal effects. However, increased amounts of NO are also associated with deleterious effects such as tissue damage.[256] Thus induction of HO-1 significantly reduces NO production and potentially restores cellular homeostatsis.[247,257] It is well accepted that HO-1 and CO play an important role in minimizing injurious inflammatory processes during infection and other inflammatory states. Recent evidence, however, has identified an antimicrobial role for CO during infection. Both in vitro and in vivo studies have demonstrated that CO increases

macrophage and neutrophil phagocytosis of the pathogenic organisms *E. coli* and *E. faecalis,* respectively.[258,259]

Cellular Elements of Innate Immunity

As discussed earlier, effective host response to incipient respiratory infection relies primarily on rapid clearance of the offending pathogen(s). When soluble components of innate immunity are insufficient to achieve organism clearance, cellular immune effectors are invoked. Cellular elements of pulmonary innate immunity include resident alveolar macrophages and DCs, as well as neutrophils and monocytes recruited to the air space. The initial interaction of these cells with microorganisms is mediated by soluble and membrane-bound PRRs that recognize and engage the common microbial motifs characteristic of PAMPs. Soluble factors such as the collectins and LBP utilize specific cell receptors to "present" organisms for phagocytosis and induce cell activation. Once activated, these cells generate signals that either further amplify innate immune responses or, alternatively, initiate transition to adaptive immunity. Of the cellular PRRs, CD14 appears to be the sentinel receptor for activating alveolar macrophages and inducing cytokines that extend pulmonary immune responses.

CD14 recognizes and binds LPS presented as a complex with LBP; however, for this interaction to induce cell activation, CD14 must interact with a second membrane protein, TLR4. TLRs are highly conserved transmembrane proteins, initially recognized in *Drosophila,* that mediate recognition of microbial products. The cytoplasmic domains of the TLRs are homologous to the IL-1 receptor, suggesting common signal transduction pathways. There are 10 TLR genes expressed in humans that are each devoted to recognizing components characteristic of pathogenic organisms. TLR4 confers responsiveness to endotoxin. TLR1 and TLR2 confer responsiveness to gram-positive bacteria, mycobacteria, and yeast. TLR3 confers responsiveness to viral double-stranded mRNA. TLR5 confers responsiveness to flagellin, and TLR9 confers responsiveness to bacterial DNA. TLRs thus provide specificity to the initial recognition of pathogens, even in the setting of "nonspecific" inflammatory cell response. Engagement of these receptors activates signal transduction pathways that overlap with IL-1β–dependent signaling pathways, generating the "early response" cytokines TNF-α and IL-1β. These cytokines enhance the microbicidal activity of alveolar macrophages and also activate other cells within the alveolus. Whereas this results in immediate amplification of inflammation, it also induces elaboration of pleiotropic cytokines that recruit lymphocytes, activate DCs, and eventually orchestrate the transition to an adaptive immune response. Innate immune pulmonary cells can be broadly classified as those that are normal residents of the lung (macrophages, dendritic cells, and mast cells) and itinerant cells that are recruited in response to infection (neutrophils and monocytes).

Macrophages

Macrophages are primary effector cells of innate immunity serving important functions of phagocytosis, microbial killing, accessory immune function, and regulation of local inflammatory processes through cytokine secretion.[260] Within the lung, pulmonary macrophages constitute a cell population of diverse function and origin. Previously thought to be monocyte derived, fetal pulmonary macrophages have been shown to precede formation of myeloid elements in the liver and bone marrow.[261] Initially present as so-called angular cells within the extravascular stroma, these cells lack the morphologic appearance of differentiated phagocytes, but proliferate and differentiate ex vivo in response to colony-stimulating factors such as granlocyte macrophage colony–stimulating factor (GM-CSF) elaborated by lung stromal elements.[262] Postnatally, descendants of fetal macrophages likely constitute a self-renewing portion of the alveolar macrophage population, which may be supplemented by cells of myeloid origin.[263] Under conditions of inflammation, peripheral blood monocytes may be recruited to the lungs where they undergo local differentiation depending on their site of influx.[264] Recruited monocytes, like the angular cells, mature into alveolar macrophages, interstitial macrophages, airway macrophages, or DCs depending on local growth factors and other stimuli; though sharing some functions, each type has slightly different characteristics, perhaps owing to its particular microenvironment.[265,266] The relative number of functional pulmonary macrophages in the neonate is uncertain, however, a recent analysis of 12 term and 11 preterm infants identified 75.8% ± 11.35% of cells in tracheal lavage fluid were alveolar macrophages.[267] Normal resident cell populations are absent from both the airway of stillborn infants and BAL of preterm infants at cesarean section.[268,269] Because true alveolar macrophages are found in infants by 48 hours postnatally, rapid expansion of this cell population clearly occurs. This is consistent with simian models, where alveolar macrophage numbers increase to near adult levels by 48 hours postnatally, temporally associated with increased alveolar surfactant levels.[270] Once macrophage population of the lungs has occurred, the relatively long life span (months) and dual sources of repletion maintain stable lung macrophage numbers, even under conditions of myelosuppression.[271-273]

Phagocytic activity of alveolar macrophages is essential for clearing air stream particulate matter, macromolecular debris (immune complexes, protease-antiprotease complexes, nonfunctioning surfactant, apoptotic cells), and microbes.[260,274] Redundancy and ruffling of the alveolar macrophage cell membrane provide an expanded surface contact area and facilitate the pseudopodal extensions characteristic of phagocytic "engulfing." Alveolar macrophage phagocytosis may be nonspecific or triggered by "pattern-recognition" cell surface receptors that recognize a number of foreign ligands. These include TLRs (TLR2 and TLR4), which bind LPS, and CD14, which recognizes LBP-LPS complexes.[275-277] Other pattern-recognition receptors bind mannose, fibronectin, or surfactant proteins, whereas more specific receptors recognize complement components (C1q and C3b) and the Fc portion of most immunoglobulins.[278-282] If the ingested material is degradable, normal alveolar macrophage surveillance function continues; otherwise, the alveolar macrophage may be removed by upward clearance mechanisms along the respiratory epithelium and mucociliary ladder or through the interstitium by means of regional lymphatic drainage.[283] Studies comparing cord blood monocytes to adult macrophages demonatrate an impaired response to LPS, owing to a decreased expression of the adaptor protein MyD88 rather than TLR4 or CD14.[284] Moreover, recent neonatal studies have demonstrated an impaired monocyte and macrophage response to multiple TLR ligands, further implicating the TLR pathway in contributing to the increased infant susceptibility to pulmonary infections.[285]

After phagocytosis, the plasma membrane–contained particle is internalized by the alveolar macrophage, forming an intracytoplasmic vacuole. This vacuole then fuses with any number of secondary lysosomes to form a phagosome. TLRs may be recruited to phagosomes to sample their contents and initiate an inflammatory response appropriate for the specific organism.[286] Within phagosomes, lysozyme, proteases, and acid hydrolases released from secondary lysosomes will digest most particles; however, because many cell wall–containing bacteria are resistant to enzymatic killing, other mechanisms for their biodegradation must be invoked. In these instances, microbicidal effect is achieved by "oxidative burst" generation of highly cytotoxic reactive species of oxygen and nitrogen, in which electron transfer to the terminal NADPH oxidase in the membrane of the phagolysosome can result in local production of superoxide anion, hydrogen peroxide, hydroxyl radical, singlet oxygen, and NO.[287,288] Alveolar macrophages can also generate NO by expression of iNOS.[289] In the

context of these important phagocytic and microbicidal roles, animal and human studies consistently describe depressed levels of neonatal alveolar macrophage function. When neonates of various species are challenged with airway bacterial inoculums in vivo, alveolar macrophage rates of phagocytosis are prolonged, especially in premature subjects; impairment of phagocytosis is also seen in vitro. [290-292] Similarly, neonatal alveolar macrophage antimicrobial activity is also diminished; this may correlate with diminished oxidative burst capacity, deficiency of stored lysosomal materials, or poor TLR4 surface expression.[293]

In contrast to commonly encountered bacteria, viruses and other nonviral intracellular pathogens such as mycobacteria have evolved mechanisms to elude macrophage killing and survive within these cells. Relevant intracellular pathogens of the neonate include *Toxoplasma gondii*, *Listeria monocytogenes*, and herpes simplex virus (HSV); control of infection caused by these organisms therefore relies on mechanisms of enhancing microbicidal activity of the host macrophage. Under most situations of intracellular parasitism, specific cytokines such as IFN-γ, TNF-α, and GM-CSF are generated to stimulate macrophage killing of these organisms.[294,295] Altered signal transduction in response to IFN-γ has been reported for neonatal alveolar macrophages; however, data suggest that these cells can be sufficiently activated by IFN-γ to achieve intracellular killing comparable with that achieved by adult macrophages, and similar data exist from animal models of *Listeria* and HSV infection.[85,296-298] These observations have led to work demonstrating markedly decreased basal and inducible levels of T cell–derived IFN-γ in neonates, attributed to lack of priming of the naive T cell by foreign antigen.[299] Decreased IFN-γ secretion by neonatal monocytes has also been reported.[300] This delay in development of antigen-specific memory T cells, coupled with suboptimal capacity for IFN-γ expression by other cells, may account for greater neonatal susceptibility to these pathogens.

In addition to microbial killing by phagocytosis, alveolar macrophages have accessory roles in multiple other immune responses. Alveolar macrophage may contribute to infection control by direct or antibody-mediated cytotoxicity for cells expressing microbial antigens.[301] Alveolar macrophage can also metabolize complex antigens and "present" small antigen fragments to T cells. There is evidence to suggest that a lack costimulatory signals for T-cell activation reduces their effectiveness in this role; however, other studies suggest that poor up-regulation of such costimulatory molecules and antigen presenting molecules, as well as other, yet unknown, mechanisms may contribute to the increased pulmonary infections in infants.[302-305] Finally, the capacity to generate various chemotaxins and cytokines allows the alveolar macrophage to recruit multiple types of inflammatory cells to the alveolus and regulate the ensuing local inflammatory response. Although macrophage-derived IL-1 production for term and preterm neonates corresponds to that of adults, both TNF-α and IL-12 production are less than seen in adults and are markedly depressed (≤25%) in premature neonates; it has been suggested that the reduced macrophage production of IL-12 is linked to IFNγ deficiency in neonates.[101,306,307] Moreover, neonatal macrophage-derived TNF-α production is less inducible by IFN-γ than in adults. Deficient production of IFN-γ by neonatal T cells, as previously discussed, may further depress neonatal alvelor macrophage TNF-α production, diminishing alveolar macrophage capacity to fully respond to alveolar pathogens, thus creating a cyclic depression of cytokine production in the neonate.

Polymorphonuclear Neutrophils

Unlike macrophages, neutrophils are not tissue-fixed. They have a short life cycle which is spent primarily in the blood until called upon to fend of an invading pathogen. Although resident macrophages are the first to respond to an infectious process in the lungs, they are soon reinforced with large numbers of neutrophils from the pulmonary circulation, a major reservoir for marginated neutrophils. Emigration of PMNs from the local circulation into the respiratory tract is a dynamic process requiring the generation of signals that sustain PMN contact with the vascular endothelium and induce transendothelial diapedesis and chemotactically directed migration to the inflammatory locus. This adherence process is dependent on the expression of specific, corresponding adhesion molecules on both the endothelial cell and PMN surfaces, whereas diapedesis and migration are induced by the local elaboration of specific chemoattractant factors. Once recruited and activated, PMNs, like alveolar macrophages, attempt to contain invading pathogens by means of receptor-mediated phagocytosis. This results in exposure of engulfed pathogens to antimicrobial substances (defensins, bactericidal/permeability-increasing protein, serprocidins, lysozyme) found in primary granules of the PMN and to reactive oxygen species produced by the PMN "oxidative burst."[287,308-310] Unlike macrophages, however, a neutrophil that has phagocytosed a foreign particle will die soon after, whereas a macrophage can repeat this process many times. PMNs may also function locally to generate further chemotactic, proinflammatory mediators such as arachidonate metabolites and IL-8, further amplifying the local inflammatory process.[311]

Several facets of PMN physiology unique to neonates may result in blunted granulocyte recruitment relative to that seen in older children or adults. Systemically, there is diminished capacity to accelerate PMN production in response to infection, owing to both a limited PMN storage pool and already near-maximal baseline levels of PMN production.[312,313] Shorter survival times of neonatal PMNs suggested by in vitro data may contribute to more rapid depletion and hence a smaller storage pool. Specific PMN functions are also compromised in the neonate, possibly secondary to diminished LPS binding capacity and hence less endotoxin responsiveness.[314] In vitro studies suggest dual defects in neonatal PMN adhesion, resulting in only 40% to 45% binding activity to activated endothelium relative to adult PMNs. Mechanisms identified are a relative deficiency of L-selectin on the neonatal PMN surface and inability of activated PMNs to up-regulate expression of the β2-integrins; the net effect is that neonatal PMNs show impaired binding to activated endothelium and bind less avidly than adult PMNs in the presence of local chemotactic factors. Deficient chemotaxis is also consistently reported in neonatal PMNs, especially in premature infants.[292,315-317] Because surface receptor density for specific chemotactic factors appears normal, postreceptor binding factors have been implicated. These factors include a constitutively smaller pool of β2-integrins—whose surface expression is required for PMN binding and diapedesis—and impaired ability of the neonatal PMN to reorganize its cytoskeleton in response to chemotactic stimulation.[316,318,319] Impaired PMN chemotaxis has also been induced in vitro by exposure to indomethacin, suggesting further potential immunologic impairment in premature neonates requiring pharmacologic closure of a patent ductus arteriosus.[320] Finally, important differences in phagocytic activity exist between neonatal and adult PMNs. Although in vitro phagocytic activity is comparable, under conditions of decreased opsonization neonatal PMN phagocytosis is less efficacious; this may be clinically significant in the relatively opsonin-deficient neonatal alveolar milieu.[321] There may also be a diminished capacity to store and release antimicrobial peptides, although other mechanisms (superoxide anion generation, lysozyme release) for intracellular killing of phagocytized organisms appear intact.[308]

Dendritic Cells

Dendritic cells make up fewer than 1% of the pulmonary cell population but serve a critical role as accessory cells in initiation of primary immune responses. Within the lung, DCs exist as

a network of interdigitating cells lying within the alveolar septa and perivascular adventitia and within the airway epithelial cell layer where their contact with air stream particles is enhanced.[322] DCs express certain membrane antigens characteristic of mononuclear phagocytes yet exhibit poor phagocytic and microbicidal activity. Conversely, DCs are exponentially more potent at T-cell activation than are macrophages.[323] This results from their capacity to present antigen in the context of major histocompatibility complex (MHC) molecules and their surface expression of the B7 ligands CD80 and CD86, which are obligate secondary signals for T-cell activation.[324]

As presently characterized, "immature" DCs migrate into the lung where they sample the environment for particles expressing PAMPs.[71,325] If encountered, they "acquire" the antigen by receptor-mediated endocytosis.[326] Antigens are degraded in specialized endosomes, where peptide fragments are loaded onto MHC class II molecules for transfer to the cell surface. Concomitantly, the DC chemokine receptor profile is altered, either by microbial products or locally generated cytokines, inducing DC chemotaxis to tracheal bronchial lymph nodes.[327] During this migration, DCs mature from "antigen processors" to antigen presenters under the influence of locally elaborated GM-CSF.[328] Once in lymphoid tissue, DCs present antigen, stimulate the clonal development of antigen-specific T cells, and activate both cytotoxic and helper T cells; they may also directly interact with B cells to regulate antibody production.[329] Engagement of the DC CD40 surface molecule by the T cell CD40 ligand induces DC-derived IL-12, which is required for T-cell differentiation and IFN-γ production. However, diminished capacity to generate IL-12 may persist among some DC subsets, limiting the range of T-cell responses that may be invoked.[325] DCs can migrate in response to bacterial peptides or LPS, complement cleavage products, early response cytokines such as TNF-α or IL-1, or chemokines; thus inflammation or infection recruits additional DCs from the peripheral blood.[330] In the basal state, pulmonary DC populations undergo complete turnover every few days, consistent with the robust antigen exposure of the pulmonary tree.[323]

Regulation of DC function is multifactorial, consistent with their central role in titrating pulmonary adaptive immune response. One mechanism of DC regulation is anatomic; although immature DCs can acquire antigen, they cannot present it until they have emigrated to regional lymph nodes. Such strict compartmentalization minimizes (possibly spurious) T-cell activation directly within the alveolus and requires the stimulated T-cell clones to recirculate to the lung in response to additional "fail-safe" homing signals.[324] DC function is also regulated by secreted products of alveolar macrophages. Alveolar macrophage–derived NO inhibits GM-CSF–mediated up-regulation of antigen-presenting activity and directly blunts T-cell activation by interfering with signal transduction.[331,332] Alveolar macrophage–derived PGE_2, TGF-β, and IL-10 also suppress antigen processing and MHC class II expression by pulmonary DCs.[333,334] In vivo, the role of alveolar macrophage–mediated regulation is shown in murine models of alveolar macrophage depletion, where hyperresponsiveness to aerosolized antigen results.[335] Finally, cytokines produced during early inflammation, including IFN-γ, TNF-α, and GM-CSF, increase MHC class II expression and allow normalization of DC function.[336]

The prenatal ontogeny of DCs is uncertain; as with alveolar macrophages, animal data suggest early derivation from angular cells of the fetal lung.[337] In humans, two functionally distinct DC precursor subsets, myeloid (m) DC and plasmacytoid (p) DC, occur in peripheral blood. Although both subsets differentiate into efficient antigen presenting cell (APC) after maturation, activated mDC and pDC display intrinsic differences and drive distinct types of T-cell responses. The relative densities of blood pDC and mDC differ between infants and adults, with pDC being more frequent in cord blood and mDC dominating in adult peripheral blood.[81] Adult human airway mucosa contains mainly mDC, whereas the population distrubtion in early life is somewhat different.[338,339] mDCs are almost exclusively expressed by cells in the epithelial compartment, and pDCs are expressed on many cells within subepithelial cellular aggregates; very few pDCs are found in the lamina propria outside these isolated lymphoid follicles.[340] Although previous studies suggested that DCs are present in only small numbers in the respiratory tract at birth, recent and more reliable data demonstrate that these cells can be found in the bronchial mucosa shortly after birth.[324,340-342]

Results from studies evaluating the MHC II antigen processing and presentation pathway in neonates are equivocal, but current evidence suggests neonatal DCs may be defective in this regard and respond poorly to maturation signals of GM-CSF.[343-345] Alternatively, recent data suggest that human neonatal DCs are fully competent in MHC class I antigen processing and presentation.[346] In vitro data suggest that neonatal DCs have less ability to modify their chemokine receptor profiles, impairing normal trafficking.[347] Neonatal DCs also exhibit an altered cytokine expression profile relative to adults; specifically, IL-12 production is markedly impaired whereas TNF-α and IL-10 are preserved, resulting in a skewed effect toward the latter two cytokines.[347] Much of the data comparing neonatal and adult DCs are derived from cord blood–derived DCs or other nonlung origins. A recent study compared the morphology, structure, and phenotype of neonatal and adult ovine lung DCs and found that they were functionally similar in antigen capture and T-cell stimulation.[348]

Immunologically Recruitable Pulmonary Structural Cells

Endothelium

Because of its anatomic location at the interface between the vascular and alveolar compartments, endothelium is uniquely situated to regulate pulmonary immune responses requiring recruitment and facilitated passage of intravascular inflammatory cells. Vascular endothelial cells express MHC class II molecules and may act as antigen presenters to T cells.[301] Endothelial cells also participate in immune processes by elaborating or responding to cytokines in the local microenvironment. For example, TNF-α is an endogenous mediator of inflammatory immune responses secreted by alveolar macrophages in response to bacterial endotoxin. Endothelial cells manifest a pleiotropic response to TNF-α, including increased expression of adhesion molecules, increased prostaglandin production, increased MHC antigen expression, and increased cytokine release including IL-1, IL-6, IL-8, GM-CSF, and monocyte chemotactic protein-1 (MCP-1).[91,349-355] The net effect of these signals is an increased chemotactic recruitment and activation of inflammatory cells at the "gate" from the vascular space to the interstitium; the TNF-induced increase in endothelial cell–leukocyte adhesivity further enhances this response. Endothelial cells also express the TLRs TLR4 (constitutive) and TLR2 (inducible by IFN-γ or TNF-α); this allows their direct response to endotoxin, manifested by up-regulation of adhesion molecule expression and induction of IL-1, IL-8, MCP-1, and GM-CSF expression.[301,354,356-360] By responding either to endotoxin directly or to endotoxin-induced macrophage-derived TNF-α, the endothelial cell may either generate an initial immune response or participate in amplifying a local inflammatory cascade.

Fibroblasts

Whereas most studies of fibroblasts have focused on their production of structural and matrix proteins, it is now evident that fibroblasts may also function as important immune-effector cells at sites of inflammation. When appropriately stimulated, fibroblasts may generate bioactive amounts of multiple cytokines, including IL-6, IL-8, IL-1α, IL-11, colony-stimulating factors, and growth factors such as TGF-β.[361] TNF-α or IL-1 can each induce

fibroblast-derived IL-6, IL-1, IL-8, and IL-11, and their combined action synergistically further up-regulates fibroblast elaboration of these cytokines.[362,363] Although fibroblasts and alveolar macrophages are often capable of elaborating the same inflammatory cytokine(s), maximal production of these cytokines typically occurs in response to different signals. This is illustrated by the distinct response of these cells to endotoxin. Endotoxin is a potent stimulator of macrophage-derived TNF-α and IL-1 that exerts little direct stimulation of fibroblasts. Conversely, pulmonary fibroblasts elaborate inflammatory cytokines in response to IL-1 and TNF-α, whereas macrophage response to these cytokines is more diverse.[364-368] This suggests that although classical immune cells such as alveolar macrophages produce inflammatory cytokines in a stimulus-specific fashion, fibroblasts produce inflammatory cytokines in response to macrophage-derived TNF-α or IL-1, independent of the precipitating stimulus. This response serves to amplify local pulmonary inflammation and illustrates the potential immunologic role of the fibroblast, transcending its putative structural function.

Epithelium

Pulmonary epithelial cells serve multiple functions including maintenance of solute fluxes, production of surfactant, and providing a surface for gas transfer. Beyond these metabolic and barrier functions, pulmonary epithelial cells are capable of augmenting and regulating local innate immunity in response to environmental signals. The airway epithelium senses bacterial exposure and responds by increasing the release of antimicrobial peptides, chemokines, and cytokines. This inflammatory reaction results in recruitment of phagocytes, dendritic cells, and lymphocytes to aid in the innate immune response and prepare an adaptive immune response if necessary. Epithelial cell recognition of these invading pathogens is a key initiating factor in mounting an adequate immune response to microbial pathogens. The mechanism by which this occurs is through the expression of a variety of PRRs including TLR1-10, CD14, and the CFTR.[73,369-375] Additionally, alveolar type II epithelial cells have collectin receptors, allowing them to internalize microbes opsonized by SP-A or SP-D.[206] Endotoxin or the early response cytokines TNF-α or IL-1β each may up-regulate epithelial-derived defensins such as human-β defensin 2 (HBD-2) by binding to cells expressing CD14 and TLR2.[374,376,377] Airway epithelial cells also exhibit tonic, high-level expression of iNOS with cytotoxic NO production.[378] The cyclooxygenase and lipoxygenase pathways are expressed at high levels in epithelial cells, resulting in production of lipid mediators including PGE_2 and the neutrophil chemoactivator leukotriene B_4 (LTB_4).[379-382] Infection with RSV can directly induce epithelial-derived IFN-β, IL-1α, and the chemokines IL-8 and RANTES.[75,383] Alternatively, pulmonary epithelial cells can also secrete several cytokines in response to various stimuli including TGF-β, GM-CSF, IL-5, IL-6, IL-8, and MCP-1; release of these cytokines facilitates chemotaxis and activation of multiple immune cells including PMNs, mononuclear phagocytes, and T lymphocytes.[384-389] Airway epithelial cells can titrate local cytokine signals by shedding soluble TNF-α receptor; this adsorbs available TNF-α and diminishes its bioactivity.[390] Airway and alveolar epithelial cells in vivo also express intercellular adhesion molecule-1 (ICAM-1), a natural ligand for complementary adhesins of PMNs and monocytes induced in response to IFN-γ, TNF-α, or IL-1. Increased epithelial expression of ICAM facilitates inflammatory cell migration along epithelial barriers; moreover, antimicrobial activity of phagocytes in vitro is enhanced by ICAM-mediated interactions with the alveolar epithelium.[391] Finally, airway epithelial cells, in response to specific cytokine stimulation, can express MHC antigens, allowing them to interact directly with T lymphocytes, possibly as antigen-presenting cells.[392] Together, these data suggest that in response to appropriate local stimuli, pulmonary epithelial cells may effect complex immune modulation within the milieu of the alveolus and airway.

CELLULAR MECHANISMS OF ADAPTIVE IMMUNE RESPONSE

Adaptive immunity requires sensitization to individually encountered antigens; once sensitization occurs, these immune responses are characterized by their high antigen specificity and long-lasting memory. Although many soluble and cellular components of host defense may link aspects of innate and adaptive immunity, adaptive immune responses are executed by lymphocytes.

Lymphocytes (T cells, B cells, and NK cells) are normally present at multiple sites in the lungs and may participate in complex immune responses to encountered antigens or act directly as effector cells against local microorganisms. Lung interstitial lymphocytes are plentiful, with numbers comparable to those of the circulating blood pool, and possess a characteristic size, distribution, subset composition, and cytokine production profile.[393] Large numbers of NK cells are also found in the interstitial space.[393]

T Cells

The pulmonary lymphocyte population is made up primarily of T cells.[393,394] Fetal and neonatal T cells express markers found on thymocytes,[395] suggesting that these T cells represent an immature transitional population; alternatively, this may reflect stress-induced release of cortical thymocytes into the circulation.[395] The neonatal T-cell phenotype corresponds closely to that of antigenically naive T cells in the adult.[396] These findings likely reflect a combination of the limited exposure of the neonate to foreign antigen and the limitations of neonatal DC function rather than intrinsic neonatal T-cell dysfunction. T cells recognize foreign peptides that have been modified by antigen-presenting cells and expressed in the context of MHC proteins. CD4+ T cells differentiate upon antigen stimulation in the context of class II MHC and can differentiate along several lineages including Th1, Th2, Th17, or Treg subsets. Important immunoregulatory functions provided by pulmonary T-cell subsets include cytokine production, enhancement of immunoglobulin production, and direct T-cell cytotoxicity.

Cytotoxic T cells mainly express the CD8 coreceptor and act to lyse host cells infected with intracellular pathogens.[397] As opposed to the CD4+ T-cell that recognizes peptide antigen in the context of class II MHC, these T cells recognize small peptide antigens that are presented by MHC class I molecules (signal I). Like other T cells these cells require a second signal to develop effective cytotoxicity, which is performed by costimulatory interaction between the T-cell CD28 molecule and B7 ligands (CD80 and CD86) expressed by the APC. In the absence of costimulation, the CD8 T cell is rendered either anergic or apoptotic.[398] Activated cytotoxic T cells can lyse and kill infected target cells through fas-mediated apoptosis or through the release of cytolytic mediators. The latter process involves the exocytosis of granules containing perforin, granzyme, and granulysin. Perforin is a glycoprotein that induces pore formation in the target cell membrane, facilitating both osmotic lysis and entry of granzymes and granulysin. Granzymes are serine esterases that activate the caspase cascade, inducing target cell apoptosis. Granulysin is an antimicrobial peptide with broad-spectrum activity against bacteria, mycobacteria, and fungi.[399] Cytotoxic lymphocytes are particularly important in host defense against nonlytic viruses such as CMV and also appear to be critical in host response to mycobacteria.[400-402] CD8+ T cells have also been shown to have activity against *Pneumocystis carinii* by up-regulating macrophage-mediated killing of the organism.[403] T lymphocytes from newborns are capable of developing into cytotoxic T cells during natural infections postnatally, and in utero infection may induce profound CD8 cytotoxic response.[404] In general, however, the incidence of neonatal cytotoxic lymphocyte development and the overall magnitude of the response tend to be diminished relative to that in older children.[405]

CD4+ helper T cells, or Th cells, function to orchestrate B-cell and T-cell responses. These CD4 cells recognize antigen presented by the MHC class II–dependent pathway and, on activation, may be induced to differentiate into specific Th phenotypes depending on the concurrent costimulatory signal (signal II) and cytokine stimulation (signal III) they receive. Undifferentiated naive T cells are called Th0 cells and can differentiate along specific T-cell subsets as outlined later.

Th1 cells

Th1 cells differentiate from Th0 cells in the presence of macrophage-derived IL-12p70, a heterodimeric cytokine consisting of Il-12p35 and Il-12p40, which are encoded by separate genes. IL-12 was the first heterodimeric cytokine discovered[406] and is the founding member of the IL-12 family of cytokines that consists of IL-12, IL-23, and IL-27 (Figure 159-6). IL-12 directs Th1 differentiation by the phosphorylation of Stat4.[406,407] Th1 lymphocytes are controlled by the transcription factor T-bet; characterized by their expression of IL-2, IL-12, TNF-α, and IFN-γ; function to activate macrophages and neutrophils; and are critical for host defense against intracellular pathogens such as *M. tuberculosis*.[408,409] In support of this, patients with defects in IL-12p40 production, IFN-γ production, or IFN-γ receptor signaling have an increased risk of TB.[410] Th1 cells can also influence the development of cytotoxic CD8+ T cells as well as facilitating class switching of B cells to produce IgG2a. In this context, Th1 response has been shown to be critical for host resistance against a variety of pulmonary pathogens, including *M. tuberculosis*, *L. pneumophila*, *C. pneumoniae*, and *P. carinii*.[411-413]

IFN-γ activates mononuclear phagocytes, augmenting phagocytosis and inducing production of oxyradical species, NO, and cytokines such as TNF-α, IL-1, and IL-6; IFN-γ up-regulates pulmonary epithelial cell and endothelial cell expression of adhesion molecules, with resultant enhanced PMN adherence.[414-419] This cytokine also increases expression of MHC molecules on epithelial cells and monocytes, enhancing their ability to function as antigen-presenting cells.[420] Finally, IFN- γ promotes proliferation of antigen-stimulated T cells, generation of cytotoxic T cells, and enhanced cytotoxic activity.[421] The net outcome of these effects is enhanced leukocyte recruitment and macrophage antimicrobial activity and amplified inflammatory tone. The enhanced antigen presentation induced by IFN-γ may facilitate later transition from macrophage-driven inflammation to a lymphocyte-executed adaptive immune response. As a sentinel mediator of the Th1 response, IFN-γ is antagonized by the Th2 cytokines IL-4, IL-13, and IL-10. IL-4 suppresses the expression of IFN-γ and other Th1 cytokines. IL-4 and IL-13 each also inhibit the expression of many IFN-γ inducible genes, as well as the ability of IFN-γ to augment microbicidal activities such as superoxide production. IL-10 is similar to IL-4 in its inhibition of IFN-γ synthesis by Th1 cells, NK cells, and macrophages. At the receptor level, Th1 and Th2 cells exhibit different responses to IFN-γ through differential expression of a specific IFN-γ receptor subunit that transduces suppressive signals.[422]

IFN-γ–activated macrophages are capable of restricting the growth of a number of microbes, such as *Legionella*, mycobacteria, *P. carinii*, pathogenic fungi, and *Chlamydia,* that parasitize macrophages [409,423,424] In vivo, IFN-γ replacement or overexpression has been shown to enhance bacterial clearance in murine modela of *L. pneumophila*, *P. aeruginosa*, and *K. pneumoniae.*[425-427] IFN-γ has been demonstrated in the BAL specimens of neonates with RSV, but the pulmonary expression of this cytokine is generally uncharacterized in this age-group.[428] Most likely, the diminished ability of neonatal lymphocytes to generate this cytokine (capacity less than 10% of adult) limits optimal alveolar macrophage activation, compromising neonatal pulmonary immune response.[429]

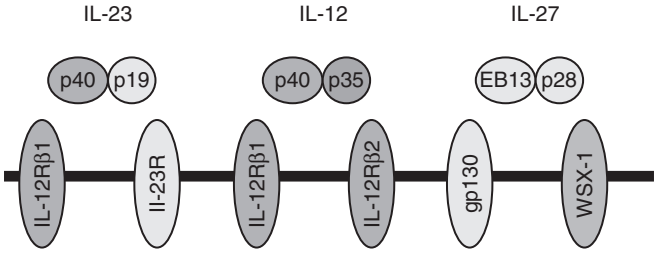

Figure 159-6 IL-12, IL-23, and IL-27 cytokine and receptor complexes. The IL-23 cytokine consists of a heterodimer of IL-12p40 and IL-23 p19, which is similar in structure to the IL-12 p35 subunit. IL-12 comprises of the IL-12p40 subunit and a p35 subunit. IL-27 consists of EBI3 and p28. IL-12p40 and EBI3 are group 3 soluble cytokine receptors. IL-23p19, p35, and p28 are members of the IL-6 subfamily of Type I cytokines. The IL-23 receptor consists of the IL-12Rβ1 and IL-23R subunits. The IL-12 receptor consists of the IL-12Rβ1 and IL-12Rβ2 subunits. The IL-12Rβ2 and IL-23R are structurally similar. The IL-27 receptor consists of a gp130 and WSX-1 subunit.

Th2 cells

Alternatively, in the absence of IL-12, activated Th0 cells are induced by IL-4 to adopt the Th2 phenotype, characterized by secretion of IL-4, IL-5, IL-6, IL-9, and IL-13. Th2 cells develop under control of Stat6 and the transcription factor Gata-3.[430,431] Th2 lymphocytes are required for expulsion of helminth parasites and also function to generate humoral immune responses and antibody production particularly IgG1, immunoglobulin A (IgA), and immunoglobulin E (IgE).[432] The Th1 cytokine IFN-γ acts on Th0 cells to induce Th1 differentiation and inhibit Th2 differentiation. Conversely, the Th2 cytokines IL-4 inhibits Th1 differentiation (Figure 159-7).

Mature T cells are capable of enhancing antibody secretion by regulating the proliferation and immunoglobulin isotype expression of B cells; this regulation is provided both through contact-dependent mechanisms and through secretion of specific cytokines. Contact-dependent interactions include cognate recognition through MHC antigens or receptor-ligand interactions primarily between the B-cell CD40 molecule and the T-cell CD40 ligand.[433] Activated Th cells markedly up-regulate their surface expression of CD40 ligand, a membrane-bound cytokine with homology to TNF.[434] Subsequent engagement with the B cell–surface CD40 molecule triggers B-cell expression of cytokine receptors. At this point, activated Th cells can begin to secrete cytokines in a directional fashion within the "immunologic synapse." Signals delivered to the B cell via CD40 binding markedly enhance immunoglobulin production and promote immunoglobulin class switching in the presence of coactivation signals provided by specific cytokines; relevant examples include IL-2, which promotes IgM secretion; IL-4 or IL-13, which facilitates IgE synthesis; IL-10, which induces IgG1 and IgG3 production; and IFN-γ, which promotes IgG2 production.[435-437] Patients with mutations in CD40L cannot undergo antibody class switching and thus have an abundance of B cells that stain positively for surface IgM. Measurement of antibodies in serum reveals mainly IgM and thus this syndrome is named Hyper IgM syndrome. The patients are at risk for infection from encapsulated bacteria as well as opportunistic fungi such as *P. carinii*.[438]

IL-5 is a major product of Th2 cells.[439] In humans, IL-5 is thought to be specific for promoting eosinophil and basophilic maturation and eosinophil survival and chemotaxis.[440] IL-5 appears to be critical for producing tissue eosinophilia and is thus of primary interest for its role in asthma. The role, if any, of IL-5 in neonatal host response remains uncharacterized. Eosinophilia is reportedly common among premature neonates and considered a marker of occult infection.[441]

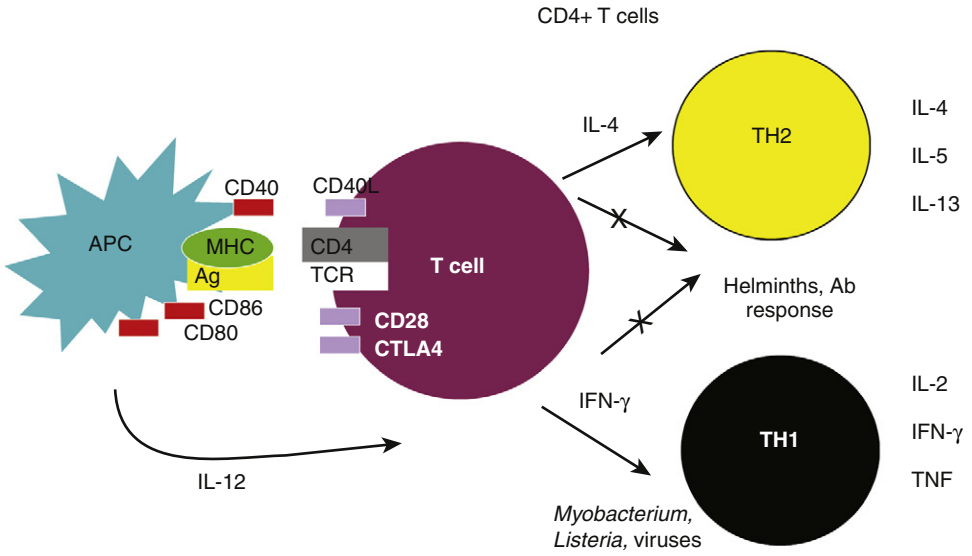

Figure 159-7 Differentiation of CD4+ Th1 and Th2 cells. Th1 cells develop after antigen presentation via class II MHC (signal I), costimulation (signal II), and under cytokine control of IL-12 (signal III). Th1 cells produce IFN-γ and are critical for intracellular pathogens as well as IgG2A production. In the absence of IL-12 and under control of IL-4, Th2 cells can differentiate and produce IL-4, IL-5, and IL-13. These cells are critical for host dense against helminths as well as IgG1 production. Both IFN-γ and IL-4 show reciprocal inhibition of Th2 and Th1 responses, respectively.

IL-4 is an 18-kDa cytokine produced by activated T cells of the Th2 subset, γδ T cells, mast cells, and basophils. IL-4 has two receptors: a high-affinity receptor that shares signaling components with IL-2 and IL-7 and an alternate receptor that shares components of the IL-13 receptor; cells expressing either receptor can transduce the IL-4 signal. IL-4 stimulation of naive T cells induces their differentiation into Th2 cells, initiating the Th2 response. Concurrently, IL-4 exhibits a number of important functions related to humoral immunity, including B-cell activation and induction of B-cell isotype switching necessary for production of IgE and some IgG subclasses.[442] Consistent with the Th2 cellular response, IL-4 facilitates the migration of eosinophils, basophils, and monocytes by up-regulating endothelial expression of vascular cell adhesion molecule (VCAM).[443] Neonatal leukocyte production of IL-4 is estimated to be less than 10% of adult capacity, and this correlates with in vivo data, in which IL-4 is undetectable in tracheobronchial aspirates of preterm and term newborns.[444,445]

IL-13 shares sequence homology (≈30%) and biologic activities with IL-4.[446,447] The activities shared by IL-4 and IL-13 likely result from a shared receptor subunit; however, IL-13-mediated effects are more restricted, and IL-13 is generally less potent than IL-4, owing to competitive inhibition resulting from the higher affinity of IL-4 for its receptor.[448] Although IL-13 does not stimulate T cells as IL-4 does, IL-13 can stimulate B cell proliferation and immunoglobulin isotype switching synergistically with IL-4.[448] IL-13 is also a potent inducer of mucins in lung epithelium.[448,449] Normal pregnancy is associated with the production of appreciable quantities of IL-13, initially by the placenta and subsequently by the fetus; IL-13 is inducible from cord blood cells by 27 weeks gestation.[450] Postnatally, higher levels of inducible IL-13 from cord lymphocytes may identify neonates at risk for later development of atopic or Th2 response-associated disease processes.[451]

Th17 cells

Th17 cells are a recently described lineage that develops from naive T cells under the control of TGF-β and IL-6. Th17 cell development requires phosphorylation of Stat3 and the transcription factors RORγ and RORα.[452,453] Once established, the IL-12 family member IL-23 regulates their proliferation and survival, as well as the expression of specific effector cytokines.[454] The effector cytokines produced by Th17 cells include, IL-17A, IL-17F, IL-22, and TNF-α. In fact IL-23 is required for IL-22 production whereas TGF-β and IL-6–directed differentiation is sufficient for IL-17A and IL-17F expression.[454] Experiments in animal models demonstrate that the Th17 lineage is critical for host defense against extracellular bacteria such as *K. pneumonia,* as well as organisms such as *Mycoplasma pulmonis* and *Citrobacter rodentium*, an enteric pathogen.[455-458] This lineage controls several aspects of mucosal immunity. IL-17R signaling has also been shown to be important for control of disseminated *Candida albicans* infection.[459] IL-17 and IL-17R signaling has been shown to critical for regulating granulopoiesis in response to infection, as well as the regulation of local chemokines such as CXCL1 and CXCL2, which are important for the recruitment of neutrophils to the infected tissue site. IL-22 synergizes with IL-17 to regulate the expression of antimicrobial peptides at epithelial surfaces.[456,460] IL-22 regulation of antimicrobial proteins has been shown to exist at several mucosal surfaces including the skin, gut, and lung.[456,458] Interestingly, although there is some overlap with types of genes induced in skin keratinocytes and lung epithelium, such as HBD-2, IL-22 appears to regulate organ specific genes in the gut. IL-22 regulates the expression of Reg proteins in GI epithelium, which are soluble lectin biding proteins that have direct antimicrobial activity.[458,461] It has recently been shown that patients with Job's syndrome or Hyper IgE syndrome have mutations in Stat3 and thus lack antigen specific Th17 cells in their peripheral blood.[462] These patients develop cutaneous infections with *S. aureus* and *C. albicans*. The individual contributions of IL-17 and IL-22 in this phenotype remain to be determined. This T-cell lineage has also been implicated in diseases of autoimmunity such as rheumatoid arthritis, Crohn's disease, and multiple sclerosis.[454,463,464]

T-cell Immunity in Neonates

As mentioned above, the majority of neonatal T cells are naive cells with reduced expression of the T-cell receptor (TCR), decreased adhesion molecule expression, and diminished

expression of the CD40 ligand.[405] Neonatal T cells also exhibit diminished cytokine production (notably IL-4, IFN-γ, IL-12, IL-15, GM-CSF), putatively owing to labile posttranscriptional regulation and markedly shortened mRNA half-life.[465-467] Although normal levels of cytokine elaboration are inducible by sustained TCR triggering, the decreased adhesion molecule expression by neonatal T cells impairs interaction with antigen-presenting cells, resulting in costimulatory signals insufficient to achieve levels of adult functioning. Similarly, diminished expression of the T-cell CD40 ligand precludes optimal contact-dependent activation of B cells.[468] Finally, neonatal T-cell differentiation appears biased toward a Th2 or Th0 profile under neutral conditions. Whether neonatal T cells are capable of Th17 differentiation remains to be determined.

Factors favoring such a "Th2 bias" include the low MHC-peptide density of neonates (favors priming of Th2 cells), relative dearth of the Th1-inducing cytokines IFN-γ and IL-12, and the greater costimulation required to elicit Th1 differentiation.[469,470] Factors favoring a Th0 state include paucity of the Th2-inducing cytokines IL-4 and IL-10. Interestingly, pregnancy is also associated with a state of T-cell tolerance with several factors (IL-4, IL-10, TGF-β) present at the maternal-fetal interface that can induce a shift from a Th1 to a Th2 profile.[471] Additionally TGF-β can also result in differentiation of regulatory T cells which have been shown to be critical for antigen specific tolerance.[472,473] The importance of this T-cell lineage in humans has been demonstrated in patients with immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome (IPEX), which is result of mutations in FOXP3—the transcription factor that controls the development of regulatory T cells.[474-476] This is an X-linked disorder that can present with neonatal diabetes mellitus, immune dysregulation with extremely high concentrations of IgE, and intractable diarrhea.[474,475] These patients also show exaggerated immune responses to viral infections.

γδ T Cells

T cells expressing the γδ receptor are present at mucosal surfaces including the skin, gut, and lung.[477] These cells do not recirculate and appear to be resident pulmonary lymphocytes. γδ T cells can develop by thymic-independent pathways and can recognize small molecules and intact proteins without the requirement for antigen processing that other T cells exhibit.[477] Small molecule recognition by γδ cells requires cell-cell contact, suggesting that non-MHC molecules may present small antigens to these cells or that costimulation from neighboring cells is required.[477,478] A germline-encoded phosphoantigen binding site enables these cells to respond to mycobacterial pyrophosphate, but they are also activated by antigen from disparate pathogens such as *L. monocytogenes.*[479,480] In vitro, γδ T cells can be induced to generate IFN-γ, TNF, IL-17, and IL-4 in stimulus-specific fashion similar to Th0 cells.[481,482] In the skin they regulate epithelial repair,[483] and whether they have a similar function in the lung remains to be determined.[483] The precise function of these cells in host defense remains unclear, but their anatomic locale and potential for cytotoxicity suggest a role in rapid initiation of immune reactions at mucosal surfaces of the airway. They are a rapid source of IL-17 in response to *K. pneumoniae* and *M. tuberculosis*[484] infection, and they are a dominant source of IL-17 in the gut.[484-486] There they may regulate granulopoiesis through IL-17 elaboration, which subsequently controls the expression of G-CSF.[486,487]

B Cells

B cells make up only a small percentage (≤2%) of the lung lymphocyte population, and this proportion of B cells or their precursors is attained in the fetal lung by 18 to 22 weeks gestation.[488] In more mature subjects, B cells of the lung interstitium participate in local humoral responses through elaboration of immunoglobulins in response to specific antigenic stimuli. In the neonate, however, this capacity is limited, attributed in part to the inability of neonatal T cells to provide either the contact-dependent help or cytokine factors required to induce B-cell differentiation into memory B cells.[445] A higher percentage of neonatal B cells are so-called B-1 cells, characterized by production mainly of polyreactive, low-affinity IgM, rather than the specific, high-affinity antibodies generated by B-2 cells.[489] Natural antibodies (nAb) are immunoglobulins existing in individuals before specific antigenic stimulation and include specificities present in cord blood or germ-free mice. The predominant nAb isotype is IgM, and in germ-free mice quantities of IgM in the serum are unchanged whereas IgG and mucosal IgA are significantly diminished, suggesting that production of IgM and IgG-IgA isotypes differ in their requirements for exogenous antigens.[490-492] nAb display low-level broad cross reactivity with self-antigens such as erythrocyte phospholipids and ds-DNA; however, selective pressures on the repertoire may relate to the role of nAb in host defense, as nAb recognize various pathogen molecules, such as bacterial phosphorylcholine, alpha 1,3 dextran, and influenza hemagluttinin. Further, they have been shown to directly neutralize viruses such as varicella zoster virus. As these antibodies are present at the earliest stages of infections and significantly earlier than the adaptive immune response, it is hypothesized that they play a critical role in the limitation of infection. Additionally, as IgM contains unique effector functions, it is thought that the early role of IgM nAb in host defense likely contributes to the quality and quantity of the emerging adaptive host immune response to infection. In addition to direct antimicrobial activity, the functions of IgM nAb appear to regulate disease processes at mucosal surfaces and adaptive immune responses. It has been shown that mice unable to secrete IgM have decreased survival and clearance of infection in response to influenza challenge. Interestingly, these mice had delayed production of influenza specific IgG1 and IgG2a, suggesting that IgM immune complexes with the virus may influence aspects of antigen presentation to B cells.[493]

Receptor ligation of neonatal B cells induces minimal upregulation of MHC class II molecules and fails to induce CD86, impairing antigen presentation by these cells.[494] Neonatal B cells also exhibit diminished expression of the complement receptor CD21, limiting their capacity to be stimulated by complement.[495] Although capable of local immunoglobulin production (primarily IgM and IgA), neonatal B cells remain unable to generate antibodies to bacterial capsular polysaccharides; this results in particular vulnerability to organisms such as *H. influenzae* and group B *Streptococcus*.[496] Neonatal B-cell function and lung humoral defense mechanisms are discussed in further detail later.

NK Cells

NK cells are large granular lymphocytes with cytotoxic function, comprising up to 15% of circulating lymphocytes, but less than 2% of the lung lymphocyte pool. They share a common progenitor with T cells but lack the TCR required for specific antigen recognition.[497] Within the lung, they are found on epithelial surfaces and in the interstitium, and they are also recruitable from the circulation in response to locally generated chemokines.[498] Activated NK cells contribute to early innate defense by lysing infected cells and generating cytokines that stimulate T cells and alveolar macrophages.[499] IL-12p70 is a key cytokine that up-regulates NK-cell perforin and granzyme, enhancing activated NK-cell lysis of infected cells.[497] As opposed to T cells, which recognize their target cells through MHC-restricted peptide expression, NK cells recognize the absence or very low levels of MHC class I antigen expressed on infected cells.[497] This has been termed the "missing self-hypothesis."Activating receptors on NK cells include NKG2D

and DAP10. DAP12 can activate or inhibit NK-cell activation and these negative regulatory adaptor proteins may avoid indiscriminate lysis of noninfected cells.

Early in infection, activated NK cells may be a primary source of IFN-γ within the lung.[500] NK cell–derived IFN-γ and TNF-α from multiple sources synergistically enhance alveolar macrophage killing of intracellular pathogens. In addition, NK cell–derived IFN-γ may initiate alveolar T cell–mediated immunity by inducing differentiation of Th0 cells into a Th1 phenotype.[501] The capacity to produce IFN-γ, augment immunity against intracellular pathogens, and effect cytotoxic responses without prior sensitization all imply a sentinel role for NK cells in neonatal host defense. Indeed, NK-cell precursors appear early in gestation by thymic-independent mechanisms and reach adult levels by term.[502] NK cytolytic function, however, remains diminished (≤50% of adult NK cells) for much of the first year of age, with more pronounced depression in premature neonates.[503] This diminished function corresponds to an immature NK-cell subset with impaired perforin-granzyme delivery[504]; this may predispose the neonatal lung to infections with agents such as HSV and CMV.[504]

Humoral Immune Responses

B lymphocytes bearing surface immunoglobulin of the IgA, IgG, and IgD isotypes appear early in gestation. Although the B-cell immunoglobulin repertoire expands during gestation, at birth it remains limited relative to older hosts.[505,506] Immunoglobulin-secreting plasma cells appear later in gestation than B cells, between weeks 15 and 30.[507] Typically, neonatal B cells can differentiate into IgM-secreting plasma cells as efficiently as in the adult, but do not differentiate into IgG- or IgA-secreting cells until these functions fully mature.[508] As previously discussed, the relative inability to achieve isotype switching in the neonate results at least in part from inadequacy of mutual signaling between neonatal T cells and B cells. The antibody response of neonatal B cells to specific antigens develops sequentially, with responsiveness to antigens requiring contact-dependent T-cell help (for example, protein antigens) preceding the development of responses not requiring such cognate help (for example, capsular polysaccharides). Although infection of neonates elicits a protective response to most protein antigens, the response to polysaccharide antigens is absent or severely blunted. This has been recently postulated to result from decreased surface expression of CD21 and to decreased complement levels, resulting in suboptimal signal transduction via CD21 and inability to achieve the CD21/B-cell receptor synergy required for B-cell activation.[509,510] Alternatively, humoral responses to bacterial capsular polysaccharides are enhanced by specific T cell–derived cytokines such as IFN-γ, IL-12, and GM-CSF, all of which are relatively deficient in the neonate.[511,512] The limited capacity of naive neonatal T cells to provide these cytokines may contribute to the poor antibody responses of neonates to encapsulated bacteria such as group B streptococci. This T-cell immaturity thus combines with differences in antibody repertoire and functional immaturity of B cells to limit the capacity of the fetus or neonate to produce antibodies to certain antigens.

Secretory Immunoglobulins

Secretory component is an epithelial-derived glycoprotein that facilitates transfer of immunoglobulins from subepithelial sites into epithelial-lined lumina by transepithelial transport and secretion.[513] IgA and IgM constitute the primary secreted immunoglobulin subclasses of the lung. IgM is more abundant in secretions of neonates than in adults.[514-516] IgM is the first immunoglobulin class to be produced in a primary response to an antigen and is the only immunoglobulin other than IgG that fixes and activates complement. It is secreted as a pentamer, and the resultant 10 antigen-binding sites render it a superb agglutinin. Whereas serum concentrations are low at birth, postnatal IgM concentrations rise rapidly in the first month, reflecting increased antigen exposure; IgM concentrations in premature infants remain lower for the first 6 months of life.[517,518] Secretory IgA is undetectable at birth but found by 1 to 2 weeks in saliva and nasopharyngeal secretions. The earlier expression of secretory IgA relative to serum IgA presumably reflects increased local production in response to encountered antigen.[519] Serum IgA largely consists of monomeric IgA whereas transported IgA is largely homodimeric. Transport occurs form the basolateral epithelial surface to the apical surface through the basolateral polymeric immunoglobulin receptor (PIGR) (Figure 159-8). Both IL-17 and IL-22 can upregulate the expression of PIGR and may facilitate IgA transport during inflammation.[456]

Other Immunoglobulins

IgG is the predominant immunoglobulin isotype at all ages, and passively derived cross-placental transfer of maternal IgG is the primary source of all IgG subclasses detected in the normal fetus

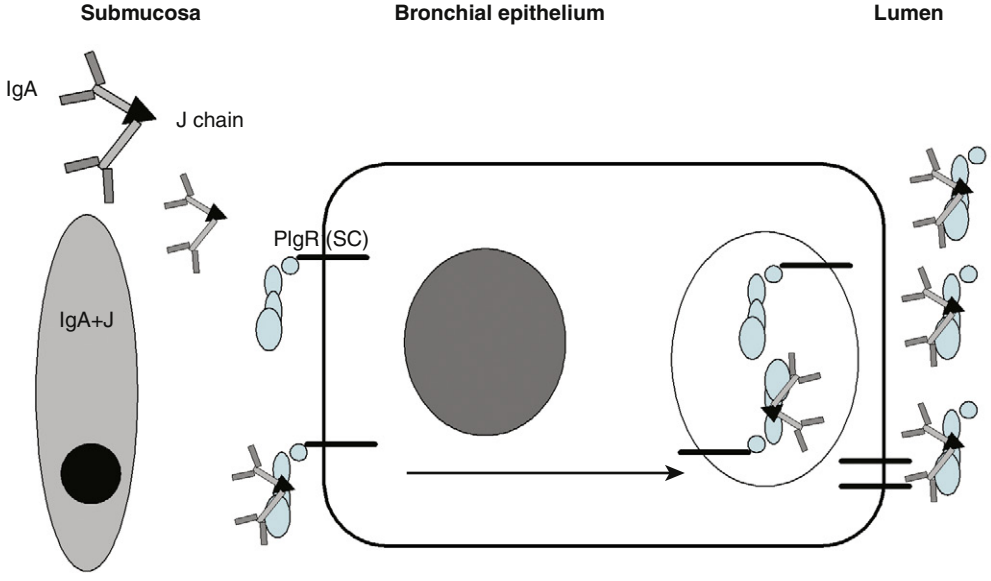

Figure 159-8 Transport of IgA across secretory epithelium. Dimeric IgA binds to the polymeric Ig receptor, also known as membrane secretory component *(SC)*. After transport and export via PIgR, secretory IgA *(SIgA)* consists of dimeric IgA with J chain *(IgA+J)*, which can function as blocking antibodies at mucosal surfaces.

and neonate.[517] These levels fall postnatally, reaching a nadir between 2 and 4 months of age (depending on gestational age) when nascent IgG production by the infant is unable to keep pace with utilization of maternally derived IgG. Preterm infants have proportionally lower IgG concentrations at birth compared with term infants, demonstrate lower serum IgG nadirs, and manifest lower serum IgG levels throughout the first year of life.[518] Although IgG is not actively transported into secretions like IgA, significant quantities of IgG may be found in fluids obtained from bronchoalveolar and airway lavage, presumably by passive transfer.[520] A critical role of IgG in the lung has been shown by patients with various IgG deficiencies such as common variable hypogammaglobulinemia and Bruton's X-lined agammaglobulinemia that suffer from pulmonary infections with encapsulated bacteria. This phenotype is a result of the critical role of IgGs in mediating opsonization as well complement fixation.

Molecules Involved in the Recruitment of Lung Immune Cells

Lipid Mediators

Lipid mediators of inflammation constitute a diverse group of biologically active products liberated from cellular membranes in response to local immune and nonimmune stimuli.[521] As opposed to cytokine synthesis, which often requires transcription, translation, and posttranslational processing steps, lipid mediators can be generated within minutes. Endotoxin directly stimulates leukocyte membrane-associated phospholipase A_2 (PLA_2), which metabolizes adjacent membrane phospholipids to release free fatty acid products such as lysophosphatidylcholine and arachidonic acid.[522] Arachidonic acid can be oxidatively metabolized by cyclooxygenase or lipoxygenase pathways to generate a number of bioactive lipid products including thromboxane A_2 (TXA_2), prostacyclin, prostaglandins, and LTs, while lysophosphatidylcholine may be acylated to produce the potent mediator PAF.[523,524]

PAF is synthesized by a number of cells, including mononuclear phagocytes, neutrophils, endothelial cells, platelets, eosinophils, and mast cells, and has demonstrable biologic effects at nanomolar concentrations.[524,525] Known for its induction of platelet aggregation and degranulation, it also stimulates chemotaxis and activation of PMNs and macrophages and augments PMN adhesion to endothelial cells.[526] Animal models of gram-negative infection suggest a role for PAF in mediating endotoxin-induced inflammation as well as a role in the impaired hypoxic pulmonary vasoconstriction and alveolar capillary leak associated with severe pneumonitis.[527] Other studies have linked PAF to transfusion-associated lung injury and reperfusion lung injury.[528] In neonates, PAF is implicated in the pathogenesis of septic complications such as disseminated intravascular coagulation and necrotizing enterocolitis.[529] Elevated PAF levels are documented in the tracheal aspirates of infants in association with meconium aspiration, pneumonia, and intrauterine infection, suggesting a role in neonatal pulmonary inflammation.[530]

Arachidonic acids are released from cell membrane phospholipids in response to a variety of inflammatory stimuli.[524] Once liberated, they are primarily metabolized by either the lipoxygenase or the cyclooxygenase pathway. The lipoxygenase pathway produces LTs, including the potent PMN chemotactic activator LTB_4, and LTC_4 and its cysteinyl degradation products LTD_4 and LTE_4.[524] LTB_4 is a potent neutrophil chemoattractant whereas the cysteinyl LTs are potent bronchoconstrictors. In addition, the cysteinyl LTs up-regulate macrophage Fc receptor expression and phagocytic activity. The important role of LTs in host response is suggested by a transgenic animal model of LT deficiency. In this model, aveolar macrophage phagocytic function was impaired, intratracheal inoculation of bacteria resulted in increased bacteremia and lethality, and alveolar macrophage function was restorable in vitro by exogenous LTB_4.[531] LT activity in the human neonatal lung has not been characterized, but animal models suggest that neonatal alveolar macrophages may have diminished capacity to synthesize LTB_4 compared with adults. This may result in part from lower inducible levels of IFN-γ and less capacity to up-regulate lipoxygenase pathway enzymes.[532]

Products of the cyclooxygenase pathway include prostacyclin (PGI_2), TXA_2, and prostaglandins. Although TXA_2 increases microvascular tone and activates inflammatory cells, prostaglandin species, particularly the PGE series, are known to block transcription of TNF, suppress leukocyte adhesion, and blunt the generation of other proinflammatory arachidonic acid metabolites.[533] Cellular constituents of the lung appear specialized in their generation of arachidonic acid products, with LTB_4, PGE_2, and TXA_2, the primary ones generated by alveolar macrophages. Because inflammatory actions of these mediators may be conflicting, and because alveolar macrophages may produce varying amounts of these mediators at different stages of the inflammatory process, this suggests another mechanism by which the alveolar macrophage may regulate local inflammatory events.

Proteins

Complement

Activation of the complement cascade by either classical or innate means results in the eventual generation of multiple components with potent inflammatory activity. C3a, C4a, and C5a all have function as "anaphylatoxins," capable of inducing histamine release and increased vascular permeability; there is evidence that C3a and C5a mediate some of these effects by inducing local production of arachidonic acid metabolites.[534,535] C3a and C5a stimulate PMN lysosomal enzyme release, while C5a is also a potent neutrophil chemoattractant (Figure 159-9).[534]

C3a and C5a may regulate a broad range of inflammatory functions by binding their cognate receptors C3aR and C5aR. Previously recognized only on myeloid cells, both receptors have been demonstrated on human alveolar epithelium and alveolar macrophages.[536] In a murine model of sepsis, putative activation of toll pathways by endotoxin increased C3aR and C5aR expression on alveolar epithelium.[537] In this model, C5a activation of C5aR was implicated in increased expression of TNF-α and IL-6. Conversely, C3a has been shown to depress TNF-α and IL-6 secretion.[534]

Neurokinins

The autonomic nervous system may participate in some aspects of airway inflammation because stimulated or injured sensory nerves can initiate or amplify leukocyte responses. Local axonal reflexes play a role through stimulation of afferent nerve fibers, leading to the release of neurokinins. Neurokinins, such as substance P, are stored in unmyelinated nerve fibers (C fibers) as well as intrinsic airway neurons and released as part of a nociceptive response.[538] Airway surface epithelium and submucosal glands are in proximity to sites of neurokinin release. Once secreted, neurokinins activate the neurokinin-1 receptor (NK-1R), mediating local increases in vascular permeability and leukocyte adherence to airway epithelial surfaces; the ensuing plasma extravasation and leukocyte infiltration constitutes neurogenic inflammation.[539] The duration and intensity of this response is determined by the rate of neurokinin breakdown by neutral endopeptidase (NEP), an enzyme produced by epithelial cells.[540] Epithelial damage caused by inflammation, mechanical injury, or viral infection reduces NEP availability, leading to sustained inflammatory effects of the neurokinins.

Beyond the classic model of neurogenic inflammation, recent work has identified other neurokinin sources within the lung. Resident lung macrophages and circulating leukocytes have been found to express neurokinin receptors, as well as the preprotachykinin A (PPT-A) gene encoding neurokinins such as substance P.[541] This suggests that lung immune cells may

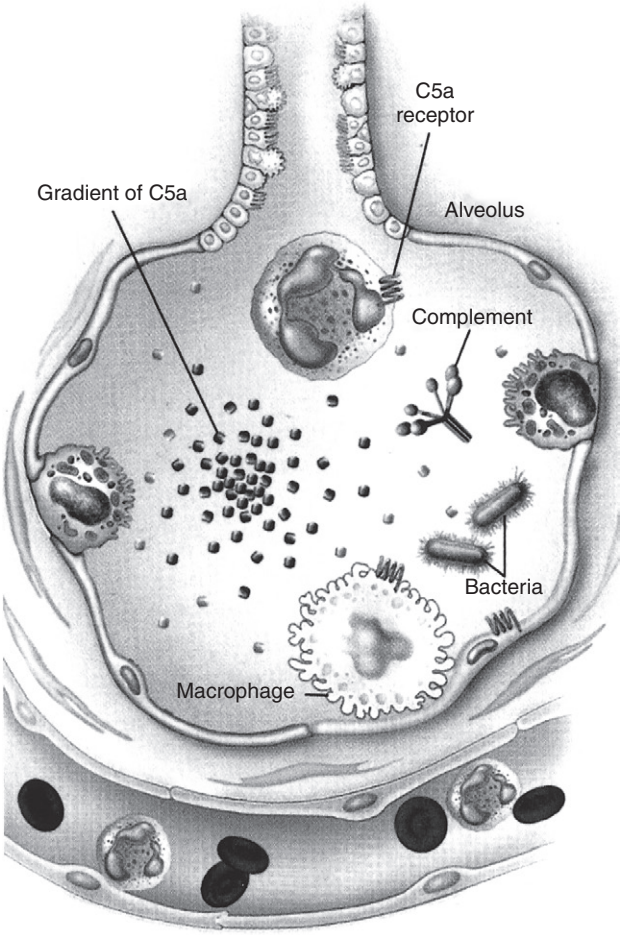

Figure 159-9 Complement components are produced within the alveolus by alveolar macrophages, pulmonary fibroblasts, and type II epithelial cells. Complement activation within this compartment generates a C5a gradient favoring PMN chemotaxis. Increasing local concentrations of C5a arrest chemotaxis and induce PMN respiratory burst and degranulation. Additional local immunomodulation (cytokine induction, IgG receptor upregulation) may occur through C5a interaction with cognate receptors on alveolar epithelium and alveolar macrophages. *(From Gerard C:* N Engl J Med *348:167-169, 2003.)*

use neurokinins for paracrine or autocrine signaling, propagating inflammation beyond the distribution of C fibers and intrinsic neurons. Such a role is supported by animal models of either NK-1R or PPT-A deletion. The injury normally induced by antigen-antibody complexes within the airway is attenuated in a transgenic murine model of NK-1R deletion, suggesting an essential rather than complementary function of neurokinins in this type of inflammation.[542] Similarly, PPT-A deficiency blunts immune complex–mediated inflammation, yielding additional important insights. First, neurokinins intervene proximally in the inflammatory cascade because airway TNF-α levels are essentially undetectable in PPT-A–deficient mice. Second, reconstitution of leukocyte PPT-A expression does not alter the blunted inflammatory response in PPT-A–deficient mice; however, transplantation of PPT-A–deficient bone marrow into "wild-type" mice is protective, underscoring the essential role of leukocyte-derived PPT-A in neurogenic inflammation.[543] These data, taken together, suggest a paradigm in which subepithelial sensory neurons interact synergistically with resident immune cells of the lung to initiate neurogenic inflammation. Secreted neuropeptides are potent chemotaxins and can recruit leukocytes directly or by the induction of cytokines by local interstitial and immune cells.

Apart from their inflammatory actions, other relevant effects of airway neuropeptides relate to alterations in mucus secretion. Substance P stimulates mucin elaboration and increases mucus secretion by stimulating serous cells and goblet cells.[544] Both substance P and vasoactive intestinal peptide (VIP) stimulate epithelial cell chloride secretion, increasing periciliary fluid level.[545] The net effect is increased local production of mucus with increased periciliary fluid secretion to maintain mucus hydration and normal viscosity. Recently it has been shown that neurokinins play a critical role in lung inflammation mediated by RSV infection.[546]

Defensins

Apart from their primary antimicrobial activity, defensins also exhibit properties facilitating pulmonary inflammation. In vitro, α-defensins have been shown to induce the neutrophil chemoattractant IL-8 from airway epithelial cells, and stimulate alveolar macrophage production of LTB_4 and IL-8.[547] Additionally, HNP-1 and HNP-2 are each directly chemotactic for monocytes and can induce monocyte-derived TNF and IL-1.[548,549] Finally, α-defensins have been shown to induce T cell–derived IFN-γ, IL-6, and IL-10, whereas β-defensins have chemoattractant effects on immature DCs and naive T cells; this suggests that beyond their antimicrobial and proinflammatory effects, defensins may also facilitate the local transition from innate to adaptive immune response.[550,551]

Proteases

Phagocytic cells (PMNs, mononuclear leukocytes) contain a number of proteolytic enzymes capable of both microbial killing and proteolytic degradation of lung structural elements.[552] PMN primary (azurophilic) granules contain serine protease homologues with cytocidal activity (serprocidins); these include neutrophil elastase, cathepsin G, proteinase-3, and azurocidin. The serprocidins are structurally related to the granzymes of cytotoxic lymphocytes and exhibit broad-spectrum microbicidal activity against bacteria, fungi, and protozoa. Proteases contained in primary granules have the capacity to degrade a number of extracellular proteins, including collagen (types I-IV), elastin, fibronectin, laminin, proteoglycans, and complement, contributing to microbicidal action; alternatively, many proteases possess antimicrobial activity unrelated to their proteolytic effects.[553,554] PMN secondary (specific) granules contain matrix metalloproteinase 9 (MMP9) and possibly gelatinase, which facilitate PMN migration.[553,555,556] Stored proteases are released extracellularly in response to various stimuli. Migration of PMN through tissues results in release of specific granule contents; this may be caused by the interaction of complement receptors on the specific granule membrane with local complement components directing PMN chemotaxis. The local proteolytic actions of secreted proteases are generally controlled by extracellular antiproteases such as α_1-antitrypsin (α_1-AT), α_1-antichymotrypsin, and α_1-protease inhibito.[557,558] Under conditions of homeostasis, a balance between proteolytic activity and antiprotease activity exists. However, when antiproteases are deficient or overwhelmed by the degree of the inflammatory response, diminished regulation of protease activity may ensue. Subsequent proteolytic generation of chemotactic extracellular matrix fragments and complement components can lead to further recruitment of phagocytic cells and intensified local inflammation.

Reactive Oxygen Species

A key component of pulmonary host defense is the generation of reactive oxygen species including superoxide and hydrogen peroxide. These molecules are often confined to the phagolysosome of PMNs and macrophages to minimize damage to host tissues.[559,560] This process is characterized by a rapid uptake of

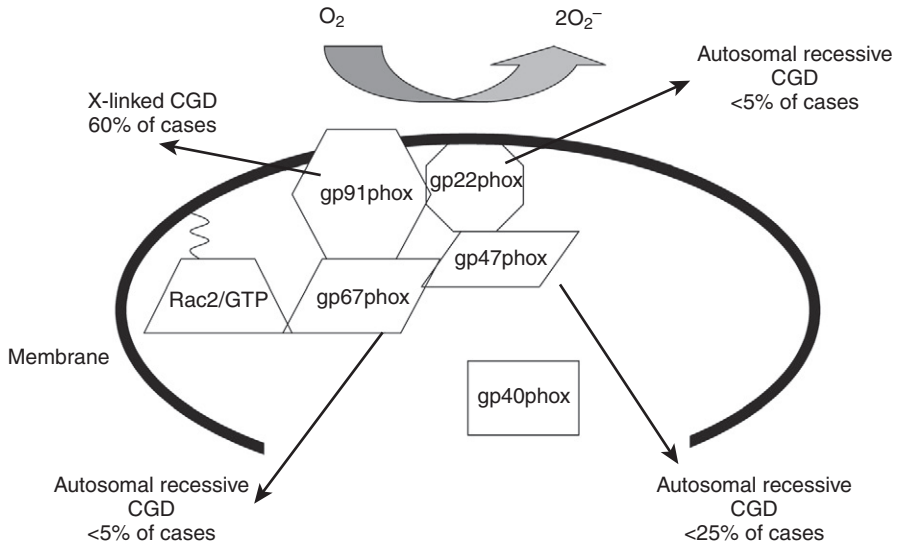

Figure 159-10 Structure of functional NADPH oxidase. NADPH oxidase consists of six subunits that are separated in different locations in the cell. p22phox and gp91phox are integral membrane proteins and form a heterodimeric structure that constitutes the catalytic core of the enzyme. Rac GTPase and p47phox, p67phox, and p40phox are cytosolic members of the complex.

molecular oxygen by the phagocyte (the "oxidative burst") that is triggered by cell membrane signaling before particle ingestion. Activation of cell membrane–associated NADPH oxidase results in shuttling of electrons from cytosolic NADPH to molecular oxygen, initiating a series of reactions responsible for producing multiple oxyradical species. NADPH oxidase consists of six subunits that are separated in different locations in the cell (Figure 159-10). p22phox and gp91phox are integral membrane proteins and form a heterodimeric structure that constitutes the catalytic core of the enzyme.[561] Rac GTPase and p47phox, p67phox, and p40phox are cytosolic members of the complex.[561,562] In the presence of activated-membrane NADPH oxidase, molecular oxygen accepts a single donated electron, becoming superoxide ion (O_2^-). Because this radical can either accept or donate an electron, it subsequently may be oxidized or reduced; when two such radicals interact in the presence of superoxide dismutase, one is oxidized and one is reduced, such that $O_2^- + O_2^- + 2H^+ \rightarrow O_2 + H_2O_2$ generate hydrogen peroxide. Transfer of a second electron to the superoxide ion via NADPH oxidase also generates H_2O_2. Neutrophil granules contain myeloperoxidase, an enzyme capable of generating further antimicrobial oxyradicals. Hydrogen peroxide reacts with myeloperoxidase and available halide species (primarily chloride in vivo) to generate hypochlorous acid (HOCl); HOCl is an extremely powerful oxidant, analogous to bleach.[563] Because it is highly reactive, it does not accumulate and is rapidly consumed in further reactions producing new oxidants. An important interaction may be with primary or secondary amines, to produce chloramines; although chloramines are weaker oxidants than HOCl, they tend to be longer lived and remain able to oxidize multiple potential targets.[564] Mutations in gp91phox or other NADPH oxidase components result in chronic granulomatous disease, and patients with this disorder suffer from both bacterial infections and infections with *Aspergillus fumigatu.*[565]

Cytokines

Cytokines play a sentinel role in the recruitment, proliferation, and survival of inflammatory cells within the lung. Cytokines are soluble proteins transiently synthesized by an appropriately stimulated immune or nonimmune effector cell and whose effects are mediated by binding to specific receptors on target cells. A cytokine may have autocrine effect when it modulates the properties of the cell producing it, paracrine effects when modulating the properties of cells proximally, and endocrine effects when it mediates its effects distally. Some cytokines may remain either cell associated or membrane bound and exert their effects through cell-to-cell contact; this may facilitate more specific regulation of local inflammatory events. A single cytokine may be produced by many cell types, and a single cell type may produce many cytokines. In general, cytokines are multifunctional molecules, participating in a wide spectrum of immune and nonimmune processes, including inflammation, metabolism, morphogenesis, fibrosis, and hemostasis. The action of a given cytokine may vary depending on its dose, receptor availability, the state of activation of the target cell, and the presence of other cytokines in the local milieu. Additionally, cytokines frequently stimulate target tissues to produce other bioactive cytokines. Accordingly, the biologic effects of cytokines result from their direct effects on target tissues and their ability to interact with one another in regulating target cell function; the eventual response of a cell to these mediators will depend on the sum of the signals received and the cell's state of responsiveness to each of these signals.

Tumor Necrosis Factor

TNF is a phylogenetically primitive mediator, based on its high degree of homology across species. It is produced primarily by monocytes and macrophages in response to LPS, as well as in response to enterotoxin, mycobacterial cell wall products, and components of complement.[566] TNF is also produced by T cells and NK cells.[566] Its half-life locale is approximately 6 minutes, with peak levels at 1 to 2 hours after LPS exposure, defining its role as an "early response" mediator in endotoxin-induced inflammatory cascades.[567] It is now clear that TNF is a key mediator of host defense against a wide range of pulmonary pathogens, including *Pseudomonas, Legionella, Klebsiella, S. aureus, S. pneumoniae,* and *Mycobacterium* species.[568-571] Alveolar macrophage–derived TNF remains compartmentalized within the alveolus where it exerts protean inflammatory effects. TNF acts on PMNs to increase phagocytosis, adhesion molecule expression, and respiratory burst capacity.[572,573] TNF acts on epithelial and vascular endothelial cells to similarly up-regulate adhesion molecule expression, thereby facilitating inflammatory cell migration.[572] TNF induces IL-1 generation by both endothelial cells and local mononuclear phagocytes, which augments the initial inflammatory signal and can directly induce production of chemokine IL-8 from multiple cell types, further amplifying inflammation.[574] TNF also induces IL-6 production by fibroblasts, epithelial cells, and endothelial cells, initiating an acute phase response (detailed later).[575] Neonatal monocytes and T cells have diminished (50% to 60%) capacities

to generate TNF relative to adult cells, and these limitations are further pronounced in preterm neonates (25% adult capacity).[576,577]

Interleukins

Interleukin-1

The IL-1 family consists of several proinflammatory agonists however this chapter will focus on two, IL-1α and IL-1β, and the anti-inflammatory IL-1 receptor antagonist protein (IL-1ra). IL-1α is primarily membrane bound whereas IL-1β is secreted. IL-1α and IL-1β are encoded by separate genes but share the same receptor by virtue of their 23% homology and thus can elicit similar effects. These receptors are ubiquitously expressed so the effects of this cytokine are pleiotropic.[578,579] Ligation of the receptor IL-1R1 activates IL-1 receptor-activating kinase (IRAK), which culminates in liberation and nuclear translocation of NF-κB.[579] Of note is that the IL-1R1 signaling cascade shares MyD88 and IRAK with the pathways for TLRs 1,2, 4, 5, 6, 7, 8, and 9 (Figure 159-11).[580] IL-1 shares many properties with TNF, including enhancement of adhesion molecule expression by PMNs and endothelial cells, up-regulation of NOS, and neutrophil priming. IL-1 acts on fibroblasts, epithelial cells, and endothelial cells to induce IL-6 and IL-8 production, thereby modulating both enhanced PMN chemoactivation and initiation of the acute phase response.[579] IL-1 is an endogenous pyrogen and within the central nervous system can elicit fever.[581] Other actions of IL-1 include stimulation of T-cell proliferation, increased IL-2 receptor expression on T and B cells, and increased release of T cell–derived IL-2.[579] IL-1β has recently been implicated in the differentiation of both murine and human Th17 cells.[582,583] Regulation of IL-1 occurs by either direct IL-1ra antagonism or sequestration of IL-1 by its "decoy" receptor, the IL-1R2.[579] Engagement of this receptor by IL-1 does not induce signal transduction; metalloprotease cleavage of this receptor from cell surfaces releases a soluble receptor that blocks IL-1–mediated effects.

Mononuclear phagocytes do not produce IL-1 constitutively, but its production is induced by multiple stimuli including viruses, microbial products (endotoxin, peptidoglycans, techoic acid, yeast cell walls), C5a, TNF, and IL-1 itself. [579] However secretion of IL-1β requires cleavage by caspase-1.[579] This enzyme is activated by proinflammatory stimuli though a series of cytosolic molecules that detect lipopetides. Similar to TLRs these proteins encode leucine-rich repeats which are critical for ligand recognition. These NOD and NALP proteins activate the "inflammasome," which is critical for cleavage of IL-1β.[584,585] Available data suggest that neonates, both term and preterm, possess adult capacity to produce monocyte-derived IL-1 and exceed adult capacity to produce PMN-derived IL-1.[576,586]

IL-1ra is an endogenous IL-1 inhibitor that competitively binds to the IL-1R1 without inducing signal.[587] It exists in two intracellular isoforms found in epithelial cells and as a third isoform secreted by monocytes.[588] IL-1ra is synthesized by alveolar macrophages (and other mononuclear cells) in response to LPS or adherent IgG.[589] Emphasizing the potential role of IL-1 in pulmonary inflammation, animal models of endotoxin-induced pneumonitis demonstrate profound antiinflammatory response to intratracheally instilled IL-1ra whereas murine models of IL-1ra deficiency show an exaggerated and persisting inflammatory response.[590,591] These data, along with known in vitro actions, suggest that IL-1ra may function as an endogenous "down-regulator" of inflammatory cytokine cascade within the alveolar space. IL-1ra is found in tracheal aspirates of preterm infants at risk for bronchopulmonary dysplasia, but this may represent release from injured epithelium rather than *de novo* immune cell production.[592] Serum IL-1ra levels are elevated in healthy newborns, decline within days of birth, and increase in response to infection, indicating capacity for stimulus-specific IL-1ra production.[593]

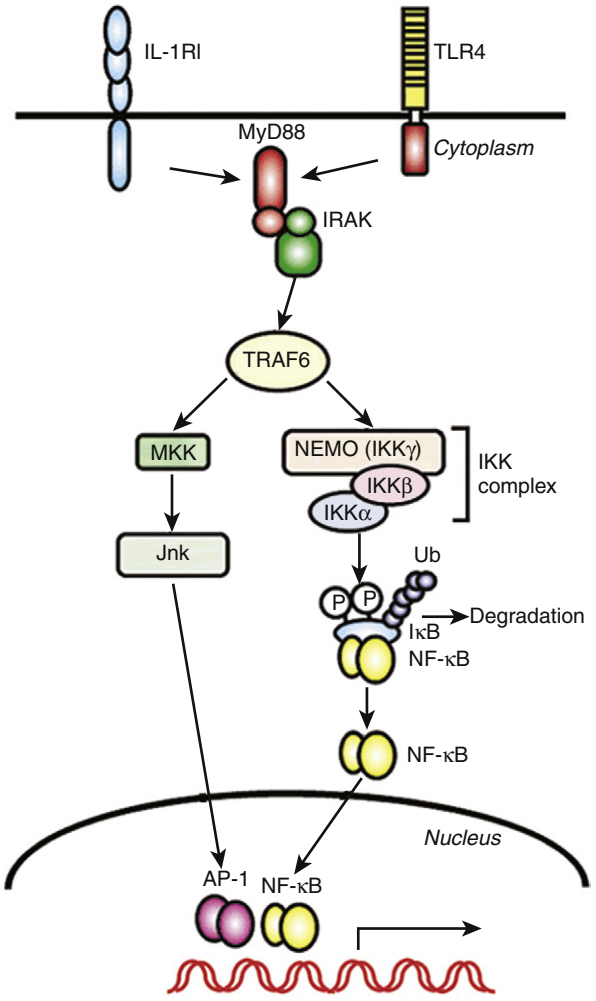

Figure 159-11 IL-1R1/TLR signaling. To illustrate the shares signaling pathway the molecular components involved in IL-1R and TLR4 signaling are shown. Both IL-1R1 and TLR4 (as well as TLR1, 2, 6, 7, 8, and 9) can associate with a cytoplasmic adaptor molecule, MyD88. This interaction occurs between the TIR domains. MyD88 encodes a death domain that mediates association with a serine-threonine kinase, IRAK. TRAF6 serves as scaffold protein can can actvite MAP kinases (MKKs) as well as the IKK complex. MKK can also lead to AP-1 activation via Jnk. The IKK complex induces phosphorylation of IκB, which allows ubiquination of IκB followed by proteasomal degradation. This allows nuclear translocation of NF-κB and gene expression *(From Akira S, Takeda K, Kaisho T:* Nature Immunology 2, *675-680 (2001) doi:10.1038/90609).*

Interleukin-6

IL-6 is primarily produced by mononuclear phagocytes, but it is also produced by T and B cells and may be produced by endothelial cells, epithelial cells, and fibroblasts in response to TNF and IL-1.[594,595] IL-6 production by stimulated neonatal mononuclear cells matches or exceeds that of adults, although diminished production is noted with marked prematurity.[596,597] IL-6 is able to exert effects on a wide range of cells, owing to the unique properties of its receptor. When activated by IL-6, the IL-6 receptor complexes with the gp130 membrane protein, which is required for intracellular signal transduction through the phosphorylation of Stat3. IL-6R also circulates in a soluble (sIL-6R) form, which binds secreted IL-6.[594] The IL-6:IL-6R complex can then activate any cell bearing the gp130 membrane protein, allowing IL-6 to

activate a wide range of cell types. IL-6 provides costimulatory signals to enhance T-cell responses and the differentiation of Th17 cells and stimulates B-cell differentiation and antibody production.[454,472,598] IL-6 also induces the acute phase response, characterized by hepatocyte production of such proteins as fibrinogen, α_2-macroglobulin, and α_1-antitrypsin and also up-regulates local acute phase protein production by mononuclear phagocytes.[599] IL-6 is found in BAL specimens of adults with pulmonary inflammation, as well as in BAL specimens of mechanically ventilated, premature neonates. It is uncertain if IL-6 is a marker or mediator of inflammation in either of these scenarios.[600,601]

Interleukin-10

IL-10 is a critical cytokine produced by T cells, B cells, and mononuclear phagocytes in response to stimuli, including LPS and TNF-α.[602] IL-10 augments proliferation and differentiation of activated B cells while up-regulating their MHC class II expression.[602] IL-10 inhibits the generation of oxyradicals and NO by macrophages and PMNs, impairing their microbicidal functions.[603,604] IL-10 also suppresses macrophage expression of MHC class II and costimulatory molecules CD80 and CD86, diminishing the capacity to present antigen.[602] Finally, IL-10 inhibits macrophage-dependent T-cell proliferation and Th1 cytokine production by macrophages, PMNs, Th1 cells, and NK cells.[602] Mice deficient in IL-10 develop spontaneous colitis.[605,606] These data, along with the fact that IL-10 is expressed by regulatory T cells, suggest that IL-10 is critical as a negative regulator of the immune response.

There is evidence that IL-10 production in the lungs may be protective in some types of inflammatory injuries; animal models of pneumonia have helped to clarify this role of IL-10 in vivo.[607] Exogenous IL-10—preceding intratracheal bacterial challenge—reduced lung TNF, and IFN-γ responses, but increased lung bacterial counts, systemic bacteremia, and morbidity in a murine model of *S. pneumoniae* infection.[608] IL-10 neutralization in this same model resulted in increased lung TNF, diminished lung bacterial counts, and increased survival rates. Similar outcomes have been shown in a murine model of *Klebsiella* pneumonia treated with systemic anti-IL-10 antibody.[609] Given these data, it is thus presumed that in the context of pneumonia, IL-10 acts to modulate the local inflammatory response initiated by the offending pathogen; this preserves alveolar structure, pulmonary gas-exchange function, and host survival. The data regarding neonatal IL-10 generation is somewhat contradictory, but does allow some broad generalizations. First, stimulated neonatal monocytes exhibit only 20% to 40% of the IL-10 production inducible from stimulated adult monocytes.[610,611] Second, available BAL data from mechanically ventilated infants indicates that IL-10 expression in the lung is diminished in preterm infants but increases with advancing gestational age.[612,613] These age-related findings parallel data indicating differential IL-10 production by lung macrophages ex vivo from term and preterm infants.[614] Such differences, if true in vivo, suggest that premature infants may be less able to attenuate alveolar inflammation in the setting of a pneumonitis or other inflammatory insult.

Interleukin-15

IL-15 is a 15-kDa peptide that shares β-and γ-receptor components with IL-2, resulting in overlapping immune functions including induction of T-cell proliferation and increased T-cell cytotoxic activity.[615,616] Like IL-2, IL-15 binding requires a distinct α-chain receptor component (IL-15Ra); this component is expressed in a variety of tissues, conferring pleiotropic immune activities distinct from those of IL-2. IL-15 induces NK cell–derived TNF-α, GM-CSF, and IFN-γ and augments IL-12 up-regulation of T cell–derived IFN-γ.[617,618] IL-15 also induces NK-cell differentiation, activation, and supports prolonged NK-cell survival. Beyond these effects, IL-15 has also been shown to induce IL-8 expression by T cells and monocytes and up-regulate monocyte-derived MCP-1 and MIP-1β, facilitating phagocyte recruitment and a proinflammatory milieu.[619] Finally, IL-15 also directly activates PMNs, inducing membrane "stiffening," enhancing phagocytosis, and delaying apoptosis.[616] Although macrophages are the primary cellular source of IL-15, gene expression of this cytokine has also been identified in lung fibroblast and epithelial cells, DCs, and endothelial cells in response to a variety of bacterial and viral stimuli, indicating a role for IL-15 in pulmonary immune regulation.[616] IL-15 is critical for homeostatic proliferation of T cells and regulates the generation of memory T cells.[620] IL-15 production has not been characterized in the neonatal air space, but stimulated neonatal monocytes in vitro exhibit diminished IL-15 mRNA stability and protein expression.[621] Given this finding, it is reasonable to speculate that attenuated IL-15 production by the neonate may contribute to impaired pulmonary cellular immunity.

Interleukin-17

IL-17 is a proinflammatory cytokine produced by activated memory CD4 T cells of the Th17 susbet that facilitates granulopoiesis and pulmonary PMN recruitment in response to local bacterial infection.[458] It is the prototypical member of a cytokine cohort collectively designated IL-17A-F, which also includes IL-25 (IL-17E).[622] IL-17A signals through the adaptor proteins Act1 to induced NF-κB and AP-1.[623,624] IL-17 stabilizes transcripts for CXCL1 and G-CSF and therefore synergizes with other inducers of NF-κB such as TNF-α.[458,625] The target cells of IL-17s actions are mainly epithelial cells, fibroblasts, and endothelial cells.[458,622] Pulmonary IL-17 has not as yet been quantified in neonatal cohorts, but may be negligible given the relative paucity of memory T cells in this population. IL-17E is the most divergent IL-17 family member showing only 25% homology with IL-17A. Interestingly IL-17E or IL-25 potently induces IL-4 and IL-13 and is involved in Th2 T-cell differentiation.[626,627]

Interleukin-18

Initially identified as IFN-γ–inducing factor (IGIF), IL-18 is an approximately 18-kDa protein that enhances IFN-γ production and exhibits other, proinflammatory, functions.[628] IL-18 is similar to IL-1β both in secondary structure and in its secretion as an inactive precursor requiring cleavage by IL-1β–converting enzyme (caspase-1) to become bioactive.[628] IL-18 also shares receptor components and signal transduction mechanisms with IL-1.[628] Binding of IL-18 to its receptor, the IL-1 receptor–related protein (IL-1Rrp), triggers a signaling pathway that requires IRAK and eventually culminates in the nuclear translocation of NF-γB and gene transcription. IL-18 may also bind to its alternative ligand, IL-18 binding protein (IL-18bp)—an endogenous, soluble, "decoy" receptor that inhibits IL-18 activity; IL-18 bioactivity may thus be titrated either by regulation of cleavage activation or by modulation of IL-18bp levels.[629] IL-18 is present constitutively within the lung, primarily derived from alveolar macrophages, although it is also inducible in vitro from pulmonary fibroblasts.[630] Like other macrophage-derived cytokines, IL-18 is up-regulated in response to microbial products (LPS, gram-positive bacterial exotoxins) and is also induced by exposure to TNF-α, chemokines (IL-8, MCP-1, MIP-1α), and mycobacteria.[628] As suggested earlier, IL-18 has important IFN-γ–inducing activity. By direct activation of the IFN-γ promoter, IL-18 achieves potent synergy with IL-12 for IFN-γ production by T cells, B cells, and NK cells but only modest induction of IFN-γ in the absence of IL-12; this augmented IFN-γ production may favor a Th1 response within the alveolus.[628] IL-18 is protective against fungal, bacterial, and viral pathogens.[631-633] Such a role has been demonstrated in vivo in a transgenic model of IL-18 deficiency, where impaired lung bacterial clearance and fulminant progression to systemic infection resulted from intratracheal inoculation with *S. pneumoniae*.[634] In neonates, however, the pulmonary expression of IL-18 remains incompletely characterized.

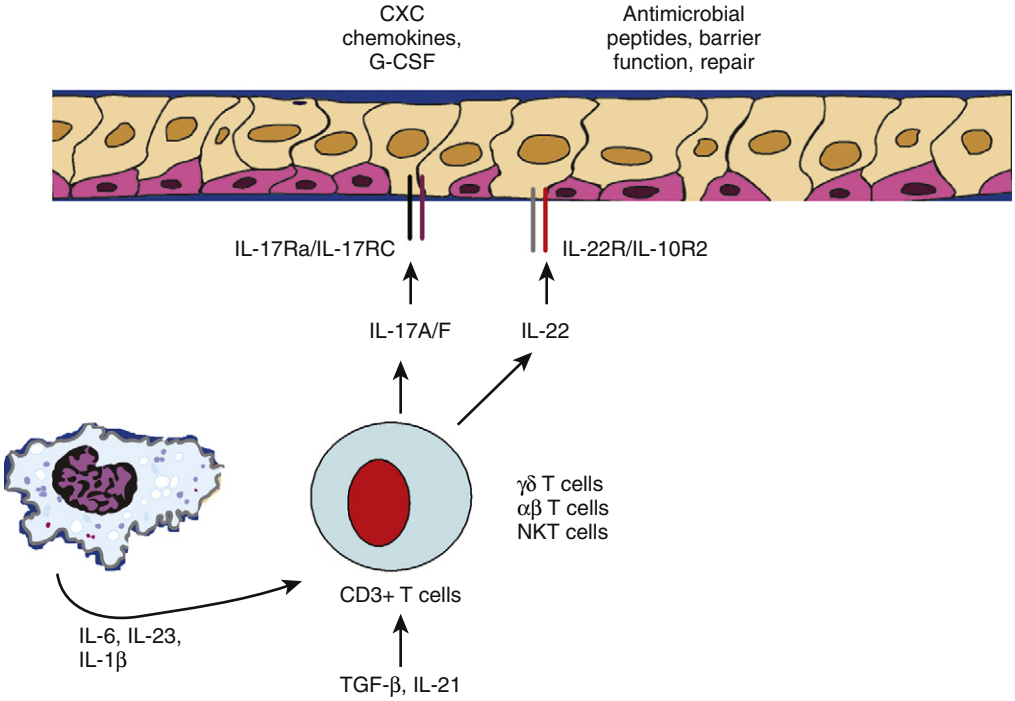

Figure 159-12 Functions of IL-17 and IL-22 during experimental *K. pneumoniae* infection in the lung.IL-17 and IL-22 are induced rapidly in experimental bacterial pneumonia and produced by several T-cell populations in the lung including δ-T cells, NK T cells, as well as effector memory αβ CD4+ T cells. IL-17 signaling regulates granulopoiesis through the regulation of G-CSF, as well as neutrophil recruitment via the regulation of CXC chemokines by epithelial cells. IL-22 along with IL-17 induces antimicrobial peptides from same target cells and can augment epithelial repair.This cooperative induction of neutrophil recruitment and antimicrobial peptide production augments epithelial barrier function and is critical for mucosal host defense against gram-negative bacterial pneumonia.

Interleukin-22

IL-22 is one of the IL-10 family cytokines, which also includes IL-10, IL-19, IL-20, IL-24, and IL-26, as well as more distantly related IL-28 and IL-29. IL-22 was first identified as an IL-10– related T cell–derived inducible factor (IL-TIF) from a lymphoma cell line treated with IL-9.[635] IL-22R and IL-10R2 were soon identified as the heterodimeric receptor complex for the function of IL-22.[458] As mentioned above, one biologic function of IL-22 is that it synergizes with IL-17 to regulate the expression of antimicrobial peptides at epithelial surfaces.[456,460] IL-22 regulation of antimicrobial proteins has been shown to exist at several mucosal surfaces including the skin, gut, and, lung (Figure 159-12).[456,458]

Chemokines

IL-8 and several other structurally homologous proteins make up the family of cytokines known as chemokines. The chemokine family consists of more than 40 small (70-130 amino acids) cytokines divided into four subfamilies based on the position of one or two conserved cysteine residues located near the N-terminus defining four structural motifs: CXC, CC, C, and CX3C.[636,637] Different leukocyte subsets express a unique chemokine receptor profile that defines the response potential of each type of cell. In turn, chemokines can be modified by proteases in the extracellular milieu to become more active or inert.[638] Although most chemokine receptors bind more than one chemokine, CC receptors bind only CC chemokines and CXC receptors bind only CXC chemokines. Chemokines play a critical role in recruitment and activation of inflammatory cells at sites of infection. Both CC and CXC chemokines have positively charged C-terminus residues that bind to negatively charged glycosaminoglycans on matrix proteins in the interstitium and on cell surfaces; this provides a mechanism to stabilize chemokines near sites of generation, achieving relatively fixed local chemotactic gradients. Proteolytic cleavage of glycosaminoglycans such as syndecan can also modify the amount of free chemokine to serve as a chemoattractant.[639] The spectrum of action of a given chemokine is thus a function of its local concentration, its posttranslational processing, and the temporal expression of chemokine receptor(s) on putative target cells. Important representative chemokines implicated in the regulation of pulmonary immune responses include members of the CXC and CC subfamilies.

CXC Chemokine Subfamily

CXC chemokines can be further subdivided into two groups based on the presence or absence of three amino acids (Glu-Leu-Arg: the "ELR" motif) preceding the first cysteine residue.The ELR+ CXC chemokines are potent neutrophil chemoattractants and angiogenic agents, whereas ELR-CXC chemokines are chemoattractant for mononuclear leukocytes and angiostatic. CXCL8 (IL-8), the prototypical ELR+ CXC chemokine, is produced by a number of pulmonary cells, including mononuclear phagocytes, endothelial cells, fibroblasts, epithelial cells, mesothelial cells, and T cells.[640 641] Chemokine production by these cells can be induced by multiple stimuli, including viruses, bacterial products, TNF, IL-1, C5a, LTB_4, IL-17 and IFN.[640,641] Actions of IL-8 on PMNs include potent chemoattraction, upregulation of adhesion molecule expression, and enhancement of PMN respiratory burst and degranulation.[640-642] IL-8 also stimulates PMN production of the inflammatory lipid mediators LTB_4 and PAF.[640,641] It is important to keep in mind that IL-8 is only one ligand for CXCR2 and that CXCL1, CXCL2, CXCL5 and CXCL6 can each serve as ligands for CXCR2. Thus the contribution of CXCL8 in humans compared to these other CXCR2 ligands remains to be defined.

IL-8 is locally expressed in patients with pneumonia, and its critical role in host response is further supported by animal models of bacterial pneumonitis; in these models, depletion of CXC chemokines, or blockade of CXC receptors, attenuates PMN recruitment and blunts pulmonary bacterial clearance.[643-646] A similar role likely exists for IL-8 in neonates; however, data regarding IL-8 production in this population is somewhat contradictory. In vitro stimulation of neonatal immune cells has typically demonstrated IL-8 production well below adult levels.[647,648] However, neonatal IL-8 production exceeding adult response has been shown using flow cytometric analysis in an ex vivo model of neonatal sepsis or neonatal stress.[649,650] Although challenging to previous conventional wisdom, these findings are consistent with other emerging data showing the presence of significant, inducible IL-8 in the BAL specimens of term and preterm newborns with lung insults such as meconium aspiration syndrome or hyaline membrane disease.[651] IL-8 should therefore be considered as a likely relevant mediator both in neonatal pulmonary host defense as well as in inflammatory lung pathology. CXCL9, CXCL10, and CXCL11 are all ligands for CXCR3, which is preferentially expressed on Th1 cells and thus these chemokines have been shown to be critical for recruitment of Th1 cells to the lung and granuloma formation.[652,653]

CC Chemokine Subfamily

CCL3 (MIP-1α), CCL2 (MCP-1), and other members of the CC chemokine subfamily are derived from multiple pulmonary cells including PMNs, mononuclear phagocytes, lymphocytes, NK cells, endothelium, fibroblasts, epithelial cells, and mesothelium.[654-656] Stimuli that induce production of the CC chemokines include viruses, bacterial products, TNF, IL-1, C5a, LTB4, and IFN; IL-10 is a potent CC chemokine suppressor. The CC chemokines have specific chemotactic activity for monocytes, lymphocytes, eosinophils, and basophils and tend to have proinflammatory properties.[657,658] Binding of CC chemokines to their corresponding receptors on monocytes produces an increased respiratory burst and induces rapid release of arachidonic acid metabolites.[656,659] CCL3 and CCL2 regulate monocyte expression of adhesion molecules, preferentially increasing monocyte expression of the β2 integrin CD11/CD18 normally associated with PMNs, rather than the usual monocyte adhesin VLA-4.[660] This enhanced expression of β2 integrins results in augmented monocyte adhesion to endothelium, putatively enhancing monocyte migration to inflammatory loci. The CC chemokines have also been identified in the recruitment of T cells, B cells, and NK cells; however, they appear to lack significant effects on PMNs.[656,661,662]

Although early in vitro work demonstrated neonatal monocytes had decreased inducible CCL3 relative to adults, recent data have challenged these findings.[663] Basal serum levels of CCL3 are found to be similar in neonatal and adult cohorts, and monocyte-derived CCL3 is comparably inducible in these two age groups.[664] Levels of CCL3 are increased in airway fluids of infants with inflammatory pulmonic processes including severe RSV infection, *Ureaplasma* infection, and respiratory distress syndrome, suggesting local inducibility of this chemokine in response to infection or insult.[665-668] Neonatal levels of MCP-1 in both serum and airway fluid are found to be similarly inducible in response to appropriate stress. Taken together, these data suggest that the CC chemokines like IL-8 should be considered relevant mediators of both pulmonary host defense and inflammatory lung injury in the neonate.

Transforming Growth Factor-β

TGF-β is a cytokine primarily associated with tissue repair and fibrosis, but one that also exerts important immunomodulatory effects. This cytokine is secreted as an inactive disulfide bond-linked dimer, and liberation of the 25-kDa active form occurs in response either to proteolytic activation or acidic condition.[669-671] TGF-β is produced by multiple cell lines, including platelets, T cells, PMNs, mononuclear cells, fibroblasts, epithelial cells, and endothelial cells and exerts pleiotropic effects relevant to host immune response.[671] It can directly, or indirectly through IL-6, induce production of acute phase proteins and together with IL-6 control the development of Th17 cells.[472,672] In the absence of IL-6, TGF-β can induce the development of regulatory T cells.[472] TGF-β can also act as a potent chemoattractant for monocytes and macrophages and can induce these cells to produce TGF-β, thereby amplifying its local effects.[673] Although TGF-β can induce monocyte-derived IL-1 and TNF-α, it inhibits LPS induction of macrophage-derived IL-1, TNF-α, and IFN-γ, thus exhibiting antiinflammatory activity in settings of immune activation.[670] TGF-β can also down-regulate macrophage NO production and MHC II expression and suppresses macrophage respiratory burst.[674] Beyond macrophage deactivation, TGF-β also down-regulates IL-2 receptors, inhibiting IL-2–dependent T-cell proliferation and IL-1–dependent lymphocyte proliferation. The net result of TGF-β activity is impairment of IL-2 effect and inhibition of Th1 response. Within the alveolus, this manifests as impaired antigen presentation and a general suppression of inflammation. Data defining the role of TGF-β in neonatal pulmonary defense remain incomplete. In vitro, TGF-β production from stimulated neonatal monocytes is only 35% to 40% of that from adult monocytes; this suggests compromised ability of the neonate to titrate inflammation through TGF production.[663] This observation is supported by in vivo data showing lower TGF-β levels in the BAL specimens of infants progressing to states of chronic lung disease.[675] Finally, additional studies have shown elevated neonatal BAL levels of TGF-β, suggesting that expression of this cytokine may be more inducible than indicated by in vitro data.[676]

Clara Cell Secretory Protein

Clara cell secretory protein (CCSP) is one of the most abundant proteins of the airway lining fluid. It is secreted by Clara cells, as well as by serous and goblet cells of the proximal airways.[677] Structurally, CCSP is a small homodimeric protein consisting of two 8-kDa subunits aligned by disulfide links to form a hydrophobic pocket.[678] This pocket can bind phosphatidylcholine and phosphatidylinositol, and CCSP was originally postulated to participate in surfactant metabolism. More recently, CCSP has been noted to modulate inflammatory responses, suggesting a potential immunoregulatory role within the airways and alveoli. In vitro, CCSP has been shown to inhibit PMN chemotaxis, as well as macrophage phagocytosis.[678] Its hydrophobic pocket allows CCSP to "scavenge" phospholipase A_2 within the milieu, further limiting PMN activation.[678] CCSP has also been shown to inhibit the production and bioactivity of IFN-γ.[678] Murine models of CCSP deficiency have attempted to further clarify the in vivo role of this protein. In a hyperoxic model of lung injury, CCSP-deficient animals exhibited higher lung levels of IL-1β, IL-6, and IL-3, increased lung inflammation, and decreased survival rates.[679] In a model of adenoviral lung infection, CCSP deficiency resulted in both earlier and increased inflammatory response; this was accompanied by increased expression of TNF, IL-1β, IL-6, and chemokines (CCL3 and CCL2).[680] CCSP-deficient animals receiving an antigenic challenge showed increased levels of Th2 cytokines with exacerbated eosinophilic inflammation.[681] Finally, CCSP-deficient mice demonstrate increased expression of IgA.[682] The exaggerated cellular response seen in each of these models is consistent with the putative role of CCSP as an antiinflammatory molecule. LPS depresses CCSP gene expression in a dose-dependent fashion, suggesting that potent signals of infection may dampen CCSP secretion as required to allow an appropriate inflammatory response.[683] In newborns, CCSP levels are detected in tracheal/alveolar aspirates obtained at birth and correlate with gestational age. Neonates with clinical signs of infection have increased CCSP levels, correlating inversely with tracheoalveolar

fluid leukocyte counts.[684] Similarly, infants who subsequently develop BPD demonstrate diminished inducibility of CCSP and generally lower CCSP levels in their airway fluid, possibly contributing to the increased lung inflammation seen in this process.[685]

Colony-Stimulating Factors

Colony-stimulating factors such as GM-CSF are also identified as participants in pulmonary host defense. These factors, including G-CSF and macrophage–colony stimulating factor (M-CSF), are generated by a number of relevant pulmonary cells including endothelial cells, epithelial cells, fibroblasts, mononuclear phagocytes, and T lymphocytes; production of these factors may be induced by an array of microbial products and pathogens.[686,687] Once elaborated at a site of potential infection, these factors exert pleiotropic effects on local immune cells, including increased membrane expression of receptors and adhesion molecules, enhanced motility, increased microbiocidal function of phagocytic cells, enhanced phagocyte survival, and stimulation of cytokine secretion by mononuclear phagocytes.[686,687] GM-CSF also acts on macrophages to stimulate their antigen presentation capabilities and directs DC differentiation and distribution in the lung.[688,689] Within the lung, GM-CSF is produced by alveolar macrophages, bronchial epithelial cells, and vascular endothelium. It is a potent stimulus for PMN degranulation, and its production by endothelial cells has been implicated in PMN-mediated alveolar injury.[690] GM-CSF deficiency results in a phenotype of pulmonary alveolar proteinosis.[691] Although the precise mechanism of this phenotype remains unclear, GM-CSF–deficient macrophages show reduced expression of the transcription factor PU.1 and reduce phagocytic capacity.[692,693] The capacity of neonatal T cells to generate GM-CSF is only 50% of adult T cells; however, neonatal mononuclear cells possess an adult capacity for production of this cytokine and may thus be able to induce local responses dependent on GM-CSF elaboration. This premise is supported by data from newborns demonstrating alveolar macrophage generation of GM-CSF.[694]

Of the colony-stimulating factors, G-CSF appears to be most critical in pulmonary host defense against bacteria. Alveolar macrophages are potent secretors of G-CSF in response to LPS, or when stimulated by TNF or IL-1. Alveolar macrophage–derived G-CSF acts locally to recruit, activate, and delay apoptosis of PMNs while acting systemically to induce granulopoiesis and increase the circulating neutrophil count. The importance of G-CSF in this context is underscored by animal studies where antibody neutralization of G-CSF results in profoundly suppressed PMN recruitment and diminished bactericidal activity against aerosolized *P. aeruginosa.*[695,696] Of note, G-CSF also induces antiinflammatory mediators such as IL-1ra and soluble TNF receptors, locally titrating the inflammatory response.[697] Neonatal monocytes can be stimulated to generate near-adult amounts of G-CSF. Preterm infants, however, appear much more compromised in their ability to up-regulate G-CSF production (10% to 30% of adult response), and this may constitute yet another deficiency of pulmonary host defense in this cohort.[698]

Adhesion Molecules

Leukocyte migration from the intravascular space to an eventual inflammatory locus within the lung is a multistep process dependent on mechanisms directing cell movement to the appropriate site; leukocytes must marginate and adhere to the vascular endothelium followed by diapedesis between endothelial cells and movement from the vascular space. Directed movement along concentration gradients of chemotaxins is one mechanism; another is haptotaxis, or directed migration along gradients of endothelial adhesiveness. This latter process requires the presence of both leukocyte- and endothelial-derived adhesion molecules and is mediated by three families of molecules: the integrins, the immunoglobulin gene superfamily, and the selectins.

The integrins are a family of proteins involved in cell adhesion and motility. Present on leukocyte membranes, these molecules adhere to specific endothelial ligands and various components of connective tissue matrix. The integrins are expressed as heterodimers, each containing one α and one β chain; subclassification of these adhesins is based on specific α/β chain content. The α4 integrins are expressed at high levels on monocytes, lymphocytes, and eosinophils. Although typically absent from neutrophils, α4 integrin is present on immature PMNs or on mature forms under conditions of transendothelial migration or chemokine stimulation.[699,700] The β1 integrins include very late antigen 4 (VLA-4), found on lymphocytes and monocyte.[701] The β2 integrins include CD11a/CD18, constitutively expressed on all leukocyte subsets, and CD11b/CD18 and CD11c/CD18, which are prominent adhesins of PMNs.[702] Because the PMN must deform to navigate the narrow alveolar capillary space, the PMN surface membranes are brought into close contact with those of the vascular endothelium, inviting adherence interactions.[703] CD11/CD18 is therefore maintained in an inactive state until chemotactic activation occurs.[704] PMN activation results in a CD11/CD18 conformational change to an activated form that recognizes its corresponding endothelial ligand.[705] PMN activation also results in mobilization of a significant intracellular stored pool of CD11/CD18, facilitating rapid additional surface expression of this molecule although the constitutively smaller pool in neonatal PMNs may tend to blunt this response.[702]

The immunoglobulin gene superfamily includes intercellular adhesion molecules 1 and 2 (ICAM-1 and ICAM-2), vascular cell adhesion molecule 1 (VCAM-1), and platelet-endothelial cell adhesion molecule (PECAM). ICAM-1, the endothelial ligand for CD11/CD18, is expressed on endothelial cells constitutively and up-regulated in response to endotoxin, TNF-α, or IL-1β; ICAM-1 is also expressed on the surface of fibroblasts and epithelial cells.[706] VCAM is similarly up-regulated by TNF-α and IL-1β, recognizes VLA-4 (and other β1 integrins), and binds monocytes and lymphocytes.[707] PECAM is present constitutively and in the pulmonary vasculature may up-regulate in response to hyperoxia.[708] Its primary counterreceptor is the P-selectin glycoprotein ligand-1 (PSGL-1), found on a variety of leukocytes, including PMNs. PECAM-mediated adhesion may be important in transendothelial cell diapedesis of PMNs from the intravascular space.[709]

The selectin family includes L-selectin, P-selectin, and E-selectin. L-selectin is expressed on the surface of PMNs and is shed shortly after activation in vitro.[710] P-selectin is stored in endothelial cells and rapidly mobilized to the surface after initial endothelial activation.[711] E-selectin (endothelial-leukocyte adhesion molecule [ELAM]) is expressed on the surface of endothelial cells only after activation by bacterial products or mediators including C1q, TNF-α, IL-1β, and IL-10.[712,713] PMN receptors for the endothelial selectins include PSGL-1 and sialyl Lewis X antigen (sLe^x), an oligosaccharide present on many proteins including the PMN adhesins L-selectin and CD11/CD18.[714,715]

The initial step in leukocyte migration to extravascular sites is a slowing of leukocyte movement through the area of inflammation by a series of loose, transient leukocyte-endothelial cell adhesions, characterized as "rolling." This step is mediated through interaction of endothelial selectins with PSGL-1 and L-selectin on the PMN surface.[715] Diminished L-selectin and sLe^x concentrations on neonatal PMN surfaces have been implicated in impaired chemotaxis, but are likely not relevant in the pulmonary circulation where the constrained vascular space obviates the need for this receptor-ligand interaction.[716] The next step entails binding of local chemotactic activators (C3a, C5a, IL-8, PAF) to the "rolling" PMN, inducing expression and activation of CD11/CD18 and shedding of L-selectin.[715] Subsequently, the leukocytes firmly attach to the endothelium via CD11/CD18 to ICAM-1 interaction, PMNs, or by means of VLA-4 to VCAM-1

interaction (mononuclear cells, lymphocytes).[717,718] The final step is diapedesis of the adherent leukocyte through the vessel wall and migration along a chemotactic gradient to the site of inflammation. Although this process remains incompletely characterized, transendothelial migration appears mediated by the adhesion molecules PECAM and the integrin-associated protein CD47.[719] Once extravasated, neutrophils appear to follow a fixed chemotactic gradient laid down in the extracellular matrix, migrating along interstitial fibroblasts and eventually squeezing between type I and type II epithelial cells to reach the air spaces of the lung.[720]

Generation of a Local Immune Response

In animal models of bacterial pneumonia, the influx of inflammatory cells follows a well-orchestrated sequence. First, neutrophils enter the lung within minutes to hours of airway inoculation. This early neutrophil recruitment is partly dependent on TNF-α, and IL-1β, which can upregulate ICAM-1 as well as via the induction CXCL1, CXCL2, and CXCL5. PMN accumulation is maximal within 2 days with cell clearance primarily through apoptosis. Later PMN recruitment is in part regulated by IL-17, which stabilizes CXC chemokine expression.[458,622] By day 2 to 3 monocytes are recruited, with maximal accrual by day 5 to 7 in resolving inflammation. Lymphocyte influx begins by 5 days, often occurring despite clearance of the organism. Although the timing of events is not consistently this rigid, the sequential appearance of each cell type is characteristic, consistent with a transition from acute inflammation to a more specific immune response. Factors unique to the lung that regulate this coordinated host response are now considered.

Intrapulmonary Neutrophil Trafficking

Most marginated neutrophils (up to 50% of intravascular PMN) reside in lung capillaries; thus compared to other organs, the lungs enjoy a large, readily mobilizable granulocyte pool.[721] The narrow caliber of these vessels (diameter 5 to 9 μm) does not allow leukocyte rolling, but rather requires neutrophils (diameter 6.5 to 8 μm) to deform and slowly "squeeze through" this vascular space; this imposes sustained PMN-endothelial contact, independent of adhesion molecules.[722] The small distance between pulmonary capillaries and their alveoli facilitates brisk PMN response to alveolar-derived inflammatory signals. In this setting, mediator activation of neutrophils induces cytoskeletal changes that reduce PMN deformability, increasing duration of capillary transit and neutrophil-endothelial contact.[723] Of note, the impaired deformability of neonatal neutrophils may engender a larger marginated pool of these cells within the newborn lung. Once activated, "stiffened" neutrophils are retained briefly (4 to 7 minutes in vivo) near inflammatory sites until appropriate adhesins can be expressed to facilitate firm attachment and eventual transendothelial diapedesis.[724]

Beyond the rheologic conditions promoting neutrophil margination, neutrophil trafficking in the pulmonary capillary differs from other vascular sites in the repertoire of adhesive interactions invoked. P-selectin is not expressed on pulmonary capillary endothelium, consistent with spatial constraints that obviate selectin-initiated "rolling" as an initial step in PMN recruitment.[725] However, once activated, neutrophils are sequestered only transiently and return to circulation unless firm adhesion to the endothelium occurs. Available data suggest that this adhesion is mediated first by L-selectin then by CD11/CD18.[726] Firm adhesion mediated by CD11/CD18 is temporally associated with resolution of neutrophil "stiffening," allowing sufficient PMN surface area to flatten and engage the endothelium.[723] Once firmly adhered, neutrophil emigration from the vascular space then proceeds in a manner that is either CD11/CD18 dependent or CD11/CD18 independent, depending on the specific stimulus. *P. aeruginosa*, *E. coli* (or its endotoxin), IgG immune complexes, and IL-1 each induce PMN emigration mediated by CD11/CD18; because these stimuli also up-regulate endothelial ICAM expression, CD11/CD18– dependent migration may result from critical availability of this counter ligand.[727] Alternatively, stimuli including hyperoxia, C5a, IL-8, LTB_4, and the organisms *S. pneumoniae*, *S. aureus*, and group B *Streptococcus,* induce PMN emigration, which is CD11/CD18 independent.[727,728]

Alveolar Macrophage Regulation of Inflammation

The ability of the alveolar macrophage to recruit and regulate other inflammatory cells is the major attribute allowing alveolar macrophages to locally regulate pulmonary host defenses. In addition to their phagocytic function, alveolar macrophages can recruit PMNs, eosinophils, interstitial and airway macrophages, and peripheral blood monocytes to the alveolar space; once present in the alveolus, these cells are either activated or suppressed by alveolar macrophage–derived mediators.

Mediators that up-regulate inflammation within the alveolus are not constitutively expressed by alveolar macrophages; their release therefore requires the alveolar macrophages to be in an activated state. Activation typically occurs through engagement of macrophage pattern recognition receptors (PRRs) and can be titrated by competitive interactions with soluble PRRs within the alveolar milieu. One example of this is the interaction between SP-A and the CD14 ligand LBP. In the basal, uninflamed state, SP-A is present at much higher concentrations than the acute phase protein LBP and therefore is the primary ligand for any LPS inadvertently deposited from the air stream into the airway surface liquid. This prevents initiation of the LBP/CD14 pathway and dampens inflammatory tone within the alveolus. However, under conditions of inflammation, SP-A concentrations may fall dramatically, owing to degradation by PMN-derived proteases and elastases, whereas LBP is concurrently up-regulated as an acute phase protein. Under these conditions, LBP becomes the dominant LPS-binding protein in the alveolus; this facilitates alveolar macrophage activation via the CD14 receptor, amplifying the bioactivity of LPS and subsequent inflammation several fold.[729] Alternatively, alveolar macrophage activation can occur in response to GM-CSF elaborated by activated alveolar epithelium or in response to IFN-γ elaborated by local NK cells or T cells.

The activated alveolar macrophage effects PMN emigration to the alveolus through its production of multiple neutrophil chemotaxins including the lipid mediators PAF and LTB_4, complement components C3a and C5a, and IL-8. Activated alveolar macrophages also produce TNF-α and IL-1β, which, although not directly chemotactic, can activate PMN and up-regulate local endothelial cell surface adhesins and may thereby facilitate PMN recruitment from the intravascular space. Additionally, alveolar macrophages have the capacity to recruit and activate other inflammatory cells. Alveolar macrophages can induce chemotaxis and activation of monocytes by secretion of the chemokines MCP-1 and MIP-1α, and in pneumonia this resulting monocyte infiltration typically peaks between days 5 and 7. Mononuclear cell response to either MCP-1 or MIP-1α includes increased respiratory burst, increased chemotaxis, increased monocyte expression of β2 integrins, and increased generation of arachidonic acid products; MCP-1 has also been shown to prime macrophages to respond to LPS, resulting in a proinflammatory amplifying loop. NK cells are also recruited and activated by these chemokines, and alveolar macrophage–derived IL-12 increases NK-cell cytoxicity and induces NK-derived IFN-γ, generating another proinflammatory amplifying loop.

Consistent with its role in regulating intraalveolar immune responses, the alveolar macrophage also induces or expresses several mediators capable of honing or down-regulating local inflammatory processes. IL-6 derived directly from the alveolar macrophage or from alveolar cells (fibroblasts, endothelium,

epithelium), in response to alveolar macrophage-derived IL-1, induces T-cell and B-cell proliferation, but down-regulates subsequent alveolar macrophage production of TNF or IL-1. More directly, alveolar macrophage–derived IL-1ra, produced in response to endotoxin or adherent IgG, inhibits local IL-1β effects by competitive binding of the IL-1 receptor. Alveolar macrophage release of PGE_2 suppresses chemotaxis and release of inflammatory LTs by PMN and alveolar macrophages, further down-regulating TNF and IL-1 production. Alveolar marcrophage–secreted TGF-β blunts further alveolar macrophage response to LPS and serves to dampen the proinflammatory amplifying loops noted earlier. Additionally, alveolar macrophages can be induced to generate IL-10, although the most prominent alveolar source of this cytokine may actually be the recruited peripheral monocytes. This cytokine exhibits protean antiinflammatory activity. It suppresses a variety of proinflammatory cytokines and facilitates transition to a T cell–mediated adaptive immune response. Finally, alveolar macrophages down-regulate inflammation in the air space through clearance of apoptotic neutrophils; this activity is enhanced by the effects of IL-10, which diminishes phagocyte killing capability but up-regulates phagocytic function. This constitutes an antiinflammatory function because failure to clear necrotic PMNs results in protease release, local cell injury, sustained inflammation, and parenchymal destruction, as demonstrated in animal models of pneumonia.[730] Alveolar macrophages are poor at antigen presentation as a result of the fact that they express low levels of costimulatory molecules. Thus it is DCs that play a key role in initiating of adaptive immunity in the lung.

Dendritic Cells and Adaptive Immune Responses

DCs are distributed throughout the airways of the respiratory tract. Moreover, their numbers can be greatly augmented within 6 to 120 minutes by TLR agonists such as LPS.[731,732] Airways contain intraepithelial DCs that can extend dendritc processes into the ASL to sample antigens from the airway surface.[731,732] DCs of the myeloid subset express TLR2, 4, 5, and 9 and are critical for recognizing many extracellular pathogens. Plasmacytoid DCs enriched for TLRs such as TLR3 and TLR7 and TLR8 (that can recognize viral RNAs) have been shown to be critical for the induction of Type I interferons in response to RSV infection.[733] As mentioned earlier, immature DCs are endocytic and upon TLR activation mature and migrate to regional lymph nodes via the upregulation of CCR7. For *M. tuberculosis,* the induction of IL-12p40 is also critical for this migration.[10] Once there, antigen presentation to T cells can occur. Naive T cells differentiate under control of both costimulation and cytokine signals to Th1, Th2, Th17 or Treg cells. It has been recently shown that inhaled antigen that lacks PRR or TLR activation fails to lead to pure anergy in the lung. In contrast, pure antigen that lacks TLR or other PRR activators can induce a population of Foxp3 regulatory T cells that expresses surface TFG-β, and this T-cell population is critical for the development of tolerance in the lung.[734] This mechanism is very important as the lung encounters a lot of inhaled particulate and cannot afford to generate robust immune responses to each particle or risk the development of chronic lung inflammation. Once an effector T cell is generated, it recirculates back to the site of infection along chemokine gradients. This is also the basis of mucosal vaccination to generate a pool of effector memory T cells that can rapidly respond to a pathogen challenge.

The mucosal IgA response is regulated by T cells, which provide an initial contact-dependent signal to the B cell and subsequently secrete TGF-β, resulting in B-cell switching of IgM expression to IgA expression.[735] The T-cell cytokines IL-5 and IL-6 are necessary for final differentiation of surface IgA–expressing B cells to IgA-secreting plasma cells. Similarly, elaboration of other cytokines during T cell–mediated activation induces B-cell switching to other immunoglobulin classes.

In the neonate, however, effective pulmonary adaptive immune response is impaired at multiple levels. As noted previously, the phenotype of neonatal T cells is essentially that of antigenically naive adult T cells, presumably caused by limited antigen exposure. These T cells exhibit decreased surface density of T-cell receptors and decreased adhesion molecules. They require sustained receptor stimulation for activation, as well as greater costimulation to achieve a Th1 phenotype. Additionally, whereas memory T cells tend to "home" to specific organs based on prior antigenic exposure, neonatal T cells preferentially reside in distal lymphoid tissues, resulting in delayed recruitment. The net effect is a neonatal lymphocyte response that is more delayed, less facile in terms of accessory cell activation, less able to rapidly evolve a Th1 cellular immune response, less focused in regard to specific antibody production, and possibly less efficient in terms of dampening inflammatory responses once initiated.

Resolution of Inflammation

Because inflammation caused by cellular responses may induce local tissue injury, the capacity to appropriately down-regulate inflammation is essential to preserve lung function. One mechanism of counterbalancing T-cell immunity is provided by networks involving Treg and Th2 cytokines. As mentioned above, both IL-10 and TGF-β can regulate Th1 immune response. It has recently been shown, for example, that depletion of Tregs markedly enhances lung inflammation and lung injury in response to *P. carinii* lung infection.[736] IL-4 can suppress the development of both Th1 and Th17 cells.[454] Recently it has been shown that another IL-12 family member, IL-27, signaling via Stat1, can suppress Th17 development and thus may also be another critical negative regulator of IL-17–induced inflammation in the lung.[737,738] Many cytokines can also induce suppressor of cytokine signaling proteins such as SOCS3 that can antagonize cytokine receptor signaling to dampen inflammation.

Systemic Cytokine Networking

Pulmonary cytokines generated in response to a local infection ideally, but rarely, remain confined to the alveolar space. Inflammatory disruption of alveolar epithelial integrity allows movement of locally generated cytokines into the intravascular space; this results in systemic cytokine networking, which may be either beneficial or deleterious to the host, depending on the specific cytokine and the context of the infection. For instance, it is likely that lung IL-6 generated during alveolar inflammation reaches the systemic circulation where it stimulates the hepatic acute phase response. Another example of systemic cytokine networking is provided by alveolar-derived colony-stimulating factors, which are generated as part of the amplification response in pulmonary inflammation. GM-CSF and G-CSF are produced by alveolar macrophages in response to LPS, TNF-α, or IL-1β, whereas GM-CSF is also produced by stimulated epithelial cells and endothelial cells. Alveolar macrophages recovered from patients with pneumonia spontaneously release G-CSF, which acts locally to activate recruited PMNs and delay apoptosis.[739] In animal models of pneumonia, levels of G-CSF rise rapidly in the lungs and are measurable in the serum within 24 hours; this response is virtually ablated by antibody neutralization of TNF, underscoring the role of cytokine networking in generating alveolar G-CSF.[740] Quinton and colleagues[740] have shown that in the first few hours of pneumonia the lung is the principal source of G-CSF. Parallel studies have demonstrated that intratracheal deposition of G-CSF induces systemic neutrophilia. Taken together, these data suggest a model in which the lung, when challenged by bacteria, produces G-CSF in response to locally generated early response cytokines. Alveolar G-CSF easily reaches the circulation, stimulates granulopoiesis, and amplifies the PMN recruitment response. This response is associated with higher PMN counts in BAL specimens, more rapid bacterial clearance, and increased host survival.[695]

SECTION XXI Neurology

160 Development of the Nervous System

Omar S. Khwaja, Scott L. Pomeroy, and Nicole J. Ullrich

The human brain arises from a few embryonic cells to become, during the brief 280 days of human gestation, one of the most complex systems in the universe. The newborn brain comprises billions of neurons arranged and interconnected in an exquisitely precise three-dimensional network; one in which even minor changes have profound implications for postnatal development and function. The remarkable process of human brain development comprises overlapping genetic and epigenetic events that are tightly regulated in both time and space. This developmental sequence transforms a thin disk of undifferentiated tissue into a multilayered system capable of processing and storing vast amounts of sensory information, and mediating the entire range of human behavior, communication, and emotion. The brain, with its massive prefrontal cortex and ability to investigate and reflect on its own nature and function, primarily differentiates human fetal development from that of other species. In this chapter we review the major temporal events in prenatal nervous system development together with the disorders and anomalies that result from perturbations of these pathways. An overview of significant stages of central nervous system development and the disorders associated with their interruption in fetal life is given in Table 160-1.

EMBRYOGENESIS AND EARLY FORMATION OF THE NERVOUS SYSTEM

The fertilized human ovum divides symmetrically into identical totipotential blastomeres, and within a few cell divisions a blastocyst forms, uterine implantation occurs, and the inner cell mass contains cells committed to formation of the embryo. The progressive specialization of cells including progenitors of the nervous system is highly dependent on intrinsic genomic expression. These critical gene networks often have pleiotropic activity, the same genes often expressed both early and late in neural development, but their functions differing through highly selective temporal and spatial expression patterns. Equally fundamental to neural development are extrinsic signals from neighboring cells and extracellular environment. The nervous system is therefore sensitive to genetic mutation (inherited or de novo) and local, epigenetic disruptions that may lead to similar or overlapping anomalies.

Genetic studies defining the molecular development of the fruit fly *Drosophila* as well as studies in organisms such as the nematode *Caenorhabditis elegans*, the zebra fish, *Xenopus* toad, and avian chick models have defined the key roles of molecular signaling systems that regulate gene expression networks to establish the pattern and polarity of the nervous system. Human molecular genetic studies have defined the highly conserved human homologues of these proteins, suggesting they play a key role in the earliest establishment of the human central nervous system.

Morphologically the key event in further successful development of a brain occurs in the third week of gestation when the inner cell mass, now established as the bilaminar epiblast and hypoblast, undergoes gastrulation to form the three embryonic germ layers. Gastrulation also marks the visible establishment of primary axes of the embryo and nervous system: lateral, anteroposterior (AP) and dorsoventral. This process begins with the appearance of the primitive streak (Figure 160-1) on the epiblast surface and a defined cephalic pole, the primitive node. Epiblast cells migrate toward the streak under control of FGF8, a growth synthesized by streak cells. FGF8 further down-regulates E-cadherin, the molecule responsible for epiblast binding, allowing migrating epiblast cells to invaginate in the region of the node and streak, and delaminate and displace hypoblast cells to form the endoderm and mesoderm. Remaining epiblastic cells differentiate into ectoderm.

TABLE 160-1

Neurology of the Newborn

Development Event	Peak Time	Anomaly
Primary and secondary neurulation	3-4 wk	Cranioraschisis/anencephaly Encephalocele Myeloschisis Myelomeningocele Dysraphic states
Prosencephalic cleavage (ventral induction)	5-6 wk	Holoprosencephaly Agenesis of the corpus callosum Septo-optic dysplasia
Neuronal proliferation		
Cerebral	2-4 mo	Micrencephaly and macrencephaly Hemimegalencephaly Tuberous sclerosis
Cerebellar	2-10 mo postnatal	Dandy-Walker malformation Vermian and cerebellar hypoplasias
Neuronal migration		
Cerebral	3-5 mo	Schizencephaly Lissencephaly-pachygyria Polymicrogyria Heterotopias
Cerebellar	4-10 mo postnatal	Joubert syndrome Rhombencephalosynapsis
Neuronal differentiation		
Axon outgrowth	3 mo-birth	Agenesis of the corpus callosum
Dendritic growth and synapse formation	6 mo-1 yr postnatal	Mental retardation Autism Angelman syndrome
Synaptic rearrangement	Birth-years postnatal	Down syndrome Rett syndrome Fragile X syndrome
Myelination	Birth-years postnatal	Cerebral white matter hypoplasia 18q- syndrome Cerebral white matter disease of prematurity Nutritional and metabolic disturbances

From Volpe JJ (ed): *Neurology of the Newborn,* ed 5, Philadelphia, Saunders, 2008.

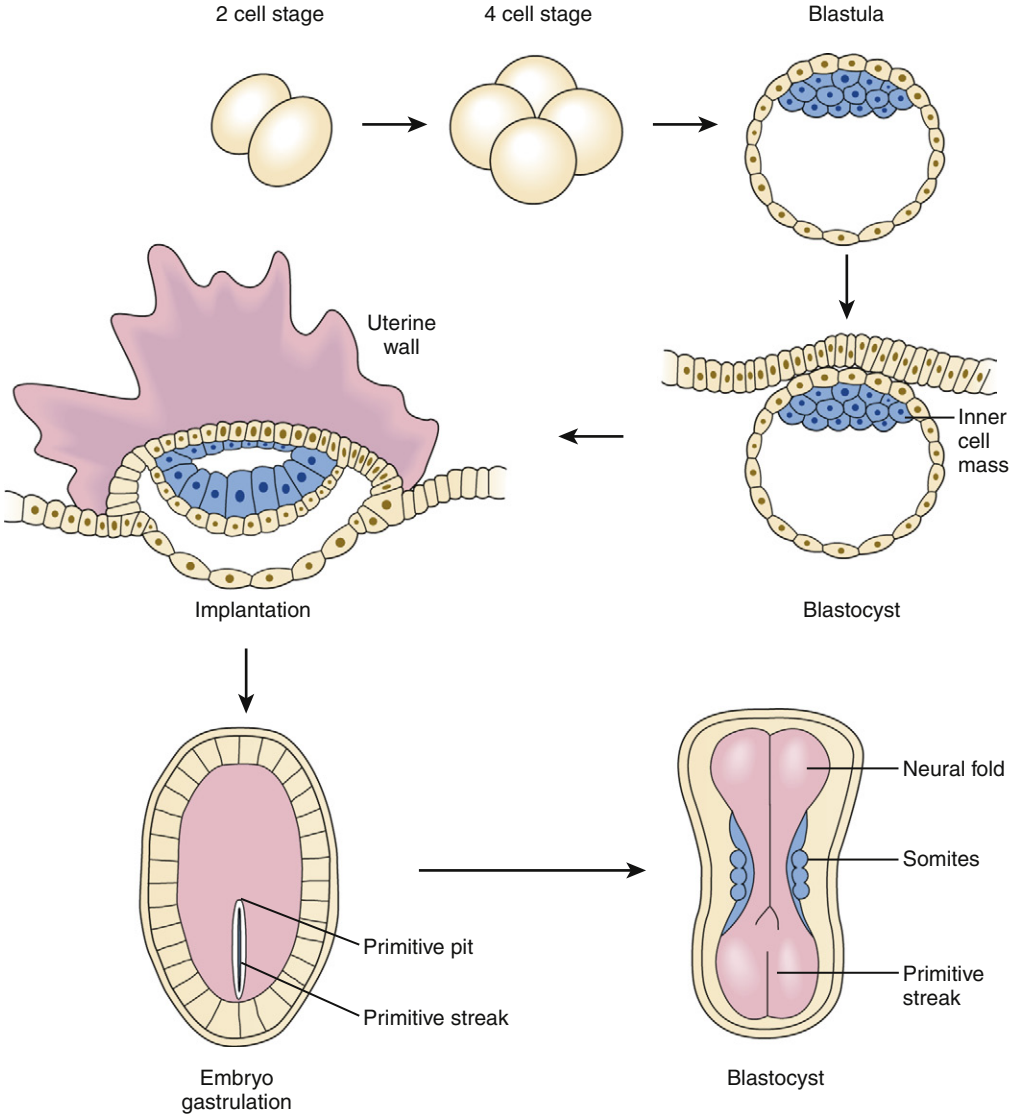

Figure 160-1 Early development of the human embryo. Initial symmetric cell divisions followed by multiple cleavage events to produce a distinct inner cell mass. This is followed by elongation of the embryo and development of the primitive streak. Cells migrate through the primitive streak to form the mesoderm. The overlying ectoderm forms the neural tube that will roll to form the brain and spinal cord. *(Adapted from Sanes DH, Reh TA, Harris WA [eds]:* Development of the Nervous System. *Academic Press, San Diego, CA, 2006.)*

Some of the first cells to migrate through the node in a cephalic direction form the prechordal plate that merges with later migrating cells to form the notochordal plate. Cells within the notochordal plate proliferate and detach from the surrounding hypoblast to form the solid definitive notochord, critical for further development of the nervous system and the basis of the fetal skeleton.

In the fruit fly, maternal effect genes establish the AP axis of the organism and regulate the expression of genes that establish the boundaries of body segments. These genes, gap genes and pair-rule genes, subdivide the embryo into smaller and smaller restricted domains of gene expression. Together with segment polarity genes, these genes subsequently regulate the expression of *homeotic* gene clusters, encoding a family of transcription factors that induce the expression of a battery of genes that induce the development of specific body segments and morphogenetic units. These homeotic *(Hox)* genes have highly conserved homologues in vertebrates with conserved 3′ to 5′ order on chromosomes that recapitulate the AP nature of their expression.

Cephalic and caudal poles of the human embryo are established prior to formation of the primitive streak. The anterior pole is characterized by formation of the anterior visceral mesoderm within the cephalad anterior hypoblast, expressing head-forming genes including *OTX2, HESX1* and *cerebrus*. The dorsoventral axis in mesoderm is established by the ventralizing action of *BMP4* in the presence of *FGF*s. Dorsalization of the mesoderm is regulated by inhibition of *BMP4* in the head region by expression of genes including *chordin*, *noggin,* and *follistatin* and more caudally by genes such as *brachyury (T)*.

The dorsal mesoderm gives rise to the notochord. The appearance of the notochord induces the overlying ectoderm to thicken and form the neural plate and subsequently gives rise to neuroectoderm, marking the end of gastrulation and the beginning of neurulation.

At the end of gastrulation the neural plate consists of the primordia of the fore-, mid-, and hindbrains and spinal cord and initially expresses the *Otx2* gene that later becomes restricted to the fore- and midbrain primordia. Complementary *Gbx2* expressing cells extend from the posterior part of the brain to the midbrain-hindbrain border. Signals from the node appear to activate a labile, preneural and preforebrain state after which

cells receive stabilizing signals from the node or prechordal mesoderm, which also caudalizes surrounding cells to form the mid- and hindbrain and spinal cord.

The default derivation of ectoderm is epidermis, by activation of elements of the bone morphogenetic protein (BMP) pathway such as chordin, noggin, and follistatin that, uninhibited, activate the Smad pathway. If the BMP signal is blocked by one of many extracellular antagonists derived from adjacent cells, the Smad pathway is inhibited allowing expression of the *Sox* proteins that activate transcription of pro-neural *bHLH* class genes. These genes code for a class of more than 20 transcription factors necessary and sufficient for nervous system formation, some expressed throughout the developing nervous system, others specific to regions such as the forebrain and spinal cord. Transcription of these genes eventually leads to transformation of cuboidal primitive ectoderm to columnar neural epithelium.

Similarly, ectodermal cells acquire a neural identity through expression of antagonists to the canonical *Wnt* pathway such as cerebrus, dickkopf, sFrp and Tlc. A second signaling system provides lateral inhibition of neuroblast development. The Notch/Delta signaling pathway allows delamination of ectodermal cells to become neuroblasts, that is, committed neural progenitors while providing lateral inhibition of other ectodermal cells from following this fate. As a result of these signals, cells destined to form the neural plate elongate in an apical-basal direction to form the neural placode, broader at its cranial end and narrowing caudally.

In addition to the differentiation of neural progenitors, the future complex shape and three-dimensional structure of the fetal brain is determined by patterning events that begin with the establishment of the neural placode and plate. Two sets of polarity are required, both under the control of local diffusible factors. The first is AP regional differentiation into future forebrain, midbrain, hindbrain, and spinal cord due to initial clonal restriction and refinement under the influence of local neural plate "organizers." The second is establishment of the dorsoventral polarity that sequestrates motor neurons from sensory neurons in the developing spinal cord, and eventually cerebral cortical regionalization into recognizable functional areas such as motor or visual cortex. This process is dependent on dorsalizing and ventralizing factors secreted from the nonneural ectoderm and notochord, respectively.

Induction of future neural tissue with a posterior identity is under the control of posteriorizing factors such as Fgfs, Wnt, Nodals, and retinoic acid. Local neural plate organizers further refine and maintain the AP identity of the neural plate and determine future cell fate and histiogenesis. These organizers include the anterior neural ridge necessary for maintenance of the forebrain, the midbrain-hindbrain organizer, and the tail organizer.

The *Hox* gene clusters have been most studied in development of the vertebrate hindbrain, which undergoes segmental development into a cluster of rhombomeres similar to the segmental formation of the fly embryo. Paralogous groups of *Hox* genes are expressed in a segmental overlapping pattern to give rise to rhombomeres with unique identities and neurons that go to innervate specific cranial nerves or interconnect within the reticular system of the brain stem. Probably the best studied regulator of *Hox* genes is the human teratogen retinoic acid (RA). RA is synthesized locally in paraxial mesoderm of the notochord, and diffuses locally to bind a cytoplasmic retinoic acid response element (RARE) receptor and then translocate to the nucleus and activate posterior *Hox* genes. Experiments show high levels of RA prevent anterior segment development, whereas low levels prevent caudalization of the embryo. Expression of fibroblast growth factors (FGFs) is similarly able to induce posterior gene expression. A further AP gradient exists of *wnt/beta-catenin* activity. The midbrain-hindbrain border appears to be the key to patterning the important anatomic subdivision of the midbrain and cerebellum. Important gene expression here includes *wnt1, en1,* and *FGF8*.

NEURULATION AND FORMATION OF THE SPINAL CORD

Neurulation is the process of formation of the hollow neural tube by folding of the epithelial neural plate (Figure 160-2). Neurulation occurs in two distinct phases: primary neurulation during weeks 3 and 4 of gestation leading to development of the brain and spinal cord (Figure 160-3) and secondary neurulation during weeks 5 and 6 with formation of lower sacral and coccygeal cord. Defects of neurulation represent the earliest abnormalities of brain development that are clinically detectable in fetal life and extend into postnatal life.

The neural plate elongates into a drop-shaped structure, broader at its cranial end and narrower in the future spinal regions. This morphogenetic event, known as convergent extension, is under control of the noncanonical Wnt/frizzled pathway and is analogous to the process of tissue polarity development in the fly, where genes such as *Frizzled, Disheveled, Strabismus/Van Gogh, Diego, Flamingo,* and *Prickle* appear to be critical. These genes have highly conserved vertebrate homologs that are implicated in the process of convergent extension.

The neural plate is further shaped by bending at the median hinge point overlying the notochord at the future upper spinal cord and at the paired dorsolateral hinge points at the levels of the brain and lower spinal cord. This differential bending appears to be under control of signals diffusing from the notochord including the signal transduction molecule sonic hedgehog. The neural plate rotates by elevation and convergence around the median and dorsal hinge points. This bending appears to be dependent on apical constriction of columnar neural tube cells to become wedge shaped under the control of actin-related genes in particular *p190RhoGap*, a negative regulator of Rho GTPase and the actin-binding protein *Shroom*.

Neural tube closure appears to continue by the development of bilateral folds at its junction with nonneural ectoderm. These folds elevate and appose in the midline with fusion occurring by interdigitation of cellular protrusions from apical cells and the formation of permanent cell contacts. Membrane-bound ephrin ligands and their eph tyrosine kinase receptors have been implicated in this process. Neural tube closure is a discontinuous process occurring at between two and five initiation sites. The open neural folds between initiation closure sites are known as neuropores: as closure progresses, the neuropores gradually shorten and close leading to an intact closed neural tube. This is subsequently covered by ectodermally derived epidermis.

Secondary neurulation is initiated after primary neurulation is complete and the posterior neuropore closes. The tail bud, a pluripotent mass of cells, a remnant of the caudal primitive streak, proliferates and condenses followed by cavitation and fusion with the central canal of the neural tube. As this process of canalization progresses during ensuing weeks, neurons and ependymal cells differentiate to form the caudal end of the spinal cord. Resorption of the tail bud and other cells of the caudal cell mass leave the filum terminale, which often contains ependymal cell nests along its length. These nests of ependymal cells can begin to proliferate later in life as a monoclonal population of glial cells. These ependymomas, uncommon glial cell tumors, are among the most common tumors of the cauda equina and filum terminale.

The closed neural tube consists of a thick pseudostratified epithelium of neuroepithelial cells that begin to divide rapidly immediately after closure and give rise to a second cell type, the neuroblast. These cells form the mantle layer, the future gray matter of the spinal cord. This further gives rise to an outermost layer, the marginal layer that will become myelinated and form the future white matter of the cord. As neuroblast proliferation continues, the neural tube develops dorsal and ventral thickenings that become the alar and basal plates that will give rise

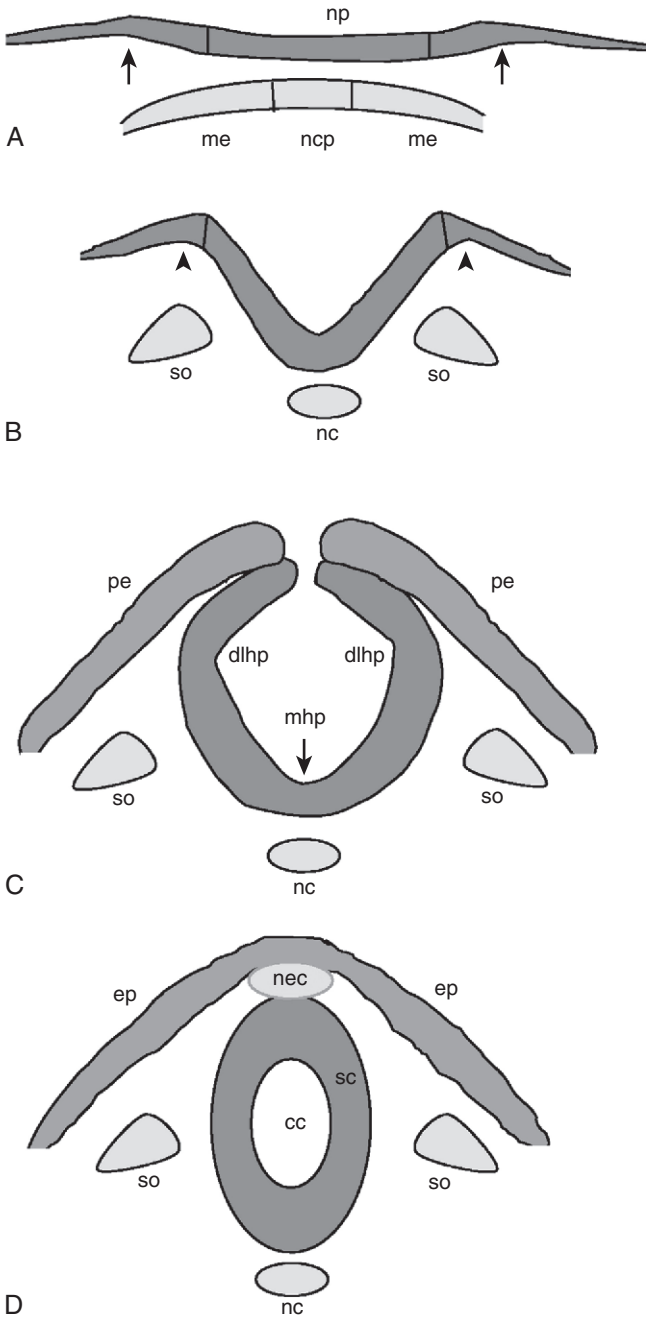

Figure 160-2 A simplified diagram of neural tube closure. **A,** Neural folds form at the lateral extremes of the neural plate (**A,** *arrows*), elevate (**B,** *arrows*) and converge toward the dorsal midline **(C),** and fuse at their dorsal tips to form the closed neural tube **(D).** Bending or hinge points form at two sites: the median hinge point *(mhp)* overlying the notochord and the paired dorsolateral hinge points *(dlhp)* at the lateral sides of the folds **(C).** *cc,* Central canal; *ep,* epidermis; *me,* mesoderm; *nc,* notochord; *ncp,* notochordal plate; *nec,* neural crest; *np,* neural plate; *pe,* presumptive epidermis; *sc,* spinal cord; *so,* somites. *(From Bassuk AG, Kibar Z: Genetic basis of neural tube defects,* Semin Pediatr Neurol *16:102, 2009.)*

to the sensory and motor areas of the spinal cord respectively. A longitudinal groove, the sulcus limitans, demarcates the boundary between the two.

As the neural tube closes, cells at the edge of the neural plate separate from the neural epithelium and migrate into the extracellular matrix to become neural crest cells. This separation is accompanied by a loss of cadherin-mediated cell adhesion from the surrounding neuroepithelium with local decrease in neural cell adhesion molecule (NCAM) levels. It is also accompanied by an increase in the cell adhesion to the extracellular matrix with increased expression of fibronectin. Migrating cells extend cellular motile processes to facilitate migration through the embryo to ultimately reach the final phenotypic sites. Neural crest cells migrate widely to become neurons and glia in dorsal root and autonomic ganglia. The fate of neural crest derived cells is also to provide innervation for the gastrointestinal tract and become neurons in the sensory ganglia of the cranial nerves (also formed in part by ectodermal placodes) and to become melanocytes, cartilage of the bone and face, and a variety of endocrine and structural tissues.

The ultimate phenotypic and developmental fate of neural crest cells is tied to the timing, mode, and pattern of migration and is in large part controlled by the environment in which they reside. There is complex interplay between the expression of inhibitory extracellular matrix components as well as the dynamic ratio between permissive versus inhibitory components. The most important players in the control of neural crest cell migration are fibronectin, laminin isoforms 1 and 8, aggrecan, and PG-M/versican isoforms V0 and V1. In chick quail chimeras, transplanted crest cells tend to assume the phenotype of the location to which they migrate rather than that of their place of origin. Cultured postmitotic crest cells can be induced to change expression of neurotransmitters in myocyte-conditioned medium. From these experiments it can be inferred that the neural crest cells retain a relatively broad developmental potential as they begin migration and that their ultimate fate is strongly influenced by local factors.

NEURAL TUBE DEFECTS

Neural tube defects (NTDs) are collectively the most common malformation of the nervous system with an incidence of 1 to 2 per 1000 births although there is significant geographic and historic variation in prevalence. This variation hints at the complex etiology of these disorders in which both genetic and environmental factors appear to be significant, including maternal age and diet, maternal diabetes and obesity, teratogen exposure, and socioeconomic class. Pathologically NTDs are characterized by a failure of closure of the neural tube at any level. Failures of primary neurulation frequently lead to "open" NTDs in which the neural defect is exposed to the environment, whereas failures of secondary neurulation frequently lead to "closed" defects in which the defect is covered by skin and integuments.

Cranioraschisis and Anencephaly

These disorders represent the most severe failures of primary neurulation. Cranioraschisis is a rare and lethal condition manifested by essentially total failure of neurulation with a neural plate–like structure present but no skeletal or dermal elements overlying it. The incidence is unknown. The equally rare disorder of failure of posterior neuropore closure known as myeloschisis represents the inverse of cranioraschisis, where a neural plate–like structure without overlying vertebrae or dermis replaces large portions of the spinal cord.

Anencephaly is a defect of anterior neural tube closure and comprises failure of formation of elements from the rostral portion of the neural tube anywhere to the foramen magnum

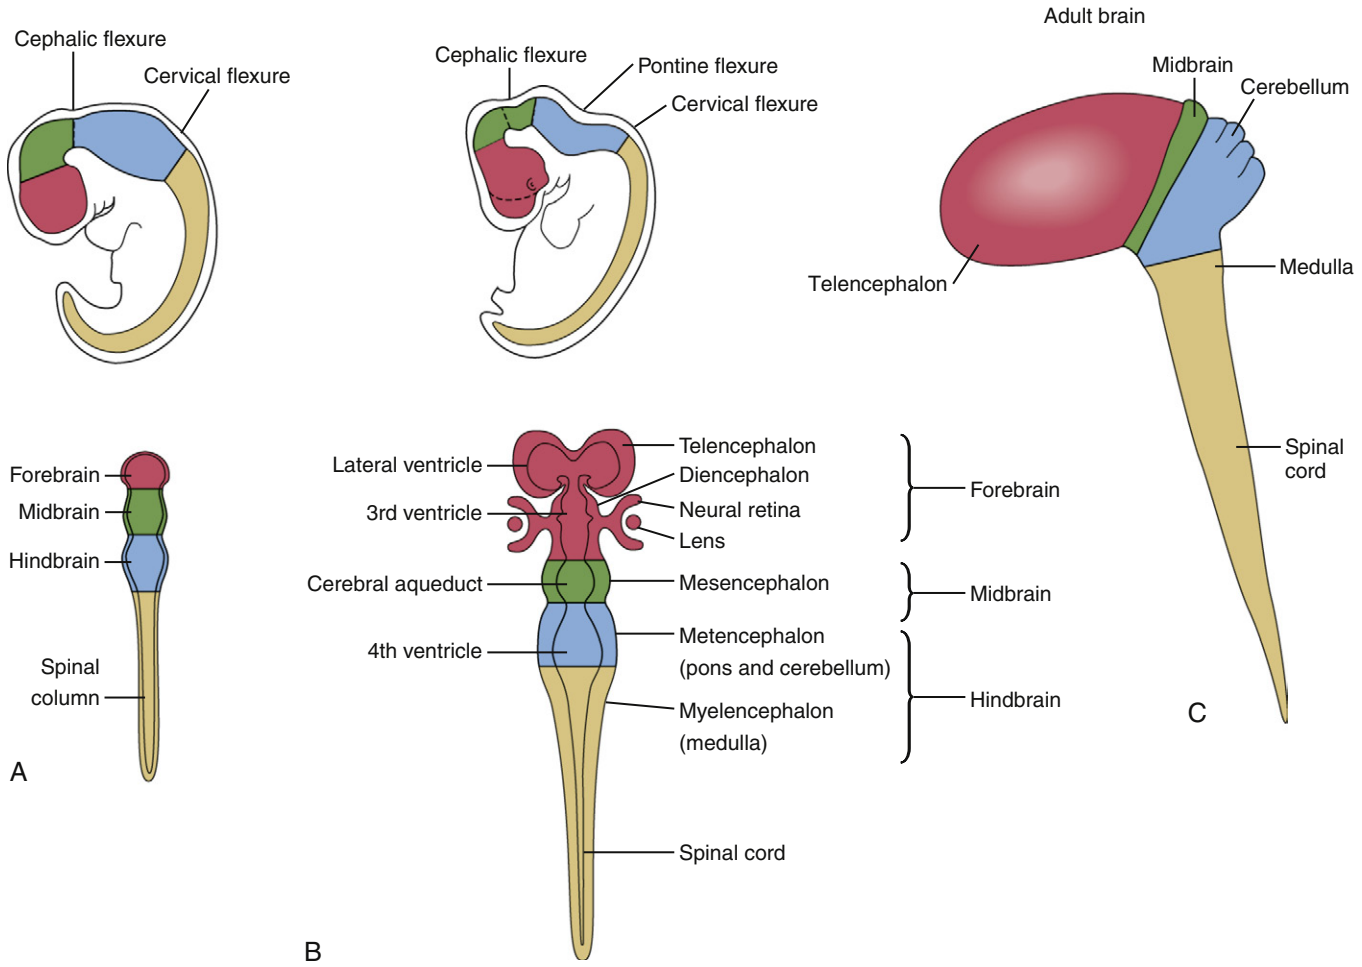

Figure 160-3 Development of the brain and spinal cord from the neural tube. *(Adapted from Sanes DH, Reh TA, Harris WA [eds]:* Development of the Nervous System. *Academic Press, San Diego, CA, 2006.)*

caudally. The forebrain and upper brain stem are usually involved, normal neural tissue replaced by a formless mass of degenerated, hemorrhagic neuronal and glial tissue and absence of the frontal, parietal and squamous occipital bones. The disorder varies considerably between geographic location, race, sex, ethnic group, maternal age, and socioeconomic status. The risk is higher in whites especially those of Irish ethnicity, very young and very old mothers, and in those of lower socioeconomic status or a history of previously affected siblings. The incidence shows a secular decline in the United States from 0.5 per 1000 live births in 1970 to 0.12 per 1000 births in 2011. Polyhydramnios is a frequent prenatal finding and the malformation is now commonly diagnosed in the second trimester during obstetric screening, allowing for elective termination of pregnancy.

Encephalocele

This group of disorders represents herniation of the brain or meninges through the skull. The underlying pathogenesis is unknown but relates in part to the failure of normal closure of the anterior neuropore. It is relatively uncommon with an estimated incidence of 1 to 3 per 10,000 live births and is increasingly detected antenatally. More than 70% of encephaloceles herniate through the occipital part of the skull (Figure 160-4, *A*), although nasofrontal encephaloceles are relatively more common in Southeast Asia. Basilar, temporal, and parietal encephaloceles are unusual. The herniated mass may comprise one or more of meninges, cerebrospinal fluid (CSF) or neural tissue—in some cases surprisingly well organized. Hydrocephalus occurs in 50% of occipital encephaloceles and other malformations are common including agenesis of the corpus callosum, Chiari III malformation, and subependymal nodular heterotopia. Encephaloceles are found in a number of multiple congenital anomaly syndromes and are associated with first-trimester maternal hyperthermia.

Myelomeningocele

Failure of posterior neural tube closure results in a malformation of the spinal cord, myelomeningocele. This is the most commonly encountered NTD in pediatric practice because most infants born with this anomaly survive. The lesion consists of neural plate or rudimentary neural tube tissue herniating through a defect in the vertebra (spina bifida) in the form of a sac containing meninges, CSF, nerve roots, and spinal cord. The dorsal cord is most affected and there may be some dermal coverings present. The vast majority of myelomeningoceles occur in the lumbar region (see Figure 160-4, *B*) and 10% may contain no neural tissue and are known as meningoceles. Hydrocephalus and Chiari II malformation are frequent associations. The incidence of myelomeningocele varies widely by ethnic population and geographic location but ranges from 0.2 to 4 per 1000 live births. Girls are more frequently affected than boys. Recurrence risk is 5%, increasing to 15% if two siblings are affected.

Occult Dysraphisms

Disorders of secondary neurulation involve the caudal spinal cord and its coverings. The occult dysraphic states are commonly associated with vertebral anomalies and are usually covered with skin. Elongation of the conus medullaris and shortening and thickening of the filum terminal with "tethering" of these structures may result in traction injuries to the spinal cord. The occult dysraphic states are commonly associated with vertebral anomalies and are usually covered with skin. A *myelocystocele* is a localized dilation of the central canal in the caudal spinal cord often associated with severe malformations, including cloacal exstrophy and vertebral anomalies. The caudal cord in *diastematomyelia* is divided by a septum arising from a vertebral body. *Diplomyelia* is a divided, and at times duplicated, spinal cord with no septum. *Meningocele* is an extrusion of subarachnoid space with no gross abnormality of either the brain or spinal cord; when associated with a lipoma, the abnormality is referred to as a *lipomeningocele*. *Lipomata* and other tumors such as *teratomata*, *neuroblastomata*, and *ganglioneuromata* may occur and extend into the dural space. A cutaneous dimple in the lumbosacral region may be contiguous with a *dermal sinus* and a *dermal (dermoid)* or *epidermal (epidermoid) cyst* or may extend into the vertebral canal. Lipoma and dermal sinus are the most common of the occult dysraphic states.

ETIOLOGY OF NEURAL TUBE DEFECTS

The etiology of NTDs is heterogeneous; syndromic associations are recognized as are a wide range of aneuploidies. Specific teratogens are associated, in particular thalidomide, carbamazepine, and valproic acid. Other maternal susceptibility factors include hyperthermia, low vitamin B_{12} levels, diabetes mellitus, and obesity. Periconceptual folate supplementation has been shown to significantly reduce the incidence of NTDs (up to 83% reductions with 4 mg of supplemental folate). Additionally, susceptibility factors related to folate metabolism have been identified; defective levels of methylene tetrahydrofolate reductase have been demonstrated in up to 20% of pregnancies affected with NTDs. Nonetheless, primary genetic variants in folate-related genes do not seem to account for the overall genetic contribution to NTD incidences.

Studies in animal models, in particular the mouse, have identified a large list of candidate genes for human NTDs, in particular genes involved in convergent extension and the tissue polarity pathway. These include *ALDH1A2, CYP26A, MSX2, NCAM1, PAX, PDGFRA, PRKCA, SLUG, T box,* and *ZIC2*. Of particular interest is the gene *VANG1*, the human homologue of the mouse gene *Vangl2,* mutated in the severe murine cranioraschisis loop tail *(Lp)* mutant. Sequencing of *VANG1* has identified a number of missense mutations in both sporadic and familial human NTDs.

Disorders of Neural Crest–Derived Cells

Defects in neural crest development are known as neurocristopathies. In Waardenburg syndrome, children have hypoganglionosis, congenital megacolon, abnormalities of the great vessels, sensorineural deafness, and abnormalities of skin, hair, and iris pigmentation. Restricted abnormalities of neural crest development are more common disorder of neural crest cells. Congenital aganglionosis (Hirschsprung disease) is characterized by a lack of neurons in the enteric plexus of the colon as a result of either failure of migration or differentiation of neural crest cells. The anomaly presents in the newborn period as megacolon and the most common cause of neonatal colonic obstruction. A mutation in *L1CAM*, a gene that encodes a neural cell adhesion molecule, has been described in newborn males with congenital hydrocephalus, aqueductal stenosis, and/or agenesis of the corpus callosum and Hirschsprung disease, suggesting a role for *L1CAM*-mediated cell adhesion.

Disorders of the spinal and autonomic ganglia are rare. Congenital insensitivity to pain with anhidrosis is an autosomal-recessive disorder resulting from defective neural crest differentiation. First-order sensory afferents, which are responsible for pain and temperature sensation, are lacking. In addition, there is neuronal loss in the sympathetic ganglia. Immunohistochemistry with antibodies directed against the S100 protein and neuron-specific enolase, markers of glial and neuronal differentiation, fail to show nerve fibers in the vicinity of the eccrine sweat glands. The presence of multiple coincident neurocristopathies has been reported, specifically with the association between congenital central hypoventilation, Hirschsprung disease, and autonomic dysfunction (Haddad syndrome) and

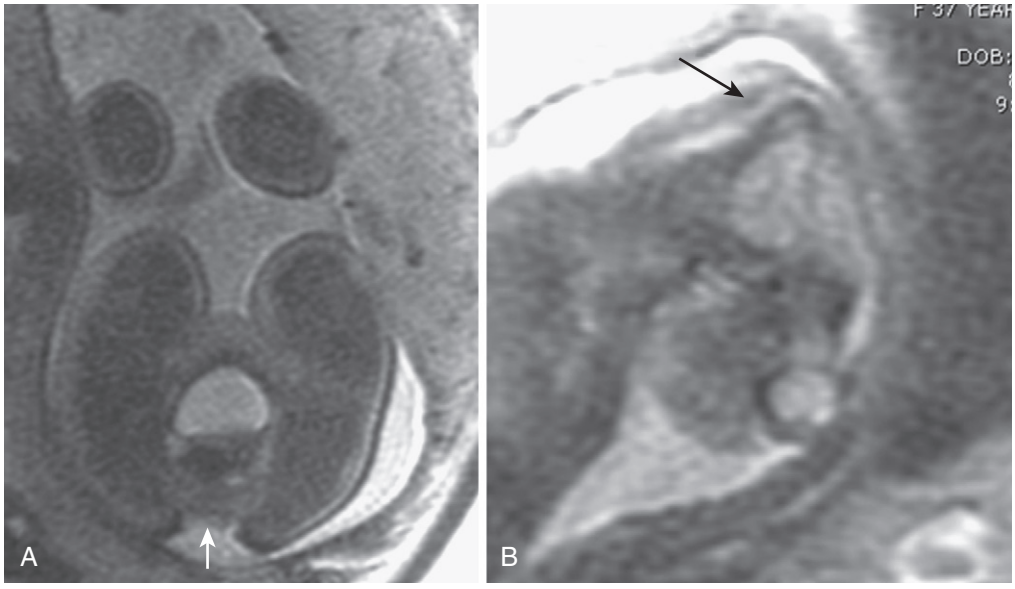

Figure 160-4 Fetal magnetic resonance imaging at 18 gestational weeks. **A,** Occipital encephalocele *(arrow)*. **B,** Lumbosacral myelomeningocele *(arrow)*.

between congenital central hypoventilation, Hirschsprung disease, and neuroblastoma.

EMBRYONIC DEVELOPMENT OF THE BRAIN AND VENTRICULAR SYSTEM

The brain forms from three vesicles that develop in the cranial neural tube: the forebrain (prosencephalon), midbrain (mesencephalon) and hindbrain (rhombencephalon).

This process occurs at weeks 4 and 6 of gestation shortly after closure of the anterior neuropore. Inductive interactions between the rostral notochord-prechordal mesoderm and the most cranial portion of the neural tube initiate formation of the fetal forebrain. As this process occurs in the ventral surface of the rostral neural tube it is often known as ventral induction. This is followed by the cleavage of the forebrain in three planes to give rise to the paired optic vesicles, olfactory bulbs, and tracts; separation of the diencephalons; and lastly the paired cerebral hemispheres, lateral ventricles, and basal ganglia.

The cerebral hemispheres develop as symmetric evaginations of the lateral wall of the prosencephalon. The median portion of the prosencephalon forms the diencephalon, giving rise ultimately to the third ventricle, thalamus, hypothalamus, and mamillary bodies. The cavities of the hemispheres form the lateral ventricles and communicate with the lumen of the diencephalon through the foramina of Monroe. The basal parts of the hemispheres begin to grow and bulge into the floor of the foramina to form the ganglionic eminence and ultimately the caudate and lentiform nuclei. The medial surfaces of the hemispheres thicken to give rise to the hippocampi. Clusters of neurons along the midline begin to form nuclei of the brain stem, thalamus, and hypothalamus. Axons from the olfactory epithelium extend and establish contact with the cerebral wall, which is followed by development of the olfactory bulbs over the sixth and seventh weeks of gestation. The remarkable expansion of the cerebral hemispheres follows during the remainder of gestation.

The sonic hedgehog signaling pathway is critical to the development of the prosencephalon, with sonic hedgehog protein (SHH) secreted from the prechordal mesoderm. SHH is an intercellular signaling molecule synthesized as a precursor that undergoes cleavage into N- and C-terminal domains. During autoprocessing a cholesterol moiety is attached to the C-terminal of SHH-N allowing the molecule to be secreted. SHH-N binds to the PATCHED-1 receptor to suppress repression of SHH signaling. SHH signaling appears to be mediated through at least three obligate mediators including GLI2. Other major molecular signaling pathways, the Nodal/TGFβ pathway and chordin/noggin/BMP pathways also appear to be critical to forebrain development primarily by maintaining dorsalization.

These events are followed by midline prosencephalic development with formation of the commissural, chiasmatic and hypothalamic plates. These structures give rise to the corpus callosum and septum pellucidum, optic nerve chiasm, and the hypothalamus.

The most prominent of these midline developments is formation of the major commissure of the brain, the corpus callosum, the earliest components of which appear at approximately 9 weeks. By 12 weeks an independent corpus callosum is definable at the commissural plate. Multiple steps are involved in formation of the corpus callosum, all primarily related to axon guidance. These include guidance by preexisting axon tracts formed by pioneering axons expressing neuropilin 1. Glial structures such as the glial wedge, midline zipper glia, and indusium griseum are present at the midline and are necessary for corpus callosum formation. The glial wedge is a symmetric structure composed of radial glial cells that prevent callosal axons entering ventrally and repel already-crossed axons away from the midline. Guidance by the glial wedge occurs through SLIT-ROBO and WNT-RYK signaling. Callosal axons are attracted through Netrin family chemoattactants and then repelled by SLIT activated ROBO molecules. Dorsal to the developing corpus callosum, the glia of the indusium griseum express SLIT2. These glia help guide commissural axons toward their crossing sites. Other signaling molecules involved in callosal axon guidance include NFIA and FGFR1.

The pituitary gland develops from two embryologically separate layers: an ectodermal outpouching of the embryonic mouth known as Rathke's pouch and a downward extension of the diencephalon, the infudibulum. Cells in Rathke's pouch increase rapidly with gestation to form the anterior pituitary gland, and the infudibulum gives rise to the posterior pituitary gland, unsurprisingly containing neuroglial cells including nerve fibers from the hypothalamus.

DISORDERS OF FOREBRAIN DEVELOPMENT

Holoprosencephaly

This group of disorders is the result of different degrees of failure of prosencephalic cleavage and distinguished by the severity of failed cleavage of the cerebral hemispheres and deep nuclear structures. The most severe form is *alobar holoprosencephaly* in which there is a single spherical cerebral structure and monoventricle with fusion of the thalami and deep nuclei together with absence of the corpus callosum and olfactory bulbs. Neuronal migration and cortical organization are severely disordered. In *semilobar holoprosencephaly* there is failure of separation of the anterior cerebral cortex and absence of the anterior corpus callosum (Figure 160-5). The least severe forms are *lobar holoprosencephaly* in which the cerebral hemispheres are fully separated and the deep nuclei are only partially separated. In the *middle interhemispheric variant* only the posterior frontal

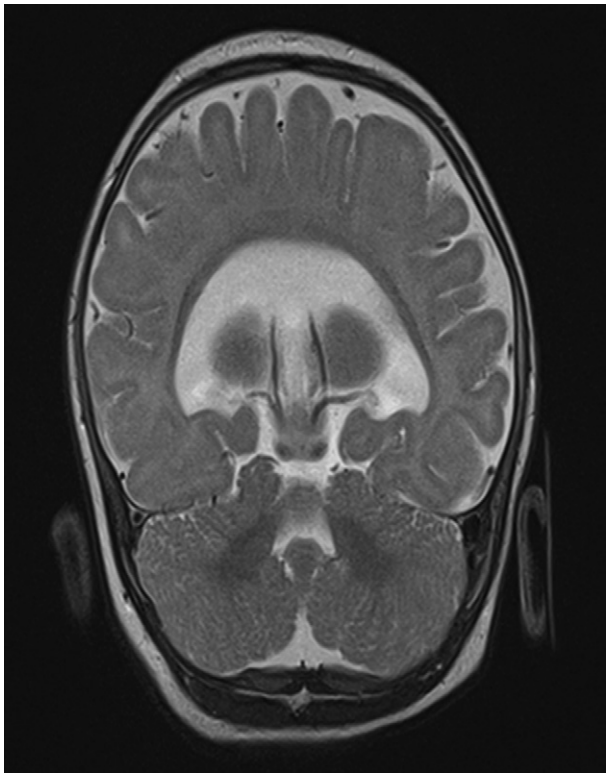

Figure 160-5 Coronal magnetic resonance image of 5-day-old infant demonstrating semilobar holoprosencephaly. Note single ventricle.

and parietal regions fail to separate. Hydrocephalus is present in most infants with alobar holoprosencephaly due to fusion of the thalami and impaired drainage of CSF through the aqueduct. Infants with semilobar and lobar forms are usually microcephalic. Facial anomalies are usual and range from severe cyclopia with proboscis through to ocular hypotelorism with a flat single nostril nose (cebocephaly) to mild hypotelorism with or without cleft palate.

The disorder occurs in 1 per 10,000 live births but is 100 times more common in conceptuses examined after miscarriage or abortion. Causes include both genetic and cytogenetic etiologies as well as teratogens. More than two thirds are related to full or partial chromosomal aneuploidies, in particular trisomy 13. A list of known etiologic factors and genetic loci is given in Table 160-2.

AGENESIS OF THE CORPUS CALLOSUM AND SEPTUM PELLUCIDUM

This group of disorders is characterized by varying degrees of failure of midline prosencephalic development. Agenesis of the corpus callosum (ACC) may be complete or partial and is associated with deformation of the lateral ventricles to give a parallel ventricular arrangement known as colpocephaly (Figure 160-6). This is usually accompanied by longitudinal fibers coursing along the medial aspect of the hemispheres known as Probst bundles. Partial ACC usually comprises absence of the posterior callosum. ACC may be isolated or in up to 40% to 50% of cases associated with other cerebral abnormalities, in particular cerebellar malformation and cortical migration anomalies. ACC is one of the most common anomalies occurring in up to 7 per 1000 live births and 3% of children with developmental delay. It is increasingly diagnosed in fetal life. ACC may be completely asymptomatic or have symptoms only detectable on very refined testing of interhemispheric transfer. In association with other anomalies, however, is a strong risk of cognitive and neuromotor impairment. ACC is associated with well over 65 known genetic syndromes, and the presence of extra-axial abnormalities or cytogenetic abnormalities is a risk factor for impaired neurologic development (Box 160-1).

Absence of the septum pellucidum is another common anomaly and frequently associated with more diffuse cerebral malformations such as schizencephaly, septo-optic dysplasia, ACC, holoprosencephaly and hydrocephalus. Failure of fusion of the septal leaflets is known as cavum septum pellucidum and

includes septo-optic dysplasia (SOD, de Morsier syndrome) in which absent septal leaflets are associated with optic nerve hypoplasia and disturbances of the hypothalamic-pituitary axis. Remnants of Rathke's pouch may give rise to the suprasellar tumors, craniopharyngiomas that may cause hydrocephalus, visual field loss, and hypothalamic and pituitary dysfunction.

FETAL BRAIN DEVELOPMENT

The embryonic events of the first 6 weeks of development establish the three-dimensional pattern of the brain and spinal cord and determine the fate of the first neural cells. For the remainder of gestation and well into postnatal life these cells are now committed to the formation and maintenance of the evolutionarily extraordinary human brain. Though capable of only limited capacity for regeneration and repair, neurons must remain dynamic and responsive to the external environment for decades making them among the most remarkable of all cells. Development is characterized by massive proliferation and differentiation of neurons and glia, migration and organization of the cerebral and cerebellar cortex, dendritic growth and synaptogenesis, and finally ensheathment of neurons with myelin. A common plan of cell layers, types and connections is modified by regional variations in cellular architecture. The result is a spectacular laminated structure with a massive diversity of neurons with trillions of local and extrinsic connections that underpin the unique cognitive and behavioral capacity of humans.

NEURONAL AND GLIAL PROLIFERATION

All neurons and glia are derived from the specialized proliferative centers close to the pial surface, the ventricular and subventricular zones (Figure 160-7). Brain growth is characterized between 8 and 15 weeks by neuronal proliferation (Figure 160-8) and generation of radial glia switching to primarily glial multiplication from 15 weeks into postnatal life. Some neuronal proliferation does occur later in gestation, primarily in the external granule cell layer of the cerebellum and the subventricular zone. Morphologic brain growth also occurs secondary to proliferation of the rich cerebral vascular supply, initially through growth of radially arranged vessels and later by proliferation of horizontal branching vessels.

The cortical primordium is composed entirely of dividing neural stem cells that collectively form the ventricular zone (VZ). Prior to neurogenesis these cells have radial processes and divide symmetrically, although are themselves highly polarized. These cells are characterized by receptors at the basal lamina such as integrin-α and apically concentrated proteins such as CD133 and tight junctions. These neural stem cells divide through the unique process of interkinetic nuclear movement, with the nucleus moving toward the ventricular surface shortly before metaphase and migrating to the pial surface during deoxyribonucleic acid (DNA) synthesis. These early proliferative events dramatically increase the thickness and surface area of the VZ, particularly in the forebrain.

Soon after neural tube closure neural stem cells begin to switch to asymmetric division, giving rise to daughter cells, one of which remains a progenitor and reenters the cell cycle, the other a postmitotic cell destined to become a neuron or radial glia and migrate out into the developing cortex. The onset of neurogenesis is marked by down-regulation of the epithelial characteristics of neural stem cells. Among the genes involved in induction of neuroepithelial differentiation are *FOXG1, LHX2, PAX6,* and *EMX2*. Postmitotic cells show regional differences in gene expression that at least partly contributes to regional specification of their progeny.

Following the onset of neurogenesis, intermediate progenitors appear above the VZ known as the subventricular zone (SVZ—conventionally the ventricular surface is considered the top of the proliferative zone and layers described downward. Apical thus refers to the ventricular surface and basal away, toward the pial surface). The SVZ is distinctively large and active in humans compared with other species, retaining the ability to proliferate late into gestation and seemingly acting as a large reservoir of progenitor cells and eventually the principal source of cortical neurons. The cells of the SVZ do not undergo interkinetic nuclear movement but undergo terminal symmetric division to create pairs of neurons. These intermediate progenitors express transcription factors TBR2, NGN2, and CUX1 and CUX2.

Derived from the ventricular zone, radial glia remain more pluripotent and are capable of producing both neurons and glial cells—astrocytes and oligodendrocytes. Radial glial cells are elongated nonneuronal cells that serve two functions; a guidance

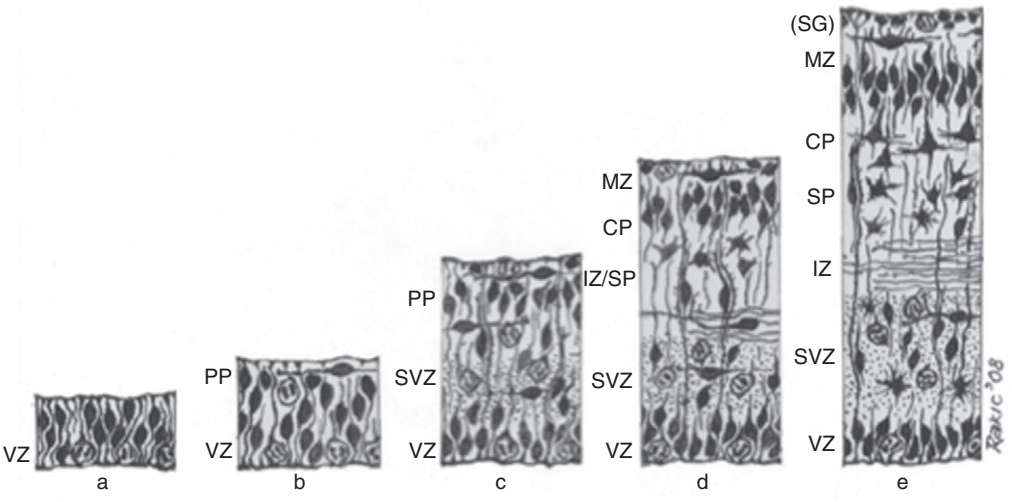

Figure 160-7 Cortical laminar development including transient fetal zones. The panels correspond to the following approximate ages (for the lateral part of the dorsal telencephalon): *a:* embryonic day (E) 30; *b:* E31–E32; *c:* E45; *d:* E55; *e:* gestational week 14. *CP,* Cortical plate; *I & IZ,* intermediate zone; *M & MZ,* marginal zone; *S & SVZ,* subventricular zone; *SG,* subpial granular layer (part of the MZ); *V & VZ,* ventricular zone. *(Modified from Bystron I, Blakemore C, Rakic P: Development of the human cerebral cortex: Boulder Committee revisited,* Nature Rev Neurosci *9:110-112, 2008.)*

scaffold for later migration of neurons and as neurogenic and glial progenitors.

The mechanisms of generation of progenitor cells are largely unclear; however, their maintenance requires molecules along the Notch pathway. Progenitor cells are also depleted in embryonic brains that are deficient for the presenilin 1 *(PS1)* gene, which is a key regulator of Notch signaling. Notch signaling is also thought to allow cells that are in direct contact to adopt different fates. Other genetic and environmental influences are important in the generation and maintenance of progenitor cells. For example, transcription factors such as NeuroD homologues of the helix-loop-helix proteins have been postulated as fate-determination factors. The role of extracellular signals in regulation of progenitor differentiation is poorly understood, but increasing evidence suggests cell adhesion molecules inhibit cell proliferation and induce differentiation to the neuronal lineage, as indicated by an increase in the number of cells staining positively for microtubule-associated protein 2.

There is growing evidence that neuronogenesis occurs into adulthood, at least in the olfactory cortex and hippocampus. Regions of the adult brain and spinal cord ventricular surface appear to have the capacity to generate new neurons. Glial proliferation, in contrast to neuronal proliferation, continues regularly throughout life. Laboratory studies have demonstrated that multipotent cerebral progenitor cells grown in vitro differentiate into neurons when exposed to platelet-derived growth factor (PDGF) and assume glial phenotype when exposed to ciliary neurotrophic factor (CNTF) or fibroblast growth factor (FGF2). Local factors appear to be important because cortical progenitors cultured over embryonic cortical slices differentiate into neurons and those cultured over postnatal cortical slices differentiate into glia, suggesting that there are developmentally and environmentally regulated signals.

The proliferative events involving the radial glial cell as neuronal progenitor are modulated by several key signaling pathways involving the Notch receptor, the ErbB receptor (via the ligand neuregulin), and the fibroblast growth factor receptor and β-catenin. Calcium waves propagating through connexin channels of the radial glial cell also appear to be important in the regulation of radial glial production of neurons.

DISORDERS OF NEURONAL PROLIFERATION

Microcephaly

Disorders related to impaired neuronal proliferation are categorized by the term "primary microcephaly," or "micrencephaly." This distinguishes the disorder from the more common microcephalies secondary to hypoxic-ischemic, infectious metabolic,

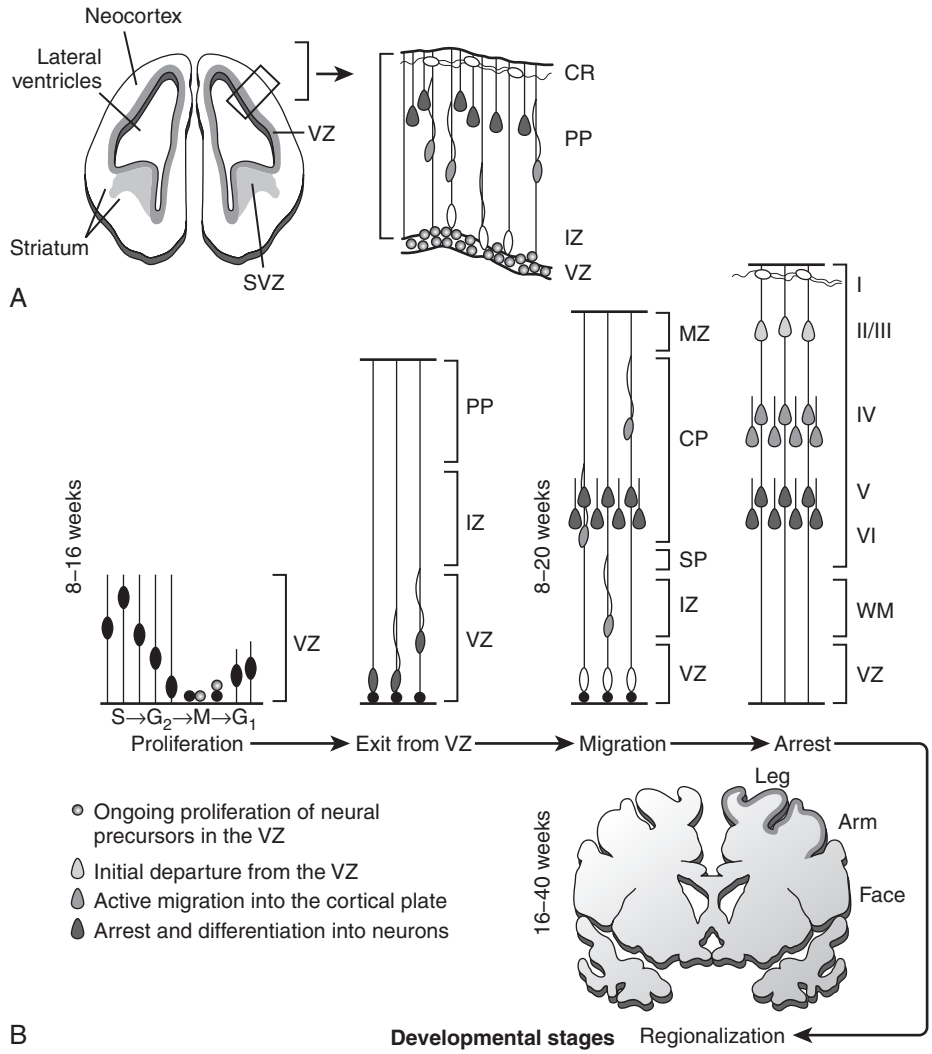

Figure 160-8 Neuronal development. *(From Lian G, Sheen V: Cerebral developmental disorders,* Curr Opin Pediatr *18(6):614-620, 2008.)*

or other destructive events. Micrencephaly vera refers to a group of autosomal recessive disorders characterized small brain size because of a derangement of proliferation (Figure 160-9). Radial microbrain is a rare disorder of particular interest because it appears to provide a clear example of a disturbance in number of proliferative units. There are at least six gene loci identified for autosomal recessive primary micrencephaly (MCPH), or micrencephaly vera. *Microcephalin* is crucial for cell cycle control, chromosome condensation, and DNA repair. *CDK5RAP2* is a centrosomal protein involved in microtubular function necessary for formation of the mitotic spindle. *ASPM* also is necessary for microtubular function at the poles of the mitotic spindle, and *CENPJ* similarly is involved in formation of the mitotic spindle.

Microcephaly can be caused by familial, teratogenic, and syndromic disorders (Box 160-2). In addition to the autosomal recessive group, inherited varieties include autosomal dominant and X-linked recessive types. The best-documented teratogenic agent producing microcephaly is irradiation, for example, by atomic bomb or radiation therapy, particularly before 18 weeks gestation. Maternal alcoholism and cocaine abuse are associated with micrencephaly. Micrencephaly, usually with mental retardation, occurs in as many as 75% to 90% of nonphenylketonuric children of women with phenylketonuria. Other teratogens for microcephaly include anticonvulsant drugs and vitamin A toxicity. Fetal infections that may cause micrencephaly include rubella, cytomegalovirus, and HIV. A vast array of syndromes feature microcephaly as one of a number of fetal anomalies, in particular those associated with aneuploidies and chromosomal rearrangements.

Macrencephaly

Macrencephaly is characterized by a large brain and may relate to either excessive proliferation or abnormally prolonged windows for otherwise normal proliferation during development. Macrencephaly may be isolated or associated with severe neurologic findings, in particular epilepsy and mental retardation, or with other anomalies of somatic growth and some neurocutaneous disorders.

Familial, isolated macrencephaly is an autosomal dominant condition in which the head is unusually large at birth (greater than the 90th percentile in approximately 50%) and continues to grow rapidly in early postnatal life. Neurologic findings are usually minor and parental head size is also usually above the 90th percentile.

Macrencephaly may be associated with generalized disorders of growth, such as Beckwith-Wiedemann syndrome, Sotos syndrome (Figure 160-10), fragile X syndrome, Marshall-Smith syndrome, Simpson-Golabi-Behmel syndrome, and Weaver syndrome. The gene mutated or deleted in Sotos syndrome, *NSD1,* encodes a nuclear receptor binding protein that may be involved in proliferative events.

Several neurocutaneous disorders are associated with evidence of excessive cellular proliferation within the central nervous system (CNS), sometimes with overt macrencephaly, and evidence of excessive proliferation of mesodermal structures. Macrencephaly occurs most consistently in this context in the multiple hemangiomatosis syndromes, and more rarely in conditions such as megalencephaly-cutis marmorata syndrome and megalencephaly-polymicrogyria-polydactyly-hydrocephalus syndrome.

Type 1 neurofibromatosis is an autosomal dominant disorder characterized by abnormal glial proliferation. The megalencephaly relates primarily to increases in cerebral white matter. The gene for this disorder, *NF1,* has been shown to encode a protein involved in the negative regulation of a key signal transduction pathway, the Ras pathway, which transmits mitogenic signals to the nucleus. Loss of the neurofibromatosis protein neurofibromin leads to increased mitogenic signaling, causing the proliferative abnormalities characteristic of the disorder.

Tuberous sclerosis is associated with abnormal proliferation of both neurons and glia associated with dysfunction of the genes *TSC1* and *TSC2* that encode the proteins hamartin and tuberin. Hamartin and tuberin form a molecular signaling system critical

for cell proliferation, cell growth, and cell adhesion/migration and lie as part of the mTOR and PTEN pathways.

Hemimegalencephaly is characterized by enlargement of part of all of one hemisphere, large and sometimes bizarre neurons, heterotopic neurons in subcortical white matter, and increased number and often size of astrocytes. This abnormality may be syndromic or sporadic. Syndromic causes include epidermal naevus syndrome, Proteus syndrome and hypomelanosis of Ito. A relatively rare neurocutaneous disorder, epidermal nevus syndrome, is associated with hemimegalencephaly in approximately half of cases.

NEURONAL MIGRATION

Between 12 and 20 weeks gestation millions of postmitotic neurons move from their sites of origin in the VZ and SVZ to the developing cortex and deep nuclei, where they will reside for life, taking up specific positions to form the six-layered cortex clearly observable by 28 weeks gestation. The timing and direction of these many simultaneous migrations are tightly regulated, and disorders of this remarkable process are surprisingly uncommon, yet when they do occur have significant consequences for fetal and neonatal well-being.

Before the neural tube even closes, specialized neurons known as predecessor cells, unique to humans, arrive at the pial surface of the forebrain, invading tangentially to form the preplate. These are bipolar cells have a variety of molecular signatures, principally TU20, and lack axons. They have long horizontal processes and may act as a scaffold for axonal navigation. These cells are largely transient and destined to die. The preplate then begins to subcompartmentalize with the appearance of *reelin*-expressing Cajal-Retzius cells. These transient bipolar cells arise from radial migration from the local VZ as well as by tangential migration from more distant extracortical sites. These cells take up a superficial subpial position as the marginal zone. Reelin terminates further migration and these cells therefore mark the pial limit of neuronal migration, the upper boundary of the protocortex, the cortical plate (CP).

Important molecular determinants of migration on radial glia include signaling pathways, involving erb B4 receptors, Notch receptors and brain lipid binding protein (BLBP). Doublecortin is the product of a gene on the X-chromosome, expressed in migrating neurons at the growing end and involved in an intracellular signaling pathway important for neuronal migration. Doublecortin is a microtubule-associated protein, and may be involved in neuronal migration by mediating the cytoskeletal changes required for cellular movement. The gene responsible for the human neuronal migration disorder, periventricular heterotopia, *filamin 1,* encodes a neuronal actin cross-linking protein that transduces ligand-receptor binding into actin again suggesting the importance of cytoskeletal movement in neuronal migration and cortical development (Figure 160-11).

The CP is a critical developmental phase in the formation of the human brain, progressively thickening with a clear temporal gradient. Radially migrating neurons accumulate in the CP in an inside-out sequence, earliest born neurons becoming the deeper layer V/VI and later born neurons becoming more superficial layer II/III. Further GABAergic interneurons migrate tangentially from the basal telencephalon as well as locally from the SVZ. Between the ventricular proliferative zones and the postmigratory neurons towards the pial surface is a heterogeneous compartment, the intermediate zone (IZ). This contains radially and tangentially migrating cells as well as extrinsic axons. Eventually the invasion of corticocortical fibers and myelination transforms the IZ into the white matter.

Between CP and IZ is a distinct neuronal compartment, the subplate (SP), that contains hetereogeneous cell populations. These include radially migrating glutamergic neurons that extend subcortical pioneer axons and express the transcription factors TBR1 and EMX1 and the p75 neurotrophin receptor. Interneurons within SP express transcription factors associated with GABAergic neurons such as DLX and LHX6. The SP expands dramatically during gestation to become four times thicker than the CP by 6 months' gestation, then gradually decreases, leaving only cell-sparse white matter by 6 months of postnatal life. The function of SP remains unclear but silver staining and dye tracing studies suggest that it acts as a waiting compartment for thalamic axons arrested until the CP becomes growth permissive and allows thalamocortical fibers to reach their target. The prolonged existence of this transient fetal zone into the third trimester and early postnatal life have profound implications for perturbations of sensory input related to premature birth or aberrant neonatal experience such as asphyxia or drugs.

As they migrate along radial glia, many neurons within the cerebral wall extend processes that are soon recognizable as axons. The formation and maintenance of axonal and dendritic arbors are largely under control of environmental cues. The tip of each process is composed of a specialized motile structure, a growth cone, which resembles the head of a club, with microspikes (filopodia) extending in all directions. Living growth cones, when viewed in a microscope, are constantly moving by local extension and retraction. When in contact with an appropriate substrate, they crawl forward and leave behind the elongating axon.

In the developing nervous system, a variety of molecules within the extracellular matrix have been shown to provide this substrate for axon outgrowth. Neurons in culture elongate their axons in a substrate-dependent manner. Two of the most active promoters of growth cone migration, laminin and fibronectin, have been shown to be expressed transiently as components of the extracellular matrix in cortical regions that have particularly active axon growth. In addition, responsiveness to laminin may be developmentally regulated and enhanced by treatments that activate integrin function. Administration of exogenous laminin favors neuronal migration and neurite growth, whereas inhibition or neutralization of laminin results in inhibition of neurite outgrowth. Proteoglycans such as chondroitin sulfate, which are macromolecules composed of core polypeptide and glycosaminoglycan chains, can modulate neurite outgrowth along with laminin. Matrix metalloproteinases, proteases that degrade extracellular matrix molecules, are thought to be involved in stabilization of laminin and cell-matrix interactions. Extracellular matrix proteins, such as collagen, also have been shown in cell culture to suppress apoptosis, or programmed cell death, and thus to provide a more nurturing substrate for neuronal survival and differentiation.

Although extracellular matrix substrates promote axon outgrowth, they alone do not provide all the directional signals required during axon outgrowth. As growth cones advance, their filopodia extend and appear to explore the local environment to find the path most favorable for continued axon growth. Growth-associated protein-43 (GAP-43) is a major growth cone protein whose phosphorylation in response to extracellular guidance cues can secondarily regulate microtubule behavior. Mice lacking GAP-43 fail to form the anterior commissure, hippocampal commissure, and corpus callosum. Growth of axons along voltage gradients or diffusible chemical gradients also occurs in the developing brain.

A growing body of evidence indicates that axon guidance is directed by the integrated and summed influence of both attractant and repulsive cues. These cues may be expressed in gradients, and they ultimately lead to the establishment of axon projection maps as found in the projection from the retina to the midbrain tectum. In fact, a family of axon-repulsive molecules, ligands of the *EPH* family of receptor tyrosine kinases, has been identified as the probable positional labels for the retinotectal projection.

Normal Development of the Cerebellar Cortex

The primordia of the cerebellar hemispheres appear in the fifth gestational week as bilateral thickenings in the lateral aspects of the dorsal surface of the rhombencephalon, the rhombic lips. By continued growth of this region the primitive vermis and cerebellar hemispheral anlage become apparent by 12 to 13 weeks. During the latter part of this period progenitor cells in the subependymal germinative zones of the rhombic lip, adjacent to the fourth ventricle, generate (1) neurons that migrate radially to form the dentate nucleus and other roof nuclei and the Purkinje cells, and (2) neurons that migrate tangentially over the surface of the cerebellum to form the external granule cell layer.

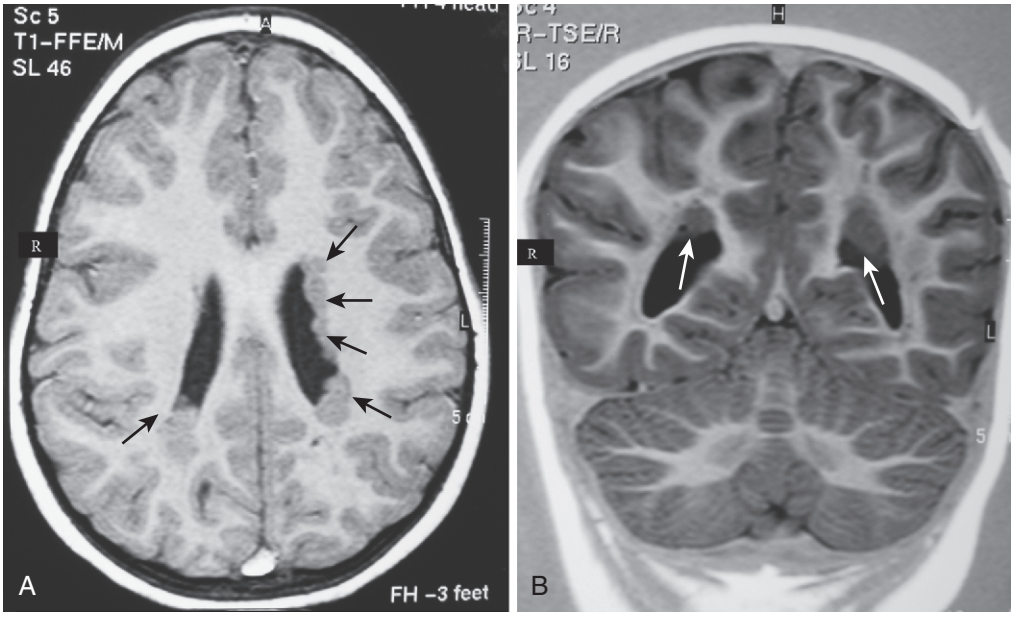

Figure 160-11 Magnetic resonance image showing bilateral periventricular heterotopia in 5-year-old child. *(From Ruggieri M, Spalice A, Polizzi A, et al: Bilateral periventricular heterotopia associated with amniotic band syndrome,* Pediatr Neurol *36(6):407-410, 2007.)*

Over the next 3 months the external granule cell layer increases to a maximum thickness of about nine rows of cells. As postmitotic neurons of the external granule cell layer are generated, they assume a deeper position within the layer. The migrating neurons pass through Purkinje cell dendrites in the molecular layer and then past the Purkinje cell bodies. After crossing the lamina dissecans, a layer just below the Purkinje cells that is rich in axon terminals of cerebellar afferents, such as the mossy fibers, the migrating neurons form the internal granular layer. Horizontal processes establish synapses with Purkinje cells and become parallel fibers, which are ordered within the molecular layer so that more recently generated fibers lie more superficially.

An unusual feature of the external granule cell layer is that it continues to generate neurons for the remainder of gestation and for as long as 7 to 9 months postnatally. This proliferation is remarkable both in terms of pure numbers as well as the protracted period of development; ultimately, cerebellar granule cells outnumber cerebral cortical neurons by more than four to one. The demonstration that medulloblastoma may arise from this layer is perhaps understandable given the long period of differentiation, which leaves neurons vulnerable to disruptions in such closely regulated pathways. Multiple genes are thought to be linked to medulloblastoma formation, including *Ptch*. The Ptch protein is a receptor for Shh, as discussed previously. Ptch normally inhibits signaling, and this inhibition is relieved by binding Shh. This in turn stimulates mitosis of the granule cell precursors. Inactivation of Ptch may therefore lead to the persistent proliferation of granule cell precursors.

Multiple influences on the complex migrations take place in the developing cerebellum. Both genetic and environmental cues are important in the establishment of cerebellar cortical migration and organization. Chemoattractive and chemorepulsive signals influence migrations. For example, netrin receptors are differentially expressed on neurons as they reach successive phases of migration. The Notch signaling pathway is also important for neurogenesis in the cerebellum. Notch1 depletion results in premature onset of neurogenesis in the midbrain-hindbrain and Notch1-deficient cells are eliminated by apoptosis and therefore result in a decreased number of neurons in the adult cerebellum. Sonic hedgehog is expressed in the cerebellum throughout life, though it promotes proliferation of developing cerebellar granule cells only in the early postnatal period, suggesting that downstream regulators may be important gatekeepers to the proliferative environment of the external granule cell layer. There is evidence that zinc finger proteins are involved in the control of cerebellar development. The mouse Zic genes are expressed in developing and mature central nervous system. Mutations in the Zic proteins lead to absent vermis and reduction of proliferation. Lastly, neurotransmitters may be important in the regulation of proliferation and migration of precursor cells via developmentally regulated, ligand-gated ion channel receptors.

Disorders of Neuronal Migration

Migrational disorders are a large and complex group of conditions characterized by relative impairments in the radial migration of neurons into the cerebral cortex and tangential migration of interneurons into the cortex. Imaging by magnetic resonance imaging (MRI) is the most useful initial investigation when a migrational disorder is suspected with the hallmark finding of gyral abnormalities and occasionally abnormalities of the corpus callosum.

Lissencephaly-pachygyria represents a spectrum of disorder marked by underdevelopment of absence of normal gyrification. In type 1 lissencephaly there is absent gyri and an immature cerebral mantle with disorganized and heterotopic neuronal layering (Figure 160-12). Type II lissencephaly is characterized by clustered, whorled arrays of neurons separated by glia and large heterotopic formations of neurons, often migrating into the pia giving a characteristic "cobblestone" appearance. Pachygyria is demonstrated by thickened simple gyri that are underdeveloped and is a continuum of lissencephaly. The known causes of these types of lissencephalies are listed in Table 160-3 together with salient clinical features and diagnostic indicators.

Polymicrogyria is characterized by numerous small folds of gyri that may have a basic four-layered anatomy, or unlayered with a poorly laminated heterotopic collection of neurons below the cerebral mantle. Polymicrogyria is associated with a number

TABLE 160-3

Causes of Type 1 and 2 Lissencephaly With Characteristic MRI or Clinical Findings

Gene	MRI Findings
LIS1	Posterior > anterior gyral abnormality (Miller-Dieker)
DCX (male)	Anterior > posterior gyral abnormality (XLIS)
RELN/DCX	Lissencephaly with cerebellar hypoplasia or male with subcortical band heterotopia
DCX (female)	Subcortical band heterotopia
ARX	Lissencephaly with agenesis corpus callosum and abnormal genitalia (XLAG)
FLNA (female)	Periventricular nodular heterotopia
POMT1	Type 2 lissencephaly with elevated CK and eye anomalies (Walker-Warburg syndrome)
POMGnT1	Type 2 lissencephaly (Muscle-eye-brain disease)
Fukutin	Type 2 lissencephaly (Fukuyama congenital muscular dystrophy)

CK, Creatine kinase; *MRI,* magnetic resonance imaging.

of primary genetic conditions as well as metabolic conditions, in particular disorders of peroxisomal biogenesis such as Zellweger syndrome (Figure 160-13). It frequently accompanies other dysgenetic brain malformations as well after in utero encephaloclastic events such as vascular insults or congenital infection (cytomegalovirus [CMV] in particular).

Neuronal heterotopias and *focal cortical dysplasias* represent arrest of migration of neurons. These may be located close to the ventricular surface in the subependyma following arrest in early radial migration. These are usually nodular and multiple. Other heterotopias are seen in the subcortical white matter and

Figure 160-13 Postmortem appearance of polymicrogyria in the region of the insula and neighboring frontal lobe in newborn with Zellweger syndrome. *(From Ellison D, Lowe J, Harding B [eds]:* Neuropathology, *ed 2. London, Mosby, 2004.)*

may be small rests of cells or more commonly bands. Focal cortical dysplasias represent abnormalities of the later stages of migration and are a cause of intractable epilepsy that may respond to epilepsy surgery. They may comprise collections of abnormally laminated normal neurons or large dysplastic multipotent cells known as balloon cells.

Schizencephaly is a severe restricted disorder of cortical formation characterized by failure of development of a portion of the cerebral wall, leaving a cleft extending from the ependymal surface to the pial surface. The cleft is usually lined by dysplastic heterotopic gray matter, in particular polymicrogyria. The lesion may be unilateral or bilateral, usually in frontal or perirolandic region. The edges of the pial surface may be opposed ("closed-lip") or more commonly widely separated ("open-lip"). Like polymicrogyria the disorder may have a primarily genetic etiology (e.g., mutation in the *EMX2* gene), but vascular disruption and congenital infection such as CMV are also associated with this abnormality.

DISORDER OF CEREBELLAR FORMATION

Cerebellar malformations include malformations of the vermis and hemispheres, typically absence or fusion as well as abnormalities of CSF flow through the aqueduct of Sylvius, draining the third ventricle into the fourth ventricle or through the medial and lateral CSF foramina in the posterior fossa. Hydrocephalus is a frequent association with cerebellar malformations.

Dandy-Walker malformation (DWM) consists of four major abnormalities: (1) complete or partial agenesis of the cerebellar vermis, (2) cystic dilation of the fourth ventricle, (3) enlargement of the posterior fossa with a resulting high position of the tentorium and torcula, and (4) hydrocephalus. Associated abnormalities

of the CNS occur in as many as 70% of cases, with the clinically most important examples being agenesis of the corpus callosum and a variety of defects of neuronal migration. DWM is related to abnormal formation of the cerebellar vermis and the roof of the fourth ventricle. The disturbance in Dandy-Walker malformation appears to be primarily failure of cavitation of the posterior membranous area of the developing roof of the fourth ventricle, allowing a buildup of CSF and development of the cystic dilation of the fourth ventricle (Figure 160-14).

Joubert syndrome is an autosomal recessively inherited syndrome of cerebellar vermis hypoplasia, hypotonia, ataxia, cognitive impairment, abnormal eye movements, and respiratory arrhythmia. The neuroradiologic hallmark of this cerebellar midbrain-hindbrain malformation on axial MRI images, is a triangular ("bat-wing" shaped) fourth ventricle, the small cerebellar vermis and large uncrossed cerebellar peduncles giving rise to the "molar tooth" sign. At least four genetic loci have been identified with multiple overlapping syndromes. The best studied thus far is *JBTS3*. The gene involved is *AHI1*, encoding the Jouberin protein, a presumed signaling molecule expressed in embryonic hindbrain and forebrain. The developmental defect involves cerebral, brainstem, and cerebellar development, perhaps at the levels of patterning, migration, and axon path finding.

Rhomboencephalosynapsis is a rare disorder characterized by hypoplasia of the vermis, fusion of the cerebellar hemispheres, and fusion of the dentate nuclei and cerebellar peduncles.

Synaptogenesis

Synaptic formation differs spatially in the human brain, but the basic principles are formation of earliest synapses in the marginal and subplate zones, an increase in synapses in cortical plate to a peak that exceeds the adult number, and a subsequent period of synaptic elimination. In the cerebrum, synapses are observed initially on neurons of the subplate and of the marginal zone. Initially, dendrites appear as thick processes with only a few fine branches. As development progresses, a great number and variety of dendritic spines appear. Synapse elimination then begins, and a large proportion of synapses is lost.

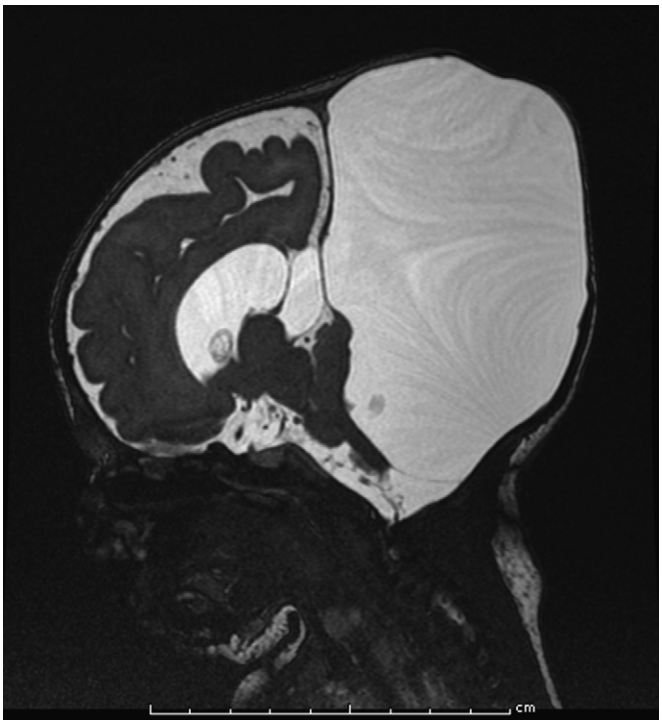

Figure 160-14 Magnetic resonance image of newborn with Dandy-Walker elevation. Note rudimentary cerebellum and massive retrocerebellar cyst.

The factors that stimulate synaptic formation and development in developing brain include both activity-independent events and activity-dependent events occurring after the development of receptors on target neurons and the generation of electrical activity. Many molecules and signaling pathways are involved in dendritic spine development and remodeling. The two principal themes are modulation of ion channels, by neurotransmitters, especially glutamate, and alteration of cell surface receptors by a variety of ligands. These intracellular events lead to effects on actin-binding proteins and the actin cytoskeleton, with resulting changes in spine shape, size, and motility.

CELL DEATH AND SELECTIVE ELIMINATION OF NEURONAL PROCESSES AND SYNAPSES

Cell death and selective elimination of neuronal processes and synapses, or pruning in brain development, are critical to normal postnatal behavior. Typically about half of the neurons in cortical region die before final maturation. This process of programmed cell death, apoptosis, is initiated and sustained by the expression of specific genes. Critical in the final phases of the sequence to cell death is the activation of caspases. Apoptosis appears to be fundamentally triggered by neuronal competition for limited amounts of trophic factors, generated by the target, afferent input, or associated glia, allowing numerical matching of interconnecting populations of neurons and elimination of projections that are aberrant or otherwise incorrect.

Neural organization is refined further by selective pruning of neuronal processes and synapses. This causes the removal of terminal axonal branches and their synapses. Activation of the NMDA type of glutamate receptor appears to be an important step in synapse elimination during development. The observations that cell death and elimination of neuronal processes and synapses occur during the organizational period of development suggest the plasticity of developing brain decreases as this period is completed but similarly has specific implications for the recovery of the neonatal brain, in particular the preterm brain, from injury.

DISORDERS OF ORGANIZATION

Several studies have shown abnormalities of development of dendritic branching and spines in children with idiopathic mental retardation. These findings indicate that a disturbance of cytoskeletal structures can cause severe dendritic abnormality and marked neurologic disturbance. X-linked genes have been shown to be particularly important. Prominent among these are four X-linked genes found mutated in families with mental retardation that encode proteins known as Rho guanine nucleotide exchange factor 6 (ARHGEF6), oligophrenin-1, p21-activated kinase, and guanine dissociation inhibitor 1. These proteins are involved in signaling pathways that regulate the actin cytoskeleton critical for neurite outgrowth, dendritic spine formation and morphology, and neurotransmitter release.

Rett syndrome is one of the most common causes of mental retardation and autism in females. It is characterized clinically by onset of deceleration of rate of head growth in the first months of life, loss of purposeful hand movement near the end of the first year, and development of stereotypic hand movements, autistic behaviors, ataxia, microcephaly, seizures, and mental retardation before the age of 5 years. The underlying molecular defect is principally loss of function of the *MECP2* gene, a transcriptional repressor expressed throughout the brain. The neuropathology consists of a small brain with an apparent disturbance of neuronal

development, characterized by dendritic spine abnormalities (Figure 160-15) and small, densely packed neurons. Animal studies suggest a fundamental perturbation in the ability to form stable synapses despite repeated experience-dependent stimulation.

Abnormalities of dendritic and axonal development have been described in infants with Down syndrome including alterations in cortical lamination, reduced dendritic branching, diminished dendritic spines and synapses, giant spines, and abnormal spine shape. Abnormalities are not apparent before 22 weeks gestation, that is, before the rapid progression of organizational events. In the first months of postnatal life an excess in dendritic branching precedes the consistent decrease observed after approximately 6 months of age. This sequence of excessive initial branching followed by deficits is similar to certain animal models of impaired dendritic development.

Fragile X syndrome is the most common form of inherited mental retardation in males and related to the amplification of a trinucleotide repeat sequence in the *FMR1* gene. The neuropathology is notable for abnormal dendritic spine morphology including long dendritic spines, fewer short spines, more immature-appearing spines, and fewer mature-appearing spines. The brain otherwise has no overt abnormalities. Similarly abnormal dendritic spines are seen in *FMR1* knockout mice.

Increasing evidence from a number of other disorders, both congenital and acquired, suggest the profound influence of structural or functional abnormalities of synaptic and dendritic formation and pruning in the genesis of severe neurologic deficits including mental retardation and epilepsy.

Autism is the leading cause of neurodevelopmental impairment with an incidence of 1 in 110 children in the United States. Evidence from studies of genetic and idiopathic forms of autism continues to accumulate that this disorder reflects fundamental failures of synaptic function or organization. The long understood phenomenologic overlap of conditions such as Rett syndrome, fragile X syndrome, and some forms of mental retardation are increasingly reflected by neurobiologic evidence of common perturbations of dendritic spine morphology, pruning, or stability of synapses. It is likely that this stage of fetal and neonatal brain development will become the most critical in understanding the major postnatal neurologic disorders of childhood.

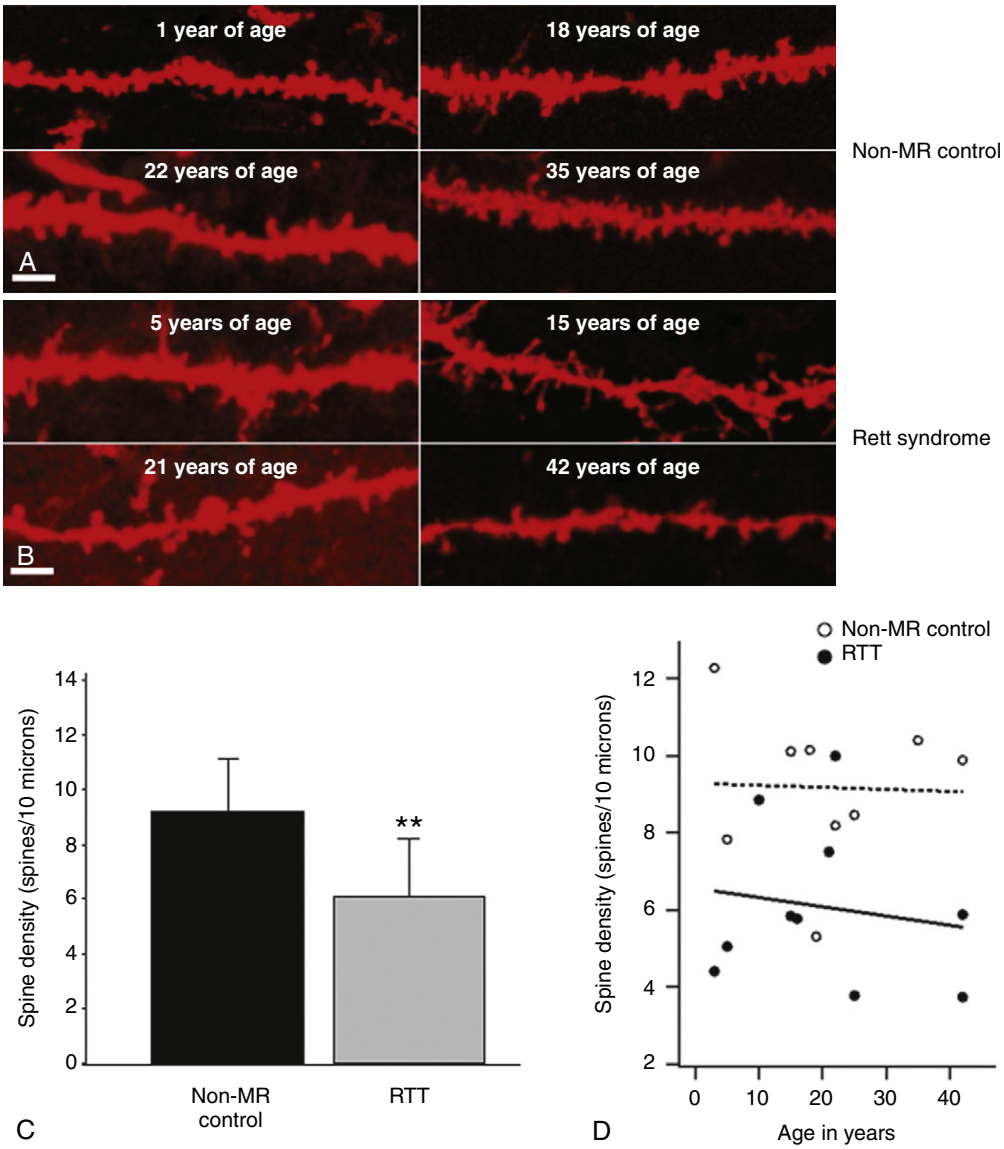

Figure 160-15 Abnormal dendritic spine morphology in patients with Rett syndrome compared with control without mental retardation. *(From Chapleau C, Calfa G, Lane M, et al: Dendritic spine pathologies in hippocampal pyramidal neurons from Rett syndrome brain and after expression of Rett-associated MECP2 mutations,* Neurobiol Dis *35[2]:223, 2009.)*

MYELINATION

Normal Development

Myelination peaks in postnatal life (Figure 160-16). Oligodendrocytes originate from progenitors in the subventricular zone and also from radial glial progenitors. The early phase in oligodendroglial lineage arising from progenitors is a mitotically active migratory cell recognized by the monoclonal antibodies A2B5 and NG2. This cell is generated from midgestation to the early postnatal life. As these precursors migrate they respond to internal cues as well as to the local influences of the other neurons and glia. These cues determine when progenitor cells exit from the cell cycle, begin to proliferate, and differentiate into mature oligodendrocytes. The waves of migration of these cells may be the anatomic correlate of the periventricular bands visualized on magnetic resonance images of the premature infant.

The O4 cell differentiates into the postmitotic immature oligodendrocyte, a richly multipolar cell recognized by a monoclonal antibody to galactocerebroside (O1). The proportion of O1 cells among the entire oligodendroglial population rises from 5% to 10% prior to 28 weeks of gestation to 30% to 40% during the premature period and to approximately 50% at term. In the third trimester of gestation the O1 cells develop linear extensions as they ensheath axons in preparation for myelination. This process is followed by differentiation to the mature oligodendrocyte. This cell becomes the predominant oligodendroglial stage in the months following term and gives rise to myelination.

The molecular determinants of this process include basic fibroblast growth factor (bFGF), neurotrophin-3 (NT-3), platelet-derived growth factor (PDGF), insulin-like growth factors (IGF-1), nerve growth factor, transferrin, iron, members of the interleukin-6 (IL-6) family, thyroid hormone, neuregulin, erbB receptors, semaphorins, neuropilin receptors, ephrin, Eph receptors, Nogo, and Nogo receptors. Cell death is an important feature of oligodendroglial development, with approximately 50% of oligodendroglia undergoing apoptosis during development.

Similar to cortical organization, myelination exhibits pronounced regional variation. These regional features have been defined well in the human cerebrum and anticipate the functional developmental milestones of the human infant. The earliest myelin is detected within the roots of motor and then sensory nerves. Myelination soon occurs within the neuraxis, in which sensory systems generally myelinate before motor systems. In cerebrum, primary projection systems begin to myelinate before associative systems. Finally, the cerebral commmissures and other corticocortical projections begin to myelinate and continue to do so for years postnatally.

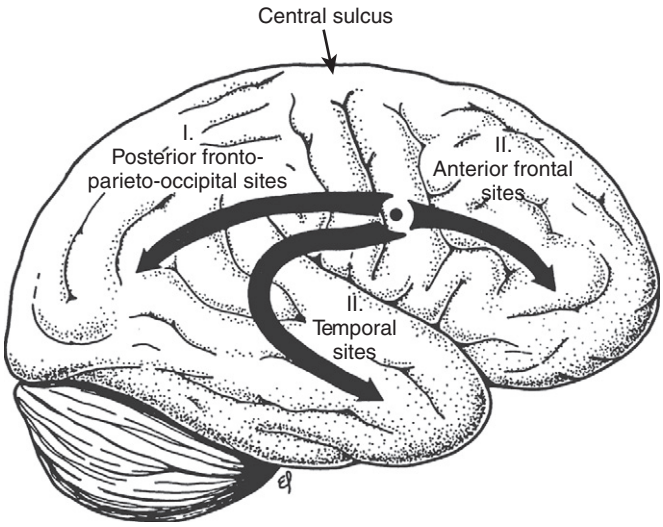

Figure 160-16 Progress of myelination. *(From Volpe JJ [ed]: Neurology of the Newborn, ed 5. Philadelphia, WB Saunders, 2008.)*

Disorders

Animal models of myelination have focused on mice deficient of membrane components. The jumpy mutation of the X-linked proteolipid protein (Plp) gene causes dysmyelination and premature death of mice with resultant hypomyelination and increased numbers of dead oligodendrocytes and astrocytes. The primary abnormality in these mice is the inability of oligodendrocytes to associate with and ensheath axons.

A primary deficiency of myelination and no other apparent neuropathologic condition has been described. Affected children demonstrate primary cerebral white matter hypoplasia, accompanied clinically by severe but nonprogressive intellectual impairment and spastic quadriparesis evident in infancy. The cause of this disorder is unknown, although a genetic abnormality is suggested by several examples of familial occurrence and by the similarity of neuropathologic features in certain mutant mice.

The occurrence of myelin deficiencies in malnutrition suggests that decreased synthesis of myelin lipids and proteins may play a major role in disorders of myelination. Inborn metabolic errors that cause abnormal neuronal storage such as GM1 gangliosidosis, have been associated with dysmature myelination on imaging studies. Evaluation of pathologic specimens from patients with infantile GM1 reveals delayed myelination of later-myelinating structures, suggesting that the metabolic defect has a direct effect on myelin development.

Dysmyelination or delayed myelination has been described in a variety of organic and amino-acidopathies, hypothyroidism, phenylketonuria, some chromosomal anomalies (in particular 18q deletion and Down syndrome) and iron deficiency.

Without doubt the most significant anomaly of myelination in current neonatal practice remains periventricular leukomalacia (Figure 160-17) and cerebral white matter injury of prematurity.

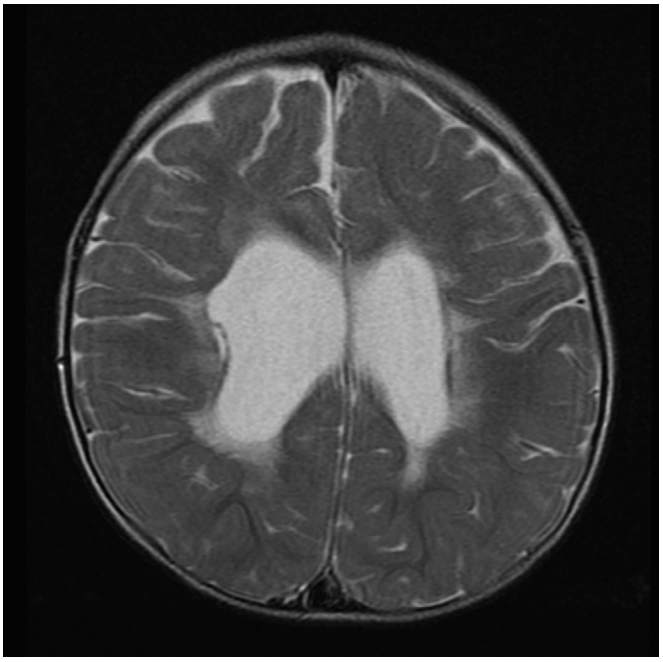

Figure 160-17 Magnetic resonance image of former 28-week premature baby at term corrected age demonstrating periventricular leukomalacia.

This clinical and neuropathologic syndrome reflects the exquisite vulnerability of the myelinating nervous system to external perturbations. Oligodendrocyte injury increasingly appears to have deleterious consequences for neuronal growth and development. The profound effects of the damage to the immaturely myelinated nervous system are reflected in the high incidence of motor, visual, and cognitive-behavioral abnormalities in survivors of preterm birth.

OVERVIEW

The development of the human nervous system is arguably the most remarkable sequence of events observable in nature. Over 40 weeks a few embryonic cells give rise to one of the most complex structures imaginable. Tightly regulated genomic expression interacts with local and distant epigenetic factors to produce trillions of functional connections that continue to grow and develop decades after birth. It is not clear when brain development truly ends because there is evidence of positive morphologic and functional changes well into adulthood.

Inevitably such a complex network of events is sensitive to damage and intrinsic perturbation, the consequences of which are at least in part determined by the phase of development in which they occur. These may represent massive failure as in anencephaly or more subtle aberrations such as cognitive disability and disorders of attention and executive control. Understanding the anatomic scaffold on which the nervous system is built allows us to predict, prevent, and potentially intervene in some of the most challenging disorders in medicine.

Development of the Blood-Brain Barrier

The blood-brain barrier is a selective diffusion barrier that maintains central nervous system homeostasis and limits the entry of substances that may potentially alter neuronal function. The main anatomic substrate of the blood-brain barrier is the specialized cerebral microvascular endothelium. Properties specific to this endothelium, in contrast with other endothelial surfaces in the body, include the presence of tight cell-cell junctions between the endothelial cells and the lack of fenestrations across the endothelial surface. The cerebral microvascular endothelium and associated astrocytes, pericytes, and neurons and the extracellular matrix components constitute the *neurovascular unit.*[1] The neurovascular unit is essential to the health and function of the central nervous system throughout development.[1] Although systematic measurements of blood-brain barrier function in the fetus and newborn infant have been limited to date, understanding of the development of the barrier continues to expand.

This chapter reviews the basic concepts of the blood-brain barrier, summarizes the molecular biology of the tight junctional complex, introduces the relatively new concept of the neurovascular unit, and places these concepts in the context of the developing fetus and neonate. Finally, the blood-brain barrier is discussed, with special emphasis on the relevance of the barrier to select aspects of perinatal medicine.

GENERAL CONSIDERATIONS

Historical Perspectives

In 1878, Paul Ehrlich, a German microbiologist, demonstrated in a seminal publication that a barrier exists between the vascular system supplying the peripheral circulatory system and the brain.[2,3] Later experiments by Edwin Goldmann, an associate of Ehrlich, further established that this barrier was truly selective and not a result of the binding properties of the dye.[4] Lewandowsky in 1900 introduced the descriptive term *blood-brain barrier* in this context.[5] Although the concept of the blood-brain barrier has been refined over the past few decades, the current understanding of its basic structure is built on the work of Reese, Karnovsky, and Brightman in the late 1960s.[6,7] Their work confirmed the presence of epithelial-like "tight junctions" in the interendothelial cleft.[6,7] Reese and Karnovsky in 1967 proposed that the capillary lumen bridged by tight junctions formed a continuous, impermeable membrane that constituted the primary anatomic substrate of the blood-brain barrier.[6] Later studies by Brightman and Reese showed that horseradish peroxidase injected into the brain could diffuse through the approximately 20-nm gaps between the astrocyte end-feet to the abluminal surface of the endothelium, indicating that astrocytes do not form the physical barrier.[7]

Key Features of the Blood-Brain Barrier

In peripheral capillaries and the nonbarrier capillaries of the central nervous system, blood-borne polar molecules diffuse across the vessel wall through spaces between adjacent endothelial cells and through transcellular routes—specifically, endothelial fenestrations and vesicular or tubulovesicular structures (Figure 161-1). By contrast, the blood-brain barrier is a selective barrier formed primarily by the specialized endothelial cells that line cerebral microvessels. The blood-brain barrier capillaries have a low nonspecific permeability to polar substances because these diffusional pathways are sparse or lacking.[6-11] The endothelia of the barrier-containing brain capillaries are nonfenestrated and are interconnected by a continuous network of complex tight junctions that functionally fuse the plasma membranes of adjacent endothelial cells. These intercellular junctions were definitively demonstrated to be the site of the barrier to passive diffusion of polar plasma solutes by the classic studies of Reese and Karnovsky[6] and of Brightman and Reese.[7]

The distinct structural characteristics of these junctions were confirmed by both transmission electron microscopy and freeze-fracture studies. Although tight junctions are found in capillaries of all tissues, they are less extensive and less complex in non–barrier-forming endothelia and contain intercellular clefts through which passive diffusion occurs. Such clefts are markedly diminished in brain capillaries. These tight junctions even

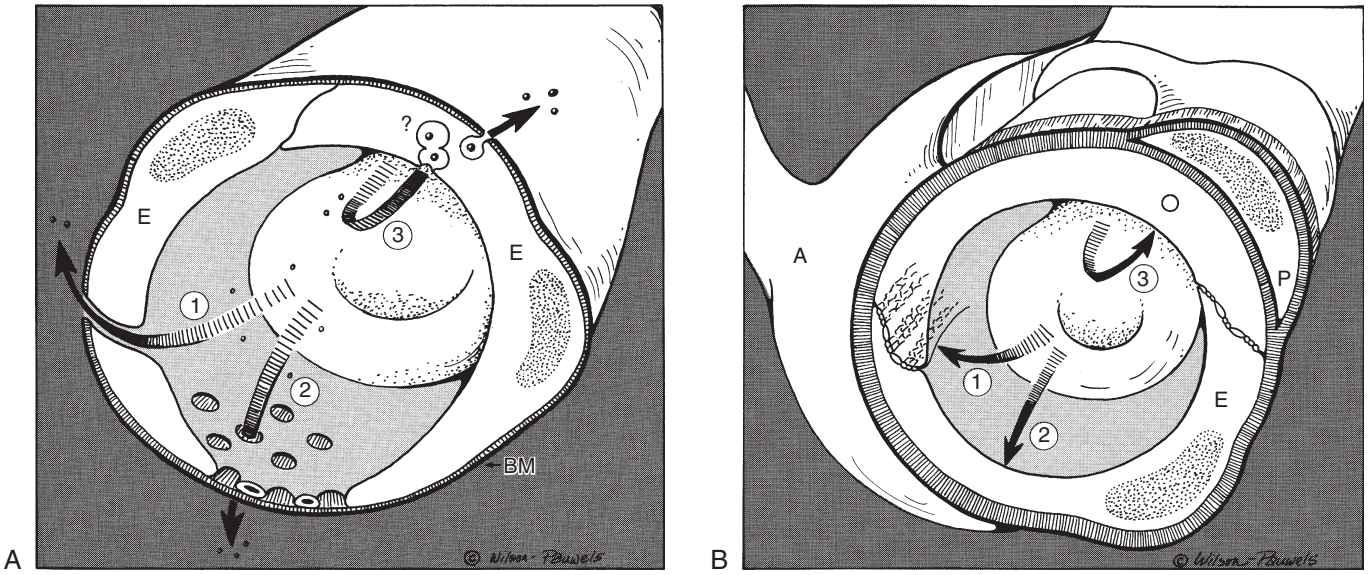

Figure 161-1 Comparative anatomic features of nonbarrier and blood-brain barrier capillaries. A, Peripheral capillaries and nonbarrier capillaries of the central nervous system lack an effective barrier to blood-borne polar molecules because of diffusion between endothelial cells *(1),* diffusion through endothelial fenestrations *(2),* and vesicular-tubulovesicular transport *(3).* **B,** Barrier capillaries are ensheathed by astrocytic foot processes, develop complex interendothelial tight junctions that block paracellular diffusion of polar substances, lack fenestrations, and contain a sparse vesicular transport system. restrict the movement of small ions such that the transendothelial electrical resistance, which is 2 to 20 ohm • cm^2 in peripheral capillaries, can be as high as 1000 ohm • cm^2 in the brain endothelium.[1,12] The unique morphology and functional characteristics of the cerebral microvascular endothelium suggest that cerebral endothelial cells are intrinsically unique or that the cellular milieu of the brain induces these distinctive properties.[13]

MOLECULAR BIOLOGY OF THE BLOOD-BRAIN BARRIER JUNCTIONAL COMPLEX

The tight junctions are the primary structures responsible for the properties of the blood-brain barrier[14] (Figure 161-2). The tight junction forms a continuous, circumferential belt separating apical and basolateral plasma membrane domains, working as a barrier within the intercellular space and as a fence within the plasma membrane.[1,14,15] They appear by transmission electron microscopy as focal contacts between membranes of adjacent cells.[7] Freeze-fracture electron microscopy showed that these contacts correspond to branching fibrils of transmembrane particles.[16] These fibrils are formed by at least two distinct transmembrane proteins: occludin and the several members of the multigene claudin family.[16,17] The blood-brain barrier transmembrane proteins, including occludin, claudins, and the junctional adhesion molecules (JAMs) such as JAM-A, JAM-B, and JAM-C, physically occlude the interendothelial space between adjacent endothelial cells (see Figure 161-2).[1,13,14] Occludin and the claudins copolymerize to form the fibrillar heteropolymers, which can be seen on micrographs prepared using freeze-fracture techniques, and are linked laterally to the JAMs.[18] The tight junction–associated proteins, also called *adapter* proteins, are located in the cytoplasm beneath the tight junctions.[16,17,19,20] These proteins are involved in scaffolding the transmembrane proteins and coupling them to the cytoskeleton.[16] This complex array of cytoplasmic plaque proteins includes the zonula occludens (ZO) proteins ZO-1 to ZO-3, symplekin, cingulin, 7H6, ZONAB (*ZO*-1–associated *n*ucleic *a*cid–*b*inding protein), AF-6 (*A*LL1-*f*used gene from chromosome *6* protein), and others (see Figure 161-2).[16,17] The ZO proteins have one or more domains that function as protein-binding modules and have a role in organizing proteins at the plasma membrane.[17] These proteins are located at the cytoplasmic surface of endothelial cells and connect tight junctions to actin, which is the primary cytoskeleton protein for the maintenance of structural and functional integrity of the endothelium.[13] A ring of actin microfilaments underlies the complex and has a role in regulating permeability and structural integrity of the tight junction complexes that are situated on the apical cell membrane.[16]

Occludin was identified in 1993 as the first integral protein localized to the tight junction.[21] It is a 60- to 65-kDa protein with a carboxyl-terminal domain that is capable of linking it to the ZO proteins.[21] The main function of occludin appears to be in tight junction regulation[1,13,22]; however, the family of claudin proteins are 22-kDa phosphoproteins that have four transmembrane domains and contribute to the high electrical resistance of the tight junctions.[1,13,14,23] Twenty-four members of the claudin family have been identified.[1,14,23] Claudin-3, claudin-5, and possibly claudin-12 are the main claudins that contribute to the high resistance of the blood-brain barrier.[1,14,23] Together, claudins and occludins form the extracellular component of tight junctions, and both are required for the formation and proper functioning of the blood-brain barrier.[24] Junction-associated adhesion proteins are members of the immunoglobulin superfamily and also are important for tight junction complex integrity.[14,25] They also contribute to the high electrical resistance of tight junctions and play a role in inflammatory cell transmigration through junctional complexes.[25]

THE NEUROVASCULAR UNIT AND THE BLOOD-BRAIN BARRIER

The association of the microvascular endothelium, astrocytes, pericytes, neurons, and extracellular matrix has been proposed to form a functional neurovascular unit[1,13] (Figure 161-3). The endothelial cells of the brain appear to be important in the modular

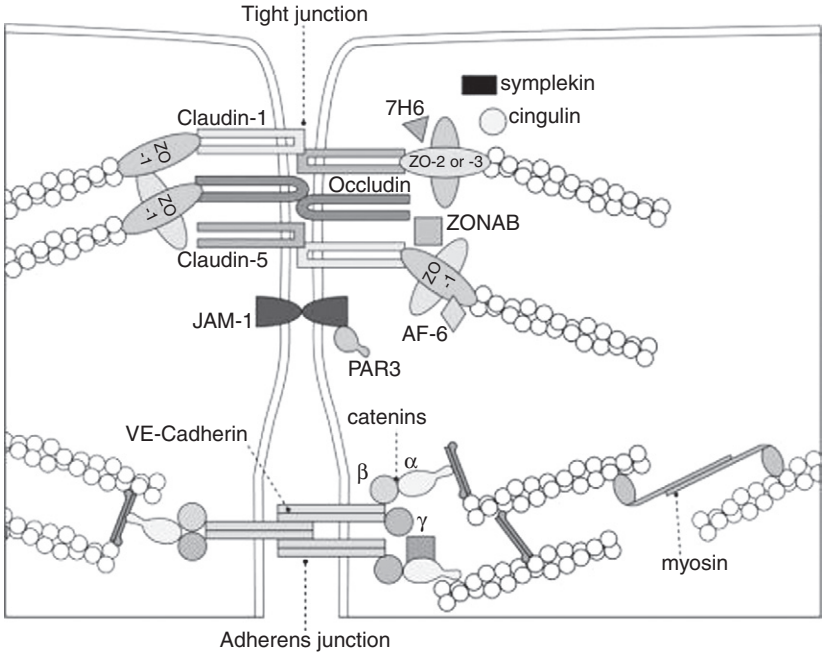

Figure 161-2 Molecular composition of tight junctions. The transmembrane proteins occludin, the claudins, and junctional adhesion molecule-1 (JAM-1) constitute the barrier formed by tight junctions sealing the paracellular space. Claudins adhere to each other in a homotypic tail of occludin and link the tight junction to the actin cytoskeleton. Proteins of the zonula occludens (ZO) family can shuttle to the nucleus to influence transcriptional processes in cellular proliferation and differentiation. The ZO proteins also have been shown to interact with claudins, and to provide molecular scaffolds for tight junction assembly. Cingulin is a 140-kDa tight junction plaque protein that associates with the actomyosin cytoskeleton. Its putative function is transduction of the mechanical force generated by the actomyosin cytoskeleton important for cellular differentiation. The Ras target AF-6 (ALL1-fused gene from chromosome 6 protein) interacts with ZO-1 and serves as a peripheral component of tight junctions in epithelial cells. Symplekin is a 126-kDa protein that occurs and probably functions in the nucleus as well as in the tight junction plaques. Localization of 7H6 tight junction–associated antigen along the cell border of vascular endothelial cells has been shown to correlate with paracellular barrier function. *(Modified from Förster C: Tight junctions and the modulation of barrier function in disease,* Histochem Cell Biol *130:55-70, 2008.)*

organization of this unit.[1,13] All components of the neurovascular unit, including the cellular constituents and components of the basement membrane, can contribute to the dynamic regulation of microvascular permeability and therefore have important interactions that regulate the function of the endothelial *physical barrier.*[1,13]

The neurovascular unit regulates the supply of nutrients to the brain by means of endothelial transporters and acts as a *transport barrier.* Some of these barrier-specific endothelial transporters include the glucose carrier GLUT1, several amino acid carriers (including LAT-1 [system-L large neutral amino acid transporter-1]), and transporters for nucleosides and nucleobases.[1] Other important efflux transporters specialize in eliminating potentially toxic substances from the brain. The *ABCB1/MDR1* gene encodes P-glycoprotein (P-gp/MDR1), which is one of the transmembrane transporters of clinical relevance. It is concentrated on the luminal membrane, constitutes a major barrier to the penetration of drugs into the brain, and serves as a physiologic barrier against the entry of xenobiotics into the brain.[26,27]

Astrocytes are integral elements of the neurovascular unit that regulate several features of the blood-brain barrier, such as the tightness of the interendothelial tight junctions,[1,28,29] and the expression and polarized localization of specialized enzyme and nutrient transporter systems.[1,30-34] The microcirculation of the brain needs to be responsive to the fluctuating metabolic demands of the tissue it supplies, and to adapt to the dynamic nature of neural activity.[13] Tissues with high levels of neuronal activity must communicate with the vasculature not only to increase regional blood flow but also to regulate the regional permeability of nutrients through the blood-brain barrier. Astrocytes are positioned to mediate the moment-to-moment regulation of cerebral microvascular permeability through their interaction with neuronal processes in the neurovascular unit.[13,35]

Pericytes (see Figure 161-3) constitute another important structural element of the neurovascular unit. Pericytes intimately embrace the abluminal surface of the brain capillary endothelium and have a role in the expression, maintenance, and regulation of the phenotypic properties of the barrier.[36,37] The degree of coverage of the cerebral microvasculature by pericytes is greater for brain capillaries than for capillaries of other tissues[38] and appears to correlate with the degree of tightness of the interendothelial junctions.[36,39] Recruitment and integration of pericytes into the endothelial wall are essential for the formation, maturation, and maintenance of the normal microvascular structure and function.[36] Pericyte-derived angiopoietin can induce endothelial expression of occludin, a major protein constituent of the blood-brain barrier.[13,40] Contractile proteins found in cerebral pericytes suggest that they also may regulate capillary blood flow and permeability.[13,41]

In addition to astrocytes, pericytes, and neurons, the extracellular matrix of the basal lamina also interacts with the cerebral microvascular endothelium. Disruption of the extracellular matrix is associated with increased blood-brain barrier permeability in pathologic states.[13,42,43] Recognition of the complex interactions of the components of the neurovascular unit continues to provide a basis for understanding the multiple mechanisms by which cerebral microvascular permeability may potentially be influenced by development, medications, and disease.[1,13,14]

DEVELOPMENTAL ASPECTS OF THE BLOOD-BRAIN BARRIER

Current knowledge regarding the development of the blood-brain barrier in vertebrates is derived from experiments in a wide spectrum of organisms ranging from hagfish to sheep. Although information derived from autopsy material from human fetuses and premature infants more recently has become available,[44-47] data on barrier function in human fetuses and premature infants are lacking. Comparisons among vertebrate classes indicate that the structural and functional aspects of the blood-brain barrier are remarkably conserved.[48] Nonetheless, caution must be exercised in analysis of experimental data on the temporal aspects of prenatal or postnatal barrier development, because the timing of brain growth and differentiation relative to the timing of birth differs considerably among species.[49,50]

Angiogenesis: Capillary Formation

The development of the central nervous system vasculature begins during embryogenesis, when angioblasts arise in the mesoderm of the head region and form a perineural vascular plexus by a process called *vasculogenesis*—in situ differentiation of the endothelial cells.[51] In 2-day-old chick and 9-day-old rodent embryos,[52-54] the perineural vascular plexus covers the entire surface of the neural tube, whereas in the human, it appears at approximately week 8 of embryonic development.[55,56] Vascular sprouts from the perineural plexus invade the proliferating neuroectoderm at 4 and 11 days of embryonic development in the chicken and rodent, respectively, and during the third month of fetal development in the human.[56] The mechanism by which the new vessels are formed from preexisting vessels is called *angiogenesis.* During angiogenesis, newly forming vessels radially invade the neuroectodermal tissue, elongate, give rise to manifold branches, and finally anastomose with adjacent sprouts to form a plexus of undifferentiated capillaries in the ventricular zone of the developing brain.

The endothelial cells later become invested with astrocytic end-feet, at which time a true capillary-astrocytic complex resembling the mature vessel is formed.[57] The basement membrane becomes recognizable concurrent with these events and appears most developed at regions of the closest endothelial-astrocytic contact. Some evidence suggests that the basement membrane forms adjacent to the membranes of each cell type, and that these membranes then coalesce or fuse. Astrocytic investment of endothelial cells and basement membrane formation are associated with marked decreases in the width of the perivascular space and in the fraction of endothelial cells that are surrounded by pericytes or their processes. These events of perivascular consolidation and basement membrane formation are most prominent from birth through the first 3 to 4 postnatal weeks in the mouse and rat. During this period in the mouse, vessel wall thickness decreases by 60%, and the basement membrane thickens from undetectable levels to 71 nm by electron microscopic criteria.[58] Paracellular diffusion diminishes during these latter stages of capillary-astrocytic complex formation, basement membrane formation, and perivascular consolidation. Nonbarrier vessels in the area postrema do not develop these differentiated features.

At 12 weeks, a claudin-5 punctate staining pattern is detected in the endothelial cytoplasm *(arrows).* At 14 weeks, the punctate pattern starts to form interrupted linear tracks *(arrowheads)* that at 18 weeks (**C**) appear as nearly continuous thick bands *(arrows). Scale bars* = 15 μm in **A** and **B** and 10 μm in **C.** *(Modified from Virgintino D, Errede M, Robertson D, et al: Immunolocalization of tight junction proteins in the adult and developing human brain,* Histochem Cell Biol *122:51-59, 2004.)*

Tight Junction Development

Development of the blood-brain barrier begins during the embryonic period with the formation of tight junction complexes between endothelial cells.[35,59-62] The exact timing of the maturation of these barrier components to macromolecules remains controversial.[57] An important point is that blood-brain barrier does not "switch" to a tight barrier at a specific time during angiogenesis, but rather the tightness of the barrier gradually increases in a region-dependent manner while angiogenesis is ongoing.[63] In rodents, vascular fenestrae disappear, pinocytosis decreases, and vessels decrease in diameter between embryonic days E11 and E17.[62,64] The onset of tight junction formation is detectable by E15, but tight junctions continue to increase in complexity through postnatal day one.[12, 65-68] Results obtained from experiments using horseradish peroxidase and freeze-fracture techniques suggest that the chick, rat, and monkey blood-brain barriers to proteins are tight from the earliest stages of development.[60] Some features of the tight junctions, however, appear to continue to mature with brain development.[59]

Molecular Biology of the Junctional Complex: Developmental Aspects

As described previously, tight junctions are composed of a complex array of transmembrane and cytoplasmic proteins.[1,13,59] As supported by experimental data, the expression of these proteins is developmentally regulated in rodents[67,69,70]: Occludin expression is low in rat brain endothelial cells at postnatal day 8 but clearly increased by day 70,[69] and ZO-1 protein expression increases between fetal days 15 and 19 and after birth in mouse brain microvessels.[67]

In contrast with the rodent, in which the development of the blood-brain barrier occurs primarily after birth, the human barrier and its tight junction protein complex develop mainly in utero.[12,70,71] More recent evidence has confirmed that the proteins of the tight junction complex are present very early during human fetal brain development.[44-47]

The first stage of human fetal intracortical vascularization is characterized by the development of radially penetrating stem vessels in fetuses from 10 to 12 weeks gestation, which is associated with the appearance of vascular basal lamina components including endothelium-specific markers and barrier-specific transporters.[46 47,72] The second stage of intracortical vascularization spans the period of midgestation and is characterized by vascular branching, increasing microvessel density, and barrier differentiation demonstrated by the detection of tight junction molecules, barrier-specific metabolic transporters, and efflux carriers.[46,47,72]

The developmental pattern of tight junctional protein expression in human fetuses and premature infants is somewhat controversial: Two studies reported maturational changes in the expression of these proteins,[44,46] whereas a third study did not find similar changes.[45] The primary endothelial tight junction molecules that have been identified so far in the developing human brain include occludin, claudin-5, JAM-1, and ZO-1.[44,46,47,73] Occludin and claudin-5 are already expressed in the primary vessels of the telencephalon by week 12 of gestation, and by midgestation (18 weeks) they show dramatic changes[46] (Figure 161-4). The most critical change occurs between 12 and 14 weeks of gestation, when occludin and claudin-5 immunoreactivity shifts from the endothelial cytoplasm to the endothelial borders and concentrates in linear, discontinuous tracts that may correspond to simple, incomplete networks of tight junctional strands.[46] Soon thereafter, a near-continuous staining pattern is detectable, and more extended and complex strands form, resembling those observed in mature tight junctions.[46] Therefore human endothelial tight junction development appears to begin earlier and proceed faster than in other vertebrate species.[66,74-77]

Consistent with the maturational changes in the tight junctional proteins during very early in fetal development,[46] occludin, claudin-5, and ZO-1 immunoreactivity was detected in the germinal matrix and cortical vessels of premature infants with postconceptual ages ranging from 24 to 42 weeks.[44] Although the immunoreactivity of occludin, claudin-5, and ZO-1 in the cortical vessels appears to increase with increasing postconceptual age, the immunoreactivity increases for these proteins appear to be greater with maturation in the germinal matrix.[44] Therefore the structural elements of the germinal matrix vascular endothelial tight junctional complexes appear to accumulate from 24 weeks until term, suggesting that the tight junctions in the germinal matrix mature during the third trimester.[44] Nonetheless, in another detailed study, the primary tight junction molecules, occludin,claudin-5, and JAM-1, were shown to be expressed in the blood-brain barrier as early as 16 weeks gestation but did not show significant differences in expression in the vasculature of the germinal matrix, white matter, or cortex between 16 and 40 weeks gestation.[45]

The early embryonic time course for the development of the blood-brain barrier raises the question of what potential inductive factors or cell types promote the early process of endothelial differentiation.[78] Neural progenitor cells are a major cell type in the developing embryonic brain, and endothelial cells have been

shown to influence the differentiation and morphology of neural progenitor cells.[79] In co-culture with endothelial cells, neural progenitor cells show reduced neurogenesis and elevated self-renewal.[79] Neural progenitors also have been observed in contact with early postnatal blood vessels, and, thus, could represent an early stage of astrocyte differentiation.[80] These findings point to the likeihood of important interactions between neural progenitor and endothelial cells. In co-culture studies, neural progenitor cells also have been shown to influence brain endothelial microvascular cells by enhancing barrier properties including increased transendothelial electrical resistance and decreased permeability to a small-molecule tracer, and by affecting tight junctions as indicated by a redistribution of occludin, claudin-5, and ZO-1 to cell-cell borders.[78] In view of these interactions between endothelial cells and embryonic neural progenitor cells, neural progenitor cells probably influence the embryonic brain endothelial phenotype.[78] Thus neural progenitor and brain microvascular endothelial cell interactions may be one of the factors responsible for inducing blood-brain barrier–like properties early in embryonic development.[78]

MATURATION OF THE BLOOD BRAIN-BARRIER

Permeability

The functional development of the fetal and neonatal blood-brain barrier has been the subject of some controversy.[53,81,82] Some investigators have claimed that a barrier is present to proteins as early as blood vessels form in the fetal brain,[81] whereas others consider this concept to be misleading.[82] This controversy[53,81,82] appeared to have been based on a paucity of quantitative blood-brain barrier permeability measurements in the same species from early fetal through later neonatal development up to maturity in adults. As described earlier, comparisons among species are difficult because of differences in rate of brain development.[50] In addition, birth is not necessarily a reliable landmark by which to stage brain and hence blood-brain barrier development.

Blood-brain barrier function was first investigated in developing fetal sheep by examining steady-state brain-to-plasma sucrose ratios in anesthetized exteriorized acutely studied fetal sheep.[83] The brain-to-blood sucrose ratios exhibited rapid decreases in early gestation, followed by smaller decreases later in gestation through the first week of postnatal life.[83] The ontogeny of blood-brain barrier permeability was later quantified with the rate constant for influx (K_i) across the blood-brain barrier using a small-molecular-weight (103-Da) synthetic inert hydrophilic amino acid, α-aminoisobutyric acid (AIB). These studies were done in a nonanesthetized chronically instrumented sheep model for three different points in development: in the last 2 months of fetal life, in the first months of postnatal life, and at full maturation (i.e., in adult sheep)[84] (Figure 161-5). The K_i measured with AIB was significantly lower in all brain regions of the adult sheep, and in most brain regions of newborn and older lambs, than in brain of fetuses at 60% and 90% of gestation. However, the blood-brain barrier was relatively impermeable to AIB in all age groups and brain regions, because the magnitude of the changes from 60% of gestation to maturity was not large.

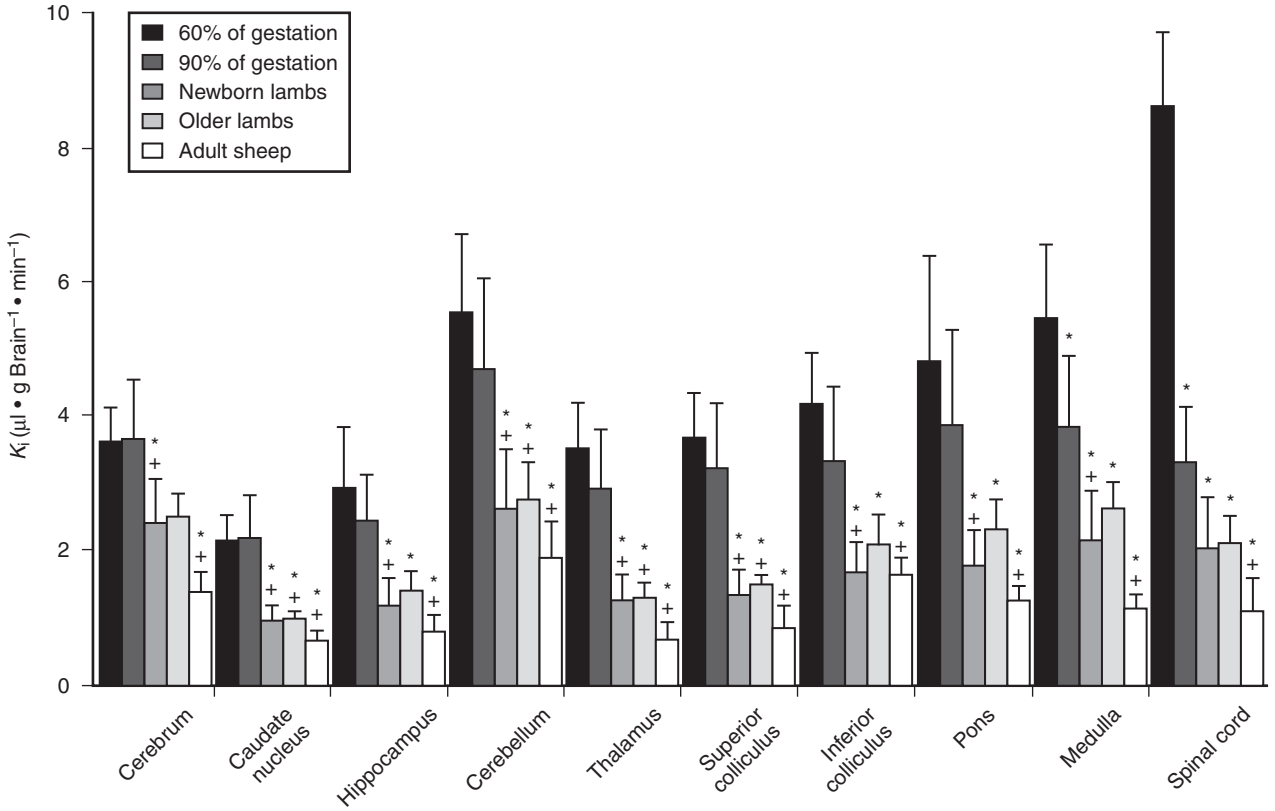

Figure 161-5 Regional blood-to-brain transfer constants for influx (K_i) to AIB, an amino acid used extensively to measure total and regional barrier permeability, decreased with development in sheep. The magnitude of the changes from 60% of gestation to maturity was not large. The low permeability to AIB suggests presence of a functionally tight blood-brain barrier from very early in gestation, which probably serves to isolate the developing brain from systemic blood constituents. *(Modified from Stonestreet BS, Patlak CS, Pettigrew KD, et al: Ontogeny of blood-brain barrier function in ovine fetuses, lambs, and adults,* Am J Physiol *271:R1594-R1601, 1996.)*

Although the permeability of the barrier to AIB was relatively low during fetal and neonatal development, the ovine fetus and neonate exhibited ontogenic decreases in barrier permeability (see Figure 161-5).[84]

The low permeability to AIB suggests that a functionally tight barrier may be present from very early in gestation, which probably serves to isolate the developing brain from systemic blood constituents. Inspection of the regional K_i values for AIB (see Figure 161-5) reveals that the cerebrum exhibits the smallest differences in the K_i between the fetuses at 60% of gestation and the adult sheep. By contrast, the more caudal brain regions, including the cerebellum, medulla and spinal cord, exhibit relatively larger developmental decreases in permeability between fetuses at 60% of gestation and adult sheep. These findings suggest that the cerebral cortex represents a relatively privileged site because of its unique neuronal composition and function. These measures of barrier function early in the sheep gestation are consistent with results suggesting very precocious barrier differentiation in the human fetal cerebral cortex as described earlier.[46,47]

The decreases in permeability to AIB in the sheep[84] were similar to developmental changes in barrier permeability measured quantitatively using potassium in rats.[85] Permeability to potassium was higher in 21-day fetal than in newborn or adult rats.[85] Taken together, the findings in sheep[84] and in developing rats[85] suggest that from fetal to adult life, barrier permeability to both a cation and small-molecular-weight hydrophilic molecules decreases from fetal to adult life.[84]

The ontogenic decreases in permeability in the sheep[84] also were similar to postnatal reductions in permeability to AIB in rabbits[86] and to inulin, sucrose, mannitol, and urea in rats.[87-90] However, in contrast with the findings in rabbits, which exhibited 80% to 90% postnatal reductions in permeability from day 1 of postnatal life to adulthood, the sheep exhibited 39% to 45% reductions in permeability from day 3 to adulthood.[84] The timing and schedule of brain growth probably are critical to maturation of the blood-brain barrier.[85] Comparison of barrier development among species requires consideration of brain growth differences. The sheep brain develops mostly before birth, the rabbit brain develops perinatally, and the rat brain after birth.[50] The prenatal brain development in the sheep may account for the more modest differences in permeability between newborn lamb and adult sheep.

Permeability and Corticosteroids

Evidence in adult subjects suggests that the blood-brain barrier is under hormonal control.[91-94] In adult rats, adrenalectomy increases blood-brain barrier permeability, and corticosterone replacement reverses this effect on the barrier.[92] These findings suggest that the pituitary-adrenal cortical axis may function as a physiologic regulator of barrier function.[92] It is well known that the pituitary–adrenal cortical axis matures during fetal development and that endogenous cortisol concentrations increase particularly in the latter part of gestation.[95] In sheep, maternally administered exogenous antenatal corticosteroids have been shown to reduce blood-brain permeability early (at 60%, 70%, and 80% of gestation) but not late (at 90% of gestation) in fetal development and in the neonatal period.[96-99] In addition, endogenous increases in plasma cortisol concentrations are associated with decreases in blood-brain barrier permeability during normal fetal development.[98] These findings suggest that the blood-brain barrier is hormonally responsive in the fetus and that corticosteroids are important in regulation of barrier maturation.[98] Furthermore, the age-related differential responsiveness of the fetal barrier to maternally administered corticosteroids probably is attributable to the fact that in early gestation, the barrier is still responsive to exogenous corticosteroids and has not yet been exposed to the endogenous increases in corticosteroids.[98,99] Later in gestation[98] and in the newborn,[99] endogenous increases in cortisol will have already accelerated the maturation of the blood-brain barrier, so it is no longer responsive to the exogenously administered corticosteroids.[98,99] These findings are important because during the perinatal period, when the brain potentially may be exposed to systemic elevations in neurotoxic substances, increases in endogenous cortisol serve to protect the fetal and neonatal brain by reducing its permeability.[98,99]

The site of action of corticosteroids on the blood-brain barrier in the fetus[96-98] is most likely on the capillary endothelial cells, because physiologic hydrocortisone concentrations have been shown to increase transendothelial resistance and to decrease permeability in cerebral capillary endothelial cells.[100] The intercellular tight junctions of cerebrovascular endothelial cells are the probable site of action of corticosteroids on the fetal blood-brain barrier, because corticosteroids in vitro have been shown to up-regulate the cerebrovascular endothelial expression of several tight junction proteins.[101,102]

ALTERATIONS IN BLOOD-BRAIN BARRIER DEVELOPMENT AND FUNCTION: CLINICAL IMPLICATIONS

Disruption of the tight junction seal and alterations in blood-brain barrier function are thought to complicate a variety of neurologic disorders.[13,14,103] It is becoming increasingly apparent that failure of the blood-brain barrier is a critical event in the development and progression of several disorders that affect the central nervous system.[13] In some cases, increased blood-brain barrier permeability is a consequence of pathophysiologic changes, such as with ischemic stroke[104] and traumatic brain injury,[105] whereas in other cases, blood-brain barrier opening may be the precipitating event, such as with multiple sclerosis.[13]

The relatively impermeable blood-brain barrier in the fetus and newborn infant serves to protect the developing brain from insults that could impair neuronal function during fetal life, at delivery, and in postnatal development.[84] Emerging evidence suggests that a number of pathologic states, prenatal-perinatal abnormalities, circulating factors, and treatment strategies may be predisposing factors for blood-brain barrier abnormalities at different stages of development.[106] Elucidation of the mechanisms that underlie alterations in blood-brain barrier function during development can be expected to help suggest strategies to protect the brain in both full-term and preterm infants. The entities summarized next represent just a few of the factors that may potentially influence barrier function or contribute to abnormalities of barrier function during development.

Inflammation and Infection

Systemic and local inflammatory mediators can impair the barrier function of the neurovascular unit.[107] Circulating inflammatory ligands such as lipopolysaccharides, locally produced activated complement proteins, and proinflammatory cytokines such as IL-1 and TNF-α can bind to corresponding receptors on various elements of the neurovascular unit and alter the integrity of the blood-brain barrier.[106,108] The expression and localization of tight junction proteins have also been reported to be disrupted during inflammatory conditions.[109]

Some evidence suggests that proinflammatory cytokines may gain access to the fetal brain after being produced during maternal inflammation or chorioamnionitis.[110] The uterus, fetal circulation, and brain represent three compartments separated by boundaries made up of the placenta and amniotic membranes and the blood-brain barrier.[110] It has been postulated that cytokines originating in the uterus, amniotic fluid, or placenta may enter the fetal circulation, or be produced because of inflammatory conditions within the fetal circulation. As a result, proinflammatory cytokines

originating from each of these sources may potentially damage the fetal blood-brain barrier or gain access to the fetal brain by crossing the barrier. Once the cytokines cross the blood-brain barrier, they may directly damage the brain.[110] These concepts are supported by studies in newborn pigs in which intracarotid injections of tumor necrosis factor-α (TNF-α) resulted in increases in cerebral cortical blood-brain barrier permeability.[111] In addition, a single dose of lipopolysaccharide administered intravenously to fetal sheep has been shown to be associated with an increase in albumin concentration in the brain parenchyma, suggesting that blood-brain barrier permeability may increase after exposure of the fetus to systemic endotoxin.[112]

Microorganisms can cause systemic inflammation and gain direct access into the brain parenchyma by breaching the integrity of the blood-brain barrier.[113-116] K1 type *Escherichia coli, Listeria monocytogenes,* and type III group B streptococci are some of the specific bacterial pathogens that represent the leading causes of severe disease in perinatal medicine. These organisms appear to have the greatest capacity to penetrate the cerebrovascular endothelium and to result in the largest increases in blood-brain barrier permeability, when compared with other organisms.[113-117] The K1 type *Escherichia coli* has been shown to have specific genetic virulence determinants that contribute to brain microvascular endothelial cell adhesion and invasion.[117-122] Moreover, increases in TNF-α in cerebrospinal fluid appear to correlate with increases in barrier permeability in experimental meningitis.[114] Inflammation, systemic infections, and meningitis during the fetal and perinatal period have been shown to seriously interfere with normal central nervous system function and development.[123] Abnormalities of the blood-brain barrier probably are important contributors to the brain injury that is associated with systemic inflammation and infection in premature and full-term infants.

Hypoxia, Ischemia, and Reperfusion Injury

Perinatal hypoxic-ischemic brain damage is a major cause of death associated with high-acuity conditions and chronic neurologic morbidity in infants.[124-126] Blood-brain barrier integrity is compromised and permeability increased as a result of hypoxia and ischemia-reperfusion injury to the central nervous system in adult subjects.[13,127] The expression and localization of various tight junction proteins and of nutrient and electrolyte transporters are disturbed, and the nonspecific transport of blood-borne proteins into the brain is increased under hypoxic or ischemic conditions in the brain.[128,129] The mechanisms that underlie these changes include the direct effects of energy failure resulting from oxygen and metabolite deprivation, damaging effects of oxygen free radicals, cessation of shear blood flow with invasion of the neurovascular unit by static leukocytes adhering to the blood vessel walls, and induction of local inflammatory cascades associated with hypoxic-ischemic injury to the tissues.[130]

The need for cardiopulmonary resuscitation is one of the most common scenarios potentially associated with barrier dysfunction and hypoxic-ischemic brain injury. Blood-brain barrier permeability was investigated in young anesthetized pigs during and after cardiopulmonary resuscitation. After 8 minutes of cardiac arrest followed by either 10 or 40 minutes of continuous sternal compression, no increase was seen in the blood-brain barrier transfer coefficient. However, after 8 minutes of arrest, 6 minutes of cardiopulmonary resuscitation, and 4 hours of spontaneous circulation, the blood-brain barrier transfer coefficient increased by 59% to 107% in 10 of 11 regions rostral to the pons. Thus, after an 8-minute period of complete ischemia, the blood-brain barrier remained intact during and immediately after resuscitation, but not after several hours of recirculation. These findings are in contrast with previous work in adult animals in which no delayed increase in permeability was demonstrated.[131]

In a model of cerebral ischemia-reperfusion injury in newborn piglets, the blood-to-brain transfer of urea, sodium, and sucrose was measured at 30 minutes and again after 2 hours of reperfusion.[132] The blood-to-brain transfer constants for the two smaller-molecular-weight tracers, sodium and urea, increased by 30 minutes after ischemia, followed by a subsequent increase for the largest tracer, sucrose, at 2 hours. The increase in blood-to-brain transfer of these small-molecular-weight tracers probably is the result of the opening of water-filled channels or "pores" at the blood-brain barrier, associated with size-dependent changes in tracer influx into the brain. These findings in neonatal piglets are consistent with the effects of hypoxia-ischemia in adults—namely, formation of a paracellular leak across the blood-brain barrier with a pore diameter, which increases with time and the severity of the insult.[132-134] In contrast with the findings just described, the barrier was found to be relatively impermeable to sodium and mannitol in newborn piglets exposed to 60 minutes of systemic hypoxia and hypercapnia and 20 minutes of hypotension, either immediately after the insult or 24 hours later.[134] Taken together, these studies suggest that the amount of damage to the barrier in the newborn probably relates to the duration and severity of the insult, because in the latter study, the brain remained relatively well perfused even though hypoxia and hypercarbia rendered brain blood flow pressure-passive and the mean arterial pressure was reduced below the lower limit of autoregulation for normal piglets.[134] On the other hand, it is likely that global ischemia in the first study resulted in complete tissue ischemia and anoxia, with a consequently relatively more severe insult.[132]

Decreased nutrient supply to neuronal tissue is a major cause of energy failure and subsequent tissue damage after hypoxia or ischemia. Studies in experimental animals and humans indicate that cerebral glucose utilization initially is low in early gestation and increases with maturation. The expression of glucose transporter proteins at the blood-brain barrier and on neuronal and nonneuronal elements in the brain parenchyma shows similar maturational patterns.[124] During nutrient deprivation, alternate energy fuels such as ketone bodies and lactate substitute for glucose, thereby protecting the immature brain from hypoglycemia.[124] These findings suggest that the immature brain may be better able to withstand episodes of decreased nutrient supply during hypoxic-ischemic episodes, because the immature blood-brain barrier may be more efficient than that in the adult at the transport of certain alternative nutrients.[135-137]

Hyperbilirubinemia

Hyperbilirubinemia has been associated with acute bilirubin encephalopathy and kernicterus in both preterm and term infants.[138] Recent evidence indicates that the unbound fraction of bilirubin in the serum is more directly related to bilirubin neurotoxicity than are total bilirubin concentrations.[139] These findings suggest that the higher the level of unbound bilirubin in the serum, the more likely it is for bilirubin to cross the blood-brain barrier and cause bilirubin-related neurotoxicity. At any given unbound serum bilirubin concentration, conditions that decrease blood-brain permeability to bilirubin are less likely to be associated with bilirubin-related neurotoxicity.

Experimental evidence has shown that hyperbilirubinemia induced by infusions of comparable amounts of bilirubin correlated with higher brain bilirubin content and higher brain-to-blood distribution ratios for bilirubin in 2-day-old than in 2-week-old piglets. These ratios were higher in subcortical regions—namely, the cerebellum and brain stem—than in the cerebral cortex.[140] The results of this study suggest that a postnatal maturation of the barrier for unbound bilirubin is likely, and that the permeability for bilirubin is relatively greater in subcortical than in cortical

regions of the developing brain.[139-141] These maturational changes in the permeability to bilirubin during development serve to protect the more mature brain from bilirubin toxicity. They also provide a basis for the clinical observation that newborn infants are at a higher risk for kernicterus at lower bilirubin levels in the first few hours after birth than later in postnatal life.[142]

Conversely, conditions that adversely affect blood-brain permeability to unbound bilirubin could be associated with higher risks for bilirubin-related neurotoxicity. Disruption of the blood-brain barrier by inflammation, or hypoxia–ischemia also could facilitate transport of bilirubin into brain.[143] Premature infants frequently are exposed to systemic fetal and neonatal inflammation, and to recurrent episodes of hypoxia and ischemia-reperfusion. These insults, combined with immaturity of the blood-brain barrier for bilirubin, places very-early-gestation preterm and late-preterm infants at a higher risk for bilirubin-related neurotoxicity compared with full-term newborns.[144] Elucidation of the role of the blood-brain barrier in relationship to the pathogenesis of kernicterus can be expected to help improve assessments of the risks of preterm and full-term infants for bilirubin-induced neurotoxicity.[145]

Hyperosmolar Stress

The phenomenon of hyperosmotic opening of the blood-brain barrier has been investigated extensively in adulthood.[146] Hypertonic solutions can open the barrier by shrinking endothelial cells and widening the intercellular space that normally is sealed by tight junctions. The degree of barrier opening varies with the concentration of the solute and the type of hyperosmotic solution used. Experiments by Cserr and co-workers[147] showed barrier opening with degrees of hyperosmolality comparable to those encountered clinically in sick premature infants.[147-150] More recently, Stonestreet and associates examined the effects of a hyperosmolar stress on blood-brain barrier function measured quantitatively during the last 2 months of fetal development and in the first month of postnatal life in sheep. Their results demonstrated that blood-brain barrier permeability increases with increases in plasma osmolality in fetal sheep and lambs.[151] These experiments also demonstrated that the barrier became more resistant to the effects of hyperosmotic stress during development. The findings suggest that the blood-brain barrier may be more vulnerable to the effects of osmotic stress in the immature fetus than in older subjects.[151]

Intraventricular Hemorrhage

Infants born prematurely are at an increased risk for intraventricular and intraparenchymal hemorrhage, which adversely affects their neurodevelopmental outcomes.[44,152] Extravasation of blood normally contained within the cerebral intravascular space into the parenchymal–ventricular space represents complete breakdown of the blood-brain barrier. Hence, understanding the pathophysiology of impaired blood-brain barrier function is of vital importance in perinatal medicine because premature infants are at high risk for brain hemorrhages.

Germinal matrix hemorrhage progressing to intraventricular or intraparenchymal hemorrhage is the prototype of intracranial hemorrhage encountered in preterm infants.[153,154] Germinal matrix capillaries have large diameters and thin basement membranes and lack direct contact with perivascular structures along a large proportion of their circumference, in contrast with capillaries in the cerebral cortex at same gestational age.[155] The blood vessel density and the percentage of blood vessel area are larger in the germinal matrix vessels than in those in the adjacent gray and white matter in autopsy material from fetuses and premature infants born between 16 and 40 weeks gestation, potentially accounting for propensity for hemorrhage in the germinal matrix.[73] As described previously, controversy exists regarding the structural elements of endothelial tight junctional complexes in the germinal matrix vasculature during development.[44-47] Two reports appear to suggest that the tight junction proteins continue to accumulate over the interval during which premature infants are at highest risk for intraventricular hemorrhage.[44,46] On the other hand, a third study suggested that because the endothelial tight junction molecules were not decreased in germinal matrix vasculature relative to the adjacent gray and white matter, a paucity of these proteins was not likely to be responsible for the fragility of the germinal matrix vasculature and not likely to account for the propensity for hemorrhage in premature infants.[45] Hence the contribution of the tight junction proteins to the structural integrity of the germinal matrix warrants further consideration.

The pericyte is another important component of the neurovascular unit, which functions to enhance the integrity of the blood-brain barrier and to provide structural stability to blood vessels.[36,39,156] The germinal matrix blood vessels have been shown to possess fewer pericytes than the vasculature of the other adjacent brain regions.[156] These findings suggest that a paucity of pericyte coverage of the germinal matrix vasculature may contribute to its fragility and increase its vulnerability to hemorrhage.[156]

Maternal treatment with antenatal corticosteroids has been associated with a decreased incidence of intraventricular hemorrhage in premature infants.[157] As described previously, maternal antenatal corticosteroid administration also results in decreased permeability of the blood-brain barrier early in ovine gestation.[96-98] Taken together, the decreased incidence of intraventricular hemorrhage in premature infants after maternal corticosteroid treatment[157] and the decreased permeability of the blood-brain barrier in lamb fetuses after corticosteroid treatment of the ewes[96-98] suggest that corticosteroids may accelerate microvascular maturation, with a beneficial effect on blood-brain barrier function in the human fetus and premature infant. In addition, endogenous changes in corticosteroids also may account for accelerated maturation of the endothelial vasculature in the fetus and premature infant.[98] Although the contributions of specific alterations in the components of the neurovascular unit to the development of germinal matrix–intraventricular hemorrhage in premature infants still have not been entirely elucidated, alterations in components of neurovascular units, such as the pericyte,[156] probably contribute to the fragility of the germinal matrix vasculature. Moreover, it remains likely that alterations in barrier function in premature infants other than hemorrhage may contribute to brain injury such as that resulting in periventricular leukomalacia, mental retardation, or cerebral palsy.

Mechanical Ventilation

Among premature infants exposed to prolonged ventilation, rates of neurodevelopmental impairment are very high.[158] Abnormalities in the blood-brain barrier may potentially contribute to the associated brain injury by allowing circulating toxic substances greater access to the brain parenchyma. Previous work has shown that elevation in mean airway pressure during positive-pressure ventilation in newborn piglets selectively alters blood-to-brain transport of small water-soluble molecules.[159] It appears likely, therefore, that increased cerebral venous pressures during ventilation cause the increases in the blood-to-brain transport of these small-molecular-weight tracers.[159] Increases in the duration of positive-pressure ventilation also predispose premature lambs to increases in regional blood-brain barrier permeability measured using a small-molecular-weight tracer (i.e.,AIB).These alterations in barrier function were shown to occur over relatively short time intervals (minutes to hours) and were not a result of changes in mean airway pressure.[160] Therefore both increases in mean airway pressure and increases in the duration of ventilation

potentially contribute to altered blood-to-brain transport, which may adversely affect neuronal function during ventilation.[159,160]

SUMMARY

The blood-brain barrier, a complex and dynamic barrier at the level of the microvascular endothelium, has a critical role in maintaining the health and function of the brain. The tight junctional complex plays an essential role in regulating paracellular permeability and can be affected in a variety of perinatal disorders and related therapies. The neurovascular unit provides an interesting model for understanding how the endothelium, astrocytes, neurons, pericytes, and extracellular matrix function together to form a protective barrier for the brain. The development of the blood-brain barrier is an important area for inquiry with a significant impact on the neurodevelopmental outcomes of preterm and full-term infants. Further understanding of this important barrier may lead to identification of clinically useful neuroprotective strategies during development.

Development of Neurotransmitters

The function of the immature brain is determined to a considerable extent by the operational state of the specialized chemical synaptic connections between neurons.[1] The capacity of immature synapses to transfer information determines functions as diverse as hormone release, breathing, and vision. Advances in analyzing and understanding the machinery of chemical neurotransmission are providing a more complete picture of the dynamic events that take place in the fetus and neonate.[2,3] Conventional biochemical assays for synaptic activities as well as methods with greater spatial resolution (e.g., receptor autoradiography) have been used to assess development of neurotransmitter pathways. These studies indicate that biochemical

features of neurotransmission are often markedly different in the immature brain compared with those in the adult brain. Distinct neurotransmitter-specific neuronal groups mature at different rates, so multineuronal networks may have a different functional "balance" at different ages.[2] Moreover, although some components of the synapse, such as neurotransmitter synthetic enzymes, are relatively undeveloped or inactive in the fetus and neonate, others, including certain neurotransmitter receptors and second-messenger systems, are expressed at much higher levels than in adults.[4,5] These developmental patterns are relevant to understanding normal physiology as well as the effects of disease in the immature brain.

Chemical transfer of messages across synapses depends on coordinated function of several biochemical processes (Figure 162-1). A neurotransmitter is synthesized by specific enzymes within nerve terminals and may be stored (e.g., catecholamines) in synaptic vesicles awaiting impulse-stimulated release. Specific biochemical uptake processes or "pumps" within axonal nerve terminals may remove transmitter released from the synaptic cleft and may prevent it from having prolonged contact with postsynaptic receptors. Similar uptake processes remove portions of degraded neurotransmitter. For example, acetylcholine is hydrolyzed to yield choline, which is transported into the cholinergic nerve terminal by a high-affinity, sodium-dependent uptake process. Stimulation of neurotransmitter release from axons and reuptake is coordinated with electrical impulse flow. In certain groups of synapses, catalytic enzymes are located within the nerve terminal and on the surface of synaptic endings to degrade released neurotransmitter. Catecholamines are degraded by the cytoplasmic enzyme monoamine oxidase and by the enzyme catechol-*O*-methyl transferase.

Actions of neurotransmitters are expressed in postsynaptic neurons through specific neurotransmitter receptors. These receptors are generally linked to ionophores (ion channels) or second-messenger systems, or both. Stimulation of receptors linked to ion channels generally produces a change in the membrane potential, such as depolarization in the case of excitatory neurotransmitters (e.g., glutamate) or hyperpolarization produced by inhibitory neurotransmitters such as γ-aminobutyric acid (GABA). Second-messenger systems may stimulate a cascade of intracellular events such as protein phosphorylation or modulation of gene expression. The relative influence of a neurotransmitter pathway during development is determined by the sum of these processes, and differential rates of development in each of them modify the relative influence of pathways markedly at different developmental stages. The separate biochemical processes involved in neurotransmission in a single neuronal group may develop at different rates, and these altered relationships (e.g., among transmitter synthesis, release, and reuptake) determine the pathway's influence.[2]

EARLY BIRTH AND DEVELOPMENT OF THE BRAIN STEM NORADRENERGIC PROJECTION TO CEREBRAL CORTEX

Norepinephrine-containing axons project into the cerebral cortex and other parts of the forebrain from the locus ceruleus in the pons.[6] The noradrenergic axonal network within cerebral cortex is thought to be involved in cortical activation and attention, and axons projected into the diencephalon influence neuroendocrine function. The cell bodies in this pathway are among the earliest to undergo neurogenesis in the developing brain.[7] This finding is consistent with the general pattern that neurons originating in the brain stem are "born" or originate before those in more rostral locations. The cell bodies of this projection originate on gestational days 12 to 14 (total gestational period of 21 days) in rats and on gestational days 27 to 36 in monkeys (total 165 days' gestation).[7] The noradrenergic projection appears to be influential in the immature cortex. In the neonatal rat, approximately one third of all cortical synapses possess

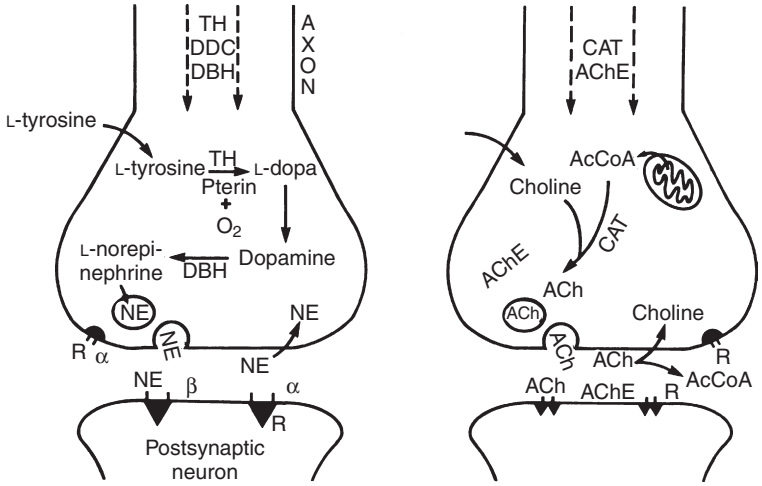

Figure 162-1 Schematic diagrams connected to an axon *(top)* projected from a noradrenergic cell body in the brain stem. The key biochemical markers, which are relatively specific for noradrenergic nerve terminals, are tyrosine hydroxylase (TH) and dopamine β-hydroxylase (DBH), the biosynthetic enzymes, endogenous norepinephrine (NE) content, and [^{3}H]NE uptake in vitro into sealed-off nerve endings (synaptosomes). The high-affinity uptake pump is shown by the *arrow* directed from the synaptic cleft into the presynaptic terminal. DBH is found only in noradrenergic axons, whereas TH is also found in dopamine nerve terminals. The cortical distributions of noradrenergic and dopamine axons are relatively distinct. β-Adrenergic receptors are found predominantly postsynaptically, whereas α-adrenergic receptors (R) are localized presynaptically and postsynaptically. On the *right,* an acetylcholine synapse is diagrammed, indicating one of the primary markers, choline acetyltransferase (ChAT), the enzyme that synthesizes acetylcholine from acetyl coenzyme A (AcCoA) and choline. Endogenous acetylcholine and [^{3}H]choline uptake into synaptosomes are also specific markers. Acetylcholinesterase (AChE) is relatively specifically localized in cholinergic cell bodies in regions such as the basal forebrain but may be nonspecific in other regions, including the substantia nigra, and in intrinsic cortical neurons. Muscarinic and nicotinic acetylcholine receptors (R) are located presynaptically and postsynaptically. *DDC,* L-Dopa decarboxylase.

an axonal uptake mechanism for monoamines, a proportion that far exceeds the density in the adult.[8] Some experimental work supports the proposal that noradrenergic axons exert a trophic effect on the developing cortex in fetal and early postnatal life. Development of the visual cortex may be regulated by norepinephrine in the "critical period" of visual plasticity.[9]

Development of the noradrenergic system in cortex has been examined by measuring endogenous levels of the neurotransmitter norepinephrine, the energy-dependent, high-affinity uptake of [^{3}H]norepinephrine into pinched-off nerve endings (synaptosomes), and the activity of the neurotransmitter synthetic enzymes tyrosine hydroxylase and dopamine β-hydroxylase during development.[6,10-13] Results of these studies have been compared in rodents and subhuman primates. When biochemical markers for this neurotransmitter system are studied during development (Figure 162-2), investigators have noted that the ability of presynaptic nerve terminals to take up [^{3}H]norepinephrine develops slightly before endogenous levels of neurotransmitters and synthetic enzyme activities rise.

Synaptic effects of norepinephrine are expressed at postsynaptic β-adrenergic and α-adrenergic receptors and at presynaptic α-receptors.[3,14,15] Development of these receptors and of associated second-messenger effects, such as norepinephrine-stimulated cyclic adenosine monophosphate (cAMP) production and phosphoinositide (PI) hydrolysis, increases rapidly in the postnatal period, as shown in Figure 162-2.[4,16] In vitro receptor autoradiography has been used to visualize the location and density of these receptors, and these studies have identified specific laminar and regional differences in their development.[3,14,17]

DOPAMINE INNERVATION

Dopamine, the other major catecholamine in the brain, is contained within neuronal projections extending from the substantia nigra in the midbrain into the basal ganglia, the hypothalamus, and restricted portions of the cerebral cortex such as the cingulum. The neurons from which these projections originate also arise relatively early, at gestational days 13 to 15 in rats and at fetal days 36 to 43 in monkeys.[7] Histofluorescence for dopamine and serotonin has been found in human fetuses as early as 3 months' gestation.[18] The biochemical markers for these axons—the dopamine reuptake system in synaptosomes, the synthetic activity of tyrosine hydroxylase, and endogenous neurotransmitter stores—undergo almost all their maturation in the postnatal period.[1,19] Use of histofluorescence to examine dopamine in the basal ganglia of postnatal animals indicates an early pattern of dopamine islands.[20,21] These islands persist as specialized groupings of axons in the adult brain, although the overall pattern of dopamine is more confluent at that stage. In the adult brain, the specialized compartments extend throughout the anteroposterior extent to form a lamellar or "striasomal" pattern. In rodent studies the turnover of dopamine in the developing brain appears to be relatively high in the postnatal period and exceeds that in the adult. The ratios of homovanillic acid (HVA) and dihydroxyphenylacetic acid, which are products of dopamine oxidation, to endogenous dopamine levels are higher in the brain of immature rodents than in adults. This estimate of turnover suggests that dopamine neurons are active in the early postnatal period.

SEROTONIN PATHWAYS

Serotonin axons emerge from the raphe nuclei in the pons and resemble the widespread projections made by noradrenergic neurons into the forebrain and spinal cord. Serotonin pathways are important for control of hypothalamic and pituitary functions, pain, sleep, appetite, and other behavioral functions. The raphe serotonin neurons also undergo early cell division, with the timing similar to that of catecholamine neurons. Biochemical studies of serotonin turnover indicate that it is relatively high in the neonatal period in rodents, a finding suggesting early establishment of active neuronal impulse flow.[22] In rodents, maturation of serotonergic biochemical markers follows a caudal to rostral gradient with brain stem levels at two thirds of adult levels at birth and hemisphere activity at 20% of adult levels. In the neonatal rodent, a transient, dense serotonin innervation has been found using an immunohistochemical technique to localize serotonin and autoradiography to image serotonin uptake sites on nerve terminals.[23] In somatosensory cortex, dense patches of serotonin innervation are aligned with specialized cellular aggregates, called *barrels,* before 3 weeks of age. Afterward, the patchy areas of hyperinnervation become more uniform and confluent. The ontogeny of serotonin receptors has been studied in the developing brain, and distinct laminar patterns have been identified.[15] These observations suggest that the pattern of serotonin innervation shares features in common with catecholamine projections from the brain stem. Both systems undergo early neurogenesis and appear

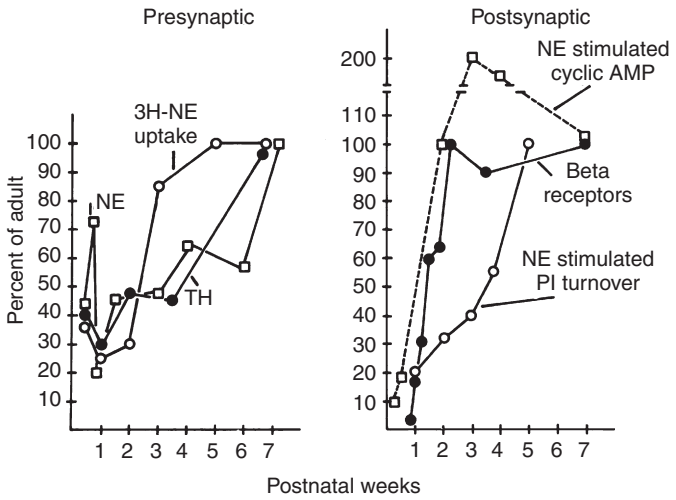

Figure 162-2 Ontogeny of biochemical markers for noradrenergic axons in rodent cerebral cortex during postnatal development. to be relatively more densely represented in the neonatal period than later. The axonal arbors of both systems reorganize during postnatal development, and both may influence cortical plasticity. Abnormalities in serotonin metabolism in cerebral cortex have been described in children with autism using positron emission tomography (PET).[24] Drugs that inhibit the reuptake of serotonin into synapses, which are used widely to treat depression, may produce a withdrawal syndrome as well as increased incidence of congenital malformations when used in pregnancy.[25]

DEVELOPMENT OF CEREBROSPINAL FLUID LEVELS OF DOPAMINE AND SEROTONIN METABOLITES IN HUMAN INFANTS

Measurement of levels of cerebrospinal fluid (CSF) metabolites of dopamine and serotonin provides an estimate of functional activity of central dopaminergic and serotonergic neurons in humans. The brain is the major site of HVA synthesis, and although up to 30% of the serotonin metabolite, 5-hydroxyindoleacetic acid (5-HIAA), is produced in the spinal cord, the neurons of origin are in the brain stem. A few studies have examined the maturation of catecholamine and serotonin pathways in the perinatal period.[26,27] In one study of neonates, 35 male and 22 female infants (gestational ages ranging from 28 to 42 weeks) were evaluated.[26] They included 38 premature infants (36 weeks or less) and 19 term infants. Common medical problems in these patients included prematurity, asphyxia, respiratory distress, and infection. Examination of the data, however, did not reveal any relationship of these conditions with the monoamine concentrations. The infants were initially grouped into four age categories for analysis: (1) young premature infants less than 32 weeks gestational age, (2) premature infants 33 to 36 weeks gestational age, (3) infants 37 to 42 weeks gestational age (full term), and (4) older infants up to 6 months of age (Table 162-1). HVA levels increased progressively with maturity ($p < .05$; analysis of variance). Although mean HVA values in girls were slightly higher than those in boys in each age-group, these differences were not statistically significant. In contrast to HVA, 5-HIAA levels were similar in these age-groups, and there were no significant sex differences. Mean 5-HIAA values in all groups of infants were considerably higher than the values in older children.[27]

In Figure 162-3, mean HVA/5-HIAA ratios are plotted for the three groups of neonates and the older infants. The mean HVA/5-HIAA ratio in the most immature infants (28 to 32 weeks gestation) was 1.0 ± 0.12 (mean ± SEM), whereas in the most mature group (1 week to 6 months old), it was 1.98 ± 0.17 ($p < .01$, comparing these two groups by the Student *t*-test). HVA concentrations increased over the period from the last trimester of pregnancy into early infancy, whereas 5-HIAA levels were relatively stable. Thus the HVA/5-HIAA ratio changes markedly over this period. The data suggest that the maturation of human dopaminergic neuronal activity lags behind that of serotonin neurons in the perinatal period.

TABLE 162-1

Homovanillic Acid and 5-Hydroxyindoleacetic Acid Levels in Cerebrospinal Fluid*

COMPARES PREMATURE AND TERM NEONATES AND OLDER INFANTS			
	n	5-HIAA (ng/mL)	HVA (ng/mL)
Group 1, premature neonates	38	96 ± 10	106 ± 10
Group 2, term neonates	19	104 ± 7	129 ± 11
Group 3, infants	13	85 ± 7	159 ± 9†

From Silverstein FS, Donn S, Buchanan K, Johnston MV. Concentrations of homovanillic acid and 5-hydroxyindoleacetic acid in cerebrospinal fluid from human infants in the perinatal period. *J Neurochem* 43:1769, 1984.

*Premature neonates range in gestational age from 28 to 36 weeks; term neonates from 37 to 42 weeks. Infants were 1 to 6 months of age. Values are mean ± SEM.

†$p < .05$ using analysis of variance to compare all HVA values in the three groups.

5-HIAA, 5-Hydroxyindoleacetic acid; *HVA,* homovanillic acid.

ACETYLCHOLINE PATHWAYS

Acetylcholine serves a variety of important functions in the brain. A major projection from the basal forebrain lateral to the hypothalamus into the cerebral cortex is believed to have a role in cortical activation, learning, memory, and cortical plasticity.[28] Cholinergic circuits in the brain stem and the diencephalon influence autonomic functions and form part of the control mechanisms for temperature regulation and hormonal release. In the basal ganglia, cholinergic circuits counterbalance the effects of dopamine pathways and serve an important role in controlling motor tone and movement.[19,21]

The developmental profile of cholinergic neurons has been studied by assaying postnatal endogenous brain concentrations of acetylcholine, [^{3}H]choline uptake into synaptosomes, and the synthetic activity of choline acetyltransferase (ChAT).[11,16,29,30] In the cerebral cortex of rodents, cholinergic markers are present at fairly low levels over the first few postnatal days, and they rise with a sigmoidal pattern during the first postnatal weeks to maturity (Figure 162-4). Labeling studies with [^{3}H]thymidine autoradiography in rodents indicate that the cell bodies from which this pathway originates in the basal forebrain develop on gestational days 12 to 15.[2,31] Therefore the neurons that form the neocortical cholinergic system originate relatively early but differentiate over a more prolonged period than do catecholamine systems.

In the human brain, the nucleus basalis of Meynert in the basal forebrain develops intense acetylcholinesterase (AChE) activity between 12 and 22 weeks gestation.[31] ChAT activity in human cerebral cortex rises after a gradual developmental pattern during the postnatal period that reaches nearly adult levels in adolescence.[32,33] Histochemical localization of the catabolic enzyme AChE is a marker for cholinergic nerve terminals

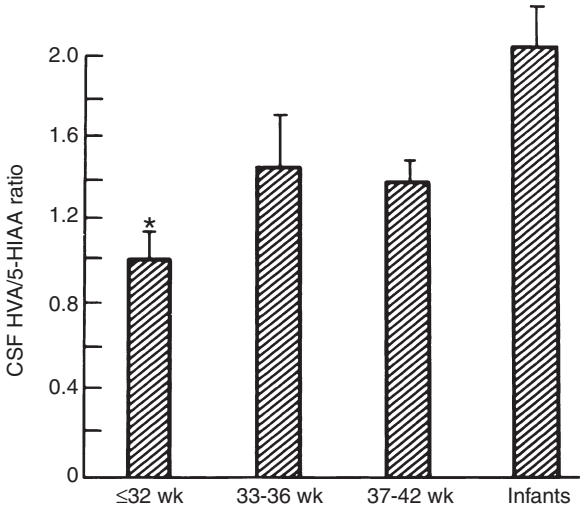

Figure 162-3 Cerebrospinal fluid (CSF) neurotransmitter metabolites in human newborns (32 weeks or less [$n = 12$], 33 to 36 weeks [$n = 26$], 37 weeks or more [$n = 19$]), and infants 1 to 6 months old [$n = 13$]; the *asterisk* indicates $p < .01$, comparing the most immature neonates with the infants using Student *t*-test. *5-HIAA,* 5-Hydroxyindoleactic acid; *HVA,* homovanillic acid. *(From Silverstein FS, Donn S, Buchanan K, Johnston MV,* J Neurochem *43:1769, 1984.)*

The cortical region assayed was the dorsolateral sensorimotor cortex. *Right,* Data on muscarinic receptors are from references 16 and 26. The ordinate at *left* is for muscarinic receptors; at the *right,* it is phosphatidylinositol (PI) turnover. *mACHR,* Muscarinic acetylcholine receptors.

in cerebral cortex, and this method has been used to examine human postmortem tissue. Kostovic and co-workers[34] found that laminar preferences in AChE staining changed dramatically in the human frontal cortex during the first postnatal year. AChE reactivity of layer three pyramidal cell bodies and the surrounding fibrillar network begins to develop after the first postnatal year and increases gradually to its peak intensity in young adults. Studies of ChAT activity and AChE histochemical features point to the coordinated development of cholinergic pathways in the brain with the relatively prolonged development of cognitive skills in humans.

Muscarinic cholinergic receptors that transmit most of the postsynaptic effects of acetylcholine increase in number during postnatal development in rodents, in concert with the development of nerve terminals.[29] In the adult cerebral cortex a distinct laminar gradient is formed, with more superficial regions relatively enriched.[17] Shaw and associates[17] found that in cats, the laminar gradient is reversed in the postnatal period, with deep layers heavily labeled. During maturation the receptors progressively reorganize into the adult pattern. Human infant neocortex also demonstrates the inversion of the adult pattern of receptor development noted in kitten cortex. In contrast to the rodent, however, muscarinic receptors in human postmortem neonatal cortex are present at a higher density than in the adult.[3]

One population of muscarinic receptors is coupled to stimulation of the PI turnover second-messenger system.[16] Despite the relatively low levels of muscarinic acetylcholine receptors present in the early postnatal period, these receptors are able to stimulate a vigorous PI turnover response. The magnitude of the PI response stimulated by the muscarinic agonist carbachol increases to a level twice that in the adult at postnatal day 7 in rodents, a finding suggesting that the muscarinic receptors are more tightly coupled to phospholipase C at this age than in the adult. Although presynaptic markers for cholinergic axons and muscarinic receptors are less abundant in the immature brain, enhancement of muscarinic-stimulated second-messenger responses may serve to compensate for this. Nicotinic cholinergic receptors also appear to be important in brain development, and transgenic mice with deletions of the β_2-subunit of this receptor are hyperactive.[35]

INHIBITORY GABA-CONTAINING NEURONS

GABA is the predominant inhibitory neurotransmitter in the brain, but it is paradoxically excitatory during fetal life and in the early postnatal period in animal models.[36] Important populations of GABA-containing neurons are found in cerebral cortex, in which they are predominantly intrinsic aspinous stellate interneurons, and in the striatonigral projection in the brain stem. GABA-containing neurons are born in the ganglionic eminence of the ventral forebrain, with neurons destined for the cerebral cortex born in the medial ganglionic eminence and those destined for the basal ganglia originating in the lateral ganglionic eminence.[37] Unlike the predominantly excitatory pyramidal neurons of cerebral cortex that are born in the dorsal forebrain and migrate to their permanent locations radially from the ventricular zone, inhibitory GABA-containing neurons migrate through the cortex following tangential pathways.[37] Development of GABAergic synapses generally precedes the development of excitatory glutamate synapses.[36]

Judged by biochemical assays, GABA-containing synapses reach maturity in rodents at a time midway between the early-developing catecholamine neurons and the later-developing cholinergic systems.[2] The activity of the synthetic enzyme for GABA, L-glutamate decarboxylase, is low in newborn rodent cortex but rises rapidly to achieve adult levels by 3 weeks of age.[38] Maturation of sodium-dependent, high-affinity uptake of [^{3}H]GABA into synaptosomes exhibits a peak at greater than adult levels in cortex at about 3 weeks of age and remains elevated until about 8 weeks of age.[38] The concentration of the neurotransmitter amino acid GABA has already reached approximately 50% of adult levels in neonatal cortex and is at adult levels by 2 weeks of age.

Neurotransmitter receptors for GABA are linked to receptors for benzodiazepine-type drugs, and together they regulate the opening of chloride channels. Stimulation of this ionophore hyperpolarizes postsynaptic neurons in older animals, but depolarizes neurons in the early postnatal period.[36] This occurs because the Na^+-K^+-$2Cl^-$ cotransporter (NKCC1) is active in the immature brain and raises the intraneuronal concentration of Cl^-. Opening of chloride channels then leads to depolarization rather than hyperpolarization.[39] The diuretic and NKCC1 blocker

bumetanide is anticonvulsant in immature rodents.[39] Neurotransmitter-binding studies showed that benzodiazepine receptors are found at relatively high levels in the neonate, and in rodents, levels are almost half the adult level.[40] Significant levels of benzodiazepine receptors have been observed in the human newborn and infant hypothalamus.[41] Binding sites for GABA are present at relatively low concentrations at birth and increase slowly in the postnatal period. Studies of postnatal maturation of $GABA_A$ receptors in children using PET and [^{11}C]flumazenil indicate that the density is 50% higher in cerebral cortex at 2 years of age than in adults, a finding suggesting age-related pruning in synaptic density with age.[42]

NEUROPEPTIDE-CONTAINING NEURONS

Neuropeptide-containing neurons comprise an important, relatively precocious segment of brain circuitry, which is important for a variety of functions in the fetus and newborn. Various neuropeptide-containing neurons found in the brain have been studied from a developmental perspective, mostly in rodents. Neurons containing enkephalin, other opiate peptides, substance P, and thyroid-releasing hormone have been observed in neurons using immunohistochemical techniques in early fetal life in both rodents and humans. Neurons containing cholecystokinin and vasoactive intestinal polypeptide comprise important intrinsic groups of neurons.[43-46] In cerebral cortex, these peptides most often coexist with GABA. In rodents, endogenous levels of cholecystokinin, somatostatin, and vasoactive intestinal polypeptide increase relatively slowly to adult levels over the first 7 postnatal weeks.[43-46] In contrast, endogenous levels of substance P reach the adult concentration in the neonatal period and by 3 weeks of age rise to more than three times that level.[2] Opiate systems appear relatively mature in the neonatal period. Metenkephalin-containing neurons and μ-opiate receptors are found in rat entorhinal cortex and hippocampus in neonates. [^{3}H]Naloxone-receptor binding in newborn rhesus monkeys demonstrates an adult-like pattern in subcortical structures. Much more remains to be learned about the development of these pathways, especially as they relate to important neuroendocrine function and control of breathing.

EXCITATORY AMINO ACID PATHWAYS

Pathways that use excitatory amino acids are prevalent in the brain and appear to convey information in many intracortical, primary sensory, and cortical projection pathways. For example, the pathways from the cortex into the basal ganglia (corticostriatal pathways), the corticospinal pathways, and the pathways from the eyes to the visual cortex appear to use the excitatory amino acid glutamate or a closely analogous compound as their primary neurotransmitter.[2,46-51] Electrophysiologic effects of visual stimuli in cerebral cortex are blocked by specific antagonists for glutamate receptors.[51]

In cerebral cortex, high-affinity, sodium-dependent [^{3}H]glutamate synaptosomal uptake into nerve terminals has been used to study development of the visual pathways.[46] [^{3}H]Glutamate uptake, which reflects development of presynaptic nerve terminals in visual cortex of developing rats, increases continuously from birth and reaches adult levels by postnatal day 15 (Figure 162-5).

Glutamate receptors have been classified into three broad groups determined by their responses to one of three synthetic agonist compounds: *N*-methyl-D-aspartate (NMDA), α-amino3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), and metabotropic receptors (Figure 162-6). NMDA and AMPA receptors are linked to ion channels that can admit calcium or sodium, or both, to the neuronal cytoplasm. Ionic receptors that respond to kainic acid are special types of AMPA receptors. Metabotropic receptors

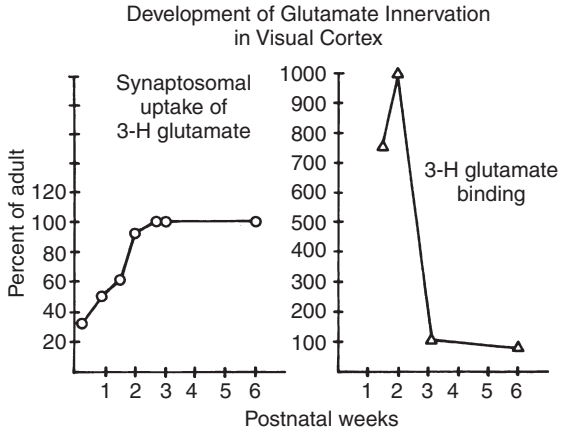

Figure 162-5 *Left,* Ontogeny of sodium-dependent synaptosomal uptake activity for [^{3}H]glutamate in synaptosomes prepared from visual cortex of the rat.[46] *Right,* Ontogeny of sodium-independent binding of [^{3}H]glutamate to visual cortex membranes.[49] Although [^{3}H]glutamate uptake approaches adult levels in the third week, total glutamate binding is 10-fold higher than adult levels. This period includes the critical period for cortical visual plasticity.

stimulated by glutamate regulate levels of the second-messenger molecules cAMP, the polyphosphoinositide IP_3, and diacylglycerol. AMPA receptors mostly mediate the "fast" excitatory activity in the nervous system, whereas the other receptors are reserved for more specialized functions. The NMDA receptor channel (Figure 162-7) opens only when glutamate and glycine stimulate the receptor at the same time that the surrounding membrane potential drops in response to opening of AMPA channels. Under normal circumstances, NMDA receptor–mediated channel opening is reserved for exceptional levels of stimulation mediated by converging stimuli, such as are thought to occur during learning, memory, and other forms of plasticity.

In contrast to the slow rise in biochemical markers for presynaptic, glutamate-containing axon terminals, expression of glutamate receptors and of second-messenger systems stimulated by glutamate is enhanced in the perinatal brain.[4,5,47-52] The ontogenetic profile of glutamate binding in rodent visual cortex has been shown to rise approximately 10-fold higher than the adult level.[49] After day 15 a marked decline in total [^{3}H]glutamate binding corresponds temporally to the pruning of functional synaptic contacts and the time of eye opening and commencement of activity in visual pathways. A similar overshoot in glutamate binding has been observed in developmental studies of the rat hippocampus and human infant temporal cortex.[5,53,54] Receptors that make up the NMDA receptor channel complex are overexpressed in the postnatal period.[53] In addition, molecular genetic studies of NMDA receptor subunits indicate that the types of receptor proteins suppressed in the immature brain create receptors and channels that open more easily than adult channels.[55] This finding corresponds to electrophysiologic studies in the kitten visual system and indicates that stimulation mediated by NMDA receptors is enhanced compared with adult cats.[50]

Binding to non–NMDA-preferring [^{3}H]glutamate sites is also markedly increased in several areas of the immature rodent and human brain in the postnatal period. In the globus pallidus and basal forebrain of the rodent brain, a marked increase in quisqualate-displaceable [^{3}H]glutamate binding in the perinatal period declines to relatively low levels in maturity.[55] Similar areas of transiently increased binding are also seen in areas of human fetal brain. Stimulation of PI turnover, the second-messenger

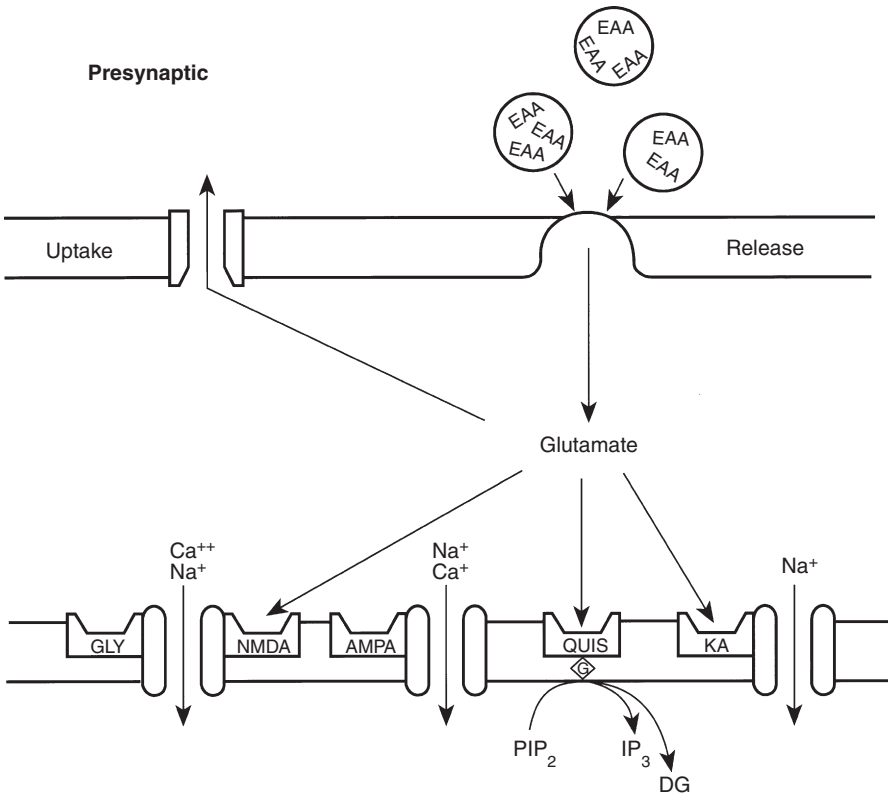

Figure 162-6 Schematic diagram of glutamate synapses. Glutamate released from presynaptic nerve terminals can interact with several postsynaptic receptors for glycine (GLY) and glutamate in the *N*-methyl-D-aspartate (NMDA) conformation linked to a calcium channel. The α-amino3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor is linked to a channel that fluxes sodium and some calcium. Glutamate in the conformation of quisqualate (QUIS) can stimulate hydrolysis of polyphosphoinositides to produce the second messengers inositol-1,4,5 triphosphate (IP_3) and diacylglycerol (DG). The kainate receptor (KA) is a special form of the AMPA receptor. *EAA,* Excitatory amino acid; *PIP_2,* phosphatidylinositol 4,5-bisphosphate.

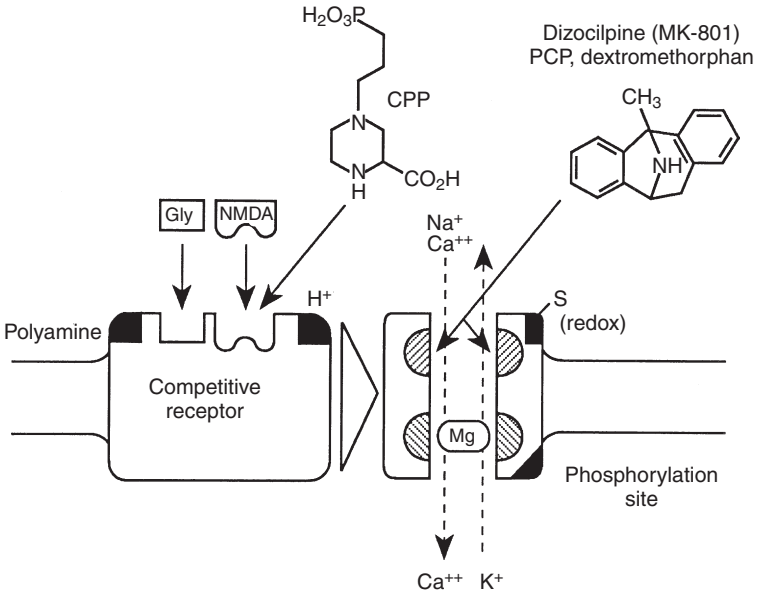

Figure 162-7 The *N*-methyl-D-aspartate (NMDA) receptor channel complex. Competitive binding sites are present for binding glutamate in the NMDA conformation and glycine (Gly). Antagonists are available to block the competitive sites and the channel. The structure of the channel-blocking drug dizocilpine is shown. Modulatory sites are shown for polyamines, hydrogen ions, redox compounds, and phosphorylation. *CPP,* NMDA antagonist; *PCP,* phencyclidine.

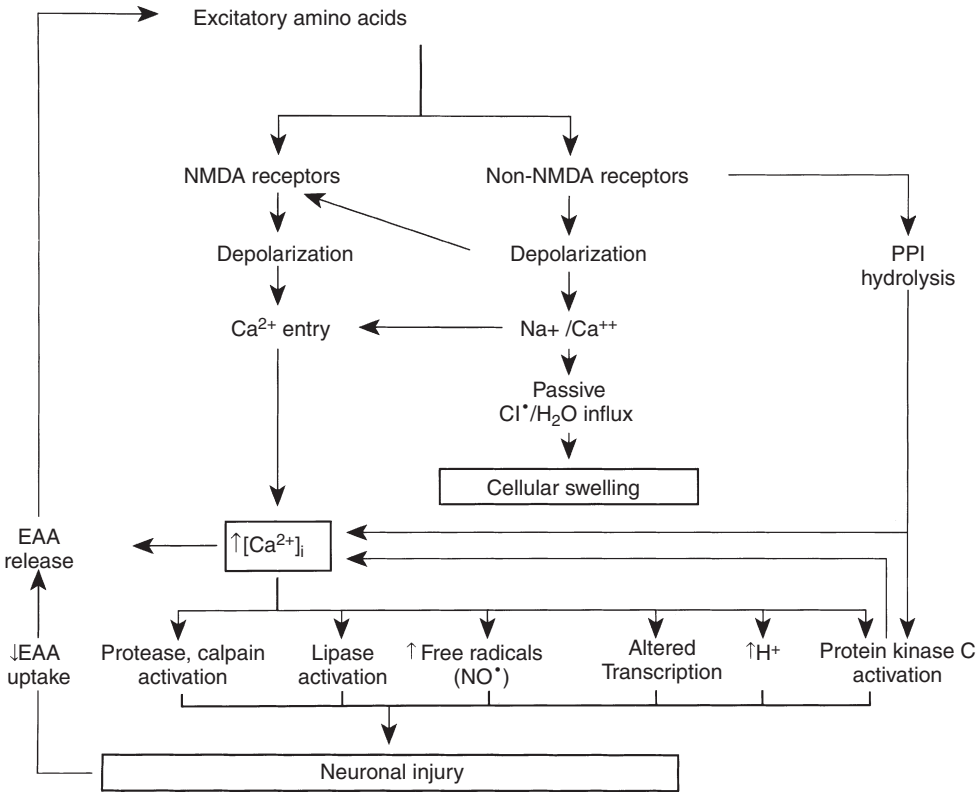

Figure 162-8 Schematic of events thought to be triggered by overstimulation of excitatory amino acid receptors in the brain during hypoxia-ischemia and other disorders. *EAA*, Excitatory amino acid; *NMDA, N*-methyl-D-aspartate; *PPI*, polyphosphoinositides.

system stimulated by a population of quisqualate-preferring glutamate receptors, is also markedly enhanced in hippocampus and striatum in the neonatal period.[4] This response is even larger than the enhanced coupling of PI turnover to muscarinic receptors already described. Immunocytochemical studies of AMPA receptors in brains from premature and term-born human infants demonstrated similar enhanced overexpression in the perinatal period.[56]

The functional enhancement of the effects of the excitatory neurotransmitter systems in developing brain may be related to their role in controlling cortical plasticity.[28] *Plasticity* in this context means the remodeling of neuronal connections, which is directly influenced by excitatory input. For example, in the developing visual system, *cortical columns,* defined physiologically, correspond to alternating inputs of each eye to the visual cortex. The remodeling of *ocular dominance columns* corresponding to one eye can be related to competition among physiologically active axons. Treatment with an NMDA glutamate receptor antagonist can prevent this remodeling in response to amblyopia, a finding suggesting that glutamate receptors mediate activity-dependent plastic changes in developing brain.[57] In this sense, glutamate receptors may mediate a portion of the physiologic activity of sensory stimulation on brain development.[58]

GLUTAMATE-MEDIATED NEUROTOXICITY

Several types of injury in the fetal and neonatal brain are mediated by excessive stimulation of glutamate receptors.[59-61] Hypoxia combined with ischemia impairs the function of reuptake pumps, leading to high levels of glutamate in the synaptic cleft. Resulting overstimulation of glutamate receptors, especially the NMDA receptor, causes influx of calcium and sodium into neurons and other cells in the brain (Figure 162-8). Hypoglycemia has a similar effect.[62] High levels of calcium trigger several intracellular events that can lead to neuronal death.[60] These include activation of nitric oxide synthetase, which catalyzes production of nitric oxide. Nitric oxide, a diffusible free radical compound, can cause death of surrounding neurons. Nitric oxide production stimulated by calcium entering through NMDA channels also appears to be a primary signal for increasing cerebral blood flow associated with increased neuronal activity. Nitric oxide and other free radical compounds can damage mitochondria through *oxidative stress.* Overstimulation of these intracellular events causes cell death by causing necrosis or *apoptosis* (programmed cell death).[60] Glutamate-mediated neurotoxicity seems to be a final common pathway for several forms of injury to the immature brain. Excessive and prolonged blockade of NMDA receptors can also lead to neuronal death, and this may be responsible for the teratogenicity of certain toxins such as ethanol.[63] Excessive stimulation of non-NMDA glutamate receptors is also implicated in damage to immature oligodendroglia-producing periventricular leukomalacia (PVL) in premature infants.[64] The timing of expression of AMPA receptor subunits that facilitate calcium permeability correlates with the vulnerability of oligodendroglia in premature infants, and the vulnerability of neurons in term infants.[56,65]

163 Perinatal Brain Metabolism

Susan J. Vannucci and Robert C. Vannucci

CEREBRAL OXIDATIVE METABOLISM

The oxidative events that operate in the immature brain appear identical to those in the brain of adult animals and humans, although quantitative differences certainly exist. Cellular respiration is that process whereby an organic substrate is consumed to produce chemical energy (stored in high-energy phosphate bonds, represented by ~P), with carbon dioxide and water as the metabolic byproducts. Respiration is a highly efficient process with minimal energy waste. Under physiologic conditions, 1 mole of glucose, the primary cerebral energy fuel, is catabolized in the presence of oxygen to yield 36 moles of adenosine triphosphate (ATP). Other substrates yield proportionately greater or lesser energy, depending on their molecular carbon structure and their point of entry into the oxidative pathway.

The biochemical machinery that comprises the oxidative pathway is divided into three components—specifically, glycolysis, a cytoplasmic process, and the tricarboxylic (Krebs) cycle and the cytochrome system, both of which operate within mitochondria[1-3] (Figure 163-1). Glycolysis proceeds under both aerobic and anaerobic conditions. In the presence of oxygen, glucose is converted to pyruvic acid, which in turn enters the Krebs cycle with little or no conversion to lactic acid. When oxygen is not available, metabolites of the Krebs cycle are depleted, and glycolysis is accelerated, with the formation of lactic acid in an attempt to maintain cerebral energy stores. However, anaerobic glycolysis is an inefficient method to generate energy (2 moles of ATP for each mole of glucose); thus brain function cannot be maintained on this process alone.

Glycolytic control points—that is, those reactions in which the activities of specific enzymes govern the rate of metabolism—include hexokinase, phosphofructokinase (PFK), and possibly pyruvate kinase. Of these enzymes, PFK is predominantly rate-limiting for glycolysis in both adult and immature brain.[4-6] Metabolites known to inhibit PFK activity and thus glycolysis include ATP, citrate, and hydrogen ions, whereas adenosine diphosphate (ADP), adenosine monophosphate (AMP), and inorganic phosphate (P_i) stimulate PFK activity.[2] These glycolytic regulatory mechanisms are of importance in the cell's response to hypoxia, acid-base imbalance, and other metabolic disturbances.

CEREBRAL HIGH-ENERGY METABOLITES

Metabolites known to exist in brain that can store and transfer energy in the form of anhydride phosphate bonds (~P) include ATP, ADP, and phosphocreatine (PCr).[1,2] Among these three, ATP plays the critical role in the coupling of energy supply to energy demand through substrate and oxidative phosphorylation. PCr

acts as a storage metabolite, whereas guanosine triphosphate (GTP) is important in biosynthetic reactions.

Cerebral high-energy metabolites have been measured in perinatal and adult animals by enzymatic, chromatographic, and magnetic resonance (MR) spectroscopic techniques.[4,7-11] Of the nucleotides, ATP predominates and remains stable from term fetal life through adulthood[12,13] (Table 163-1). Lower concentrations have been found in embryonic brain tissue.[11] PCr concentration is lower in the brains of newborn animals than in adults, as is that of total creatine (PCr + creatine), but the PCr-to-creatine ratio changes little with postnatal development.[12,13] The lower PCr-to-creatine ratio in the fetus presumably is the result of a lower brain pH, owing to increased tissue lactate concentrations and hypercapnia (the creatine kinase equilibrium reaction is pH-dependent).[12]

MR spectroscopy is a technique whereby the concentration of an organic compound in tissue can be determined by the realignment of selected molecules using a supraconducting magnet.[14] Almost any substance can be analyzed according to the strength, duration, and other characteristics of the magnetic field. Commonly examined metabolites in brain are the phosphorus-containing compounds, including PCr, ATP, mono- and diphosphate esters (including AMP and ADP, respectively), and P_i.[15-18] Proton MR spectroscopy provides a measurement of numerous hydrogen-containing metabolites; including lactate and creatine.[19-21] Thus MR spectroscopy is capable of ascertaining the energy status of brain tissue in vivo under both physiologic and pathophysiologic conditions, although usually the measurements are semiquantitative in nature (Figure 163-2).

An investigation using MR spectroscopy in premature and full-term newborn infants confirmed evidence from earlier studies in animals indicating that ATP levels remain relatively stable throughout maturation.[17] A more recent study, however, has suggested that ATP concentrations in the human brain almost double between the newborn period and adulthood.[18] As in animals, levels of PCr, P_i, and the phosphodiesters are low at birth, increasing with advancing age. Calculated intracellular pH, as measured from the chemical shift of the P_i peak relative to the PCr peak, is 7.1 in healthy newborn infants. As anticipated, the PCr-to-P_i and the PCr-to-ATP ratios are lower in newborn infants than in adult animals. Although the reported findings in newborn infants are preliminary in nature, the continued use and further sophistication of MR spectroscopy can be expected to contribute substantially to a full understanding of the bioenergetics of the perinatal human brain (see further on).

QUANTITATIVE ASPECTS OF OXIDATIVE METABOLISM

Measurements of cerebral oxygen consumption give a quantitative estimation of energy production by the brain, since oxygen is required for the oxidative phosphorylation of ADP to ATP in electron transport by way of the cytochrome system (see previous discussion). Oxygen consumption measurements often are referred to as the cerebral metabolic rate for oxygen ($CMRo_2$), expressed as mL/100 g/minute. Estimates of the CMR in developing animals initially were obtained in vitro with the use of the Warburg respirometer to measure oxygen consumption in brain slices or homogenates in nutrient media. Himwich and co-workers[22] found that the oxygen consumption (expressed as wet weight of tissue) of minced cerebral tissue with glucose as substrate is 38% lower in 7-day postnatal rats than in adults. Subsequent in vitro studies of oxygen consumption in either the whole brain or cerebral cortex from other species, including humans, indicated that the CMR is low at birth and increases with maturation[22-25] (Figure 163-3). Changes in the rates of glucose utilization during development tend to parallel the increases in oxygen consumption.[24]

Both immature and adult animals exhibit regional differences in brain oxygen consumption in vitro.[24,26,27] Himwich and Fazekas[27] found that although total oxygen consumption in the brain of 1-week postnatal dogs is 83% of the adult level, significant regional differences exist that change with increasing age. The medulla oblongata exhibits the highest rate of consumption in the immediate newborn period but has the lowest rate for all regions studied in the adult brain (see Figure 163-3). By contrast, the oxygen consumption in the cerebral cortex is the lowest for all regions analyzed in the newborn period but doubles within 5 weeks of development. These in vitro findings of regional

differences in brain metabolism between young and adult animals, including humans, have been substantiated by more recently developed in vivo techniques to measure metabolism (see further on).

Oxygen consumption can be calculated in vivo from the Fick principle by measuring cerebral blood flow (CBF) and the arteriovenous difference for oxygen across the brain:

$$CMRo_2 = CBF(A-Vo_2)$$

With use of this technique, oxygen consumption has been determined in immature animals of several species, including humans.[28-38] As shown in Table 163-2, notable species differences exist for the rates of oxygen consumption by brain, which reflect the age and functional immaturity of the animal at the time of the measurement as well as species variations in the brain's intrinsic metabolic requirements. Specifically, $CMRo_2$ is lower in perinatal animals than in adults of the same species, and the more immature the animal at birth, the lower the rate of oxygen consumption. This assumption is supported by measurements in newborn dogs, which are functionally immature at birth, with values for both CBF and $CMRo_2$ that are 40% of respective values in adult dogs[32,33] (Table 163-3). By contrast, the newborn lamb is relatively mature at birth and already exhibits a $CMRo_2$ that is equal to or even greater than that in adult sheep.

Oxygen consumption of the brain also has been determined in humans, including newborn infants. The $CMRo_2$ in young, healthy adults is 3.3 mL/100 g/minute.[37] Oxygen consumption in unanesthetized healthy children aged 3 to 10 years actually is higher by 23% than it is in adults; Kennedy and Sokoloff[39] reported a value of 5.2 mL/100 g/minute. Settergren and colleagues[38] measured $CMRo_2$ in children aged 11 days to 15 years who were anesthetized with nitrous oxide. The mean value for $CMRo_2$ was 3.2 for the entire group, and no age-related differences could be ascertained. Garfunkel and co-workers[36] found $CMRo_2$ values of 1.1 to 2.1 mL/100 g/minute in three newborn infants anesthetized with barbiturate. These low values may not apply to healthy, awake infants, however, because barbiturates are known to depress the $CMRo_2$,[40] and the subjects had severe central nervous system anomalies.

With the use of positron emission tomography (PET), the cerebral metabolic rate for oxygen as well as cerebral glucose utilization (see further on) can be ascertained in human subjects. PET is based on computed tomography (CT) except that the source of radiation for external detection is transmitted from within the brain outward, rather than passed through the brain as x-rays. In PET, a positron-emitting, rapid-decay isotope, prepared by a cyclotron, is administered to the subject. The substance circulates to the brain, where it is metabolized, during which its positrons combine with electrons to form γ-rays. The γ-rays penetrate the brain, skull, and scalp and are recorded externally on a circular array of scintillation detectors. A computer mathematically reconstructs the spatial distribution of the radioactivity within the brain, which either is quantified or is displayed on a cathode ray screen. Thus PET offers a noninvasive regional assessment not only of $CMRo_2$ but also of many other biologic processes.

Using PET with ^{15}O-labeled water as the positron-emitting isotope, Altman and colleagues[41] measured $CMRo_2$ in 11 newborn infants of gestational ages ranging from 26 to 40 weeks. $CMRo_2$ was low in all of the infants and was beyond the lower range of detection in two. In those infants in whom radioactivity was detectable, $CMRo_2$ ranged from 0.2 to 1.3 mL/100 g/minute, well below the measured value for human adults of 3.3 mL/100 g/minute. The findings indicate that as discussed earlier for perinatal animals, cerebral oxidative metabolism, especially in small premature infants, is low, reflecting the functional immaturity of the brain (as also suggested by the work of Yoxall and Weindling[42]). A less likely proposal, offered by Altman's group,[41] is that the energy requirements of the fetal and prematurely newborn brain are met by nonoxidative metabolism, that is, anaerobic glycolysis (but see further on).

GLYCOLYSIS

As mentioned previously, rates of glycolysis or the glycolytic flux is controlled by specific, rate-limiting enzymes that are either inhibited or activated by changes in the biochemical milieu of the cytoplasm. Thus aerobic glycolysis is stimulated by those

stresses that increase the energy demands of the tissue—specifically, stimulant drugs and hormones, hyperthermia, and seizures. Anaerobic glycolysis is stimulated by hypoxia or cerebral ischemia, or both, in an attempt to maintain optimal cellular energy balance despite the oxygen debt. Glycolysis is inhibited by sedative and anesthetic agents, hypothermia, and acidosis, all of which are associated with reduced energy needs of the tissue. Glycolysis can never cease completely, because at least some energy is always required to maintain ionic gradients across cellular and subcellular membranes, without which cellular integrity is compromised.

The extent to which glycolysis and thus oxidative metabolism can be turned on or off is not entirely known. In adult animals, deep barbiturate anesthesia sufficient to produce an isoelectric signal on the electroencephalogram reduces metabolism by no more than 50%,[43] suggesting that up to 50% of cellular energy production is required for maintenance of biochemical and morphologic integrity, whereas the remainder is devoted to the generation of action potentials and to biosynthetic processes. The extent to which glycolysis can be stimulated (glycolytic capacity) also is conjectural, although studies in experimental animals suggest that glycolytic flux can be accelerated up to 8- to 10-fold during extreme metabolic stress, that is, seizures or hypoxia-ischemia.[2] In this regard, both basal glycolytic flux and glycolytic capacity are lower in immature animals than in their adult counterparts, in keeping with intrinsically lower rates of oxygen consumption and hence metabolic demands. For example, the calculated rate of cerebral glycolysis of the perinatal rat is approximately 10 μmol of glucose/100 g/minute,[44] which is one tenth of the calculated rate for adult rat cerebral cortex.[45] During total cerebral ischemia, produced by decapitation, glycolytic flux in newborn rat brain increases five-fold, compared with an eight-fold increase in adult rat brain.[44,45] Thus the ability of perinatal animals to survive a prolonged period of hypoxia or anoxia compared with that of adults[46] cannot be explained by a heightened capacity of the immature brain to generate energy equivalents through anaerobic glycolysis. Rather, lower cerebral energy demands and hence metabolic requirements underscore the perinatal animal's resistance to hypoxia-ischemia.[9,44]

MITOCHONDRIAL DEVELOPMENT

Because the mitochondria produce the vast bulk of energy utilized for cellular needs, these "powerhouses" have been investigated during maturation of the brain. Investigators have demonstrated a relative deficiency in the oxidative phosphorylating capacity of mitochondria that characterizes the immature brain.[47] Simply put, the immature brain appears to be less able to synthesize ATP per molecule of oxygen consumed. This coupling of ATP to oxygen, expressed in terms of the ATP/O or P/O ratio, is 3 for the oxidized form of nicotinamide-adenine dinucleotide (NAD^+)-linked cytochrome components in adult rat brain.[48] Holtzman and Moore[49] have measured P/O ratios in several regions of rat brain during maturation. Ratios for 1.5 for NAD^+-linked substrates were found in animals 1 to 11 days of postnatal age. Thereafter, ratios increased to 2.4 in pons-medulla and 2.8 in cerebral cortex. The data indicate that the brain cell's increasing efficiency for oxidative phosphorylation (improved coupling) reflects both an increase in the number of mitochondria and an inherent change in their function.

The functional advantage of these mitochondrial changes appears to lie in the pattern of growth of the central nervous system. A striking increase in mitochondrial cell number accompanies neuronal and glial cell hypertrophy secondary to axonal and dendritic expansion.[50] Furthermore, as individual cells enlarge, the cell surface-to-volume ratio increases—a circumstance that raises the energy required to maintain ionic gradients across the membrane and to propagate action potentials.[51]

CEREBRAL ENERGY UTILIZATION

Energy utilization by the brain can be inferred from measurements of oxygen or substrate consumption, because under steady-state conditions, energy demand and supply are equivalent. Cerebral energy utilization also can be measured directly in the experimental animal by a novel decapitation technique.[4] Lowry and co-workers[4] devised this technique to determine the rate of energy use in brain during the total cerebral ischemia that follows decapitation. The investigators assumed that because the isolated head is a closed metabolic compartment (no inflow or outflow), rates of depletion of potential (glucose + glycogen) and endogenous (ATP + ADP + PCr) high-energy stores would be a direct measure of cerebral energy utilization occurring before decapitation. Using this method, various investigators have shown that the calculated rate of cerebral energy use in perinatal animals, like the $CMRo_2$, is substantially less than in adults.[4,9,44] For example, the energy use rate of the 1-day postnatal rat is 1.3 mmol of ~P/kg/minute,[44] 20-fold less than the calculated rate of 27 mmol of ~P/kg/minute for the adult rat brain.[45]

$CMRo_2$ can be calculated from the rate of cerebral energy use if the ADP/O or P/O ratio is known. As already mentioned, P/O ratios for immature rat brain are 1.5 for NAD^+ and 1.2 for the oxidized form of flavin-adenine dinucleotide (FAD^+)-linked substrates.[49] A source of ATP other than that derived from oxidative phosphorylation of ADP is substrate phosphorylation, which occurs twice in glycolysis and once in the Krebs cycle. Substrate phosphorylation yields 6 moles of ATP for every mole of glucose consumed; 2 moles are required for the initial phosphorylation of glucose and fructose-6-phosphate in glycolysis. Thus, for every mole of glucose consumed, 4 moles of ATP are ultimately generated by a source other than oxidative phosphorylation; this amounts to 20% of the total energy production. Assuming a yield of 3 moles of ~P/mole of oxygen reduced (P/O ratio of 1.5), and taking into account the ATP formed by both oxidative and substrate phosphorylation, the rate of cerebral energy utilization for newborn rats translates to a $CMRo_2$ of $[1.3 - (1.3 \times 0.2)]/3 = 0.35$ mmol/kg/minute, or 0.78 mL/100 g/minute. This value is far less than in adult rat brain, for which the measured $CMRo_2$ value is 5.4 mL/100 g/minute[52]—nearly six-fold higher. The fetal rat at term exhibits a rate of cerebral energy utilization comparable with that in the newborn rat pup.[44]

The low cerebral energy requirements of most mammals at birth reflect an immaturity of the central nervous system at this stage of development. It has been suggested that cerebral energy demands in the fetal brain are even less well developed than in the newborn brain[53] and that such demands in embryonic life are met predominantly or entirely by anaerobic glycolysis, with only a small contribution from oxidative metabolism.[23,50] Using the aforementioned Lowry technique to evaluate cerebral energy utilization, Gonya-Magee and Vannucci[11] measured rates of cerebral metabolism in chick embryos at 9, 14, 16, and 19 days of incubation and in newly hatched peeps (Table 163-4). Calculated cerebral metabolic rates were not different in the 9-, 14-, and 16-day-old embryos but doubled between 16 and 19 days and doubled again between 19 days and hatching. The extent to which total cerebral energy utilization could be derived from anaerobic glycolysis (Δ lactate/Δ ~P) increased from a low at day 9 (0.29) to a maximum at day 16 (0.78). The findings in this investigation suggest that cerebral oxidative metabolism becomes progressively lower with decreasing embryonic age, but that a nadir is reached below which metabolism can no longer support cerebral function and growth. Furthermore, the data indicate that despite the low metabolic activity of the embryonic brain, at no time during development is anaerobic glycolysis capable of entirely supporting the energy needs of the tissue.

CEREBRAL GLUCOSE UTILIZATION

In all animal species studied, including humans, glucose is the predominant or exclusive organic fuel for cerebral metabolism under physiologic conditions. This dictum also appears to hold true for the fetus and developing postnatal animal. As with $CMRO_2$, glucose consumption in brain can be measured from a knowledge of CBF and the arteriovenous difference for glucose:

$$CMR_{glucose} = CBF\,(A - V_{glucose})$$

When $CMR_{glucose}$ (or other organic substrate) and $CMRO_2$ are measured simultaneously, the substrate-oxygen quotient, which expresses the relative contribution of the substrate to overall oxidative metabolism, can be ascertained:

$$\frac{\text{Substrate}}{O_2} = \frac{CMR_{substrate}\,(\text{number of C atoms}) \times 100}{CMRO_2}$$

Using these measurements, cerebral glucose utilization has been determined in several perinatal animal species as well as in postnatal human infants[35,38,54-56] (Table 163-5). As in adult humans,[57,58] glucose serves as the major organic substrate to support cerebral metabolism in all species studied. Furthermore, the vast bulk of glucose consumed is aerobically degraded to carbon dioxide and water or is used in biosynthesis, with little or no production of lactic acid (anaerobic glycolysis). Thus, at least under physiologic conditions, glucose is efficiently utilized to produce the maximal amount of chemical energy possible.

In the past, only global estimates of glucose consumption in brain could be ascertained, using the method described earlier. Thanks to the pioneering work of Sokoloff and colleagues,[59,60] regional cerebral glucose utilization (rCGU) now can be determined in both experimental animals and humans. These investigators[60] used radioactive 2-[^{14}C]-deoxyglucose (2-DG) to measure CGU in 30 or more component structures of adult rat brain. The rationale for the use of 2-DG rather than [^{14}C]-glucose is that the radioactive analogue of native glucose is lost from the brain as carbon dioxide and water during the course of an experiment, so calculated CGU would underestimate the true CGU value. Deoxyglucose, like glucose, is taken up by brain and phosphorylated by hexokinase but, unlike glucose, is unable to be metabolized further along the glycolytic pathway. The theoretical basis for this technique and its successful application in the experimental animal together support its usefulness for measuring rCGU in humans by means of PET. Furthermore, because glucose is the predominant cerebral energy fuel, and glucose utilization is stoichiometrically related to oxygen consumption (see previous discussion), the measurement of rCGU is considered to reflect local rates of cerebral energy utilization and intrinsic functional activity.[59]

Using the 2-DG technique, rCGU has been investigated in fetal sheep and in newborn rats, lambs, dogs, and monkeys.[61-65] The studies confirm early in vitro experiments (see preceding discussion) that CGU in the perinatal animal is high in brain stem gray matter structures, declining in a caudal-to-rostral progression through the neuraxis to the cerebral cortex[62,63] (Table 163-6; Figure 163-4). As in adults, CGU is lowest in subcortical and other white matter structures. Duffy and co-workers[62] suggest that the hierarchy of rates of glucose consumption reflects the functional immaturity of the perinatal animal, with its limited, albeit present, sensory and motor capabilities but with little or no memory or learning abilities at this early stage of development.

Using PET with [^{18}F]fluoro-2-deoxyglucose as the positron-emitting isotope, Chugani and Phelps[66,67] measured rCGU in humans from full-term birth through adulthood (Figure 163-5). In infants 5 weeks of age and younger, glucose utilization was highest in the sensorimotor cerebral cortex, thalamus, midbrain-brainstem, and the cerebellar vermis—a distribution of glucose consumption similar to that described in term fetal sheep and in newborn dogs and monkeys (see Figure 163-4).[61-63] By the age of 3 months, glucose metabolic activity in the infants had increased in the parietal, temporal, and occipital cortices and in the basal ganglia, with subsequent increases in frontal and various association regions of cerebral cortex occurring by 8 months. Little further change in rCGU was observed between 8 and 18 months of postnatal age. The investigators emphasized that the maturational increases in rCGU, measured with PET, are in agreement with the

behavioral, neurophysiologic, and anatomic changes known to occur during infant development.

Other investigators have used PET to measure global and regional rCGU in premature newborn infants.[68,69] Gestational ages ranged from 25 to 37 weeks. Whole brain CGU was less than that in full-term infants, when the two age groups were compared.[68] As in full-term infants, glucose utilization was higher in brain stem and cerebellar structures compared with cerebral cortex. The lower rCGU in premature infants correlates with the low $CMRo_2$ observed at similar gestational ages.[41]

RELATIONSHIP BETWEEN CEREBRAL BLOOD FLOW AND GLUCOSE UTILIZATION (FLOW-METABOLISM COUPLE)

With the availability of methods to measure CBF and metabolism in animals and humans, investigators were quick to recognize a quantitative relationship between these two important biologic processes in brain. Further investigation revealed that under physiologic conditions, CBF was essentially controlled by intrinsic mechanisms that reflect local rates of metabolism, that is, the extent of tissue carbon dioxide and hydrogen ion accumulation. Thus it is not surprising that CBF and metabolism are tightly linked or coupled. Specifically, when the rate of oxidative metabolism in brain is high, so is CBF, and vice versa. Metabolic diseases are capable of altering this critical relationship, during which neurologic dysfunction occurs and, if the disturbance is severe enough, brain damage supervenes.

The brain flow-metabolism couple appears to be a universal phenomenon that encompasses all animal species of all ages and under all physiologic conditions* (Figure 163-6). In those animals in which CBF and $CMRo_2$ have been measured simultaneously, the relationship has been apparent regardless of age, although differences in the intrinsic rates of metabolism do exist among species. A regional coupling of CBF to metabolism also exists in both adult and immature animals[60,62-64] when rCBF, determined with an inert, radioactive tracer, is compared with rCGU[64] (Figure 163-7). A visual comparison of the published figures depicting rCBF and rCGU, using PET, also suggests the existence of a regional CBF-metabolism couple in the newborn human infant.[66,67,73] Occasional exceptions to the rule have been observed for individual structures (e.g., cerebellum), which may reflect local differences in the contribution of glucose versus alternate substrates to overall metabolism or to the use of glucose in biosynthetic processes (see further on).

ALTERNATIVE SUBSTRATES FOR OXIDATIVE METABOLISM

As mentioned previously, glucose is the predominant or exclusive cerebral energy fuel at all ages under physiologic conditions. In certain clinical situations, however, glucose availability to the brain is limited by hypoglycemia. In such circumstances, the perinatal brain is capable of incorporating and metabolizing substitute organic substrates, the most notable of which are lactic acid and the ketone bodies, β-hydroxybutyrate and acetoacetate. Indeed, the immature brain appears to be capable of consuming a large number of organic metabolites, including free fatty acids and amino acids as well, so long as they are available in reasonable concentrations in blood and the appropriate enzymes for their degradation are present in brain.

The most widely studied substitute fuels for metabolism in perinatal brain have been the ketone bodies and lactic acid. Because all developing mammals are nourished with milk with a high fat content, these animals readily generate ketone bodies by means of the liver, which in turn appear in substantial concentrations in blood. Thus, during suckling, ketone bodies partially substitute for glucose to sustain cerebral metabolism and can account for up to 20% of total energy production.[74-76] As in adults, nutrient fasting induces endogenous ketone body formation, which contributes significantly to overall cerebral metabolism during starvation-induced hypoglycemia.[77]

Hypoglycemia also is encountered in the immediate newborn period before the initiation of sustained oral or parenteral feeding. During this time, as well as during fetal life, ketone bodies are essentially nonexistent in blood and therefore contribute little

*See references 28, 30-36, 38, 39, 52, 58, 70-72.

to cerebral metabolism.[78,79] By contrast, lactic acid is elevated in late fetal and early postnatal life to the extent that its concentration often exceeds that of glucose.[80-82] Studies in newborn dogs have shown that during hypoglycemia, lactic acid not only is incorporated into the perinatal brain but also is consumed to the extent that the metabolite can support up to 58% of total cerebral oxidative metabolism[55,83] (Figure 163-8). The versatility of the immature brain in its capacity to utilize substitute fuels, sparing glucose, undoubtedly contributes to the resistance of the newborn nervous system to the known deleterious effects of hypoglycemia.

The ability of the immature brain to incorporate and metabolize alternate energy fuels resides, at least in part, in the unique

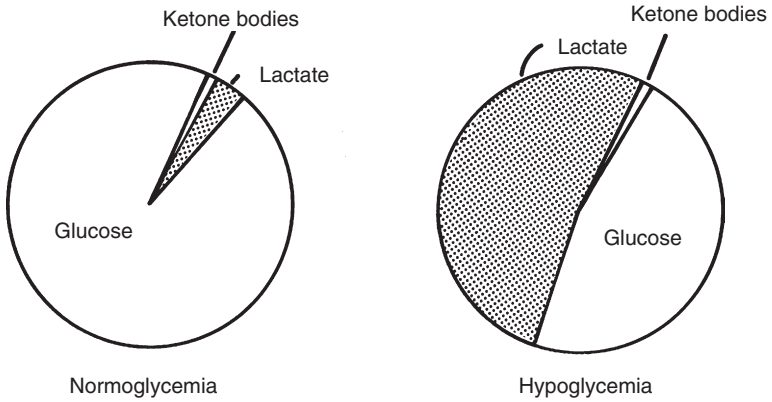

Figure 163-8 Substrate-oxygen quotients as percentage of total cerebral oxidative metabolism in normoglycemic and hypoglycemic newborn dogs. Substrate-oxygen quotients were calculated according to a formula described in the text. *(Data from Hernandez MJ, et al: Cerebral blood flow and metabolism during hypoglycemia in newborn dogs,* J Neurochem *35:622, 1980.)*

characteristics of its blood-brain barrier. All organic metabolites enter the brain from blood predominantly by way of a carrier-mediated transport system. Cremer and co-workers[74,84] first demonstrated the existence of a transport "carrier" for monocarboxylic acids, including ketone bodies and lactate, in the brain of immature rats, the Michaelis constant (K_m) of which is 10 times greater than that demonstrated for adult rat brain. The blood-brain uptake capabilities for β-hydroxybutyrate, acetoacetate, and lactate actually exceed those for glucose at an early postnatal age, facilitated by the high capacity of this transport system. Thus alternative substrates can be readily transported into the perinatal brain to support oxidative metabolism during periods of systemic glucose deficiency.

GLUCOSE AND MONOCARBOXYLIC ACID TRANSPORTERS

Transport of these nutrient substrates from the blood to the brain, as well as into neurons and glia, occurs by facilitated diffusion mediated by specific integral membrane transport proteins. These integral membrane proteins comprise two distinct families: the facilitative glucose transporter proteins (GLUTs) and the monocarboxylic acid transporter proteins (MCTs), the latter of which mediate proton-coupled co-transport. GLUT1 was cloned in 1985, and today, this and other similar proteins with distinct tissue distribution and kinetic characteristics—GLUT1 to GLUT12 and HMIT, the myoinositol transporter—are collectively known as the *SLC2 family* of proteins.[85] Although all 13 of these proteins have been detected in mammalian brain, GLUT1 and GLUT3 are the isoforms primarily involved in cerebral glucose uptake and utilization.[86] The initial transport of glucose across the endothelial cells of the blood-brain barrier is mediated by a heavily glycosylated form of GLUT1, 55-kDa GLUT1; a less glycosylated product of the same gene, 45-kDa GLUT1, is highly concentrated in choroid plexus and the ependymal lining of the ventricles and also in glial cells. GLUT3 is the neuronal glucose transporter.[86] The 14 MCT proteins were cloned a decade later and make up the *SLC16 family*; of these, only MCT1 to MCT4 have been definitively shown to transport metabolically relevant monocarboxylic acids.[87] MCT1, the most widely distributed, is detected in cerebral microvessels and appears to be expressed by all neural cells, whereas MCT2 expression is more restricted and primarily neuronal.

Both the GLUTs and the MCTs are developmentally regulated in brain.[88] GLUT concentrations are quite low in immature rat brain,[89] in keeping with the well-described low rates of cerebral glucose transport into immature rat brain,[84] and increase sharply after the second postnatal week (Figure 163-9). The observation

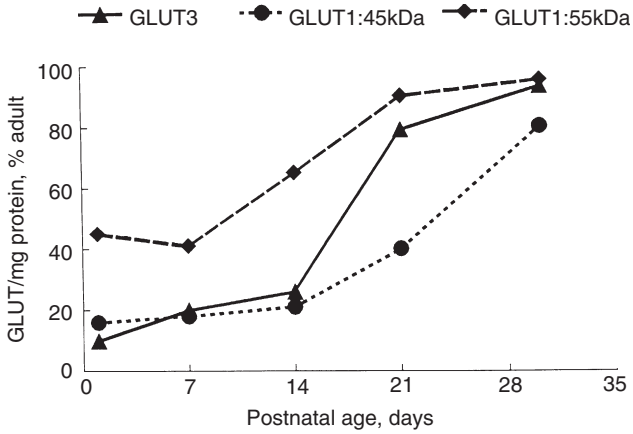

Figure 163-9 Brain glucose transporter proteins (GLUTs) during development in the immature rat. Isolated microvessels and cortical membranes were prepared from postnatal rats between birth and 30 days of age and adults. GLUT1 and GLUT3 membrane protein content was determined by Western blot analysis with specific antipeptide antisera for GLUT1 and GLUT3 and ^{125}I-protein A. Representative autoradiograms are depicted in the *upper part* of the figure. *S,* Brain microsomal membrane "standard" included in all blots for purposes of interblot comparisons and quantification. *Lower part* of the figure represents the quantification of values for four to six animals in each age group, expressed as a percent of the adult value.

of greatly reduced brain glucose concentrations during hypoxia-ischemia (see further on) provides evidence that GLUT concentration is limiting to cerebral glucose utilization at this age. Because the delivery of glucose from the blood into the brain is a function of both the substrate concentration in the blood and the transporter concentration, an increase in substrate concentration produced by glucose supplementation maintains a near-normal or even elevated brain glucose level. In addition, although calculated intracellular glucose concentrations in immature rats become very low during hypoxia-ischemia, the level of glucose in the cerebrospinal fluid—as a reflection of the concentration in the brain extracellular compartments—does not decrease.[90] Accordingly, it appears that an even greater limitation may be imposed at the level of the neurons and glial cells than at the blood-brain barrier.

The developmental expression of the MCTs shows the reverse pattern. Rodent milk is very high in fat, and suckling pups are naturally ketotic, with circulating levels of β-hydroxybutyrate

approaching the millimolar range by the second postnatal week.[88,91] At this time, cerebral ketone body utilization also is maximal,[91] and this is further reflected in the level and extent of expression of MCT1, especially in the cerebral microvessels.[88] Thus the high levels of ketone body transporter in the blood-brain barrier, as well as in neurons and glial cells, not only facilitate ketone body transport into the brain but also can aid in the uptake and clearance of lactic acid. With cerebral maturation and the switch to reliance on glucose as the primary oxidative fuel of the brain, blood-brain barrier MCT1 falls to adult levels coincident with the rise in blood-brain barrier GLUT1 and the nonvascular glucose transporter proteins, especially neuronal GLUT3.[88] Some years ago, Magistretti and colleagues proposed that it is the astrocytes that play the primary role in cerebral glucose utilization by first metabolizing glucose to lactate, which subsequently is transported to the neuron to be oxidized to fuel neuronal energetics.[92] Although this theory, referred to as the *astrocytes-neuron lactate shuttle hypothesis* (ANLSH),[92] gained wide favor for several years, a more recent modeling of cerebral nutrient uptake and utilization that incorporated the concentrations and kinetic parameters of these transport proteins has demonstrated that the neurons are indeed the primary consumers of glucose, and actually produce lactate on activation.[93] Thus, although both lactate and ketone bodies are important fuels for neuronal metabolism in the fetal brain, cerebral development involves the transition to glucose utilization.

CEREBRAL ENERGY METABOLISM IN HYPOXIA-ISCHEMIA

Hypoxia-acidosis or asphyxia is a frequent cause of acute brain damage in human fetuses and newborn infants and contributes substantially to the chronic neurologic sequelae of cerebral palsy with or without associated mental retardation, epilepsy, or learning disability. Experimental and clinical evidence indicates that hypoxia alone does not produce brain damage but that superimposed cerebral ischemia is a necessary prerequisite for tissue injury to occur. Cerebral ischemia in the setting of asphyxia is a consequence of hypoxic-acidotic cardiovascular depression with secondary systemic hypotension. Cerebral ischemia also may be secondary to occlusive vascular disease of the brain (reviewed by Vannucci RC[94,95]).

Brain hypoxia denotes a cellular oxygen debt, owing to inadequate oxygen delivery (CBF × oxygen saturation [Sa_{O_2}]) by nutrient arteries. When the tissue (mitochondria) partial pressure of oxygen falls below a critical value (<0.1 mm Hg), the cytochrome system of mitochondria becomes unsaturated, and reducing equivalents (NADH, FADH) begin to accumulate.[96,97] ATP production by oxidative phosphorylation is curtailed, with concurrent increases in cellular ADP and AMP, because cytosolic ATP hydrolysis continues to drive endergonic reactions.[2] The elevations in ADP and AMP serve to stimulate glycolysis, through activation of its key regulatory enzyme, PFK (see earlier discussion). Unlike oxidative phosphorylation, which produces 36 moles of ATP for every mole of glucose consumed, glycolysis is an inefficient method to generate ATP by substrate phosphorylation, with net production of only 2 moles of ATP for each mole of glucose consumed. To produce the amount of ATP equivalent to that generated by oxidative phosphorylation, glycolysis would need to increase to a rate of 18 times its basal flux. In reality, glycolysis, even when maximally stimulated, is capable of increasing only four- to five-fold, owing in part to the concurrent accumulation of H^+ ions derived from the accumulated NADH, which ions serve to inhibit PFK activity.[4,44] In the immature rat, hypoxia-ischemia leads to a 135% stimulation of glycolytic flux, which equates to 62% of its maximal capacity.[98] Thus glycolysis can never completely substitute for mitochondrial oxidation, although its stimulation can supplement oxidative phosphorylation under conditions of a partial oxygen debt.

Cerebral hypoxia-ischemia severe enough to produce irreversible tissue injury is always associated with major perturbations in the energy status of the brain.[2,99,100] Alterations occur not only in the adenine nucleotides but also in PCr, in which changes actually precede those in ATP, ADP, and AMP. These perturbations have been well characterized in an experimental model of perinatal hypoxic-ischemic brain damage.[101] During hypoxia-ischemia, changes in the tissue concentrations of the high-energy phosphate reserves occur early during the course of the metabolic insult and persist well into the recovery period[102-104] (Figure 163-10). As expected, greater depletions in PCr relative to ATP occur as the cell attempts to maintain optimal levels of ATP through the CK equilibrium reaction driven also by the accumulation of ADP and H^+ ions. With the eventual decline in tissue ATP, ADP and AMP accumulate in proportion to the loss of ATP. Ultimately, the total adenine nucleotide pool (ATP + ADP + AMP) also decreases as AMP is catabolized slowly to adenosine and further breakdown products. The concentrations of ATP and the total adenylate compounds never completely recover after resuscitation, and their persisting partial depletions reflect the presence and severity of tissue destruction[102-104] (see Figure 163-10).

Of necessity, the loss of cellular ATP during hypoxia-ischemia severely compromises those metabolic processes that require energy for their completion. Thus ATP-dependent Na^+ extrusion (efflux) through the plasma membrane in exchange for K^+ is curtailed with a resultant intracellular accumulation of Na^+ and Cl^- as well as water (cytotoxic edema). Equally vital to cellular function is the prompt restoration of high-energy phosphate reserves during and after resuscitation. Without regeneration of ATP, endergonic reactions cannot resume, especially those involving the critical event of ion pumping at plasma and subcellular membranes. Intracellular Na^+ and Cl^- ions and water will continue to accumulate, and electrochemical gradients cannot be reestablished. Just how long the cell can survive under these conditions is not known, but other factors are called into play that prominently influence ultimate cellular integrity; including the secretion of potentially toxic excitatory amino acids into the synaptic cleft, the intracellular accumulation of free calcium, the intracellular production of nitric oxide, and the production of oxygen free radicals, the last especially during the recovery period (Figure 163-11).

The mechanisms by which ATP disruption persists into the recovery period relate to lingering alterations in the function of mitochondria. In this regard, the classic histopathologic studies of Brown and Brierley[105,106] indicate that the earliest morphologic alteration of the neuron arising from hypoxia-ischemia is a dilation of mitochondria with an accompanying separation of their cristae. Biochemical studies support the morphologic alterations to the extent that after hypoxia-ischemia in vitro, analysis of mitochondria reveals a disturbance in substrate oxidation, suggesting an "uncoupling" of oxidative phosphorylation.[107-109] An in vivo investigation in immature rats recovering from cerebral hypoxia-ischemia also suggests the occurrence of an uncoupling of oxidative phosphorylation before or concurrent with the development of morphologically apparent tissue injury.[110] It is assumed that reducing equivalents are oxidized in the presence of oxygen but ATP is not formed from the energy generated. Such energy is consumed internally (not transferred to the cytosol) or is lost as heat. That oxidative phosphorylation is compromised after hypoxia-ischemia is confirmed also by studies showing that the brain can be well oxygenated concurrent with a persistent depletion in ATP.[103,111-113]

The experimental data regarding the persistent depletion of cerebral high-energy phosphate reserves during recovery from hypoxia-ischemia have relevance to the clinical situation in the asphyxiated newborn human infant. Using MR spectroscopy (as described previously), investigators have shown a correlation between lingering alterations between the ratio of PCr to P_i or of ATP to P_i and ultimate brain damage as measured by

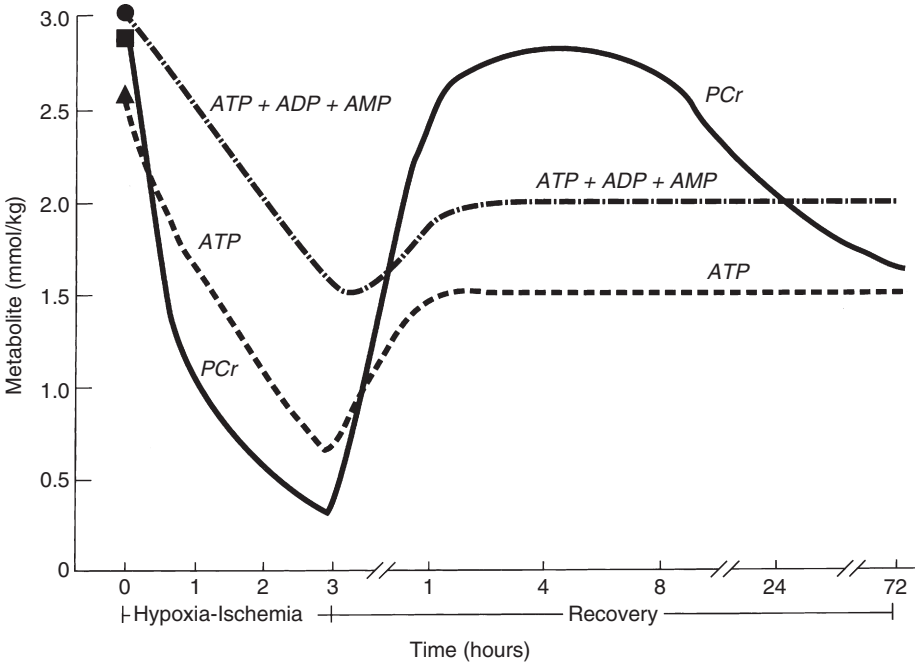

Figure 163-10 Changes in cerebral high-energy phosphate reserves during and after hypoxia-ischemia in the immature rat. Seven-day postnatal rats were subjected to unilateral common carotid artery ligation followed by exposure to systemic hypoxia with 8% oxygen at 37° C. *Symbols* represent means for ATP, PCr, and total adenine nucleotides (ATP + ADP + AMP). *ADP,* Adenosine diphosphate; *AMP,* adenosine monophosphate; *ATP,* adenosine triphosphate; *PCr,* phosphocreatine. *(Data from Rice JE 3rd, et al: The influence of immaturity on hypoxic-ischemic brain damage in the rat,* Ann Neurol *9:131, 1981; Palmer C, et al: Carbohydrate and energy metabolism during the evolution of hypoxic-ischemic brain damage in the immature rat,* J Cereb Blood Flow Metab *10:227, 1990; and Welsh FA, et al: Columnar alterations of NADH fluorescence during hypoxia-ischemia in immature rat brain,* J Cereb Blood Flow Metab *2:221, 1982.)*

neurodevelopmental status or neurologic assessment.[16,114,115] In this regard, PCr/P_i ratios can be normal in the human infant even when brain damage is present,[16,115] as has also been shown in experimental animals.[102,104,116]

A secondary depletion in brain PCr occurs at 18 to 24 hours of recovery from hypoxia-ischemia and beyond in immature experimental animals (see Figure 163-10),[102-104,117,118] which mimics the late changes in PCr/P_i observed in newborn human infants suffering asphyxial encephalopathy.[16,114,115] In newborn pig experiments, PCr/Pi ratios are depressed initially by hypoxia-ischemia only to normalize in the early recovery interval.[117,118] Thereafter, a secondary decrease in the ratio occurs, as indicated by measurements at 24 hours and again at 48 hours of recovery. From the human and animal studies, it has been proposed that the secondary failure in cerebral energy status after hypoxia-ischemia is a significant contributor to the ultimate brain damage and neurologic compromise.

However, the secondary decline in PCr does not necessarily denote a delayed energy failure of the brain but rather may reflect a loss of total creatine from the tissue or its conversion to creatinine. The late reduction in PCr, be it in an experimental animal or a human infant, appears to occur as a mass action effect of the CK equilibrium reaction.[104] Furthermore, the loss of creatine from the brain or its conversion to creatinine, which also would be lost, should result in detectable or increased concentrations of one or both metabolites in cerebrospinal fluid (CSF). The presence of these compounds in CSF may potentially serve as a biochemical marker of previous cerebral hypoxia-ischemia in a manner similar to and perhaps more sensitive than the adenine nucleotide derivatives xanthine and hypoxanthine.[119]

To clarify the issue of whether or not the secondary energy failure causes or contributes to the ultimate brain damage, Vannucci and associates[120] subjected immature rats to hypoxia-ischemia of the brain. During recovery, the brains were individually processed for histopathologic analysis and measurements of high energy reserves and the neuronal protein markers MAP-2 and SNAP-25. PCr and ATP, initially depleted during hypoxia-ischemia, both were partially restored during the first 18 hours of recovery, with secondary depletions at 24 and 48 hours (see earlier). During the initial recovery phase (6 to 18 hours), a significant correlation was observed between PCr and the severity of brain damage determined on histopathologic analysis, but not for ATP. During the late recovery phase (24 to 48 hours), a highly significant correlation was found between all measured energy metabolites and the severity of brain damage. Significant correlation also was observed between the neuronal markers MAP-2 and SNAP-25 and PCr, as well as the sum of PCr and creatine at both phases of recovery. The close correspondence of PCr with histologic brain damage and the loss of the neuronal markers during both the early and late recovery intervals suggest evolving cellular destruction as the primary event, which precedes and lead to the secondary energy failure.

CEREBRAL ACIDOSIS IN HYPOXIA-ISCHEMIA

Hypoxia-ischemia of a severity sufficient to produce brain damage also is associated with a tissue acidosis, owing to the accumulation of lactic acid.[2,99,100] The intracellular lactacidosis results from a shift in glucose utilization from oxidative metabolism to either partial or total anaerobic glycolysis which occurs during the tissue oxygen debt. Indeed, some investigators have suggested that lactacidosis is a major contributor to hypoxic-ischemic injury in vulnerable regions of the brain and that a minimum concentration of 15 to 20 mmol of lactate/kg of brain

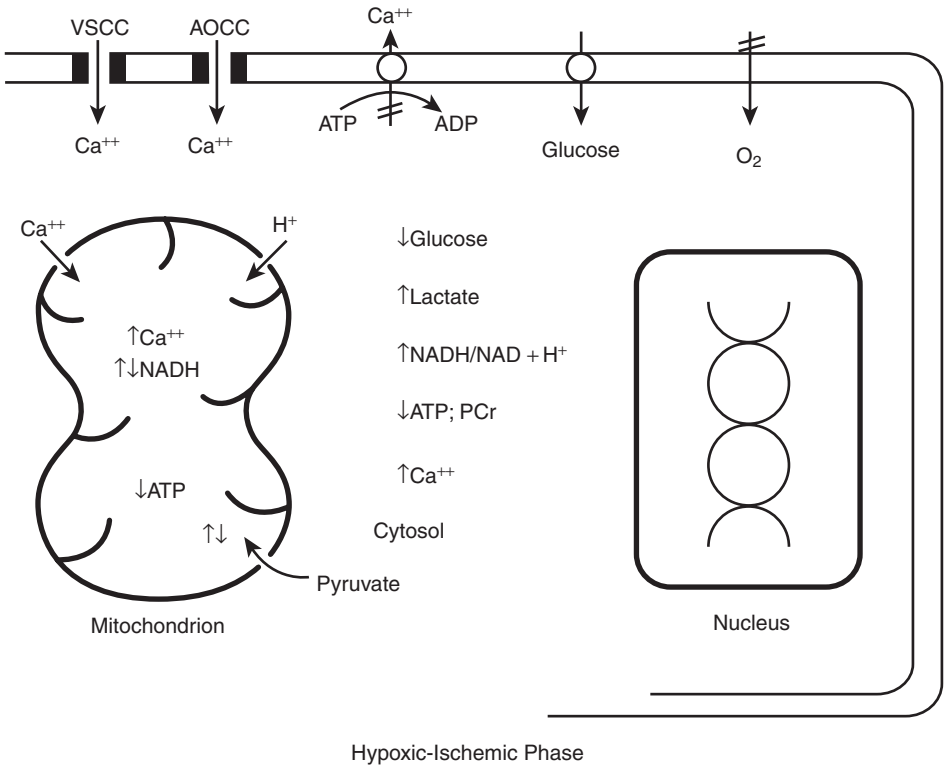

Figure 163-11 Cellular metabolism during cerebral hypoxia-ischemia. During a cellular oxygen debt, anaerobic glycolytic flux is accelerated, resulting in a depletion of intracellular glucose and an accumulation of lactate and H^+ ions (acidosis). The energy generated from anaerobic glycolysis cannot keep pace with energy demand, and ATP and PCr decline in the cytosol and mitochondria. Calcium entry into the cell is accentuated by voltage-sensitive (VSCC) and agonist-operative (AOCC) calcium channels, by which calcium accumulates in the cytosol and mitochondria. These disturbances are only partially reversed during reoxygenation and reperfusion, and continuing metabolic perturbations ultimately result in brain damage. *ATP,* Adenosine triphosphate; *PCr,* phosphocreatine.

tissue is required for irreversible damage to occur.[121-123] Furthermore, it has been shown that the injection of lactic acid into the cerebral cortex of adult rats leads to histopathologic alterations resembling those characteristic of ischemic infarction—an injury that does not occur after the injection of other organic acids of comparable pH.[124-126] In general, the more severe the tissue lactacidosis, the more profound the cerebral blood flow and metabolic alterations that occur after cessation of the insult,[123,127,128] portending greater ultimate brain damage.

It must be emphasized that hypoxia-ischemia leads to cellular acidosis by means of sources of H^+ ions in addition to lactic acid. Major sources of reducing equivalents include products of the acid hydrolysis of ATP and the formation of NADH + H^+, which accumulates during the cellular energy debt.[129] In this regard, Welsh and colleagues[103] examined the oxidation-reduction (redox) state of immature rat brain undergoing hypoxia-ischemia by the technique of reflectance fluorometry (Figure 163-12). Alterations in regional fluorescence, representing the intracellular accumulation of NADH (+ H^+), were prominent in the cerebral cortex and the CA1 sector of the hippocampus during the first hour of hypoxia-ischemia. The pattern of NADH fluorescence mimicked closely the distribution of selective neuronal necrosis observed in this model of perinatal injury. The close correspondence between altered NADH fluorescence and neuropathologic outcome suggests an important role for intracellular acidosis in the pathogenesis of hypoxic-ischemic brain damage. That a cellular acidosis occurs during the course of cerebral hypoxia-ischemia in the immature rat also is indicated by a progressive reduction in intracellular pH, calculated from the tissue concentrations of high-energy phosphate reserves.[130]

Using proton MR spectroscopy, several investigators have demonstrated a persistent elevation in brain lactate after cerebral hypoxia-ischemia in human newborn infants.[20,21,131-133] The persisting elevations in lactate concentration were associated with a brain alkalosis. The previously asphyxiated infants uniformly demonstrated severe neurodevelopmental impairment at 1 year of age. Robertson and associates[133] suggested that the accompanying cerebral lactic alkalosis is the consequence of a prolonged change in the redox state within neuronal tissue, the presence of phagocytic cells, the proliferation of glial cells, or altered buffering mechanisms. Further research can be expected to clarify these lingering biochemical abnormalities after cerebral hypoxia-ischemia in newborn human infants.

CONCLUSIONS AND OUTLOOK

In the overview of current knowledge on the major aspects of perinatal cerebral metabolism presented in this chapter, the emphasis is on substrate and energy transformations under physiologic conditions and during hypoxia-ischemia. These and other disturbances recently have undergone extensive investigation in both experimental animals and human newborn infants. Further characterization of the mechanisms underlying the cerebral metabolic derangement that characterizes hypoxia-ischemia will be fundamental to development of a rational approach to prevention and treatment.

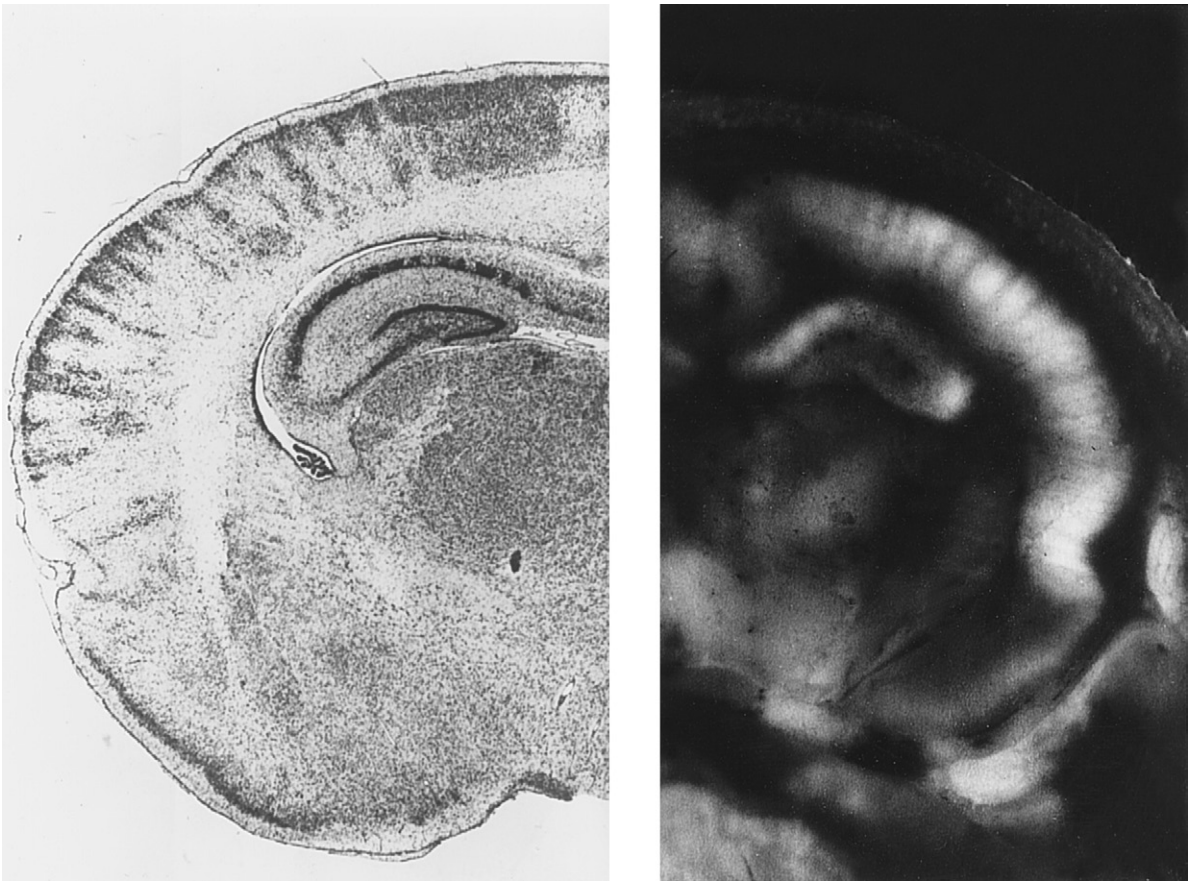

Figure 163-12 Coronal section of immature rat brain showing alterations in NADH fluorescence *(right)* during hypoxia-ischemia and histopathologic alterations *(left)* at 24 hours of recovery. Seven-day postnatal rats were subjected to unilateral cammon carotid artery ligation followed by systemic hypoxia with 8% oxygen at 37° C.[100] During hypoxia-ischemia, the rat brain was frozen in situ and the coronal section illuminated with ultraviolet light; the fluorescent image then was recorded photographically.[102] Note the columnar pattern of NADH fluorescence *(lighter areas)* in cerebral cortex and the enhanced fluorescence in the CA1 and CA3 sectors of the hippocampus, which correspond closely to the distribution of selective neuronal necrosis seen on histopathologic examination. *NADH,* Nicotinamide-adenine dinucleotide (reduced form).

Electroencephalography in the Premature and Full-Term Infant

The escalation of interest in the electroencephalogram (EEG) of the premature and full-term neonate in the past decade has been remarkable. A lot of attention has been directed to scrutinize the biological underpinnings of EEG in the neurodevelopmental context of brain growth, migration, and neuronal-synaptic connectivity. What is the fundamental basis of the large scale discontinuity that typifies EEG maturation in the immature brain and what gives rise to some of the distinctive patterns of the EEG of premature infants, such as the familiar but short-lived delta brush?[1] Another area that has enjoyed especially robust growth is the use of bedside "cerebral function monitors" intended to be applied and interpreted by nonspecialized caregivers, such as neonatal nurses and physicians.[2-4] Although they represent reduced, simplified EEG formats, their ease of use, greater availability and proficiency to display EEG background trends over very long time periods have sparked much interest in their use across the world. Thus it would be helpful to begin by differentiating the three broad levels of EEG recording.

Conventional EEG recording is the major focus of this chapter[5] (Table 164-1). It refers to the traditional style of EEG examination in which an EEG technologist is summoned to the bedside to carefully measure the scalp to apply about 9 to 11 recording electrodes. A routine EEG runs for 45 to 60 minutes and may capture one or more sleep cycles. The EEG amplifiers filter the "raw" EEG signal, allowing frequencies from 0.3 to 70 Hz to pass. The filtering of the very low frequencies allows for the appearance of a stable signal "platform" that facilitates easier interpretation in the clinical arena. A common recording rate is 1 sec of EEG per 15 mm of display (Figure 164- 1). Long-term EEG monitoring can be conducted by continuous conventional EEG recording at the bedside, often accompanied by time-synchronized digital video. Thus a long-term record that combines a video of the clinical activity of the child with coincident EEG is generated and is very useful to detect and quantify electroencephalographic seizures.

High-fidelity neonatal EEG examinations are currently a research tool intending to provide better spatial resolution by high-density recordings obtained by increasing the number of scalp electrodes using specially developed multielectrode caps and more faithful capture of ultra-low frequency signals that are characteristic of the most immature brains.[6] Because of the limited cortical-to-cortical connectivity of the immature cortex, it is possible that a higher number of electrodes can better measure the degree of electrical connectivity between adjacent or distant cortical areas and how this changes *pari pasu* with underlying brain development (such as the emergence of thalamocortical connections or the appearance of short- and long corticocortical connections). Because very slow EEG frequencies are one of the hallmarks of the immature brain, high-fidelity EEG does not arbitrarily filter out low frequency signals as does conventional EEG. Instead, it attempts to capture even the slowest signal by using direct current (DC)-coupled amplifiers that record down to zero frequency (that is, stationary or DC waves).[7] High-fidelity EEG examinations can be combined with video recordings and are usually recorded for 1 to 2 hours.

Cerebral function monitoring (CFM) was first introduced by Prior and Maynard in the 1960s in adult intensive care unit settings. By the early 1980s, they were used increasingly in neonatal care.[8] CFM is intended to be a simplified method of displaying EEG data over extended time periods that can be applied and interpreted by nonneurology specialists, such as neonatal physicians and nurses. Currently the most popular format of CFM is called amplitude-integrated EEG or aEEG.[2,9-11] It is derived from 1 or 2 channels (2 or 4 *recording* electrodes) placed on the scalp by bedside caregivers. The signal is heavily filtered, removing everything except 2 to 15 Hz frequencies. It is rectified, smoothed, and extremely time compressed with 1 minute of EEG per millimeter of display (see Figure 164-1). The signal is displayed linearly from 0 to 10 μV and semilogarithmically from 10 to 100 μV. This provides a very convenient method to follow the "envelopes" of the upper and lower margins of cerebral electrical activity over extended time periods. In healthy infants, the upper amplitude margin ranges from 30 to 50 μV, and the lower margins range from about 6 to 11 μV. In contrast, an abnormally suppressed aEEG has less than 10 μV for the upper margins and less than 5 μV for the lower amplitude margins.

The CFM, which can be continued for many hours or days, generates a simple output signal that provides useful information of the status of the central nervous system that can be interpreted by nonneurologists. Two competing background classification systems are currently employed by neonatologists to judge the normality of the EEG background. One uses simple voltage

TABLE 164-1

Comparisons of Contemporary EEG Recording Techniques

Type of EEG Recording	Typical Duration of Recording	Number of Recording Electrodes	Low Frequency Cutoff (Hz)	High Frequency Cutoff (Hz)	Recording Speed	Display Length of One Minute EEG
Conventional EEG	45-60 mins	9 to 11	0.3 (AC-coupled amplifiers)	70	15 mm/sec	900 mm
"High fidelity" EEG (research)	60 to 120 mins	20 or more (up to 100)	0 (DC-coupled amplifiers)	70	15 to 30 mm/sec	900 to 1800 mm
Amplitude integrated EEG	hours to days	2 or 4	2	15	1 mm/min (6 cm/hr)	1 mm

criteria[2] and the other a visual pattern recognition system[12] to classify records as normal or abnormal. These two methods are compared in Table 164-2.

The CFM can be used to estimate brain functional integrity quickly in the immediate wake of an acute encephalopathy, such as hypoxia-ischemia (e.g., deciding when a patient is appropriate for enrolment in a neuroprotection trial, which typically must be started within a few hours of the insult), screen for electrographic seizures automatically, and show trends of brain status during serious illness or response to treatment,[9,13,14] but its usefulness in neuroprotection trials has been questioned.[15]

Other Methods to Mathematically Process EEG Signals

Although the EEG "signal" is extremely complex, it is still describable in mathematical terms and subject to signal processing, quantitative analyses, and statistical manipulations. Just as an optical prism can separate white light into its component colors, the neonatal EEG can be decomposed into the sum of its component frequencies in the traditional bandwidths of delta (≤ 3 Hz), theta (4-7 Hz), alpha (8-12 Hz), and beta (≥ 13 Hz) frequencies.[16] EEG signal quantification based on this principle of analysis[17] simply describes the amount of electrical power (measured in picowatts) that is confined to each of these frequency "bins." In healthy neonates, the robust power of the neonatal EEG is largely relegated to the slow (theta and delta) frequency bins (Figure 164-2). Using this relatively simple approach, the EEG of the healthy neonate can be used to develop normative quantitative profiles of electrical power distribution across frequency bandwidths in the awake and asleep states, which serve as a benchmark to compare with those demonstrating acute encephalopathy.[10] The intensity and frequency distribution of the neonatal EEG can similarly be determined by *spectral analysis*. The spectral edge frequency is defined as the frequency below which 90% of the EEG's power falls. It has been shown, for example, that in premature infants, progressively lower spectral edge frequencies predict increasing severities of periventricular leukomalacia.[18]

Mathematicians may choose from an array of other analytical approaches to analyze or quantify the neonatal EEG. The short-time Fourier transform, higher-order spectral analysis (the so-called bispectrum), and autoregressive segmentation are the names of some of the more popular mathematical tools used to analyze and model complex biologic signals, such as the EEG background.

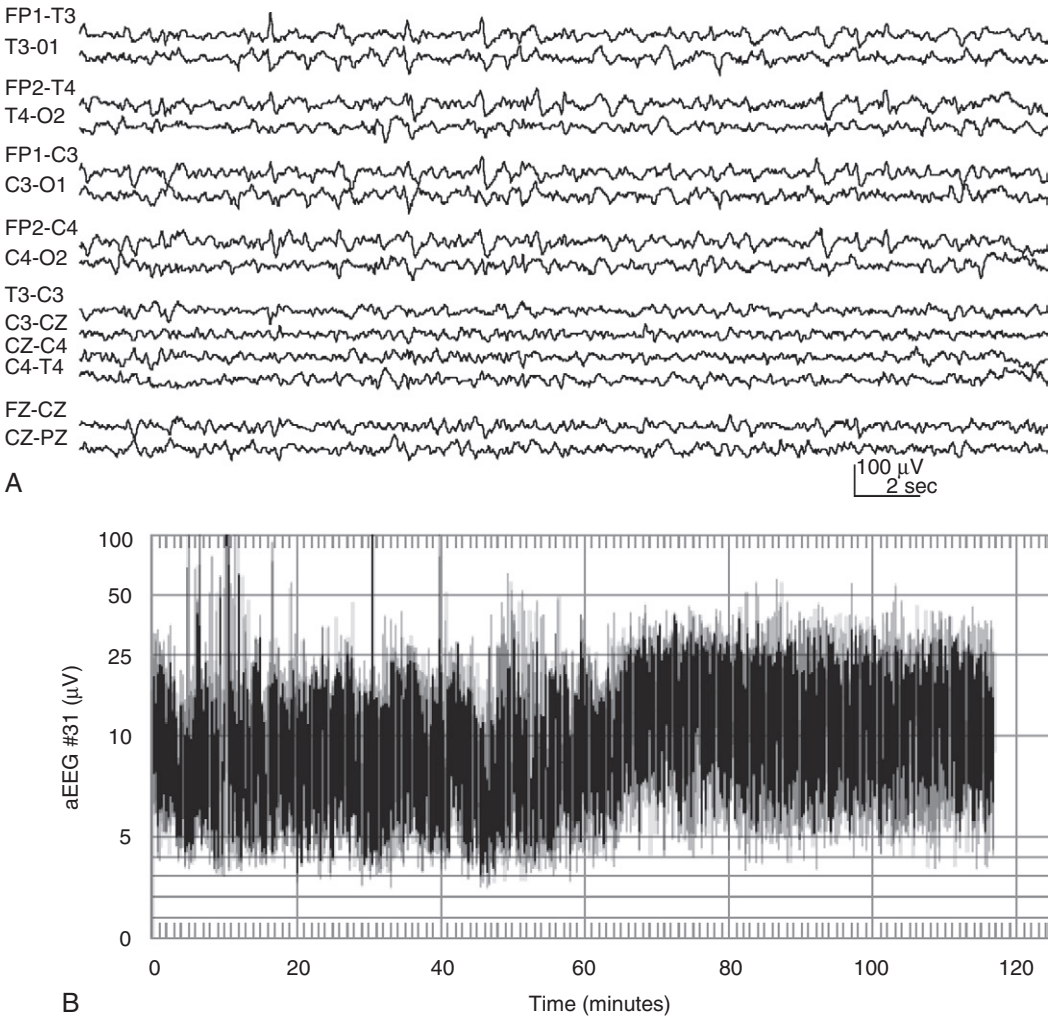

Figure 164-1 A, 30-second segment of a conventional neonatal electroencephalogram (EEG) examination, recorded from a 7-day-old full-term infant during wakefulness. During this portion of the record, the child is alert but calm. The EEG itself is low-to-medium voltage, continuous, and represents an "average" mixture of EEG frequencies (activité moyenne). During active sleep, the EEG has a similar appearance. **B,** Example of nearly 120 minutes of a normal amplitude-integrated EEG recorded from a 5-day-old infant with an estimated gestational age of 39 weeks. The upper margin exceeds 10 µV and the lower margin exceeds 5 µV.

A unique approach is the application of nonlinear dynamics or chaos theory to neonatal EEG analysis. The principle is simple. The normal neonatal EEG is extremely rich in its complexity and inherent "unpredictability." The status or appearance of the background at one moment in time does not predict the next with any probability. The normal neonatal EEG has many "dimensions" of chaos or complexity (unpredictability). In contrast the EEG of a sick neonate with an extremely low voltage, featureless background. or burst suppression (with its regular cycles of "off-signal" and "on-signal") becomes predictable with reduced dimensions of chaos. Finally CFM may analyze the raw EEG signal by neural networks, constructed to achieve an artificial intelligence approach to "decide" whether a novel *test* EEG segment is normal. The network is first instructed to "learn" the boundaries of the normal EEG based on input from a wide assortment of normal EEG samples representing many healthy neonates in a variety of biobehavioral states. After the network has "learned" how normal EEG segments appear, a test EEG sample can be submitted for analysis. If the neural network algorithm recognizes the test segment as comparable with previous normal segments in its memory, the analysis designates the test segment as "normal." Thus this approach does not generate a graphic depiction of EEG function but rather categorical variables, such as a "normal," "moderately abnormal," or "markedly abnormal" EEG.

Analytic algorithms can also be written to recognize EEG seizures. Computer-based EEG seizure detection algorithms are highly sensitive in older children and adults, but they are more challenging to design for use in neonates because of the different ictal waveform frequencies and characteristics.[19-21] Brief, low-amplitude electrographic neonatal seizures are especially difficult to detect. The distinctive clinical motion of some neonatal seizures can even be recognized by algorithms that evaluate the digital video images of babies during their seizures.[22]

TABLE 164-2

Comparison of Two aEEG Classification Systems

Background Classification	Simple System[2] Discrete Voltage Criteria	Advanced System[12] Pattern Recognition Criteria
Normal	Upper margin >10 μV and lower margin >5 μV	"Continuous normal voltage" Continuous EEG activity with amplitudes ranging from lower values of 7-10 μV to upper values of 10-25 μV; sleep-wake cycles evident
Moderately abnormal	Upper margin > 10 μV and lower margin <5 μV	"Discontinuous" Discontinuous background with lower amplitudes <5 μV and upper amplitudes >10 μV
Markedly abnormal	Upper margin <10 μV and lower margin <5 μV	1. "Burst suppression" Invariate, discontinuous background with low amplitude interbursts (0-1 μV) intermixed with higher amplitude (≥25 μV) bursts. 2. "Continuous low voltage" Continuous background of very low voltage (≤5 μV). 3. "Flat tracing" Mainly isoelectric, with some very low amplitude activity

EEG Monitoring for Neuroprotection Trials

One of the goals of contemporary neonatology is the successful completion of neuroprotection trials. Some trials involve obvious selection criteria of suitable candidates. Premature infants are at high risk for the development of periventricular leukomalacia[23] and have been the subjects of pharmacologic trials with allopurinol, magnesium, steroids, caffeine,[24] and other agents to reduce its occurrence. Likewise, infants with complex congenital heart disease, requiring surgery that uses deep hypothermic circulatory arrest, commonly experience postoperative seizures and long-term neurocognitive disorders and are easily recognized for enrollment in neuroprotection trials.[25] On the other hand, neuroprotection trials in hypoxic-ischemic encephalopathy in the term neonate have difficult challenges.[26-30] Currently no universally agreed upon research definition of hypoxic-ischemic encephalopathy is used to select candidates for enrollment. In this setting, the time for identification of truly encephalopathic infants is short. The window of enrollment into a protection trial, such as deliberate hypothermia, must be determined immediately after birth. Both conventional and aEEG have been proposed to assist in the identification of suitable candidates for neuroprotection trials because the quality of the EEG signal shortly after birth is one of the best early predictors of mortality and morbidity.[31,32]

BIOBEHAVIORAL STATES AND CONCEPTIONAL AGE

Normal brain development is intimately connected with the appearance and maturation of sleep cycles. Rather than being a passive period of "rest," sleep is actually an active process that is crucial for neurosensory development, memory, and the preservation of brain plasticity. During wakefulness, our brains are constantly barraged with an array of stimuli from all of our senses. Some of these stimuli have importance for survival and are worthy to consolidate into short- and long-term memory, but many

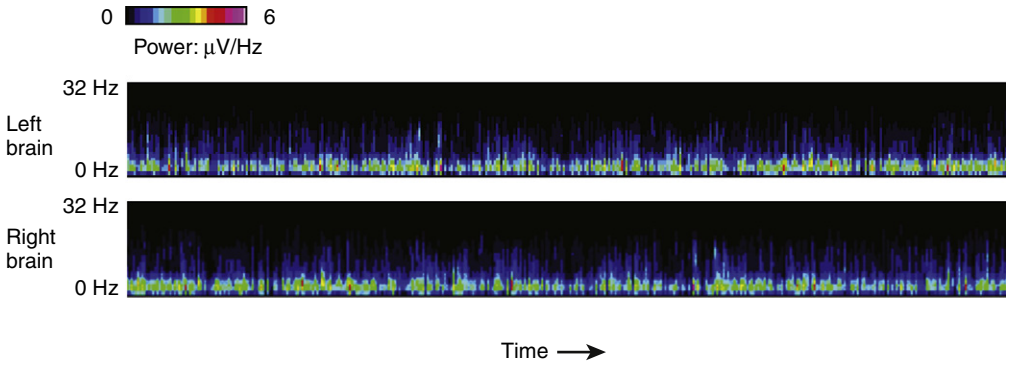

Figure 164-2 Power spectral array display of 12 hours of electroencephalogram from electrodes originating in the left *(upper figure)* and right *(lower figure)* hemispheres. Power, represented as μV/Hz, is displayed as the brighter colors concentrated in the slower (0-5 Hz) frequencies.

others are not. During sleep without rapid-eye movement (REM), the brain somehow selects those experiences to remember that seem advantageous for survival. During REM sleep, these memories are consolidated, organized, and entered into long-term memory, ready for later recall upon the correct cue. Deprivation of REM and non-REM sleep disturbs the development of sensory systems, learning, memory, plasticity in adulthood and even the ultimate size of the brain.

Recognizable patterns of activity that can be assigned as "sleep" (as opposed to wakefulness or drowsiness) first appear between 25 to 30 weeks gestational age (GA).[33,34] Sleep cycles in utero can be inferred by fetal heart rate monitoring. which shows cycles of increased fetal heart variability associated with movements (active sleep), interspersed with periods of diminished fetal heart rate variability and reduced or absent movements (quiet sleep).[35,36] In the infant born with substantial prematurity, sleep cycles can be inferred by direct visual observation of periods of movement and associated changes in the character of the EEG background. The length of the sleep cycle is long in the very premature infant (up to 90 minutes). Thus it is more difficult using conventional EEG (which may only record 45 to 60 minutes) to identify sleep cycles in the very premature baby. Typically sleep cycling can be identified in approximately 50% of premature infants as early as 25 to 30 weeks.[33] On the other hand, aEEG, which is typically recorded for many hours or days, has an advantage of showing periods of sleep cycling at an earlier age than conventional EEG. Thus, using aEEG, some investigators report the onset of definite sleep cycling at an earlier GA and even "acceleration" of EEG maturity compared with conventional EEG.[37]

It is no surprise that the harsh environment of the neonatal intensive care unit may disrupt normal sleep cycles. In contrast to the natural protection of the womb, with no light or pain and less sound and tactile stimulation, the sick neonate is subjected to multiple daily painful procedures, high ambient noise and light, and constant disruption of their sleep cycles. Indeed, it is a wonder that they can establish sleep cycles at all! These observations have lead to philosophies of care in some nurseries that attempt to minimize handing, pain, and sleep disruption. One approach, called "kangaroo care" involves sessions in which the premature baby sleeps peacefully and undisturbed skin-on-skin with the mother. Simultaneous EEG examinations have shown significant improvement in quiet sleep cycles with even a limited number of these sessions.[38]

LABILITY OF BEHAVIOR STATES AND CONCEPTIONAL AGE

The rhythms of our daily lives are not uniform but are woven into a rich variety of activities and behavior. In the early morning we awaken in a relaxed, refreshed, and replenished *state.* Soon we generate activities in preparation to begin the day's work—we are then in a different behavioral *state* of increased activity and heightened physiologic alertness and anticipation. At the peak of the day's work, a *state* of intense concentration, activity, and arousal may exist. By evening, our activity level retraces its steps back through similar behavioral states as we wind down for the day. At night a drowsy state heralding the onset of light sleep approaches. Light sleep surrenders to a deeper sleep state until the crisp onset of our first dream *state.* These *sleep states* are organized into patterns that repeat through the night until we awaken the next day and a new cycle begins.

Despite the superficial appearance of disorganization and anarchy that marks a brief and casual inspection of human newborn infants, they display remarkably predictable and recognizable states: constellations or functional clusters of physiologic, behavioral, and neurologic parameters that describe the net condition of the infant.[39,40] An infant's state is the outward and inward expression of neural activity, which can be modified by the environment. The state of a peacefully sleeping infant can be transformed into an aroused or awake state by a sufficiently potent environmental stimulus (light, noise, or touch). State can also fluctuate in response to an internal trigger—a happy and content infant can quickly engage in a frenzy of crying once the pangs of hunger surface. The ability of an infant to display organized and cyclic behavioral states is a useful yardstick to measure the maturity and health of the neonatal brain.[41] Extremely premature infants lack the physical neurologic sophistication required to harmonize and orchestrate the ingredients of recognizable states. Full-term infants do possess the neural equipment for explicit state organization, but this can be altered by the presence of disease. Drugs, medical disorders, unnatural environmental stresses, or neurologic disease consequently may disrupt and distort the normal predictable flow of infantile behavioral states.[42]

Because the presence and organization of electroclinical states are a reflection of neurologic health and maturity, the *conceptional age* (CA) of the infant should be known. Conceptional age is calculated by adding the estimated gestational age (EGA) to the legal age or chronologic age since birth. Thus a healthy 29-week EGA premature baby with a legal age of 11 weeks has the same CA (29 weeks + 11 weeks = 40 weeks) as a 1-day-old full-term 40-week baby. Although some small neurologic-behavioral differences exist between these 40-week CA babies, they are essentially equivalent in terms of their state of organization and EEG activity.[37,43,44]

Early Development of the EEG in Relationship to Developing Brain Morphology

Early infancy is a period of explosive growth and development unparalleled by any other epoch in the human life span.[45,46] The clinical changes observable are the outwardly visible signs of underlying anatomic, physiologic, and metabolic central nervous system (CNS) maturation.[47] A general description of early brain development, the ontogeny of early infantile states, and associated EEG maturation follows.

The cortex of the human fetus has established its foundation by week 8 of gestation (Table 164-3). Brain function, as measured by the first appearance of an EEG signal, commences shortly thereafter.[46,48] Early fetal movements after 8 weeks gestation are demonstrable by real-time ultrasound. However, at that age, motor activity is almost entirely issued by the brain stem, subcortical structures, and the spinal cord itself.[49]

Correlated neuronal activity plays a pivotal role in cortical development by influencing neuronal differentiation, migration, synapse formation, and integrated neural networks.[50] The relationship between observed EEG patterns that for decades have been recognized purely as empirical phenomena and specific details of neurodevelopment that underlie them have just recently begun to be unraveled.

The earliest cerebral activity appears in the form of spontaneous, high-voltage, random electrical bursts that are believed to arise from pyramidal neurons of the cortex, connected by excitatory synapses.[1] These spontaneous bursts arise before sensory mechanisms have become functional. That is, they are not provoked by arrent volleys but arise intrinsically. The process of cortical folding begins just after 23 weeks gestational age (GA) and continues predictably and sequentially well beyond term. Biagioni and colleagues[51] reported the relationship between cortical folding shown by brain MRI examinations and a number of well-known EEG characteristics in premature babies between 23 and 29 weeks GA. EEG characteristics such as discontinuity and delta brushes were examined for correlation with brain anatomy. The degree of cortical folding was significantly associated with age and the degree of EEG background discontinuity. However, delta brushes and other transient EEG elements were not.

TABLE 164-3

Electroclinical Timetable

Age Since Conception	Behavior	Electroencephalogram (EEG)
<8 wk	Incomplete cortex; intermittent muscle activity generated by the brain stem	No EEG activity
8+ wk	Periods of more sustained motor activity	First appearance of EEG activity
12-14 wk	Onset of intermittent bursts of regular respiratory muscle activity (breathing movements)	
16-20 wk	Quickening	
24 wk	Eyelids unfuse; operationally, wakefulness (eyes open) altermates with sleep (eyes closed)	Invariant, discontinuous EEG
30 wk	First organization of state: consolidation of physiologic and behavioral parameters that distinguish wakefulness and sleep states	EEG relatively continuous during wakefulness or active sleep; more discontinuous EEG during quiet sleep
32-34 wk	Further consolidation of behavioral state: the child spends most of the time in an indeterminant sleep state; sleep cycle times are brief; better concordance between simultaneous behavior state and the EEG	Clear differences are seen in the awake, transitional sleep, active sleep, and quiet sleep EEGs; the tracing is discontinuous (tracé discontinu) mostly during quiet sleep; the EEG can be modified by external stimulation (reactivity)
36-38 wk	At least six distinct behavior states are defined; most of the infant's time is spent asleep; sleep onset begins with active asleep	As concordance improves there is less indeterminant sleep and more quiet sleep; mature continuous slow-wave sleep makes its appearance during quiet sleep; continuous slow- to moderate-voltage mixed frequency activity (activité moyenne) presides during wakefulness and active sleep
40-44 wk	Well-defined behavioral states continue; the infant spends most of the time asleep	Dissolution of many immature EEG patterns (e.g., waning of the Δ brush); emergence of mature quiet sleep states and sleep spindles
4 mo postdelivery	The infant has "settled" through the night and established daytime patterns for eating, naps, and play; onset of deliberate volitional motor patterns such as reaching for items of interest; sleep onset is quiet sleep	The percentage of active sleep approaches adult value; longer sleep cycle time and asynchronous sleep spindles in quiet sleep; during wakefulness precursors of α and μ rhythms appear

These spontaneous bursts of EEG activity serve as the most conspicuous feature of the premature EEG until they eventually yield to the appearance of continuous EEG activity as GABAergic neurotransmission evolves from excitatory to inhibitory. One of the deep mysteries surrounding neurodevelopment is the identification of the factors that select and cement precise neuronal connectivity and produce functionally connected networks. The number of neurons and their synaptic connections vastly dwarfs the number of genes that could conceivably be involved in fashioning them. Because genetics alone cannot account for all of the functionally relevant connections, the process is considered *epigenetic*. The sculpturing process requires spontaneous signals, such as the "self-organizing" bursts of the immature discontinuous EEG, to initiate functional contact with neighbors. The connections within the fledgling network are then reinforced through repeated usage.[1] The operational mantra of these incipient networks is that neurons that "fire together, wire together." Because brain development is so dependent on sensory feedback and the fetus has limited contact with the environment, it has been challenging to understand how both the visual[52] and somatosensory system possess endogenous mechanisms that advance neuronal connectivity.

The actual bursts of spontaneous cerebral activity are themselves complex electrical events. They are comprised of multiple EEG frequencies and several easy to recognize patterns, such as delta brushes,[50,53] rhythmic occipital theta bursts, positive slow waves,[54] rhythmic temporal theta bursts, and other specific named patterns. An elegant neurodevelopment story can now be told of the delta brush (Figure 164-3), which will be discussed again later from a clinical EEG perspective. In the course of normal gestation, expectant mothers report the onset of perceived fetal movements ("quickening") around week 17 to 18 of gestation. Such movements arise spontaneously from discharges in the fetal brainstem or the motor nuclei of the spinal cord. The resulting limb movements, however, trigger a set of functionally associated sensory messages that report back cutaneous sensations and volleys from muscle and joint position sensors. These ascend through sensory pathways to the thalamus, subplate, and overlying cortex, creating a learned, integrated sensori-motor physiologic loop specific to that particular sequence of movement. It is now understood that the familiar "delta brush," an EEG pattern only encountered in the immature brain, is the electrical embodiment of that process.[50] It has recently been shown that the delta brush can appear in response to an endogeneous event (such as fetal kicking) but can also be elicited by gently stroking the skin of a premature baby.[50] Thus sensory feedback from spontaneous muscle activity triggers delta brush oscillations in a somatotopic manner. The delta brush plays a critical role in the development of thalamocortical connections. Delta brushes are consistently seen over the sensorimotor cortex by 24 weeks CA, peak around 30 weeks CA when interneurons begin their extension from the temporary subplate to the overlying cortex, and begin to fade after 35 weeks. In the youngest premature infants, these functional columns behave as isolated islands, answering only to their specific assigned sensorimotor task. Later, however, as long and short range cortical-to-cortical connections appear, functional columns become integrated with and between the hemispheres. With the appearance of corpus callosal fibers around 34 weeks CA, it can be shown that delta brushes appear somewhat synchronously between homologous regions of the two hemispheres, required for sensorimotor coordination (Figure 164- 4). The era of neonatal EEG as a strictly phenomenological description of visual "graphoelements" empirically useful to the bedside clinician has begun to be supplanted by a deeper appreciation of its real message as revealed by the work of developmental neuroscientists.[7]

Fetal EEG

Early attempts in 1970 to record fetal EEG were unsuccessful; investigators attached recording electrodes to the mother's abdomen and the distant and feeble (microvolt) brain electrical activity was not consistently detectable with conventional recording

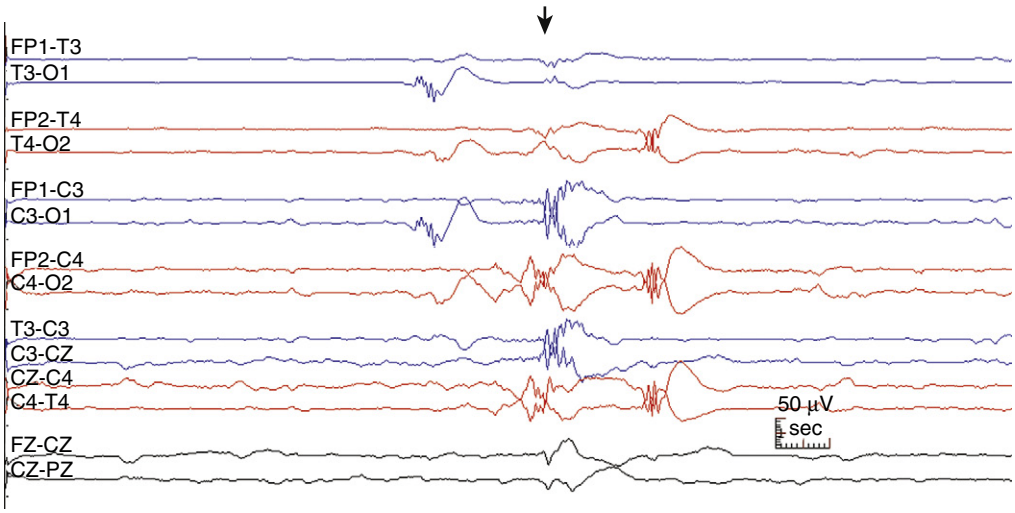

Figure 164-3 The delta brush is a premier example of a distinctive waveform that is a hallmark of the premature electroencephalogram. The delta brush represents a combination of a surface positive slow (delta) transient with an overlying burst of faster (beta) rhythms. It is now believed that delta brushes result from sensory feedback to the cortex from spontaneous limb movements or can be elicited by tactile stroking of the skin. It is believed that such electrical patterns help shape the consolidation of developmental sensory-motor networks.

equipment.[55,56] It is now possible to briefly record fetal EEG during the process of labor and delivery after the maternal membranes have ruptured so that fetal scalp electrodes can be attached. However, this line of investigation simply attempts to measure fetal brain response to the stresses of labor, similar in some respects to using "reassuring" or "nonreassuring" fetal heart rate monitoring to gauge the fetus tolerance to labor. Such brief fetal EEG recordings are not useful in measuring developmental or maturity-based observations. The use of magnetoencephalography (MEG) has opened a new window on examining the developing fetus in situ.[57,58] MEG exploits the fact that synchronized neuronal electrical currents induce very weak magnetic fields that can be measured by extremely sensitive recording devices, such as superconducting quantum interference devices. However, the magnetic strength of the brain is weak compared with fields generated by the general environment or maternal somatic muscle and heart activity. In the case of fetus MEG, specially constructed detection arrays are fabricated to conform to the gravid abdomen and the magnetic fields generated by the fetal heart and the mother's body detected and cancelled. The resulting filtered and processed signal displays the salient features of conventional EEG recorded from prematurely born infants. For example, fetal MEG showed the common features of the premature EEG recognized for decades, such as discontinuity, delta brushes, and sharp EEG transients.

Clinical Recognition of State

In the postnatal arena, the operational definition of the awake state requires that the eyes be open (Table 164-4). This is not possible before week 24 of gestation when the eyelids are fused together. Thereafter, it is possible to distinguish an *awake* infant (with eyes open) from an *asleep* infant (with eyes closed). However, except for this eyes open–eyes closed awake-asleep dichotomy, the behavioral state of the infant remains amorphous and primordial. No distinctive EEG changes uniquely discriminate between the aroused and the sleeping infant.[59] Scher and colleagues[33] reported the appearance of sleep-wake cycles in 33 preterm infants between 25 and 30 weeks CA. Some form of sleep-wake cycles was visible in 24 (73%) with a sleep cycle time ranging from 37 to 100 minutes. By 30 weeks gestation, the first differences between the EEG in awake and sleeping infants emerges, and the notion of "concordance" arises. Concordance describes the agreement between the electrographic and clinical expression of the infant's state: an awake (eyes open) infant displays a more continuous and low-voltage "aroused" EEG background, whereas a sleeping (eyes closed) infant has a different-appearing EEG that is appropriately matched to the clinical sleep state.

Concordance is only marginally and inconsistently established in the 30-week premature infant. At that age, some segments of the tracing demonstrate some agreement between the clinical and electrographic expressions of state. Thus an awake infant who displays eye opening, irregular respirations, and motor activity has a coincident EEG showing a somewhat continuous pattern that is in agreement (concordant) with wakefulness. In contrast, in quiet sleep, the eyes are closed, the baby is relatively still, respirations are more regular, and the EEG assumes greater discontinuity than during wakefulness or dream sleep.[60] In a few more weeks (approximately 32 to 34 weeks gestation), the healthy premature baby demonstrates much better concordance for longer portions of each tracing. Indeed, at that age, a 1-hour EEG recording might capture several electroclinical behavioral states.

At term, a typical sequence of electroclinical states can be demonstrated (see Table 164-3). During wakefulness, the eyes remain open, and the appearance of alert vigilance presides. The level of muscular activity varies from calm quiet to vigorous limb thrashing with crying. The respiratory pattern is irregular. The simultaneous EEG is essentially continuous; interruptions in the nonstop production of low-to moderate-voltage, mixed-frequency cerebral rhythms are few.[61] The infant may next enter a drowsy state as the harbinger of sleep. The voltage of the continuous EEG pattern increases as more slow activity (Δ) appears. As drowsiness deepens, slow, rolling eye movements begin and the eyelids close. The infant may briefly occupy a transitional or indeterminant sleep state. Criteria to unequivocally classify the electroclinical state as fully developed active or quiet sleep are insufficient. However, the infant's state soon crystallizes into definite active sleep. Sleep onset that begins with active sleep contrasts sharply

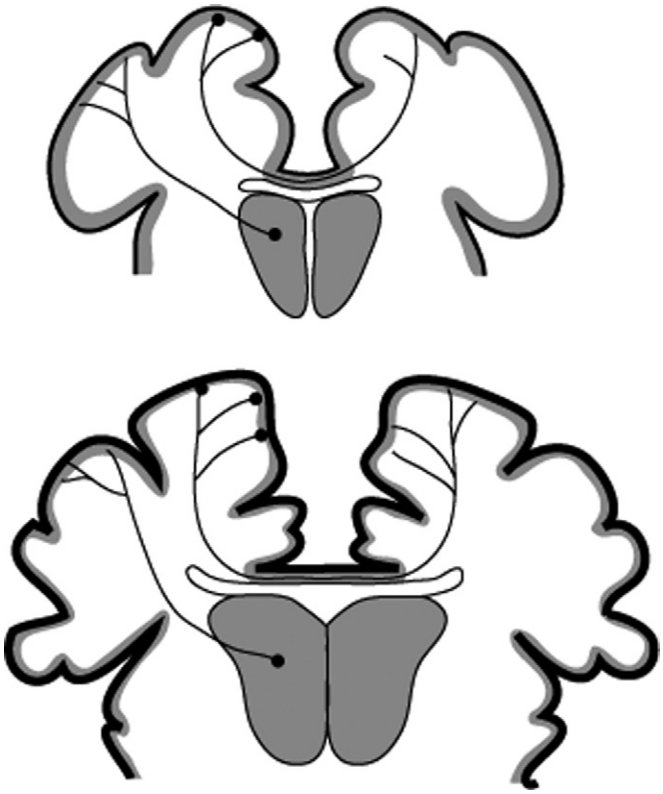

Figure 164-4 Thalamocortical and long corticocortical connections evolve rapidly in early brain development. At 28 weeks gestation *(upper figure),* the thalamocortical projections are just being connected to the transient subplate region below the cortex, and long corticocortical projections through the corpus callosum fall short. By 30 weeks gestation *(lower figure),* the subplate is receding and thalamic projections actually impinge on the cortex while corticocortical projections are just arriving there. *(Adapted from Vanhatalo S, Kaila K: Development of neonatal EEG activity: From phenomenology to physiology,* Semin Fetal Neonatal Med *11:471, 2006.)*

with the onset of sleep in healthy older children and adults who usually enter quiet sleep first. Individuals with the sleep disorder narcolepsy also begin their sleep cycle with active or REM sleep. During active sleep, the eyes remain closed. There are bursts of conjugate, jerky, rapid, predominantly horizontal eye movements. REMs are not homogeneously distributed during active sleep but appear in grouped clusters. The coincident EEG mostly resembles that of wakefulness, that is, a continuous low-to-medium-voltage mixture of EEG frequencies. Indeed, the cerebral cortex is in a similar "aroused" mode whether the subject is awake or engaged in the mental activities of active sleep. The voltage of the EEG signal attenuates in the setting of wakefulness, dreaming, or arousal from quiet sleep because of the removal of the synchronization that exemplifies quiet sleep. The low-voltage EEG is a result of desynchronization of cortical activity.[62]

After the first active sleep period concludes (the first active sleep state may last only 15 to 25 minutes at that age), the infant again enters transitional or indeterminate sleep that culminates in quiet or non-REM sleep. The baby's body is then "quiet" or motionless except for deep, regular, slow excursions of respiration. The face is expressionless, save for occasional bursts of sucking automatisms. The EEG substantially changes its character as the pattern becomes discontinuous. The voltage of the cortical signal then regularly fluctuates between higher voltage segments

TABLE 164-4

Electroclinical States at Term

		ASLEEP	
Electroclinical Parameters	**Awake**	***Active (REM or Dream Sleep)***	***Quiet (NREM)***
Behavior

Tonic EMG	Variable	Off	On
Phasic EMG	Variable	On	Off
Respirations	Irregular	Irregular, brief apneas	Regular
EEG	Continuous (activité moyenne)	Continuous (activité moyenne)	Discontinuous (tracé alternant) and continuous slow-wave sleep

EEG, Electroencephalogram; *EMG,* electromyographic; *NREM,* non-rapid eye movement (sleep); *REM,* rapid eye movement.

of activity and lower voltage periods of quiescence. French electroencephalographers have coined the terms *tracé discontinu* and *tracé alternant* to describe these normal discontinuous quiet sleep patterns (Figure 164-5). Quiet sleep is a delicate electroclinical state. During mild encephalopathies, more of the EEG may appear as indeterminate sleep at the expense of quiet sleep[63]; that is, the percentage of total sleep time classified as indeterminate sleep increases directly as the percentage of quiet sleep diminishes. Although the EEG may appear normal during wakefulness or active sleep in mild encephalopathies, abnormalities may be confined to quiet sleep.

As term gestation approaches (36 to 38 weeks CA), additional signs of electrographic maturity emerge. Although the circadian rhythms at birth are already set at the adult value (24.8 hours), sleep cycle time at term is 50 minutes and gradually lengthens to mature values of 90 minutes.[64] The EEG pattern of quiet sleep is subtly different from the previous tracé discontinu of the more immature infant. Although the pattern remains discontinuous, the quiescent period is not as low in voltage. The record demonstrates repetitive *alternations* between bursts of higher voltage activity and lower voltage quiescent periods. French investigators designate this alternating tracing as *tracé alternant.*

At term, quiet sleep is divisible into two distinct patterns. The immature quiet sleep pattern of tracé alternant is the remnant of earlier quiet sleep patterns that evolved from tracé discontinu. More mature quiet sleep then emerges as continuous slow-wave sleep in which *continuous* high-amplitude θ and Δ activity dominates the record.[43] This resembles in principle the quiet sleep of older infants and children. By 4 to 6 weeks after term, continuous slow-wave sleep also displays, for the first time, the unmistakable sentinel of mature non-REM sleep—the sleep spindle or σ rhythm. Thus, by 6 weeks after term, most healthy infants have cemented the groundwork for the electrocerebral cycles of their future life. By 4 months postterm, the basic architecture of sleep-awake cycles has been transformed from the primitive undifferentiated electroclinical state of the very premature baby to one that basically satisfies the criteria of electroclinical maturity.

By this age, most babies exit wakefulness into non-REM sleep. Furthermore, the proportion of total sleep time occupied by active sleep has fallen from a high value of 50% at term to a mature value of about 20%[43] (Figure 164-6). During quiet sleep, well-formed sleep spindles flourish but do not appear simultaneously in the two hemispheres (i.e., they are asynchronous) until 2 years of age. Poorly developed sleep sharp waves are also visible

from the central vertex (C_z) by 4 months of age and are explicit by 6 months of age.[65] During wakefulness, substantial spatial organization of EEG frequencies and rhythms has appeared. The precursors of the well-known μ rhythm (the "idle" rhythm of the motor cortex) and α rhythm (the "idle" rhythm of the visual cortex) dominate the rolandic and occipital areas, respectively.[66] Although at this age the frequency of these waveforms (around 3 to 4 Hz) is too slow for these patterns to be rightfully labeled as a true μ or α rhythm, their morphologic characteristics, rhythmicity, and reactivity to movement or vision impart them with their fundamental characteristics.

The value of an understanding of the concept of state and EEG ontogeny becomes more tangible when discriminating between abnormal and normal EEGs. The EEG is expected to be temporarily low voltage during wakefulness and dream sleep or after behavioral arousal. However, this normal low-voltage signal is interspersed with higher-voltage EEG segments in quiet sleep. In contrast, the pathologic low-voltage EEG represents a fixed, monotonous, invariant pattern that does not cycle with spontaneous higher voltage activity of quiet sleep. In a similar context, the highly abnormal pattern of "burst suppression" must be distinguished from the normal discontinuity (tracé discontinu and tracé alternant) of immature quiet sleep. The former represents an immutable pattern from which the patient cannot be rescued by the strongest external stimulation (see Figure 164-5). The cerebral activity during the bursts of burst suppression displays an

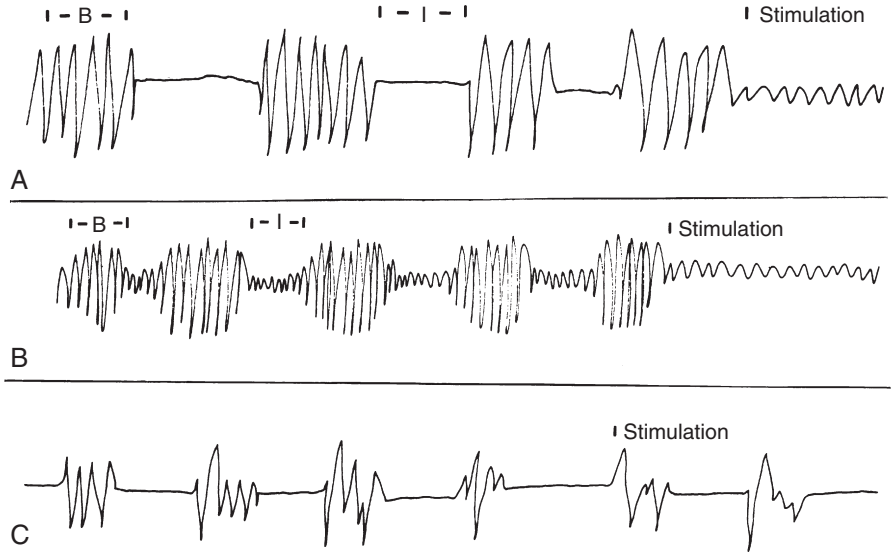

Figure 164-5 Discontinuous electroencephalogram (EEG) activity. A, Normal quiet sleep in a 33-week preterm baby: During tracé discontinu, the bursts *(B)* are composed of normal EEG patterns; the interbursts *(I)* represent low-voltage periods of quiescence. Following stimulation, there is behavioral and EEG reactivity and a transition to a more aroused state. **B**, Normal quiet sleep in a full-term baby: During tracé alternant, the bursts *(B)* are composed of normal EEG signals; the interburst voltage is higher (<25 μV) than tracé discontinu and spectrally resembles the EEG signal during active sleep. Following stimulation, the EEG changes to a continuous, lower-voltage, mixed-frequency signal. **C**, The critically ill premature or full-term infant displays hyporesponsive eye closure signifying lethargy or coma; the bursts of activity are composed of abnormal EEG patterns; the interburst periods are low voltage and tend to be longer than the duration of the interburst during tracé discontinu and tracé alternant. Despite stimulation, there is no EEG reactivity, and the fixed, invariant EEG pattern remains.

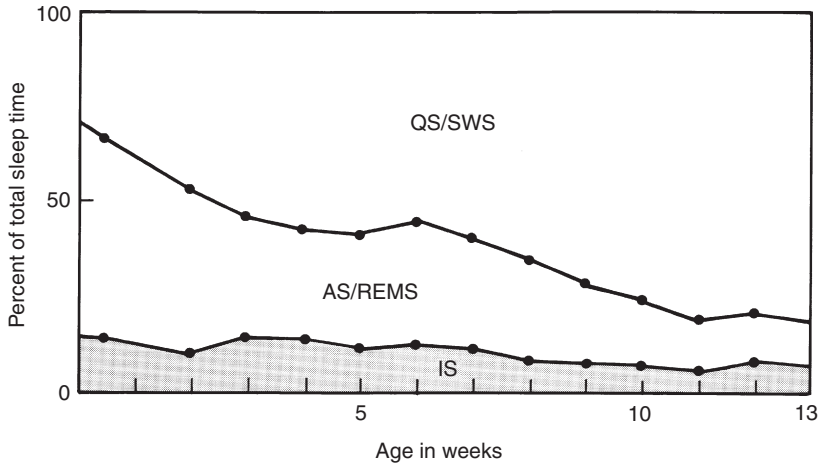

Figure 164-6 Quiet or slow-wave sleep (QS/SWS), active or REM sleep (AS/REMS), and indeterminante sleep (IS) as percentages of total sleep time in normal full-term infants, 1 to 13 weeks old. *(From Ellingson RJ, Peters JF:* Electroencephalogr Clin Neurophysiol *49:112, 1980.)*

abnormal morphologic condition, with admixed spikes, sharp waves, or unusual fast (β) activity.

In just a few months, the anatomic, physiologic, synaptogenic, and electrophysiologic properties of the cortex undergo an unparalleled metamorphosis.[47] This introductory overview paints a broad picture of the electroclinical events that encompass early life outside the womb. The next task is to consider the specific details of recording and interpreting the EEG itself.

TECHNICAL ASPECTS OF CONVENTIONAL NEONATAL EEG RECORDINGS

Conventional EEGs are recorded in the clinical neurophysiology laboratory or at the infant's cribside in the intensive care nursery.[67] The recording technologist must be careful to obtain the most technically acceptable tracing. The EEG is recorded for 45 to 60 minutes to sample EEG activity during several spontaneous state changes. At the conclusion of the EEG, the technologist stimulates the patient with light, sound, and touch to witness arousal patterns that demonstrate reactivity of the EEG signal.

The recording session begins by noting the clinical condition of the baby. The medical and neurologic diagnoses are recorded.[68,69] The infant's level of consciousness, drugs consumed, respiratory status, arterial blood gas values, and other pertinent laboratory data are noted.

The infant's head is carefully measured from standard bony landmarks (e.g., the inion and nasion) (Figure 164-7), and the scalp is marked with a crayon at several key locations.[70] When measured properly, these prescribed locations can be reproducibly located by the same or a different technologist on subsequent EEG recordings. Because the scalp surface area of the neonatal skull is small, a limited number of sites is used rather than the full electrode array employed in older individuals. The EEG recording sites are chosen to provide a fair sampling of cortical electrical activity from several representative brain regions. In the international 10/20 system modified for neonates, surface disk electrodes are applied with electrode paste in the following locations: FP_3-FP_4 (halfway between the conventional frontal polar [FP_1-FP_2] and frontal [F_3-F_4] regions); C_3-C_4 (central, rolandic, or parasagittal areas); T_3-T_4 (midtemporal or paratemporal); O_1-O_2 (occipital); and F_z (frontal vertex), C_z (central vertex), and P_z (parietal vertex) (Figure 164-8). Additional polygraphic monitors are placed to detect eye movements, nasal airflow, chest wall excursions, and the electrocardiogram (ECG). Altogether, at least 20 recording channels on the electroencephalograph are needed for a complete study. Usually a single montage is used for the whole session.

Figure 164-7 Infant undergoing an electroencephalographic examination.

The neonatal EEG is largely composed of Δ and θ activity, with a relative paucity of faster rhythms (see Figure 164-2). The technique of EEG recording is conducted to exploit the rich presence of this slower activity; the usual EEG recording speed is 30 mm/sec, but neonatal tracings are recorded at a slower paper speed (15 mm/sec). This compresses the signal in the time domain and facilitates visual analysis by enhancing the visibility of the Δ activity. The filter settings are also chosen to permit faithful reproduction of the dominantly slow frequency signal. The lower linear frequency is 0.3 to 1 Hz, and the high linear frequency is 70 Hz.

While the tracing is actually being conducted, it is mandatory for the recording technologist to make accurate and copious notations on the unfolding EEG record that describe the patient's behavior and activity. The presence of eye opening or closure, movements, sucking, hiccups, startles, squirming, and so on help the encephalographer to understand the behavioral state and identify possible sources of recording artifact.

GENERAL PROPERTIES OF THE NEONATAL EEG

The neonatal EEG is exceptional in many ways. Not only are the specific bioelectric rhythms that compose the signal unique and age-specific but the fundamental *organization* of the signal is confined to infancy. The next section covers the infrastructure of neonatal EEG: continuity, synchrony, symmetry, and reactivity. Independent criteria have been provided to define the normal parameters of aEEG.[4,11]

Continuity and Discontinuity

The property of continuity confers an uninterrupted voltage level to the tracing (Figure 164-9). No substantial voltage breaks or interruptions occur in a continuous EEG tracing. Continuous EEGs unravel nonstop. Segments of the EEG that show clear-cut interruptions or reductions of voltage are "discontinuous"[71] (Figure 164-10). The "burst" segments of cerebral electrical

TD during quiet sleep. *D,* Activité moyenne (AM) continuous low to medium voltage mixed-frequency signal while awake. Tracé alternant (TA) while asleep. *E,* AM during wakefulness. Mixture of immature (TA) and mature continuous slow wave sleep (CSWS) during quiet sleep. *F,* AM during wakefulness. Mostly CSWS during quiet sleep. *G,* AM during wakefulness. Quiet sleep entirely CSWS and sleep spindles (σ) first appear.

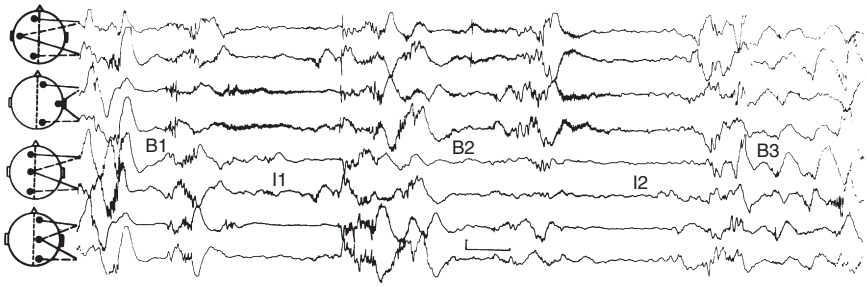

Figure 164-10 Tracé discontinu. Electroencephalogram (EEG) segment recorded from a 1-week-old (29 weeks estimated gestational age [EGA]) premature infant. The infant is in indeterminant sleep. The background activity is discontinuous and characterized by a series of bursts (*B1, B2, B3*) separated by lower-voltage periods of quiescence or interbursts (*I1, I2*). The cerebral electrical activity that makes up the bursts is of normal character, and the duration of the interburst periods is not excessively long for this conceptional age.

activity refer to the active periods in which the EEG voltage is "on." The specific rhythms and patterns that compose the burst activity are then visible. (These specific individual patterns are described in a later section.) Between the bursts of activity are lower voltage interburst periods of relative quiescence. The EEG is "off" in the interburst period. The signal amplitude at a standard recording sensitivity may then fall to zero or a value that is clearly less than the preceding burst activity.

In the extremely young infant (24 to 28 weeks CA), the entire EEG is essentially discontinuous.[72-74] Whether the child is clinically awake or asleep, active or quiet, the EEG itself is comprised almost entirely of a discontinuous background. Stimulation of the patient or spontaneous state changes provoke little qualitative change in the discontinuity.

By 30 weeks of age, more extended periods of relative continuity may appear.[65] The continuous EEG may occasionally persist without interruptions for many minutes as active sleep first materializes and consolidates. By 32 weeks of age, most healthy infants are capable of prolonged, continuous segments of EEG activity during definite active sleep periods. Indeed, this is a landmark CA because for the first time the continuous EEG dominates over the discontinuous portions of the record. Perhaps it is no coincidence that key CNS anatomic and physiologic landmarks mature at the same age.[75]

After 32 weeks of age, EEG discontinuity is mostly confined to quiet sleep. The voltage of the interburst activity, as recorded from the scalp surface with standard recording sensitivity, remains less than 25 μV. This discontinuous quiet sleep tracing (tracé discontinu) resembles the more primitive discontinuity that pervades all states in the very young preterm baby. With advancing maturity, the voltage of the interburst period exceeds 25 μV. The label assigned to this more mature discontinuous quiet sleep activity is tracé alternant, signifying the *alternations* between the higher voltage bursts and lower voltage interbursts[76] (Figure 164-11). The distinction between tracé discontinu and tracé alternant is thus somewhat arbitrary. Except for the higher interburst voltage, little else is fundamentally different. A curious feature of the interburst activity of tracé alternant is that it comprises voltages and frequencies that typify the continuous EEG during wakefulness and active sleep.[77] It is as though tracé alternant quiet sleep were comprised of brief portions of active sleep (i.e., the interburst segments) separated by bursts of higher voltage slowing.

By 1 month after term, the discontinuous quiet sleep pattern has all but disappeared. Tracé discontinu and tracé alternant gradually yield to the more mature, continuous slow-wave sleep, during which nonstop high-voltage θ and Δ activity dominate the tracing. Eventually the more sophisticated trappings of

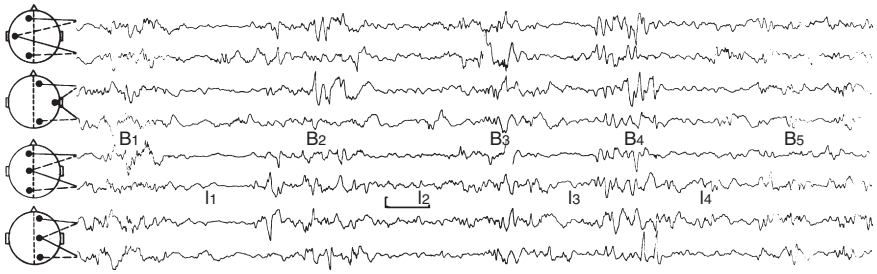

Figure 164-11 Tracé alternant. One-week-old full-term infant in quiet sleep. The cerebral electrical activity is discontinuous and composed of a series of bursts (*B1, B2, B3, B4, B5*) separated by interburst periods (*I1, I2, I3, I4*) of lower voltage and brief duration. Compared with tracé discontinu recorded from younger infants, the interburst periods are briefer and higher in amplitude.

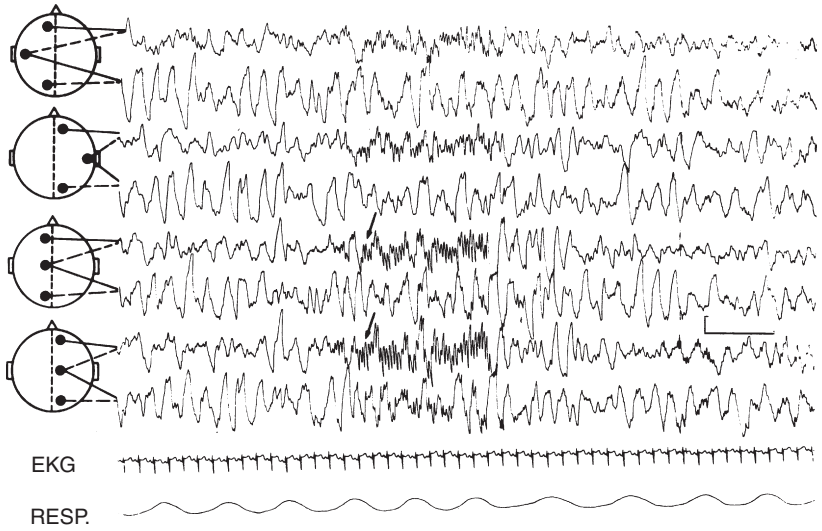

Figure 164-12 Continuous slow wave sleep (CSWS) and spindle. This segment was recorded from a healthy 8-week-old full-term infant during quiet sleep. CSWS is noted with semirhythmic high-amplitude Δ-activity maximally expressed in the bioccipital scalp regions. Twelve-hertz sleep spindles (*arrows*) arise synchronously from the frontal-central regions bilaterally. Although in this segment the spindles arise synchronously, they often do not at this age. Notice that the respiratory pattern is exquisitely regular and that there is a paucity of limb movements during quiet sleep.

non-REM sleep (spindles and vertex waves) punctuate the tracing (Figure 164-12).

Duration of Interbursts

The duration of the burst and interburst periods is maturation (CA)-dependent[59] (Figure 164-13). The length of the interburst is relatively longer in the younger preterm infant and decreases near term). Most investigators have reported a range of values for the duration of interburst as a function of CA.[75,78] The discrepancies in specific reported values reflect differences in technical recording aspects, EEG criteria that define the boundaries between the burst and interburst intervals, and the clinical condition of the babies.[79-81] Tharp[78] has shown that concurrent medical conditions of the baby may transiently influence the interburst duration. With transient hypoxia, the interburst period lengthens in parallel[78] (Figure 164-14). It is probably true that other physically stressful medical conditions (ischemia, hypercapnia, hyponatremia, sepsis, and so on) similarly increase the degree of discontinuity.

Another source of disparity in reported measurements of interburst duration is the selection criteria for individual premature babies. Most "healthy" premature babies have relatively brief interburst periods and eventually mature into developmentally and neurologically normal children. Some sick premature infants have much longer interburst periods and yet fortunately also recover and develop relatively normally. For example, Lombroso[82] historically cited "allowable" interburst periods up to 2 minutes because some of the neonates from whom the measurements were recorded were later developmentally normal. Another perspective is that such excessively long interburst periods are indeed abnormal but do not predict a permanent adverse outcome in all. The situation is not different from the healthy youngster whose EEG is excessively slow and disorganized following a head injury. The pattern itself is abnormal even though the individual can still have a healthy outcome later.

Excessive Discontinuity

Excessive discontinuity is an electrographic abnormality in which bursts of normally composed EEG signal are separated by longer than normal interburst periods. Mildly excessive discontinuity may reflect a temporary metabolic imbalance or mild encephalopathy. Markedly excessive discontinuity usually connotes more serious metabolic or neurologic abnormalities.[83,84] As the acute encephalopathy passes, the excessive discontinuity gradually subsides. In the setting of an acute encephalopathy, the term *burst suppression* denotes a markedly abnormal EEG background in which nonreactive, abnormally composed EEG signals are separated by abnormal low-voltage quiescent periods (Figure 164-15).

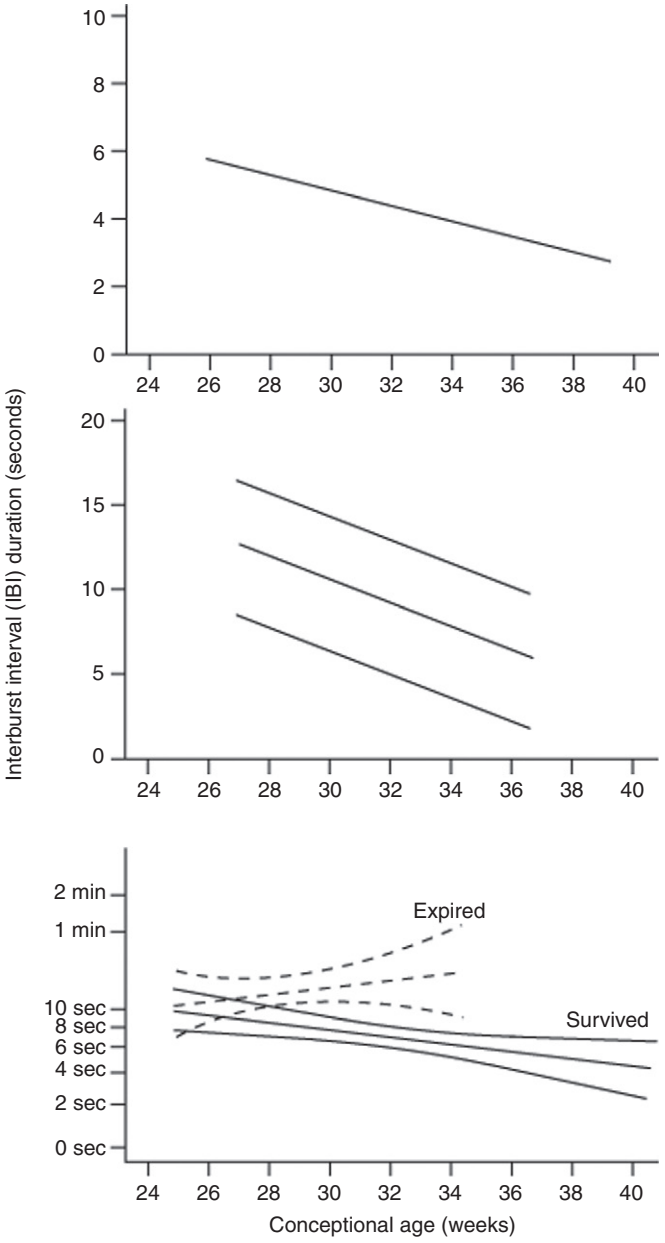

Figure 164-13 The durations of interburst intervals (IBIs) are shown at corresponding conceptional ages (CA), adapted from three separate studies.[79-81] The selection of patient populations, definitions of interburst intervals and recording methodologies differ among the studies. Nevertheless, all show that in healthy or surviving premature infants, the duration of the IBI is relatively brief (mean of 6 to 15 seconds), even at very young CAs, and decreases to a few seconds near term.

NORMAL CONTINUITY

By 30 weeks CA, many healthy babies display relatively protracted periods of continuous EEG activity during which the patient's clinical behavior suggests active sleep. By 32 weeks CA, most records demonstrate definite continuous segments. However, the specific patterns that make up the burst in the discontinuous records appear similar to the continuous segments. As term approaches, the actual composition of the continuous segments differs from the discontinuous quiet sleep record. During wakefulness and the active sleep that immediately follows quiet sleep, the continuous EEG is relatively low voltage and represents a rich mixture of frequencies (β, α, θ, and Δ). This continuous "average" background is called *activité moyenne* by French authors (see Figure 164-1). At term, most quiet sleep still displays the immature tracé alternant pattern, which later yields to the more sophisticated *continuous* slow-wave sleep pattern that is the foundation of adult quiet sleep activity.

Although a progressive substitution of continuous EEG activity to replace discontinuity is desirable, all forms of continuity are not desirable. Some infants electrographically respond to CNS insult with a continuous, but invariant, monotonous EEG that does not display spontaneous-state lability and is unreactive to external stimulation.

Synchrony and Asynchrony

The isolated cerebral cortex generates a discontinuous EEG pattern.[85] Cortex disconnected from deeper pacemakers and remote from coticocortical modulation produces a pattern that inherently fluctuates its voltage (high voltage alternating with low voltage). In the discontinuous portion of an EEG, the two cerebral hemispheres can discharge at the same time (i.e., synchronously) or they can fire independently at different times (i.e., asynchronously). Although the temporal relationship of the signal *between* hemispheres is the usual focus of synchrony, the activity *within* each hemisphere can also be examined. Near term, individual regions within each hemisphere discharge simultaneously. For example, at 38 weeks, signals generated in the left frontal, central, temporal, and occipital areas arise together. In the very young premature baby, separate regions within one hemisphere may discharge independently or out of sync. Thus the temporal regions may be silent while the occipital areas robustly discharge.

Lombroso[86] has proposed an operational definition of interhemispheric synchrony that has been widely adopted. In a synchronous burst of a discontinuous segment of an EEG, the signal begins in both hemispheres within 1.5 seconds. In an asynchronous burst, one hemisphere leads the other by 1.5 or more seconds. Defined in this fashion, synchrony is a measurable property of the background that evolves with maturity.

Curiously, in the very young premature infant with primordial discontinuity, interhemispheric synchrony approaches 100%. By 30 to 31 weeks, when the EEG first demonstrates distinguishable state-dependent patterns, synchrony is only approximately 50% during the discontinuous portions of the recording. It is suspected that the neurologic substrate that underlies synchrony differs in these two circumstances.[82] With advancing maturity, a greater percentage of the bursts are synchronous until term, when nearly 100% of the bursts of tracé alternant begins simultaneously in the two hemispheres.

Excessive interhemispheric asynchrony for CA is an electrographic abnormality (Figure 164-16). It is most commonly seen following diffuse encephalopathies (e.g., intraventricular hemorrhage, meningitis, or asphyxia). No unique type of pathologic condition underlies the EEG expression of excessive asynchrony.[87] Excessive interhemispheric asynchrony can also be seen in cerebral dysgenesis, including agenesis of the corpus callosum or Aicardi syndrome. Although it would be tempting to speculate that the corpus callosum is the anatomic prerequisite for synchrony, the situation is probably more complex because the paired thalami and several commissures also serve as conduits that synchronize activity between the two hemispheres.

Although synchrony is usually intended to describe the temporal unity of the entire hemisphere, some individual EEG signals are also notably synchronous. In the very young premature infant, the occipital regions display remarkably synchronous high-voltage monorhythmic Δ activity. Frontal sharp waves (encoches frontales) and frontal slow transients (anterior dysrhythmia) are also usually synchronous. In contrast, the normal sleep spindles of

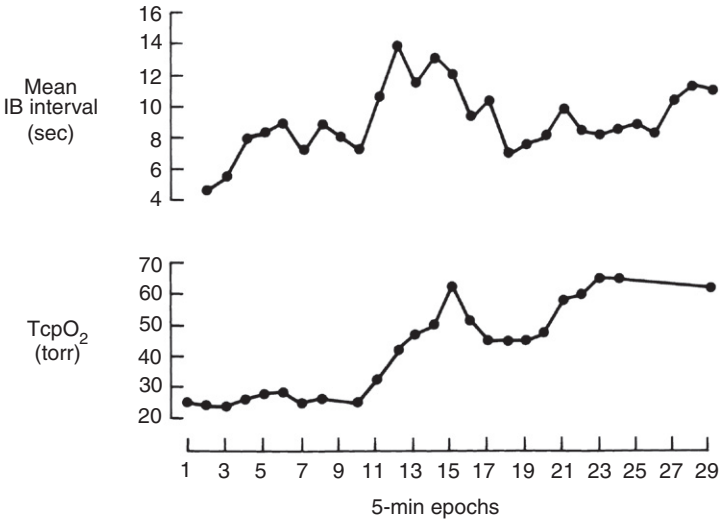

Figure 164-14 The relationship between oxygenation ($TcpO_2$) and mean interburst (IB) intervals/5 minutes in a premature infant with a hypoxic-ischemic encephalopathy and pulmonary hypertension. *(From Tharp BR: Intensive video/EEG monitoring of neonates,* Adv Neurol *46:107, 1986.)*

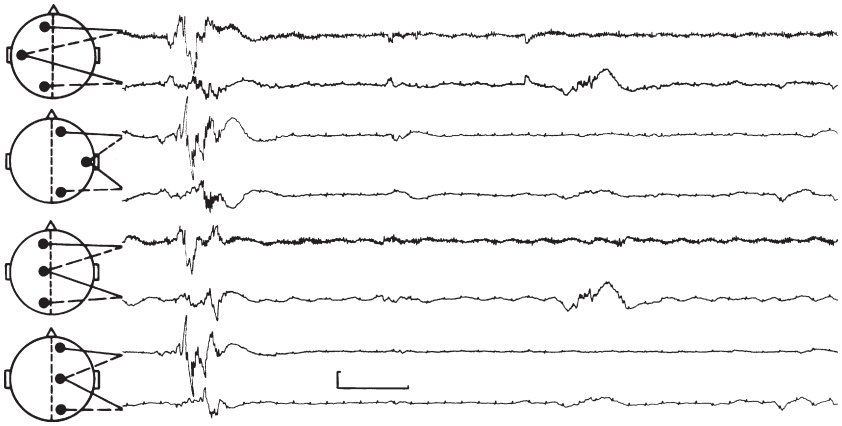

Figure 164-15 Burst suppression. Electroencephalogram (EEG) segment recorded from a severely asphyxiated 35-week estimated gestational age (EGA) infant. During the tracing, the child is comatose. The background shows burst suppression. There is a brief burst of erratic cerebral electrical activity that features an atypical bifrontal sharp wave. The burst of activity is followed by a long period of low-voltage suppressed background. There was no reactivity of the EEG to external stimulation.

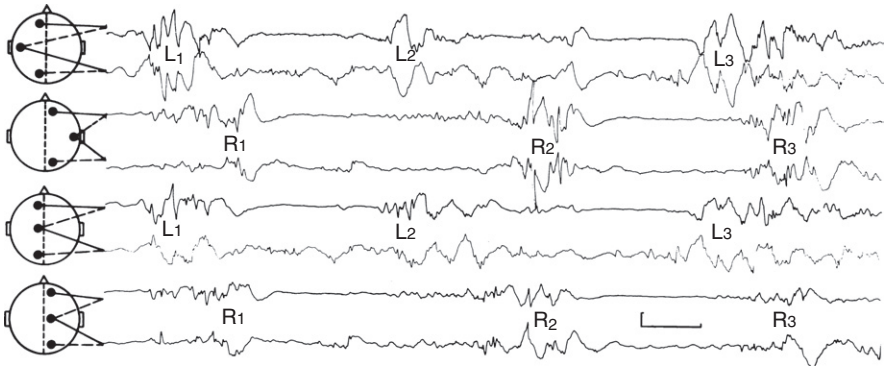

Figure 164-16 Interhemispheric asynchrony. Electroencephalogram (EEG) segment recorded during indeterminate sleep in a 3-day-old (37 week estimated gestational age [EGA]) infant with congenital heart disease. This EEG segment is discontinuous and shows excessive interhemispheric asynchrony. Notice that discharges from the left central and temporal regions (*L1, L2,* and *L3*) are displaced in time from bursts originating from the right central and temporal regions (*R1, R2,* and *R3*).

mature quiet sleep do not achieve full bihemispheric synchrony until 2 years of age.

Symmetry

The average voltage or amplitude of electrical activity in both cerebral hemispheres is generally symmetric.[16] The EEG amplitude and composition are equivalent when a suitably long sample is inspected. Although brief transient asymmetries are common, the overall impression from reading an extended EEG sample should convey the sense that both hemispheres (for that matter, homologous regions of both hemispheres) have equivalent representation of voltage, frequency, and specific background patterns.

The voltage of the background is roughly equal between homologous brain regions and between the two hemispheres. Near term it may be easier to detect voltage asymmetry during quiet sleep because the naturally higher voltage of tracé alternant exceeds that of wakefulness or active sleep. Care must be exercised in labeling a tracing abnormal because of voltage asymmetry alone (i.e., unaccompanied by a change in the frequency composition of the signal). The voltage at a given scalp location can be reduced by improper electrode placement or electrode gel bridging. Two electrodes accidentally placed too close together register the same EEG scalp signal. The differential amplifiers of the electroencephalograph may therefore detect only a modest voltage differential between the two sites, and a low-amplitude output signal results. An artificially low-voltage signal also can result from scalp edema, which removes the recording electrode farther from the cortical surface, the generator source of the signal. This can result from edema caused by a dependent head position or the infiltration of a scalp intravenous infusion. However, similar voltage depression can occur with subdural fluid (blood or cerebrospinal fluid) collections.

A transient voltage-frequency asymmetry may be observed occasionally during the transition between tracé alternant and active sleep in some healthy term babies. As the child enters or exits quiet sleep, one hemisphere desynchronizes into a low-voltage, continuous, mixed-frequency background, whereas the other displays the high-voltage tracé alternant quiet sleep pattern. This obvious asymmetry may persist for several minutes until voltage-frequency equality is restored to the two hemispheres. This phenomenon implies that the cycling of sleep and arousal is modulated independently for both hemispheres.

Although symmetry of voltage is the easiest EEG parameter to detect, symmetry of *composition* is equally important. Localized or lateralized pathologic features may give rise to an asymmetry in the type of EEG signal. There may be a circumscribed paucity of faster or rhythmic waveforms or excessive focal slowing that earmarks a localized cortical functional disturbance (Figure 164-17). Transient patterns such as Δ brushes or frontal sharp waves are also generally symmetric. For example, an equal number of brushes per minute can be counted from corresponding regions of both hemispheres.

Reactivity

EEG reactivity describes a change in the appearance of the cerebral background activity after a specific provocative stimulus (see Figure 164-5). Reactivity is both state- and CA-dependent. EEG reactivity should be distinguished from the clinical neurologic reaction to stimulation. The latter may include eye opening, crying, grimacing, limb movement, or a change in the respiratory pattern. These are not always time-locked to a coincident departure from the baseline EEG.

In the very young premature baby, the primordially discontinuous EEG shows no consistent response to external stimulation. However, by 32 to 34 weeks CA, some change can be induced in the EEG background by an arousing stimulus. As such, the quietly sleeping infant whose EEG shows a tracé discontinu pattern can be redirected into an alert state (wakefulness or active sleep) by external stimulation with a corresponding switch to a continuous EEG background.

By term, healthy, quietly sleeping babies show two basic arousal patterns after external stimulation: a temporary increase in discontinuity (longer duration of the interburst period) and attenuation of voltage or desynchronization of the background signals. During quiet sleep, the discontinuous tracé alternant pattern usually displays interburst periods of 4 to 6 seconds. After a suitably intense stimulus, the discontinuity of the tracing can temporarily increase, with longer interburst intervals and lower amplitude of interburst activity, thus resembling a brief reversion into tracé discontinu. However, unless the arousal persists and a complete state change ensues, the record soon reverts back to the previous tracé alternant pattern. During either tracé alternant or continuous slow-wave quiet sleep, the second major arousal pattern is an abrupt, widespread voltage reduction and the disappearance of the slowest Δ activity.

Reactivity is best visualized in the EEG of a quietly sleeping infant when increased discontinuity or desynchronization is unmistakable. Stimulation of an awake and alert infant or

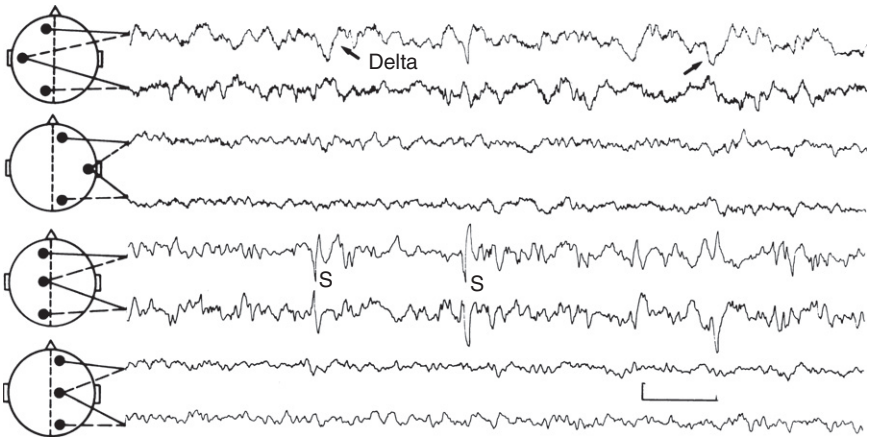

Figure 164-17 Interhemispheric asymmetry. Electroencephalogram (EEG) segment recorded from a 4-day-old full-term infant with an unexplained stroke in the distribution of the left middle cerebral artery. In this rhythm strip, there is a clear asymmetry between the two hemispheres. The left temporal and central regions have abundant high-amplitude Δ-activity *(arrows)* that is not present in similar regions in the opposite healthy hemisphere. Furthermore, excessive sharp EEG transients *(S)* are seen in the left central region.

provocation during active sleep may not produce a dramatic change in the EEG despite a brisk behavioral response.

Nonreactivity

A lack of reactivity is an ominous sign in a suitably mature infant (see Figures 164-5 and 164-15). Indeed, in the healthy infant, spontaneous-state lability and reactivity to external stimulation are expected markers of health. Infants whose tracings are invariant—lacking spontaneous lability or stimulus-provoked state changes—usually harbor an encephalopathy.

SPECIFIC COMPOSITION OF THE ELECTROENCEPHALOGRAM

The EEG background refers to the collective presence of all ongoing moment-to-moment cerebral electrical patterns. The background can be high or low voltage, continuous or discontinuous, normal or abnormal. The prevailing *ingredients* ("graphoelements") that collectively constitute the background emerge and fade at different CAs. The background may be considered a foundation or infrastructure. It serves as a stage that is punctuated by short-lived transients, such as sharp waves, or fleeting events, such as electroencephalographic seizures.

During the perinatal period, the infrastructure of the signal is normally dominated by slow activity (θ and Δ). With maturity, the frequency of the dominant rhythms increases, with a gradual evolution to higher frequencies.

Many of the specific patterns that make up the EEG background exhibit spatial or state-dependent properties, or both (Table 164-5). For example, bursts of monorhythmic θ activity are spatially maximal in the temporal-occipital regions but are independent of state. Sleep spindles exhibit both spatial and state specificity. They originate from the midline vertex-rolandic regions and are confined to quiet sleep.

Monorhythmic Occipital Δ Activity

The posterior regions of the healthy premature baby are dominated by runs of high-voltage, positive-polarity, slow, bioccipital monorhythmic Δ activity (Figure 164-18). The runs of Δ activity can last from 2 to 60 seconds and are often synchronously displayed bilaterally, although minor voltage asymmetries are common. This stereotyped Δ activity serves as the most visible dominant posterior rhythm in this age group. It is present in the youngest viable premature infant, peaks between 30 and 33 weeks of age, and clearly begins to recede by 34 weeks of age. It serves as the Δ constituent of occipital brush activity (see the discussion on Δ brushes). It is a hardy rhythm; sometimes it is among the last of the "named" EEG background patterns to disappear after a significant encephalopathy.

Central-Temporal Δ Activity

The central and central-temporal regions in the young premature infant show sustained trains of semirhythmic Δ activity that is not nearly as bilaterally synchronous as the monorhythmic occipital Δ activity (Figure 164-19). It also serves frequently as the Δ foundation for rolandic brush formation. It also fades from the background by 34 weeks of age.

TABLE 164-5

Summary of General Organization of Electroclinical States

Parameter	27-28 Weeks CA	29-30 Weeks CA	31-33 Weeks CA	34-35 Weeks CA	36-37 Weeks CA	38-40 Weeks CA	41-49 Weeks CA
Behavioral states	Primordial; no difference in behavioral states	Some early behavior organized to suggest early states	Behavioral states easier to define; definite periods of AS/QS	Well-defined states	Well-defined states	Well-defined states	Well-defined states
Continuity/ discontinuity	Entirely discontinuous	Relatively more continuous during AS	Sustained continuity while awake/ASTD; mostly QS, a little in AS 60%	Continuous in awake/AS; TD in QS only	Well-defined TA; traces of CSWS	TA/CSWS	By 1 mo, AS and QS continuous
Synchrony	80%–90%	50%	60%	70%	80%	100%	
Specific EEG patterns							
Rhythmic occipital Δ	+	++	+++	±	—	—	—
Rhythmic temporal θ	+	++	+++	±	—	—	—
Rhythmic occipital θ	++	++	+	±	—	—	—
Δ brushes	+	++ AS > QS	++ AS > QS	+ QS > AS	+ QS > AS	± QS AS	± QS only
Irregular central temporal Δ	+	++	+	—	—	—	—
Anterior dysrhythmia (encoches frontales)	—	—	±	+	++	++	±
Sleep spindles	—	—	—	—	—	—	— (+ after 44 weeks)
Reactivity	Inconsistent	Inconsistent	Variable	Usually present	Reliably present	Present	Present
Concordance	Poor; awake and asleep EEG are similar	Poor; awake and asleep EEG are similar	Fair; EEG relatively continuous during behavioral AS	Good	Good	Good	Good

AS, Active sleep; *CA,* conceptional age; *CSWS,* continuous slow wave sleep; *EEG,* electroencephalogram; *QS,* quiet sleep; *TD,* tracé discontinu; *TA,* tracé alternant; +, present; ++, abundant; —, absent; ±, variably present.

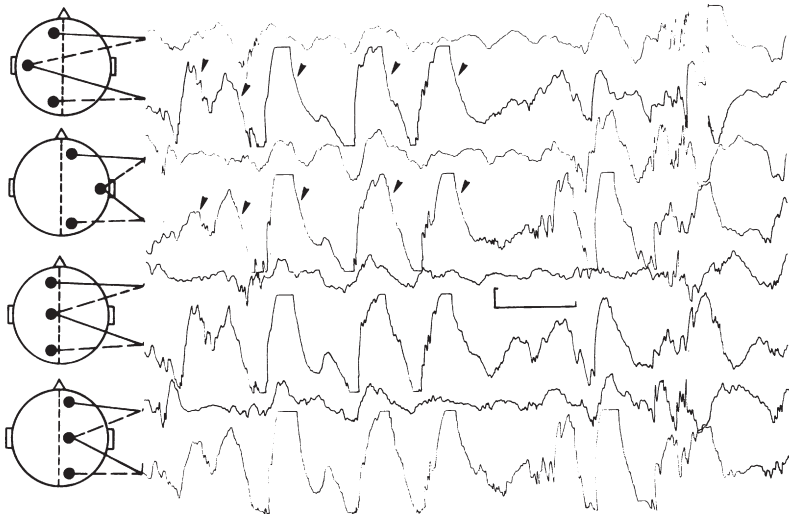

Figure 164-18 Monorhythmic occipital Δ-activity. This electroencephalogram (EEG) segment was recorded from an awake 32-week estimated gestational age (EGA) infant. During this relatively continuous segment, the EEG background is dominated by high-amplitude rhythmic occipital Δ-activity (*arrowheads*). Note that the occipital δ-activity on the left arises at the same time (synchronously) with the occipital Δ-activity on the right.

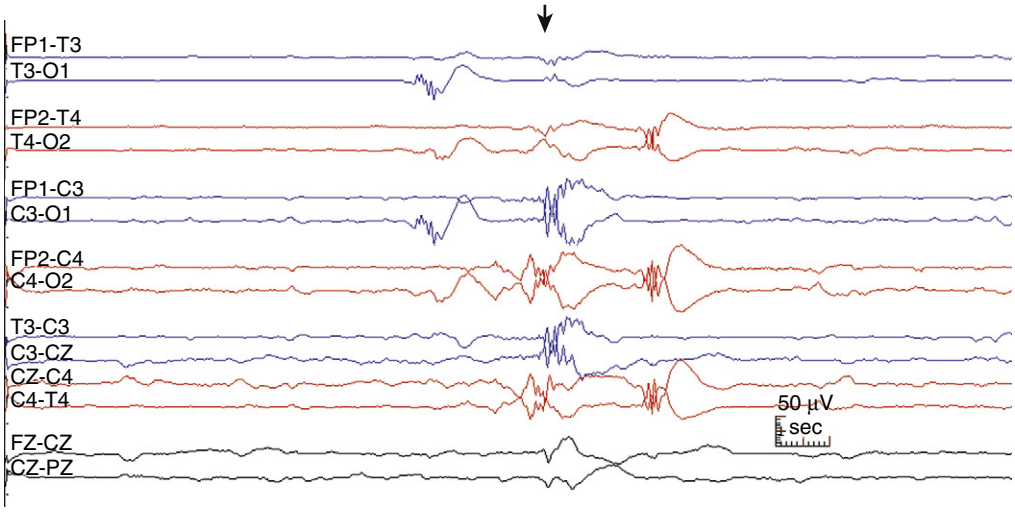

Figure 164-19 Central-temporal Δ-activity. Electroencephalogram (EEG) segment recorded from a sleeping 5-day-old (28-week estimated gestation age [EGA]) infant. Note the series of surface-positive, semirhythmic Δ-transients that are maximal in the central regions *(C_3* and *C_4)*. Many of these are also incorporated into delta brushes.

Rhythmic θ Activity (Sawtooth θ)

Short bursts of very rhythmic θ activity arise in the occipital regions of the premature baby less than 30 weeks of age (Figure 164-20, *A)* and in the temporal-occipital regions in premature infants 30 to 34 weeks of age (Figure 164-20, *B).* It occurs in all behavioral states. Although rhythmic, the waveform may be sharply contoured. The duration of the burst is variable and may last several seconds. If the burst is very brief, a "larval" discharge can occur, resembling a fragment of sharply contoured activity, and mimic "potentially epileptiform activity" in the temporal areas.

Brushes (Δ Brushes, Spindle-Like Fast Rhythms, Ripples of Prematurity)

The quintessential waveform of prematurity is the Δ brush, a pattern that represents the simultaneous fusion of two subunits: an underlying Δ transient and a superimposed, rhythmic, fast activity. Brushes occur during wakefulness, active sleep, and quiet sleep. They are not analogous to or the precursor of the conventional sleep spindle (σ rhythm). Usually no major asymmetries in brush abundance (the number of brushes per hour) occur compared between homologous regions of the two hemispheres.

In the very premature infant, brushes are more common in the rolandic regions[59] (Figure 164-21). When they obtain the highest expression (32 to 34 weeks CA), brushes are seen in the occipital, rolandic, and temporal regions. Frontal brushes are relatively rare at any age.

Even though brushes occur in all states, their abundance is state-dependent. Up to 34 weeks CA, brushes appear more frequently in active sleep than in quiet sleep.[86] By 34 to 36 weeks CA, the number of brushes in quiet sleep exceeds those in active sleep. By term, brushes are infrequent during wakefulness and may only be seen in quiet sleep, especially tracé alternant. By 1 month after term, brushes have largely vanished as greater maturity emerges.

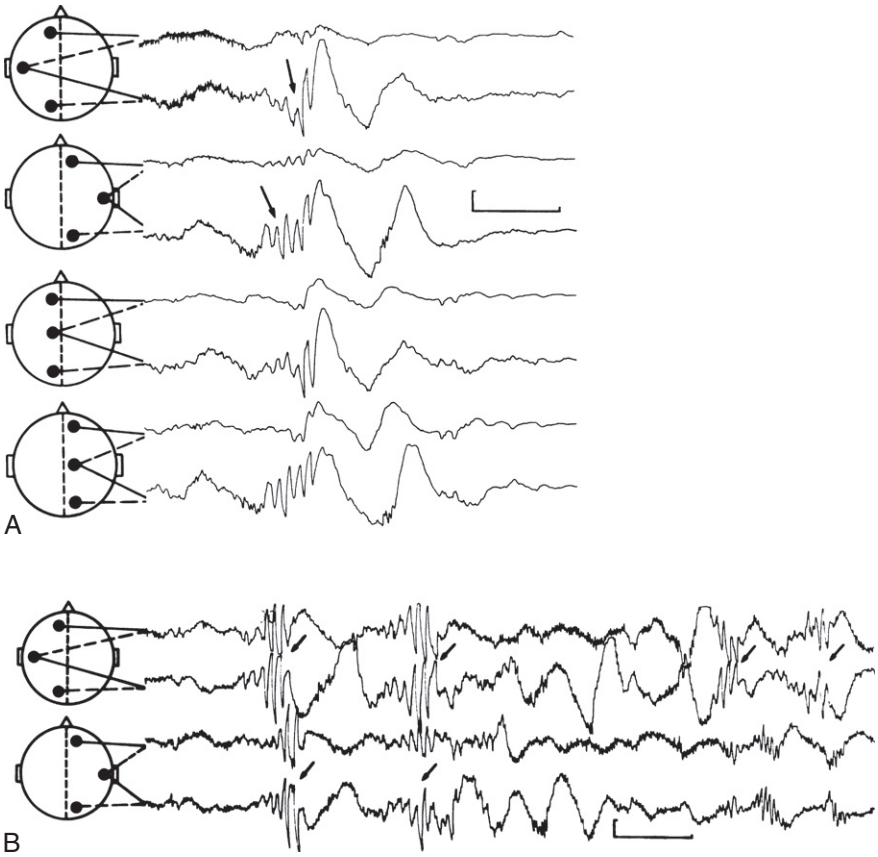

Figure 164-20 Rhythmic θ activity. A, This segment was recorded from a 3-day-old (27-week estimated gestational age [EGA]) premature infant in indeterminate sleep. Notice the appearance of rhythmic bioccipital θ activity (*arrows*) superimposed on high-amplitude monorhythmic bioccipital Δ activity. **B,** Same patient 2 weeks later. The rhythmic θ activity has largely migrated anteriorly and now principally engages the temporal regions (*arrows*). Rhythmic temporal θ activity is frequently asynchronous between the two temporal regions.

Anterior Dysrhythmia (Anterior Slowing)

Brief bursts of high-amplitude, relatively symmetric, and synchronous bifrontal rhythmic Δ activity begin between 33 and 34 weeks CA (Figure 164-22). Despite the usual pathologic connotation of the prefix *dys-*, this pattern is entirely normal. Anterior dysrhythmia appears in all states but is most abundant in transitional sleep preceding quiet sleep. In this context it behaves as a "drowsy pattern." It is also common during quiet sleep but comparatively infrequent in alert wakefulness or dream sleep. Anterior dysrhythmia usually begins to disappear by 1 month after term. Although it is a normal pattern, excessive anterior dysrhythmia is abnormal and may be seen in the setting of a mild diffuse encephalopathy.

Encoches Frontales (Frontal Sharp Waves)

The pattern of encoches frontales consists of a biphasic (negative-positive polarity), notched frontal sharp wave that is inextricably entwined with anterior dysrhythmia[88] (see Figure 164-22). Indeed, the two patterns often comingle and seem harmonically related, implying they share a common neural generator. They are frontally dominant and usually synchronous and symmetric between the left and right frontal regions. Like anterior dysrhythmia, they first appear in immature form at 33 to 34 weeks CA and in complete form by 35 weeks CA. They start to wane by 1 month after term and decay in parallel with anterior dysrhythmia (Figure 164-23).

During mild encephalopathies, encoches frontales mildly increase in frequency, and their morphologic characteristics become more variable. Sometimes the pattern shows a sharper (i.e., briefer duration) morphologic appearance. Encoches frontales convey no

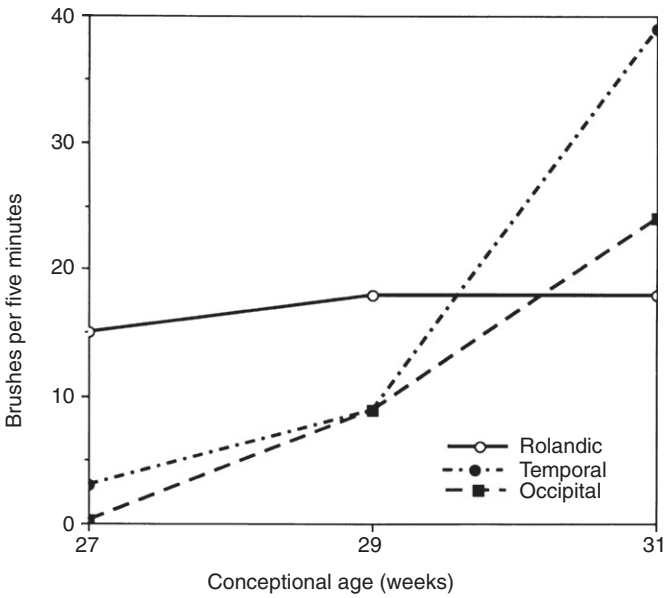

Figure 164-21 Brush abundance. The abundance of brushes is a function of both maturity and location. The graph depicts the abundance (number of brushes/5 minutes of electroencephalogram [EEG] background) seen in the occipital, temporal, and rolandic regions at 27, 29, and 31 weeks conceptional age.[59]

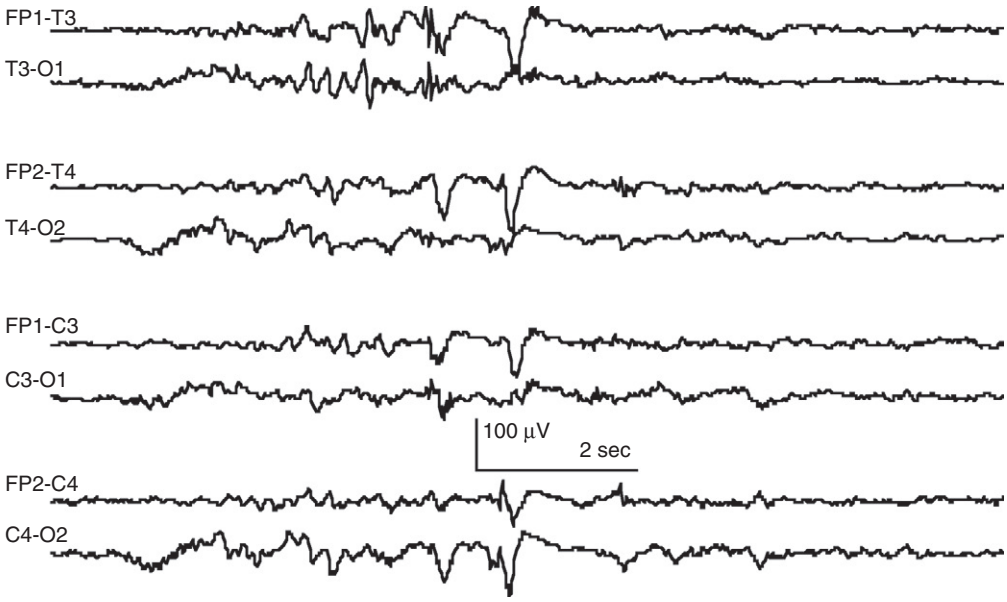

Figure 164-22 Anterior dysrhythmia (frontal delta) evolving into an encoches frontales (physiologic frontal sharp wave) in a quietly sleeping 3-day-old (33-week estimated gestation age [EGA]) infant. Encoches frontales are recognized as synchronous and symmetric biphasic (negative-positive) bifrontal sharp waves. This pattern often appears simultaneously (i.e., synchronously). Frontal sharp waves are most abundant during drowsiness and in quiet sleep and are least evident during alert wakefulness. Sometimes these normal sharp EEG transients are mistaken as "epileptiform" by inexperienced electroencephalographers.

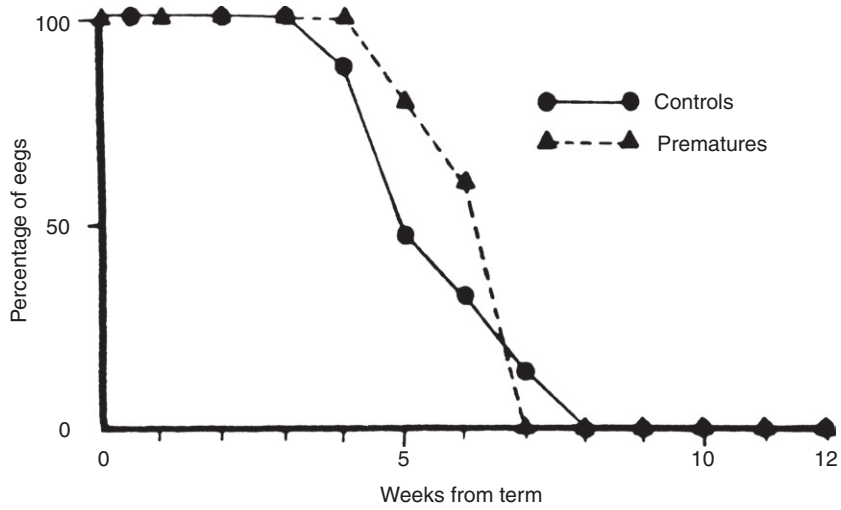

Figure 164-23 Encoches frontales. Proportion of electroencephalograms (EEGs) showing frontal sharp transients in premature and full-term infants. *(From Ellingson RJ, Peters JF: Development of EEG and daytime sleep patterns of low risk premature infants during the first year of life: Longitudinal observations,* Electroencephalogr Clin Neurophysiol *50:165, 1980.)*

implication for epileptogenesis. They are an expected normal EEG signal and do not connote a "lowered seizure threshold."

Other Sharp Waves

Healthy babies have occasional sharp EEG transients in the temporal,[89] central, and occipital regions (Figure 164-24). These transients are most abundant between 37 and 42 weeks CA, gradually decline in abundance by 4 to 6 weeks after term, and entirely vanish from the background by 10 weeks after term[90] (Figure 164-25). They are most common in the temporal areas. They are usually sharp waves rather than spikes, arise solitarily rather than in bursts or consecutive runs, and recur with a frequency of about one sharp EEG transient/minute of active sleep (Table 164-6).

Sleep Spindles

By 44 to 46 weeks CA, quiet sleep sheds its immature tracé alternant pattern and establishes its mature foundation as continuous slow-wave sleep. Sleep spindles (12 to 14 Hz) then appear from the midline vertex (C_z) or the central regions (C_3 and C_4)[65] (see Figure 164-12). Sleep spindles are often asynchronous between the two hemispheres and remain so until 2 years of age.

Dominant Rhythmic Patterns of Early Infancy

Soon after the healthy infant leaves the neonatal period, the organization of the EEG begins to resemble, at least in principle, that of the young child. In early infancy, poorly sustained rhythmic activity first emerges in the occipital and rolandic regions (Figure 164-26). The rhythmic occipital patterns are the precursor

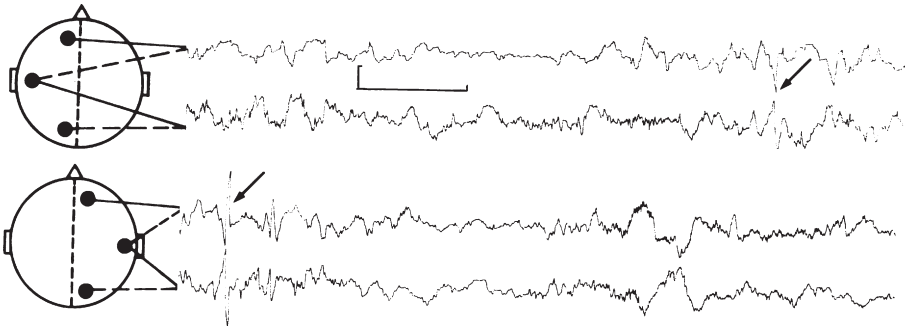

Figure 164-24 Normal sharp electroencephalogram (EEG) transients. This segment was recorded from a healthy, 3-day-old, full-term infant during active sleep. Occasional sharp EEG transients (SETs) are recorded independently from the temporal regions (*arrows*).

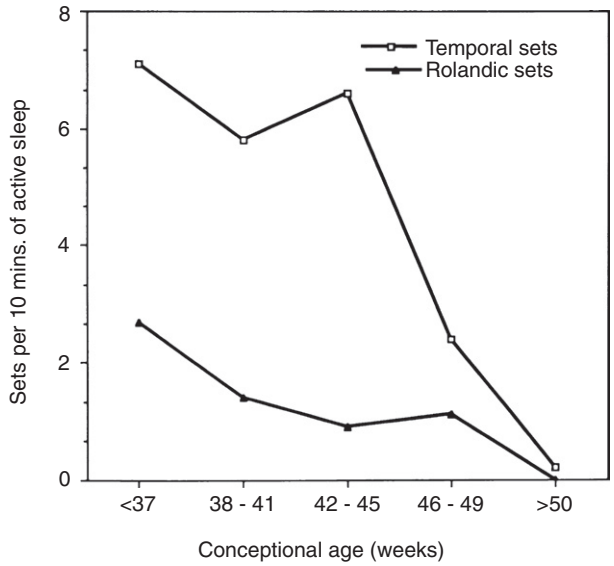

Figure 164-25 The graph depicts the abundance of sharp electroencephalogram (EEG) transients (SETs) in the temporal and central regions during 10 minutes of active sleep. Notice that there are more SETs in the temporal than in the central regions at all ages studied. There is a gradual decline in the frequency of SETs until these patterns disappear from the record near 50 weeks conceptional age.

TABLE 164-6

Comparison of Sharp Electroencephalogram Transients Recorded in Healthy Infants and Those With Confirmed Electroencephalogram Seizures

EEG Parameter	Healthy Infants	Infants with Seizures
Background	Normal	Frequently abnormal
SET abundance	Total SETs from left and right central and temporal regions are maximum near term and recur about 1 SET/1.0 min to 1 SET/1.5 min	
Morphologic characteristics	Usually sharp waves (rarely spikes)	Spikes or sharp waves
Repetitive behavior	Isolated, solitary transients	Solitary; runs or bursts of SETs
Pattern of spatial distribution	Temporal > central > occipital during active sleep; no striking asymmetry between left and right hemispheres	Asymmetries may be present between left and right temporal, left and right central, or left and right hemispheres

EEG, Electroencephalogram; *SETs,* sharp EEG transients.

of the α rhythm. The slow frequency (<8 Hz) of this dominant occipital rhythm precludes labeling it as "true" α, but its location and reactivity to visual stimuli earmark it as an immature version of the genuine article. The frequency of this pattern gradually increases until it is 8 Hz or faster (usually by age 2 years), at which time the label "α rhythm" can be employed with full justification.

Similarly, runs of central rhythmic patterns appear that resemble an immature μ rhythm, the idle rhythm of the motor cortex. This μ rhythm precursor tends to be about 0.5 Hz faster than its corresponding α precursor in each individual and is 8 Hz or faster by age 2 years.

Abnormal EEG Patterns

Newborn infants are exposed to a wide variety of potentially CNS-damaging events. The EEG, a sensitive reflection of cerebral cortical activity, commonly displays an assortment of abnormalities, depending on the injury's severity and topography, and the patient's CA. Most EEG abnormalities are not specific for etiology. Consequently, the tracing does not reveal the cause of the abnormality but rather describes its presence, acuteness, location, and severity. Even though the EEG has little value in revealing the underlying basis of an infant's encephalopathy, it is considered an ideal prognostic indicator.[91-93] Table 164-7 shows common interpretative criteria for mildly, moderately or markedly abnormal EEG backgrounds for near-term and term infants,[94,95] Neonates with normal or only mildly abnormal EEGs generally survive and escape permanent brain damage. On the other hand, those with severe abnormalities, such as isoelectric or burst-suppression recordings, face high mortality and significant morbidity. Those with moderately abnormal EEGs have a mixed outcome: Some do well but others later exhibit a chronic static encephalopathy. The prognostic value of the EEG may be particularly important when the design of a neonatal neuroprotection intervention is contemplated. Infants with well-preserved EEGs (good prognosis) may not be suitable candidates for a protection trial because their outcomes are already favorable, even before the research intervention or placebo. Those with marked EEG abnormalities (dismal prognosis) may be so profoundly injured that they are beyond the reach of benefit from trial enrollment. Those with moderate EEG abnormalities could "go either way," and the balance might be favorably tipped by help from a neuroprotection intervention.

Clinical seizures are among the most common reasons for neonates to undergo an EEG examination. It is a challenge for all involved in the care of neonates to distinguish epileptic-based neonatal seizures from the wide array of nonepileptic "paroxysmal" behaviors, which may occur in healthy or sick infants. A brief discussion of pathologic EEG "sharp waves" and electrographic neonatal seizures follows.

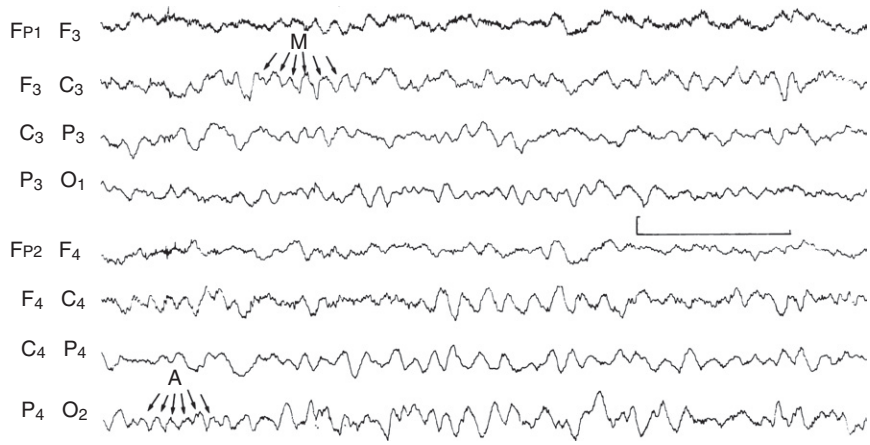

Figure 164-26 Precursors of μ and α rhythms. This electroencephalogram (EEG) segment was recorded from an awake, alert, and quiet 5-month-old infant. Notice the appearance of rhythmic Δ activity in the central regions that are the precursor of μ activity *(M)*. In the occipital regions, rhythmic θ activity is also noted *(A)* and is the precursor of α activity.

TABLE 164-7

Criteria for Conventional EEG Background Interpretation

Interpretive Criteria Near-Term*	Normal	Mildly Abnormal Background	Moderately Abnormal Background	Markedly Abnormal Background
Continuity				
Continuous segments	Mostly continuous in awake (W) and active sleep (AS) states	Continuous in W and AS states	Small percentage of the EEG is continuous	Little or none of the EEG is continuous
Discontinuous segments	Interburst intervals (IBIs) <4 secs in quiet sleep (QS)	IBIs range from 4 to <7 secs in QS	IBIs range from 7 to <15 secs	IBIs ≥15 secs
Amplitude	W or AS: 25-50 μV (p-p)†	W or AS: 25-50 μV	W or AS: 5-15 μV	< 10 μV ("depressed and undifferentiated")
	QS: burst amplitude >50-100 mV	QS: burst amplitude >50-100 mV	QS: 10-25 μV "persistent low voltage"	Some IBIs <2 μV
	QS: amplitude of the IBIs ≥25 μV	QS: amplitude of IBIs <25 μV	Some IBIs <5 to 10 μV	All EEG <2 μV ("isoelectric")
Symmetry	Symmetric	Symmetric	May be asymmetric‡	May be asymmetric
Synchrony	In QS, the bursts of discontinuous portions of EEG are nearly 100% syncronized§	In QS, a few of the bursts may not be syncronized	May show persistent asynchrony in the discontinuous segments of the EEG	May show persistent asynchrony in the discontinuous segments of the EEG
State lability	Spontaneous cycling among W, AS, and QS states and reactive to external stimuli	States cycle spontaneously and react to external stimuli	Poor state differentiation and modest clinical and EEG response to external stimuli	No recognizable states; ("undifferentiated") little or no EEG response to external stimuli
EEG composition graphoelements	Rich variety of frequencies and specific, named patterns such as "delta brushes"	Rich variety of frequencies and specific, named patterns such as "delta brushes"	Poorly developed background with paucity of features	Poverty of all background patterns with few or no specific graphoelements such as "delta brushes"

Modified from Shellhaas RA, Gallagher PR, Clancy RR: Assessment of neonatal electroencephalography (EEG) background by conventional and two amplitude-integrated EEG classification systems. *J Pediatr* 2008:153, 369.

*Near term is defined by a conceptional age of 34 to < 37 weeks; term is a conceptional age from 37 to 44 weeks.

†All voltages presented as peak-to-peak (p-p) values.

‡Asymmetry is present if the ratio of the amplitudes of two homologous brain regions is > 2:1.

§Bursts are synchronized if there is less than 1.5 seconds separating their onset between hemispheres.

Pathologic Sharp Waves

Many forms of sharp waves are an expected, normal feature of the EEG background. However, certain characteristics may render them pathologic[96] (Figure 164-27). For example, contrast the usual behavior of normal temporal sharp waves with pathologic sharp waves recorded *between* seizures in a sick neonate (see Table 164-6). The latter transients are often faster (duration ≤ 100 msec), more abundant, and repetitive and may be unusually distributed spatially in a highly localized fashion. Many times, EEGs recorded to "rule out" seizures in a newborn are not fortuitous to actually capture a seizure in progress. Such interictal tracings may still provide evidence that the patient has a "lowered seizure threshold" by revealing an excessive number of negative-polarity spikes and sharp waves. The EEG spikes or sharp waves are not direct proof of seizures but certainly are consistent with their presence.

Positive-polarity sharp waves are different pathologic EEG transients that do not imply a lowered seizure threshold[97,98] (Figure 164-28), but rather are a marker for injury to the deep

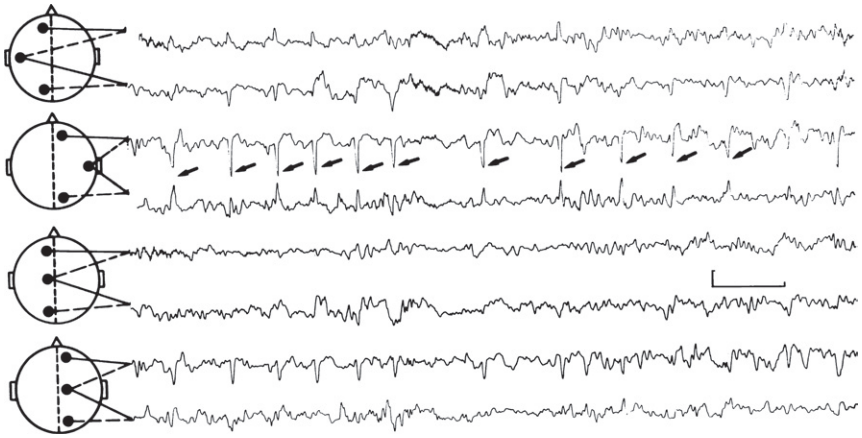

Figure 164-27 Abnormal sharp electroencephalogram (EEG) transients. EEG segment recorded from a 1-week-old (37-week estimated gestational age [EGA]) infant with meningitis and seizures. This segment was recorded between electrographic seizures. Note the excessive abundance of sharp EEG transients (*arrows*), which are virtually entirely confined to the right temporal region except for mild spread into the adjacent rolandic area. This type of electrographic abnormality suggests a lowered seizure threshold and is not usually seen in healthy infants.

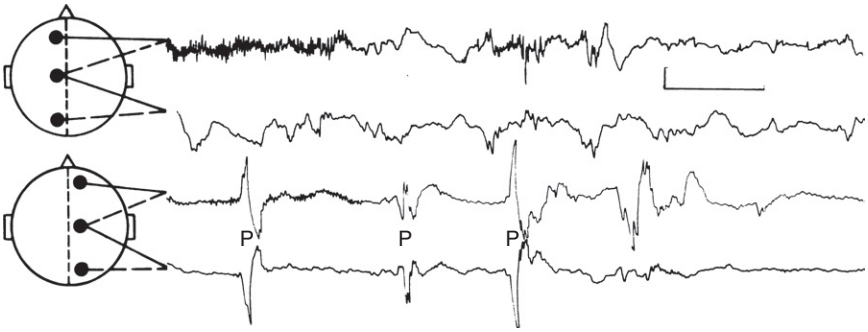

Figure 164-28 Positive rolandic sharp waves. This electroencephalogram (EEG) segment was recorded from a 2-week-old (28-week estimated gestational age [EGA]) infant with a right-sided grade IV intraventricular hemorrhage. On subsequent cranial ultrasound examinations, periventricular leukomalacia was noted on the right. Positive rolandic sharp waves *(P)* are seen as definite sharp EEG transients of positive polarity, which are clearly distinguished from the background activity.

cerebral white matter, such as periventricular leukomalacia. They are usually seen in the midline vertex or rolandic region but can also arise in the temporal areas.[99]

Seizures

In contrast to an isolated sharp wave, which is a fleeting transient EEG pattern, an electrographic neonatal seizure (ENS) unfolds as an *event* with a distinctive beginning and end (Figure 164-29). A typical ENS lasts about 2 minutes and arises focally from a restricted cortical region.[100,101] The knowledge of the relationship between clinical and electrographic seizures has changed over the years, aided by the emergence of video-EEG monitoring. Whereas a routine bedside EEG examination does not capture video and may miss ENSs in a 45-minute recording session, longer-term video-EEG monitoring may be more revealing in evaluating many neonates with seizures.

The valuable role of video-EEG monitoring for characterizing neonatal seizures was established by Mizrahi and Kellaway,[102] who analyzed video-EEGs from 349 neonates between ages 28 and 44 weeks CA with a clinical suspicion of seizures. In 71 patients, 451 paroxysmal clinical events were recorded, but only 29% of the clinical events in 23 patients had a close temporal association with electrographic seizure activity. In other words, some of the abnormal clinical "seizures" were not *epileptic*, but rather a type of abnormal brain stem release or postural reflex. Conversely many electrographic seizures occurred that were not accompanied by any clinical signs of seizure. Such ENSs, termed subclinical or occult, have been identified in other populations. A recent large series from the Neonatal Seizures Clinical Research Centers[103] described 207 infants with video-EEG confirmed seizures. One third of the infants demonstrated only subclinical ENS: Despite the definite electrographic seizures, no obvious clinical seizure occurred at the same time. In 10%, all the patients' abnormal-appearing "seizures" were not accompanied by ENS, even though the EEG background was often seriously abnormal, reflecting their acute encephalopathies. Finally, half of patients had one or more electroclinical seizures that feature simultaneous clinical and electrographic seizures. The clinical events in these instances of electroclinical seizures were frequently recurrent, focal, *clonic* twitching of the face, trunk or extremities.

The hallmark of ENSs is the sudden appearance of a repetitive discharge event containing a definite beginning, middle, and end. ENSs evolve in frequency, morphology, and amplitude. Although no two ENSs appear identical, a few simple criteria aid in their recognition:

(1) An individual ENS arises from a specific focus. ENSs are rarely, if ever, "generalized" (affecting all brain regions in an organized, synchronized, and symmetric fashion). However, after an ENS originates at its focus, it is free to spread or migrate to other locations.

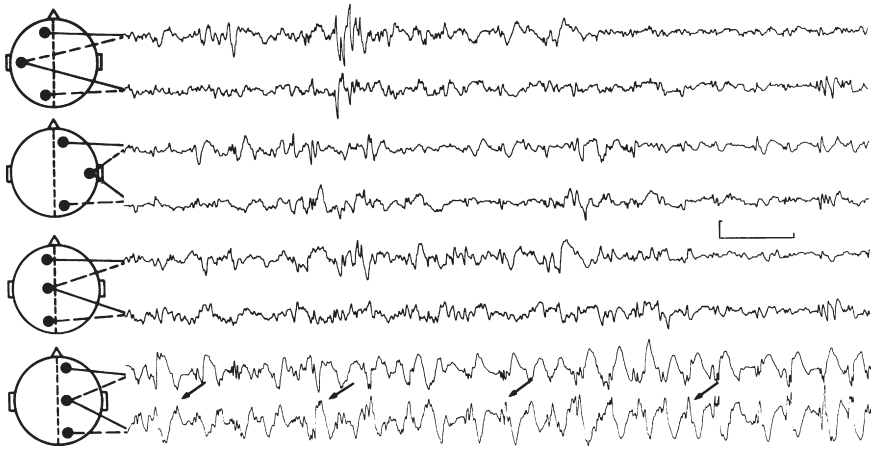

Figure 164-29 Electrographic seizure. This segment was recorded from an asphyxiated 1-day-old full-term infant. An electrographic seizure is in progress (*arrows*).The electrographic seizure is an event with a characteristic evolution of repetitive, stereotyped, rhythmic waveforms or spikes/sharp waves that replace the underlying background rhythms locally. During this particular electrographic seizure, no clinical signs were exhibited by the asphyxiated infant.

(2) The minimum duration of an ENS is conventionally defined as 10 seconds. Most ENSs are shorter than 2 minutes, but it is common to observe multiple, serial, brief ENSs.
(3) The specific shape or morphology of the waveforms that make up the ENS varies widely within and between neonates (see Figure 169-29). Any EEG frequency (e.g., theta activity) may compose the seizure. However, the morphology and amplitude of the ENS evolve; the end of the seizure looks different in amplitude and shape from the beginning.

Laroia and colleagues[104] suggested a strategy to target high-risk neonates for video-EEG monitoring. In their study, 51 neonates with specific intensive care unit admission diagnoses (e.g., asphyxia, meningitis) had a 30 to 60 minute screening EEG, followed by continuous EEG monitoring for 18 to 24 hours. The initial EEG background at admission was classified as normal, immature for age, or mildly, moderately, or severely abnormal. Only 1 of 24 infants (4.2%) with normal or immature EEG backgrounds had subsequent ENS. However, 22 of 27 infants (81%) with abnormal EEG backgrounds had ENS. Thus the initial EEG background significantly predicted the presence or absence of seizures in the subsequent 18 to 24 hours.

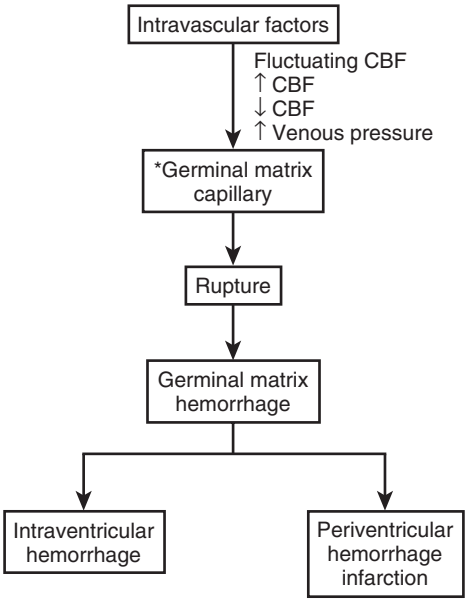

Figure 165-1 Schematic depicting the important vascular changes in the pathogenesis of intraventricular hemorrhage. *Both vascular factors (i.e., involving capillary bed) and extravascular factors (i.e., poor vascular support) likely contribute in the pathogenesis of IVH.

vary has not been determined for newborn infants. Because systemic blood pressure is lower in newborn infants than in older children or adults, the range of pressures at which CBF is constant is expected to be lower than in adults. In newborn animals, the range of blood pressures at which CBF is constant is lower than in adult animals.[20,21] More importance, in fetal lambs, resting blood pressure is only slightly higher than the lower limit of the autoregulatory curve.[21] If a similar situation existed in newborn infants, moderate hypotension would result in reduced CBF and possible ischemic brain injury.

Increasing evidence suggests that the autoregulatory response is intact in human neonates who are experiencing mild asphyxiation or respiratory distress. Thus, in several studies in preterm infants with normal brains, CBF is unaffected by fluctuations in mean arterial blood pressure within the physiologic range of 25 to 60 mm Hg.[22-25] These observations were consistent for infants of various gestational and postnatal ages. By contrast, Lou and colleagues[26] concluded that CBF was impaired in distressed asphyxiated newborns—that is, CBF was significantly related to systolic blood pressure. The conclusions presented by these investigators have been questioned, however, because the study group was heterogeneous with regard to gestational age and birth weight, and some infants had an elevated $Paco_2$ at the time of study.[27] In support of this concern in a recent study using the Doppler technique, the autoregulatory slope was found to increase with progressive increase in Pco_2, suggesting that the cerebral circulation becomes pressure-passive with hypercapnia.[8] Earlier Doppler measurements of flow velocity suggested poorly developed pressure autoregulation in the very premature infant.[28] The limitations of the Doppler technique in this regard are discussed further on.

Systemic Factors and Cerebral Blood Flow

Effect of Carbon Dioxide Tension

The cerebral vessels react to both $Paco_2$ and blood pH. Carbon dioxide has a marked relaxant effect on cerebral vascular muscle, and changes in $Paco_2$ produce a significant change in CBF. Moderate hypocarbia leads to a reduction in CBF, and moderate hypercarbia leads to an increase in CBF without changes in cerebral oxidative metabolism.[29-31] If the $Paco_2$ falls to less than 15 to 20 mm Hg, the reduction in CBF is associated with mild reduction in cerebral oxidative metabolism.[32] Although chronic severe hypercarbia elevates CBF, cerebral oxidative metabolism is not altered. Acute elevations in $Paco_2$, however, may depress cerebral metabolism.[33] Most importance, hypercarbia abolishes the autoregulatory response because of marked vasodilation, and in the premature infant, this effect, not influenced by postnatal age, is noted as the Pco_2 values increase progressively above 45 mm Hg.[8] This disturbance may add to the risk of hemorrhagic brain injury.[34,35]

The cerebral vessels of fetal and newborn animals are responsive to acute changes in $Paco_2$, although the reactivity varies as a function of postnatal age and sickness. As reported in two different studies, spontaneously breathing preterm infants demonstrated appropriate CBF-$Paco_2$ reactivity shortly after birth[22,36] whereas the reactivity was significantly less in mechanically ventilated preterm infants also studied in the first hours of life.[36] In the latter group of infants, CBF-$Paco_2$ reactivity on the second postnatal day was similar to that observed in adults.[36] Attenuated CBF-$Paco_2$ reactivity similarly has been noted in ventilated newborn animals in the immediate postnatal period.[32,37] The mechanism accounting for this attenuated CBF-$Paco_2$ reactivity is unclear, and it is considered perhaps to be a consequence of the hypercapnia state in utero.[23]

Effect of Arterial Oxygen Content

Arterial hypoxia produces cerebral vasodilation and increases CBF.[38,39] The effect of hypoxia is related directly to Cao_2, and not directly to arterial oxygen tension (Pao_2). Cao_2 is determined by the hemoglobin (Hb) concentration in the blood, that is, the oxygen affinity of the Hb and Pao_2. Thus mild to moderate reductions in Pao_2 that are associated with little change in Cao_2 increase CBF only slightly. A reduction in Cao_2 produces a proportional increase in CBF such that cerebral oxygen delivery (CBF × Cao_2) does not change and cerebral oxygen metabolism is constant. The effects of Cao_2 have been studied in detail in experimental animals and in human adults, but data for newborn infants are limited. Both Pryds and Younkin and their colleagues[40,41] found an inverse relationship between CBF and hematocrit or Hb. The increase in CBF with a lower hematocrit or Hb presumably is the result of a reduced Cao_2, although Cao_2 was not measured in either study.

Effect of Blood Glucose

In adult humans, hypoglycemia of mild or moderate degree is not associated with a change in CBF.[42,43] During hypoglycemic coma, however, CBF increases.[44] In experimental animals, CBF increases during hypoglycemic coma and correlates with a loss of electrical activity on the electroencephalogram.[45-48] The increase in CBF appears to result from increased systemic blood pressure and loss of autoregulation.[49] Thus, if the blood pressure is reduced during hypoglycemic coma, CBF returns to baseline.

Pryds and colleagues[50] reported increased CBF in preterm infants with hypoglycemia. CBF was significantly higher at 26 mL/100 g/minute in infants with blood glucose levels lower than 30 mg/dL than in those with blood glucose levels greater than 30 mg/dL, in whom CBF was only 11.8 mL/100 g/minute. None of the infants with low blood glucose levels exhibited clinical signs of hypoglycemia, nor did any progess to coma. Moreover, no abnormalities of the electroencephalogram were apparent. These data suggest that the response to hypoglycemia in preterm infants is different from that in adults. Furthermore, cerebral glucose metabolism may be critically important to provide the energy requirements of the preterm brain. These findings are in agreement with those for a study in which Altman and colleagues[51] reported that cerebral oxygen metabolism in some preterm infants may be minimal, and that cerebral glucose

metabolism may provide the necessary energy for preterm cerebral growth and function.

In summary, the newborn circulation shows many of the same characteristics as those of the adult circulation. The magnitude of the CBF responses and the quantitative relationships of CBF with changes in blood pressure and with a variety of systemic factors have not been fully elucidated. The relationship of these circulatory regulatory responses with the development of IVH and their role in its pathogenesis in sick preterm infants remain to be determined.

MEASUREMENT OF CEREBRAL BLOOD FLOW

Cerebral Arterial Blood Flow Velocity

Cerebral arterial blood flow velocity (CBFV) has been measured in the major intracranial arteries of the developing brain by the Doppler technique for many years. Although this technique does not measure CBF, it has certain advantages: It is both noninvasive and readily available at the bedside.

Principle

The ultrasound technique for the measurement of blood flow velocity makes use of the *Doppler effect*—that is, the frequency of sound waves reflected from a moving object is shifted by an amount proportional to the velocity of the object. When ultrasound studies are used for measurement of blood flow velocity, the sound waves emitted by the transducer are reflected, and their frequency is shifted by moving red blood cells.[52] The Doppler signals are directly related to the frequency of the transmitted ultrasound waves and to the cosine of the angle of incidence of the sound beam to the axis of blood flow, and they are inversely related to the velocity of the ultrasound waves in the tissue. For practical purposes, both the frequency of the transmitted sound waves and their velocity in the tissue are constant from one determination to another; thus, if the angle of incidence is held constant, blood flow velocity will be the main determinant of the Doppler frequency shift.

Attempts to *quantitate* arterial blood flow velocity have used determinations of the pulsatility index (PI) or the area under the velocity curve. The PI is calculated from the formula $PI = \frac{S - D}{S}$, where S is the peak systolic velocity and D is the end-diastolic velocity.[53,54] Changes in probe angle affect the values for S and D similarly, so the PI can be used to minimize the effect of changes in probe angle and to allow meaningful comparisons of serial determinations of CBFV. PI was described initially as a measure of peripheral vascular resistance in large systemic arteries; accordingly, in the current context, PI is assumed to reflect changes in cerebrovascular resistance. Serial measurements of PI also may reflect changes in cerebral perfusion as well as cerebrovascular resistance, especially if either the systolic or diastolic velocity changes individually. If, however, both systolic velocity and diastolic velocity change proportionately, serial determinations of the PI will not reveal a change in absolute flow velocity or tissue perfusion. To avoid this problem, determination of the area under the velocity waveforms (determined automatically by ultrasound machines) has been used. Two types of Doppler systems have been used in the study of the cerebral circulation: continuous-wave and range-gated Doppler systems.

Continuous-Wave Doppler Ultrasound

The continuous-wave system uses a bidirectional probe that is placed over the anterior fontanelle and is oriented toward the pericallosal artery (terminal branch of the anterior cerebral artery) as it courses over the genu of the corpus callosum; alternatively, the right or left middle cerebral artery can be insonated transcranially through the coronal suture. Maximum arterial pulsations of advancing flow are used for measurements.

Range-Gated Doppler Ultrasound

The pulse range-gated Doppler technique selectively detects blood flow in a certain area at a specific distance from the probe and usually is incorporated into a conventional ultrasound imaging instrument, and the vessel to be insonated can be visualized directly. This visualization provides the capability to determine the angle of insonation and to identify specific arteries (e.g., at the circle of Willis) to be insonated. Current technology, however, does not allow for the measurement of the cross-sectional area of the insonated artery, but if the resolution of the ultrasound instruments can be improved to provide this measurement, a major step toward measurement of total volume of arterial blood flow, rather than only velocity of arterial blood flow, will have been accomplished.

Other advantages of this technique are the capability to record the velocity profile of all moving red blood cells in the insonated artery and the capability to compute the instantaneous average blood flow velocity. Because blood flow through a vessel is related to the average velocity and not to the peak velocity, this advantage should help in estimating CBF in situations in which CBF and blood pressure change rapidly.

Relation of Cerebral Arterial Blood Flow Velocity to Cerebral Blood Flow

The degree to which CBFV reflects CBF is of considerable importance, because accurate measurement of CBF involves techniques that are complex, expensive, and invasive, whereas measurement of CBFV is a readily available, noninvasive bedside technique. By convention, CBF is measured as the volume of blood perfusing a mass of brain tissue per unit of time. The volume of blood flowing in a specified artery is related to the instantaneous average velocity of flow (not peak flow velocity) times the cross-sectional area of the vessel. Thus measurements of velocity and arterial caliber are essential to provide an estimate of CBF. If the mass of tissue perfused by a given artery and the cross-sectional area of the artery were to remain constant, CBFV would be the major determinant of CBF. However, both the vessel diameter and the mass of tissue supplied by a given artery may change under normal physiologic circumstances and in pathologic conditions. For example, during autoregulation, CBF is maintained constant over a broad range of perfusion pressures by mechanisms that include change in arterial diameter and resistance. Therefore flow velocity may change inversely relative to vessel diameter even though CBF is unchanged.

In summary, accurate calculation of CBF should be based on average (not peak) CBFV as well as arterial cross-sectional area. Measurements based only on peak CBFV may be misleading. In steady-state conditions in which arterial caliber does not change, such measurements may provide useful information. By contrast, under conditions of changing arterial blood pressure and CBF, estimation of CBF from peak arterial blood flow velocity is of uncertain value and may not reflect changes in CBF.[15]

Experimental Studies

Several studies have examined the relationship of CBFV with CBF in newborn animals and in the human newborn infant. In experimental animals, CBF was raised or lowered by altering $Paco_2$ or Co_2.[55-57] CBFV was measured in the anterior cerebral artery, and CBF was determined by either the microsphere technique or autoradiography. All studies were performed under steady-state conditions, and the results were based on measurement of peak, not average, CBFV. Arterial cross-sectional diameter was not measured but can be assumed to change little in the steady state. Changes in CBFV (i.e., systolic velocity, diastolic velocity, area under the velocity curve, and PI) were significantly related to a change in CBF. This result may have been anticipated, because blood flow velocity is one of the

major determinants of CBF. However, the degree of correlation in the preceding studies, as determined by the correlation coefficient (r), varied, ranging from 0.3 (PI) to 0.9 (area under the velocity curve). In the preceding examples, variation of the PI ($r^2 = 0.09$) accounted for only approximately 10% of the variation in CBF, whereas variation in the area under the velocity curve ($r^2 = 0.81$) accounted for approximately 80% of the variability of CBF.

Therefore changes in CBF produced experimentally are associated with a significant change in CBFV. Furthermore, changes in CBFV may account for up to 80% of the variability in CBF *under steady-state conditions.* Because the PI accounts for only approximately 10% of the variability of CBF (at least under the conditions studied), it is not prudent to use this index as a general indicator of CBF.

Studies in the Human Newborn

Attempts have been made to correlate CBFV with CBF in human newborn infants. Greisen and co-workers[58] compared CBF, measured by the xenon technique, with anterior cerebral artery and common carotid artery flow velocities. All arterial blood flow velocity variables measured were significantly related to CBF. However, the correlation coefficients ranged from 0.4 to 0.8, and diastolic flow velocity exhibited the highest correlation. A similar relationship was found in newborn infants by comparing anterior cerebral artery blood flow velocity with CBF in the frontal region (anterior cerebral artery distribution) measured with positron emission tomography (PET).[59] In 25 premature infants with various neurologic disorders (IVH, asphyxia, hydrocephalus), CBF measured with PET was significantly related to arterial blood flow velocity with a correlation coefficient of 0.7.

Clinical Studies of Cerebral Arterial Blood Flow Velocity and Intraventricular Hemorrhage

Changes in Cerebral Blood Flow Velocity with Respiratory Distress Syndrome and Its Complications

The Doppler technique has been used for many years to study the relationship of changes in the cerebral blood flow profile and the subsequent development of IVH. The most striking association noted was that between fluctuations in CBFV in infants with respiratory distress syndrome and IVH. Thus infants with fluctuations in CBFV in the first 24 hours were significantly more likely to experience IVH than those with a stable pattern of CBFV[60] (Figures 165-2 and 165-3). These fluctuations were attributed to the changes in intrathoracic pressure caused by the infant's breathing out of synchrony with the ventilator.[14] These critical observations led to a study designed to prevent IVH by eliminating the fluctuations in CBFV[56] (Figure 165-4). The infant's respiratory effort was abolished by muscle paralysis with pancuronium; this effect was associated in a significant reduction in IVH and, in particular, severe IVH.[61] Since these initial observations, several changes have evolved in neonatal care that have

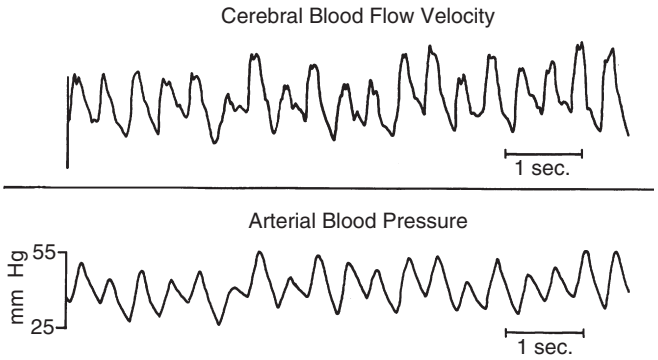

Figure 165-3 Fluctuating arterial blood flow velocity pattern and simultaneously recorded arterial blood pressure in a ventilated premature infant with respiratory distress syndrome. Marked fluctuations are apparent in systolic and diastolic flow velocity and blood pressure. *(From Perlman JM, et al: Reduction of intraventricular hemorrhage by elimination of fluctuating cerebral blood flow velocity in preterm infants with respiratory distress syndrome,* N Engl J Med *312:1353, 1985; reprinted by permission of the New England Journal of Medicine.)*

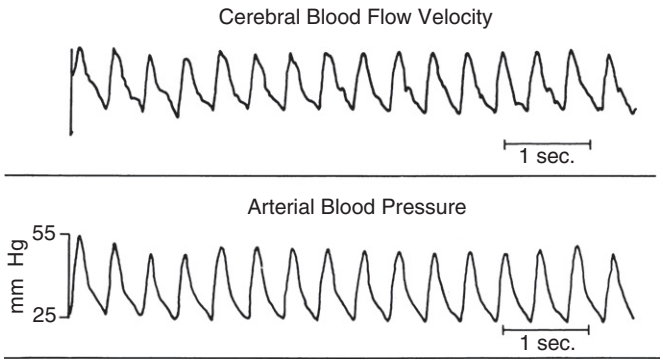

Figure 165-2 Stable arterial blood flow velocity pattern and simultaneously recorded arterial blood pressure in a ventilated premature infant with respiratory distress syndrome. Equal peaks and troughs can be seen in systolic and diastolic flow velocity and blood pressure. *(From Perlman JM, et al: Reduction of intraventricular hemorrhage by elimination of fluctuating cerebral blood flow velocity in preterm infants with respiratory distress syndrome,* N Engl J Med *312:1353, 1985; reprinted by permission of the New England Journal of Medicine.)*

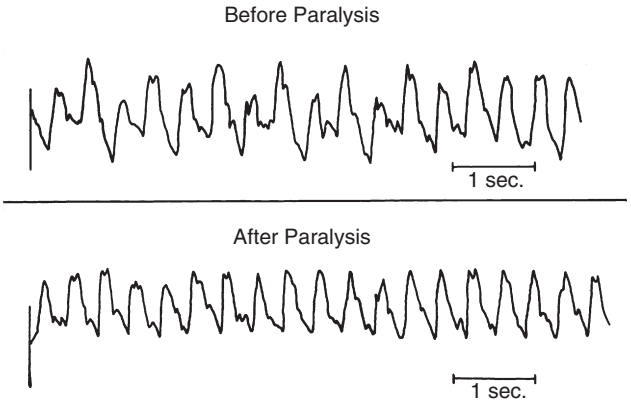

Figure 165-4 Effect of muscle paralysis on fluctuating cerebral blood flow velocity. After paralysis was induced by pancuronium, the fluctuating pattern was eliminated. *(From Perlman JM, et al: Reduction of intraventricular hemorrhage by elimination of fluctuating cerebral blood flow velocity in preterm infants with respiratory distress syndrome,* N Engl J Med *312:1353, 1985; reprinted by permission of the New England Journal of Medicine.)*

modified the impact of these perturbations in CBFV. First is the antenatal administration of steroids, which has been associated with a significant reduction in IVH, perhaps by stabilizing the germinal matrix capillaries.[9,61,62] The second such advance, in neonatal ventilator strategies, is synchronized mechanical ventilation, which has minimized the perturbations in cerebral blood flow.

Additional striking changes in CBFV have been observed in infants in whom IVH developed after pneumothorax.[63] These changes included a significant decrease in the PI, in large part accounted for by an increase in the diastolic flow velocity, which gradually returned to normal over the subsequent 36 hours after evacuation of the pneumothorax. The changes in CBFV were associated with significant changes in systemic blood pressure; that is, mean blood pressure and diastolic blood pressure increased significantly after evacuation of the pneumothorax. It is unclear whether these arterial changes, or alternatively, the increases in systemic venous pressure that have been shown to occur simultaneously in such infants, could have provoked hemorrhage.[64]

Cerebral Blood Flow Velocity Changes Under Other Circumstances

After Surfactant Replacement Therapy

As noted earlier, a strong association has been recognized among respiratory distress syndrome, fluctuations in CBFV, and IVH.[60] However, the introduction of surfactant replacement therapy with improvement in respiratory function has not been associated with a reduction in IVH.[65] The reasons for this unanticipated finding remain unclear. Cowan and co-workers[66] demonstrated acute changes characterized by a marked decrease in CBFV of 36% within 2 minutes after surfactant administration, with almost complete loss of the diastolic velocity pattern. The decrease in diastolic flow velocity is considered to be secondary to shunting across the patent ductus arteriosus (PDA) (see later). In another study, Jorch and associates[67] demonstrated continuous CBFV variability in treated infants, comparable with that seen in untreated infants, at 12-hour intervals after surfactant therapy.[67] Most recently, Kaiser and co-workers demonstrated a striking increase in mean CBFV of 75% ± 52% that peaked approximately 15 minutes after surfactant administration. These changes in CBFV were significantly associated with increasing P_{CO_2} ($P < .0001$) and were not related to changes in mean blood pressure.[68] The significance of these changes to the subsequent development of IVH in infants receiving surfactant therapy has not been determined.

Patent Ductus Arteriosus

Changes in CBFV have been observed in infants who develop symptomatic PDA characterized by a fall in the diastolic flow velocity that reflects the low systemic diastolic blood pressure[69] (a so-called steal phenomenon).

Endotracheal Suctioning

Marked changes in CBFV also may occur in association with routine procedures such as endotracheal suctioning.[70] In particular, a prominent increase in diastolic flow velocity has been documented. Concomitant increases in systolic, diastolic, and mean blood pressures also may be noted.

Summary and Implications

Changes in CBFV and blood pressure have been described in premature infants with respiratory distress syndrome or pneumothorax, after surfactant administration, in babies with PDA, and in association with routine neonatal procedures. In some instances, observed CBFV changes have had a temporal relationship with the subsequent development of IVH. The precise mechanism by which these changes lead to IVH is not clear. Moreover, the changes enumerated earlier have been observed in infants with these conditions in whom IVH did *not* develop. This finding suggests that additional factors are important in the genesis of IVH.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) refers to an optical technique that can provide information concerning changes in cerebral oxygen saturation, CBF and volume, cerebral venous oxygen saturation, and cerebral oxygen utilization in the brain.[71] The method is based on two principles: (1) Light in the near-infrared range of wavelengths between 700 and 1000 nm can pass through skin, bone, and other tissues relatively easily and illuminates approximately 6 to 8 cm of newborn brain; and (2) characteristic absorption bands of oxygenated and deoxygenated Hb and of the mitochondrial enzyme cytochrome oxidase are present in the near-infrared range. Changes in absorption bands can be used to monitor quantitative changes in the amounts of oxyhemoglobin (HbO_2) and deoxygenated Hb; total Hb (HbO_2 + deoxygenated Hb) is used as an indicator of blood volume. These changes also can be used to monitor the oxidation reduction state of cytochrome oxidase, a critical terminal enzyme of the respiratory mitochondrial electron transport chain, which facilitates electron passage to molecular oxygen for oxidative phosphorylation and adenosine triphosphate synthesis.

When the near-infrared beam is passed through the tissue, a decrease in signal intensity results from the absorbance of a particular chromophore in the medium. Thus a band of maximum absorption is present at approximately 810 nm for Hb, above which HbO_2 has greater light absorption and below which deoxygenated Hb has greater absorption. A much smaller peak at approximately 830 to 840 nm has been observed for cytochrome oxidase.

Instrumentation

The spectroscope typically contains diodes that serve as a source of near-infrared light.[72] The lasers are pulsed sequentially in a rapid on-off fashion. The light from the lasers is captured in glass fiberoptic strands grouped in a bundle. The end of the bundle is applied to the side of the infant's forehead, commonly against the parietal bone at a point equidistant from the anterior fontanelle and the external auditory meatus. The light traverses the head, where a second fiberoptic bundle attached to the opposite side of the head collects the transmitted light photons and conveys them to a photomultiplier tube. The signals are then amplified, expressed as a ratio of a reference signal, and changed into logarithmic form. To prevent interference from background illumination, the infant's head is wrapped in a light-tight bandage.

The attenuation of light by absorption is a measure of the concentration of the chromophore present. The relationship between the absorption and the concentration of the chromophore is best described by a modified Lambert-Beer law,[73] which, for the purpose of describing optical absorption in a highly scattered medium, can be expressed as follows:

$$\text{Absorption (OD)} = (a \times c \times L \times P) + G$$

where OD = optical density, a = extinction coefficient of the chromophore (mM × cm), c = concentration of the chromophore (mM), L = distance between the point of entry and exit (in centimeters), P = a path length factor accounting for scattering of light in the tissue, and G = a factor related to tissue and optode geometry. If L, P, and G are assumed to remain constant during a study, then changes in chromophore concentration can be expressed as follows:

$$\Delta C = \frac{\Delta OD}{aLP}$$

The chromophore concentration can be calculated because the extinction coefficient, a, has been determined for HbO_2, deoxygenated Hb, and cytochrome oxidase,[73,74] and the value of P in the

brains of premature infants measured after death has been determined by the time-of-flight method and found to be 4.39 ± 0.28 (SD). The latter determination is not straightforward, however, because of scattering of light within the head.[75] This scattering effect may be modulated by several factors including myelination, bone mineralization, and cell concentration. Moreover, path length factor *P* values differ for the various wavelengths used (775 to 903 nm), with a longer path length at shorter wavelengths.[76]

Clinical Application

Attempts have been made with NIRS to quantitate cerebral blood volume (CBV) and to measure CBF. Wyatt and colleagues reported a mean CBV value of 2.22 ± 0.40 (SD) mL/100 g in 12 newborn infants with "normal" brains who were born at 25 to 40 weeks gestation and studied at postnatal ages of 10 to 240 hours—similar to values obtained by PET[77,78] (see later). Mean CBV values were significantly higher at 3.00 ± 1.04 mL/100 g in 10 brain-injured infants ($P < .05$).[77] Similar CBV values were obtained in a subsequent study from the same investigators.[79] In clinical studies, increases in CBV have been observed in association with sharp increases in blood pressure and changes in $Paco_2$[80-83] (Figure 165-5). By contrast, an increase in CBV accompanied by a decrease in HbO_2 has been noted after endotracheal suctioning; under these conditions, the increase in CBV is consistent with elevated central venous pressure.[84] The response of CBV to $Paco_2$ has been shown to increase with advancing gestational age.[82]

Noninvasive measurement of CBF by NIRS uses the Fick principle by determining the rate of increases in cerebral HbO_2 after an increase in arterial oxygen saturation induced by a brief inhalation of oxygen.[85] The mean value of CBF obtained in the 13 premature infants, that is, 18 mL/100 g/minute, is comparable to values obtained by the xenon technique and by PET (see later).

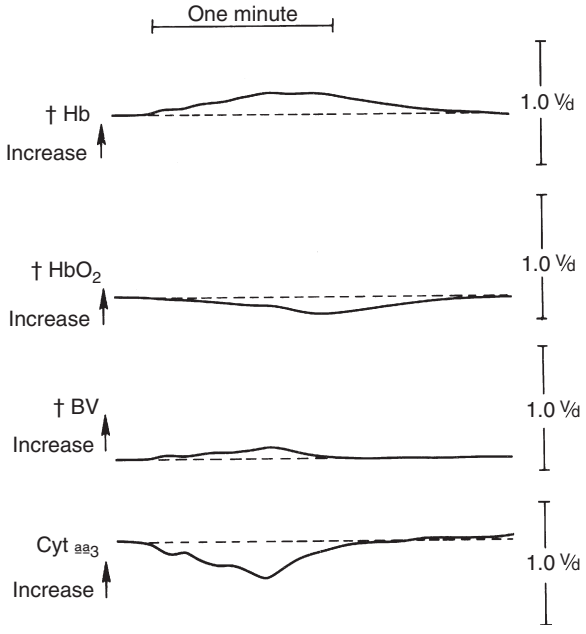

Figure 165-5 Typical response to decreased oxygenation: Oxyhemoglobin ($tHbO_2$) decreases, whereas deoxyhemoglobin (tHb) rises. An overall increase in blood volume (tBV) results, probably as a consequence of increased cerebral blood flow in response to hypoxia. Levels of cytochrome aa_3 (cyt a,a_3) decrease still further, concurrent with the decrease in oxyhemoglobin. *(From Brazy JE: Near infrared spectrophotometry. In Nelson NM, editor:* Current therapy in neonatal-perinatal medicine, *ed 2, Toronto, 1990, BC Decker, pp 439-444.)*

When estimations of CBF obtained using near-infrared spectroscopy were compared with those acquired using ^{133}Xe clearance techniques, a significant correlation was found between the two measurements: $r = 0.80$, $P < .001$ in one study[86] and $r^2 = 0.84$, $P < .001$ in a second study.[77] Certain methodologic problems need to be considered: The test-retest variability in the same subject is reported at 15% to 20%; and in one study, up to two thirds of the NIRS recording was unsuccessful because of inferior quality.[86] NIRS estimation of CBF may be significantly underestimated in the high flow range because of methodologic constraints.

Clinical Studies of Near-Infrared Spectroscopy and Intraventricular Hemorrhage

The relationship between CBF measured in the first 24 hours of life and IVH was determined in 24 premature infants.[87] Infants were divided into three groups on the basis of cranial ultrasound appearance: a group with normal findings, a group with minor IVH, and a group with moderate to severe IVH. Infants with any form of IVH had lower median CBF (7.0 mL/100 g/minute) than those without IVH (12.2 mL/100 g/minute). On subgroup analysis, those infants with severe IVH had the lowest CBF values (median 5.8 mL/100 g/minute). In a second study, quantitative changes in cerebral concentrations of HbO_2 and deoxygenated Hb coupled with simultaneous measurements of arterial oxygen saturation by pulse oximetry and mean arterial pressure were obtained within the first hours of life in 32 premature infants with birth weights less than 2000 g.[24] In addition, an index of cerebral intravascular oxygenation, the continuous hemoglobin difference signal, defined as $Hb_D = HbO_2 - Hb$, which has been shown to be correlated with CBF, was determined as well.[88] Concordant changes in Hb_D and mean arterial pressure consistent with autoregulation were observed in 17 of the 32 infants; either severe IVH or periventricular leukomalacia developed in 8 of these 17 infants. Only 2 of the 15 infants with nonconcordant changes experienced IVH. These observations are akin to the Doppler findings described earlier.[60]

Near-Infrared Spectroscopy Changes Under Other Circumstances

Surfactant

The acute effects of surfactant replacement therapy on cerebral hemodynamics also have been studied with NIRS.[89] Observations were made before and after surfactant administration in 20 sick premature infants. Surfactant administration was associated with acute, small transient perturbations in cerebral HbO_2 concentration and CBV.

Treatment of Patent Ductus Arteriosus with Indomethacin

Acute cerebral hemodynamics and oxygen delivery were studied in 13 preterm infants with a PDA who were treated with indomethacin delivered either rapidly (over 30 seconds) or by slow infusion (20 to 30 minutes).[90] Irrespective of the rate of administration, indomethacin produced a consistent rapid decrease in CBF, oxygen delivery, and reactivity of blood volume to carbon dioxide.

Impact of Chorioamnionitis

Premature infants exposed to chorioamnionitis are at increased risk for the development of IVH.[9,91] The effects of chorioamnionitis on cerebral oxygen delivery as determined by NIRS were assessed in 43 premature infants during the first week of life.[92] Variability in the NIRS tracing was categorized as long-term, intermediate, or short-term. Chorioamnionitis-exposed infants exhibited reduced intermediate variability in cerebral oxygenated and deoxygenated hemoglobin but not in total hemoglobin. Infants with IVH had the lowest intermediate variability on the first postnatal day. No differences in short-term variability were found between chorioamnionitis-exposed

and -nonexposed infants or in those with and without IVH. The significance of these observations with regard to the development of IVH remains unclear.

Quantitative Cerebral Blood Flow Measurements

Positron Emission Tomography

Methodology

The use of PET to measure CBF requires a cyclotron to generate the positron-emitting radionuclides, a PET scanner to measure accurately the regional radioactivity in vivo, and mathematical models of radiotracer kinetics that relate tissue radioactivity measured by PET to a quantitative value, for example, CBF.[93,94] In the early 1980s, this technique was applied for study of the cerebral circulation, but it has not been used since. For completeness, however, the technique and the studies that are relevant to IVH are briefly reviewed next.

Emission tomography is a technique that produces an image of the distribution of a previously administered radionuclide in any desired part of the body (e.g., the head). Certain radionuclides (e.g., ^{15}O) decay by the emission of a positron, which is a small, positively charged particle. After traveling a few millimeters in tissue, the positron interacts with an electron, with destruction of both. The resultant annihilation event produces two high-energy γ-photons that travel in opposite directions (Figure 165-6). These photons can then be detected almost simultaneously by a pair of external detectors placed on opposite sides of the positron-emitting source (i.e., 180 degrees apart). If the detector pair is connected by an electronic coincidence circuit so that a signal is recorded only when two photons arrive virtually simultaneously, only photons originating from annihilation events between the detector pair will be recorded.[95] Thus most scattered photons are not recorded.

To correct for the other problem, that of absorption of photons, a correction factor is derived as follows: Before an individual scan is performed, an external positron-emitting source is placed within the detector field, and the number of coincidences for each detector is recorded. The infant's head is then placed in the detector field (with the external source still in position), and the number of coincidences that each detector now registers is recorded. The difference in recorded coincidences results from absorption (attenuation) of the photons by the infant's head. An attenuation fraction can then be calculated and used to correct data from the subsequent blood flow scans. Failure to correct for attenuation will underestimate the radioactivity present in the sampled tissue, resulting in an erroneously low value.

Positron Emission Tomograph

The PET scanner is composed of rings of external detectors, connected by coincidence circuits, which surround the head. The multiple rings allow simultaneous reconstruction of multiple transverse slices. The information recorded by the detectors in the multiple rings is used by a computerized system to reconstruct an image that is an accurate quantitative representation of regional tissue radioactivity.

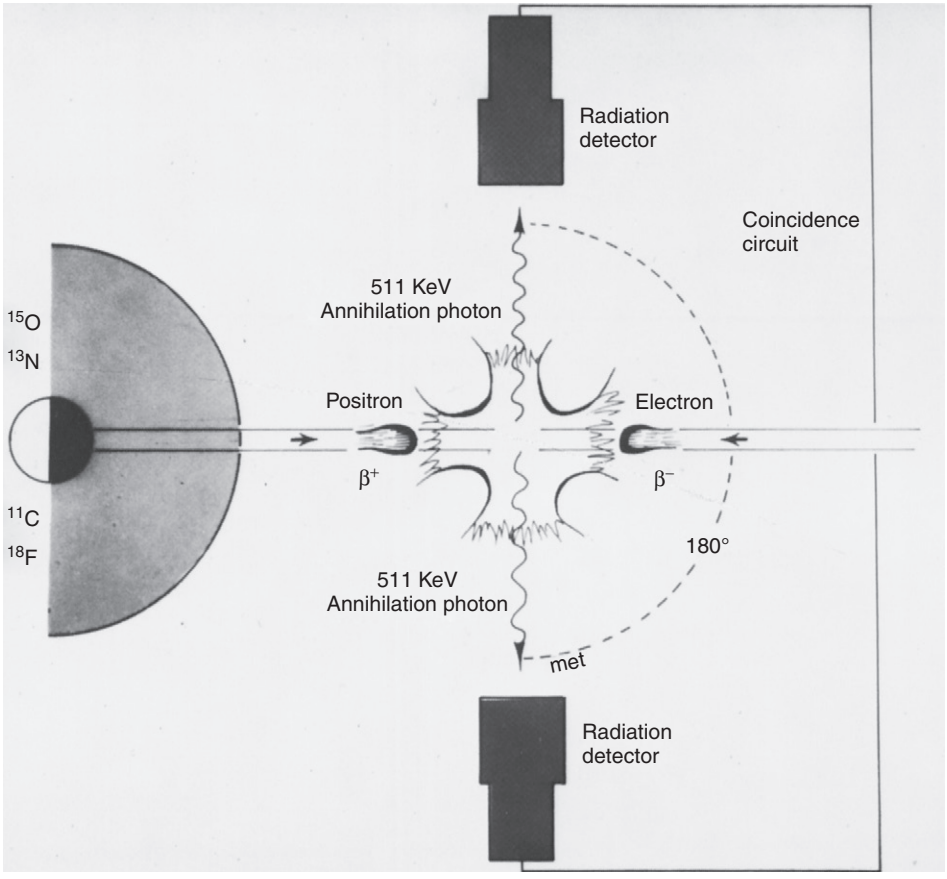

Figure 165-6 Basic principle of positron emission tomography. Isotopes decay by emission of a positron (β^+), which travels a few millimeters before colliding with an electron (β^-), producing an annihilation event. The latter event results in emission of two high-energy photons, which travel at approximately 180 degrees from each other and are detected by radiation detectors, which are linked in coincidence circuits. *(From Raichle ME: Positron emission tomography,* Annu Rev Neurosci *6:249, 1983; reproduced with permission from the Annual Review of Neuroscience, © 1983 by Annual Reviews, Inc.)*

One aspect of PET that is especially important in studies of newborn infants and requires special mention is *spatial resolution.* In the PET image, radioactivity from a given region is redistributed or "smeared" over a larger area. As a result of this redistribution, a given region in the reconstructed PET image contains only a portion of the radioactivity actually emitted from that region in the original structure. The remainder of the radioactivity is redistributed into surrounding areas of the image. Similarly, radioactivity from the surrounding regions is redistributed into the region of interest. Thus the regional radioactivity measurement made with PET represents the combined contribution of the radioactivity actually within that region and a contribution from radioactivity in surrounding regions.[93,96-99] This effect is known as *partial volume averaging.* It is therefore impossible to sample pure cortical gray matter and subcortical white matter because of the small size. In addition, recording in any region that is close to the surface of the brain or to the ventricles will include activity from the cerebrospinal fluid. Inclusion of this physiologically "inactive" fluid will lead to underestimation of the regional measurement for contiguous brain regions.

Measurement of Cerebral Blood Flow with ^{15}O-Labeled Water

The radiotracer used to measure CBF in infants by PET is ^{15}O-labeled water. Accuracy of the method has been described in detail elsewhere[98-100] and is reviewed briefly here: ^{15}O has a half-life of 123 seconds, and this rapid decay of radioactivity allows the absorbed radiation dose to be maintained at a safe, low level. A 40-second PET scan is obtained after the intravenous injection of ^{15}O-labeled water. The relationship between regional cerebral radioactivity and regional CBF is essentially linear, so measured radioactivity in a given region closely approximates mean CBF in that region. Quantitation of absolute values of CBF requires a simultaneous arterial time-activity curve, which is plotted using values for rapid arterial blood sampling obtained either from a peripheral artery (radial, tibial) or from the descending aorta (through an umbilical arterial catheter).

PET Measurements of Cerebral Blood Flow in Newborn Infants with Intraventricular Hemorrhage

A single study used PET methodology to measure regional CBF in six premature infants with IVH associated with a unilateral parenchymal echodensity indicative of hemorrhagic parenchymal infarction.[101] Analysis of the regional CBF images revealed the expected reduction in blood flow in the region of the parenchymal echodensity (Figure 165-7). However, blood flow was apparently reduced more globally in the affected hemisphere in areas distant to and not involved by the hemorrhage. Neuropathologic studies in these infants revealed hemorrhagic infarction in the region of the parenchymal echodensity and nonhemorrhagic infarction in the periventricular regions distant to the hemorrhagic infarction and apparently corresponding with the areas of reduced blood flow. These findings suggest that the hemorrhagic parenchymal infarct is part of a larger lesion that presumably is ischemic. However the mechanisms of pathogenesis andthe timing of the more extensive lesion are unclear.

Measurement of Cerebral Blood Flow by Xenon Clearance Techniques

Methodology

The measurement of CBF by xenon techniques is based on the recording of clearance of ^{133}Xe from the brain by an external detector. The intraarterial xenon method requires introduction of the tracer directly into the carotid artery. Blood flow is calculated from the clearance curve and the partition coefficient of xenon.[102,103] Use of this technique is restricted to patients undergoing internal carotid artery catheterization for clinical indications, and the procedure has not been performed in newborns. Lou and colleagues[104,105] adapted the technique to the newborn by injecting the radiotracer in the aortic arch or the common carotid or innominate artery through an umbilical artery catheter advanced to the appropriate position for the study.

Because of the invasiveness of administering the radiotracer through an arterial line, some investigators introduced the radiotracer by inhalation through an endotracheal tube or mask or by intravenous administration.[106,107] Like PET, this technique was applied for study of the cerebral circulation in the 1980s and early 1990s but has been used infrequently since. For completeness, the technique and relevant studies are briefly reviewed next.

Detection of Xenon

External detectors placed over the infant's head record the clearance of the tracer from the brain, and the windows are set to record the rather low-energy γ-waves emitted by the decay of the ^{133}Xe. Certain characteristics of these detector systems may influence the accuracy of measurements of regional CBF in the newborn infant and particularly in the premature newborn.[108,109] First, the detectors record emissions primarily from a volume of brain that is shaped like a truncated cone. Second, because of Compton scattering of the low-energy γ-waves, radioactive disintegrations from outside the detector field are recorded and may contribute up to 35% of the recorded counts. Third, up to 40% of observed counts in a detector placed over the parietal region will arise from the contralateral hemisphere. This last problem makes it difficult to measure regional CBF accurately and to compare hemispheric differences in blood flow.

Quantitation of Cerebral Blood Flow

Several methods are available to calculate CBF from clearance curves, which are recorded either linearly or semilogarithmically.[110-113] A two-compartment mode of analysis has been used to describe the clearance from a fast-flow compartment

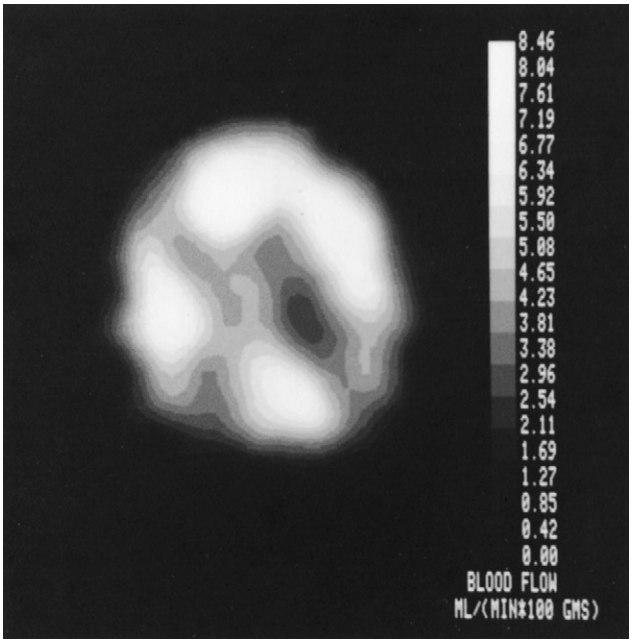

Figure 165-7 Positron emission tomography scan in a premature infant with intraventricular hemorrhage and hemorrhagic parenchymal infarct in the right cerebral hemisphere. Scans represent a horizontal section, with the right side of brain at the *right.* The *scale* is a linear representation of cerebral blood flow (CBF). Extensive impairment of CBF in the hemisphere containing the intracerebral blood is apparent.

(considered to represent gray matter) and from a slow compartment (considered to represent white matter). The fidelity of this relationship, however, can change fundamentally under pathologic conditions, especially with infarcts and intracranial hemorrhage (see later). A solution to this problem is provided by a noncompartmental index that represents global CBF and is based on analysis of the washout curve for relatively long periods (e.g., 15 minutes). An alternative solution is to analyze only the first part of the clearance curve, that is, the initial slope index. Data from the first 2 minutes of the curve are analyzed, and the value obtained is considered to represent mainly cortical flow, with a small contribution from white matter. Further refinements of this index method are based on performing curve analysis at 1-minute intervals during the early part of the washout curve. Theoretical limitations arise for each method when used to detect changes in CBF in infants with cerebrovascular disease.[112,114-115] In addition, the partition coefficient of xenon in the newborn is lower than in adults, probab as a consequence of the fact that the newborn brain contains less myelin, and because xenon is lipid-soluble.[116] This variance renders interpretation of changes in CBF especially difficult and indicates that caution should be exercised in interpreting values when marked tissue injury has occurred.

Clinical Studies of Xenon in Cerebral Blood Flow and Intraventricular Hemorrhage

Measurement of CBF with the xenon clearance technique has been performed in term and preterm infants with perinatal asphyxia and respiratory distress.[104,105,117,118] Ment and coworkers[106] reported CBF measurements in 16 infants weighing less than 1250 g who had evidence of IVH (n = 9); no infant was found to have a parenchymal infarction. At the time of the first CBF measurement (at 24 hours), blood flow changes were unpredictable. Thus asymmetric hemispheric blood flow was documented in five cases: In three of the cases, higher flow occurred on the side of the larger hemorrhage; in a fourth case, higher flow occurred on the side of unilateral subependymal hemorrhage; and in the fifth case, lower blood flow occurred on the side of maximal IVH. In addition, asymmetries in hemispheric flow were noted in four infants with symmetric IVH. These asymmetries in blood flow were not apparent on the subsequent measurements. These conflicting findings in CBF makes it difficult to draw conclusions regarding the relationship of CBF to the development of IVH.

In a follow-up study in 31 infants with birth weights less than 1250 g, CBF measurements were taken at an average postnatal age of 6 hours (range, 4 to 11 hours) and again on postnatal day 5.[119] Cranial ultrasonography, used to document IVH, was performed within 6 hours of birth and then every 12 hours. Infants were divided into three groups on the basis of the ultrasound findings: no IVH, early IVH (i.e., present at 6 hours), and interval IVH (appearing after 6 hours but before 5 days). The early IVH group exhibited hemispheric asymmetries in CBF, and five of the infants had reduced CBF to one or both hemispheres. Three of these infants (who had IVH and no initial parenchymal hemorrhagic involvement) progressed to grade IV hemorrhage (i.e., IVH and a hemorrhagic parenchymal infarct). The following pathogenetic mechanisms may therefore be postulated to account for development of the hemorrhagic parenchymal infarct in these infants: First, infarction of the hemisphere could have occurred perinatally, as evidenced by the reduced CBF at 6 hours, with secondary hemorrhage into this area between 6 hours and 5 days. Thus these data could be used to support the theory that the hemorrhagic parenchymal lesion represents hemorrhagic periventricular leukomalacia. Second, the IVH (and germinal matrix hemorrhage) could have caused the reduced CBF. Reduction in CBF has been observed experimentally after introduction of blood and potassium into the lateral ventricles of animals. Third, the IVH and germinal matrix hemorrhage could have obstructed venous return from the periventricular white matter (see earlier), thereby reducing CBF and resulting in subsequent infarction. These hypotheses must be considered with caution; evidence indicates that functional integrity of the newborn brain can be preserved with very low CBF (as low as 5 mL/100 g/minute).[79] Because the reported CBF values were in this range, occurrence of infarction cannot be established with certainty.

In another report, from Ment and associates,[120] xenon study results in two premature infants included unilateral reduction in hemispheric CBF at 6 hours of age. These infants also exhibited no evidence of IVH. The first infant, on day 5, was shown to have IVH and hemorrhagic infarcts of the basal ganglia (with later cortical atrophy noted on CT scan). The second infant, on day 4, demonstrated bilateral subependymal hemorrhages and an occipital porencephalic cyst. These two cases provide further support for the hypothesis of perinatal cerebral infarction and subsequent IVH.

Intraventricular Hemorrhage in the Neonate

Germinal matrix–intraventricular hemorrhage (IVH) is the commonest form of intracranial hemorrhage in the newborn and is characteristic of the premature infant.[1] The incidence of IVH in premature infants was documented to decline from very high rates of 34% to 49%[2-4] in the 1970s to approximately 20% in the late 1980s.[5,6] However, over the 1990s and early 2000s, the incidence of IVH has remained unchanged with an overall incidence for all IVH of 25% (Figure 166-1). In one of the largest series, 160,506 very-low-birth-weight infants were observed between 2001 and 2005 from 582 neonatal intensive care units (NICUs) as part of the Vermont-Oxford Database (data provided from 2001-2005 from Vermont Oxford Network Database; see Figures 166-1 and 166-2).

The incidence of all grades of IVH remained static over this 5-year period at 25% to 26% with the incidence of the most severe forms of IVH (grade III and IV) approximating 10%. It has

Intraventricular Hemorrhage in the Neonate

Germinal matrix–intraventricular hemorrhage (IVH) is the commonest form of intracranial hemorrhage in the newborn and is characteristic of the premature infant.[1] The incidence of IVH in premature infants was documented to decline from very high rates of 34% to 49%[2-4] in the 1970s to approximately 20% in the late 1980s.[5,6] However, over the 1990s and early 2000s, the incidence of IVH has remained unchanged with an overall incidence for all IVH of 25% (Figure 166-1). In one of the largest series, 160,506 very-low-birth-weight infants were observed between 2001 and 2005 from 582 neonatal intensive care units (NICUs) as part of the Vermont-Oxford Database (data provided from 2001-2005 from Vermont Oxford Network Database; see Figures 166-1 and 166-2).

The incidence of all grades of IVH remained static over this 5-year period at 25% to 26% with the incidence of the most severe forms of IVH (grade III and IV) approximating 10%. It has

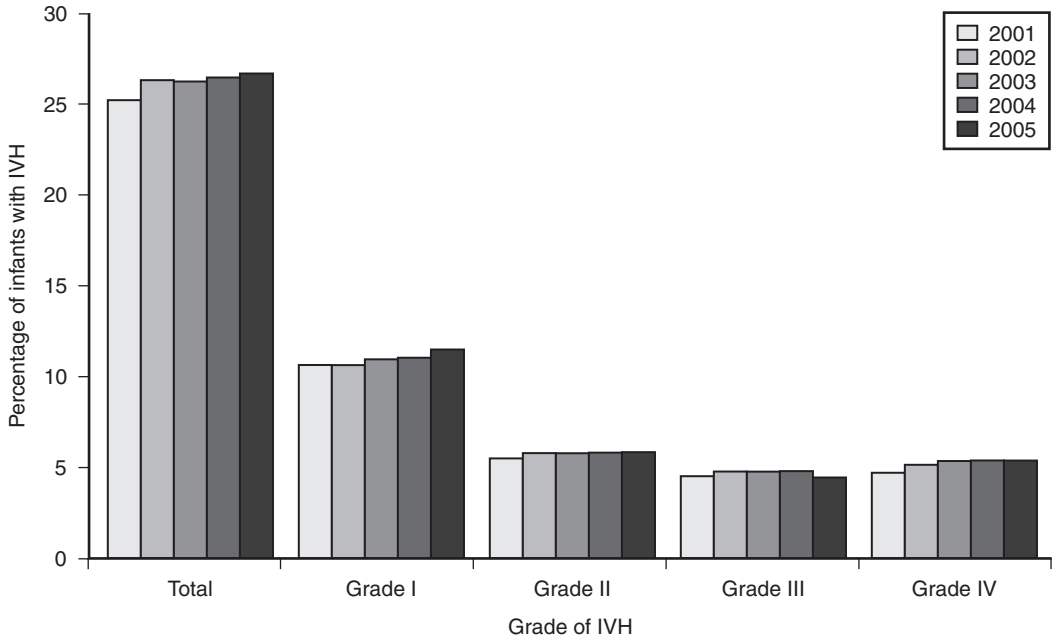

Figure 166-1 The incidence of (percentage of all infants with) all IVH, grade I, II, III, IV IVH, in the Vermont-Oxford Network 2001 to 2005 (n = 160,506). Note that the incidence of IVH is static across all grades and across the 5-year period. *(From Horbar JD:* Vermont-Oxford Network Database Summary. *Burlington, Vermont, Vermont-Oxford Network, 2007.)*

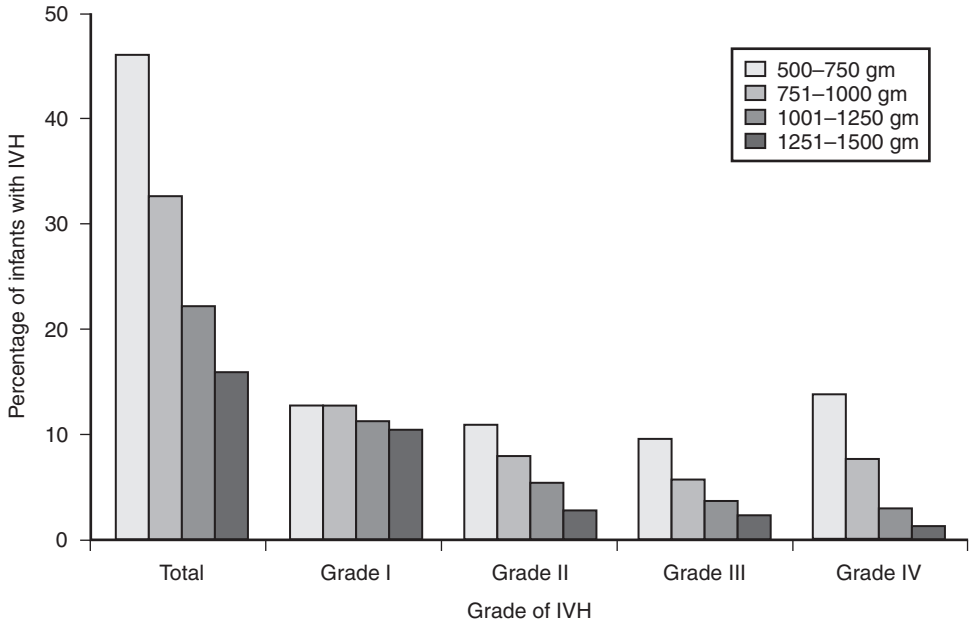

Figure 166-2 The incidence of (percentage of all infants with) all IVH, grade I, II, III, IV IVH, in the Vermont-Oxford Network 2005 (n = 38,383) for each grouping of birth weight from 500 to 750 g, 751 to 1000 g, 1001 to 1250 g, and 1251 to 1500 g. *(From Horbar JD:* Vermont-Oxford Network Database Summary. *Burlington, Vermont, Vermont-Oxford Network, 2007.)*

been hypothesized that the rates of IVH may not be improving because of the greater number of extremely immature infants, with a higher risk of IVH, who are being resuscitated and surviving. However, the data from Vermont-Oxford Database over 2001 to 2005 demonstrate that the percentage of preterm infants less than 750 g across this 5-year period did not alter at 17%, and thus the population of extremely preterm infants remains unchanged in recent years.

Although the percentage of the most immature infants has remained constant over the last 5 years, a very clear increased risk for all forms of IVH still exists in these smallest preterm infants (see Figure 166-2).[7] For infants less than 750 g the risk of any IVH is three-fold higher than for a preterm infant over 1250 g (45% vs. 15%) with a 10-fold higher risk of grade III-IV IVH (22% vs. 2.5%; see Figure 166-2). The most immature infants are also at greatest risk for the more severe forms of IVH. For an infant less

than 750 g an equal risk exists for development of grade I through IV at approximately 10% risk for each grade. In comparison, an infant over 1250 g has a 10% risk for grade I IVH and 1% risk for grade III or IV IVH (see Figure 166-2).

Thus IVH remains a significant problem in the preterm infant, particularly for the most immature infants. Currently in the United States approximately 55,000 very-low-birth-weight infants are born each year, of whom approximately 15,000 will have IVH, and more than 2000 infants will have periventricular hemorrhagic infarction.

In this chapter, we briefly discuss the background of diagnosis and clinical presentation for IVH before a more detailed discussion of the neuropathology and pathogenesis of the lesion, highlighting both experimental and human study findings.

CLINICAL FEATURES

The most common clinical presentation for IVH is a *clinically silent* syndrome occurring in up to 50% of infants with IVH in whom even careful and serial clinical assessments may fail to reveal any abnormal signs indicative of the lesion.[8-10] Thus the timing of the onset of IVH is often limited by clinician recognition. From cranial ultrasound (US) studies it appears that the *onset of IVH* is by the first day of life in at least 50% of affected infants with up to 90% of these lesions being present by 72 hours[5,11] and all lesions being visible by 7 days.[12] However, further *progression* of the lesions occurs in approximately 20% to 40% of the affected infants, with the maximal extent of the lesion seen by 3 to 5 days after the initial diagnosis.[13,14]

DIAGNOSIS

The diagnosis of IVH is most commonly established at the bedside of the sick preterm infant with use of portable cranial US. A vast experience demonstrates the reliability and versatility of cranial US for the diagnosis of IVH in the premature infant.[2,15-21] The determination of the presence of blood in the germinal matrix is best made on the coronal cranial US scan at the level of the caudothalamic notch, whereas the determination of the amount of blood in the lateral ventricles is most accurate on the parasagittal cranial US scan (Figure 166-3).

In comparison with the bedside technique of cranial US, computed tomography (CT) and magnetic resonance imaging (MRI) have the major disadvantages of requiring the sick premature infant to be transported to another site. Historically, CT scanning played a role in the early diagnosis of IVH and clearly demonstrated the site and extent of IVH in the premature infant.[3,4,22,23] However, recent concerns have been raised about the effects of ionizing radiation on the developing nervous system, which, until clarified, should restrict the use of CT scanning to neurosurgical emergencies in the newborn.[24] MRI has been shown to provide excellent images of IVH, but the real advantage of MRI lies in its superior ability to demonstrate the nature and severity of any parenchymal injury[25-28] (Figure 166-4) alongside a more extensive evaluation of the cerebral white matter, deep nuclear gray matter, cerebellum, and gyral development as indicators of additional neuropathology. Finally, in addition to imaging for the diagnosis of IVH, *lumbar puncture* can provide a characteristic cerebrospinal fluid (CSF) profile consisting initially of increased

red blood cell count and elevated protein content, followed shortly by xanthochromia and depressed glucose content. The degree of elevation of CSF protein correlates approximately with the severity of the hemorrhage.[29]

Classification of Intraventricular Hemorrhage

The grading system most commonly used for IVH in the infant was first reported by Papile and colleagues[4] and is based on the presence and amount of blood in the germinal matrix and the lateral ventricles seen on any form of neuroimaging (Table 166-1 and see Figure 166-3). Grade I represents hemorrhage confined to the subependymal germinal matrix, grade II has hemorrhage within the lateral ventricles without ventricular dilatation, grade III IVH has hemorrhage with ventricular dilatation and/or hemorrhage occupying more than 50% of the ventricle, and grade IV IVH has parenchymal hemorrhage. Although grade IV IVH is now considered as a periventricular hemorrhagic infarction rather than IVH per se, most reports continue to classify the cranial US findings according to this earlier established classification system and because of its common pathway of pathogenesis (see later).

Clinical Risk Factors

The clinical risk factors for IVH have been studied by two scientific approaches: first, by experimental and case-control studies outlining factors related to the pathogenesis in a preterm infant, which will be outlined in more detail later, and, second, by epidemiologic or registry-type studies that may also identify factors related to therapeutic or NICU factors. For example, a recent study of the incidence of IVH across 19,507 preterm infants admitted to 17 NICUs in the Canadian Neonatal Network over an 18-month time period demonstrated that on Bayesian hierarchical logistic regressional modeling 30% of the risk for high-grade IVH was related to baseline population risks (male gender, gestational age, initial severity of illness, and outborn status).[30] A further 14% of the risk was accounted for by admission-day therapies such as treatment for acidosis and hypotension, and the largest fraction of variation, 31%, was related to NICU characteristics. NICUs with high patient volume and high neonatology staffing had lower rates of severe IVH. These findings that NICU structure and care practices influence the risk of IVH are supported by others[31] and suggest that high patient load and neonatal physician experience may be associated with improved care practices and reduction in risk of severe IVH. The variation between NICUs in registry data in the incidence of IVH does not appear to relate to differences in the interpretation of cranial US scan.[32]

NEUROPATHOLOGY

The neuropathology of IVH is considered best in terms of the site of origin, that is, primarily the germinal matrix, the spread of the hemorrhage throughout the ventricular system, the neuropathologic consequences of the hemorrhage, and the neuropathologic accompaniments not necessarily related directly to the IVH.

The basic lesion in germinal matrix–IVH is bleeding into the subependymal germinal matrix. Over the final 12 to 16 weeks gestation, this matrix becomes less and less prominent and is essentially exhausted by term. This region is highly cellular, gelatinous in texture, and richly vascularized (as would be expected for a structure with active cellular proliferation).

TABLE 166-1

Grading of Severity of Germinal Matrix–Intraventricular Hemorrhage by Ultrasound Scanning

Severity	Description
Grade I	Germinal matrix hemorrhage with no or minimal intraventricular hemorrhage (10% of ventricular area on parasagittal view)
Grade II	Intraventricular hemorrhage (10%-50% of ventricular area on parasagittal view)
Grade III	Intraventricular hemorrhage (>50% of ventricular area on parasagittal view; usually distends lateral ventricle)

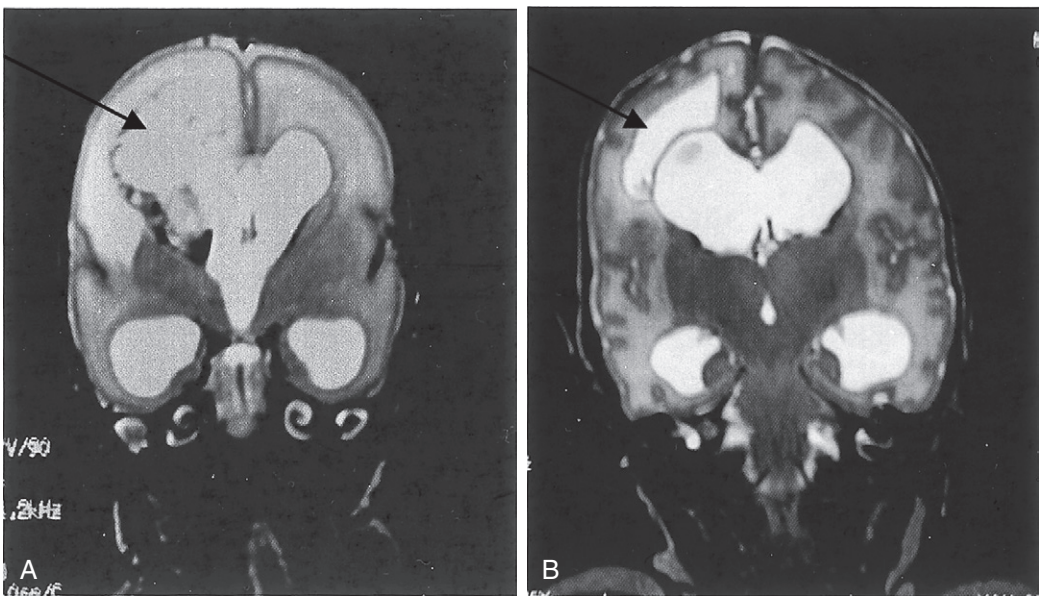

Figure 166-4 Coronal T2-weighted MRI scans of acute periventricular hemorrhagic infarction. **A,** Note the fan-shaped distribution of increased signal in the parenchyma *(arrow)* and the generalized increased signal in the white matter in the area surrounding the infarct. **B,** Later image of the same infant with cystic transformation of the infarct *(arrow).* Note the ventriculomegaly present in both images.

Site of Origin

The site of origin of IVH characteristically is the *subependymal germinal matrix*. This cellular region immediately ventrolateral to the lateral ventricle serves initially as the source of cerebral neuronal precursors between approximately 10 and 20 weeks gestation. Later in the third trimester, the matrix provides glial precursors that will become cerebral oligodendroglia and astrocytes. The matrix undergoes a progressive decrease in size, from a width of 2.5 mm at 23 to 24 weeks, to 1.4 mm at 32 weeks, to nearly complete involution by approximately 36 weeks.[33] The many thin-walled vessels in the matrix are a prime source of bleeding. Hemorrhage from the choroid plexus occurs in nearly 50% of infants with germinal matrix hemorrhage and IVH,[34] and, in more mature infants especially, it may be the exclusive site of origin of IVH.

The vascular *site of origin* of germinal matrix hemorrhage within the microcirculation of this region appears to be the prominent endothelial-lined vessels of the matrix and not the arterioles or arteries.[35-38] The vessels in free communication with the venous circulation appear to be of particular importance, such as the capillary-venule junction or small venules. This has been shown by careful histochemical studies of germinal matrix vessels at the site of hemorrhage[38] and by the emergence of solution into the germinal matrix hemorrhage from postmortem injection into the jugular veins but not from injection into the carotid artery.[37]

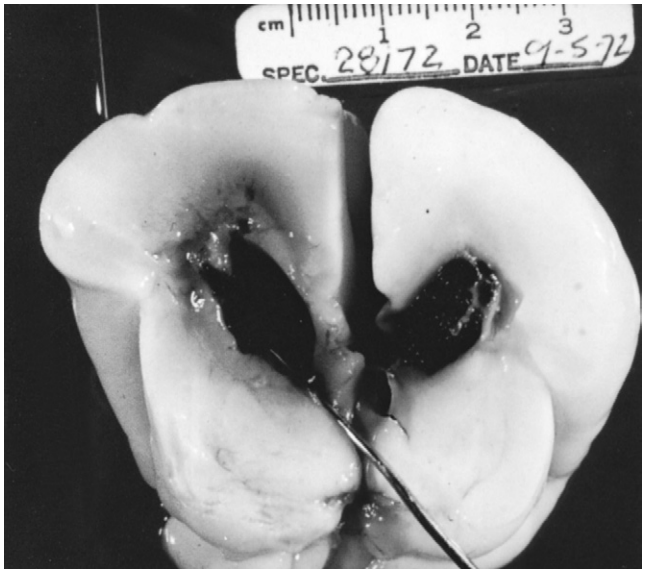

Figure 166-5 Periventricular hemorrhagic infarction with IVH; coronal section of the cerebrum. Note the evolving hemorrhagic infarction on the same side as the larger germinal matrix–IVH.

Spread of Intraventricular Hemorrhage

In approximately 80% of patients with germinal matrix hemorrhage, blood enters the lateral ventricles and spreads throughout the ventricular system.[36,39] Blood proceeds through the foramina of Magendie and Luschka and tends to collect in the basilar cisterns in the posterior fossa. With substantial collections, the blood may incite obliterative arachnoiditis over days to weeks with impairment in CSF flow. Other sites at which particulate blood clot may lead to impaired CSF dynamics are the aqueduct of Sylvius and the arachnoid villi.

Neuropathologic Consequences of Intraventricular Hemorrhage

Several neuropathologic states occur as apparent consequences of IVH, including, in temporal order of occurrence, germinal matrix destruction, periventricular hemorrhagic infarction, and posthemorrhagic hydrocephalus.

Germinal Matrix Destruction

Destruction of germinal matrix and, perhaps of importance, of its glial precursor cells is a consistent and expected feature of germinal matrix hemorrhage.[35,36] The hematoma is replaced frequently by a cyst, the walls of which include hemosiderin-laden macrophages and reactive astrocytes. This destruction of glial precursor cells in the germinal matrix may have a deleterious influence on subsequent brain development and neurodevelopmental outcomes (see later).

Periventricular Hemorrhagic Infarction

Approximately 15% of infants with IVH also exhibit a characteristic parenchymal lesion, *periventricular hemorrhagic infarction.* The incidence of this lesion increases with decreasing gestational age, such that in infants of 500 to 750 g, periventricular hemorrhagic infarction accounts for approximately one quarter of all cases of IVH (see Figure 166-2).[40,41] The neuropathology of periventricular hemorrhagic infarction consists of a relatively large region of hemorrhagic necrosis in the periventricular white matter, just dorsal and lateral to the external angle of the lateral ventricle (Figure 166-5). The necrosis is strikingly *asymmetric*—in the largest series reported, 67% of such lesions were exclusively *unilateral,* and, in virtually all of the remaining cases, they were grossly asymmetric, even though bilateral.[42] Approximately half of the lesions are extensive and involve the periventricular white matter from the frontal to the parieto-occipital regions. Approximately 80% of cases are associated with large IVH, and, commonly (and mistakenly), the parenchymal hemorrhagic lesion is described as an "extension" of the hemorrhage. That simple extension of blood into cerebral white matter from germinal matrix or lateral ventricle does *not* account for the periventricular hemorrhagic necrosis has been shown clearly by several neuropathologic studies.[34,40-44] Microscopic study of this periventricular hemorrhagic necrosis indicates that the lesion is a *hemorrhagic infarction*.[42-45] The careful studies of Gould and associates[43] and Takashima and colleagues[45] emphasize that the hemorrhagic component of the infarction tends to be most concentrated near the ventricular angle where the medullary veins draining the cerebral white matter become confluent and ultimately join the terminal vein in the subependymal region. Thus it appears that periventricular hemorrhagic necrosis occurring in association with large IVH is, in fact, a *venous infarction*.

The pathogenesis of periventricular hemorrhagic infarction appears in most cases to be related directly to the associated germinal matrix–IVH; the association of large asymmetric germinal matrix–IVH and progression to *ipsilateral* periventricular hemorrhagic infarction has been clearly documented.[42,46,47] These data raise the possibility that the IVH or its associated germinal matrix hemorrhage may lead to obstruction of the terminal veins with secondary hemorrhagic venous infarction.[42] A similar conclusion was suggested by a neuropathologic study.[43] This pathogenetic formulation received further support from two imaging studies. Doppler determinations of blood flow velocity demonstrated obstruction of flow in the terminal vein by the ipsilateral germinal matrix hemorrhage during the evolution of the infarction in the living premature infant.[48] In addition, an MRI study of acute periventricular hemorrhagic infarction showed an appearance consistent with a combination of intravascular thrombi and perivascular hemorrhage along the course of the medullary veins within the area of infarction.[49] The pathogenetic scheme that we

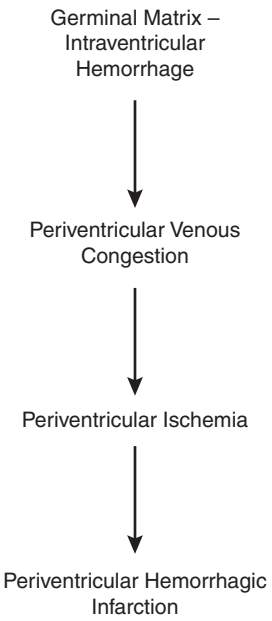

Figure 166-6 Pathogenesis of periventricular hemorrhagic infarction. The formulation indicates a central role for germinal matrix–IVH in causation of the periventricular venous infarction.

consider to account for most examples of periventricular hemorrhagic infarction is shown in Figure 166-6.

Hydrocephalus

A third neuropathologic consequence of IVH is progressive posthemorrhagic ventricular dilation, that is, *hydrocephalus.* The likelihood of and the speed of evolution of hydrocephalus after IVH is related directly to the quantity of intraventricular blood. Thus, with large IVH, hydrocephalus may evolve over days (*acute* hydrocephalus), and, with smaller IVH, the process evolves usually over weeks (*subacute-chronic* hydrocephalus).

Acute hydrocephalus is accompanied by particulate blood clot, which may impair CSF absorption by obstruction of the arachnoid villi. This mechanism may be particularly likely in the newborn with only microscopic arachnoid villi and not larger, later-appearing arachnoid granulations.[50] Other contributing factors to the development of acute hydrocephalus may include an impaired ability to mediate clot lysis with extremely low plasminogen levels and elevations in plasminogen activator inhibitor in the CSF of infants with recent IVH.[51]

Subacute-chronic hydrocephalus relates most commonly either to obliterative arachnoiditis in the posterior fossa resulting in obstruction of fourth ventricular outflow or flow through the tentorial notch or to aqueductal obstruction by blood clot, disrupted ependyma, and reactive gliosis.[35,52,53]

Neuropathologic Accompaniments of Intraventricular Hemorrhage

Several neuropathologic states are commonly associated with IVH but are not directly caused by it. The two most common accompaniments are periventricular leukomalacia and pontine neuronal necrosis.

Periventricular Leukomalacia

Periventricular leukomalacia was observed to occur in 75% of one series of infants who died with IVH.[34] In contrast to parenchymal hemorrhagic infarction, periventricular leukomalacia is a generally symmetric, nonhemorrhagic, and apparently ischemic white matter injury in the arterial end zones (Table 166-2). The frequent association of periventricular leukomalacia with IVH has also been emphasized in three other neuropathologic reports.[45,54] Takashima and colleagues[45] suggested that the two lesions, that is, periventricular hemorrhagic infarction and hemorrhagic periventricular leukomalacia, may be distinguishable in part on the basis of topography. Thus hemorrhagic periventricular leukomalacia has a predilection for periventricular arterial border zones, particularly in the region near the trigone of the lateral ventricles. Venous infarction, especially its most hemorrhagic component, is particularly prominent more anteriorly; that is, the lesion radiates from the periventricular region at the site of confluence of the medullary and terminal veins and assumes a roughly triangular, fan-shaped appearance in periventricular white matter.

TABLE 166-2

Periventricular White Matter Lesions of the Premature Infant

Term disturbance	Symmetry	Gross hemorrhage	Probable site of circulatory insult
Periventricular leukomalacia	Predominantly symmetric	Uncommon	Arterial
Periventricular hemorrhagic infarction	Predominantly asymmetric	Invariable	Venous

Pontine Neuronal Necrosis and Hippocampal Injury

Hypoxic-ischemic neuronal injury may accompany IVH in premature infants, and one subtype of such injury, *pontine neuronal necrosis,* is particularly common. In two carefully studied neuropathologic series,[34,54] 46% and 71% of infants with IVH exhibited pontine neuronal necrosis. Accompanying neuronal necrosis in the subiculum of the hippocampus was also common.[54-56] All the infants with IVH accompanied by pontine neuronal necrosis in the series of Armstrong and associates[34] died of respiratory failure. Previous investigations had suggested that pontine neuronal necrosis is related to hypoxic-ischemic insult, hyperoxia, and hypocarbia.[57,58]

PATHOGENESIS

The pathogenesis of IVH is considered best in terms of intravascular, vascular, and extravascular factors.[1] Clearly, the pathogenesis of IVH is multifactorial, and thus different combinations of these factors are operative in different patients.

Intravascular Factors

Intravascular factors are those that relate primarily to the regulation of blood flow, pressure, and volume in the microvascular bed of the germinal matrix (Box 166-1, Figure 166-7).

Fluctuating Cerebral Blood Flow

Significant fluctuations in *cerebral blood flow* appear important in the pathogenesis of IVH. It has been shown that a *fluctuating pattern* of arterial blood pressure, characterized by marked, *continuous alterations* in both systolic and diastolic flow velocities, was associated with similar trends in the cerebral blood flow velocity tracings and a high risk of subsequent occurrence of IVH. Smaller fluctuations in arterial pressure of less than 10% (coefficient of variation) did not appear to produce this adverse outcome.[59-61] The cause of the fluctuations in both the systemic and cerebral circulations was related to the mechanics of ventilation,[62,63] as well as to the severity of the infant's illness, with contributing factors of hypercarbia, hypovolemia, hypotension, "restlessness," patent ductus arteriosus, and relatively high inspired oxygen concentrations.[60,63-65]

Increases in Cerebral Blood Flow

The close temporal correlation between the occurrence of IVH and abrupt increases in arterial blood pressure, increases in cerebral blood flow, and cerebral blood flow velocity[66-69] supports the earlier hypothesis[69] that increases in cerebral blood flow play an important pathogenetic role in IVH. One major contributing factor to the premature infant's apparent propensity for dangerous elevations of cerebral blood flow is a pressure-passive state of the cerebral circulation.[70-76]

BOX 166-1

Pathogenesis of Germinal Matrix Hemorrhage

Intravascular factors

- Fluctuating blood pressure
- Increase in cerebral blood flow—systemic hypertension in the setting of a pressure-passive circulation, rapid volume expansion, hypercarbia, decreased hematocrit, decreased blood lucose
- Increase in cerebral venous pressure—venous anatomic arrangement, labor and vaginal delivery, respiratory disturbance
- Decrease in cerebral blood flow (followed by reperfusion)—systemic hypotension
- Platelet and coagulation disturbance

Vascular factors

- Tenuous capillary integrity—the germinal matrix is an involuting remodeling capillary bed with deficient vascular lining and a large vascular and luminal area
- Vulnerability of matrix capillaries to hypoxic-ischemic injury—the area has a high requirement for oxidative metabolism and lies at a vascular border zone

Extravascular factors

- Deficient vascular support
- Excessive fibrinolytic activity

Elevations of Arterial Blood Pressure and Pressure-Passive Cerebral Circulation

Investigators have shown that intact cerebrovascular autoregulation is found in clinically stable preterm infants and a pressure-passive cerebral circulation is present in sick preterm infants in whom IVH subsequently develops.[72,77,78] The relationship between a pressure-passive cerebral circulation and the occurrence of IVH was clearly demonstrated in a study in 57 preterm infants[71] in whom US signs of severe IVH developed only in infants with earlier evidence of a pressure-passive cerebral circulation. In those infants with intact cerebrovascular autoregulation either no hemorrhage or only mild hemorrhage developed.[71,74] Consistent with a potential role for arterial hypertension in this setting is the demonstration of a relation between maximum systolic blood pressure above a threshold value and the subsequent occurrence of IVH.[79] The limit for the highest tolerable peak systolic blood pressure was markedly lower for the smaller infants.[79]

Causes of Increased Arterial Blood Pressure in the Human Newborn

Abrupt elevations in arterial blood pressure, which may be accompanied by increased cerebral blood flow velocity, are clearly important to detect and prevent, whenever possible. These causes of elevated arterial blood pressure include the following: such "caretaking" concomitants as inadvertent noxious stimulation, abdominal examination, handling, instillation of mydriatics, and tracheal suctioning; such systemic complications as pneumothorax, exchange transfusion, and rapid infusion of colloid; and such neurologic complications as seizures.[66,67,69,80-86] Pneumothorax has been consistently associated with an elevated risk of IVH.[87,88] In one study in nine infants, pneumothorax was uniformly accompanied by abrupt elevations of systemic blood pressure and cerebral blood flow velocity, and these circulatory changes were followed within hours by IVH.[89] Studies in newborn dogs documented abrupt increases in arterial blood pressure on rapid evacuation of pneumothorax.[87]

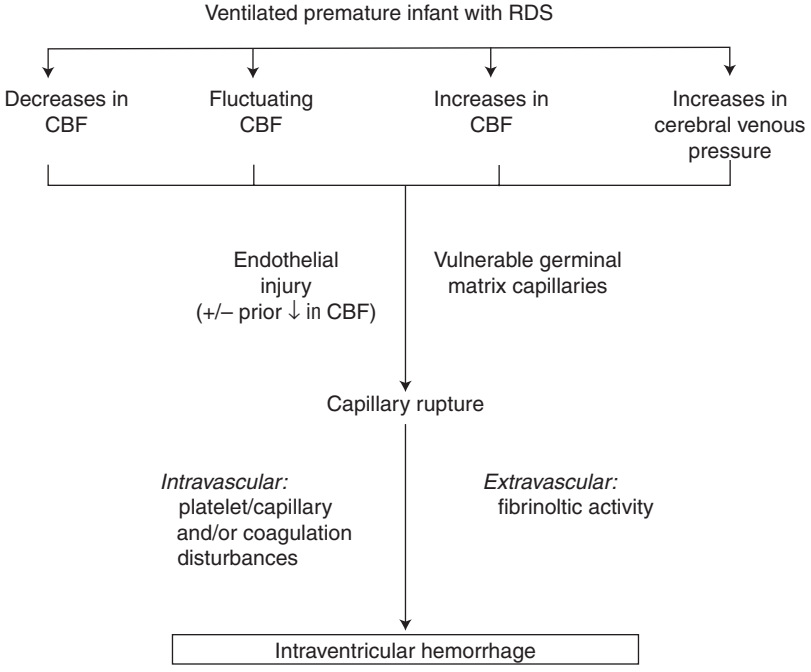

Figure 166-7 Interaction of the major pathogenetic factors for the occurrence of germinal matrix–IVH in the premature infant. *CBF,* Cerebral blood flow.

Relevant Experimental Studies: Role of Hypertension

The importance of abrupt increases in systemic blood pressure and cerebral blood flow in the pathogenesis of IVH was demonstrated in *experimental* studies in the newborn beagle puppy[89-93] and in the preterm sheep fetus.[94] A highly predictable and pattern of germinal matrix–IVH hemorrhage clinically similar to that of the human premature infant is produced in the beagle puppy by a sequence of hypotension and hypertension produced by blood removal and volume reinfusion.[95]

Hypercarbia

Careful studies in preterm infants receiving mechanical ventilation show a pronounced reactivity of cerebral blood flow to changes in arterial carbon dioxide tension ($Paco_2$) with an approximately 30% increase in cerebral blood flow per kilopascal increase in $Paco_2$ after the first 24 hours of life.[72,96,97] However, in the first 24 hours of life, the period of greatest risk for IVH, this reactivity is more attenuated, with an approximately 10% increase in cerebral blood flow per kilopascal increase in $Paco_2$ in well premature infants, and, most strikingly, this reactivity is *absent* in infants with subsequent severe IVH.[71] In contrast, Cooke observed that very-low-birth-weight infants with IVH had significantly higher maximum $Paco_2$ during the first week of life compared with infants without IVH.[98] Van der Bor and colleagues[99] demonstrated that elevated $Paco_2$ preceded the development of IVH in premature infants. Other investigators have observed univariate relationships between $Paco_2$ and risk of IVH, but this has not remained independently significant after controlling for other perinatal variables.[47,61,88,100] Szymonowicz and colleagues[101] were the first to report an association using multivariate analysis between hypercarbia and risk for IVH in a small observational study. After this Kaiser and colleagues documented an association between the maximum $Paco_2$ and risk of grade III-IV IVH in a study in 574 very-low-birth-weight infants between 1999 and 2004.[102] On multivariate logistic modeling controlling for gestational age, gender, 1-minute Apgar score, multiplicity, and inotrope use, maximum $Paco_2$ during the first 72 hours of life was related to the risk of severe IVH in a dose-dependent manner with the risk elevating with a $Paco_2$ >56 mm Hg. The adjusted odds ratio for severe IVH was nearly five-fold greater when the maximum $Paco_2$ was >75 mm Hg. These findings must be considered in light of the trend in newborn medicine toward more permissive hypercapnia.

Decreased Hemoglobin

The role of *decreased hematocrit* as a pathogenetic factor for IVH may be greater than previously suspected. An inverse correlation exists in the human infant between hemoglobin concentration and cerebral blood flow.[72,103,104] In one study in premature infants in the first days of life, cerebral blood flow increased by 12% per 1 mmol/L decrease in hemoglobin.[72] Cerebral blood flow presumably increases to maintain cerebral oxygen delivery constant, but, with increasing cerebral blood flow, risk for IVH will be enhanced in those premature infants born with anemia. These associations and that of total blood volume being related to the risk of IVH are further supported by the recent studies of the timing of cord clamping. Delayed cord clamping (30 seconds) compared with immediate cord clamping (6-7 seconds) is associated with a slightly higher baseline hematocrit (49% vs. 46%), higher mean blood pressure (33.8 vs. 31.9 mm Hg), but a significantly reduced risk for IVH (14% vs. 36%).[105] This reduction in IVH with delayed cord clamping is also supported by a meta-analysis of all randomized trials in preterm infants.[106]

Decreased Blood Glucose

Decreased blood glucose should be considered in the evaluation of pathogenetic factors for IVH in view of the observation that cerebral blood flow increases two- to three-fold when blood glucose declines to levels lower than 1.7 mmol/L in the premature infant.[72,96] Blood glucose levels lower than 1.7 mmol/L in premature infants are not rare in the first days of life in many NICUs. More data are needed on a potential contributory role for low blood glucose concentrations in the pathogenesis of IVH.

Increases in Cerebral Venous Pressure

Elevations of cerebral venous pressure may contribute to the occurrence of IVH. Indeed, potential importance of venous factors is suggested by the demonstration that, with postmortem injection of the carotid artery or jugular vein in infants with germinal matrix hemorrhage, the injected material entered the hemorrhage only by venous injections. The *most important causes* of such increases are labor and delivery, asphyxia, and respiratory complications.

Importance of Venous Anatomy

The importance of increased venous pressure in the pathogenesis of IVH relates in part to the *venous anatomy* in the region of the germinal matrix. The direction of deep venous flow takes a peculiar U-turn in the subependymal region at the level of the foramen of Monro, which is the most common site of germinal matrix hemorrhage.

Labor and Delivery

During labor and delivery, marked increases in cerebral venous pressure may occur. Measurement of "fetal head compression pressure" was determined by a compression transducer positioned between the fetal head and the wall of the uterus during labor, with the overall mean pressure found to be 158 mm Hg.[107] Consistent with this hypothesis of increased venous pressure during labor, an increased risk of the occurrence of IVH appears to exist in the premature infant with vaginal delivery and particularly with prolonged labor (10 to 12 hours).[47,108-111] A more recent study failed to find an association between mode of delivery and risk of IVH in 2674 preterm breech births in Sweden, although the mortality and 5-minute Apgar score were both improved with cesarean section delivery.[112] Head position, both before delivery and in the neonatal nursery, may also alter cerebral venous drainage. One study documented, using near-infrared spectroscopy, that cerebral venous drainage may be impaired in prone or side positions.[113]

Asphyxia

The importance of increased venous pressure in association with asphyxia in the causation of IVH has been shown in experimental studies of preterm fetal sheep.[94]

Respiratory Disturbances

Data suggest that such factors as positive pressure ventilation with relatively high peak inflation pressure, tracheal suctioning, abnormalities of the mechanics of respiration, and pneumothorax may be major causes of increased cerebral venous pressure in the premature infant.[114-117] Doppler measurements of blood flow velocity in the superior sagittal sinus demonstrated a striking sensitivity of the venous circulation to the level of peak inflation pressure with the smallest infants exhibiting the most marked effects.[117]

Tracheal suctioning and pneumothorax have also been shown to produce pronounced changes in venous pressure.[59,118,119] Studies of mode of ventilation in premature infants have raised concerns over associations between high-frequency oscillatory ventilation (HFOV) and increased rates of IVH, particularly high-grade IVH.[120] A meta-analysis of the eight randomized controlled studies comparing HFOV and conventional ventilation demonstrated a significant increase in the risk of grade III or IV IVH (summary relative risk, 1.19 [1.03, 1.38]) with adverse

neurodevelopmental outcome in the two trials with follow-up (relative risk, 1.26 [1.01, 1.58]).[121] An increased risk of high-grade IVH was documented in a randomized controlled trial of HFOV that documented an increased rate of IVH in those infants who were switched from conventional ventilation to HFOV.[122] The potential mechanism of increased IVH in premature infants receiving HFOV may relate to increased intrathoracic pressure with decreased cerebral venous return.[123] However, these findings have led some authors to recommend that conventional ventilation should remain the ventilatory mode of choice in premature infants with respiratory distress syndrome.[121,122]

Decreases in Cerebral Blood Flow

Importance of Pressure-Passive Cerebral Circulation

Decreases in cerebral blood flow may play an important role in the pathogenesis of IVH. The principal consequence of the decreased cerebral blood flow is injury of germinal matrix vessels, which rupture subsequently on reperfusion. As indicated earlier, hemorrhagic hypotension preceding volume reexpansion is the optimal means to produce IVH experimentally in the newborn beagle puppy. In the premature infant, decreases in cerebral blood flow are most likely with perinatal asphyxia and systemic hypotension. Because of the pressure-passive cerebral circulation in sick premature infants, this hypotension can lead to a parallel decrease in cerebral blood flow.

Perinatal Hypoxic-Ischemic Events

Perinatal hypoxic-ischemic events presumably explain, at least in part, the relationship among low Apgar scores, early acidosis, the early use of bicarbonate, and the subsequent occurrence of IVH, particularly cases that develop in the first 12 hours.[124,125] The mechanism for provocation of IVH with perinatal asphyxia is complex and includes increases in cerebral venous pressure; changes in cerebral blood flow associated with impaired vascular autoregulation, such as decreases in cerebral blood flow associated with hypotension; and resulting injury to matrix capillaries. Studies of the concentrations of brain-specific creatine kinase isoenzymes in umbilical cord blood or blood samples obtained early in the postnatal period or of the hypoxanthine metabolite, uric acid, in blood samples obtained on the first postnatal day in preterm infants in whom IVH later developed support the notion that late intrauterine injury (perhaps asphyxia) may be involved in at least some cases of IVH.[126-128] Moreover, the possibility of a perinatal hypoxic-ischemic insult to brain as a predecessor to IVH is suggested also by the finding of electroencephalographic abnormalities before the occurrence of IVH.[129,130]

Postnatal Ischemic Events

The importance of postnatal decreases in arterial blood pressure in the pathogenesis of IVH is indicated by several studies in which arterial blood pressure was monitored continuously from birth or shortly after birth. In a study in approximately 25,000 very-low-birth-weight infants, severe IVH was three times more common in those infants requiring cardiopulmonary resuscitation at delivery (15.3%) than in those not requiring resuscitation (4.9%).[131] A relationship between postnatal arterial hypotension and increased risk of IVH has been frequently documented.[132,133] Near-infrared spectroscopy in the first 24 hours of life in preterm infants has shown that cerebral blood flow is significantly lower in infants in whom IVH subsequently developed (median 7.0 mL/100 g per minute) than in those without IVH (median 12.2 mL/100 g per minute).[134] In addition, supportive of a relation between postnatal ischemic events and the occurrence of IVH is the demonstration of decreased cardiac output in the first 36 hours of life in infants in whom the lesion developed, especially severe IVH.[135] Finally, the potential importance of ischemic injury in pathogenesis is supported further by the demonstration of a beneficial effect of administration of superoxide dismutase in prevention of IVH in the beagle puppy model.[136] This enzyme is critical in the defense against free radicals, the formation of which is provoked by hypoxic-ischemic insult.

Platelet and Coagulation Disturbances

Disturbances of platelet-capillary function and coagulation may contribute to the pathogenesis of IVH, although uniformity is lacking in results of studies designed to investigate the pathogenetic role of such disturbances.

Platelet-Capillary Function

Forty percent of infants of less than 1500 g birth weight in one study[126] exhibited platelet counts less than 100,000/mm^3, and most of these infants with thrombocytopenia had abnormal bleeding times. The incidences of IVH in infants with thrombocytopenia versus those without thrombocytopenia were 78%, versus 48% for those weighing less than 1000 g. The presence of thrombocytopenia appeared to be an independent pathogenetic factor for causation of IVH. Subsequent work has both confirmed and refuted a role for thrombocytopenia in pathogenesis of IVH.[137,138] Some evidence also suggests that premature infants demonstrate elevated levels of prostacyclin before the occurrence of IVH.[139] Because prostaglandins have an impact not only on platelet function but also on factors such as cerebral blood flow and free radical production that also may be important in pathogenesis of IVH, it is not clear to what extent effects on platelet-capillary function were independently related to causation of IVH.

Coagulation

Disagreement exists concerning the role of coagulopathy in the causation of IVH.[137,140-142] Because disturbances of coagulation are not uncommon in preterm infants with other provocative factors for IVH (e.g., serious respiratory distress syndrome, asphyxia) or they may occur *secondary* to major hemorrhage, an independent pathogenetic role for such disturbances has been difficult to establish. Although administration of fresh frozen plasma was shown in one study to decrease the incidence of IVH,[143] no effect on coagulation measures accompanied the apparent beneficial effect. Moreover, a later investigation failed to show a beneficial effect of prophylactic early fresh frozen plasma in premature infants.[144,145]

Several investigators have examined the potential role of mutations in coagulation proteins as possible risk modifiers for IVH. Several common mutations in coagulation proteins are associated with increased tendency to thrombotic events. Those that have been investigated most included factor XIII Val34 Leu mutation, factor V Leiden, factor II (prothrombin) G20210A, and MTHFR C677T.

Factor XIII stabilizes the fibrin clot, and thus it is hypothesized that low levels of factor XIII may predispose to IVH. Low factor XIII levels in preterm infants may be a risk factor for the relatively higher fibrinolytic activity that occurs in preterm infants.[146] Factor V Leiden is a common mutation in the white population associated with thrombotic events with decreased inactivation of factor V leading to greatly increased thrombin generation. The role of factor V Leiden and risk of IVH is unclear. Results have been conflicting as to the role of factor V Leiden in the risk of IVH with some studies suggesting a significant role,[147,148] whereas others suggest no role.[149]

Two mutations (C677T and A1298C) in the 5,10-methylene tetrahydrofolate reductase (MTHFR) lead to hyperhomocysteinemia under conditions of decreased folate or B_{12} concentrations leading to an increased risk of thrombosis. No association has been found with this mutation and IVH.[146]

Vascular Factors

Vascular factors that may predispose the blood vessels of the germinal matrix to hemorrhage include the tenuous integrity of matrix capillaries and the vulnerability of these vessels to hypoxic-ischemic injury.

Tenuous Capillary Integrity

Three lines of anatomic evidence suggest that the capillary integrity is tenuous in the germinal matrix. First, these vessels, like the germinal matrix itself, are in a process of involution. Pape and Wigglesworth[56] characterized the elaborate capillary bed of the germinal matrix as "a persisting immature vascular rete," an immature microvascular network that is remodeled into a mature capillary bed when the matrix disappears. This involuting remodeling capillary bed may be expected to be more susceptible to rupture than more mature vessels. Second, many studies have emphasized that the matrix microcirculation is composed of simple endothelial-lined vessels, often of a larger size than capillaries but not categorizable as arterioles or venules because of absence of muscle and collagen.[35,38,39,56] Careful studies have documented the absence of muscle[150] and of type VI collagen.[151] It has been postulated that such vessels are likely to be more susceptible to rupture. Third, an electron microscopic study of cortical and germinal matrix vessels shows a two- to four-fold greater diameter of both the vessels and the lumina of the vessels of the germinal matrix than those of the cortical plate in infants of 25 to 33 weeks gestation.[152] Thus, in the age range of greatest propensity for occurrence of IVH, the diameters are unusually large, a finding of potential pathogenetic importance because of Laplace's law, which states that the larger the vessel diameter is, the greater the total force on the wall will be at any given pressure.

The possibility should be considered that effects of these maturational deficiencies of germinal matrix vessels underlie the interesting observation that women with a diagnosis of preeclampsia exhibit a much lower risk for an infant with IVH (2.5%) than do women without this diagnosis (17%).[153] This lower risk for IVH has been confirmed.[154,155] Infants born to mothers with preeclampsia exhibit a variety of features suggestive of accelerated maturation of brain and other organs.[156,157]

Vulnerability to Hypoxic-Ischemic Injury

The matrix capillaries have an increased vulnerability to hypoxic-ischemic injury. Takashima and Tanaka[158] showed that a vascular border zone exists between the end-fields of the striate and thalamic arteries at the usual site for matrix hemorrhage. Thus it can be postulated that the matrix vessels could be readily injured by ischemia, and, on reperfusion of these injured vessels, hemorrhage could occur. In addition, matrix capillaries, like other brain capillaries, appear to have a high requirement for oxidative metabolism. These brain endothelial cells have been shown to contain three to five times more mitochondria than do systemic capillary endothelial cells.[159] This intense oxidative activity would further enhance the vulnerability of matrix vessels to ischemic insults.

Extravascular Factors

Extravascular factors are those referable to the space surrounding the germinal matrix capillaries. The most prominent vulnerability in this region is related to deficient vascular support. The germinal matrix can be seen by gross examination to be a gelatinous, friable structure and by microscopic examination to be deficient in supporting mesenchymal elements.[35,160,161] It appears that the extravascular space provides poor support for the large, endothelial-lined capillaries that course through it and that are the site of the hemorrhage. Gould and Howard[161] assessed astrocytic fibrillary development by immunocytochemical staining for glial fibrillary acidic protein showing minimal astrocytic development as late as 27 weeks gestation and prominent glial fibrillary acidic protein staining not until 31 weeks in the matrix region. Because of the role of glial fibers in capillary stabilization, these data suggest that deficient astrocytic development may play a role in the pathogenesis of IVH in the premature infant.

MECHANISMS OF BRAIN INJURY

Major Factors

The principal mechanisms of brain injury in the premature infant with IVH relate to one or more of at least the following six major factors (Box 166-2): (1) hypoxic-ischemic injury that may precede the IVH; (2) destruction of germinal matrix with its glial precursors; (3) destruction of periventricular white matter, that is, periventricular hemorrhagic infarction; (4) periventricular white matter injury resulting from intraventricular blood products; (5) a marked increase in intracranial pressure and concomitant defects in cerebral perfusion at the time of severe IVH; and (6) posthemorrhagic hydrocephalus.

Preceding Hypoxic-Ischemic Injury

Neuropathologic studies indicate that infants who die with IVH exhibit two principal lesions related to hypoxic-ischemic insults: periventricular leukomalacia and a subtype of selective neuronal necrosis, pontine and subicular neuronal necrosis. Periventricular leukomalacia has been reported in neuropathologic series in as many as 75% of cases of IVH, and pontine neuronal necrosis is noted in nearly 50%. Moreover, the finding that ventricular dilation correlates strongly with subsequent neurologic and cognitive deficits after IVH, in the absence of progressive hydrocephalus or periventricular hemorrhagic infarction,[162-165] further suggests that concomitant periventricular leukomalacia and cerebral white matter atrophy are common and important in the outcome of infants with IVH.

Destruction of Germinal Matrix and Glial Precursors

One of the consistent neuropathologic consequences of IVH is destruction of germinal matrix with its glial precursor cells. These glial precursor cells are destined to give rise to both oligodendroglia and astrocytes. The loss of the glial precursor cells may affect subsequent cerebral development through the oligodendroglia or astrocytic cell loss. Loss of oligodendroglia cells may lead to a subsequent impairment of myelination after germinal matrix destruction, although evidence to establish such an influence is lacking. The loss of glial precursor cells may also

BOX 166-2

Mechanisms of Brain Injury With Germinal Matrix—Intraventricular Hemorrhage

- Preceding hypoxic-ischemic injury, especially periventricular leukomalacia
- Destruction of glial precursors in germinal matrix—effect on myelination
- Destruction of periventricular white matter (i.e., periventricular hemorrhagic infarction) and subsequent impairment of cortical organization
- Periventricular white matter injury resulting from intraventricular, parenchymal, or subarachnoid blood products with vasoconstriction and generation of free radical products
- Intracranial hypertension and impaired cerebral perfusion
- Posthemorrhagic hydrocephalus

impair subsequent astrocytic development. Gressens and Evrard and their co-workers[166,167] showed that astrocytes destined for supragranular (upper) cortical layers originate and migrate after the occurrence of neuronal migration and are crucial for normal organizational development of the supragranular cerebral cortex. These astrocytic precursors are likely to be destroyed by germinal matrix hemorrhage, a finding raising the possibility of a subsequent disturbance in cortical development.[167] Such a disturbance would not be detectable by conventional neuropathologic techniques.

Destruction of Periventricular White Matter: Periventricular Hemorrhagic Infarction

Numerous follow-up studies have correlated cranial ultrasonographic findings in the neonatal period in patients with IVH with the occurrence of subsequent neurologic deficits. These studies confirm that the presence of periventricular hemorrhagic infarction is the single most important determinant of neurologic outcome. Of all survivors of IVH, this lesion accounts for the largest proportion of the subsequent severe neurologic deficits. The deleterious neurologic effects of periventricular hemorrhagic infarction may relate not only to destruction of cerebral white matter per se but also to the effects of the white matter injury on cerebral cortical development. Thus careful neuropathologic study of cerebral cortical organization in infants who died with major hemorrhagic white matter lesions has shown marked alterations in neuronal axonal and dendritic ramifications in areas overlying the white matter destruction.[168] These abnormalities are postulated to be caused by disturbances of afferent input to and efferent input from the areas of cortex by disruption of the respective white matter axon. Another potential cause for the cortical abnormalities could be destruction of subplate neurons by the white matter infarction.[169] These neurons are critical for cerebral cortical organization and are abundant in subcortical white matter in the human premature infant. Whatever the mechanism, these *cerebral cortical* abnormalities with periventricular hemorrhagic infarction could be important in determination of subsequent cognitive deficits and seizure disorders.

Periventricular White Matter Injury Caused by Blood Products

The presence of blood products may have a direct pathogenetic role in the evolution of periventricular white matter injury, as demonstrated by the observation that the presence of IVH is associated with a five- to nine-fold increased risk of ultrasonographic correlates (e.g., echolucencies) of white matter injury.[15] Experimental studies suggest that two interacting mechanisms could be operative to produce white matter injury in the presence of IVH: impairment of cerebral blood flow and increased generation of free radicals. *Disturbances of cerebral blood flow* with parenchymal or subarachnoid blood have been demonstrated resulting from local release of vasoconstricting potassium from hemolyzed red blood cells[170] or prostanoids[171] or 5-hydroxytryptamine.[171] Because the walls of cerebral parenchymal vessels do not contain a muscularis necessary for vasospasm in the human premature infant,[150] it seems unlikely that local cerebral blood flow could be affected by this mechanism. However, subarachnoid blood potentially could cause vasoconstriction of major leptomeningeal cerebral vessels, which do contain a muscularis in the human premature infant.

The more likely mechanism of white matter injury with intraventricular or parenchymal blood involves *increased free radical formation*, provoked by local release of iron from the blood.[172] The presence of blood products is particularly dangerous in the premature infant because the expression of heme oxygenase is especially high in the immature cerebral white matter,[173] thus enhancing formation of Fe^{2+} when hemorrhage is present. The Fe^{2+} could then catalyze the generation of the highly reactive and dangerous hydroxyl radical through the Fenton reaction. The early differentiating oligodendroglia has been shown to be exquisitely vulnerable to free radical attack,[174] and thus the enhanced hydroxyl radical generation could accelerate cerebral white matter injury. Although free radical–mediated cellular injury has been proposed as a key pathogenetic factor in cerebral white matter injury in the premature infant, direct evidence heretofore has been lacking. Studies in the premature infant are the first to document an elevation in the early postnatal period in measures of free radical products in the CSF of premature infants with cerebral white matter injury later apparent on MRI at term.[175,176]

COMPLICATIONS OF INTRAVENTRICULAR HEMORRHAGE

Hydrocephalus

Incidence and Definition

Hydrocephalus, which is a progressive ventricular dilatation (PVD) resulting from a disturbance in CSF dynamics, is a not uncommon sequel to IVH (Table 166-3).[2,3,101,177-180] As could be expected, the incidence of posthemorrhagic PVD is related closely to the severity of the initial hemorrhage. A clear clinical distinction between ventriculomegaly resulting from periventricular cerebral atrophy and ventriculomegaly resulting from hydrocephalus with attendant impairment of CSF dynamics can be difficult but is critical for the formulation of appropriate management decisions. In general, the development of ventriculomegaly, resulting from atrophy, occurs slowly, over several weeks; is not associated with the development of increased intracranial pressure or rapid head growth; and evolves to a state of stable ventricular size; that is, ventricular size neither decreases, as in transient hydrocephalus, nor continues to increase, as in persistently progressive hydrocephalus. The evaluation of progressive ventricular dilatation after IVH can be best undertaken with cranial US, particularly for the systematic evaluation of ventricular size. Previously, cranial US images have been typically evaluated qualitatively for ventricular size. Although this strategy has proved useful, it would appear more

TABLE 166-3

Short-Term Outcome of Germinal Matrix–Intraventricular Hemorrhage as a Function of Severity of Hemorrhage

	DEATHS IN FIRST 14 DAYS		PVD IN SURVIVORS 14 DAYS OLD		SURGERY + LATE DEATH			
Grade	<750 g (n = 173)	751-1500 g (n = 75)	<750 g (n = 165)	751-1500 g (n = 56)	<750 g (n = 165)	751-1500 g (n = 56)	Mortality	Surgery in Survivors

PVD, Progressive ventricular dilatation.

informative to evaluate ventricular size in a quantitative fashion, on the basis of established norms.[181] Further, the occipital horn is the first and the frontal horn is the last to enlarge after IVH.[182] Thus measurement of the thalamo-occipital dimension of the ventricle,[181] via the posterior fontanelle, is the most sensitive indicator of ventriculomegaly. Frequent cranial US monitoring of the ventricular dimensions, particularly in the acute period, may assist in assessing the infant's course and determining the need for intervention with ventricular drainage. It may also guide the frequency and volume of CSF drainage necessary to decrease ventricular size. The role of aggressive drainage of CSF with posthemorrhagic ventricular dilatation in preterm infants in improving outcomes remains unproved although retrospective comparisons between NICUs suggest that earlier intervention may be associated with a reduced need for ventriculoperitoneal shunt and improved neurodevelopmental outcomes.[183] This requires further investigation in a randomized controlled trial. The amount of CSF that requires to be drained may also vary greatly between infants with some infants requiring large volumes of CSF to be removed to reduce the pathologic consequences. In a case of posthemorrhagic ventricular dilatation that we studied, the removal of 60 mL/kg over a 12-hour period led to improved volumes of gray matter suggesting improved brain structure but with persisting ventriculomegaly suggesting that very high volumes of CSF may be removed in the subacute period of this disease process.[184]

Pathogenesis

The pathogenesis of posthemorrhagic hydrocephalus can be considered in terms of either the acute process, apparent within days, or the subacute-chronic process, apparent within weeks. Acute hydrocephalus appears to be a result of an impairment of CSF absorption caused by particulate blood clot and demonstrable by US scan (Figure 166-8).[185] Subacute-chronic hydrocephalus presumably is related to obliterative arachnoiditis in the posterior fossa where the blood tends to collect.[35] The ventricular dilatation may begin essentially with the hemorrhage, especially with marked IVH. More often, definite ventricular dilatation and, particularly, the progression thereof begin within 1 to 3 weeks of the hemorrhage.

Relation of Ventricular Dilation to Brain Injury

The precise relation of progressive posthemorrhagic ventricular dilation to brain injury is unclear. This issue is discussed in experimental and clinical studies.

Experimental Studies

The deleterious effects of hydrocephalus on the brain may include disturbances of cerebral white matter, cerebral blood vessels, and cerebral cortex. For *cerebral white matter*, the earliest changes are seen within 1 week after induction of experimental hydrocephalus and involve oligodendrocytes and myelin, with a decrease in myelin-associated enzymes (e.g., ceramide galactosyltransferase) and structural proteins (e.g., myelin basic protein). Later, after several weeks, axonal loss and impaired myelination are apparent. Shunting at 1 week but not at 4 weeks, when axonal loss had occurred, has been shown to allow recovery of myelination.[186] The late occurrence of axonal loss with hydrocephalus was noted in earlier studies.[187-189] Thus intervention must occur before this stage if prevention of such permanent structural deficits is to be achieved.

A potential role for *cerebral vascular changes and ischemia* in the genesis of the white matter injury in experimental hydrocephalus is demonstrated by morphologic studies that show an alteration in the caliber of major cerebral vessels with a decrease in the secondary and tertiary vessels in the cerebral white matter.[190,191] These changes may explain, at least in part, the decrease in cerebral blood flow and energy metabolism in hydrocephalic animal models.[192-194] Further supportive of cerebral ischemia are the findings in cerebral white matter of increased cerebral rates of glucose metabolism (presumably anaerobic glycolysis), elevated lactate, decreased high-energy phosphates, and elevated free radicals.[195-197] Enhanced free radical production is particularly relevant, in view of the particular vulnerability of differentiating oligodendroglia to free radical attack.[198] These biochemical changes and neurochemical signs of axonal loss have been shown to be prevented by early shunting in the various experimental models.[194,196]

Of additional interest are the documented alterations in *cerebral cortical neurons* in hydrocephalic animal models. Disturbances in catecholaminergic and serotonergic neurotransmitter development and in synaptogenesis with evidence of neuronal degeneration have been delineated.[199-209] These effects may reflect disturbance to ascending and descending axon in cerebral white matter with secondary anterograde and retrograde effects on organizational development of cerebral cortex. Again, these deleterious effects have been shown to be reversible when the hydrocephalic state is corrected early.

Human Studies

Data from studies in infants concerning the deleterious effect of progressive posthemorrhagic ventricular dilation relate to cerebral hemodynamics, neurophysiologic function, morphologic disturbances, biochemical indicators of hypoxia, and clinical outcome. The data are difficult to interpret conclusively because such details as rate of progression, degree and duration of ventriculomegaly, intracranial pressure, preceding parenchymal injury, and neurologic outcome are often not provided.

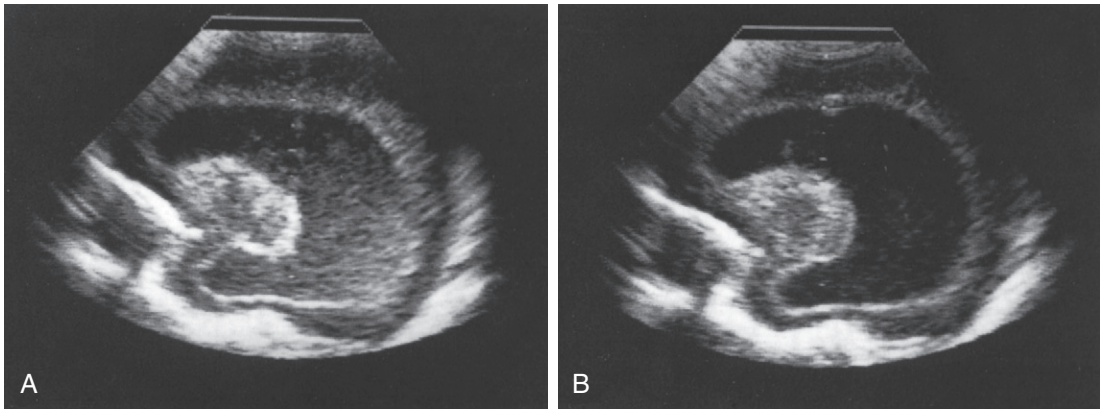

Figure 166-8 **A** and **B,** Acute hydrocephalus with IVH. *(From Volpe JJ:* Neurology of the Newborn, *Philadelphia, ed 4, Saunders, 2001, p 458.)*

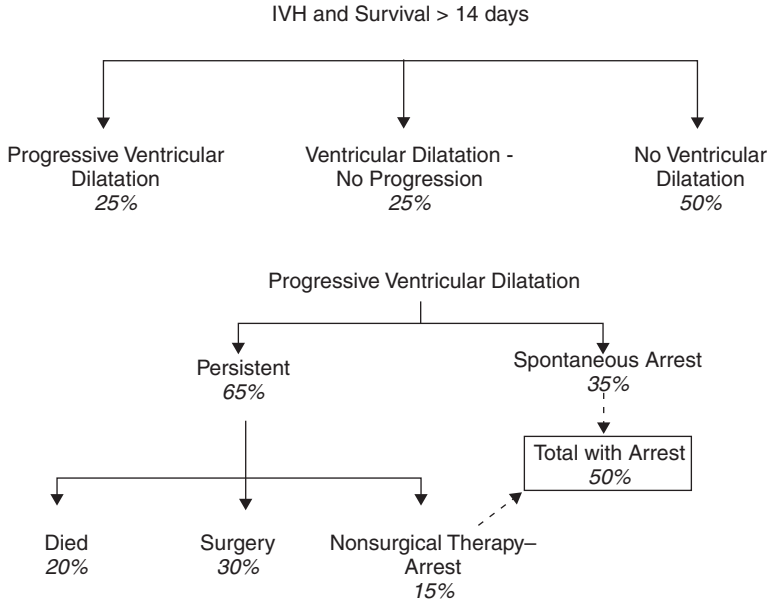

Figure 166-9 Natural history of very-low-birth-weight infants with posthemorrhagic ventricular dilatation.

Concerning *cerebral hemodynamics*, posthemorrhagic hydrocephalus initially has been demonstrated to be associated with *impaired blood flow velocity,*[67,210-213] which can be reversed with therapy to correct the hydrocephalic state.[67] This disturbance of cerebral blood flow velocity appears to correlate more closely with ventriculomegaly than with increased intracranial pressure.

Concerning *neurophysiologic function,* visual evoked potentials, brain stem auditory evoked potentials, and somatosensory evoked responses have all been shown to be altered by posthemorrhagic ventricular dilatation. The studies have demonstrated prolonged latencies of these evoked potentials with posthemorrhagic hydrocephalus in the premature infant.[214-216] Improvement in latencies was demonstrated after CSF removal by placement of a ventriculoperitoneal shunt or direct removal of ventricular fluid.[214-216] These data suggest that an axonal disturbance is caused by ventricular distention, and this disturbance can be reversed by effective therapy.

Concerning *morphologic evidence of brain injury* with posthemorrhagic ventricular dilation, a paucity of data exists from studies of autopsies of human infants who did not have markedly advanced disease. Studies of biopsy specimens taken at the time of ventriculoperitoneal shunt placement have shown four major findings: (1) disruption of ependyma, (2) direct evidence of axonal injury ("axonal ballooning"), (3) lipid-laden microglia, and (4) diminished numbers of myelinated axons.[188,217-220] These findings are consistent with the experimental models of hydrocephalus.

Biochemical evidence of hypoxia has been observed and suggests injury to brain that is reversible by therapy.[221] *Elevated CSF levels of hypoxanthine*, a marker for hypoxic tissue, have been found in infants with posthemorrhagic hydrocephalus that reduced significantly after successful treatment.[221] Although the morphologic effects of hydrocephalus on cerebral vessels and the resulting deleterious cerebral hemodynamic effects are a probable explanation for tissue hypoxia, elevated levels of vasoconstricting eicosanoids (e.g., thromboxanes) or edema-producing eicosanoids (e.g., leukotrienes) appear important. These eicosanoids have been shown to be elevated in CSF of infants with posthemorrhagic hydrocephalus.[222] The source of these compounds remains unclear, and their specific relation to the posthemorrhagic ventricular dilatation remains to be established. Biochemical evidence of oxygen deficiency at the mitochondrial level is found with the demonstration by near-infrared spectroscopy of an increase in *brain levels* of *oxidized cytochrome* aa_3, after lumbar puncture in infants with posthemorrhagic hydrocephalus accompanied by increased intracranial pressure.[223,224] This observation is consistent with the demonstration by positron emission tomography of increases in cerebral metabolic rate for oxygen in several infants (one newborn) after treatment of hydrocephalus.[225] More data are needed on these issues.

Natural History

Management of progressive posthemorrhagic ventricular dilation must begin with recognition of the natural history of the disorder.* We undertook a large study in premature infants to reflect the natural history of PVD. In this cohort of 248 very-low-birth-weight infants with IVH (mean gestational age, 27 weeks), 25% of the infants exhibited PVD (Figure 166-9). Arrest of PVD occurred without treatment in one third of infants with PVD. Of the remaining two thirds of infants who did not have arrested PVD and thus had persistent PVD, most received nonsurgical therapy consisting of pharmacologic therapy or drainage of CSF by serial lumbar punctures only. Half of the patients with persistent PVD received surgical therapy with insertion of a ventriculoperitoneal reservoir or shunt, and one third of the infants with persistent PVD died (see Figure 166-9). The development of PVD after IVH and the occurrence of adverse short-term outcome, such as the requirement for surgical therapy, were predicted most strongly by the severity of IVH (see Table 166-3). These data demonstrate that despite a slight reduction in the overall incidence of PVD, a more aggressive course with appreciable mortality and morbidity appears to exist in the extremely premature infant characteristic of current NICU facilities. The major predictor of adverse short-term outcome, defined as death or the need for surgical intervention for PVD, was the severity of IVH (see Figure 166-9 and Table 166-3).

*References 2, 3, 19, 89, 101, 178-180, 182, 226-241.

TABLE 166-4

Long-Term Outcome: Neurologic Sequelae With Germinal Matrix–Intraventricular Hemorrhage as a Function of Severity of Hemorrhage

Severity of hemorrhage	Incidence of neurologic sequelae (%)
Mild	5-10
Moderate	15
Severe	35
Severe + apparent periventricular hemorrhagic infarction	50-100

PROGNOSIS

The prognosis of IVH is considered best in terms of the short-term outcome (mortality rate and development of PVD) and the long-term outcome (neurologic sequelae). The *short-term outcome* relates clearly to the severity of the hemorrhage. The mortality rates and incidences of progressive posthemorrhagic ventricular dilation (i.e., hydrocephalus) are shown in Table 166-3 as a function of the severity of the hemorrhage, documented primarily by US scan.[3,15,242-245] With small lesions, confined to the germinal matrix or accompanied by small amounts of intraventricular blood, mortality rates are low, and the likelihood of PVD in survivors is rare. In contrast, infants with severe lesions, that is, blood filling the ventricles, have high mortality rates (approximately 20%), and more than half of the survivors exhibit PVD. The *long-term neurodevelopmental outcome* of the infant with IVH depends on the degree of parenchymal injury. A large literature describes associations between cranial US findings with only an approximate relationship existing between the quantity of intraventricular blood and the neurologic outcome (Table 166-4).* The largest, most recent study relating IVH to outcomes is the EPIPAGE study in 1954 infants of <32 weeks gestation.[256] A clear relationship existed between an increased risk of adverse outcome with increasing grade of IVH. However, it is notable that even in isolated grade I-II IVH the rates of cerebral palsy increased substantially for grade I IVH (n = 229) from 5.5% to 8.1% and grade II IVH (n = 168) to 12.2%. Notably, cerebral palsy rates with isolated grade I-III IVH also rose with immaturity from 5% in 31 to 32 weeks to 10% to 15% in 27 to 30 weeks and 33% in 24 to 26 weeks. For school-aged outcomes, Sherlock and colleagues[257] examined 298 preterm infants less than 1000 g at age 8 years to determine the impact of IVH in relation to neuromotor and cognitive outcomes. They documented that no IVH was associated with cerebral palsy rates of 6.7% with no rise in association with grade I IVH (6.4%) but a marked elevation with grade II IVH to 24%. Patra and colleagues[258] also report that grade I-II IVH was associated with a two-fold increase in the risk of lower cognitive performance (Mental Developmental Index) and a 2.6-fold increase in the risk of neuromotor abnormalities (cerebral palsy and tone) after controlling for social and neonatal factors (gender, bronchopulmonary dysplasia, sepsis, necrotizing enterocolitis, maternal marital status, race, and education). Although the studies do differ in their findings, the more recent contemporaneous studies in similar populations of very preterm infants demonstrate similar rates of cerebral palsy with grade I-II IVH approximating a 10% risk, clearly double that of no IVH. It is not clear whether this risk is elevated with grade I IVH alone or whether any elevated risk exists for subsequent cognitive deficit. The major limitation of these studies is the inability to truly distinguish the key neuropathologies that may be leading to the subsequent impairment in neurodevelopmental outcome. Cranial US has been demonstrated to have very poor diagnostic utility for diffuse white matter injury, which has been shown to occur in up to 75% of preterm infants. The cerebral white matter is also the commonest site of neuropathologic impact for IVH, as described earlier. In such a manner, low-grade IVH may be merely a visible marker on cranial US for the true neuropathology of cerebral white matter injury, which on MR imaging has been shown to be highly predictive of both motor and cognitive deficits.[259] Of note, the elevation of risk for poor outcomes with low-grade IVH with increasing immaturity may also be suggesting an independent role for the loss of the astrocytic and glial precursors from the immature germinal matrix.

Pathophysiology of Neural Tube Defects

Neural tube defects are the most common and most severely disabling malformations of the central nervous system (CNS). They include a wide spectrum of malformations comprising open defects, such as myelomeningocele and anencephaly, and skin covered lesions, such as encephalocele and lipomyelomeningocele. The clinical heterogeneity of neural tube defects results from a diversity of underlying mechanisms.[1] In the United States, neural tube defects are one of the most prevalent neonatal anomalies, second only to cardiac malformations. Worldwide, 300,000 or more infants are born each year with neural tube defects.[2] The incidence varies according to geography, ethnicity, and seasonal variation, ranging from 1 to 4 per 1000 live births. The fetal prevalence may well be even higher because neural tube defects detected by screening amniocentesis and ultrasound often result in elective termination of the pregnancy. The highest incidence of neural tube defects is found in Great Britain, Ireland, Pakistan, Northern India, and Egypt. The lowest incidence is observed in Finland, Japan, and Israel. Even within in the United States, a geographic and ethnic distribution of these defects occurs, with the highest incidence in the East and the South, and the lowest in West.[3] There is an increased prevalence of neural tube defects among Hispanics, especially if the mother was born in Mexico.[4] There is also a high incidence of neural tube defects among Sikhs. However, the lesions are frequently restricted to the thoracic level with minimal associated neurologic deficit, suggesting a separate etiology.[5] Women in the United States who have had an infant or fetus with a neural tube defect have a 2% to 3% risk for a subsequent affected pregnancy.[6]

The most common types in humans are anencephaly and myelomeningocele (spina bifida aperta). Anencephaly is almost always lethal, whereas myelomeningocele, although not usually lethal, has enormous personal, familial, and social costs. The life of most affected children is characterized by recurrent hospitalizations, multiple operations, and physical and cognitive impairments. The associated handicaps are dependent on the level of the spinal lesion, the degree of damage to the exposed neural tissue, and the presence of the Chiari type II malformation.[7] Less than 20% of neural tube defects are associated with malformation of nonneural tissues, chromosomal defects, or specific genetic syndromes,[8] such as amniotic bands,[9] trisomies 13 and 18, and the autosomal recessive Meckel-Gruber syndrome.

Despite intensive investigation, the etiology of neural tube defect remains unclear, and the controversy over its pathogenesis continues.

EMBRYONIC DEVELOPMENT

Normal human brain development can be summarized in six basic stages: (1) primary and secondary neurulation; (2) proencephalic development; (3) neuronal proliferation; (4) neuronal migration; (5) organizational events; and (6) myelination.[10] Understanding the process of CNS development is important in understanding the features of the CNS abnormalities in children affected by neural tube defects. Development of the CNS begins prenatally and continues postnatally with overlapping developmental periods (Table 167-1). The embryonic development of the fetal brain and the spinal cord are described in detail in Chapter 160. The embryology, specifically of neural tube formation, is briefly presented here in order to understand neural tube defects in the context of normal CNS development.

Primary Neurulation

The formation of the neural tube begins on the dorsal aspect of the gastrula stage embryo as a plate of tissue differentiating in the middle of the ectoderm. Neurulation occurs between the third and fourth weeks of gestation. According to Smith and Schoenwolf,[11] neurulation can be subdivided into four broad morphologic steps: (1) induction of the neural plate; (2) molding of the neural plate; (3) longitudinal bending of the neural plate; and (4) fusion of the neural folds. The stages of primary neurulation are coordinated with progressive and regressive movements of the primitive streak.[12] The critical event in this process is neural induction, which involves interaction between the ectoderm and the underlying mesoderm (notochord). The notochord and chordal mesoderm induce formation of the neural plate, which occurs between 16 and 18 days gestation. The inductive signals are generated by Hensen node, the avian equivalent of Spemann organizer.[13,14] Cell proliferation and shape change then result in extension and folding of the primordial neural plate, the precursor of both the brain and the spinal cord. As the notochord forms and elongates, the neural plate enlarges and extends beyond the edges of the notochord. The midline, however, remains tethered to the underlying notochord. The neural plate begins to invaginate along the central axis, forming a longitudinal median groove with neural folds on its sides. In the region of the future spinal cord, this process remains, obliterating the groove and bringing the edges of the plate in apposition. At approximately 22 days gestation, the neural tube forms by fusion of the opposed neural folds in the region of the future lower brain stem. Fusion progresses rostrally and caudally. The neural tube remains open at both ends, the anterior and the posterior neuropores, which

TABLE 167-1

Normal Human Brain Development and Time of Occurrence

Normal Human Brain Development	Time of Occurrence
Formation of the brain structure	0-20 weeks gestation
• Primary and secondary neurulation	• 3-4 weeks gestation
• Proencephalic development	• 4-12 weeks gestation
Neuronal migration	5-20 weeks gestation
Neuronal proliferation and brain growth	0 weeks gestation to 12 years of life
Organizational events	12 weeks gestation to 12 years of life
• Differentiation, maturation, synaptogenesis	• 16 weeks gestation to 12 years of life
• Apoptosis	• 24 weeks gestation to 1 month of life
Myelination	13 weeks to 30 years of life

Modified from Volpe JJ: Overview: Normal and abnormal human brain development, *Ment Retard Dev Disabil Res Rev* 6:1-5, 2000.

allow for the fluid of the amniotic cavity to communicate with the neural tube lumen. The anterior end of the neural tube closes at approximately 24 days and the posterior end closes at approximately 28 days gestation.[15]

The mechanisms responsible for neural tube formation are not completely understood, but two theories have been advanced. In the "zipper closure model," the neural tube closure begins in the cervical region, and fusion then proceeds bidirectionally until the neural tube is closed.[16] More recently, the "multisite closure model" has been suggested.[17] This model of multisite neural tube closure may provide the best explanation for neural tube formation (Table 167-2).[18,19] In addition, the complex morphologic events of neural tube formation result from the unity of intrinsic and extrinsic features and may also involve nerve cell adhesion molecules (NCAMs) [20] or other components within the extracellular matrix.[21] Intrinsic processes include microfilament contraction actively changing cell shape[22] and passive folding caused by rapid cell proliferation and underlying membrane tethering.[23] The relationship between the neural plate and the adjacent embryonic tissue constitutes the extrinsic forces in neural tube development.

Primary neurulation results in a closed neural tube with its caudal limits in the upper lumbar spinal cord. Secondary neurulation, the process in which the remaining caudal elements of the spinal cord (i.e., conus medullaris, lower lumbar, and sacrococcygeal segments) are fashioned is related to the future vertebral level S2. An open neural tube defect results if closure is not completed during this developmental window.

EMBRYONIC AND MOLECULAR MECHANISMS OF NEURAL TUBE DEFECTS

Insights From Mouse Genetic Models

Because neurulation in mouse and human embryos appears to be quite similar anatomically, the mouse has been used as a model for investigating the embryonic mechanisms of neural tube defects. Direct genetic analysis of human neural tube defects has been difficult because of the rarity of familial cases and the lack of specific candidate genes involved. To date, more than 80 mouse mutant models have been described (i.e., *curly tail*, *loop tail*, *splotch*, *vacuolated lens,* and *Mlp-knockout* mice) that exhibit a genetic cosegregation of anencephaly, exencephaly, and myelomeningocele analogous to the human condition.[24] However, most of these mutants present additional defects that are never or only infrequently seen in humans with neural tube defects. For example, the malformations in the mouse mutant splotch are similar to those found in human Waardenburg syndrome type I[25,26] and in Greig cephalopolysyndactyly.[27] Absence of the corpus callosum or thinning of the cerebral cortex and retina are rarely found in humans with neural tube defects but frequently present in the Mlp-knockout mouse.[28] Finally, some knockouts, such as *CSK*, *BRCA1*, and *P53*, show neural tube defects but also exhibit growth retardation and other malformations and are associated with a high embryonic lethality.[29-31]

TABLE 167-2

Multisite Closure Model for Neural Tube Formation

Closure	Region of Fusion at the Neural Tube
1	At the midcervical region and proceeds cranially and caudally
2	At the prosencephalon-mesencephalon boundary and proceeds bidirectionally
3	Proceeds rostrally from the stomadeum and convenes cranially with closure
4	At the rhombencephalon and proceeds rostrally
5	Unidirectional closure of the caudal end of the neural tube

Despite these limitations, investigations in two mouse mutants led to two hypotheses to account for the failure of the posterior neuropore to close, resulting in open defects of the spine. The curly tail (ct/ct) mouse mutant, first described by Gruneberg in 1954,[32] exhibits failure of both the anterior and posterior neuropore closures, resembling common nonsyndromic forms of human neural tube defects. The basic defect in the curly tail mouse is not within the neuroepithelium but rather is in the nonneural tissues.[33] In curly tail (ct/ct) mouse mutants, the notochord and the hindgut endoderm demonstrate decreased cell proliferation causing enhanced curvature of the caudal region. This curvature mechanically opposes the closure of the neuropore, leading to the development of open neural tube defects.[34,35] In addition to the altered cell proliferation rates, curly tail mouse embryos exhibit a reduced accumulation of newly synthesized hyaluronan within the extracellular matrix in the notochord and hindgut endoderm.[36] Because hyaluronan significantly contributes to cell proliferation in a variety of cell types, Copp and Bernfield[37] suggested that alteration in hyaluronan synthesis resulting in suboptimal proliferation of the notochord and hindgut endoderm may result in neural tube defects.

Curly tail (ct/ct) mouse mutants demonstrate an increased level of alpha-fetoprotein in the amniotic fluid of fetuses with neural-tube defects,[38] as well as an incomplete penetrance (60%), which varies with genetic background supporting the hypothesis of the presence of modifier genes.[39] Similar to humans, environmental factors (i.e., retinoic acid, mitomycin C, hydroxyurea, and 5-fluoruracil) are important, with alteration in penetrance and expressivity of the curly tail phenotypes.[40] Although treatment with folate and methionine is effective in reducing the incidence of neural tube defects in humans, they have no effect on the incidence or type of neural tube defects in curly tail mice.[41-43] Inositol treatment reduces curly tail neural tube defects by stimulating protein kinase C activity by 70%, suggesting that the curly tail model is a folate-resistant model of neural tube defect phenotypes.[40]

By contrast, homozygous splotch (Sp/Sp) mice were recently found to have a mutation in the paired domain of the *PAX3* gene responsible for the phenotype of these mutants.[44] The failure to express a normal Pax3 protein (a critical embryonic gene involved in neural tube development in mice and humans) in the neuroepithelial cells appears to impair the ability of the neural plate to undergo folding and fusion during the neurulation process.[44,45] Although the cellular mechanisms are unknown, Yang and Trasler[46] and Moase and Trasler[47] have suggested that the failure of Pax3 protein expression affects the cell-cell interaction within the neural plate. Linkage studies of Pax3 and neural tube defects in U.S. and Dutch families, however, have failed to identify the relationship between Pax3 expression and neural tube defects.[48] In addition, mouse models of *HOX*-deficient mice showed delayed closure and aberrant formation of the neural tube.[49] However, analysis of the four known clusters of *HOX* genes (A, B, C, D), which play an important role in neural tube development in humans, found no evidence for their involvement in human neural tube defects.[50] A report of linkage between human neural tube defect and the region of the T locus homologue[51] has not been supported by other studies.[52,53]

In double mutant mice for splotch and curly tail, the incidence and the severity of spina bifida significantly increase, indicating an additive effect in the disruption of the neurulation process.[54] The neural tube defect phenotypes seen in curly tail mutants resemble those of *F52-* (also called MacMARCKS)-deficient mice, and the *F52* gene and ct have both been mapped to distal chromosome 4.[55] The penetrance and severity of ct gene expression, however, are affected by the modifier genes mapped to murine chromosome 3 and 5.[55] About 60% of *F52*-deficient mice are exencephalic, and approximately 10% have spinal neural tube defects.[28] The question that has been raised is whether the curly

tail mouse is a mutation of the *F52*-deficient mouse.[28] However, it is thought that the curly tail mutation addresses cellular defects in the extrinsic forces of neurulation, whereas the MacMARCKS-like protein regulates morphogenesis in various tissues by meditation of cell-cell signaling, changes of actin-cytoskeleton dynamics, and regulation of cytosolic protein expression.[56] Thus modulations regulated by protein kinase C substrates[56] within the neuroepithelial cells play an integral role as intrinsic forces during neurulation.

To summarize, for most mouse models of neural tube defects, there is still a gap between identifying the gene involved in the development of neural tube defects and the morphogenetic mechanism it contributes to the formation of the neural tube. However, it is possible and perhaps likely that neural tube defects in humans result from a combination of common, disease-associated alleles in the population or even from a subtle change of function in specialized neurulation genes.

Insights From Teratogenic Models

Various teratogenic neural tube defect models have been examined in order to understand the mechanisms of abnormal neurulation and to test etiologic and environmental hypotheses suggested by human epidemiologic data. A number of teratogens, such as ethanol, insulin, trypan blue, vitamin A, folic acid antagonists, GABA-receptor agonists, and hyperthermia, have all been used to induce neural tube defects in vitro and in vivo.[57,58] More than 30 classes of chemicals and drugs are listed in the literature that result in neural tube defects.[59] However, the phenotype of neural tube defects, as well as the development of hindbrain herniation, depends on the timing of administration.[60,61]

Administration of valproic acid on day 8 of gestation in the mouse results in high rates of malformations of the anterior neural tube (i.e., exencephaly),[62] whereas a similar dosing regimen of valproic acid on day 9 of gestation results in spina bifida occulta.[63] Having demonstrated the feasibility of creating a spinal defect resembling a human myelomeningocele with valproic acid, Ehlers and colleagues[64] reported that the administration of methionine (70 mg/kg body weight) to valproic acid–exposed mice fetuses significantly reduced the valproic acid–induced spina bifida rate. The interactions of methionine in neural tube formation are not completely understood. However, methionine may play an important role in normal neural tube formation because the absence of methionine causes neural tube defects in cultured rat embryos.[65]

More recently, Danzer and co-workers[66] developed and characterized a novel short-gestational animal model of isolated myelomeningocele in fetal rats by maternal administration of all-*trans*-retinoic acid. Exposure to retinoic acid at the time of posterior neuropore closure (E10 in rats) leads to a pathology that has striking morphologic and clinical similarity to human myelomeningocele in approximately 60% of the fetal rats.[66,67] Prenatal administration of retinoic acid induces a primary defect during the neural tube formation. With respect to fetal surgical intervention (see later), this animal model may facilitate investigations in the very early developmental abnormalities of spina bifida. Furthermore, the fetal rat is large enough for surgical manipulation and has minimal propensity for preterm labor after fetal surgery, allowing the potential use of this model to study various approaches for prenatal coverage of myelomeningocele and the subsequent effect on postnatal neurologic outcome.

Insights From Mechanical Models

In addition to the genetic and teratogenic models of neural tube defects, new models of mechanical disruption of normal neural tube development have been described. These models in particular provide further evidence for the "two-hit hypothesis." The first "hit" is the failure of neurulation early in gestation. The second "hit" is the spinal cord injury resulting from prolonged exposure of the neural tissue to the intrauterine environment. The first was a primate model[68] in which a fetal lumbar laminectomy (L3-L5) was performed late in gestation. One group of animals was repaired immediately with allogeneic bone paste, and a control group had no repair. The unrepaired fetuses showed cystic myelomeningocele-like lesions at birth and showed severe neurologic impairment, including paraplegia, incontinence, and somatosensory loss. The repaired group was neurologically normal at birth. Unfortunately, the experiment did not include a period of exposure to the intrauterine environment before closure.[68] These results nevertheless support the hypothesis that prolonged exposure of the spinal cord to amniotic fluid causes considerable damage to the neural tissue in a myelomeningocele-like lesion. Heffez and colleagues[69,70] reported similar findings in fetal pigs and fetal rats. In both studies, late-gestation fetuses underwent surgical creation of a myelomeningocele-like defect with immediate or delayed (24 hours later) surgical closure resulting in preservation of neurologic function compared with the untreated group. Notably, in some of the animals, dehiscence of their skin closure occurred, resulting in neurologic deficit.[70] Histologic examination of the exposed neural tissue revealed erosion and necrosis, findings similar to those described in children with myelomeningocele. More recently, Correia-Pinto and associates[71] demonstrated in a surgically created rat model that late-gestation exposure to meconium increases damage to neural tissue.

These studies show that exposure of the fetal spinal cord to the intrauterine environment results in significant acquired neural tissue damage with corresponding neurologic deficit at birth. In addition, these studies demonstrate that closure of a surgically created myelomeningocele-like lesion is feasible and improves neurologic function at birth. The model that is most similar to simulating the human disease is the fetal lamb model of myelomeningocele introduced by Meuli and co-workers in 1994.[72] The myelomeningocele-like defect was surgically created in fetal lambs at 75 days gestation (term 145 to 150 days) by excision of skin, paraspinal musculature, and vertebral arches of lumbar vertebrae 1 through 4 exposing the dorsal dura mater. At 100 days of gestation, a reversed latissimus dorsi flap was used to cover the exposed spinal cord, and the animals were delivered by cesarean section just before term.[73,74] As in the primate, rat, and porcine models, the untreated fetuses showed myelomeningocele-like lesions at birth with similar neurologic deficits: complete sensorimotor paraplegia, incontinence of stool and urine, and lack of sensory function of the hind limbs.[73,74] Animals that underwent closure of the defect had healed skin wounds and near-normal neurologic function. Despite mild paraparesis, they were able to stand, walk, perform demanding motor tests, and had no signs of incontinence. Furthermore, sensory function of the hind limbs was present clinically and confirmed electrophysiologically.[73,74]

Hindbrain herniation in children with myelomeningocele is hypothesized to result from leakage of cerebrospinal fluid through the open neural tube at a critical time in posterior fossa formation.[75] Based on this hypothesis, Paek and colleagues[76] added a myelotomy to the surgically created myelomeningocele in fetal sheep. They demonstrated severe hindbrain herniation in lambs with a myelotomy and an unrepaired myelomeningocele. In contrast, the brains of lambs that underwent in utero repair of the lesion were normal. Bouchard and co-workers[77] similarly observed the hindbrain pathology in 85% of fetuses that underwent myelomeningocele creation with myelotomy (75 days gestation). The hindbrain anatomy was restored in 88% of the fetuses that underwent fetal myelomeningocele repair (102 days gestation). In other words, creation of a myelotomy allowed the egress of cerebrospinal fluid from the central hindbrain herniation. Closure of the myelomeningocele defect, by blocking the

leakage of cerebrospinal fluid, is thought restore the hindbrain anatomy.

To summarize, the fetal sheep model of myelomeningocele demonstrated that a spinal cord lesion could be created in utero and repaired at a later time with improved neurologic function after birth. Unlike the previous animal models,[68-70,78] this sheep model more closely resembled that of human myelomeningocele in duration and exposure of the spinal neural tissue to the intrauterine environment as well as in clinical and histologic outcome. Furthermore, brain anomalies such as the hindbrain herniation characteristic of the Chiari II malformation could be replicated with the addition of a myelotomy to the creation of myelomeningocele.

The results of these studies suggest that the intrauterine environment plays a considerable role in secondary neural tissue injury, perhaps as much as the primary defect during the neural tube formation. In addition, these models establish the feasibility of in utero repair and its potential for preserving neurologic function.

NEURAL TUBE DEFECTS AS MULTIFACTORIAL DISORDERS

Family History

A family history of spina bifida or anencephaly is one of the strongest risk factors for these disorders. The risk for neural tube defects in the siblings of affected individuals ranges from 3% to 8% and is consistently higher than that of the general population.[79-81] An increase risk for spina bifida or anencephaly, or both, has also been reported for second- and third-degree relatives of affected individuals.[80,82,83] One report suggested that the risk for having a child with neural tube defect might be increased in couples who have had a child with Down syndrome, and the risk for having a child with this trisomy 21 might be increased in couples who have had a child with a spina bifida.[84] However, subsequent studies could not confirm or rule out any potential link between these two disorders.[85]

Genetic Features

Genetic or inherited features are important to understand the etiology of neural tube defects. However, as with most congenital defects, the role of genetic and environmental factors in the development of neural tube defects in humans is not completely understood. Several lines of evidence support the existence of a genetic predisposition, including (1) variable incidence among ethnic groups and geographic locations; (2) familial recurrence risks; (3) genetic syndromes associated with neural tube defect; (4) alterations in genes involved in folate metabolism associated with an increased risk for neural tube defects; (5) altered sex ratio; and (6) mouse models with at least 80 mutant gene loci that are associated with neural tube defects. This genetic distribution has been interpreted as indicating 60% heritability for human neural tube defects.[86] Neural tube defects, however, have a familial allocation that cannot be accounted for by simple mendelian traits. In addition, the large numbers of mouse models of neural tube defects suggest not only the relative ease with which the neurulation process can be disturbed but also the genetic heterogeneity of these abnormalities.

Supplementation with folate during early pregnancy significantly decreases the risk for neural tube defects (see later).[87] The reason for this effect is unknown.[88] Colas and Schoenwolf[12] suggested that supplementation of folate only neutralizes a genetic defect in folate homeostasis, like a metabolic deficiency in its maternal supply[43] or mutations in the methylenetetrahydrofolate reductase gene in the embryo.[89] These genes, however, account only for a small amount of the total genetic environment of neural tube defects.[90] Additionally, folate supplementation reduces the incidence of several congenital malformations,[91] questioning the specificity of its effect in neural tube formation. It appears that the degree and duration of folate deficiency necessary to inhibit DNA synthesis may be greater than the underlying gene defect that is necessary to produce the neural tube defect. In addition, folate deficiency is not by itself adequate to induce neural tube defects in mice.[92]

In view of the complexity of the developmental processes involved in neurulation, the fact that the identification of genetic variants influencing spina bifida risk has proved to be challenging is not especially surprising. The challenge now is to define innovative hypotheses that address the complexity of neural tube defects, including gene-gene and gene-environment interactions and the potential roles of maternal and paternal genotypes. Such a novel and innovative hypothesis has been recently proposed by Rothenberg and colleagues.[93] They suggested that the development of neural tube defects might be associated with the presence of autoantibodies to folate receptor membrane proteins in genetically predisposed women. Such autoantibodies to the folate receptors were found in 9 of the 12 women (75%) with a pregnancy complicated by a neural tube defect, whereas autoantibodies were detected in only 2 of the 24 (8.3%) controls.[93] However, additional studies of larger populations of women with children affected by neural tube defects are warranted to evaluate whether the observed association of autoantibodies against folate receptors and the development of neural tube defects in this pilot study indeed reflects a causal relation.

Environmental Features

Over the years, environmental studies have been instrumental in elucidating the nongenetic causes of neural tube defects in humans. These data suggested that maternal nutrition is important and that vitamin deficiencies, especially of folic acid, play an essential role in the pathogenesis of neural tube defects.[94-96] A lack of folic acid is a common condition usually caused by a low dietary intake and may be correlated to socioeconomic factors. This may be particularly important during pregnancy, when the folate requirement is increased but the availability of folate may be reduced owing to changes in intestinal absorption and renal clearance.[97] The risks for neural tube defects and rates of anencephaly are usually higher in groups with lower socioeconomic status.[98]

Identifying specific causal environmental features has proved difficult. In a National Institutes of Health–sponsored Collaborative Perinatal Project that reviewed the pregnancies of 53,000 women, Myrianthopoulos and Melnick[99] demonstrated that maternal diabetes mellitus, heart disease, lung disease, and the use of diuretics, antihistamines, and sulfonamides were all associated with an increased risk for neural tube defects. In most of the cases, the neural tube defect was not associated with other malformations or syndromes. In addition, women who had a short interval between the end of a previous pregnancy and the current pregnancy had an increased risk for neural tube defect.[99] Maternal diabetes and other modifications of glucose metabolism such as obesity are well known risk factors for offspring with neural tube defects.[100] The risk ranges from as low as 2% in the United States to as high as 8% in England.[101] The mechanism underlying this teratogenic effect has not been established, but it is clearly related to the degree of maternal metabolic control. Indeed, there is evidence that the risk for congenital malformations in the offspring of diabetic women is associated with first-trimester blood glucose concentrations.[102] Whether increased glucose concentrations are directly teratogenic or whether they serve as a marker for another teratogenic agent (i.e. ketone bodies, free oxygen radicals) is unclear.[103]

In addition to diabetes mellitus, there is substantial evidence that the risk for having a child with spina bifida or anencephaly

is increased in obese women. This risk appears to increase with increasing body mass index.[104-106] Whether the increased risk for neural tube defects in obese women could be connected to hyperinsulinemia is under dispute; because hyperinsulinemia might precede or coexist with obesity and diabetes, this metabolic state provides a potential link between these two maternal risk factors. On the other hand, in women who have undergone gastric bypass surgery for the treatment of obesity, the risk for having a offspring with spina bifida is also increased, most attributable to the reduced absorption of nutrients and vitamins.[107]

Other factors include fever and hyperthermia in early pregnancy,[108] viral infection,[109] parental occupation,[110] and maternal diarrhea.[110] An increased risk for neural tube defects is associated with in utero exposure to valproic acid or carbamazepine, or in combination with each other or other anticonvulsants.[111-113] In infants exposed to valproic acid or carbamazepine prenatally, the risk for neural tube defects might be as high as 2%.[114] Women who use these drugs for indications other than epilepsy (i.e., bipolar disease, migraine, chronic pain) are also at increased risk for having a child with spina bifida if they become pregnant while taking these drugs. The mechanisms by which valproic acid and carbamazepine increase the risk for neural tube defects and whether periconceptional folic acid supplementation can reduce these risks remains speculative.[115] The role of maternal and paternal age in the etiology of neural tube defects is still under debate. For example, McIntosh[116] and Strassburg[117] and their colleagues suggest that both advanced maternal age and paternal age are risk factors for neural tube defects. However, other studies have not confirmed this association.[118,119]

NUTRITIONAL STATUS AND PRIMARY PREVENTION

The relation between nutritional status, especially folate intake, and the occurrence of neural tube defects provides a powerful tool for primary prevention of these congenital lesions. However, based on the wide phenotypic spectrum and the multifactorial etiology of neural tube defects, it is surprising that only a single agent, folic acid, has been demonstrated to reduce the incidence of neural tube defect significantly. Smithells and associates[120] demonstrated that administration of a multivitamin preparation to women who had already one or more affected pregnancies resulted in a marked reduction of recurrence of risk for neural tube defect. A subsequent nonrandomized case study and retrospective observational studies supported these initial findings.[121-123] However, the strongest evidence comes from two randomized, double-blind clinical studies. The British clinical trial conducted by the Medical Research Council UK demonstrated a significant protective effect with periconceptional supplementation of 4 mg folate per day in preventing neural tube defects.[95] The Hungarian trial[87] revealed that periconceptional multivitamins (containing 12 vitamins, 0.8 mg of folate, 4 minerals, and 3 trace elements) prevented not only recurrences but also the first occurrence of neural tube defects. In addition, a recent national study of U.S. birth certificate data indicated a 19% decline in the birth prevalence of neural tube defects and 23% decline in spina bifida incidence among births conceived after folic acid supplementation (October 1998 through December 1999) compared with the neural tube defects before folate administration (October 1995 through December 1996).[124]

However, the underlying mechanisms of prevention of neural tube defects are not completely understood. Folic acid is essential as a cofactor for enzymes involved in DNA and RNA synthesis and vitamin B_{12} and vitamin B_6 in the metabolism of methionine.[125] After it was reported that pregnant women with neural tube defects have an elevated blood level of homocysteine,[126] research has been focused on the homocysteine-methylation cycle. As seen in Figure 167-1, reactions regulating this cycle are dependent on one or more of these vitamins. Inadequate levels of methionine may result from inadequate tissue levels of either the coenzyme, vitamin B_{12}, as methylcobalamin, or folate

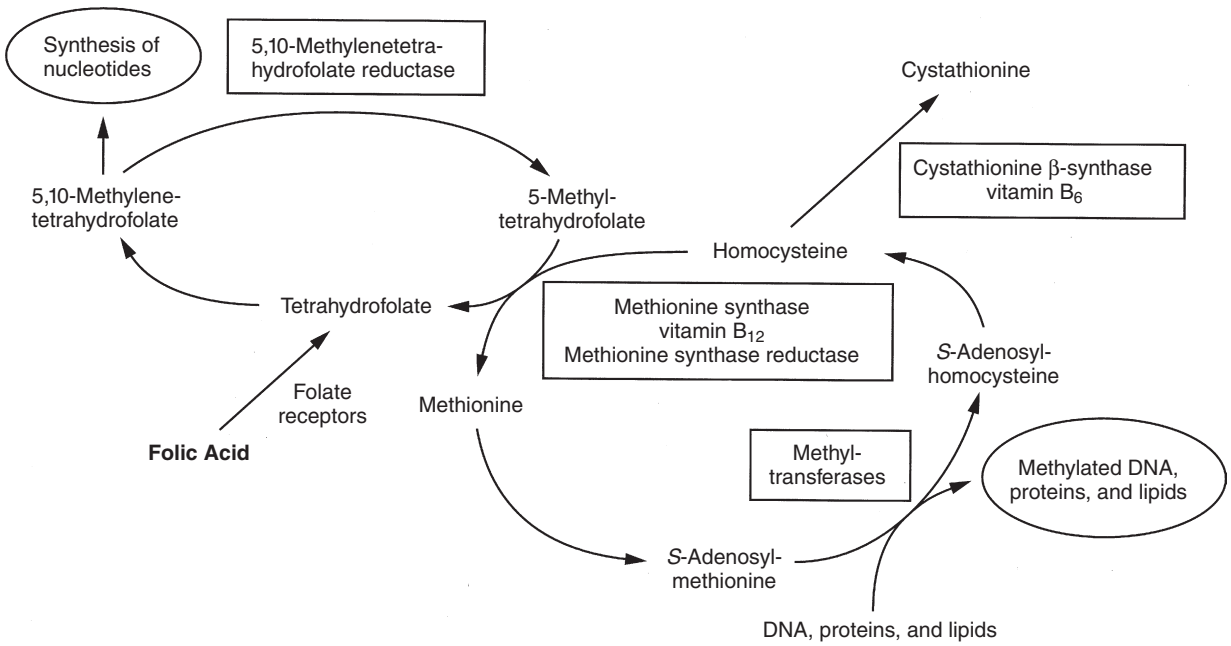

Figure 167-1 The metabolic roles of folic acid. After entering the cell, folic acid, possibly with the aid of folate receptors, is involved in the transfer of carbon atoms that are used to synthesize nucleotides or, through the conversion of homocysteine to methionine, for the methylation of various substrates. These processes are regulated by numerous molecules, including enzymes and vitamins other than folic acid (e.g., vitamins B_6 and B_{12}). The activity of some enzymes, such as methionine synthase, may be influenced by other enzymes, such as methionine synthase reductase. Enzymes and factors that may be important in neural tube development are indicated by *boxes*.

as 5-methyl-THF, of the methionine metabolism. Vitamin B_6 is involved in the first irreversible step in the transsulfuration pathway from methionine to cysteine. Disturbance in the activity of cystathionine β -synthase results in homocysteinemia. Therefore alterations of the vitamin B_{12}–dependent methionine synthase, folate-dependent methylenetetrahydrofolate-reductase and vitamin B_6–dependent cystathionine β -synthase may play a causative role in the development of neural tube defects. Treatment with vitamin B_6 normalizes the hyperhomocysteinemia and hypermethioninemia in approximately 50% of patients[127] and may result in a decreased risk for neural tube defects. These hypotheses are supported by experimental studies. For example, neural tube defects are prevented by methionine and folate supplementation in some rodent models,[43,128] or the effect of homocysteinemia in the pathogenesis of neural tube defects in chick embryo can be ameliorated by simultaneous folate supplementation.[88] However, the link between common mutations of the genes for methionine synthase, methylenetetrahydrofolate-reductase, and cystathionine β -synthase in humans could not be documented.

To summarize, despite the progress in the research on pathogenesis and approaches to primary prevention, the interpretation of these findings remains difficult. Prevention is not possible in all cases of neural tube defects, but supplementation of folate in a periconceptional dose of 0.4 to 4.0 mg/day can prevent the first occurrence and up to 85% of recurrent neural tube defect.[87,95,129,130]

SPECTRUM AND CLINICAL PRESENTATION

Although most studies of neural tube defects deal only with anencephaly and myelomeningocele, the clinical spectrum also includes craniorachischisis totalis, encephalocele, exencephaly, myeloschisis, and iniencephaly (Fig. 167-2). Malformations of the normal midline fusion are often referred to as being dysraphic and vary in clinical significance and outcome. Several different schemata are used to categorize neural tube defects; however, the nomenclature is confusing and even contradictory. Most of the lesions involve a failure of neural tube closure. The term *neural tube defect* is used to characterize this entire group of anomalies. Because the varying forms of neural tube defects probably arise by different mechanisms, it is important to appropriately describe and classify each defect. Based on the clinical significance and embryology, neural tube defects should be subdivided into cranial neural tube defects, open spinal neural tube defects, and closed spinal neural tube defects. Disorders of neural tube formation are reviewed next in order of decreasing severity.

Cranial Neural Tube Defects

Craniorachischisis Totalis

This malformation is characterized by a total failure of neurulation. This is the most severe form of neural tube defects. It occurs before 20 to 22 days of gestation.[131] A neural plate remnant is present throughout, and there is no overlying axial skeleton or dermal covering. Because most cases with craniorachischisis totalis are aborted spontaneously and only few have survived to term, the incidence remains unknown.

Anencephaly

Anencephaly (congenital absence of major portion of the brain, skull, and scalp)[132] is the single most common prenatally detected neural tube defect with an incidence ranging from 1 in 1000 live births and stillbirths in the United States to 1 in 100 live and stillbirths in some of the British Isles.[133] In one study, the prevalence of this neural tube defect was noted to change over time owing to the impact of prenatal sonographic examination and maternal serum screening. Limb and Holmes[134] reported an incidence of anencephaly that varied between 1.0 and 0.4 per 1000 live births and stillbirths during two different study periods (1972 to 1974 and 1979 to 1990). Female fetuses are more commonly affected than males, with a frequency of 3:1 to 4:1.[135] Furthermore, there is an increased incidence of anencephaly in Hispanics, who are 45% more likely than whites to have an affected pregnancy.[136] Anencephaly is associated with maternal hyperthermia as well as with maternal folate, copper, and zinc deficiencies.

In affected fetuses, there is a failure in the development of structures associated with the anterior neural tube closure. The defect is estimated to occur between 24 to 26 days gestation.[137] The anomaly involves variable amounts of the forebrain and upper brain stem. In some cases, the defect extends through the level of the foramen magnum (holoacrania or holoanencephaly are the more severe form,) or may be limited (merocrania or meroanencephaly are the milder forms). In addition to the absent cerebral hemispheres, fetuses with anencephaly demonstrate abnormal patterns in the hypothalamus and cerebellum. The frontal, parietal, and squamous parts of the occipital bones fail to develop; instead, the defect may be covered by a variable amount of angiomatous stroma.[9] The exposed neural tissue appears as a hemorrhagic, fibrotic, and degenerated mass of neurons and glia, with no functional cortex.[138]

Anencephaly is uniformly fatal. Most affected fetuses are spontaneously aborted or stillborn. Through reliable prenatal diagnosis, anencephaly is one of the few universally accepted indications for third-trimester termination.[139] The diagnosis of anencephaly can be confirmed on physical examination when the following criteria are met: (1) a large portion of the skull is absent; (2) the scalp is absent over the skull defect; (3) a hemorrhagic fibrotic mass of degenerated brain tissue is exposed to the environment; and (4) no recognizable cerebral hemispheres are present. Because orbits and eyes in anencephalic fetuses are well developed, this malformation imparts a remarkable froglike appearance to the patients. There is no functioning cerebral cortex, but brain stem function is present in varying degrees. Almost all fetuses born with anencephaly die within the first week, but rarely survival for several months has been reported.[132]

Exencephaly

Exencephaly is a rare fetal anomaly that is incompatible with extrauterine life. This malformation is characterized by partial or complete absence of the calvaria with abnormal development of brain tissue.[140] According to Papp and associates,[141] who screened 36,075 pregnancies for neural tube defects, the incidence of exencephaly is 3 per 10,000 pregnancies. Cox and associates[142] concluded that exencephaly probably represents an embryonic precursor to anencephaly. However, reopening or degeneration of a previously closed neural tube is also possible. Stagiannis and colleagues[143] considered the development of exencephaly related to a failure in mesenchymal migration. The exact pathogenesis remains uncertain.

The absence of the calvaria causes brain destruction by exposing the developing brain to amniotic fluid and repeated trauma. The exposed brain may be destroyed as early as 8 to 10 weeks gestation.[142] In pathologic studies, the exencephalic brain is observed to be covered by a highly vascular epithelial layer. In exencephaly, two relatively equivalent cerebral hemispheric remnants are present within a reddish mass of disorganized tissue, remnants of deep cerebral neural elements, blood vessels, fibrotic tissues, and fluid-filled spaces.[144] In addition, in exencephalic brain tissue, the gyri and sulci are shallow, flattened, and disorganized.

Experimental studies have demonstrated that hyperglycemia can induce exencephaly in mice,[145] and administration of clomiphene citrate before ovulation in female mice increases the incidence of exencephaly.[146] These effects in mice are similar to the inhibition of neural tube closure seen in newborns of diabetic mothers.

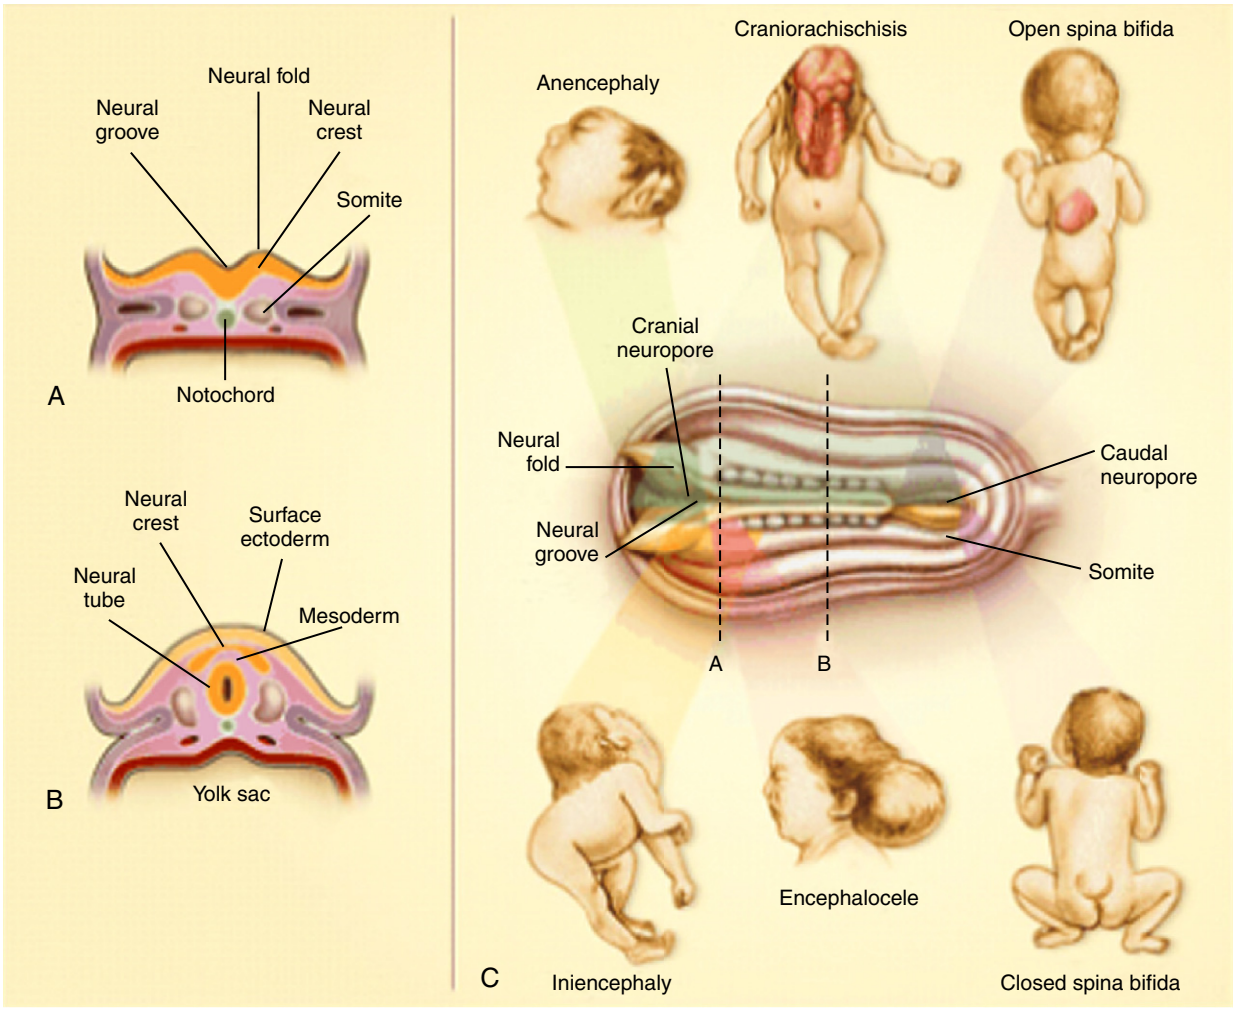

Figure 167-2 Features of neural tube development and neural tube defects. A, Cross section of the rostral end of the embryo about 3 weeks after conception, showing the neural groove in the process of closing, overlying the notochord. The neural folds are the rising margins of the neural tube, topped by the neural crest, and demarcate the neural groove centrally. **B,** Cross section of the middle portion of the embryo after the neural tube has closed. The neural tube, which will ultimately develop into the spinal cord, is now covered by surface ectoderm (later, the skin). The intervening mesoderm will form the bony spine. The notochord is regressing. **C,** Developmental and clinical features of the main types of neural tube defects. The diagram in the center is a dorsal view of a developing embryo, showing a neural tube that is closed in the center but still open at the cranial and caudal ends. The *dotted lines* marked *A* and *B* refer to the cross sections shown in **A** and **B.** *Shaded bars* point to the region of the neural tube relevant to each defect. In anencephaly, the absence of the brain and calvaria can be total or partial. Craniorachischisis is characterized by anencephaly accompanied by a contiguous bony defect of the spine and exposure of neural tissue. In open spina bifida, a bony defect of the posterior vertebral arches (in this case, the lower thoracic vertebrae) is accompanied by herniation of neural tissue and meninges and is not covered by skin. In iniencephaly, dysraphia in the occipital region is accompanied by severe retroflexion of the neck and trunk. In encephalocele, the brain and meninges herniate through a defect in the calvaria. In closed spina bifida, unlike open spina bifida, the bony defect of the posterior vertebral arches (in this case, the lumbar vertebrae), the herniated meninges, and neural tissue are covered by skin. *(From Botto LD, Moore CA, Khoury MJ: Neural-tube defects,* N Engl J Med *341:1509, 1999.)*

Encephalocele

This condition arises as a failure of fusion of restricted parts of the anterior neural tube closure between 26 and 28 days gestation and demonstrates a variable degree of cerebral herniation through a midline defect of the cranium. However, it is difficult to explain the development of encephalocele merely on embryologic grounds, and its precise pathogenesis remains unknown. Additionally, it has been suggested that the anomaly may occur secondary to herniation of brain through the cranium in the second trimester because of hydrocephalus and is not a primary defect of neural tube closure. In a U.S. study comprising a 17-year survey of births occurring in armed forces hospitals, Wiswell and colleagues,[147] recognized 112 cases of encephalocele in 763,364 live births. This yields an incidence 0.15 per 1000 live births. However, the incidence varies within ethnic groups and geographic regions.[148] In the Western world, 75% occur in the occipital region, and frontoethmoidal encephaloceles are more common in Malaysia, Thailand, Indonesia, Burma, and parts of Russia.[149-151] The neural tissue within the defect may be relatively normal, although hemorrhage, necrosis, and cortical dysplasia are present in some cases.[152]

Encephaloceles are frequently associated with microcephaly, maternal rubella, maternal diabetes, and genetic syndromes. In addition, encephaloceles are often found with other

malformations,[150] including agenesis of the corpus callosum, lissencephaly (in Walker-Walburg syndrome) and craniosynostosis (Apert syndrome), or even with renal cystic dysplasia and polydactyly (Meckel-Gruber syndrome). Encephalocele can be produced experimentally by irradiation, trypan blue, or hypervitaminosis.

The prognosis and long-term outcome are dependent on the associated brain malformations and syndromes. Large size is not important prognostically because large encephaloceles may not contain neural elements. Microcephaly and the presence of neural tissue in the encephalocele are associated with a poor prognosis.[153] The surgical challenges in affected newborns include closing the anatomic defect in the cranial vault and achieving as near normal a functional outcome as possible with minimal psychomotor defects.[154]

Myeloschisis

The essential defect in myeloschisis is failure of posterior tube closure. This anomaly arises not later than 26 days gestation. The exposed neural plate–like formation involves large portions of the spinal cord and appears as a flat, raw, velvety structure with no vertebrae or dermal covering. Most of these fetuses are stillborn and merge with the category of more restricted anomalies of neural tube development, such as myelomeningocele.

Iniencephaly

Iniencephaly is an abnormality in cervical vertebrae associated with cervicothoracic spinal retroflexion and neural tube defect. Lewis[155] classified iniencephalus into two subtypes: iniencephalus apertus, in which there is involvement of the brain with an encephalocele present; and iniencephalus clauses, in which no malformation of the occipital bone or brain is present. In iniencephaly, developmental disturbances of the neural tube and spine arise very early in embryogenesis, generally between day 26 and 30 after conception.

Iniencephaly is a rare condition with an estimated incidence between 1 in 1000 to less than 1 in 100,000.[156] Because most iniencephalic fetuses dies in utero, it is difficult to estimate the true incidence accurately. Experimentally, iniencephaly can be produced with administration of vinblastine, streptonigrin, or triparanol.[157] The pathogenesis of iniencephaly in humans, however, remains unknown. It has been noted that in geographic areas where there is an increased prevalence of anencephaly, there is also an increased prevalence of iniencephaly.[158] Different hypotheses for the pathogenesis of iniencephaly have been developed. It is possible that a primary defect in fetal cervical development resulting in extreme dorsal flexion of the head (lordosis) causes a failure of neural tube closure or even dilation and rupture of a previously closed neural tube.[157] Additionally, iniencephaly may be a primary defect in neural tube formation. Gardner[159] suggested that iniencephaly might be a severe form of the Klippel-Feil syndrome or may belong to the spectrum of malformations of the Dandy-Walker syndrome and the Arnold-Chiari malformation.

In the series of David and Nixon,[160] of 50 fetuses with iniencephaly, 84% had multiple associated malformations. The most frequent malformations were hydronephrosis, cardiovascular malformations, single umbilical artery, diaphragmatic hernia, facial clefts, omphalocele, and clubfoot.[160] Associated abnormalities of the CNS include anencephaly, encephalocele, hydrocephalus, hydromyelia, microcephaly agenesis of the cerebellar vermis, and presence of cerebellar cyst.[157,161] The abnormal fetal growth occurring at such an early stage in gestation might be the reason for the multiple associated malformations, owing to subsequent hindering and cramping of structures related to the retroflexed fetal neck.[160] Despite two case reports that discussed the same surviving iniencephalic patient,[156,158] iniencephaly is almost always lethal.

Open Spinal Neural Tube Defects

Myelomeningocele

Myelomeningocele, or open spina bifida, is a nonlethal neural tube defect with sequelae that affect both the central and peripheral nervous systems. The lesion is characterized by the protrusion of the spinal cord and meninges from the spinal canal with an abnormality in the overlying vertebral arches, muscle, and skin. The lesion is generally cystic and contains cerebrospinal fluid that drains when the thin sac is disrupted. It is a severe form of spina bifida affecting about 1 of every 2000 children born worldwide.[162,163] Not included in this figure are the 23% of pregnancies ending in elective termination of affected fetuses.[164,165]

More than 80% of children with a neural tube defect can be detected by maternal serum alpha fetoprotein screening before birth.[166] Although the determination of amniotic fluid acetylcholinesterase can be helpful, ultrasound is the method of choice in the diagnosis of neural tube defects. Direct visualization of the fetal spine can usually be accomplished by 16 weeks gestation. In the past two decades, the sonographic diagnosis of myelomeningocele has been enhanced by the introduction of high-resolution imaging tools and by recognition of specific brain abnormalities.[167] The CNS abnormalities associated with neural tube defects include cerebral ventriculomegaly, microcephaly, abnormalities of the frontal bone, and obliteration of the cisterna magna with anterior curving of the cerebellar hemisphere (banana sign) or an abnormal concavity of the cranium (lemon sign).[168] The abnormal findings of the CNS are thought to be a consequence of the hindbrain herniation (Arnold-Chiari II malformation). First described by Arnold and Chiari at the end of the 19th century,[169,170] the Arnold-Chiari II malformation is defined as the maldevelopment of a small posterior fossa and the herniation of the cerebellar vermis and brain stem (including the fourth ventricle) through an enlarged foramen magnum. Additionally, agenesis of the corpus callosum, enlargement of the massa intermediata, cortical heterotopia, and polymicrogyria can be seen. The etiology of the Arnold-Chiari II malformation remains in dispute. The predominant hypothesis maintains that an imbalance of hydrodynamic forces occurs secondary to loss of cerebrospinal fluid from the lesion.[76,77,171,172] An alternative theory interprets the hindbrain herniation as the consequence of a traction injury caused by cranial growth imbalance.[171,173-175] Overgrowth of the cerebellum and the brain stem, along with a posterior fossa that is smaller than normal, leads to downward dislodgment of these structures and results in Arnold-Chiari II malformation.[176] Despite these controversies about the etiology of myelomeningocele-associated hindbrain herniation, they are identifiable in the embryo from as early as 8 weeks gestation and are established in the fetus by the 12th week.

Pathologic studies of human embryos and fetuses with myelomeningocele in earlier stages of gestation reveal an open neural tube but undamaged neural tissue with almost normal cytoarchitecture.[177] This suggests that neural degeneration occurs at some point later in gestation (the two-hit hypothesis).[178] The first hit is the failure of neurulation early in gestation. The second hit is the spinal cord injury resulting from prolonged exposure of the neural tissue to the intrauterine environment. In theory, this secondary event can be prevented if an adequate prenatal covering of the exposed neural tissue can be provided. To have the best outcome, this repair must be fashioned before the onset of irreversible neural damage. There are several observations in human embryos, fetuses, and infants to support this premise.[178,179]

Osaka and co-workers[180] studied 18 embryos with classic caudal myelodysplasia and found an everted neural plate but preservation of the membranes. Interestingly, Chiari II malformation was not found in any of these embryos, whereas hindbrain herniation was present in two fetuses with caudal myelodysplasia in the same series. Additionally, pathologic signs of ventriculomegaly

were not noted in the embryos but were found in one fetus with Chiari II malformation.[180]

In pathologic examination of spinal cords of stillborn human fetuses with myelomeningocele (19 to 25 weeks gestation), varying degrees of neural tissue loss at the site of the lesion were observed, but the dorsal and ventral horns were normal proximal to the defect.[178] This group was among the first to suggest the two-hit hypothesis because they attributed these alterations to injuries occurring subsequent to the failure of primary neural tube formation. A study of 10 additional fetuses had similar findings.[179]

Marin-Padilla[181] examined a number of human dysraphic malformations and concluded that the primary anomaly was a disturbance of the axial chordomesodermal tissue to support adequate lodging and protection of the developing nervous system and that degeneration and destruction of the neural tissue occur secondarily. Additional support exists for the two-hit hypothesis from recent in vitro studies. Drewek and colleagues[182] reported that damage to open neural tissue appears to be progressive and results from exposure to toxic substances in the amniotic fluid during the third trimester.

Korenromp and colleagues[183] observed that fetuses with myelomeningocele exhibited leg movement at 16 to 17 weeks gestation. They suggested that these affected fetuses did have good function at that point in gestation. No follow-up could be reported in this series because pregnancies were interrupted. Furthermore, Sival and associates[184] compared the leg movements of 13 fetuses with myelomeningocele prenatally and postnatally. Only 1 of the 13 had abnormal leg movement before birth, but 11 demonstrated abnormal leg movements postnatally. Two possible explanations for this phenomenon exist. The prenatal leg movements could be secondary to spinal cord reflex rather than of cerebral origin, thus permitting motion without electrical impulses conducted through the damaged spinal cord tissue. In addition, leg movement early in pregnancy could be due to cerebral function conducted through an exposed spinal cord that is not yet damaged.

Most newborns with myelomeningocele show neurologic impairment of the lower extremities at birth, suggesting that the neurologic injury might occur later in gestation or even at the time of delivery. It is remarkable that patients with lipomeningomyelocele, in which the neural tissue is covered and protected by skin, often have almost normal lower leg and continence function, despite a neurulation abnormality that is nearly identical to that present in newborns with open neural tube defect. These studies support direct injury as the primary cause of damage and loss of function because neural tissue is injured exclusively from the protruding spinal cord.[178,179] As the pregnancy progresses, the volume of the amniotic fluid decreases, which may result in more frequent contact of the exposed neural tissue with the uterine wall. Chick models of oligohydramnios, in which pressure necrosis of prominent areas of the body developed, support this hypothesis.[185]

Closed Spinal Neural Tube Defects

Clinically, closed neural tube defects should be subdivided from open neural tube defects because the embryogenesis appears to differ in most cases. In open defects, there is an essential failure during the primary neurulation, whereas closed neural tube defects appear to result from another form of disturbance during neural tube formation.[186] With few exceptions, the structural malformations of closed neural tube defects are limited to the spinal cord and are not associated with the Arnold-Chiari II malformation or hydrocephalus. In contrast to open defects, newborns with a closed neural tube defect have no exposed neural tissue and do not leak cerebrospinal fluid. Additionally, the prognosis of an infant affected by a closed defect is significantly better than one with an open neural tube defect. Children born with closed defects generally have an intellectual function that is of the same distribution as the normal population, do not require cerebrospinal fluid–diverting shunts, and have considerably fewer problems with lower extremity sensory-motor function and bladder and bowel function.[186] Because the clinical manifestations of closed defects can be undetected for days or even years, the etiology of this group of neural tube defects is unidentified, and no link to genetic, environmental, or dietary factors has as yet been found. The major forms of closed neural tube defect are briefly described below.

Meningocele

This defect is commonly located in the lumbosacral region. Meningoceles are often covered with skin, and the bony abnormality rarely involves more than two to three vertebrae. The sac of the meningocele consists of both arachnoid and dural meninges and contains cerebrospinal fluid. Most meningoceles also contain neural elements. Meningoceles are an infrequent and heterogeneous group of cystic lesions. The accurate prevalence of meningocele is subject to debate because meningoceles are often grouped with myelomeningoceles. Furthermore, the pathogenesis remains unknown. The neurologic outcome of affected newborns is normal, but surgical correction and resection of the herniated meninges are indicated.[187]

Lipomatous Malformations

This abnormality includes all the closed neural tube defects with excessive lipomatous tissue present within or attached to the spinal cord or filum terminale. These lesions are called *lipomyelomeningocele, lipomyelocele, leptomyelolipoma, lumbosacral lipoma,* or *lipoma of the filum terminale*. The origin of lipomatous closed neural tube defects is controversial. Recently, two different theories have been advanced: (1) lipomas arise from cells originating from the somatic mesoderm and (2) lipomatous closed neural tube defects are a true malformation resulting from defective neurulation.[188] Most affected infants have a good prognosis with nearly normal leg and urologic function.

Dermal Sinus

A dermal sinus is a deep squamous epithelium–lined tract found on or near the midline. They are most common in the lumbosacral region (63%),[189] sometimes containing hair or occasionally communicating with the dura. Abnormal adhesions between the ectoderm, which form the neural tube and that which is destined to form the skin, are discussed as the primary cause of dermal sinuses.[187] Surgical removal of the lesions is indicated because of the risk for infection and compression of underlying neural elements by the progressive enlargement of the dermal sinus.

Diastematomyelia

The caudal cord in diastematomyelia (split cord malformation) is divided by a median septum arising from a vertebral body. Each of the hemicords has a single set of dorsal and ventral nerve roots, each contained within its own dural sheath. It has been suggested that the defect results from a failure during neurulation and that a second neuroenteric canal becomes advanced with mesenchyme to form an endomesenchymal tract that splits the notochord and neural plate.[190] A few studies have reported that up to 39% of split cord malformations are associated with myelomeningocele.[191,192] Because of the considerable rate of coexistence of these two neural tube defects, Pang and co-workers[190] proposed a common embryogenesis for split cord malformations and myelomeningocele.

THE BURDEN OF NEURAL TUBE DEFECTS

Anencephaly and myelomeningocele are important contributors to fetal and infant mortality. All newborns affected by anencephaly are stillborn or die shortly after birth, whereas children born

with a myelomeningocele usually survive. However, the risk for death with neural tube defects varies significantly worldwide, depending not only on the severity of the defect but also on such aspects as availability, use, and acceptance of medical and surgical intervention. For example, in some regions of northern China nearly 100%,[193] in the Netherlands 35%,[194] and in the United States 10%[195] of children affected by neural tube defects die.

For those infants affected by myelomeningocele, the significant lifelong disabilities accompanying this malformation include paraplegia, hydrocephalus,[196] pulmonary dysfunction,[197] sexual dysfunction, skeletal deformations and spinal deformities,[198] incontinence, and cognitive impairment,[199] with approximately 15% requiring some form of custodial care.[200,201]

Infants with myelomeningocele almost always have evidence of Chiari II malformation on magnetic resonance imaging.[202] This represents a caudal displacement of the inferior portion of cerebellar vermis, the medulla, and lower pons, and an elongated fourth ventricle through the foramen magnum. Despite aggressive postnatal intervention, nearly 14% of neonates with spina bifida do not survive past 5 years of age, with the mortality rate rising to 35% in those with symptoms of brain stem dysfunction secondary to the Chiari II malformation.[203] Clinical symptoms include swallowing difficulty, apnea, and stridor. Strabismus, a nonlethal Chiari II complication, is found in as many as 61% of patients with myelomeningocele.[204] Furthermore, the hindbrain deformity leads to ventriculomegaly in most cases because of impaired circulation of cerebrospinal fluid. Complications of ventriculomegaly may lead to the impaired cognitive development seen in children with myelomeningocele.[205]

Rintoul and associates[196] performed a retrospective review of 297 patients born with myelomeningocele and described the natural history of ventricular shunting in myelomeningocele patients in relation to radiologic and functional criteria. Most closures (92%) and shunt placements (62%) were performed in the first week of life. The timing of shunt placement and the number of shunt revisions were independent of the level of lesion. The overall incidence of shunting was 81%, which is consistent within the generally accepted range of 80% to 85% for an unselected spina bifida population.[206,207] The rate of ventricular shunting is significantly correlated to the anatomic level of the lesion.[196] All patients with a thoracic functional level required postnatal shunting, compared with 88% of lumbar level and 68% of sacral level patients.

The availability of new medical and surgical treatment modalities has significantly decreased the risk for some long-term medical complications, such as renal failure and severe dermatologic problems, affecting the risk for death among adults with myelomeningocele.[208] For example, Shurtleff and colleagues[209] and Hunt[210] documented that the survival rate to nearly the third decade of life was more than 50% in affected persons in whom the defect was surgically repaired shortly after birth.

The maldevelopment of the spinal cord is generally associated with some degree of weakness and lack of sensation in the lower limbs. Children younger than 8 years can often walk, sometimes without any assistance. However, as the children get older and heavier, their weight-power ratio increases, and walking becomes more difficult; later, many of the affected children need wheelchair assistance.

Another, potentially preventable complication of patients with spina bifida is a disease-associated latex sensitization.[211,212] Up to 43% of children with spina bifida are affected.[211] However, it remains unclear whether this association is a consequence of repeated exposure to latex-containing products (e.g., gloves or catheter material)[213] or is due to a potential genetic contribution and alteration of the human leukocyte antigen phenotype.[214]

In addition to the emotional impact on the family, the financial burden for family and community are enormous. In the United States, the costs of care for infants born with spina bifida in 1988 were almost $500 million per year (in 1992 dollars) or $294,000 for each infant.[215]

TREATMENT OPTIONS

Standard Treatment

Most fetuses with myelomeningocele that are not electively terminated receive no treatment until after birth. Several studies have investigated whether the method of delivery influences the neurologic outcome in infants with myelomeningocele. Although studies by Luthy[216] and Shurtleff[195] and their associates suggest that cesarean section before the onset of labor for fetuses with myelomeningocele may reduces injury to the exposed neural tissue by minimizing contact with the uterine wall and birth canal associated with labor and vaginal delivery, subsequent investigations showed that there is no conclusive evidence that cesarean section improves neurologic outcome in infants with myelomeningocele relative to vaginal delivery.[217,218] However, none of these studies compared vaginal delivery with elective cesarean section in a randomized, controlled fashion.

An initial neurologic evaluation of the newborn by the neonatologist, pediatric neurologist, and neurosurgeon is essential to assess the functional level, the neurologic deficit, and the potential complications (e.g., hydrocephalus, deformities of the lower legs, lower leg movement problems, and future continence problems) and should include a sensory examination to determine the level of the lesion and prognosis for motor ability. Surgical repair of the defect is usually performed within the first 24 to 48 hours of life to minimize the risk for infection.[219] The goal of postnatal myelomeningocele repair is to untether the placode and cover the lesion while preserving function. Because neurologic function typically exists only above the exposed spinal cord, sacrifice of some spinal cord tissue and nerve roots has been considered acceptable.[220]

Fetal Neurosurgical Intervention

Prior to 1997, fetal surgery was considered only for fetuses with life-threatening anomalies.[221,222] However, the severe morbidity and significant mortality associated with myelomeningocele (MMC), combined with the promising results of animal research, led to consideration of prenatal intervention for this disorder. The first case of open fetal MMC (fMMC) surgery was performed in 1994 using an endoscopic technique.[223] This approach at Vanderbilt University proved disastrous (two of four fetuses died) and was abandoned. Percutaneous fetoscopic patch coverage has been tried more recently in a small series of patients, and has also proved enormously problematic.[224,225] Investigators from the University of California, San Francisco[224] (UCSF) reported three patients that underwent fetoscopic MMC surgery. Fetoscopic coverage was successfully completed in one patient. However, the patch partially detached after fetal surgery and the newborn required standard repair and shunt placement postnatally. Due to technical difficulties, the MMC defect in the second fetus was never completely covered and the fetus was delivered prematurely at 31 weeks gestation. Postnatally, the newborn required neurosurgical repair of the lesion and ventriculoperitoneal shunt placement, and subsequently died of urosepsis at one month of age. The third fetus required conversion to an open approach secondary to an anterior placenta and difficulties to appropriately position the fetuses. In the case series by Kohl and associates,[225] endoscopic coverage of the MMC defect in three fetuses resulted in fetal patch detachment in one fetus, successful completion of the operation in the second, and fetal death in the third. Premature rupture of membranes is a substantial problem with the multiple port site fetoscopic approach.

The first successful (that is, improved postnatal neurologic function) fMMC surgery in an early gestation human fetus was performed by our group at the Children's Hospital of Philadelphia

(CHOP) in 1998.[226] A 23-week gestation fetus with T11-S1 lesion, hindbrain herniation, and normal lower extremity movements assessed by preoperative high-resolution ultrasonography, underwent open surgical coverage of the dysraphic defect. Surgery and recovery were uneventful, and the fetus was delivered by cesarean section at 30 weeks gestation after the onset of preterm labor. Postnatally, the infant had a right clubfoot deformity and neuromotor function at the L4 level on the right and L5 level on the left. Whereas hindbrain herniation was documented preoperatively, postnatal magnetic resonance imaging confirmed complete resolution of hindbrain herniation and absence of ventriculomegaly, and as a consequence, a ventriculoperitoneal shunt was not required.

Subsequent studies from CHOP and Vanderbilt University suggest that infants that were treated prenatally had improvement in hindbrain herniation as early as 3 weeks post fMMC surgery and appeared to have a diminished need for shunting relative to infants that underwent standard postnatal neurosurgical repair.[227,228] Compared with historical controls, it was estimated that fMMC surgery may reduce the need for ventriculoperitoneal shunt placement from 80%-90% to 40%.[196,229] The functional significance of the more normal position of the hindbrain, reduced shunt rate, and the restoration of near-normal cerebrospinal fluid (CSF) hydrodynamics[230,231] is that the vast majority of fMMC children demonstrated absent to mild brain stem dysfunction symptoms at 6 years follow-up.[232,233]

Recent evaluation of children that underwent fMMC surgery at CHOP not only showed that the initial improvement in lower extremity function at birth persisted into preschool age, but also revealed that 69% of fMMC children were independent walkers at a mean follow-up age of 66 months.[234] However, toddlers and preschool children often continue to demonstrate coordinative deficits and gait disturbances that are characteristic of children with MMC. Despite these promising findings, recently a few of the patients have developed clinical symptomatic spinal cord tethering in association with dermoid inclusion cysts at the fetal closure site and have required repeat surgery, usually with restoration of function.[235] A possible late decline in neuromotor function owing to tethering with or without a dermoid inclusion cyst underscores the importance of investigating better coverage materials and techniques for fMMC surgery as well as careful, continued, long-term neurologic surveillance of these children.

Regarding preschool neurocognitive outcome, 30 of the initial 54 fMMC survivors (56%) at CHOP underwent standardized preschool neurodevelopmental assessment.[236] At a mean follow-up age of 61 months, the majority of fMMC children had neurocognitive scores in the average to high-average range and are at an age-appropriate point in schooling. Although fMMC children who did not require ventriculoperitoneal shunt placement were more likely to have better scores, for the entire cohort there was a pattern of consistently higher scores in the verbal areas compared with scores for visual-motor or nonverbal learning skills, suggesting the possibility of later learning difficulties.[236] More recently we evaluated the impact of prenatal intervention on daily life functional status in children who underwent fMMC surgery at CHOP prior to the randomized trial.[237] Our results showed that although the majority of fMMC children achieve neurocognitive and neurofunctional independence, nearly one-third continue to require maximal assistance when carrying out self-care tasks (e.g. toileting, bladder and bowel management). These functional studies confirm previous findings by other centers that show only minimal impact of prenatal MMC surgery on continence function.[238,239]

Comparisons of infants with spina bifida who were treated *in utero* with previously reported postnatally repaired controls are subject to substantial bias. Additionally, the medical management of such infants might differ from that of historical controls for reasons unrelated to fetal surgery. For these reasons, the National Institutes of Health sponsored a multicenter, prospective, randomized clinical trial, comparing outcome after in utero and postnatal surgery for MMC. The Management of Myelomeningocele Study (MOMS) was initiated in 2003, and in December 2010 enrollment was stopped because the efficacy of prenatal surgery was demonstrated after recruitment and randomization of 183 of a planned sample size of 200 patients.[240] The study was performed by three fetal surgery units (CHOP, Vanderbilt, and UCSF), the Data Study and Coordinating Center at George Washington University, and the Eunice Kennedy Shriver National Institute of Child Health and Human Development. The objective of the trial was to determine if intrauterine surgery of MMC between 19 and 25 weeks gestation improves outcomes compared with standard postnatal neurosurgical repair. One primary outcome was a composite of fetal or neonatal death or the need for placement of a CSF shunt by the age of 12 months, and another primary outcome at 30 months of age was a composite of mental development and motor function. A variety of secondary neonatal and maternal outcome measures were also examined. Similar to the earlier, nonrandomized results of patients who underwent fMMC surgery, the MOMS trial showed a significant reduction of ventriculoperitoneal shunt placement at one year of age following fMMC surgery (prenatal group: 40% vs. postnatal group: 82%, $P < 0.001$).[240] The trial also demonstrated a substantial improvement in the overall neuromotor function at 30 months of age by a variety of measures including the finding that 42% of fMMC children were walking independently compared with only 21% in the postnatal group ($P < 0.01$). Finally, there was much less hindbrain herniation in the fMMC surgery group than in the postnatal surgery group (no hindbrain herniation in 36% and 4% of the infants, respectively, and severe herniation in 6% and 22%, respectively, $P < 0.001$).[240] The impact on mental capacity, bladder and bowel continence, and sexual function remains to be elicited as these infants advance in age and development.

Despite these promising results, the MOMS trial also revealed that fMMC surgery increases the risks for spontaneous rupture of membranes (prenatal surgery: 46% vs. postnatal surgery: 8%, $P < 0.001$), oligohydramnios (21% vs. 4%, $P = 0.001$), and preterm delivery (79% vs. 15%, $P < 0.001$) including 13% of fMMC children that were born before 30 weeks gestation.[240] The average gestational age at delivery in the prenatal surgery group was 34.1 weeks gestation compared with 37.3 weeks gestation in the postnatal surgery group. Also, at the time of delivery, approximately 25% of mothers in the fMMC surgery group showed evidence of thinning of the uterine wound, and 10% demonstrated variable degrees of dehiscence at the hysterotomy site, but none had a hysterotomy rupture.

Consequently, additional research is necessary to further elucidate the pathophysiology of MMC, to define the ideal timing and technique of fetal closure, and to evaluate the long-term implication of prenatal intervention.

Xq28, cause X-linked aqueductal stenosis and agenesis of the corpus callosum, occuring about once in 20,000 births.[7,8] The flat dorsal aspect of the embryo develops lateral furls, and then invagination of the neural plate forms a fold. A tube appears along the length of the fetus by fusion of this fold, proceeding both forward and backward.The anterior neuropore closes at day 24, and the posterior neuropore closes at days 26 to 28.[9,10] The neural tube initially consists of a single layer of neuroectodermal cells. These cells proliferate and generate neuroepithelial progenitors for neurons and neuroglial cells. Radial glial cells, which appear early during neural tube formation, are stretched as the neural tube enlarges. Neurons originate at the inner lumen border of the neural tube and then migrate outward along the radial glial cells.Thus the deepest cortical region contains the ontogenically oldest neurons.[11,12]

Neural crest cells, derived from neuroectoderm of the dorsolateral neural tube, form the peripheral and enteric nervous systems.The neural crest cells migrate from the neural tube into the surrounding mesenchyme at about the time of neural tube closure.The cephalic neural crest gives rise to cells that contribute to the formation of the facial skeleton, branchial arches, and, in conjunction with placode-derived cells, the lower cranial nerves. Neural crest cells also migrate from the dorsolateral aspects of the spinal neural tube, there serving as progenitors for the peripheral and enteric nervous systems, the adrenal medulla, and melanocytes.[13-15]

Although the "proper study of mankind is man" (according to D.H. Lawrence), it is difficult to obtain human neural tissue in amounts adequate for complete study. Therefore experimental studies of neural development most often use rodent and other experimental animal models.[16] Mouse CNS at birth is at a developmental stage similar to 5 to 6 months gestation in human CNS. By 10 days post partum, mouse CNS has matured to a stage equivalent to that of human brain at term. Cerebral cortical neurogenesis is largely completed by birth in both human and mouse, although some new neurons continue to be generated from neural stem cells that persist in both mouse and human CNS throughout life, particularly in the hippocampus.[17-19] Differentiated oligodendroglial cells are already present in the human CNS at the time of birth, and CNS myelination in humans commences during the third trimester, whereas in rats and mice, differentiated oligodendroglial cells first appear around the time of birth, and myelination is an entirely postnatal process.[20]

NEUROTROPHIC PROTEINS

Various terms are applied to proteins present in extracellular fluids that modulate the behavior of cells, including *hormone, trophic protein, morphogen, growth factor, cytokine,* and *chemokine*. In general, hormones are secreted proteins and other molecules that circulate in the bloodstream and act on distant tissues, whereas trophic proteins act on neighboring cells (paracrine factors) or the synthetic cells themselves (autocrine factors).[21] Morphogens are proteins, concentration gradients of which provide epigenetic control of cellular specification and commitment during early development, and contribute to axonal guidance at a later stage in development.[22] Examples of neural morphogens are Shh, the Wnts, and the bone morphogenetic proteins (BMPs).[23] The term *trophic,* derived from *trophe,* or "sustenance," should properly be assigned to proteins with a nutritive role, but it is usually used to refer to proteins that influence cell survival and differentiation (e.g., nerve growth factor), rather than to proteins that truly provide nutrients (e.g., plasma lipoproteins). Proteins that enhance proliferation of target cells are referred to as *growth factors,* but many also exert morphogenetic and trophic as well as mitogenic effects. The term *cytokine* initially was applied to bioactive proteins released by lymph node– and bone marrow–derived cells, but it is now clear that other cell types, including those derived from neuroectoderm, can also synthesize these proteins. Chemokines, which are cytokines that exert chemotactic effects on cells, are involved both in recruitment of cells of the immune system from the bloodstream to the CNS and in migration of neural progenitors within the CNS.[24,25] To minimize this semantic complexity, the term *neurotrophic protein* is used in this chapter to refer to any protein present in extracellular fluid that exerts a paracrine or autocrine effect on the proliferation, differentiation, or survival of neurons or neuroglial cells.

In this section, rather than attempting a global description of the many neurotrophic protein classes, we briefly consider three morphogens that govern dorsoventral patterning during CNS development: Shh, the BMPs, and the Wnts. We then focus on three well-characterized neurotrophic protein families that regulate neural cell proliferation, differentiation, and survival: the fibroblast growth factors (FGFs), platelet-derived growth factors (PDGFs), and neurotrophins.

A concentration gradient of Shh, a morphogen secreted by the notochord and floor plate, signaling through activation of Patched (Ptc) receptors and Gli transcription factors, stimulates production from ventral neural stem cells of motor neurons and oligodendroglial cells. In opposition to this ventralizing action of Shh, members of the BMP and Wnt families, produced by the roof plate and the ectoderm above it, inhibit generation of motor neurons and oligodendrocytes, while stimulating production of sensory neurons and astroglial cells.[26] Mutations in Shh signaling pathways give rise to holoprosencephaly, medulloblastoma, and the nevoid basal cell carcinoma syndrome.[27] Mutations in Wnt signaling pathways may prove to be of etiologic importance in anomalies of forebrain development related to autism and schizophrenia.[28] BMP signaling mutations have been linked to familial pulmonary arterial hypertension and limb malformations, and may participate in cerebral malformations.[29,30]

The FGFs, which exert their effects through activation of plasma membrane protein tyrosine kinase receptors, interact with the retinoids and Wnts during the early development of the posterior aspects of the CNS and later, are important in regulating corpus callosum formation.[31,32] FGF receptor mutations are a cause of craniosynostosis and achondroplasia,[33,34] and mutations in one member of the family of FGFs, FGF14, are a cause of spinocerebellar ataxia.[35] The PDGFs, like the FGFs, signal by activating plasma membrane protein tyrosine kinase receptors. PDGF exerts mitogenic effects of oligodendroglial progenitors, and enhances the specification of neural stem cells to both neuronal and neuroglial lineages.[36,37] Mutations involving PDGF or PDGF receptors are involved in the pathogenesis of various human tumors but have not been linked to human neurodevelopmental defects.

Much of what is known about the regulation of the early stages of neuronogenesis by neurotrophic proteins pertains to neural crest. The neural crest originates as a population of stem cells that arises between nonneural and neural ectoderm. At the neural tube closure stage of development, these stem cells generate migratory progenitors.[38-40] Neural crest stem cells give rise to progenitors restricted to neuronal, glial, and melanogenic lineages.[41-43] The neurotrophins—nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and the specific factors NT-3 and NT-4/5—play leading roles in governing the fates of neural crest neuronal progenitors.[44,45] They are synthesized as precursor proteins (proneurotrophins), which signal by activation of the p75 neurotrophin receptor (p75NTR). However, after they are proteolytically processed to the mature neurotrophins, their primary receptors are members of the Trk family of protein tyrosine kinases. Activation of p75NTR often leads to target cell apoptosis, whereas activation of the Trks enhances neuronal survival and regulates neuronal transmitter phenotype.[46-49] Pioneering in vivo experiments by Hamburger and Levi-Montalcini

demonstrated that excess NGF during development causes sympathetic neuronal hyperplasia, whereas NGF depletion results in partial sympathectomy.[50] Inactivating mutations of the TrkA NGF receptor cause congenital insensitivity to pain with anhidrosis (hereditary sensory and autonomic neuropathy type IV),[51] whereas an inactivating mutation of the TrkB BDNF receptor results in impaired nociception, developmental delay, and hyperphagic obesity.[52]

VITAMINS

Vitamin A and Other Retinoids

Three forms of vitamin A are biologically active: *Retinol* (vitamin A_1 alcohol) maintains mucous membrane structure and function and is the circulating form of the vitamin; *retinal* (vitamin A_1 aldehyde) plays a role in retinal development through conversion to a derivative that incorporates into rhodopsin; and *retinoic acid* (RA) contributes to the regulation of pattern formation in the early embryo.[53-55] At least five natural biologically active forms of RA are known: all *trans*-RA; 9-*cis*-RA; 3,4-didehydro-RA; 14-hydroxy-4,14-retroretinol; and 4-oxo-RA. All can act as dysmorphogens.[56]

Observations in experimental animals and humans that correlated retinoid exposure with CNS malformations led to recognition of the retinoid receptors and homeodomain-encoded transcription factors as effectors for retinoid actions. Megadoses of retinol and therapeutic oral doses of its analogue, isotretinoin (13-*cis*-RA), elicit teratogenic effects in the human fetus, causing both microcephaly and hydrocephalus.[53,57,58] Either vitamin A deficiency or excess can increase intracranial pressure in human infants.[59,60] The teratogenic potential of retinoids is powerful: Malformations resembling RA embryopathy have occurred up to a year after discontinuance of the oral use of the RA analogue etretinate, a form stored in fat and slowly released into the circulation.[61]

The retinoids play important roles during normal neural development at the earliest stages of neurogenesis, at the time of neural plate formation, and, later, when the form of the mature nervous system is established. The neural plate originates from cells in and around Hensen node and the notochord in vertebrate embryos. These three tissues are *zones of polarizing activity*—restricted regions containing signals that determine the anteroposterior axis of parts of the embryo.[62] The neural plate binds retinol and is the site for its most efficient conversion to RA.[62] The region most sensitive to RA is the posterior midbrain–anterior hindbrain area of the neural plate.[54] Later in development, retinoids are found in the developing inner ear[63] and the developing neural retina.[64] In retinal tissue, retinoids play a role in cell fate determination by promoting rod photoreceptor development from progenitor cells.[65] Experiments dramatically demonstrating the effects of retinoids on CNS development were performed in the *Xenopus* embryo, in which RA or 4-oxo-RA treatment at the late blastula to early neurula stage produces microcephaly and absence of eyes, forebrain, and midbrain.[56,66,67] After maternal dietary manipulation to expose rats to RA at embryonic day 10 (E10), isolated myelomeningocoele, with the full range of severity, developed in 60% of the fetuses.[68]

Much of the impetus to pursue RA as an important signaling molecule in the CNS came from observation of the startling and diverse patterns of defects in both deficiency and excess of retinoids. RA exposure, for instance, inhibits migration of cranial neural crest cells in the cultured mouse embryo.[69] Conversely, mice mutants deficient in the RA-synthetic enzyme retinaldehyde dehydrogenase 2 demonstrate failure to develop neural crest derivatives including enteric ganglia elements of pharyngeal pouch outgrowth and also the heart.[70]

RA regulates CNS segmentation by inducing the expression of members of a superfamily of genes that contain a conserved homeodomain, the *HOX* and *HOX*-related genes. These genes occur in four separate clusters, *Hoxa* to *Hoxd*, that encode transcription factors—proteins regulating embryonic segmentation and organogenesis.[71] Their orderly patterns of spatial interaction are regulated by local concentrations of the retinoids.[55,72-74] For example, *Hoxb2*, one of the members of this superfamily, codes for a transcription factor that is expressed in the mouse CNS up to the rhombomere 2–rhombomere 3 border. Studies show that *HOX* genes and RA regulate neural cell adhesion molecule, a key adhesion molecule that modulates cell movement. RA is thought to act in part through increased expression of the target gene, *Hoxa1*. RA has a significant role in cortical development as shown in the postnatal mouse brain (correlating with the second trimester human brain) as RA synthetic enzyme maps to basal ganglia, hippocampus, auditory, visual, and olfactory cortex.[75]

Folic Acid

Neural tube closure defects in the human have been firmly linked to folic acid deficiency. The many studies of folate and the brain in animals were prompted by a sentinel study in 1965 by Hibbard and Smithells[76] that showed folate deficiency in 69% of mothers of children with CNS abnormalities, compared with 17% of control women. Other observations suggesting an important role for folic acid in the prevention of NTDs included the increased occurrence of anencephaly and meningomyelocele in offspring of women of lower socioeconomic status with less than adequate nutrition and the increased incidence of defects associated with the use of folic acid inhibitors in pregnant women.

Folate plays an essential role in methyl group transfer reactions. Methylation is cyclic, involving the interchange of methyl groups between homocysteine and methionine, mediated by the enzyme methionine synthase (5-methyltetrahydrofolate-homocysteine *S*-methyltransferase, designated Enzyme Commission [EC] number 2.1.1.13).[77] Methionine, when activated by adenosine triphosphate, becomes *S*-adenosylmethionine. *S*-adenosylmethionine is a central source for methyl group transfer to proteins, lipids, and nucleic acids. One of the products of methyl transfer is *S*-adenosylhomocysteine, which is then hydrolyzed to homocysteine. In most cells, homocysteine is converted by vitamin B_{12}–dependent methionine synthase back to methionine by remethylation.[77] The latter, which is the only reaction in the human that requires both folic acid and vitamin B_{12} as cofactors, is responsible for the dependency of cellular folate levels on adequate availability of vitamin B_{12}.[77]

Virtually all cells in all organisms contain folate coenzymes, mediating methyl transfer. A small amount of folate is in nuclei, but cellular folate-binding proteins are associated both with surface membranes and, intracellularly, within the cytosol and mitochondria. Most of these intracellular folate-binding proteins are enzymes that use folate as a coenzyme in methyl transfer. The placenta and choroid plexus are sites that exhibit folate receptors.[78,79]

Holmes, more than a decade ago, found the prevalence of NTDs in a New England cohort to be 1.2 per 1000[80]; among the 146 cases in his 15-year survey, 54 infants had spina bifida, 74 had anencephaly, and 19 had encephalocele. Anencephaly, more common in girls than in boys, occurs before 24 days of gestation in the human, and approximately 75% of affected fetuses die in utero. Ethnic differences in the frequency of NTDs also have been reported. For instance, in British Columbia, the incidence of NTDs in the Sikh population was approximately double that in non-Sikhs.[81] Moreover, a recurrence risk of 2.3% between 1958 and 1984 contrasted with 0.24% recurrence risk between 1985 and 1993. This decrease probably was the result of the recommendation of folic acid and multivitamins before conception for

at-risk families in British Columbia.[81] More recently, birth incidence in this province has sharply declined (from 1.16 in 1000 to 0.47 in 1000) thought to be largely secondary to prenatal diagnosis and termination of affected pregnancies.[82]

Both RA and folic acid have been studied in several mouse mutants manifesting NTDs. The effect of RA is not uniform: Although it increases the incidence of exencephaly (precursor of anencephaly) in four different mutant mouse strains, it also decreases the incidence of caudal spina bifida and tail defects in several of the same strains. Other studies have shown that simple maternal folate deficiency in non–genetically predisposed rodents does not produce NTDs,[82,83] and folate treatment does not prevent NTDs in the genetically predisposed *Axd* mouse, whereas methionine does.[84]

Administration of folate, however, does reduce the incidence of valproic acid (VPA)-induced NTDs in the mouse.[85] Arachidonic acid and inositol, which contribute to anchoring of folate-binding protein to the plasma membrane, reduce the incidence of mouse NTDs associated with exposure to phenytoin or hyperglycemia.[86,87] VPA is a potent teratogen in the human, with an estimated 20-fold increase in the frequency of NTDs in offspring. Epileptic mothers with fetal malformations exhibit low folate levels.[88]

VPA's action probably alters the expression of multiple genes, and recently in a rat embryo model,[89] it has been postulated that the mechanism of action of VPA may be through elevated and uncoordinated Hoxa1 expression, the same molecular pathway involved in RA action. Alteration of Wnt-dependent gene expression (see earlier under "Neurotrophic Proteins") and block of histone deacetylase are other postulated mechanisms of action for VPA.

The fetal incidence of NTDs is estimated to be 2.5% in 26-day human embryos just completing neurulation, decreasing to 0.06% at term, as a result of fetal loss.[90] In 1991, the effect of early folic acid supplementation to prevent recurrent NTDs was demonstrated in a multicenter, randomized, double-blind trial. Administration of 4 mg of folic acid daily before conception and during early gestation resulted in a six-fold diminution in risk (0.6% versus 3.6%) of recurrent NTDs.[91] First occurrences of NTDs also are prevented with folic acid supplements.[92]

Since the early 1990s, folic acid has been recommended at 0.4 mg daily before conception and until 3 months gestation for the general population and 4 mg daily for women who have already had children with NTDs.[93]

In 1998, when an estimated 300,000 infants with spina bifida or anencephaly were born yearly throughout the world, a next step in prevention was begun in the United States with mandatory folic acid fortification of cereal grain products. This was accomplished by the minimum addition of 0.14 mg of folic acid to 100 g of cereal grain, calculated to increase intake by an average of 0.1 mg/day. Subsequently, the prevalence of NTDs in the United States dropped by 36%, from 10.8 per 10,000 population in 1995-1996 to 6.9 per 10,000 in late 2006. Similar results followed cereal fortification in several other countries.[94] This approach was shown to be effective in a Southern California study, which demonstrated that levels of serum and red cell folate greatly exceeded minimal acceptable levels in both socioeconomically disadvantaged and advantaged women.[95] In a survey of multiple states, the NTD prevalence before and after fortification was shown to decrease by 19%, to 30.5 per 100,000 live births[96]; however, no drop occurred among patients with either no or only late prenatal care, confirming the major role of early specific folate prophylaxis.

Most but not all cases of spina bifida and anencephaly are preventable with folate supplementation.[97] To investigate such "resistance" to folate, a study of the response to folate loading in women who had had two pregnancies with NTDs was undertaken.[98] The women in the group with two documented NTD pregnancies and the control subjects with no affected pregnancies attained similar serum and red cell folate levels, but no correlation between levels and intake existed in the women with two affected pregnancies, implying altered folate metabolism in the women whose folate levels were unpredictable. In other studies, homocysteine levels also were reported to be elevated in women who had had children with NTDs, although classic homocystinuria is not associated with such anomalies. Mothers of children with NTDs also were shown to have impaired metabolism of homocysteine when their plasma vitamin B_{12} levels were in the low-normal range.[99-101] Thus a defect was postulated in the enzyme requiring both vitamin B_{12} and folic acid as cofactors, methionine synthase. Further implication of this enzyme derives from the delay in incorporation of 5-methyltetrahydrofolate into DNA (another methionine synthase–catalyzed reaction) in trophoblast cells of women who gave birth to NTD-affected infants.[101-103]

Abnormality of another enzyme, 5,10-methylenetetrahydrofolate reductase (MTHFR), estimated to be present in 5% to 15% of the general population, is associated with defective transfer of a methyl group to homocysteine to form methionine. Finally, two mutations in the *MTHFR* gene, C677T and A1298C, which lead to increased homocysteine levels, also significantly increase risks for NTD in children. Homocysteine levels in women with these *MTHFR* variants can be normalized with large doses of folate.[104]

FATTY ACIDS AND CHOLESTEROL

The brain is rich in lipid. Research in animal models shows that brain lipid can be changed by alterations in intake of essential fatty acids.[105] The essential fatty acids of the diet are linoleic (C18:2*n*-6) and linolenic (C18:3*n*-3) acids. Premature and growth-restricted infants are born with essential fatty acid deficiency, and studies in experimental animals indicate that such deficiency can be associated with cognitive and visual impairments. Studies of essential fatty acid supplementation in humans have included analyses of the effects of *n*-3 fatty acid supplementation or breast milk feedings on retinal[105] and mental[106] function, the latter as reflected by intelligence quotient (IQ), in premature infants. Maternal supplementation with these same acids during pregnancy and lactation may have a beneficial effect on the mental development of breast-fed healthy term infants,[107] but significant effects on development from supplementation of formula thus far seem unlikely.[108]

Inborn errors of cholesterol metabolism have pointed to many links to embryonic development. Smith-Lemli-Opitz syndrome, the prototypic and first-described disorder of cholesterol biosynthesis, is caused by any of more than 100 inherited mutations of the 3β-hydroxysterol-δ7 reductase (DHCR7) gene, resulting in deficient enzyme and hypocholesterolemia in tandem with high 7- and 8-dehydrocholesterol levels. Clinical manifestations consist of dysmorphic facies, mental retardation, hypotonia, and various anomalies of the heart, lungs, intestine, kidneys, genitalia, and limbs; cardinal signs are hypospadias, microcephaly with agenesis of the corpus callosum and holoprosencephaly, small or proximally placed thumb, and second-third toe syndactyly.[109] The effectors in this and other sterol-related brain developmental disorders are postulated to lie within the Shh signaling cascade or its receptors, because this protein requires covalently bound cholesterol for its function.[110] Ptc and Smoothened (Smo) are receptors that mediate the early developmental effects of Shh on morphogenesis and commissural axon growth in the ventral and lateral telencephalon.

Most aspects of synaptogenesis and maintenance of synapses require cholesterol as well.[111] Roux had demonstrated, with the use of teratogens, that varying the maternal supply of cholesterol to the developing rat fetus alters the frequency and severity of Shh-related malformations.[112] More recently, Kelley found

a significantly lower mean cholesterol level in mothers (but not fathers) of children with isolated holoprosencephaly, and other workers have found a correlation of maternal apoE genotype and the severity of Smith-Lemli-Opitz syndrome.[113] Apolipoprotein E plays an important role in regulation of intracellular cholesterol trafficking, especially in transport of CNS lipids. Reliable early identification of the affected fetus is possible, and prenatal maternal dietary treatment has been tried only once, without success.[114] Postnatal dietary cholesterol treatment, although not been remedial for all aspects of the disorder, is recommended; therapy with hydroxymethylglutarate coenzyme A (HMG CoA) reductase inhibitor therapy may be detrimental.[115]

HORMONES

Although the effects of hormonal deficiency or excess on neural function in the adult may be profound, they are in general reversible. By contrast, perturbations in availability of hormones during the critical periods of neuronal and glial cell development often result in permanent and profound abnormalities in synaptogenesis and myelination. This section focuses on thyroid and steroid hormones, with emphasis on the special vulnerability of the immature nervous system to deficiencies of these hormones.

Thyroid Hormones

Thyroid disorders are the most prevalent endocrine derangements in the world, even more common than diabetes mellitus. In estimates from 1990, endemic hypothyroidism primarily resulting from low dietary iodine intake affected approximately 750 million people in the world, largely in Asia and Africa, and approximately 43 million were affected by brain damage secondary to low iodine intake either prenatally, in infancy, or in early childhood.[116] Recently, it was estimated that as many as 1.9 billion people worldwide have inadequate iodine nutrition.[117]

In a major inland region of Guinea, in West Africa's goiter belt in the 1990s, 70% of the adults had goiters. Environmental variables responsible for this high incidence included the low iodine content of the water and soil, excessive intake of goitrogens such as thiocyanate (in cassava) and flavonoids (in millet), and protein malnutrition. Many infants had goiter at birth, and 55% of preschoolers were affected. At puberty, 58% of boys and 80% of girls had goiter.[118] Although the incidence of myxedematous cretinism, manifested by retardation and deafness, was only 2% in this population, this figure is likely to have been spuriously lowered due to early deaths of severely neurologically impaired children in this environment. Introduction of iodized salt has decreased the incidence of hypothyroidism and gradually decreased the incidence of goiter in western Africa in the last decade.[119]

Debate is ongoing over optimal iodine intake, with the World Health Organization (WHO) recommending intakes of 200 μg daily in pregnancy and lactation, 150 μg daily in other adults, 120 μg daily in 6- to 12-year-olds, and 90 μg daily in children younger than 5 years of age. These intakes should lead to iodine sufficiency as manifested by urinary iodine excretion of approximately 100 to 200 μg/L.[115] Studies of iodine supplementation in China, however, have suggested that more than adequate or excessive levels of iodine intake may actually increase the incidence of hypothyroidism, probably secondary to autoimmune thyroiditis. These studies imply that the addition of iodine must be carefully adjusted for the baseline iodine intake of the population to be supplemented.[120]

The neurologic consequences of early hypothyroidism vary with the degree of maternal, fetal, and neonatal hypothyroidism. Maternal thyroxine (T_4) is not available to the fetus for brain protection when the mother is iodine-deficient, and this lack accounts for the severe CNS damage associated with endemic goiter, This contrasts with minimal to no neurologic deficit in the hypothyroidism that may be present in a child born to a euthyroid mother.[121]

Sporadic hypothyroidism occurs in approximately 1 in 4000 live births. Screening programs for this abnormality are widespread among developed countries. Knowledge gained from these programs has shown that the fetus usually is unaffected by intrinsic in utero hypothyroidism, even when athyrotic. Preservation of brain thyroid status in the hypothyroid rat and human fetus is effected by maternal T_4 that crosses the placenta.[122]

Experimentally elicited neonatal hypothyroidism in rodents causes deficiencies in CNS neuronogenesis, synchronization of axonal and dendritic outgrowth, synaptogenesis, and myelination.[123] Thyroid deficiency also can interfere with the responsiveness of neural tissues to neurotransmitter-mediated and neurotrophic signals. For example, adequate supplies of triiodothyronine or T_4 are necessary for normal expression of NT-3 and its receptor, TrkC, by immature rat cerebellar granule cells.[124]

Thyroid hormone deficiency also alters the metabolism of the thyroid hormones themselves. The conversion of T_4 to triiodothyronine in the brain of hypothyroid rat fetuses is accelerated, owing to the induction of astroglial type II deiodinase, probably secondary to an elevation in thyrotrophin levels in the fetuses.[125] This homeostatic mechanism helps to preserve brain function in the presence of hypothyroidism in the fetus.

Important interactions between thyroid hormones and retinoids are recognized.[126-128] Thyroid hormone receptor-α_1 (TR-α_1) inhibits RA-responsive gene expression but also cooperates with retinoids in supporting the formation of embryonic mouse cerebral neurons. Moreover, retinoids cause a 200-fold, specific induction of type III deiodinase (the enzyme responsible for degradation of brain T_4) in astroglial cells in culture.

The effects of thyroid hormones on neural and other tissues are transduced by nuclear thyroid hormone receptors TR-α and TR-β, encoded by genes on chromosomes 17 and 3, respectively.[129-131] These nuclear receptors bind both to thyroid hormone and to thyroid response elements, which are specific DNA sequences in noncoding regions of thyroid hormone--responsive genes, often encoding neurotransmitters and cytoskeletal proteins. Thyroid-responsive genes are numerous and are identified frequently.

TR-α and TR-β are homologous to nuclear receptors for steroids, RA, and vitamin D_3 and are detected as early as 10 weeks in the human fetal brain.[132] They are expressed in a spatially and temporally regulated pattern in the CNS. This pattern is of some clinical significance. For example, the anlage of the cochlea is particularly rich in these nuclear receptors. The role of these receptors at a critical period for auditory end-organ development is demonstrated by frequent abnormalities in auditory brain stem responses in hypothyroid children (which tend to persist despite early replacement therapy),[133-135] and it also is shown by the syndrome of isolated deafness in humans with a chromosomal deletion syndrome involving most of the thyroid receptor-β gene.[136] The nuclear thyroid receptors also are subject to mutations that result in inherited thyroid hormone resistance.[137]

Environmental exposure of pregnant animals to dioxins and polychlorinated biphenyls (PCBs) leads to behavioral changes similar to those associated with fetal hypothyroidism.[138] These substances are industrial pollutants that have persisted despite their ban in the 1970s. This continued presence in the environment is especially concerning because of their concentration in fatty tissues and human milk.[139] Several mechanisms for the hypothyroid effects of these toxins have been postulated: reduction of thyroid hormone at low levels of PCBs and thyroid receptor–mediated thyromimetic effects at high levels of both classes of toxins.[140] Structural similarity between these toxins and thyroid hormones permits them to bind to the same transporters and nuclear receptors, thereby interfering with the effects of thyroid hormone on the fetal brain.[141]

Steroid Hormones

Glucocorticoids, estrogens, progesterone, androgens, and vitamin D metabolites influence CNS development. A common feature of all these steroids is that their actions are transduced by cytosolic receptors that, on binding of their ligand steroid, are released from complexes with other cytosolic proteins and move to the nucleus, where they modulate transcription of target genes.[142,143] The biologic effects of the steroid hormones on neural tissues are dictated by the distributions of expression and patterns of gene activation of their receptors. These biologic effects include regulation of the secretion of neurotrophins by neuroglial cells and of the incidence of apoptosis of nascent neurons.[144-146]

Type I adrenal corticosteroid receptors bind both mineralocorticoids and glucocorticoids with high affinity, and they are concentrated largely in the hippocampal system. Type II corticosteroid receptors, which bind glucocorticoids with high affinity, are distributed throughout the brain, but they are most abundant in the anterior pituitary and the preoptic region of the hypothalamus.[143-147] In the developing nervous system, glucocorticoids regulate the frequency with which nascent neurons undergo apoptosis.[148] Excess glucocorticoid has complex effects on the immature brain, by stimulating cholinergic neurotransmission through a neurotrophin-dependent mechanism,[149,150] but also by eliciting neuronal loss in the hippocampus, which is associated with lifelong impairment of memory.[151]

In the relatively recent past, antenatal glucocorticoid was injected weekly for threatened preterm labor to induce fetal lung maturation. Often this regimen was continued for several weeks until birth. Subsequent magnetic resonance images of the brains in these children revealed simpler gyral patterns and reduced surface area when compared with those in brains of control children.[152]

Receptors for estradiol, progesterone, and androgens are widespread in the developing CNS. Their activation, by maternal steroid hormones and by progesterone, estrogens, and androgens synthesized endogenously in the CNS, influences the motility of neuroblasts and the development of neurons in sexually dimorphic motor nuclei of the hypothalamus, brain stem, and spinal cord. These receptors also have effects on synthesis of neurotransmitters.[153-156] Endogenous synthesis of progesterone in the neonatal rat CNS promotes the maturation of cerebellar Purkinje cells.[157]

Activation of CNS neuroglial cell receptors for the vitamin D metabolite, 1,25-dihydroxyvitamin D_3, stimulates neuroglial neurotrophin synthesis.[158] 1,25-Dihydroxyvitamin D_3 also acts on hippocampal neurons and, by down-regulating their expression of L-type calcium channels, protects them from excitotoxic injury.[159]

CONCLUSIONS AND FUTURE PROSPECTS

The 1970s and 1980s were marked by substantial advances in knowledge of environmental influences on neural development. These advances, generated largely by epidemiologic studies, included recognition of the ill effects of various toxins, such as methylmercury and lead,[160] and the validation of iodized salt– and folate-supplemented flour as prophylaxis against gestational hypothyroidism and neural tube defects.[161,162] The decreases in incidence of neonatal hypothyroidism and spina bifida that followed introduction of these dietary manipulations helped investigators to focus during the 1990s on kindreds in which mutations, rather than environmental influences, were responsible for abnormalities in neural development.[163,164] Research today is entering yet a third phase of analysis of the interplay between environment and genome, using array-based technologies and comprehensive atlases of neural gene expression to elucidate how the interplay between environmental factors and the neural transcriptome dictates development and function of the nervous system.[165,166]

Developmental Aspects of Pain

Within the past several decades the field of neonatology has made vast strides in the reduction of infant morbidity and mortality. This progress, however, comes with increasing exposure to painful and stressful stimuli.[1,2] A study of neonates in a neonatal intensive care unit revealed that patients underwent a mean of 14 invasive procedures per day with a range of 0 to 53 procedures per day.[3] Yet the assessment and treatment of pain has been included only relatively recently in the management of these critically ill neonates.

Until the 1980s, newborns frequently underwent invasive procedures, including surgery, with no analgesic or anesthetic. There were several reasons for this. It was widely believed that the immature neonatal brain could not respond in a manner that perceived or localized painful stimuli.[4,5] In addition, clinicians frequently assumed that neonates neither experienced pain as severely as adults nor remembered painful experiences.[6] Concerns about the potential adverse side effects of analgesic and anesthetic agents in the neonate overwhelmed the perceived benefits.[7] It was not until the literature revealed the relative safety of anesthetic agents and the improved outcomes of patients undergoing surgery with anesthesia that the field of neonatal pain research, both clinical and basic science, evolved.[8,9-12]

This chapter reviews the development of pain sensation in the fetus and neonate as well as the clinical markers of pain and the impact of pain in this vulnerable patient population.

DEFINITION OF PAIN

The International Subcommittee for the Study of Pain defined pain in 1979 as "an unpleasant sensory and emotional response associated with actual or potential tissue damage, or described in terms of such damage."[13] Schechter[4] proposed that pain perception is dependent on two components. The first, nociception, is a sensory component that is neurophysiologically determined. The second is an emotional component based, among many factors, on affective state, past experience, and development. Understanding of both of these components in the infant continues to evolve with ongoing research.

DEVELOPMENT OF NOCICEPTION

Pain may be described as a process in which stimulation of peripheral sensory nociceptors produces responses conducted via the spinal cord neurons to sensory areas of the cerebral cortex. The basic mechanisms of pain perception in the fetus and neonate are similar to those of adults though differences exist as a result of neuroanatomic, neurophysiologic, and neurochemical developmental immaturity.

Neuroanatomy, Neurophysiology, and Neurochemistry

Cutaneous sensory receptors first appear in the perioral area of the human fetus in the seventh week of gestation and spread throughout the fetus by the twentieth week of gestation, as outlined in Table 169-1.[14] Evidence suggests that the density of cutaneous nociceptor receptors in the late fetus and neonate is comparable or may even exceed that of adult receptor density.[15] Nociceptors may be divided into two broad types: high-threshold mechanoreceptors that respond to pressure and polymodal nociceptors that respond to heat or chemical irritation as well as to pressure. The mechanoreceptor axons, A-delta fibers, are large and myelinated and conduct rapidly, providing the rapid onset of sharp, localized pain following injury. The polymodal receptor axons, C fibers, are small and unmyelinated, conducting relatively slowly and yielding slow, prolonged, poorly localized pain.

Cutaneous nociceptor afferents have cell bodies in the dorsal root ganglia of the spinal cord, and there is evidence that sensory fiber–to–dorsal-horn interneuron synapse development occurs as early as the sixth week of gestation.[16] Development and differentiation of dorsal horn cells begin at around 13 weeks gestation, and the laminar arrangement, as well as synaptic interconnections and neurotransmitter vesicles, mature in some regions of the spinal cord by 30 weeks gestation.[17] The A-delta and C fibers divide and make connections at the entering spinal cord level as well as at dermatomes above and below. Muscle spasm, the

Pain may be described as a process in which stimulation of peripheral sensory nociceptors produces responses conducted via the spinal cord neurons to sensory areas of the cerebral cortex. The basic mechanisms of pain perception in the fetus and neonate are similar to those of adults though differences exist as a result of neuroanatomic, neurophysiologic, and neurochemical developmental immaturity.

Neuroanatomy, Neurophysiology, and Neurochemistry

Cutaneous sensory receptors first appear in the perioral area of the human fetus in the seventh week of gestation and spread throughout the fetus by the twentieth week of gestation, as outlined in Table 169-1.[14] Evidence suggests that the density of cutaneous nociceptor receptors in the late fetus and neonate is comparable or may even exceed that of adult receptor density.[15] Nociceptors may be divided into two broad types: high-threshold mechanoreceptors that respond to pressure and polymodal nociceptors that respond to heat or chemical irritation as well as to pressure. The mechanoreceptor axons, A-delta fibers, are large and myelinated and conduct rapidly, providing the rapid onset of sharp, localized pain following injury. The polymodal receptor axons, C fibers, are small and unmyelinated, conducting relatively slowly and yielding slow, prolonged, poorly localized pain.

Cutaneous nociceptor afferents have cell bodies in the dorsal root ganglia of the spinal cord, and there is evidence that sensory fiber–to–dorsal-horn interneuron synapse development occurs as early as the sixth week of gestation.[16] Development and differentiation of dorsal horn cells begin at around 13 weeks gestation, and the laminar arrangement, as well as synaptic interconnections and neurotransmitter vesicles, mature in some regions of the spinal cord by 30 weeks gestation.[17] The A-delta and C fibers divide and make connections at the entering spinal cord level as well as at dermatomes above and below. Muscle spasm, the

TABLE 169–1

Development of Cutaneous Sensory Receptors in the Human Fetus

Week of Gestation	Location of Receptors
7th	Perioral area
11th	Face, palms, and soles
15th	Trunk, arms, and legs
20th	All cutaneous and mucous surfaces

withdrawal reflex, is produced with spread of the nociceptive signal to the anterior horn cells, and vasoconstriction of the skin and splanchnic circulation occur with spread of the signal to the preganglionic sympathetic neurons of the autonomic nervous system. Reflecting this development, the cutaneous withdrawal reflex, mediated through the spinal cord, can be evoked at least as early as 25 weeks gestation.[18]

Most nociceptive signals to the cerebral cortex travel via second-order neurons in the spinothalamic, spinoreticular, and spinomesoencephalic tracts to synapse in the thalamus. The cerebral cortex neurons develop by 20 weeks gestation but undergo a process of dendritic branching, developing synaptic targets for thalamocortical fibers. Synaptogenesis of thalamocortical connections is established between 20 and 24 weeks gestation. Myelination of the pain pathways of the spinal cord and brain stem is completed during the second and third trimesters of gestation.[19] Overall development and myelination of pain pathways occur simultaneously with fetal cortical maturation, dendritic arborization, and thalamocortical fiber synaptogenesis (see Table 169-1).[20]

Impulses from A-delta fibers are transmitted to the somatosensory cortex, and C fibers are transmitted to the limbic cortex. Fibers also go to the periaqueductal gray area, reticular activating system, and hypothalamus with subsequent further cortical spread. Thus there is no one focal cortical pain center. Near-infrared spectroscopy has been used to demonstrate cortical activity in response to nociceptive-inducing stimuli in neonates studied as premature as 25 weeks postmenstrual age.[21,22] This cortical response became more robust as postmenstrual age advanced. In addition, facial responses to painful stimuli can be provoked as early as 24 weeks gestation, suggesting the development of these functional pathways from the spinal cord to the brain.[18]

The complex nature of the pain response is modified by dozens of neurotransmitters within the nervous system. Pain-related neurotransmitters including the neuropeptide, substance P, thought of as the primary afferent nociceptive neurotransmitter, appear in the spinal cord dorsal horn early in gestation. Release of these neurotransmitters activates dorsal horn interneurons and thus the ascending pathways. Inhibition of the pain response at the level of the spinal cord, the periaqueductal gray matter, and medulla occurs through the descending corticospinal, raphe spinal, and reticulospinal tracts. This inhibition is mediated through release of neurotransmitters—serotonin, dopamine, and norepinephrine—that inhibit excitatory neurotransmitters.

Several lines of evidence suggest that neonates are actually more sensitive to pain—with lower pain thresholds, poor discriminative abilities, and increased tendencies to sensitization— than adults. Anatomic and physiologic mechanisms in rat pups supporting this increased sensitivity are shown in Table 169-2.[23] Maturation of these pain pathways is reflected in the decreasing cutaneous withdrawal response, increasing pain threshold, and decreasing receptive field size with increasing postnatal age.

The foregoing neuroanatomic and neurochemical evidence, in addition to the well-established behavioral and physiologic responses to pain, leads one to conclude that both the fetus and infant have nociceptive systems capable of communicating painful stimuli from the periphery to the cerebral cortex and regulating the response via efferent inhibitory pathways.

CLINICAL AND PHYSIOLOGIC MARKERS ASSOCIATED WITH PAIN

The physiologic changes associated with pain encompass responses that include those of the cardiovascular, respiratory, endocrine, metabolic, and immune systems.

The hemodynamic and respiratory changes associated with pain frequently have been used as indices of reactivity to assess painful events in preterm and term infants. These responses occur through activation of the autonomic nervous system by nociceptive impulses reaching the periaqueductal gray matter. An increase in an infant's heart rate and blood pressure during and following a painful procedure such as circumcision or heel lance has been well documented.[24-27] This presumably reflects increased sympathetic modulation as well as parasympathetic withdrawal.[28] In many cases this increase can be prevented or attenuated by the use of local or topical anesthetics.[29-32] Whereas infants of all gestational ages demonstrate heart rate reactivity in response to painful stimuli, both gestational age and postmenstrual age appear to be factors in determining the magnitude of this physiologic response.[33,34]

Neonates undergoing surgery have been observed to experience large fluctuations in measured transcutaneous oxygen tension.[35,36] Decreases in transcutaneous oxygen tension also were observed during circumcision and could be attenuated or prevented by the use of local anesthetic agents.[32,37] Tracheal intubation, another example of a noxious procedure, caused decreased transcutaneous oxygen tension measurements as well as increased arterial blood pressure and intracranial pressure in both term and preterm infants.[38,39] These cardiovascular responses could be diminished by the administration of anesthetic agents.[40,41]

Stress response is a term used to describe the wide range of hormonal and metabolic changes associated with trauma, both physical and emotional.[42-44] This encompasses the release of pituitary, pancreatic, and adrenal hormones that affect metabolic

TABLE 169-2

Mechanisms Supporting Increased Pain Sensitivity in Neonates

Components of Pain System	Developmental Processes in Newborn Rat Pup
Cutaneous receptors Polymodal nociceptors High-threshold mechanoreceptors	Mature soma membrane properties (membrane thresholds, firing frequencies, neurotransmitter expression) in the late fetal rat and at birth immature soma membrane properties (low thresholds, low frequencies)
Cutaneous nerve terminals	Superficial plexus of nerve terminals becomes subepidermal with development of the stratum corneum, density regulated by NGF expression
Skin or tissue injury	Marked hyperinnervation of neonatally injured skin, decreased threshold
C fiber terminals in the dorsal horn	Delayed entry into the substantia gelatinosa, synaptogensis at 3 weeks
A fiber terminals in the dorsal horn	Early synaptogensis in laminae 3-5, collaterals to substantia gelatinosa
Nociceptive neurons in the substantia gelatinosa (laminae 1,2)	Large receptive fields, marked overlapping of adjacent neurons, low thresholds, early expression of excitatory neurotransmitters/receptors delayed development of descending inhibition (5-HT, NE, dopamine); single stimuli evoke long-lasting excitation, which lowers the threshold to subsequent stimuli, repeated stimuli cause immense background activity
Dorsal horn substance P receptors	Sixfold greater density as compared to the adult, diffuse localization
NMDA receptors in the dorsal horn	Peak density at 6 to 10 days age, increased affinity for NMDA and [Ca^{++}] release
Inhibitory transmitters: GABA, glycine	Fast inhibitory transmitters in the adult spinal cord actually depolarize immature spinal neurons and cause increases in intracellular [Ca^{++}]
Somatosensory cortex pyramidal cells	Large receptive fields, which may be caused by a lack of surround inhibition

5-HT, 5-Hydroxytryptamine, GABA, γ-aminobutyric acid; NE, norepinephrine; NGF, nerve growth factor; NMDA, *N*-methyl-D-aspartate.

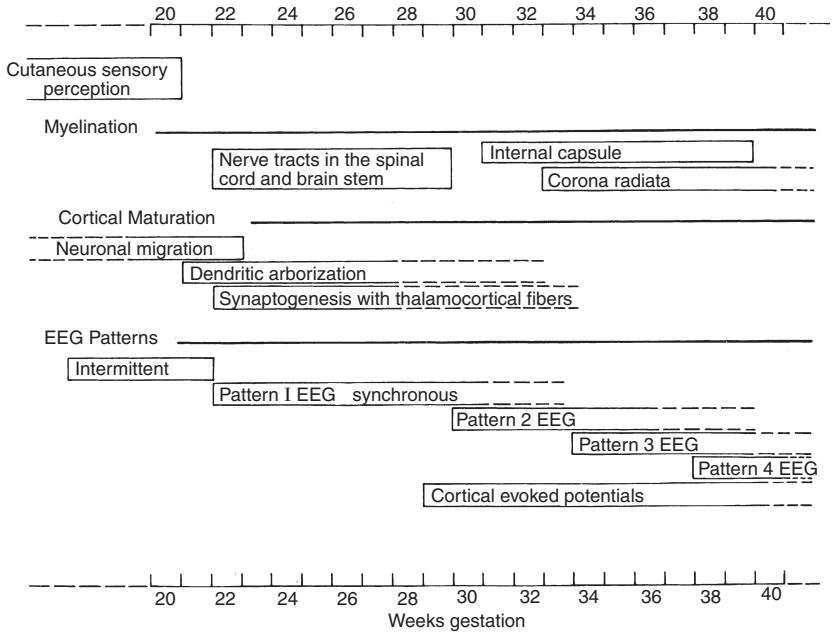

Figure 169-1 Depiction of the maturation of nociceptive pathways and functions during the third trimester of fetal gestation. *(From Anand KJS, Hickey PR: Pain and its effects in the human neonate and fetus,* N Engl J Med *317:1321, 1987, with permission.)*

balance and once may have played a part in allowing injured mammals to catabolize their own body stores, thereby improving survival.[43] The hormonal responses to surgically induced stress in infants have been shown to include increases in catecholamines (both epinephrine and norepinephrine), cortisol, β-endorphins, insulin, glucagon, renin-aldosterone, growth hormone, and prolactin.[45-47] Giannakoulopoulos and colleagues[48] demonstrated that fetuses of 24 to 34 weeks gestation have shown increases in cortisol and β-endorphin levels in response to intrauterine abdominal needling.

As mentioned earlier the stress response in neonates has been most closely investigated in response to surgery and relatively minor procedures such as circumcision and venipuncture. Anesthesia generally has been shown to attenuate this stress response, both intra- and postoperatively.[9,11,12] It is interesting that in one study the neonatal cortisol response to circumcision was not significantly reduced by the administration of a local anesthetic nerve block.[49] Further investigation is needed to confirm this phenomenon. The investigators theorize about the potential problem of awake procedures with only regional afferent neuronal blockade causing a stress response via cortical and adrenal pathways in infants because of their fear, anxiety, and inability to respond to verbal reassurance.

BEHAVIORAL MARKERS ASSOCIATED WITH PAIN

Anand and Hickey[20] described the behavioral changes associated with pain and divided them into four general categories: simple motor response, facial expressions, crying, and complex behavioral responses. Simple motor response includes flexion and adduction of extremities in response to a painful stimulus. Much of this response is mediated through spinal cord reflexes. Distinct facial expressions have been associated with pain and are the basis for portions of many pain assessment techniques.[50,51] Facial response is also thought to be mediated through the periaqueductal gray matter. These facial reactions become more pronounced with increasing postnatal age in contrast to the withdrawal reflex, which decreases in intensity with increasing postnatal age. The cry response to painful stimuli has been shown to have specific characteristics and acoustic features that can be differentiated by adult listeners from other crying behavior such as hunger.[52] Complex behavioral responses include altered sleep-wake cycles and irritability following painful stimulus. Changes in complex behavior were noted following circumcision in boy infants; these effects were absent in infants given local anesthesia before the painful procedure.[53]

PAIN ASSESSMENT IN THE NEONATE

Assessment of pain in infants is a difficult task given that their preverbal developmental state prohibits communication of their pain in words. Research in the late 1980s and early 1990s established that pain could be assessed in infants by means of cardiorespiratory, neuroendocrine, and behavioral responses to painful stimuli.[54,55] Refinement of infant pain assessment scales continued throughout the 1990s and into the new millennium. Although more than three dozen scales have been developed, no single tool has emerged as the "gold standard" for assessment of neonatal pain.[51,56,57] However a multidimensional pain scale should be used with limitations recognized in infants who are pharmacologically paralyzed or have severe neurologic impairment. It is also important to understand that the behavioral and physiologic responses to pain are modified with increasing gestational age at birth, increasing postnatal age, and previous experiences thus making any one pain scale difficult to use in all neonatal populations.

EFFECTS OF PAIN

There is a growing body of evidence that pain is associated with more than the immediate effects such as elevated heart rate, blood pressure, intracranial pressure, and the endocrine- metabolic stress response. Andrews[58] and colleagues showed that in infants with unilateral hydronephrosis and presumed referred visceral pain, abdominal skin reflex thresholds did not increase and reflex radiation did not diminish with postnatal age when compared with controls. This suggests that the presence of pain may interfere with the normal maturation of pain pathways. In

addition, other long-lasting pathophysiologic effects occur with exposure to pain-inducing stimuli in the neonate.

Procedures that result in tissue injury produce a local inflammatory response. This inflammation elicits nociceptor recruitment and sensitization resulting in primary hyperalgesia and increased sensitivity to noxious stimuli. Lasting hyperinnervation can occur as the result of release of neurotrophic factors by the damaged tissue, resulting in a dendritic sprouting of local sensory nerve terminals. This response seems to be most pronounced with tissue damage that occurs in the immediate perinatal period. This phenomenon is demonstrated in preterm neonates who have lower reflex withdrawal thresholds in the foot exposed to repeated heel sticks.[59] This hypersensitivity was ameliorated and in some cases totally abolished by the use of a topical analgesic cream. In addition, secondary hyperalgesia may occur with allodynia—pain caused by a stimulus that is nonnoxious—in the surrounding area. This secondary hyperalgesia and allodynia is caused by increased excitability of the sensory neurons in the dorsal horn of the spinal cord and brainstem with repetitive inputs by A-delta and C fibers, the so called wind-up phenomenon.

Bhutta and Anand[60] described an enhanced vulnerability of immature neurons to degenerative changes and noted that repetitive pain during the neonatal period might have a significant impact on neuronal survival. They proposed two mechanisms that lead to neuronal cell death in the immature brain. The first was excitotoxic cell death initiated by an *N*-methyl-D-aspartate (NMDA) receptor–mediated neuronal cell calcium influx. The second was enhanced neuronal apoptosis potentially caused by maternal separation or metabolic stressors.

The hormonal response to stress-inducing stimuli also seems to be altered in neonates exposed to painful procedures. Extremely low-birth-weight infants studied at 8 months corrected age had higher cortisol levels both at baseline and after exposure to a visual novelty than term and very low-birth-weight neonates.[61] The number of skin-breaking procedures correlated with higher basal cortisol levels in the extremely low-birth-weight infants. Morphine exposure was not associated with the cortisol response.

The pain associated with neonatal circumcision and its effect on future behavioral changes has been the focus of several studies. Neonatal circumcision was shown to increase the pain response to vaccination at 4 to 6 months of age.[62] Further studies confirmed that there was a stronger pain response to subsequent routine vaccination in circumcised versus uncircumcised infants.[63] Treatment with a topical anesthetic before circumcision attenuated this enhanced pain response during 4- and 6-month routine immunizations. Major surgery performed with preemptive analgesia within the first 3 months of life was not associated with an increased response to pain at later (14- or 45-month) immunization.[64] This implies either that the enhanced pain responses noted earlier diminish over a relatively prolonged period following exposure to the noxious stimulus or that preemptive analgesia prevented the memory-associated response.

Altered behavioral and physiologic reactivity to later painful stimuli has been demonstrated in extremely low-birth-weight infants and has been correlated with increased exposure to painful procedures.[65-67] Although term infants show increased behavioral response to vaccination after neonatal exposure to a painful procedure (circumcision),[63,64] preterm infants show dampened behavioral responses even up to 8 months corrected age with exposure to a pain-provoking stimulus.[65] In addition to the alteration in behavioral response, lasting variations in heart rate reactivity to painful stimuli have also been found.[65,66] These alterations are dependent on gestational age at birth, postnatal age, number of painful procedures, and exposure to analgesia.

SUMMARY

Infants have the capacity to perceive pain. The neuroanatomic, neurophysiologic, and neurochemical substrates for pain perception are developed by midgestation and continue to mature throughout late gestation and infancy. Term and preterm infant responses to pain, both physiologic and behavioral, have been well described and are used to perform multidimensional pain assessments. Research supports the concept that exposure to pain in the neonatal period has both short- and long-term effects. Prevention or treatment of pain may reduce the potential sequelae of intense, repetitive, and/or prolonged pain and improve outcomes in the vulnerable fetal and neonatal populations. However, further research is needed to define the best way to treat pain to prevent these effects without introducing detrimental effects from the analgesics themselves. Several organizations have developed consensus statements to help the practitioner approach and treat pain and to define gaps in knowledge and research that should be conducted to fill these gaps.[68-70]

Helen A. Mintz-Hittner

Retinal Development and the Pathophysiology of Retinopathy of Prematurity

Retinal development occurs in an orderly process after the formation of the optic cup (vesicle). The differentiation of the cellular components of the retina occurs from the optic disk (posterior portion of the eye) toward the ora serrata (anterior extent of the retina) and from the internal (vitreal) surface toward the external (scleral) surface of the eye. Differentiation of the most highly specialized region of the retina, the macula, is not complete for the first decade of life. The choroidal vasculature is present on the external side of the retina by 6 to 7 weeks gestational age. As the retina thickens, inner retinal vessels develop on the internal side of the retina from the optic disk at 14 to 16 weeks gestational age to the ora serrata at approximately week 40.

Interruption of normal inner retinal vascularization by premature birth is the initiating event of retinopathy of prematurity (ROP). The timing of the occurrence of observable clinical and histological changes and of measurable growth factor levels is very predictable. Modulation of the infant's extrauterine environment can reduce or prevent the development and severity of ROP.

In clinical practice, knowledge of the classification of ROP, the rules for screening for ROP, and the recommendations for treating ROP is essential to optimize visual outcomes. ROP is one of the most common causes of blindness in both developed and developing nations of the world today and remains a focus of intense clinical investigation.

DIFFERENTIATION OF THE CELLULAR COMPONENTS OF THE RETINA

The ganglion cells are the first identifiable cells in the developing retina and establish the innermost layer of the retina by 20 weeks gestation. Shortly thereafter, cellular migration progresses, and the inner plexiform and inner nuclear layers differentiate. This event is followed by differentiation of the outer plexiform and outer nuclear layers. The nuclei of the outher nuclear layer are the nuclei of the photoreceptors, which develop radially from the optic disk to the ora serrata beginning at approximately 26 weeks gestation.[1,2] Photoreceptor maturation occurs on a gradient, with the most mature photoreceptors near the optic disk and the more immature photoreceptors toward the ora serrata. During stage I of photoreceptor development, the photoreceptor has no outer segment. In stage II, a small, balloon-like outer segment develops. By stage III, disk development can be seen. By stage IV, the outer segments are better developed, with stacks of disks evident to the ora serrata by 29 weeks gestation[1,2] (Figure 170-1).

As the photoreceptor matures, an increasing amount of interstitial retinol-binding protein is present. This protein binds both fat-soluble antioxidant vitamins A and E. Thus, by week 29, the protein is secreted by photoreceptors from the optic disk to the ora serrata, allowing the transport of these antioxidant vitamins to the inner layers of the retina.[1,2] The water-soluble antioxidant vitamin C does not require this protein for transport and thus can traverse the neurosensory retina freely.

The development of the foveal region takes much longer and is not complete until several years after birth.[3] The fovea can first be identified around week 14 of gestation. A central migration of photoreceptors, with remodeling of cones toward the foveal region, is a key event. Maturation proceeds very slowly, with the ganglion cells and glial cells thinning in this area. This process is not complete until after the age of 10 years. This area becomes the region of the retina with highest visual acuity and color perception.

The neuronal elements and their connections and signal processing in the retina are complex, with many types of bipolar, amacrin, and ganglion cell connections to more than 120 million rods and 6 million cones.

NORMAL VASCULARIZATION OF THE RETINA

Vasculogenesis

Vasculogenesis is a process defined by the appearance of angioblasts arising from the optic disk forming a superficial plexus of inner retinal vessels located just beneath the inner limiting

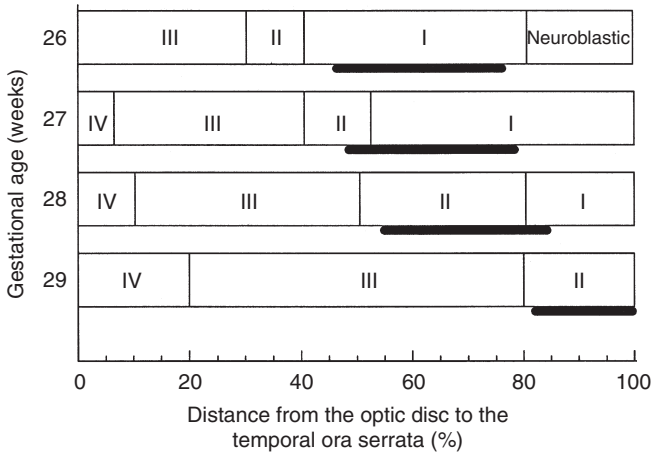

Figure 170-1 Gradient of photoreceptor development from 26 to 29 weeks gestation. *Roman numerals* indicate the stage of photoreceptor development, and the *solid black lines* mark the location of the embryonic vascular elements. *(Modified from Kretzer FL, Hittner HM: Pathogenesis and antioxidant suppression of retinopathy of prematurity. membrane (on the vitreous surface) and progressing toward the ora serrata from 10 to 20 weeks gestational age.[4] VEGF is normal at this time, and the fetus is not yet viable. However, VEGF is secreted by these superficial astrocytes after preterm birth in response to hypoxia. Embryonic retina has a pool of precursors that enlarge centrifugally during fetal development and migrate anteriorly into the nerve fiber layer, with ultimate canalization of new vessels regulated by various factors.[5]

Angiogenesis

Angiogenesis is the process defined by the appearance of vascular precursors arising in the area of the future macula forming a deeper plexus of inner retinal vessels located in the inner nuclear layer and progressing toward the ora serrata from 20 to 40 weeks gestational age.[6] This plexus normally secretes relatively low levels of VEGF. However, VEGF is secreted at higher levels by the Müller cells in the inner nuclear layer after preterm birth in response to hypoxia.

These two processes, vasculogenesis and angiogenesis, probably constitute a continuum, with growth factors orchestrating the formation of final vessel formation of the inner retina while differentiation with thickening of the retina acts as a driving force[7] (Figure 170-2).

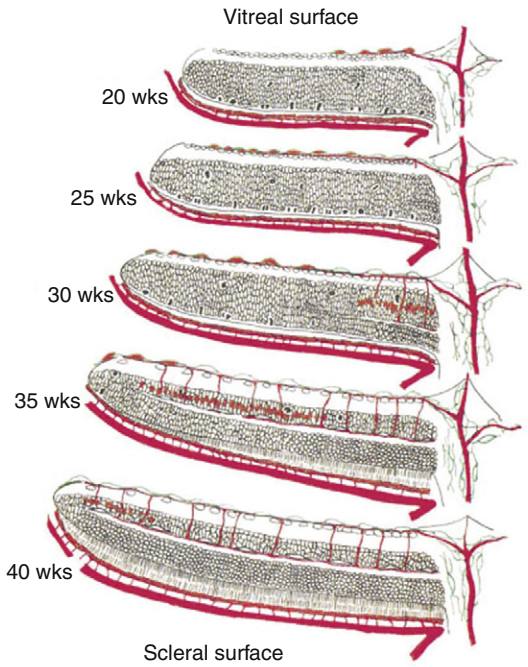

Figure 170-2 Differentiation of the cellular elements and development of the vascular components of the retina during late gestation. *(Modifiea from Stone J, Itin A, Alon T, et al: Development of retinal vasculature is mediated by hypoxia-induced vascular endothelial growth factor (VEGF) expression by neuroglia,* J Neurosci *15:4738-4747, 1995.)*

ABNORMAL VASCULARIZATION OF THE RETINA: RETINOPATHY OF PREMATURITY

Histologic Changes in Vascular Precursors and Predictions of Angiogenic Factors

Both Michaelson in 1948[4] and Ashton in 1970[8] had proposed that an angiogenic factor was released from the retina causing retinopathy of prematurity. However, it was not until 1986 that Kretzer, et al. identified an angiogenic factor in the avascular retina in preterm infants and quantified this factor at different time points after birth in infants with and without retinopathy of prematurity. The presence of an angiogenic factor was indicated in peripheral angioblasts by (1) an increase in the gap junction area between altered angioblasts in the avascular retina indicating cross-chatter between adjacent cells; (2) an increase in the surface area of rough endoplasmic reticulum in these altered angioblasts denoting production of a large amount of an unknown substance; and (3) the ability of retinal homogenates of the peripheral avascular retina to induce neovascularization on chorioallantoic membrane substrates (Figure 170-3).

It has been shown that vascularization may not proceed normally in infants born prematurely in whom ROP develops subsequently. With ROP in an infant born at or before 28 weeks gestation, vascularization may never extend to the ora serrata.[9] The extent of vascularization is dependent on the location of vascular precursors at the time of birth. The initially avascular fovea may revascularize under the influence of abnormally increased angiogenic factors, with new vessels growing toward its center, making the fovea appear to be small or absent.[10]

Additionally, it has been shown that both rod and cone differentiation and function may be delayed or interrupted in preterm infants as a result of environmental changes.[11,12]

Growth Factors and Pathologic Vascularization

Phase I

Vasculogenesis is the formation of normal inner retinal vessels in utero in an environment of relative hypoxia with physiologic levels of VEGF. At the time of premature birth, the infant retina becomes hyperoxic (even in room air) with decreased levels of VEGF. For a period of time, vasculogenesis is halted at the interface between the vascular and avascular retina, usually with some loss of capillaries in the posterior retina (phase I—in clinical terms, between 22 and 30 weeks postmenstrual age). The retinal vessels often vasoconstrict; however, the vessels of the choriocapillaris do not, thereby allowing environmental oxygen free radicals ready access to the external retina (Figure 170-4).

Phase II

As the eye grows, the avascular retina continues to increase both in thickness and in area, without accompanying inner retinal vessels, and areas of capillary fallout remain. This creates a peripheral as well as a posterior area of hypoxic retina, resulting in increased levels of VEGF, which stimulate pathologic neovascularization at the interface between the vascular and the avascular retina (phase II—in clinical terms, 31 to 45 weeks postmenstrual age) (see Figure 170-4).

This two-phase process leads to vision-threatening ROP, most frequently in extremely immature infants with other comorbid disease of prematurity (i.e., risk factors for ROP).[13] Thereafter, VEGF becomes less important. Either intravitreal fibrosis with membrane formation and resultant retinal traction becomes the determinant of ROP outcome or regression of ROP with resumption of relatively normal vessel growth occurs (if laser ablation of the peripheral avascular retina has not been performed).

PATHOPHYSIOLOGY OF RETINOPATHY OF PREMATURITY

ROP is manifested clinically by the abnormal growth of developing retinal vessels. The requisite pathophysiologic mechanisms include both incomplete vascularization of the retina and

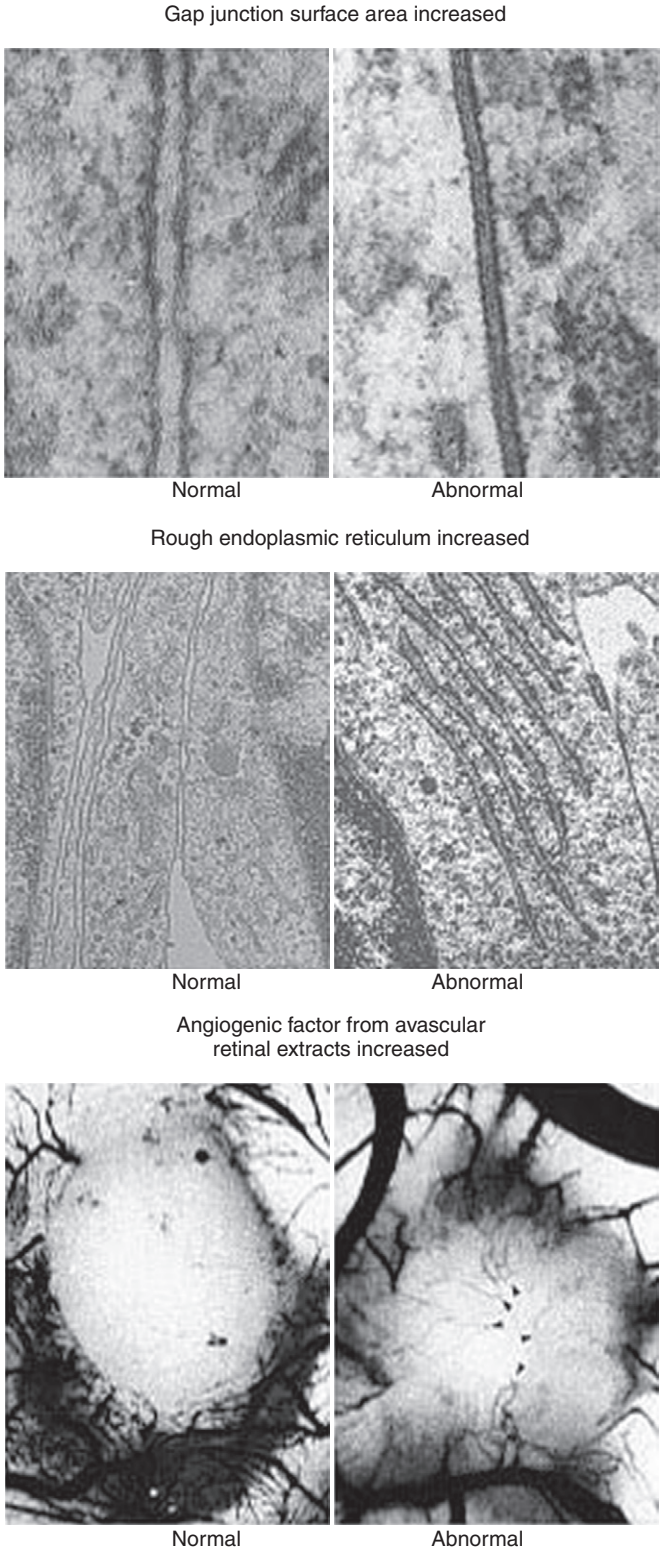

Figure 170-3 Evidence of the production of angiogenic factors by angioblasts. *(Modified from Kretzer FL, Hittner HM: Initiating events in the development of retinopathy of prematurity. In Silverman WA, Flynn JT, editors:* Retinopathy of Prematurity, *Boston, 1985, Blackwell Scientific Publications, PP 121-152; and Kretzer FL, Hittner HM: Pathogenesis and antioxidant suppression of retinopathy of prematurity. In Miguel J, Quintanilha AT, Weber H, editors:* CRC Handbook of Biomedicine of Free Radicals and Antioxidants, *Boca Raton, FL, 1989, CRC Press, pp 315-332.)*

exposure of this immature retina to an abnormal environment[13] (Table 170-1). Children who are born very prematurely are at higher risk for the development of ROP, especially in the presence of multiple other risk factors.

In determining timing for the first ROP screening examination, a predictable relationship has been recognized regarding the onset of ROP and gestational age at birth, postmenstrual age, and postnatal age (see Table 170-2).[15,16] It is clear that in terms of postmenstrual age, ROP first develops and then progresses to more serious stages at a predictable time in type I ROP (i.e., classic ROP). The severity of ROP progresses in an orderly fashion from stage 1 to stage 2, and so on, with "plus" disease ("prethreshold" and "threshold") developing after stage 2 (see Figure 170-4).[14] The development of type II ROP, also called aggressive posterior retinopathy of prematurity (AP-ROP) and formerly known as RUSH disease, is quite different. The plus develops early in the disease process, and the traditional stages of ROP, which occur earlier than in type I ROP and usually in zone I (see Figure 170-4), are replaced by the development of "flat" neovascularization.[15]

Modulating the Environment of the Developing Retina

Modulating the environment of the developing retina to recreate the intrauterine environment of the third trimester should be the goal of all pharmaceutical interventions to suppress retinal neovascularization. Retinopathy can be suppressed by preventing vessel loss, which produces hypoxia and stimulates neovascularization, or by direct inhibition of neovascularization. If these measures fail, then intervention with drugs that oppose neovascular stimulants may be the only option. These approaches are summarized in Table 170-1, which lists the multiple methods to prevent, screen, and treat ROP by attempting to restore balance to the premature infant's retinal environment.

Vascular Endothelial Growth Factor

Vascular endothelial growth factor (VEGF) is a hypoxia-induced growth factor (HIF) that is produced primarily in the retinal Müller cells and endothelial precursors in response to hypoxia and is essential for normal retinal vascularization. Hyperoxia in phase I creates areas of capillary fallout with decreasing retinal levels of VEGF.[16-20] Hypoxia in phase II stimulates neovascularization with increasing VEGF levels. A small case series has used anti-VEGF therapy (bevacizumab [Avastin]) for monotherapy of vision-threatening (stage 3 with plus disease) ROP in zone I and posterior zone II,[21,22] and a multicenter clinical trial of anti-VEGF therapy (intravitreal bevacizumab) with conventional laser to the avascular retina as a control group (BEAT-ROP [Bevacizumab Eliminates the Angiogenic Threat of Retinopathy of Prematurity]) is now being conducted to establish safety and efficacy of this therapeutic approach to ROP[23] (see Table 170-1). Bevacizumab also has been used in combination with laser therapy for treatment of stages 3, 4, and 5.[24]

Erythropoietin

EPO, another HIF, is produced primarily in the kidney in response to anemia and hypoxia and subsequently stimulates both cellular and vascular elements. EPO activates the production of red blood cells as well as retinal angiogenesis. Systemic administration of recombinant human erythropoietin (rhEPO) in phase I has a beneficial effect, not only in treating anemia but also in preventing ROP by limiting vessel loss (by increasing TNF and decreasing capase).[25-27] Systemic administration of rhEPO in phase II has an adverse effect, however, and should be avoided after 30 weeks gestational age (see Table 170-1).[28-30]

Recent studies have demonstrated that inhibiting EPO mRNA with EPO small interference RNA (siRNA) by intravitreal

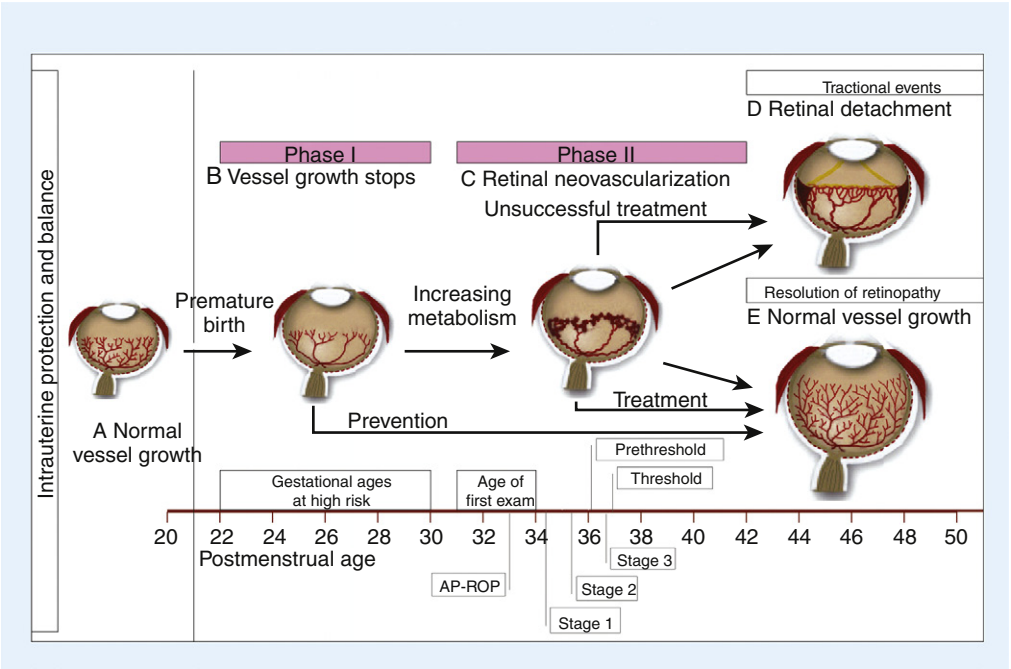

Figure 170-4 Pathogenesis of retinopathy of prematurity. injections during phase II decreases neovascularization in the mouse model of ROP.[31,32] This promising area of clinical research can be expected to lead to development of a second therapeutic drug for use as an adjunct to bevacizumab.[33,34]

Insulin-Like Growth Factor

Insulin-like growth factor (IGF) is a growth factor provided by the maternal circulation until premature birth. Thereafter IGF levels drop precipitously, and supplementation of IGF may be an early treatment that may completely prevent ROP. More recently, observation of early weight gain and IGF decrease has been shown to predict ROP in 100% of infants requiring treatment and correctly identified a majority of infants with ROP who did not require treatment.[35,36] The simple measurement of early postnatal weight gain can markedly reduce the repeated, stressful, and costly ocular screening examinations in all infants with birth weights of 1500 g or lessthat benefit only 10% of the infants actually needing treatment. Thus prediction rather than diagnosis is the goal, with the caveat that postnatal factors that are likely to increase the risk of ROP, as provided by use of the WINROP algorithm (*w*eight, *in*sulin-like growth factor, *n*eonatal *r*etinopathy *o*f *p*rematurity), may be appropriate for identifying vision-threatening ROP.[35]

ω-3 Polyunsaturated Fatty Acids

Polyunsaturated fatty acids (PUFAs), both ω-3 and ω-6, have been studied for possible benefit in ROP. The major PUFAs found in the retina are docosahexaenoic acid (DHA) (i.e., C22:6 ω-3) and arachidonic acid (C20:4 ω-3), found in the vascular cell membrane phospholipids, and eicosapentaenoic acid (EPA) (i.e., C20:5 ω-3), the precursor to DHA found in the retinal vascular endothelium. Vascular regrowth after injury was increased by ω-3 PUFAs, and neovascularization was reduced by ω-3 PUFAs and their derived mediators neuroprotectionD1, resolvinD1, and resolvinE1. This effect was mediated partly by suppression of tumor necrosis factor-α, whose major source is monocyte-derived cells near blood vessels in the retina.[37] This antiinflammatory cytokine is located in a subset of microglial cells that are associated with retinal vessels.[38]

Oxygen

The role of inspired oxygen has long been established as a contributing factor in the development of retinopathy of prematurity. Monitoring blood gases after birth has been a standard of care for decades. More recently, the strict control of oxygen saturation throughout the newborn infant's hospitalization has significantly decreased the incidence of ROP.[39-41] Oxygen stresses have recently been identified as a trigger for ROP through reactive oxygen species (ROS) by way of the Janus kinase-signal transducer and activator of transcription (JAK/STAT) pathway and NAPDH oxidase signaling.[42]

Antioxidant Defenses

Multiple mechanisms serve as antioxidant systems, including those mediated by vitamins (C and E), and several nonenzymatic systems to maintain an effective environment for scavenging of

TABLE 170-1

Methods to Restore Balance to Premature Infant's Retinal Environment

Approach	Principle/Rationale	Clinical Intervention/Comment
Prevention*	Growth factor administration	Administer insulin-like growth factor-I (IGF-I)
	Fatty acid administration	Administer ω-3 polyunsaturated fatty acids (ω-3 PUFAs)
	Prevent angiogenesis with VEGF	Administer vascular endothelial growth factor (VEGF) but NOT after 30 weeks PMA
	Prevent angiogenesis with erythropoietin (EPO)	Administer EPO in first few weeks for anemia but NOT after 30 weeks PMA
	Oxygen monitoring	Utilize blood gas analyzer and cutaneous probes
	Antioxidant administration	Administer antioxidant multivitamins (and minerals): vitamins A, C, E (plus selenium)
	Avoid activating NADPH oxidase and JAK2/STAT2 pathways	Oxygen supplementation and fluctuations may create intravitreal neovascularization
	Prevent sepsis	Avoid oxygen surge secondary to macrophage ingestion of bacteria
	Minimal stimulation	Decreases intraventricular hemorrhage (IVH)
	Delay feedings	Decrease necrotizing enterocolitis (NEC)
Screening†	WINROP	Measure body weight and IGF-I
	Indirect ophthalmoscopy	Gentle examination: without speculum and scleral depression
	Telemedicine	Primarily for remote sites and research documentation
Treatment‡ Early stage 3 ROP (before membranes form)	Laser ablation of peripheral retina	Current standard of care: decreases VEGF by destroying angioblasts and Müller cells in peripheral retina
	Treat neovascularization with intravitreal anti-VEGF	Administer anti-VEGF for neovascularization—but *only* after 31 weeks PMA: bevacizumab (Avastin) as *monotherapy* (NOT with laser): 0.625 mg in 0.025 mL; sterile; small needle (31 gauge)

**Prevention* is best achieved by simulating third-trimester events in Phase I. (See references 16-44.)

†Screening should improve the specificity and sensitivity of early recognition of Type I ROP (described in ETROP). (See references 35, 36, 50, 51.)

‡Treatment is best given early in Phase II: early Stage 3 (before significant membranes form) rather than in late Stage 3, or in Stages 4 and 5, when thick membranes have formed and retinal detachment is occurring. (See references 15, 51.)

PMA, Postmenstrual age; *ROP,* retinopathy of prematurity; *WINROP,* weight, insulin-like growth factor, neonatal retinopathy of prematurity.

oxygen-derived free radicals.[43] In addition, glutathione peroxidase and glutathione-*S*-transferase covalently bind or initiate peroxidation of electrophilic sites of compounds that could damage cellular membranes.[44]

Clinical Standards

Classification: Plus Disease, Zones, Stages

The International Classification for ROP (ICROP) was published in 1984 to define ROP in terms of location (zones I to III) (Figure 170-5), severity (stages 1 to 5), extent (hours 1 to 12 on a clock face), and vascular dilatation and tortuosity (so-called plus disease).[45] This classification was revisited in 2005 to include aggressive posterior ROP (AP-ROP) (formerly called "rush disease"), or pre-plus disease, and is a practical way to estimate the extent of zone I in clinical practice using indirect ophthalmoscopy[46,47] (Figure 170-6).

TABLE 170-2

Timing of First Eye Examination Based on Gestational Age at Birth*

Gestational Age at Birth (wk)	AGE AT FIRST EYE EXAMINATION (WK)	
	Postmenstrual Age	Postnatal Age
22[a]	31	9
23[a]	31	8
24	31	7
25	31	6
26	31	5
27	31	4
28	32	4
29	33	4
30	34	4

*This guideline should be considered tentative rather than evidence-based for infants with a gestational age of 22 to 23 weeks because of the small number of survivors in this gestational age category.

Data from Section of Ophthalmology AAoP, American Academy of Ophthalmology, American Association for Pediatric Ophthalmology and Strabismus: Screening examination of premature infants for retinopathy of prematurity (policy statement), *Pediatrics* 117:572-576, 2006 [erratum in *Pediatrics* 118:1324, 2006].

Screening Rules

Who needs to be screened: All infants whose birth weight is 1500 g or less *or* whose gestational age at birth is 30 weeks or less should be screened for ROP,[48,49] that is, the "15(00) or 30" rule.

When initial screening should be performed: Infants should attain 4 weeks of chronologic age *and* at least 31 weeks of postmenstrual age before the initial screening examination is performed (see Table 170-2)[48,49]—the "4 and 31" rule.

How screening should be performed: Any of several methods of screening can be used. In teaching centers and other locations in which pediatric or retinovitreal ophthalmologists are readily available, conventional indirect ophthalmoscopy is the usual method of screening. With the advent of RetCam imaging systems (Clarity Medical Systems, Plesanton, California), an additional means of screening has emerged, especially useful if a pediatric or retino-vitreal ophthalmologist is not available.[50] The most recent and simplest method of monitoring longitudinal postnatal weight and IGF-I may prove to be extremely valuable in limiting the number of indirect ophthalmoloscopic examinations and RetCam imaging sessions.[36]

How frequently follow-up examinations should be performed: Follow-up examination should be performed from twice a week to every 3 weeks, in accordance with recommendations published in 2006 (Figure 170-6).[48]

Treatment Rules

Who needs to be treated: Retinas that develop plus disease or stage 3 in zone I need to be treated (Figure 170-6).[51]

When treatment needs to be done: Since 2003, emphasis has been placed on early treatment, expecially in cases of AP-ROP.[15,52] Treatment before the extensive formation of membranes is necessary if vitrectomy is to be avoided.

How infants should be treated: Early laser therapy to destroy VEGF by ablation of the peripheral retina has generally replaced (as standard of care)[51] the use of cryotherapy which is more damaging and painful. A point worthy of emphasis is that both laser and cryotherapy are basically destructive processes, invariably resulting in some loss of peripheral retina and often the development of myopia. This loss of peripheral retina and development of myopia is generally more extensive in zone I cases.

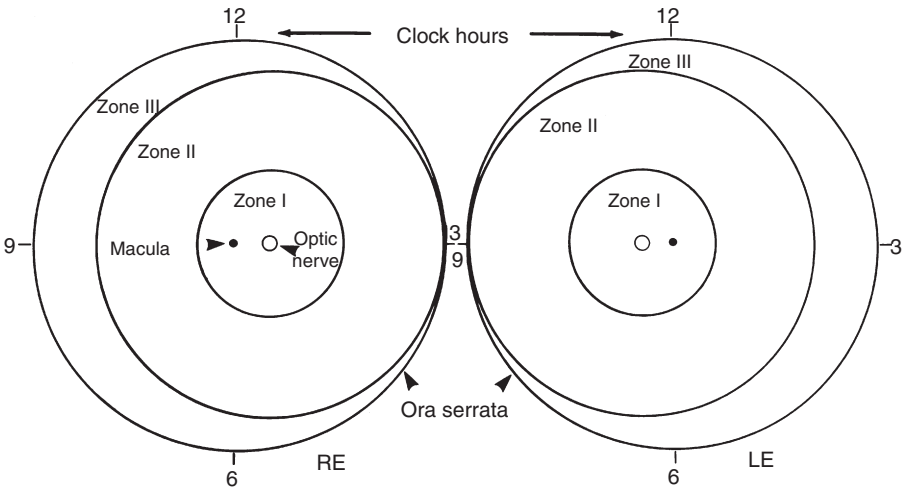

Figure 170-5 Zones of the International Classification of Retinopathy of Prematurity. Scheme of right and left eyes showing the zone of vascularization to indicate the location of retinopathy of prematurity. *(Diagrammatic representation from: An international classification of retinopathy of prematurity. The Committee for the Classification of Retinopathy of Prematurity,* Arch Ophthalmol *102:1130-1134, 1984. Copyright © 1984, American Medical Association.)*

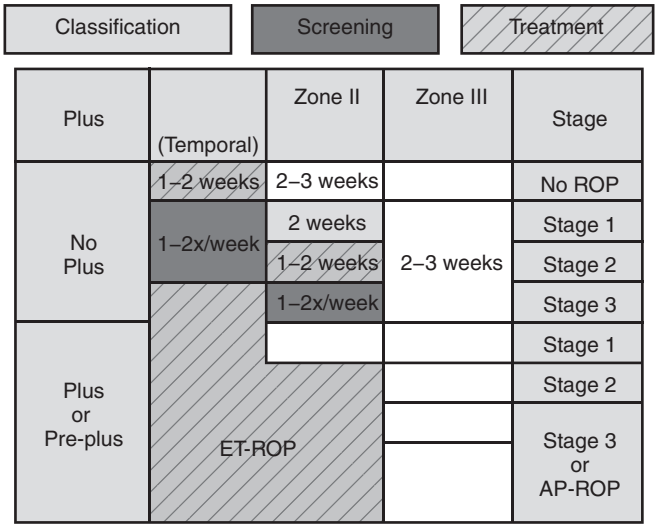

Figure 170-6 Schematic approach to classification, screening, and treatment for retinopathy of prematurity. Use of this summary will allow nurseries to comply with current standards of care for classification *(light shading),* screening *(darker shading),* and treatment *(cross-hatched)* for retinopathy of prematurity. It also permits better communication between neonatologists and ophthalmologists regarding the initiation and frequency of screening and indications for treatment for retinopathy of prematurity. *(Modified from ICROP Committee:* Arch Ophthalmol *123:991-999, 2005 and* Arch Ophthalmol *124:1669-1170, 2006; Section of Ophthalmology AAoP, American Academy of Ophthalmology, American Association for Pediatric Ophthalmology and Strabismus: Screening examination of premature infants for retinopathy of prematurity [policy statement],* Pediatrics *117:572-576, 2006 [erratum in* Pediatrics *118:1324, 2006]; Early Treatment for Retinopathy of Prematurity Cooperative Group: Revised indications for the treatment of retinopathy of prematurity: results of the Early Treatment for Retinopathy of Prematurity randomized trial,* Arch Ophthalmol *121:1684-1694, 2003.)*

With the more recent use of an anti-VEGF drug (bevacizumab [Avastin]) as monotherapy for treatment of ROP in several case reports and case series, and with the publication of the early results of a prospective, randomized, controlled, multicenter trial (BEAT-ROP), another weapon can now be suggested for use against the most devastating cases of ROP (especially severe zone I cases).[21,23] Additionally, anti-EPO treatments may be additive to anti-VEGF drugs and may ultimately become available.[33,34] The development of multiple other treatments can be expected in future research.

How often laser treatment should be performed: Although no standards of care have been established by evidence-based medicine, it is clear that the return of plus disease with the advance of vessels onto retina previously treated with laser is an indication for retreatment. If recurrence is identified early and additional laser therapy is applied, vitrectomy often can be avoided.

171 Early Development of the Human Auditory System

Lynne A. Werner

In all vertebrates, the auditory system begins to function before the visual system (Figure 171-1). In many mammalian species, hearing begins only after birth. In humans, the first responses to sound probably occur by the 24th week of gestation, and, by birth, hearing is quite functional if not adultlike. The fact that human hearing begins before birth suggests that hearing is very important to human function and survival. The early onset of human hearing also implies that experience with sound has the potential to influence auditory function and behavior, even in the prenatal period. Because development may capitalize on universally occurring experience with sound to guide its course,[1] it is especially important to recognize the possible effects of early abnormal auditory experience, as in the case of premature birth.

The prenatal onset of hearing in humans also means that many aspects of early auditory physiology have not been well described in humans. It is difficult to elicit and interpret responses in utero. Because of the medical complications associated with premature birth, basic research on premature infants' auditory function is not often a high priority, and, of course, there is no guarantee that the development of the auditory system in this special population follows the same course as it would in utero. The major landmarks in auditory morphologic development are quite similar in all vertebrates, however. Where structure-function correlations have been established in other species, it is possible to make reasonable predictions about the functional status of the human auditory system even in the prenatal period. At the same time differences are bound to exist among species, and each auditory capacity depends on many structures, any of which may develop differently in different species. Thus any conclusions about human auditory physiology based on development in nonhuman species must be recognized as tentative.

This chapter begins with an overview of the morphologic and physiologic development of the human auditory system. Where physiologic data are not available for humans, data from nonhumans are described. The gold standard of hearing, however, is auditory behavior; the limited information about the fetal and neonatal development of auditory behavior is reviewed in the second section, and the likely anatomic and physiologic substrates of early auditory behavior are discussed.

EARLY MORPHOLOGY AND PHYSIOLOGY

This section presents in broad outline the course of morphologic development of the auditory system and the physiologic correlates of these events as measured in both humans and nonhumans. In studies of nonhumans, the function of the auditory system is primarily measured as potentials recorded at the site of generation, such as single-unit responses. Gross, scalp-recorded evoked potentials are less frequently used (but see, e.g., Blatchley and colleagues,[2] Smith and Kraus,[3] and Walsh and colleagues[3-6]). Many of the same auditory capacities—sensitivity, frequency resolution, temporal resolution—have been measured in human fetuses and neonates. In the case of humans, however, these measurements are largely based on gross, scalp-recorded evoked potentials. Although the same capacities can be measured in this way, it is obviously more difficult to understand the source of immaturity when instruments such as evoked potentials are used. And, of course, a satisfactory approach to assessing auditory function in fetuses in utero has yet to be developed. Despite these difficulties, many of the developmental trends that have been observed in nonhumans have also been described in human fetuses and neonates.

Peripheral Auditory System: The Ear

The ear is generally divided into three sections: the external ear, including the pinna and ear canal; the middle ear, including the tympanic membrane and ossicles suspended in the tympanic cavity; and the inner ear, including the semicircular canals, vestibule, and cochlea (Figure 171-2). Functionally, the external and middle ears comprise the conductive component of the ear. They shape the spectrum of sound arriving at the inner ear. The cochlea is the site of auditory transduction: displacement of the stereocilia of auditory hair cells resulting from the mechanical displacement of the basilar membrane begins a chain of electrochemical and biochemical events that ends with the generation of an action potential in the neurons of the spiral ganglion (Figure 171-3). A detailed account of current understanding of sound conduction and transduction in the auditory system can be found in Moller[7] and Musiek and Baran.[8] Several classic texts describe the embryology and later morphologic development of the peripheral auditory system.[9,10] Recent texts on this topic are widely accessible.[11,12]

Conductive Apparatus

The ear canal forms at the dorsal end of the first branchial groove. The cells known as the meatal plug can be identified by 6 gestational weeks; these cells subsequently degenerate to form the ear canal. The distal end of the ear canal closes as it elongates and does not reopen until approximately the time that responses to sound can first be recorded. In addition at approximately 6 gestational weeks, six mesenchymal protuberances, the auricular hillocks, appear at the edges of the first branchial groove. The auricular hillocks fuse to form the pinna. Both the ear canal and the pinna continue to grow in size well into childhood, although in form they are well developed by the time that responses to sound can first be recorded.

The mesenchyme that will form the middle ear ossicles is first identifiable at approximately 5 weeks of gestation. As the ossicles grow and begin ossification, the tympanic cavity expands around them. Eventually the ossicles will be suspended in the cavity. The tympanic cavity continues to increase in size well into childhood. The linear dimensions and mass of the ossicles are still increasing between 21 and 40 weeks gestation and, in fact, continue to increase somewhat in the postnatal period.[13] The tympanic membrane is derived from the membrane of the first branchial groove. Mesenchyme that grows between the endoderm lining the presumptive tympanic cavity and the surface ectoderm eventually differentiates into the collagenic fibers that give the membrane its elasticity. As development proceeds the tympanic membrane thins in cross-section and expands in surface area. The tympanic membrane area is more or less adultlike by approximately 28 weeks gestation.[14] It is the ratio of the area of the tympanic

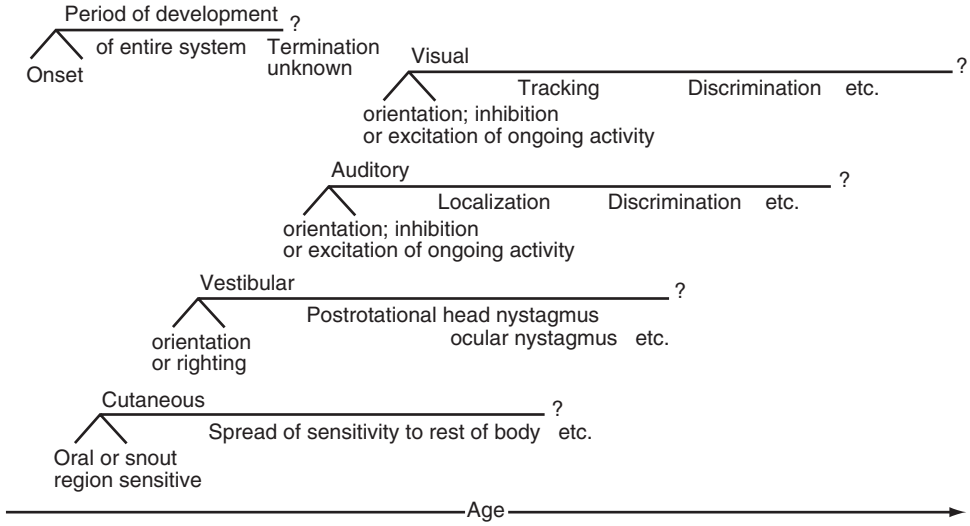

Figure 171-1 The ontogenetic sequence of development of four sensory systems. *(From Gottlieb G: Ontogenesis of sensory function in birds and mammals. In Tobach E, Aronson LR, Shaw ES [eds.]:* The Biopsychology of Development, *New York, 1971, Academic Press, p 69.)*

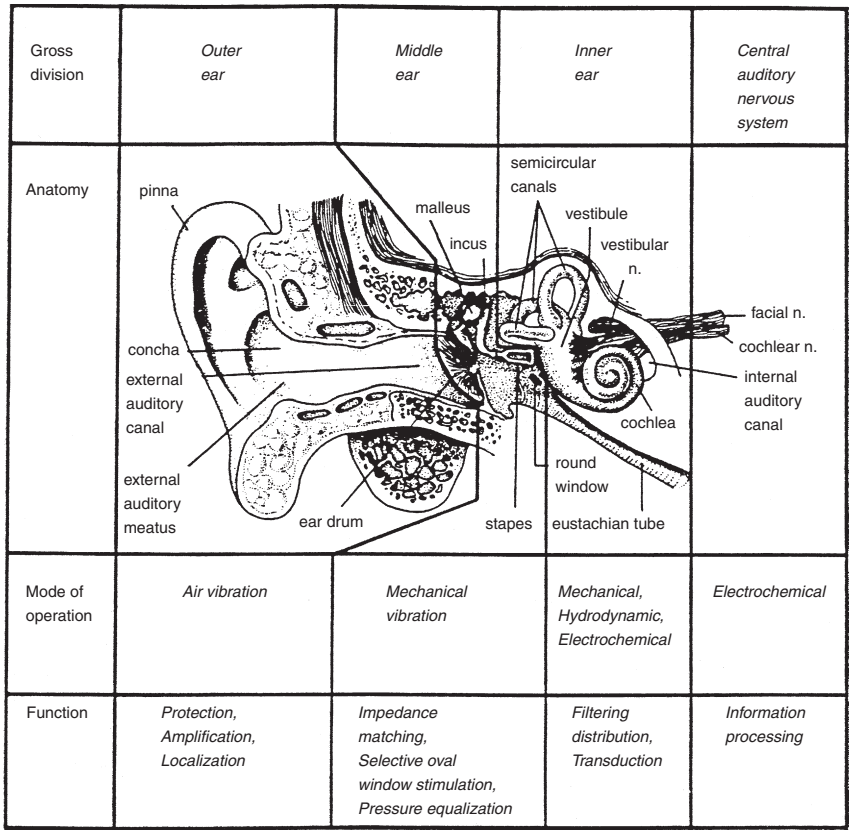

Figure 171-2 Cross-section of the human ear, showing the external, middle, and inner ear and the major functions of each subdivision. *n,* Nerve. *(From Yost W:* Fundamentals of Hearing, *New York, 1994, Academic Press, 1994, p 62.)*

membrane to the area of the stapes footplate that allows the middle ear to overcome the impedance mismatch between air and the fluids of the inner ear. Although this ratio has not been followed during development in humans, in cats the ratio changes little over the period when hearing function begins.[15]

Around the time that responses to sound can first be recorded, the conductive mechanism has several characteristics that appear to be common to all mammals.[16] The ear canal and pinna are small. At term birth, the human ear canal is still only 14 to 15 mm long, compared with the adult length of 23 mm.[17-19] The ear canal may not be completely open. The ear canal walls are more compliant in young animals than in adults. The middle ear cavity is also small. The ossicles are not completely ossified, and they are somewhat smaller and lighter than in the adult. The tympanic membrane appears less stiff than in the adult. Many of these characteristics persist in the term neonate.

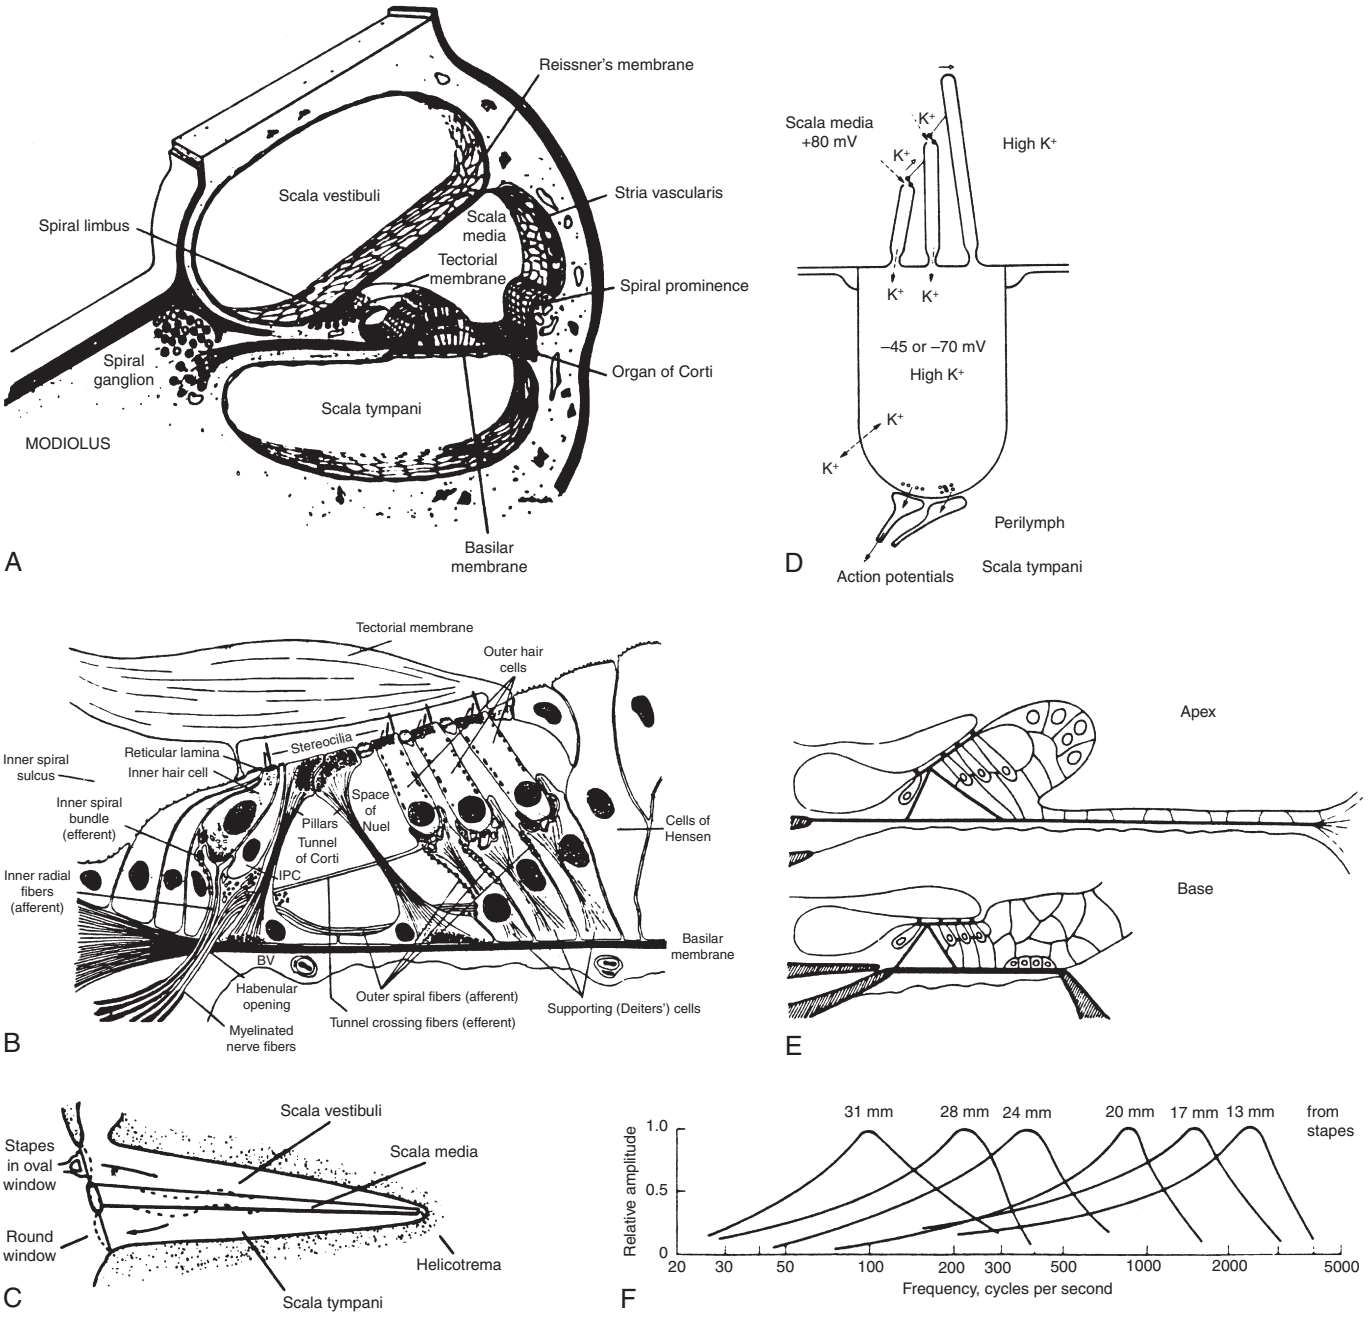

Figure 171-3 Series of drawings illustrating the process by which sound energy is transduced into a neural response by the inner ear. **A,** Cross-section of the cochlear duct. **B,** Schematic cross-section through the organ of Corti. The hair cells are the auditory receptors. **C,** Longitudinal cross-section through the cochlear duct, here represented as if uncoiled. Sound coming through the external and middle ear causes movement of the stapes in the oval window, which results in a traveling wave along the cochlear partition. **D,** Movement of the basilar membrane causes a shearing action across the hair cell stereocilia, opening ion channels in the stereocilia tips, depolarizing the hair cell, and leading to a response in the auditory nerve fiber. **E,** Schematic cross-sections through the organ of Corti near the apex and the base of the cochlea. The basilar membrane is wider and floppier near the apex and narrower and stiffer near the base. **F,** The amplitude of basilar membrane displacement as a function of frequency at various locations along the basilar membrane, specified in distance from the stapes (cochlear base). The structural differences along the length of the basilar membrane have the results that higher frequencies produce maximum displacements near the base of the cochlea, whereas lower frequencies cause maximum displacements near the apex of the cochlea. Thus the position of maximum activity along the length of the cochlea provides information about a sound's frequency. *APs,* Action potentials, *cps,* cycles per second. *(From Pickles JO:* An Introduction to the Physiology of Hearing. *New York, 1988, Academic Press, pp 28-30, 39, 60.)*

The functional implications of conductive development are quite different for animals that begin to hear in utero than they are for animals that begin to hear after birth. If the neonate first begins to hear airborne sounds, then the external and middle ear will determine the spectrum of the sound reaching the inner ear. Obviously the situation in utero is quite different. The normal conductive route to the inner ear becomes irrelevant in a fluid environment, and it is likely that little of the sound that reaches the fetus is transmitted through the external and middle ear. (How much sound reaches the fetus is a separate issue considered in a subsequent section.) If sound reaches the inner ear, it is most probably conducted through the skull, that is, by bone conduction. The response of the cochlea is the same whether a sound reaches it by conduction through the middle ear or through the skull. However, the way that the skull shapes the spectrum of sound reaching the inner ear will be different from the way that the external and middle ears do. When sounds are transmitted to the adult inner ear by bone conduction, with use of a vibrator placed on the mastoid, much greater sound energy is required to elicit a response. The difference is on the order of 40 dB at 1000 Hz. Furthermore, the response of the skull has a "high-frequency emphasis": Compared with air conduction, high frequencies are transmitted relatively more efficiently than low frequencies. For example, for adults, the detection threshold at 1000 Hz is approximately 15 dB lower than that at 250 Hz for air-conducted tones, but approximately 22 dB lower for bone-conducted tones. Of course, the fetal skull is not as well ossified as the adult skull, and in utero sound is transmitted to the skull from the fluid surrounding the fetus, not from a mechanical vibrator. Thus, although it is clear that the route of sound transmission to the fetal inner ear will have substantial effects on what the fetus hears, the nature of these effects is not entirely predictable from the data on hearing by bone conduction in adults. One clear implication of the differences between air-conducted and bone-conducted sound is that infants who are born prematurely will be exposed to a qualitatively different set of sounds than they would have been in utero.

The acoustic consequences of the structural characteristics of the immature conductive apparatus are predictable after birth. The resonance characteristics of a small ear canal and pinna will mean that for sounds of equal amplitude approaching the listener, high frequencies will reach the middle ear at relatively higher amplitude than low frequencies. If the ear canal is not fully open, of course, significantly less sound energy will reach the middle ear. Immaturity of the tympanic membrane and ossicles may decrease the efficiency of the middle ear in transmitting sound to the inner ear, and the response of the middle ear may be biased toward lower frequencies. Studies of the acoustic response of the conductive apparatus in nonhuman species confirm these predictions.[20-22]

The acoustics of the external and middle ear have not been described in premature human infants. Data exist for 1-month postterm infants. The external ear data are in the form of sound-field–to–ear-canal transfer functions, which show the level of sound in the ear canal as a function of frequency, when the level of sound in the surrounding field is equal at all frequencies. In adults, this function shows a broad peak of approximately 10 dB between approximately 2000 and 5000 Hz as a result of the resonance of the ear canal and pinna (Figure 171-4, *A*). The peak resonance frequency of the adult external ear is typically given as 2700 Hz. Keefe and colleagues[19] characterized the acoustic response of the infant external ear. The youngest infants included were 1-month-olds. The average resonance frequency in this age group was 4000 to 5000 Hz (see Figure 171-4, *B*), consistent with physical measurements of ear canal length. Thus, relative to adults, the level of sound reaching the neonatal middle ear at frequencies in the 1000 to 3000 Hz range will be lower. Keefe and colleagues[19] also found that the sound-field–to–ear-canal transfer function is not mature by 24 months postnatal age, but the age at which the transfer function becomes adultlike is not known.

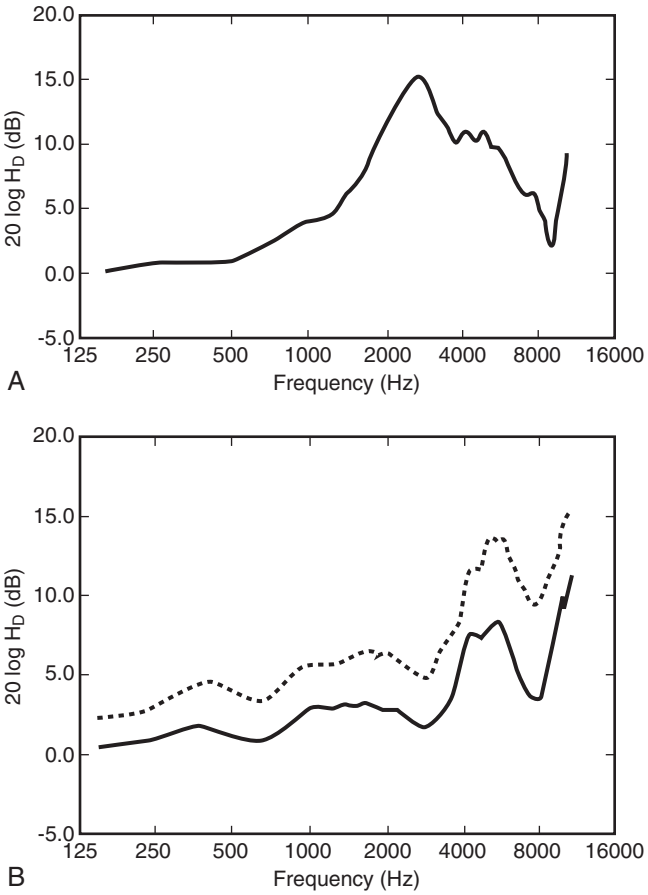

Figure 171-4 Diffuse field transfer functions measured in a KEMAR human adult manikin **(A)** and for the average 1-month-old infant **(B).** The *solid line* is the average; the *dashed line* is the average plus 1 SD. H_D, Diffuse field transfer function magnitude. *(From Keefe D, Burns EM, Bulen JC, et al: Pressure transfer function from the diffuse field to the human infant ear canal,* J Acoust Soc Am *95:355, 1994.)*

Keefe and colleagues[23,24] have also published the only comprehensive studies of the acoustic properties of the infant middle ear. Keefe and colleagues[23,24] estimated the acoustic conductance, or flow of acoustic energy, looking into the middle ear in the ear canals of newborns and 1- to 24-month-olds. The results for newborns, 1-month-olds, and adults are shown in Figure 171-5. The conductance of the infants' middle ear is smaller than that of adults for frequencies above 500 Hz, and the greatest difference is at the higher frequencies. For frequencies above 1000 Hz some improvement appears to occur in conductance in the first postnatal month, but at approximately 4000 Hz infants would be expected to lose 10 to 15 dB relative to adults. The combined effects of external and middle ear immaturity could lead to a relative loss of 15 to 20 dB in the higher frequencies. At frequencies below 500 Hz, both neonates and 1-month-olds actually appear to generate higher levels of sound in the middle ear than adults do. In fact, conductance appears to decline between birth and 1 month and again between 1 month and adulthood in the low frequencies. This result is consistent with the presence of a low-frequency resonance in the neonatal ear canal, perhaps resulting from the greater compliance of the ear canal walls. This

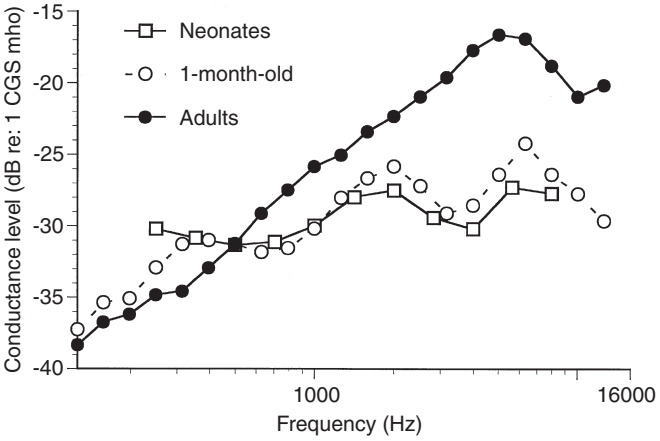

Figure 171-5 Ear canal conductance level, indicating energy flow into the middle ear, as a function of frequency for adults, neonates, and 1-month-old infants. *CGS,* Centimeter-gram-second. *(From Keefe D, Bulen JC, Arehart KH, et al: Ear-canal impedance and reflection coefficient in human infants and adults,* J Acoust Soc Am *94:2617, 1993; and Keefe D, Folsom RC, Gorga MP, et al: Identification of neonatal hearing impairment: ear-canal measurements of acoustic admittance and reflectance in neonates,* Ear Hear *21:443, 2000.)*

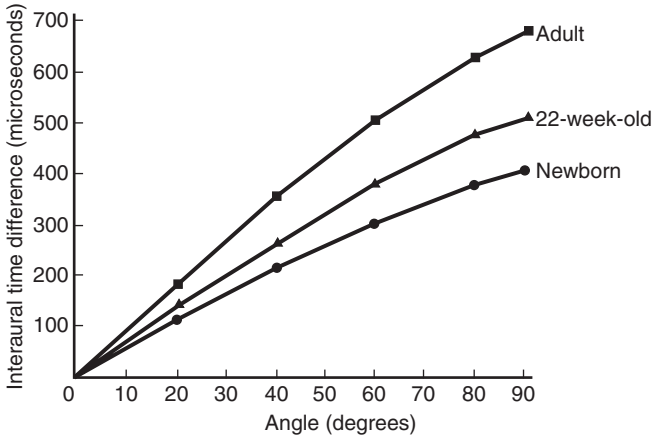

Figure 171-6 Interaural time differences produced by sounds as a function of their position in azimuth, for adults, 22-week-old infants, and newborns. *(From Clifton RK, Gwiazda J, Bauer J, et al: Growth in head size during infancy: implications for sound localization,* Dev Psychol *24:477-483, 1988.)*

could further explain why tympanometry may not be a useful diagnostic tool in young infants.[25]

It is not often appreciated that growth of the pinna, ear canal, and head also has important implications for sound localization. The primary cues to the location of a sound source in the horizontal plane are differences in the phase and intensity of the sound arriving at the two ears.[26] Small heads would produce smaller interaural differences. Clifton and colleagues[27] measured head diameter longitudinally in a group of infants from birth to 22 weeks of age. From these measurements, they estimated that the largest interaural time difference that an infant's head could produce increased from 420 microseconds at birth to 520 microseconds at 22 weeks of age. The average adult head, on the other hand, could produce an interaural time difference on the order of 700 microseconds. Thus, for any sound source location, the infant must work with a smaller cue (Figure 171-6). Similar effects would be expected for interaural intensity differences. Interaural differences would also vary with sound frequency differently when the head is small: interaural phase differences would be useful to fairly high frequencies, but interaural intensity differences in the midfrequency range would be relatively poor.[28] Finally, the sound-field–to–ear-canal transfer function changes with the position of the sound source relative to the ear. These "spectral cues" are used to localize sounds in elevation and to distinguish sound source locations behind the head from those in front of the head. One would expect that smaller pinnas and ear canals would produce poor spectral cues for the localization of sound sources in the midfrequency range. However, the relative contributions of conductive, cochlear, and neural maturation to the development of sound localization remain to be established.

Cochlea

The earliest structures that can be identified as external, middle, and inner ear arise in close temporal proximity. The otic placode, a thickening of the surface ectoderm at the level of the caudal hindbrain, can be seen early in the fourth week of gestation. The placode invaginates, closes off, and detaches from the epidermal surface to form the otocyst, or otic vesicle, a few days later. Shortly thereafter the precursors of the spiral ganglion migrate out of the otocyst and come to lie ventromedial to the developing inner ear. As the precursors of the specialized support cells and hair cells are born, the otocyst elongates and the older cells are "pushed" toward the distal end of the presumptive cochlea.[29] These undifferentiated cells form a mass along the dorsal wall of the tube. The otocyst coils at it elongates, eventually forming two and a half turns by the 25th week of gestation. These events are illustrated schematically in Figure 171-7.

The bony labyrinth that contains the cochlea begins to ossify at approximately 16 weeks gestation. This process must be closely coordinated with cochlear growth and innervation. In fact Van De Water and colleagues[30-33] have demonstrated that a complex series of interactions between epithelial and mesenchymal tissues regulates the growth, ossification, and differentiation of the inner ear structures. The otic capsule appears to be largely ossified by approximately 20 weeks gestational age.[34]

In a series of papers, Lavigne-Rebillard, Pujol, and colleagues[35-43] have described the early development of the human cochlea using electron microscopy. Their results are quite similar to those reported for nonhuman mammals.[43] As described in other vertebrates, the afferent processes of the spiral ganglion grow into the presumptive cochlea and make contact with undifferentiated cells by 9 weeks gestation. These cells then separate from their basement membrane and migrate toward the luminal surface of the epithelium. Once the cells have reached the luminal surface, stereocilia form, and other features of hair cells become evident. Efferent processes are not identified in the cochlea until some time later, approximately 12 weeks gestation in humans.[38,44-46] The stria vascularis, which is responsible for maintaining the high resting potential of the cochlea, appears at 9 weeks gestation, matures slowly between 14 and 20 weeks, and by 34 weeks appears adultlike.[37] The tectorial membrane also appears at approximately 9 weeks gestation. Inner hair cells tend to differentiate and mature ahead of outer hair cells. Innervation and differentiation of support cells and hair cells tend to occur earlier at or near the base of the developing cochlea.[38,47] These developmental gradients have later functional implications, because inner and outer hair cells play quite different roles in the transduction process and because the frequency eliciting the greatest response decreases progressively along the length of the cochlea from base to apex.

When responses to sound can first be observed, the inner ear is immature in several respects. The fluid spaces within the cochlea are not well developed, the basilar membrane is thick,

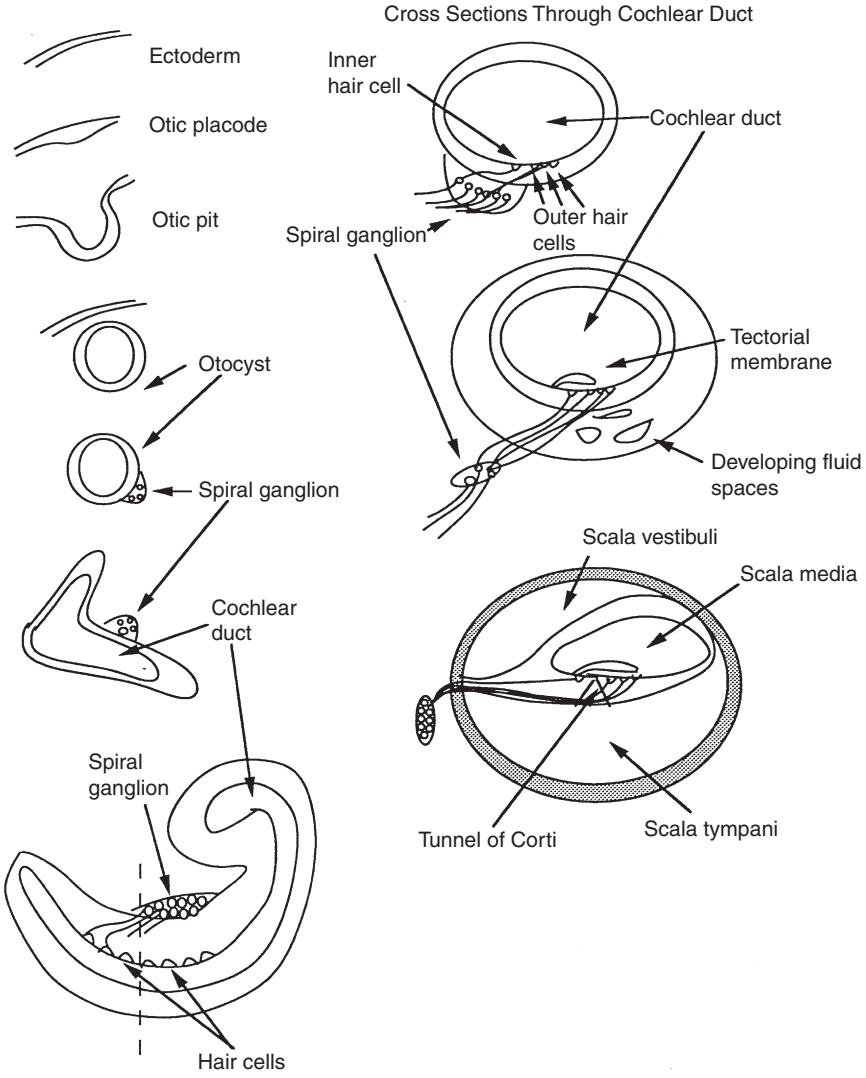

Figure 171-7 Major events in the development of the inner ear.

and the physical arrangement of the support cells and hair cells is immature (Figure 171-8). Such factors are likely to limit the mechanical response of the cochlea. In addition, the innervation of the hair cells is immature.[36,38,42,48] In mature mammals, afferent endings predominate on inner hair cells, and efferent fibers synapse on afferent fibers, not on the inner hair cell membrane. Around the time that cochlear responses can first be recorded, both afferent and efferent synapses can be found on the inner hair cell membrane. Mature outer hair cells feature massive efferent endings encapsulating their basal membrane and a few small afferent endings. At the onset of hearing, the number of afferent and efferent endings contacting outer hair cells is more nearly equal, and both types of ending are rather small and bouton-shaped (Figure 171-9). The stria vascularis still differs from the adult in several respects, suggesting that the endocochlear potential, the "battery" that drives the transduction process, is immature. In recent electron microscopic studies, Lavigne-Rebillard and colleagues[35-37] have shown that these features are characteristic of the human cochlea approaching 20 to 22 weeks gestational age.

An obvious implication of the structural immaturity of the cochlea at this stage of development is that sensitivity to sound will be quite poor. More acoustic energy will be required to set the basilar membrane in motion, and energy will be transferred to the stereocilia less efficiently. Inner hair cells undoubtedly transmit their message to the central nervous system. The outer hair cells, however, are known to act as effectors, mechanically amplifying the basilar membrane response and increasing the frequency specificity of the response. To the extent that the outer hair cells are immature, sensitivity may be poorer by 30 to 40 dB.

It is well documented in nonhumans that the combination of conductive and cochlear immaturity is reflected in cochlear responses[49]; in single-unit responses in the auditory nerve, brain stem, and cortex (e.g., Woolf and Ryan[50] and Brugge and colleagues[51-53]); and in gross evoked potentials.[3,6,54] When responses to sound are first observed, thresholds are quite high, on the order of 100 dB sound pressure level (SPL). Although the precise time course varies across species, sensitivity improves quite dramatically in the subsequent days or weeks. In humans, this rapid maturation of auditory sensitivity probably occurs between 24 and 35 weeks gestational age. Unfortunately, no data document the course of auditory physiologic development before approximately 28 weeks gestational age.

Otoacoustic emissions (OAE) are sounds generated by the action of the outer hair cells that can be recorded in the ear canal that provide a direct measure of cochlear function.[55] OAE can generally be recorded in normally functioning cochleas, as long

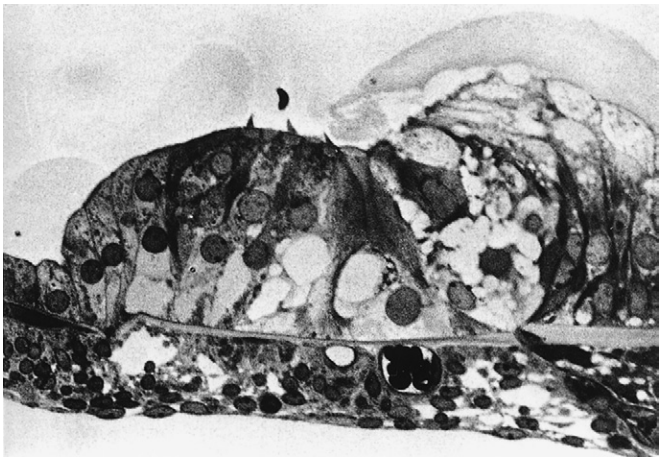

Figure 171-8 Cross-sections through the cochlea of a 20-week-old human fetus, near the upper basal coil. The fluid spaces and mechanical arrangement of cells are underdeveloped. *(From Igarashi Y, Ishii T: Embryonic development of the human organ of Corti: electron microscopic study,* Int J Pediatr Otorhinolaryngol *2:51, 1980.)*

as their transmission through the middle ear is not blocked. OAE have been recorded in infants as young as 30 weeks conceptional age. Click-evoked OAE have been recorded in nearly all infants by 33 weeks conceptional age, at a threshold 10 to 15 dB higher that that of adults.[56] The amplitude to OAE to a fixed-level click also increases between 30 and 40 weeks conceptional age.[57-59] A frequency-specific OAE can also be recorded when two tones close in frequency, f_1 and f_2, are presented to the ear. In this case, the emission is a pure tone with a frequency equal to $2\ f_1\text{-}f_2$ and is known as a distortion product OAE (DPOAE). Lasky[60,61] recorded DPOAE in preterm infants, term infants, and adults. The minimum stimulus level required to elicit a DPOAE was similar across age groups, at least for stimulating tones at approximately 4000 Hz. Lasky concluded that nearly all of the observed age-related differences in DPOAE could be accounted for by conductive factors.

The *auditory brain stem response* (ABR) is a scalp-recorded potential reflecting the aggregate response of neurons in the auditory nerve and brain stem. Wave I of the ABR is known to arise from the auditory nerve; the inferior colliculus makes a major contribution to wave V, though it is not clear that it is the sole generator.[62] Adult ABR thresholds for a click are typically approximately 10 dB normal adult hearing level (nHL).[62] The ABR can first be reliably elicited from preterm infants at approximately 28 weeks postconceptional age, although a few

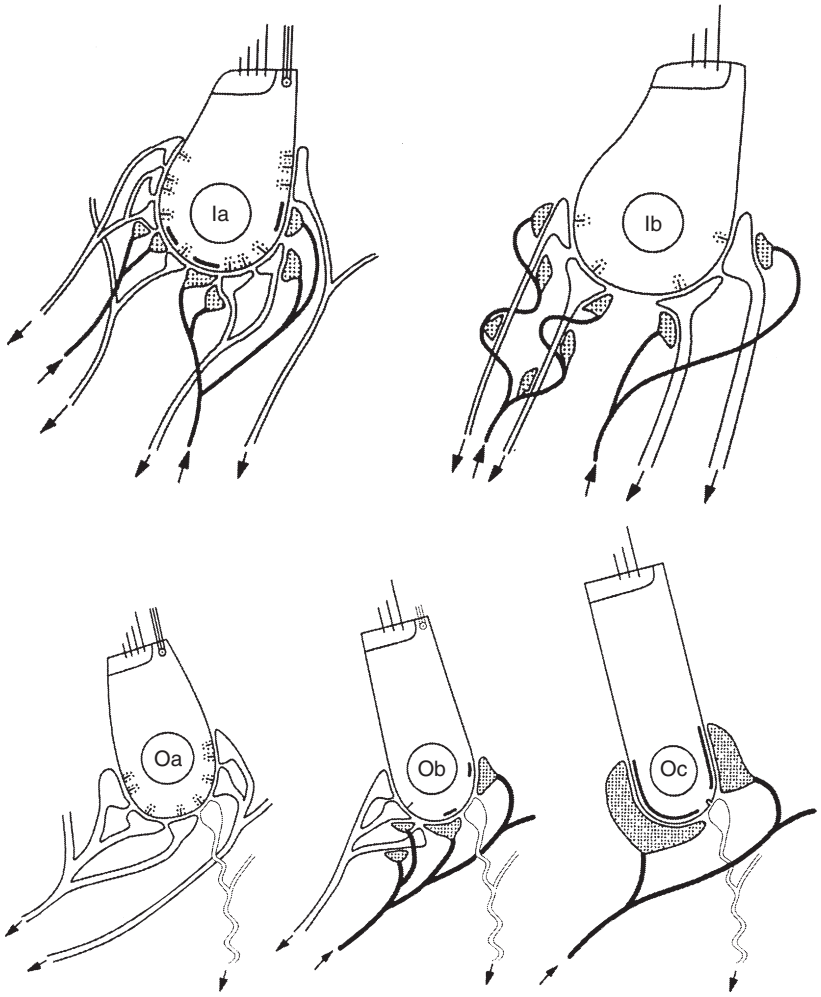

Figure 171-9 Changes in the innervation patterns of inner and outer hair cells around the time that the cochlea begins to function. Efferents are filled fibers with vesiculated profiles and *inward arrows*. Afferents are open fibers with *outward arrows. I,* Inner; *O*, outer. *(From Pujol R, Lavigne-Rebillard M, Lenoir M: Development of sensory and neural structures in the mammalian cochlea. In Rubel EW, Fay RR, Popper AN, et al, editors:* Development of the Auditory System, *New York, 1998, Springer Verlag, pp 146-192.)*

reports exist of responses at 26 or 27 weeks.[63,64] Lary and coworkers[64] reported that the average click intensity required to elicit an ABR decreased from approximately 55 dB nHL at 27 weeks conceptional age to 21 dB nHL at 38 weeks conceptional age. Subsequent studies have confirmed this result.[65,66] This pattern is consistent with an improvement in auditory sensitivity on the order of 25 to 30 dB between the onset of the response and term birth, but the relative contributions of conductive, cochlear, and neural sensitivity to the ABR threshold are not known. The latency of wave I decreases between 33 and 44 weeks conceptional age,[63] but latencies may be prolonged without concomitant sensitivity loss.[67]

One result that seems to be consistent across studies is that by the time of term birth, thresholds for cochlear responses elicited by broadband sounds are within 10 or 15 dB of adult values. This is the case for wave I of the ABR,[62] OAE,[56] and electrocochleograms (scalp-recorded cochlear potentials).[68] Because a threshold shift of that magnitude can easily be accounted for by conductive factors,[23] these reports suggest that the cochlea is probably mature by 40 weeks postconceptional age.

Coincident with the improvement in sensitivity, a dramatic improvement in the frequency selectivity of the cochlear response occurs in nonhumans just after hearing begins. In the mature mammal, each inner hair cell and the afferent fibers connected to it respond over a range of approximately one third of an octave. When the cochlea begins to respond to sound, many auditory nerve fibers are essentially "untuned," and the best fibers respond over a range as broad as three octaves (Figure 171-10).[69] Frequency specificity is closely correlated with sensitivity during development, and its maturation is likely the result of both mechanical maturation of the basilar membrane and the outer hair cells. Many functional consequences of reduced frequency selectivity would be expected, although few of these expectations have been put to the test. Sensitivity in noise is known to be especially poor.[70] The internal representation of the spectrum of a complex sound will also be "fuzzy" to the novice listener, and similar frequencies would be difficult to distinguish.

Frequency selectivity at the cochlear level has been studied with DPOAE. The amplitude of DPOAE can be reduced by presenting external sounds that are close to the emission in frequency; the emission is said to be "suppressed." In fact, the better the cochlear frequency selectivity, the narrower the range of frequencies that will suppress the emission. The curve that shows the level of an external tone required to reduce the emission by a criterion amount, as a function of the frequency of the tone, is termed a *suppression tuning curve*. Abdala[71-73] has found that preterm and term infants demonstrate sharper suppression tuning curves, or better frequency selectivity, than adults (Figure 171-11). Abdala argued that early in development, the human cochlea "overshoots" the amplification required, as observed in young gerbils by Mills and colleagues.[74] However, it is also true that suppression tuning curves measured at lower intensity are generally sharper than those measured at higher intensity. Thus attenuation of the sound reaching the infant cochlea by an immature middle ear could be responsible for the age difference in tuning. Three articles now support the hypothesis that apparent differences in cochlear tuning in neonates result from immaturity of the middle ear.[75-77] Of course, neural limitations may effectively limit the frequency selectivity of the system, as discussed later.

As noted earlier, many events in cochlear development tend to occur in structures located at or near the base of the cochlea before they occur in structures located at the apex. Because the mass and stiffness of the basilar membrane vary along its length, in mature vertebrates high-frequency sounds produce greater responses than low-frequency sounds at the base of the cochlea, whereas low-frequency sounds produce greater responses at the apex. Thus one might predict that responses to high-frequency sounds might appear and mature earlier than those to low-frequency sounds. In fact, just the opposite is typically observed: the initial responses to sound are limited to the low or low-to-middle part of the mature animal's range of hearing. The range of frequencies that elicit responses gradually increases as sensitivity improves during development. The most likely explanation for this apparent paradox is that the basal cochlea is most responsive to relatively low frequencies at the time that it begins to respond.[78-81] Recent studies suggest that the immature frequency response of the basal cochlea is the result of mechanical properties of the basilar membrane.[74] Although such effects have yet to be demonstrated in humans, they would be predicted to occur between 24 and 37 weeks gestation.

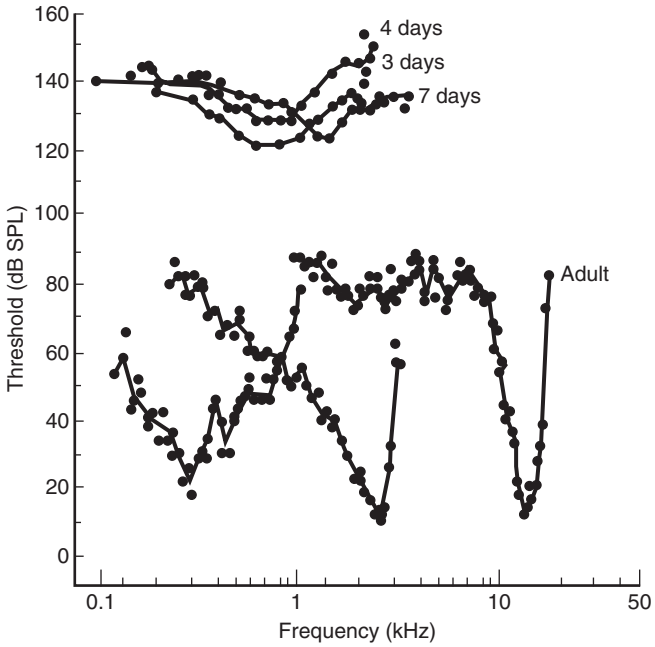

Figure 171-10 Level required to produce a threshold response in fibers of the cat auditory nerve as a function of frequency. Each curve represents the response of a single nerve fiber. Adult responses tend to be "tuned." The fiber tends to respond to very low sound levels within a restricted frequency range. Responses of 3- to 7-day-old kittens require very high sound levels and are not well tuned. *SPL,* Sound pressure level. *(From Walsh EJ, McGee J: Postnatal development of auditory nerve and cochlear nucleus neuronal responses in kittens,* Hear Res *28:97-16, 1987.)*

Congenital hearing loss occurs in 2 or 3 per 1000 neonates.[82,83] Because cochlear response can be readily assessed in neonates with use of OAE and ABR and because the vast majority of congenital hearing losses originate in the ear, these measures are commonly used in newborn hearing screening.

Early Hearing Detection and Intervention (EHDI) Programs

Click, or *transient*, evoked OAE, DPOAE, and ABR have been shown to be equally sensitive screening measures, with similar referral rates.[84,85] Concurrent measurement of middle-ear function may allow distinction between transitory or permanent conductive impairment and cochlear impairment.[24] Ideally, infants who fail the initial screen are evaluated before 3 months of age, and early intervention services are implemented before 6 months. Early intervention is associated with near-normal language development by the preschool period.[86,87] Early cochlear implantation is now a good option for infants with severe-to-profound hearing loss. It should be noted, however, that children with mild-to-moderate or unilateral hearing loss may be missed by EHDI programs. Furthermore, if OAE alone are considered, hearing

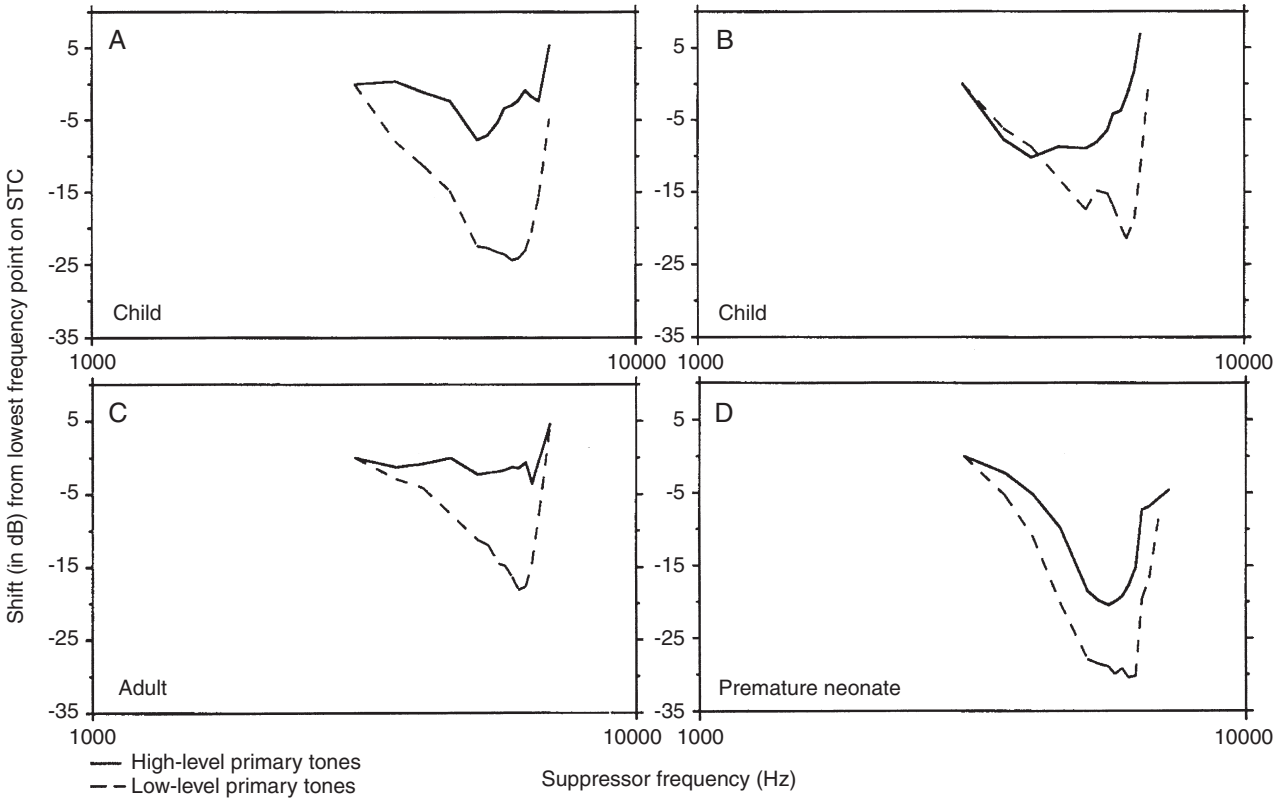

Figure 171-11 Relative level of a suppressor tone required to suppress a distortion product otoacoustic emission, as a function of the frequency of the tone, so-called suppression tuning curves *(STC),* for high- and low-level stimulating ("primary") tones. Each emission tends to be suppressed with low-level tones close to its own frequency. **A** and **B,** Responses from children 8 to 12 years of age. **C,** Response from an adult. **D,** Response from a premature infant. The premature infants' response is sharper than those of other subjects, and the sharpness is maintained at high levels of stimulation. *(From Abdala C: DPOAE suppression tuning: cochlear immaturity in premature neonates or auditory aging in normal-hearing adults?* J Acoust Soc Am *110:3155-3162, 2001.)*

disorders that result from so-called *auditory neuropathy* will also not be identified.[88]

More than half of congenital hearing losses have genetic causes, with the remainder resulting from infection, exposure to ototoxic drugs, prematurity, or other environmental causes.[89,90] Hearing loss is associated with several hereditary syndromes, including Waardenburg, branchio-oto-renal, Stickler, Pendred, and Usher among others. The majority of genetic deafness, however, is nonsyndromic. Tremendous progress has been made in the last decade in identifying the genes responsible for many types of nonsyndromic hearing loss. More than 70% of nonsyndromic congenital hearing losses are autosomal recessive; approximately half of these result from mutations of *GJB2* and/or *GJB6.*[91] Approximately 1 in 33 people of northern European descent in the United States is a carrier of a recessive deafness-causing mutation of *GJB2.*[92] *GJB2* and *GJB6* encode Connexin 26 and Connexin 30, respectively. These proteins form the gap junctions that provide intercellular bridges for the recirculation of potassium ions into the cochlear endolymph. The other cases of nonsyndromic congenital hearing loss result from mutations of numerous other genes, and some of these occur in only one or two families.[93,94] Some types of genetic hearing loss, particularly syndromic and autosomal dominant types, have their onset later in childhood or in adulthood.[95]

Central Auditory Nervous System

The limited data concerning the development of the human auditory nervous system are often found in articles dealing with the development of the whole brain.[96] Although this situation has begun to be remedied,[97-104] the available information with respect to human auditory neural development remains sparse. What data are available suggest, however, that substantial differences do not exist between humans and nonhumans in the development of the primary auditory pathways. In all vertebrates the neurons of the auditory pathways undergo final mitosis, migrate to their mature locations, and form appropriate connections in parallel with developmental events at the periphery; by the time that the cochlea begins to respond to sound, gross evoked responses can be recorded in primary auditory cortex.[105,106]

Early sensitivity to sound, however, may be limited by brain stem immaturity. Sininger and Abdala[107] estimated newborns' frequency-specific ABR threshold, calibrating their stimuli in the ear canal to control for age differences in ear canal size. Their data show that newborns are close to adultlike in sensitivity at 500 Hz but that they are 20 to 25 dB less sensitive than adults above 4000 Hz. The high-frequency age difference is greater than can be accounted for by middle-ear immaturity alone.

Neural immaturities appear to limit the frequency selectivity of the auditory system early in human development. Two recent studies show that the ABR to a high-frequency sound is affected by a broader range of interfering frequencies, or "maskers," in 3-month-old infants than in adults.[108,109] This suggests that the frequency selectivity of the infant brain stem response is poorer at high frequencies. Because the cochlear response appears to be mature by this age,[110] the source of the immaturity in frequency selectivity is likely to be neural. Presumably, these immaturities will be more pronounced for still younger infants, and the immaturities may extend to lower frequencies as well.

Of course, at younger ages, cochlear immaturities may also be present, and it is not known how cochlear and neural immaturities may interact.

The work of Sanes and his colleagues has been important to understanding how neural maturation and experience with sound contribute to the development of frequency resolution. Sanes and Constantine-Paton[111] reported that exposing young mice to repetitive clicks resulted in a reduction in neural frequency selectivity that could not be explained by peripheral effects. The selectivity of neural connections, then, can affect frequency selectivity, and normal experience with sound appears to be necessary to induce or maintain the nervous system's ability to accurately transmit the selective response established at the cochlear level. Sanes and Rubel,[112] moreover, noted that fine frequency selectivity was not characteristic of all neurons in the auditory brain stem. Within a single frequency region, neurons with mature selectivity and neurons with very immature selectivity could be found. Because all of these neurons receive their afferent input from the same cochlear location, it is difficult to see how cochlear factors could produce such variability in response. In other studies Sanes and co-workers[113] directly measured the increased specificity of neural connections in one auditory brain stem nucleus, and Sanes[114] showed that maturation of structural specificity was reflected in maturation of neural response specificity. Finally, it should be noted that although some neural response patterns appear mature when described on a relative scale, they appear quite immature on an absolute scale. Thus it is becoming increasingly evident that neural immaturities impose a fundamental limitation on early auditory function, although a detailed description of these immaturities is not yet possible. Certainly in humans, structural maturation of auditory cortex continues until 11 or 12 years of age.[102,103]

A commonly reported characteristic of immature auditory neurons is that they cannot sustain a continuous response.[115] In addition, their maximum response rate is quite low (summarized by Sanes and Rubel[116]). Such response characteristics would have profound influences on all aspects of acoustic coding. A reduction in the range of intensities that could be processed would be expected, the ability to distinguish a change in intensity would differ, and, of course, sensitivity would be reduced as well. The "fatigability" of young neurons is almost certainly not a result of cochlear limitations, although the reduction in dynamic range may well reflect similar limitations in the cochlear response. Although no data are available in this regard for preterm infants, Durieux-Smith and colleagues[117] have reported a similar limitation in the neonatal ABR: increasing the intensity of a click results in a smaller increase in response amplitude for term neonates than it does for adults (Figure 171-12). Cornacchia and colleagues[118] reported that this characteristic of the ABR is adultlike by 6 months after term.

Neural maturation is also clearly reflected in the development of temporal aspects of the neural response. Progressive myelination of neural pathways is noted during development in all vertebrates. It is often stated that myelination of the brain in general, and of the auditory pathway in particular, proceeds in a peripheral-to-central gradient.[96] More recent studies suggest that this gradient holds only on a coarse scale. Moore and colleagues[101,119] have found that, in the human auditory system, the brain stem pathway is myelinated at approximately the same time along its length but that the brain stem pathway is well myelinated before myelin is observed in the brain stem–to–midbrain pathway. Increased myelination would certainly increase the speed with which information is transmitted through the auditory system. In fact, the latency of both single-unit responses and of gross evoked potentials progressively decreases during development, and the age-related change in response latency is greater in more central nuclei.[5,53] Increased myelination might also be expected to produce improvements in auditory functions that depend on a precise temporal representation of the stimulus, such as sound localization. Variability in the latencies of action potentials, both within and between neurons, would be reduced in well-myelinated nerve fibers.

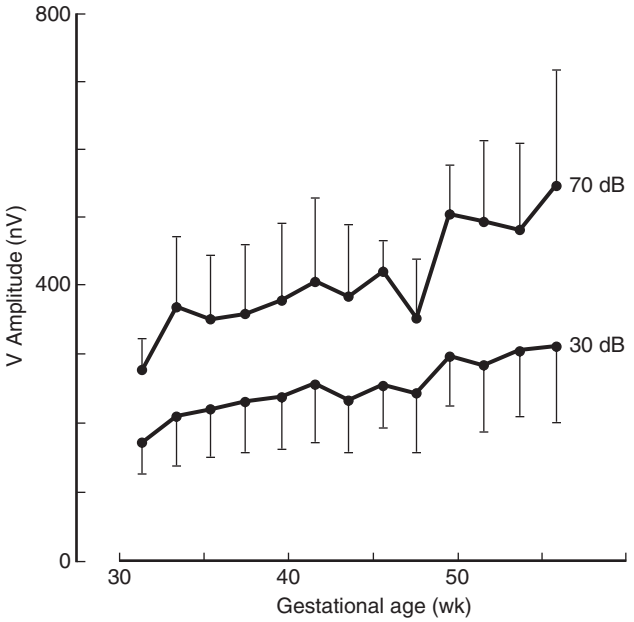

Figure 171-12 Amplitude of wave V of the auditory brain stem response as a function of gestational age for two sound intensities. The effects of increasing intensity are greater at later gestational ages. *(From Durieux-Smith A, Edwards CG, Picton TW, et al: Auditory brainstem responses to clicks in neonates,* J Otolaryngol *14:12-18, 1985.)*

Response latency is the most frequently studied characteristic of evoked potentials in humans, and it is one of the few measures that has been made extensively for both preterm and term neonates. Gorga and colleagues,[63] for example, reported that between 33 and 44 weeks conceptional age, wave I latency in response to 80 dB nHL clicks decreased from approximately 1.8 milliseconds to approximately 1.6 milliseconds. Wave V latency decreased from 7.0 milliseconds to 6.5 milliseconds over the same period. The implication of the fact that wave V latency decreases more than wave I latency is that most of the decrease in wave V latency stems from neural maturation. One interesting aspect of these results is that the effects of increasing intensity were no different for the youngest (33-34 weeks conceptional age) and oldest (43-44 weeks conceptional age) infants (see also Zimmerman and colleagues[120]). In fact, the effects of level on wave V latency were adultlike in the youngest preterms examined (Figure 171-13). By 40 weeks conceptional age wave I latency is close to adult values, but wave V latency continues to decrease into the second postnatal year (e.g., Hall[62] and Eggermont and Salamy[121]).

Two issues concerning the infant ABR have both developmental and clinical implications. First, some reports exist of rapid improvements in ABR detectability, amplitude, and latency in the first 48 hours after birth.[122-125] Explanations for these rapid postnatal changes vary. The typical explanation is that early postnatal changes result from clearing of fluid or other material from the middle ear,[125-127] although some argue that cochlear adaptation to extrauterine life is responsible.[127-131] Yamasaki and colleagues[122] found that the wave I-V interwave interval, the so-called central conduction time, also decreased in the immediate postnatal period. How differences in central conduction time could result from either conductive or cochlear factors is not

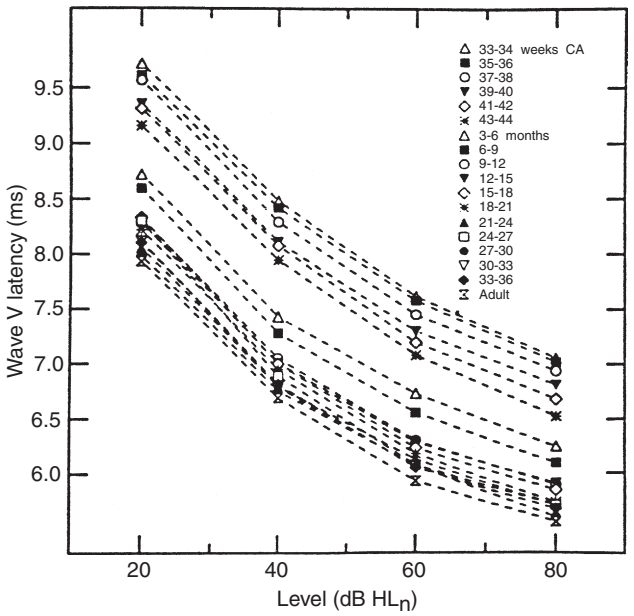

Figure 171-13 Latency of wave V of the auditory brain stem response as a function of sound intensities at various ages. The curves are more or less parallel. HL_n, Normalized hearing level. *(From Gorga MP, Kaminski JR, Beauchaine KL, et al: Auditory brainstem responses from children three months to three years of age: normal patterns of response II, J Speech Hear Res 32:281-288, 1989.)*

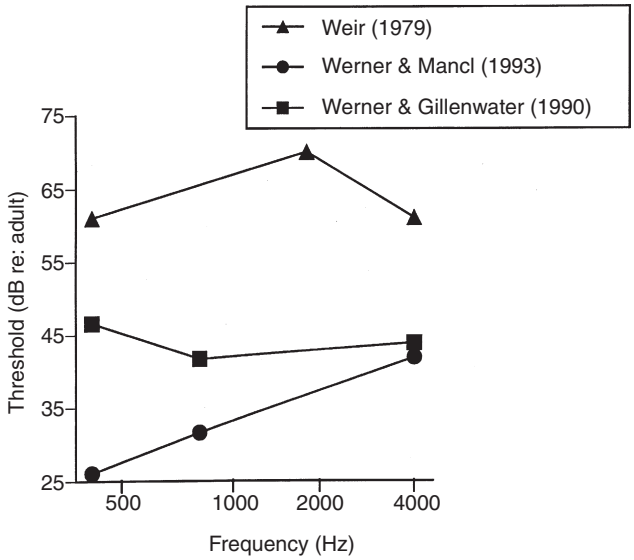

Figure 171-14 Comparison of detection thresholds, expressed relative to adult threshold, at three frequencies from 0- to 1-month-old infants in three studies. *(From Werner LA, Marean GC:* Human Auditory Development, *Boulder, CO, 1995, Westview Press.)*

clear. Thus, although the reason for rapid changes in the ABR after birth are not settled, a consensus seems to exist that stable ABRs are most readily obtained after 48 postnatal hours.

The second issue concerns the use of the ABR in the preterm population. Essentially the question is whether extrauterine experience affects ABR parameters independently of conceptional age. In other words, is the ABR of a 40-week conceptional age infant whose gestational age is 32 weeks different from the ABR of a 40-week conceptional age infant who was born yesterday? Some studies report no differences between preterm and term infants of equal conceptional age.[132,133] Eggermont and Salamy[121] found that preterm infants tended to have longer wave latencies but equivalent interwave latencies. Eggermont and Salamy[121] propose that this difference arises from the higher incidence of otitis media in the preterm population. Collet and colleagues,[134] in contrast, report shorter interwave intervals among preterm infants and conclude that the smaller head size of preterm infants is responsible. In any case, the differences between term and preterm infants of the same conceptional age are small, and little evidence exists of a direct effect of extrauterine experience on the development of the ABR.

At least three factors influence the latency of evoked potentials and are, thus, potential explanations for developmental changes. First, sensitivity at sites peripheral to the generator of a given wave contributes to its latency. For example, latencies of all ABR waves are longer for lower intensities of sound and in cases of conductive or sensorineural hearing loss.[62] The changes in wave I latency with conceptional age are consistent with approximately a 20-dB conductive immaturity at 33 to 34 weeks conceptional age and a 10- to 15-dB conductive immaturity at term birth, as suggested by the middle-ear data.[23] To achieve a wave V latency of 7.5 milliseconds, however, the data of Gorga and colleagues[135] indicate that a term infant requires a level approximately 25 dB higher than an adult (Figure 171-14). It is clear that neither conductive nor cochlear factors can account for such a large difference. Second, myelinization of the auditory pathway would increase conduction velocity; it is well established that myelinization of the auditory pathways progresses through the postnatal period and into childhood.[96,119] This is the most clearly established contribution to ABR latency development; by some accounts, conduction time improvements can completely account for changes in the latency of the ABR during development.[136] Third, synaptic efficiency may play a role. The number of synapses in the auditory brain stem continues to increase throughout childhood and into adulthood,[137] although the efficiency with which each synapse operates, an unknown quantity, may be more relevant. One finding that suggests that synaptic efficiency may be important is that the wave I-V interwave interval is positively correlated with behavioral thresholds in early infancy.[138] No evidence exists that neural latency directly affects sensitivity; in fact, latencies can be very abnormal while sensitivity remains normal.[67] A loss of information resulting from inefficient synaptic transmission could well affect both sensitivity and evoked response latency. Rotteveel and colleagues[65] also note an association between ABR threshold and interwave intervals among preterm infants.

Other evoked responses, such as the middle and long latency responses that originate from the midbrain and cortex, have not been studied extensively in neonates (see Hall[62] for a review). It appears that the difference between infants and adults in threshold for the middle latency response (MLR), for example, is greater than the difference in ABR threshold,[139] and MLR latencies take longer to reach adult values.[140-142] Cortical responses have been recorded, even in preterm infants,[106] but again the developmental course of such responses is prolonged. Although the factors that contribute to the delayed maturation of MLRs and late responses have not been delineated, their later development is consistent with the later myelinization of the midbrain and cortical pathway. Other factors may also be involved.

Of course, latency is not the only temporal characteristic of neural responses. Because of the characteristics of the transduction process, auditory neurons tend to fire at the same phase of the stimulus on each cycle of a periodic sound; the neural response is said to be "phase-locked." Phase locking is strong

enough and the neural transfer of the phase-locked response is precise enough that the period, and thus the frequency, of a sound could be estimated quite well on the basis of the interval between action potentials. The precision of neural phase locking is likely to depend on both the efficiency of synaptic transmission and the extent of myelination of nerve fibers. Phase locking is believed to contribute to pitch perception, among other things, and it is the basis of interaural phase difference processing in sound localization. Of the basic auditory neural response properties, phase locking is the one that takes longest to develop. Brugge and colleagues[51] reported that phase locking in the cat's auditory nerve matured over a 2-week period, with fibers responding to low frequencies achieving mature phase locking earlier. The development of phase locking at the level of the cochlear nucleus followed the same frequency gradient but took as long as 2 months to complete.[143] The course of its development in nuclei central to the cochlear nucleus has not been described. The relative contributions of synaptic maturation and increased myelination (see later) to the development of phase locking have not been assessed. The frequency-following response (FFR) is a scalp-recorded response that has the same frequency as the tone used to elicit it. The FFR is believed to reflect the aggregate phase-locked responses in the auditory nerve and brain stem.[62,144] Two studies have examined the FFR in term neonates[145-147]; in general, the response appears to be adultlike. Similar measures of phase locking at more central locations in the nervous system have not been developed. Again, no data on the development of temporal processing are available for preterm infants.

Another property of neurons that has implications for temporal coding is adaptation. Auditory nerve fibers show a characteristic high response rate at stimulus onset, followed by a rapid decrease in response rate to a lower, steady rate. This decrease in response over time is known as adaptation. After the offset of the stimulus, a recovery period occurs during which it is difficult to elicit responses from the neuron; even spontaneous activity is absent during recovery. Evidence exists that the immature auditory system is more susceptible to adaptation than the mature system and that it takes longer to recover from the effects of adaptation. In human infants increasing the rate of presentation of clicks used to elicit the response has a greater effect on response latency for newborns.[126,148-150] The size of the latency shift with increasing stimulus rate decreases progressively between 28 and 50 weeks conceptional age,[151] and the effect is more pronounced for wave V than it is for wave I, suggesting a neural contribution to the effect on wave V. By 3 months of age, the ABR shows "rate effects" similar to those seen for adults. Responses originating at more central locations, such as the MLR and cortical responses, continue to be more susceptible to increased stimulation rate well into childhood.[140,152]

In a series of studies summarized by Altman and Bayer,[153] the first neurons to undergo their final mitosis, in nearly all auditory nuclei, were the neurons that in adulthood would respond to high-frequency sounds. The same gradient has been reported for at least some aspects of neural differentiation.[154] Although the first cochlear hair cells to undergo final mitosis are apparently the ones that respond to low-frequency sounds,[29] the gradient in neural development mirrors the near basal to apical gradient of cochlear differentiation and innervation. Thus the most mature cochlear hair cells would appear to be connected to the most mature neurons in each auditory nucleus. Interestingly, two recent studies of the frequency-specific ABR of human infants reveal a similar frequency gradient. ABR wave I-V interwave interval appears to mature first at frequencies of 2 to 4 kHz and later at both lower and higher frequencies.[155,156] In other words, maturation begins in the middle- to high-frequency range and proceeds to the highest and lowest frequencies simultaneously with development. The first response to mature does so between 1 and 2 years of age, whereas the last is not mature at 2 years.

BEHAVIORAL DEVELOPMENT

An obvious and important question is how the morphologic and physiologic properties of the fetal and neonatal auditory system are reflected in auditory behavior. It is also one of the more difficult questions to answer.

Sensitivity

In the last 45 years many studies of fetal motor or cardiac responses to external "sounds" have been published.[157-172] Numerous methodologic difficulties exist with these studies. Not the least of these is that a frequently used stimulator is an artificial larynx applied to the maternal abdomen. Much of the energy delivered by such a device will be in the frequency range to which tactile receptors are sensitive.[173] Frequently the mother is aware of when stimulus presentations are occurring, so that fetal responses to sound may actually represent a response to maternal physiologic state. In any case, the actual sound intensity delivered to the fetus can be estimated only in a very broad fashion, and it is also difficult to estimate the level of intrauterine noise.[167]

Nonetheless a general consensus is that the first fetal motor responses to sound occur at approximately 26 weeks gestation. This is the case even in studies that use tighter controls on the stimulus and stimulus delivery system.[162] The proportion of fetuses demonstrating responses increases progressively with gestational age,[157,162] and some indication is seen that older fetuses (34-39 weeks gestation) respond to lower sound intensities than younger fetuses (26-28 weeks gestation) do.[157,161] In general, the external SPL required to elicit a fetal response is on the order of 90 to 110 dB SPL. Lecanuet and colleagues,[165] however, reported late-gestation heart rate responses to a syllable played at an external level of only 80 to 90 dB SPL. Lecanuet and colleagues[164] showed that late-gestation fetuses responded most often to high-intensity, high-frequency (5000 Hz) sounds. Although responses were recorded to 500- and 2000-Hz stimuli, these were less frequent and tended to occur only at the highest intensities presented. This finding is puzzling in that mammals that begin to hear after birth respond first to low- to middle-frequency sounds.[174] Differences in the transfer of sound through the maternal abdomen cannot account for the difference: the maternal abdomen appears to attenuate frequencies above 1000 Hz rather dramatically.[167] The spectrum of intrauterine noise, however, is weighted toward low frequencies[167] and so may mask other low-frequency sounds. Probably the most important factor is that the spectrum of sound delivered to the fetal inner ear is shaped by the skull, rather than by the external and middle ears (see discussion earlier), so that the effective level of the high-frequency sound entering the system is higher than that of low frequencies. The apparent sensitivity differences across frequency could be easily accounted for by the acoustic properties of the skull.[175]

If the frequency dependence of the fetal response to sound is determined by how sound is transmitted to the inner ear, then one might predict that preterm infants' responses would be different. However, Gerber and colleagues[176,177] reported that both term and 29- to 37-week conceptional age neonates respond motorically to approximately only 25% of the presentations of a wide-band noise of 90 dB SPL centered at approximately 3000 Hz. Although Schulman[178] showed that preterm infants' heart rate changed in response to a doorbell with a level estimated at approximately 80 dB SPL, no information about the frequency dependence of the response is available.

Our knowledge of the fetal behavioral response to sound, then, is easily summarized: fetuses begin to respond to intense

external sounds at approximately 26 weeks gestation. Late-gestation fetuses appear to respond to somewhat lower intensities, particularly for an appropriate stimulus, and to be more sensitive to high-frequency external sounds. Rather high sound intensities are also required to elicit a motor response from preterm infants at the same conceptional age, but the frequency dependence of the preterm response is unknown.

A few studies have estimated thresholds for frequency-specific sounds among term neonates. These data are summarized in Figure 171-14. Weir[179] used a combination of respiratory and motor responses to judge 1- to 8-day postterm infants' sensitivity to pure tones. She found that few infants would respond consistently to the stimuli, but those who did respond consistently had thresholds that would be on the order of 30 to 70 dB higher than those of adults. Thresholds were more adultlike at lower frequencies. Subsequent studies in 2- to 4-week-olds using more sensitive measures of behavior have reported more realistic thresholds, 25 to 35 dB higher than those of adults between 0.5 and 4 kHz.[180,181]

Early threshold immaturity is at least partly accounted for by conductive immaturity. Immature brain stem pathways are also involved, as suggested by the similarity of the behavioral thresholds to those reported for the ABR by Sininger and Abdala.[107] Furthermore, Werner and colleagues[138] demonstrated a moderately high correlation (approximately 0.7) between behavioral threshold and ABR wave I-V interwave latency among 3-month-olds, suggesting that some factor such as synaptic efficiency is at least partially responsible for threshold immaturity in early infancy.

Regardless of the mode of sound transmission in utero, it is clear that fetuses hear and are affected by the sounds they hear. For example, newborn infants recognize their mother's voice very soon after birth[182,183] and even recognize sounds and speech patterns to which they were exposed only in utero.[184-186]

Sound Localization

Among the most widely studied of infant auditory capacities is the ability to localize a sound source. Interest in this topic stems from the observation that sound localization must change after birth as the head and external ears grow, as well as the recognition that neural development could well involve maturation of the ability to make comparisons between ears and across frequencies. In fact, the precision with which changes in sound source location can be detected improves progressively between term birth and approximately 5 years of age.[187,188]

Despite some early controversy on this topic,[189-191] it is now well established that term neonates will turn their head and eyes to the left or right toward a sound source.[192-196] Neonates orient toward a sound source slowly, and their heads must be supported to allow the response to occur.[193,194] The frequency, duration, and repetition rate of the stimulus are important in determining whether a response will occur.[197-201] Muir[202] reported that the orienting response was present in infants as young as 32 weeks conceptional age.

Sound location is typically specified in terms of angle in azimuth—the horizontal plane intersecting the ears—and angle in elevation above or below that plane. Although nearly all studies of newborns' orientation to sound sources have asked infants to make only a left-right discrimination, Muir[202] reported that the extent of the neonate's head turn toward a sound source was related to the position of the sound source in azimuth. The precision with which a newborn can assign a location to a sound source along either dimension has not been established; however, by 1 month of age infants respond to a change in azimuth on the order of 27 degrees.[203] This figure decreases progressively through infancy and early childhood to a value of 1 to 2 degrees.[187,188] Similarly, Muir[202] reported that neonates would turn their heads up or down appropriately toward sound sources above or below azimuth. Morrongiello and colleagues[204,205] have reported that infants can detect a change in elevation on the order of 15 degrees at 6 months of age; this value decreases to a value of 4 degrees among adults, along a developmental time course similar to that seen for localization in azimuth. Finally, although neonates are able to discriminate left and right sound source locations, they are unable to suppress echoes as adults do[26] and thus would have difficulty in identifying sound source locations in a reverberant environment.[197,206] Even 5-year-olds are less able than adults to localize in a reverberant environment.[188]

The sources of early immaturity of sound localization are only beginning to be understood. Although physical limitations on head and ear size modify and limit the cues available for localization, it is clear that other factors are involved. According to head size measurements by Clifton and colleagues,[27] a newborn would need a change in sound source azimuth of 20 degrees to produce an interaural time difference similar to that produced by a 10-degree change for adults. Recall that adults can detect changes in azimuth of 1 to 2 degrees, whereas newborns cannot detect a change in azimuth as small as 20 degrees. Ashmead and colleagues[207] found that infants could detect interaural time difference changes smaller than those produced by a change in sound source spatial location that they could just barely detect. Both of these findings could be taken to mean that the limitation is neither in the physical cue available nor in the coding of the physical cue but in the assignment of a spatial location to the physical cue. Until additional information on infants' utilization of interaural intensity differences is available, however, it cannot be determined whether interaural intensity cues or their coding also play a role.

To summarize, neonates are capable of distinguishing the location of a sound source on the basis of auditory cues alone to an accuracy of approximately 25 degrees in both azimuth and elevation. The age at which sound localization can first be observed is not known. Although the physical size of the neonates' head and ears limits the acoustic information available about sound source location, both the accuracy with which acoustic cues are coded in early infancy and the precision with which values of acoustic cues are mapped onto locations in space are probably greater limitations.

Speech Perception

Some of the most interesting studies of infant auditory perception are those describing the infant's ability to discriminate between speech sounds. Eimas and colleagues[208] demonstrated that 1-month-old infants discriminated between /b/ and /p/, speech sounds differing in only one phonetic feature. Since that demonstration, the development of speech perception has been one of the most active areas of infant research. The results of these studies are easily summarized, although their interpretation may be more complicated than originally thought. A major finding is that even newborn infants appear to be capable of discriminating between all of the pairs of speech sounds that have been examined to date.[209,210] Furthermore, this ability appears to extend to the sounds of all spoken languages.[211] Second, although it is clear that the newborn can represent speech sounds sufficiently well to discriminate between sounds under many conditions, the newborn's representation of speech sounds may be less detailed than that of adults or older infants.[212-215] The ability to make fine distinctions among speech sounds probably continues to develop into childhood.[216-224] Abnormal experience with sound may retard this process of refinement.[225] Third, infants appear to be sensitive to many aspects of speech besides phonemic distinctions. For example, they are sensitive to changes in intonation that signal clause boundaries.[226,227] Newborns are capable of distinguishing between different languages, although this ability depends on the native language to which the infant was exposed before birth, as well as the specific languages under consideration.[228]

The major events in the development of speech perception during the first year of life involve a progressive specification of native language sounds, sometimes at the cost of losing the ability to discriminate nonnative speech sounds. By 2 months of age, infants appear to recognize the predominant stress pattern that occurs in their native speech.[229] By 6 months of age, they tend to categorize the vowels of their native language in a broader way than they categorize the vowels of other languages.[230,231] The extent to which these tendencies depend on prenatal experience with speech sounds is not clear; the age when infants first demonstrate these aspects of language-specific perception has not been determined.

By 12 months of age, infants have lost the ability to discriminate among many nonnative consonants.[232-235] Some nonnative consonants appear to be discriminable by infants and remain discriminable into adulthood, such as Zulu "clicks" by American speakers of English.[236] This appears to occur when the nonnative sound is so different acoustically from native sounds that the specification of native speech sounds has no effect on the nonnative speech category. Other speech sounds are discriminable by 6-month-olds, not discriminable by 12-month-olds, and remain very difficult for adults to discriminate, such as Nthlakampx (a native American language) glottal stops by Canadian speakers of English.[235] In this case it appears that, as native speech sounds are specified, native speech categories "absorb" acoustically similar nonnative speech categories. Finally, some nonnative vowel sounds are discriminable by 6-month-olds and not discriminable by 12-month-olds but can be discriminated by adults, such as German back rounded vowels by Canadian speakers of English.[237] Apparently the refinement of speech perception that occurs during childhood can have the effect of redefining a native speech category in such a way that it no longer includes nonnative speech sounds that it may have "absorbed" early in development.

An important issue for future research in this area is the importance of specific language experience on both the initial specification of native language sounds and of the subsequent refinement of speech sound categories. What experience is necessary, how much experience is necessary, and when experience is necessary are not known. Although these issues are difficult to address, they are very important ones for certain populations—preterm infants, infants with congenital hearing loss, infants with chronic otitis media—whose early experience with sound is abnormal to varying degrees. Of high interest in this regard are recent studies that demonstrate that adults exaggerate phonetic differences in the speech they direct to infants.[238-240]

A final note with respect to the development of speech perception is that despite the young infant's sometimes amazing ability to process speech, immature primary auditory processing remains an important constraint on speech processing. Speech is not privileged over other sounds. Six-month-olds require just as much of a boost in SPL to detect and discriminate speech sounds as they do to detect and discriminate pure tones.[241-243] Newborn infants are less sensitive to sound. They may be particularly vulnerable to interference from noise, and their representations of the spectral shape of speech sounds may be "fuzzier" than those of older infants and adults. They may be less capable of following rapid changes in a sound (but see Jusczyk and colleagues[244]). Thus it is not surprising that their representations of speech are not detailed[213] or that adults exaggerate many acoustic properties of speech when they speak to infants.[245] Another important issue for future research will be to determine precisely how immature sensory processing limits early speech perception.

SUMMARY AND CONCLUSION

Between the time that the cochlea begins to function during gestation and the neonatal period, the auditory system undergoes dramatic development. Although few data from humans exist, all indications from the available data are that the auditory system of a 28-week fetus is immature indeed: sensitivity is known to be poor, and both spectral and temporal representations of suprathreshold sounds are likely to be fuzzy. By term birth, hearing has improved dramatically; neonates are capable of discriminating among many complex sounds. Nonetheless the term neonate is still less sensitive and still less able to process the details of a stimulus than an adult. During very early development, the major contributor to improvements in hearing is probably the maturation of the cochlea. The middle ear and the auditory nervous system, however, continue to develop over a longer time period. These are probably the major limitations on hearing in the neonatal period. Beyond the neonatal period, as the middle ear and auditory nervous system mature, higher-level processes such as attention and memory still limit auditory perception. At some point during infancy, it is likely that these higher-level processes become more important than sensory limitations in determining what infants hear. At present, we do not know when that transition occurs.

Development of Taste and Smell in the Neonate

This chapter provides a critical overview of the literature on human taste and smell function in the prenatal and neonatal periods, with some consideration of later infancy and early childhood, by integrating and updating our previous reviews and those of our colleagues.[1-7]

Taste and smell share a common stimulus class—chemicals. Functionally, taste is intimately connected to the ingestion or rejection of potential foods and perhaps plays a role in the utilization of ingested foods.[8] Smell also contributes to the identification and acceptance of foods and may be involved in regulating human social interactions (e.g., individual and sexual identification and attraction), as it is in many other animals.[9] Flavor, as an attribute of foods and beverages, is defined as the integration of multiple sensory inputs from the gustatory (taste), olfactory (via retronasal olfaction), and trigeminal (touch, temperature, irritation) systems that a substance elicits in the oral and nasal cavities. In particular, retronasal olfaction, the aromas of substances we put in our mouths, contributes significantly to the complexity of flavor, and a discussion of the ontogeny of flavor perception and preferences is highlighted in the section on smell.

Taste and smell have much in common, but major differences exist as well. Most striking are the apparent differences in the ranges of qualitative experiences aroused by these two senses. Although it is still somewhat controversial, most investigators believe that taste is composed of a restricted set of qualities or categories, namely, sweet, salty, sour, and bitter, with umami, the taste associated with monosodium glutamate (MSG), having more recently gained widespread acceptance as a fifth basic taste after the discovery of taste receptors for L-glutamate.[10,11] It has been hypothesized that this small number of qualities evolved because of the functional importance of the primary stimuli (e.g., sugars, sodium chloride, organic acids, bitter toxins, amino acids) in nutrient selection. A practical consequence of this classification scheme in developmental (as well as other) taste research has been to limit the range of stimuli examined.

In contrast, no widely accepted classification scheme exists for smell stimuli, and this situation has resulted in the absence of an agreed-on set of stimuli to use in sensory tests. Thus olfactory stimulus selection tends to be based on the availability and presumed safety of single compounds or on ecologically significant odor sources that are not chemically specified (e.g., amniotic fluid, mothers' breast odors).

Human studies can provide data relevant to two aspects of chemical sensation: the sensitivity of the system to chemical stimuli and the hedonic valence of the sensation. In studies in adults, the distinction between these two is usually unambiguous. Measures of sensitivity include thresholds, just-noticeable differences, intensity judgments, sensory adaptation, and so forth, whereas measurements involving a hedonic dimension usually consist of ratings of pleasantness or preference. In studies in infants and young children, these two classes of response to chemical stimuli can be more difficult to distinguish. For taste, very few studies have attempted to evaluate sensitivity specifically; almost all response measures are associated with acceptance or rejection and thus presumably involve a hedonic component. Although published developmental studies on olfaction historically focused

Development of Taste and Smell in the Neonate

This chapter provides a critical overview of the literature on human taste and smell function in the prenatal and neonatal periods, with some consideration of later infancy and early childhood, by integrating and updating our previous reviews and those of our colleagues.[1-7]

Taste and smell share a common stimulus class—chemicals. Functionally, taste is intimately connected to the ingestion or rejection of potential foods and perhaps plays a role in the utilization of ingested foods.[8] Smell also contributes to the identification and acceptance of foods and may be involved in regulating human social interactions (e.g., individual and sexual identification and attraction), as it is in many other animals.[9] Flavor, as an attribute of foods and beverages, is defined as the integration of multiple sensory inputs from the gustatory (taste), olfactory (via retronasal olfaction), and trigeminal (touch, temperature, irritation) systems that a substance elicits in the oral and nasal cavities. In particular, retronasal olfaction, the aromas of substances we put in our mouths, contributes significantly to the complexity of flavor, and a discussion of the ontogeny of flavor perception and preferences is highlighted in the section on smell.

Taste and smell have much in common, but major differences exist as well. Most striking are the apparent differences in the ranges of qualitative experiences aroused by these two senses. Although it is still somewhat controversial, most investigators believe that taste is composed of a restricted set of qualities or categories, namely, sweet, salty, sour, and bitter, with umami, the taste associated with monosodium glutamate (MSG), having more recently gained widespread acceptance as a fifth basic taste after the discovery of taste receptors for L-glutamate.[10,11] It has been hypothesized that this small number of qualities evolved because of the functional importance of the primary stimuli (e.g., sugars, sodium chloride, organic acids, bitter toxins, amino acids) in nutrient selection. A practical consequence of this classification scheme in developmental (as well as other) taste research has been to limit the range of stimuli examined.

In contrast, no widely accepted classification scheme exists for smell stimuli, and this situation has resulted in the absence of an agreed-on set of stimuli to use in sensory tests. Thus olfactory stimulus selection tends to be based on the availability and presumed safety of single compounds or on ecologically significant odor sources that are not chemically specified (e.g., amniotic fluid, mothers' breast odors).

Human studies can provide data relevant to two aspects of chemical sensation: the sensitivity of the system to chemical stimuli and the hedonic valence of the sensation. In studies in adults, the distinction between these two is usually unambiguous. Measures of sensitivity include thresholds, just-noticeable differences, intensity judgments, sensory adaptation, and so forth, whereas measurements involving a hedonic dimension usually consist of ratings of pleasantness or preference. In studies in infants and young children, these two classes of response to chemical stimuli can be more difficult to distinguish. For taste, very few studies have attempted to evaluate sensitivity specifically; almost all response measures are associated with acceptance or rejection and thus presumably involve a hedonic component. Although published developmental studies on olfaction historically focused

more on sensitivity and discrimination, more recent studies have also investigated the hedonic aspects of odors.

TASTE

Prenatal Development

Taste receptors or buds are composed of modified epithelial cells and are found throughout the oral cavity, on the hard and soft palates, the tonsils, the pharynx, the larynx, the epiglottis, and the esophagus[12]; however, they are most numerous on the papillae of the tongue. Peripheral innervation of these cells is via branches of three different cranial nerves: the facial (VII), glossopharyngeal (IX), and vagus (X). Four morphologically distinct types of lingual papillae can be identified in humans, but only three bear taste buds. These are the fungiform, the foliate, and the circumvallate papillae. Fungiform papillae are mushroom-shaped buttons found mainly at the tip and along the front edges of the tongue; many of these may contain no taste buds at any given time, but, of those with buds, most have one to three.[13] Most taste buds are found in the foliate and circumvallate papillae. The former consist of parallel folds along the rear edges of the tongue; the latter are flat mounds surrounded by a trench on the posterior dorsal border between the oral and pharyngeal tongue (typically 8 to 12 arranged in an inverted V in humans).

Specialized taste cells first appear in the human fetus at 7 to 8 weeks of gestation, and morphologically mature cells are recognizable at 13 to 15 weeks.[14,15] The taste buds of fetal sheep, the development of which parallels that observed in the human fetus, have been shown to respond to chemical stimulation as early as the 80th day of gestation.[16,17] Fetal taste receptors may be stimulated by chemicals present in the amniotic fluid. The fetus begins to swallow episodically at approximately the 12th week of gestation[18] and may swallow 200 to 760 mL/day by term.[19] Amniotic fluid contains glucose, fructose, lactic acid, pyruvic acid, citric acid, fatty acids, phospholipids, creatinine, urea, uric acid, amino acids, polypeptides, proteins, and salts.[20] Moreover, the chemical composition of the amniotic fluid varies over the course of gestation and may be abruptly altered by fetal urination.[16,21] Reported differential fetal swallowing after injections of sweet or bitter substances into the amniotic fluid of pregnant women suggests that fetuses may show a preference for sweet and a rejection of bitter,[20,22] but a strong demonstration of preferential responding by human fetuses to taste stimuli is lacking.

What may the organism gain from in utero taste experience? Swallowing amniotic fluid appears to be necessary for the proper development of the gut, but gustatory stimulation is probably not essential.[23] Neural development of the central and peripheral taste systems could be influenced by the intrauterine chemical milieu, such that acceptance and rejection of substances after birth may coincide with prior amniotic contents and concentrations.[16,24] Animal model studies support this hypothesis.[25]

Direct studies of taste in the preterm infant are rare, partly because of methodological limitations. As discussed later, in term infants, investigators have monitored facial expressions, autonomic responses, consummatory intake, and sucking behavior when the infants are offered flavored solutions. This is problematic for preterm infants who risk fluid aspiration as a result of immature suck-swallow coordination.

To avoid this problem, nonnutritive sucking was studied in preterm infants (33 to 40 weeks after conception) exposed either to brief, intraoral presentations of very small amounts of glucose solution[26] or to sucrose embedded in a nipple-shaped gelatin medium that released small amounts when mouthed or sucked.[27] Both approaches demonstrated that these infants, who had little or no extrauterine taste experience, possessed the ability to detect sweet and showed an avidity for it by producing stronger and more frequent sucking responses than they did when presented with no-taste controls.

This ability on the part of the preterm infant to respond to sweet gustatory stimulation behaviorally, and presumably physiologically, suggests a possible intervention aimed at stimulating these responses to augment development of the infant. In other words, it may be possible that taste stimulation presented during tube feedings would enhance growth efficiency beyond that achieved by allowing infants to suck on a pacifier during this time.[28-32]

Palatable, sweet-tasting stimuli also promote "calming," analgesic-like reactions in preterm, as well as more mature, infants during heelstick and other invasive procedures. When sweet-tasting sugars are present in the oral cavity, crying is reduced, heart rate increases are attenuated, and facial expressions of pain are blunted in preterm infants as young as 25 weeks after conception.[33] Moreover, this analgesic effect appears to be the result of taste per se, because the same sweet solution is ineffective in producing analgesia when administered intragastrically in preterm (32 to 36 week) infants.[34]

These studies indicate that not only are taste buds capable of conveying gustatory information to the central nervous system by the last trimester of pregnancy but also this information is available to systems organizing changes in sucking, facial expressions, and other affective behaviors.

Sensitivity and Discrimination: Newborns

The principal response measures that have been used to assess neonatal taste perception are tongue movements, autonomic reactivity, facial expressions, and differential ingestion and sucking patterns. With one exception, all these responses are believed to reflect preference or acceptance or pleasure. When infants exhibit affective responses to taste stimuli, it can be inferred that they are sensitive to them; however, failure to observe such responses does not indicate whether the infant failed to detect the stimulus or was simply hedonically indifferent to it.

The single, clear exception to hedonically motivated taste responses is the *lateral tongue reflex*.[35,36] This reflex is elicited by the application of microdrops of fluid to the newborn's tongue, and neither its form nor frequency is affected by qualitative changes in the fluid. Thus the occurrence of the response appears to be solely dependent on sensory mechanisms. Studies using this measure suggest that newborns possess distinct functional taste receptors for sweet and salty; however, differential responding has only been reliably observed with concentrated taste solutions, for example, 2 mol/L salty, which is undoubtedly a trigeminal, as well as a gustatory, stimulus, producing irritant sensations.[37-39] Consequently, the utility of this response as a measure of absolute gustatory sensitivity is questionable.

Autonomic reactivity may also provide information on gustatory sensitivity. Crook and Lipsitt[40] and Lipsitt[41] published the only modern studies of infant taste perception using such measures, and their research was limited to sweet taste responsivity. In both studies, heart rate was found to be positively correlated with the concentration of sucrose presented to infants. Lipsitt proposed that the heart rate response is a signal of "the joy that the infant derives from [the] 'pleasure of sensation'"[41]; however, the possibility cannot be discounted that the heart rate response reflects arousal rather than pleasure and could provide a measure of gustatory sensitivity, as opposed to preference, in infancy.

Hedonics: Newborns

Facial expressions, suggestive of contentment and liking or discomfort and rejection, were used to assess the newborn's responsiveness to taste stimuli in some of the earliest investigations of human taste development.[42-44] Steiner and colleagues[45-49] reported that consistent, quality-specific facial expressions can be elicited in the first few hours of life by sweet (sucrose, 0.73 mol/L), sour (citric acid, 0.12 mol/L), and bitter (quinine sulfate,

0.003 mol/L) stimuli. Because the stimuli used to elicit these responses were concentrated, differences among the responses to each taste could be at least partially reflective of differences in the extent of trigeminal involvement. In one study, these investigators examined responses to less concentrated taste stimuli and provided data on the frequency of occurrence of specific facial features.[48] High concentrations of tastes (0.0001 mol/L quinine, 1.0 mol/L sucrose, and 0.25 mol/L urea) elicited more responses than the other stimuli (distilled water, 0.1 mol/L sucrose, and 0.15 mol/L urea), and the patterns of response to the quinine and more concentrated urea differed from that elicited by 1.0 mol/L sucrose. However, considerable overlap existed in the frequency distributions of facial features elicited by all the stimuli, and responses elicited by the weaker concentrations of sucrose and urea were similar to those observed after water presentations. Finally, infants displayed distinctive positive facial expressions to soup to which MSG was added when compared with unadulterated soup.[49] MSG alone (i.e., in water) did not appear to elicit these facial responses, however, a finding that raised the question of exactly what it is about the soup-MSG mixture that is of apparent positive hedonic valence.

The most detailed study of newborns' facial responses to taste stimuli was conducted by Rosenstein and Oster.[50] Consistent with the findings of Steiner and colleagues,[45-49] analyses of the patterns of full-face expressions indicated that the newborns discriminated sweet from nonsweet solutions and, among nonsweet solutions, between the sour and bitter taste stimuli. However, such analyses also indicated that taste-elicited facial expressions are not highly stereotyped. Overlap appears to be considerable in the distribution of not only discrete facial actions but also full-face configurations elicited by the different taste stimuli, as well as considerable individual variation in facial responses. Moreover, although hedonically negative facial components were more common in responses to all three nonsweet tastes than in responses to sweet, untrained observers found only the responses to the bitter tastant to be highly negative. Even with their fine-grained analysis and a concentrated salt stimulus (0.73 mol/L), a distinctive facial response to salt was not identified.

Differential ingestion has been used more frequently than any other response to study taste preference during infancy. Several limitations, however, are associated with this measure. First, because multiple stimuli cannot be presented simultaneously to human infants, thereby providing a true choice situation, the measure should probably be viewed as one of relative acceptance rather than of preference. More critically, the number and range of stimulus concentrations that are either feasible or ethical to present to infants in an unrestricted feeding situation are limited. Finally, the strength of the sucking reflex in young infants is quite strong, and this may mitigate clear rejection of a taste stimulus.

Intake studies have repeatedly demonstrated strong acceptance of sweet tastes by infants at birth and have shown that newborns respond to even dilute sweet tastes and can differentiate between varying degrees of sweetness.[51-53] However, they have generally failed to demonstrate differential responding to sour or bitter tastes, as well as to salt. In the single exception to this generalization, Desor and colleagues[54] used responses to a mild sweet solution rather than plain water as the baseline measurement (ensuring the infants were capable of responding at levels both higher and lower than baseline) and presented salty (NaCl), sour (citric acid), and bitter (urea) tastes in this sweet base. Under these circumstances, relative suppression of intake was observed with the addition of citric acid concentrations at and above 0.003 mol/L, but no significant changes in intake occurred in response to the addition of either NaCl (0.05 to 0.20 mol/L) or urea (0.18 to 0.48 mol/L). The failure to observe rejection of urea (0.12 to 0.24 mol/L) by newborns, even when presented in a sweet base, has been replicated.[55] In the same study, however, significant rejection of all concentrations of urea was observed in slightly older infants (14 to 180 days, with no difference between responses of infants less than or more than 3 months of age), a finding suggesting an early developmental increase in sensitivity to bitterness.

Absence of differential responding to salt in newborns is consistent with results from the studies of facial expression described earlier, but the apparent indifference to bitter is not. Three points should be noted, however. First, for adults, urea is a much less intensive bitter stimulus than quinine and seems to fall into a separate class of bitter stimuli that may be coded by a different receptor mechanism.[56] Second, although 0.25 mol/L urea elicited facial actions that included apparently negative components similar to those elicited by a quinine stimulus, the urea also elicited more apparently positive facial actions, such as sucking and licking, than did the quinine.[48] Third, when taste stimuli are mixed, the intensity of each of the component tastes tends to be suppressed; sour taste intensity may be less susceptible to suppression than the other primary tastes.[57] Thus the discrepancy among findings concerning bitter responsivity in newborns could partially reflect differences in the type or intensity of bitter stimuli presented.

Finally, the study of sucking patterns has been used as an alternative to the measurement of intake in full-term newborns, as well as premature infants. Techniques for recording multiple parameters of sucking in response to small stimulus volumes can potentially allow for the study of responses to sapid substances one would be reluctant to have infants consume in any quantity. Conversely, the relative significance of individual parameters of the sucking response and the relationships among different parameters are not well understood. Presentation of minute amounts of sweet solution leads to concentration-dependent increases in the number and length of bursts of sucking activity and to decreases in the time between bursts, all of which are intuitively consistent with a positive hedonic reaction and thus with the results of studies using measures of intake and facial expressions,[58,59] although, seemingly paradoxically, the rate of sucking within bursts after sweet stimulation has been found to decrease.[40,58] Similarly, the number and strength of sucks in response to urea are relatively depressed in infants older than 2 weeks of age, but not newborns, a result paralleling that seen with intake measures (see earlier).[55]

Responses to sour stimuli have not been formally evaluated by using this kind of procedure. In the case of salt, however, sucking parameters seem to reveal a subtle response by newborns not evident in measures of intake or facial expression. Crook[59] reported that even a weak salt solution (0.1 mol/L) significantly decreased the length of sucking bursts. Similarly, Beauchamp and associates[60] found that, relative to water, both 0.2 and 0.4 mol/L NaCl significantly depressed the number of sucks and of sucking bursts produced by newborns, although relative intake of the moderately salty solution (0.2 mol/L) was not significantly depressed.[54]

Each of the measures used in studies of taste responses in very young infants has its limitations, but the convergence of results from different measures of sweet taste perception in newborns gives confidence in the conclusion that infants are quite sensitive to this taste and display an innate preference for it. Similarly, even though sour taste perception has been studied less extensively, measures of intake and facial expression suggest that sour taste perception may be reasonably well developed at birth and that newborns reject substances having this taste. The highly concentrated sour stimuli that have been used to elicit facial expressions do, however, pose some interpretive problems, and additional studies of sour taste responsivity are necessary before strong conclusions can be drawn with regard to sour perception in early development.

Neonatal responses to bitter are more problematic. Newborns respond with highly negative facial expressions to concentrated quinine but not necessarily to urea. They also do not reject

moderately strong urea solutions relative to water as assessed by either intake or sucking measures, although significant rejection seems to appear within a few weeks of birth. As noted, evidence exists of multiple bitter taste transduction sequences.[56,61] In addition, sensitivity to different bitter compounds may be differentially affected by aging.[62] Thus the early developmental course of bitter taste perception may also be compound specific.

The newborn's response, or lack thereof, to salt is perhaps most puzzling. Given the subtlety of the responses that have been observed, and the evidence for postnatal development of salt taste reception in other mammalian species,[63-66] it seems likely that humans are relatively insensitive to salt at birth. However, to the extent that this stimulus is perceived, the newborn's hedonic response to it appears to be negative.

Hedonics: Older Infants and Young Children

Relatively few studies have been done of taste perception in older infants and children as compared with neonates, and many of those that have been reported were based on small samples and not described in detail. For all practical purposes, the measures obtained have been limited to intake (i.e., differential ingestion) and paired comparison or rank ordering of taste stimuli to determine preference, and, with few exceptions, only responses to sweet and salty tastes have been assessed.

Babies beyond the neonatal period (1 to 24 months) have been most neglected in studies of taste development. In part, this is probably because of the lack of clearly appropriate measures of either preference or sensitivity for subjects in this age range. Differential ingestion has been the default option in almost all studies. However, certain problems are encountered with older infants that do not arise with neonates. For example, older infants may be less willing to accept unfamiliar bottles or foods from an unfamiliar person, and, as Filer noted, the amount of any particular food eaten in a natural feeding situation may depend as much on the mother's "mechanical skill… and determination to feed her infant"[67] as on the infant's preference. Finally, because intake has been the only measure obtained from older infants, no cross-validation of the meaningfulness of this measure has been done. Nonetheless, a few notable findings, suggestive of developmental or experiential changes in taste preferences during infancy, have been reported.

In the context of studies on effects of protein-calorie malnutrition on taste, sucrose, citric acid, urea, and salt acceptability was evaluated in well-nourished and malnourished Mexican infants from 2 months to 2 years of age.[68] Relative to water, infants less than 1 year of age preferentially ingested 0.1 and 0.2 mol/L NaCl. A preference for sucrose was observed for infants at all ages. The bitter (urea, 0.12 and 0.24 mol/L) and sour (citric acid, 0.006 and 0.012 mol/L) stimuli were tested with the same mild sucrose solution as diluent as used by Desor and colleagues[54] (see earlier). Consistent with findings in newborn infants, citric acid was rejected relative to the diluent. Both concentrations of the bitter urea were also rejected by these infants, as was also found by Kajiura and associates[55] in their group of older infants.

In addition to the classic taste stimuli, a sample of Mexican infants was also tested with a mixture of amino acids and peptides (casein hydrolysate) and with MSG.[69] For these two taste substances, a low-glutamate soup was used as the diluent. Consistent with Steiner's report on newborns,[49] both malnourished and well-nourished infants preferred the soup with MSG (0.4%) to the soup alone. This preference was observed even in the youngest infants tested (2- to 4-month-old infants). In contrast, nutritional state influenced responses to the casein hydrolysate. Infants who were malnourished preferred soup with added casein hydrolysate when compared with soup alone; the opposite response was observed in well-nourished infants[68] and in recovered malnourished infants.[69]

Newborn infants have been found to be indifferent to or to reject salt relative to water, whereas Vazquez and colleagues[68] reported that older infants found salt solutions more acceptable than water. This suggestion of a developmental shift in salt acceptability was supported in studies in a sample of children from the United States. Preferential ingestion of salt water relative to plain water emerged at approximately 4 months of age. Beauchamp and associates[70] and Cowart and Beauchamp[71] argued that experience with salty tastes probably does not play a major role in the shift from apparent indifference to (or rejection of) salt at birth to acceptance in later infancy; rather, this change in response may reflect postnatal maturation of central or peripheral mechanisms underlying salt taste perception, allowing for the expression of a largely unlearned preference for saltiness.

Conversely, some evidence exists that, at least by 6 months of age, frequency of dietary exposure to high-sodium foods (although not total dietary sodium) may affect the degree of preference for salted versus unsalted cereal. In a study in 10 6-month-old infants, Harris and Booth[72] determined the difference between the amount of salted cereal eaten during feedings on 2 days and the amount of unsalted cereal eaten on 2 different days and used that as a measure of salt preference. These investigators found relative preference to be significantly correlated with the number of times the infants were exposed to foods containing at least the amount of sodium in the salted cereal during the week preceding testing; none of the infants actually rejected the salted cereal relative to the unsalted one, however, and all but one exhibited some preference for it by consuming more salted than unsalted cereal.

Effects of early experience on the preference for salt taste are also suggested by the finding that 16-week-old infants of mothers who had had extreme morning sickness during pregnancy consumed larger volumes of 0.2 mol/L NaCl than did infants whose mothers had not exhibited this symptom.[73] Moreover, adult children (college students) of mothers who had considerable morning sickness during their pregnancies had greater salt preferences than did students whose mothers had little or no morning sickness.[73,74] The proposed mechanism is that morning sickness leads to transient fluid and sodium depletion in a manner analogous to that reported in animal model studies. Consistent with these findings, 12- to 14-year-old children who had been exposed to a chloride-deficient formula during early development showed heightened preferences for salty (but not sweet) foods relative to their unexposed sibling controls[75]; chloride deficiency leads to hormonal alterations that mimic those occurring during sodium deficiency.[76]

Similarly, evidence exists of an effect of experience on the expression of sweet preferences in 6-month-old infants.[77] Intake of sweetened versus unsweetened water was assessed in the same infants at birth and at 6 months. Although the infants preferred sweetened water at both ages, only the 6-month-old infants who had received sugared water as part of their diet continued to exhibit the same degree of preference for sweet in water that they had at birth.

Dietary experience—in particular, familiarity with specific foods and with tastes in specific food contexts—has also been shown to play an important role in the preferences of preschool children.[78-81] The other major finding concerning taste preferences in early childhood has been that children prefer more concentrated sugar and salt than do adults, although the bases for these extreme preferences have yet to be elucidated.[71,82,83]

SMELL

Prenatal Development

The human olfactory epithelium lines the roof of the nasal cavity, part of the nasal septum and the superior turbinates, and may extend to the middle turbinates. The olfactory receptor cells are bipolar neurons, with dendrites that bear motile cilia lying

in a layer of mucus covering the epithelium. The axons of these cells comprise the olfactory nerve (cranial nerve I) and travel in unmyelinated fascicles through the bony roof of the nasal cavity into the olfactory bulb, where they terminate and synapse with second-order cells. The nasal cavity is also innervated by the nasopalatine branch of the trigeminal nerve (cranial nerve V), which mediates pain, touch, temperature, and proprioception and the receptors of which also respond to many odorous volatiles.

The ethmoid and nasopalatine branches of the trigeminal nerve have differentiated and respond to tactile stimulation by approximately the 10th gestational week.[84,85] The olfactory bulbs and receptor cells have attained adultlike morphology by the 11th week of gestation.[86,87] Olfactory marker protein, which appears to be a biochemical correlate of olfactory receptor functioning in fetal rats,[88] has been identified in the olfactory epithelium of human fetuses at 28 weeks gestation.[89] Because the epithelial plugs that obstruct the external nares resolve between gestational weeks 16 and 24,[90] a continual turnover of amniotic fluid takes place through the nasal passages. Even in air-breathing organisms, volatile molecules must penetrate the aqueous mucus layer covering the olfactory epithelium to reach receptor sites on the cilia. Thus no fundamental distinction exists between olfactory detection of airborne and waterborne stimuli.

In fact, amniotic fluid provides a natural, ever-changing olfactory, as well as taste, environment for the fetus.[91-95] In particular, the fetus may learn about the dietary choices of the mother through odorants found in the amniotic fluid that derive from foods eaten by the pregnant mother and reflect their flavors. This was demonstrated experimentally in a study in which amniotic fluid samples were obtained from 10 pregnant women who were undergoing routine amniocentesis and who ingested either garlic or placebo capsules approximately 45 minutes before the procedure.[92] The odor of the amniotic fluid obtained from the women who ingested the garlic, as judged by adult human evaluators, was stronger or more like garlic than amniotic fluid from the women who did not consume garlic.

Several lines of evidence suggest that, at approximately 28 weeks, the olfactory system is capable of detecting chemical stimuli. Studies in premature newborns demonstrated reactions to odorants (odorous chemicals) in infants as young as 28 weeks gestation.[42,96,97] For example, 8 of 11 sleeping preterm infants (29 to 32 weeks) initiated sucking or displayed arousal-withdrawal within 30 seconds of the presentation of a peppermint extract odorant.[98] Although similar responses were observed in one infant who was 28 weeks gestation, this was not characteristic of other infants (n = 5) that age. All infants younger than 28 weeks gestational age failed to respond differentially to the peppermint and control trials, whereas all infants between 32 and 36 gestational weeks did.

Although these data appear to support the hypothesis that functional olfaction has its inception at approximately 28 gestational weeks, three caveats must be put forth. First, the failure of infants who were less than 28 weeks gestation to respond to an odor stimulus in a reliable manner may reflect a response limitation as opposed to an inability to detect the stimulus. In studies of term neonates, change in respiratory rate provides a more reliable measure of the ability to detect odorants than motoric responses,[98,99] and therefore it may provide a more sensitive test of the preterm infant's ability to detect odorants. Second, it is not clear whether responses in the aforementioned studies were mediated by the olfactory or trigeminal system. Finally, these studies tested only a small subset of odorants, and it is possible that different odorants could elicit responses in younger preterm infants.

Sensitivity and Discrimination: Newborns

Numerous studies have shown that newborn infants can detect and discriminate various qualitatively distinct odorants.[98,100-109] In one of the earliest controlled studies, Engen and colleagues[98] compared newborns' responses to odor pairs, the members of which varied in intensity and hedonic valence: 100% acetic acid and phenylethyl alcohol (experiment 1) and anise oil and tincture of asafetida (experiment 2). Odors on cotton swabs were presented to infants during sleep, and general activity, leg withdrawal, respiration (experiments 1 and 2), and heart rate (experiment 2) were monitored. The investigators concluded that newborns were sensitive to the odors and that they discriminated among them. The most reliable elicitor of a response was acetic acid, followed in descending order by asafetida, anise, and phenylethyl alcohol. Because the odors were not equated for perceived intensity, it is unclear whether these differences are best accounted for by differences in quality, intensity, hedonicity, or trigeminal component. For example, 100% acetic acid surely stimulates not only the olfactory receptors but also receptors sensitive to irritation in the nose and in the eyes.

Some evidence suggests that the neonate may be remarkably sensitive to other nonbiologic odors, such as the homologous alcohols.[110-112] The observation that preschoolers[113] and prepubescent school-aged children[114] are more likely to be sensitive to a biologic odor, androstenone, than are older children and adults, lends further credence to the possibility that newborns' olfactory acuity may equal or exceed that of adults. Finally, comparisons of olfactory neuroepithelium in fetuses and physiologically normal adults reveals degeneration in adults and a higher ratio of olfactory to respiratory epithelium in fetuses.[115]

Nonetheless, Lipsitt and colleagues[116] suggested that olfactory sensitivity may increase over the first few days of life. They tested 10 infants' responsiveness to increasing concentrations of asafetida over the first 4 days of life. Because the concentration step required to produce a response, relative to no-odor control trials, decreased for each of the 10 infants over test days, it was concluded that olfactory threshold decreases during the first 4 days of life.

It is not clear whether this change in response is best explained in terms of (1) a stimulus-independent postnatal maturation of peripheral or central neural processes including those that may underlie a shift to more nasal—relative to mouth—breathing, (2) the induction of sensitivity contingent on odor exposure, or (3) merely the development of a more coordinated response system. Although the first and third alternatives are probably the most likely, three findings are consistent with the second alternative. First, newborns tested in a longitudinal design over the first 3 days of life showed more reliable respiratory responses to several odors on the third day of testing than did 3-day-old infants who had not received any prior exposure to the odorants.[100] Second, repeated exposure to one odorant (i.e., androstenone) can induce the ability to detect that odorant in adults.[117] Finally, changes occur in the olfactory system of rodents exposed to odors as either neonates[118-121] or adults.[122] These findings are merely suggestive, and human neonatal studies that directly manipulate odor exposure conditions in relation to age and developing olfactory sensitivity are necessary to discriminate among these alternatives.

Certain other aspects of olfactory function have been examined in infants. Engen and associates[98] reported that exposure to an odorant may result in decreased responsiveness to the odor when assessed as a change in respiratory rate. A subsequent study by the same group provided evidence that this phenomenon is best explained in terms of response habituation, as opposed to sensory fatigue.[99] In infants who showed a decrement in response to a mixture of two odorants (anise oil and asafetida or amyl acetate and heptanol), the response recovered when they were tested with a component of the mixture at the same concentration as in the mixture. Moreover, the magnitude of the recovery was a function of how perceptually similar (as rated by adults) the component was to the mixture, even when

the components were equated for perceived intensity. This finding suggests that perceived similarity among odors is much the same in the newborn as in the adult, although it would be premature to endorse this view without demonstrating similar effects with other odorants. The possibility that odor categories are not dependent on either a language system or much experience with odors is intriguing and is worthy of further study. As yet, there is no agreed-on method for categorizing odors, and the extent to which different schemes of categorization are dependent on experience and language is unclear. Studies of odor similarity in infants could aid in determining "basic" categories for odorous chemicals.

The relationship between perceived intensity and molecular structure of homologous alcohols appears to be much the same in adults and newborns. The likelihood of newborns' responding (using change in respiratory rate as a dependent measure) to each in a series of full-strength homologous alcohols (ethanol to decanol) decreases as the chain length increases, in much the same way as the perceived intensity of these alcohols decreases with increased chain length for adults.[112] Although the short-chain alcohols elicit the greatest response when tested at full concentration, the long-chain alcohols elicit responses more systematically when threshold concentrations are evaluated. Adult psychophysical data suggest an explanation, showing that the effect of dilution on perceived intensity of these alcohols varies as a function of the chain length: for example, a 50% dilution of a long-chain alcohol results in a smaller change in perceived intensity than the same dilution of a short-chain alcohol.[112] A subsequent study in which newborns' responses were scaled, with use of degree of general movement as a measure, revealed a similar relationship between intensity functions and alcohol chain length,[111] a finding confirming an essential similarity between olfactory processing in adults and that in newborns.

The ability to localize an odor source appears to be another perceptual capacity of the newborn. Newborns (1 to 5.5 days old) systematically turn their heads away from a source of ammonium hydroxide located to either the right or left of midline, just below the nostrils.[101] As with many of the foregoing phenomena, it is unclear whether this ability is mediated by the olfactory nerve, the trigeminal system, or both, because ammonium hydroxide is a potent stimulant of the trigeminal nerve. Evaluation of neonates' responses to odorants that appear selectively to stimulate the olfactory nerve, such as phenylethyl alcohol or vanillin,[123] could help to distinguish among these possibilities.

Finally, several adult studies have demonstrated that exposure to certain olfactory stimuli can inhibit perception of structurally related chemicals. It is presumed that the interaction of the first odor with many of the same receptors responsive to the second results in a decrement in responsiveness to the second odor. Cross-adaptation studies, like similarity judgments, have been taken as a way to explore basic odor categories. The opposite effect, facilitation of one odor by prior exposure to another, is less common but has been reported.[124] Both cross-adaptation and facilitation have also been observed in human neonates,[111,125] a further indication of the similarity between infant and adult olfactory function.

In addition to studies of newborns' responses to the odors of arbitrarily chosen, single-chemical compounds, a growing body of literature now exists that characterizes the neonate's response to odors associated with the mother and her amniotic fluid and breast milk. Most of these studies have used preferential orientation as a response measure and are discussed in the following section on odor hedonics. In this context, however, it is worth noting that, within hours after birth, infants can recognize their mothers through the sense of smell alone.[102-104,106-109] Like much of the work discussed earlier, this finding suggests exceptional olfactory acuity in the newborn.

Hedonics: Newborns, Older Infants, and Young Children

Given the striking resemblance between the neonate and the adult in sensitivity and discrimination, as outlined earlier, it is somewhat surprising that the origin of hedonic responses to odors has not been unequivocally traced to the neonatal period; in fact, controversy on this issue is substantial. This is particularly puzzling because hedonic valence is the most salient psychologic attribute of an odor for adults,[126] and, anatomically, olfactory structures have relatively direct access to brain structures that govern emotion.[127] Moreover, innately determined hedonic reactions to odors could be hypothesized to play a role in mediating components of food selection and social interaction.

The strongest evidence of affective odor reactions in very early infancy comes from neonatal studies of preferential responses to maternal and milk odors, alluded to earlier.[102-104,106-109] That these maternal odors have both a calming and feeding preparatory effect on the infant is demonstrated by the findings that newborns spend more time orienting toward a breast pad previously worn by their lactating mothers than one worn by an unfamiliar lactating woman,[106] and infants move the head and arms less, mouth more, and cry less during exposure to their mothers' body odors.[106,128] Moreover, shortly after birth, infants prefer their mothers' breast unwashed as compared with when it is thoroughly washed and is less odorous.[102] Thus, as for other mammalian young, the recognition of and preference for maternal odors may play a role in guiding the infant to the nipple area and facilitating early nipple attachment and breast-feeding. Both early experience and genetic determinants may underlie these preferences.

Several findings suggest that newborns' affective reactions to orthonasally presented odors are influenced by experience. First, unlike breast-feeding infants, bottle-fed infants do not preferentially orient toward their mothers' axillary odors when paired with those of either a nonparturient woman or an unfamiliar lactating woman.[104] Similarly, breast-feeding infants evidence no recognition of or preference for the axillary odors of their own father relative to another father's.[104] Third, 7-day-old, breast-fed newborns turn toward a perfume that has been worn on the mother's breast during feedings in preference to perfumes worn by other mothers.[129,130] Fourth, after a 20- to 24-hour period of exposure to an artificial odor (wild cherry or ginger) in the ambient air, female newborns less than 2.5 days old turn their heads in the direction of that odorant (presented on a gauze pad) as opposed to an equally pleasant (to adults) but unfamiliar odorant.[105] A similar preferential response to the familiar odor has been observed in both sexes when testing was delayed for 2 weeks after the initial exposure, thus indicating that neonates retained a memory trace of the exposed scent throughout this period.[131]

Studies also indicate that infants' preferences for retronasally presented odors are mediated by experience. Various volatile flavors (e.g., garlic, alcohol, vanilla, carrot, mint) enter human milk via the mother's diet, altering its smell and, presumably, flavor.[132-136] Both garlic[132] and vanilla[135] in the mother's milk stimulate increased sucking and ingestion by the nursing infant. Enhanced sucking is also observed when the flavor of vanilla is added to bottle-fed infants' formula.[135] Repeated consumption of garlic by nursing mothers modifies their infants' response to garlic-flavored milk, eliminating the enhancement in intake (relative to a day on which a bland diet is consumed) that is seen when mothers have maintained a bland diet for a period of time.[111] Thus, in the case of foods, infants' odor or flavor preferences may largely reflect a positive response to novelty or variety in milk flavor.

Experience with flavor cues in amniotic fluid, mother's milk, or both can lead to enhancement of preferences for the flavors of

foods eaten by the mother during pregnancy and lactation. First, day-old infants born to mothers who regularly consumed anise-flavored beverages during pregnancy preferred the odor of anise relative to a control odor, whereas those infants whose mothers did not consume anise displayed aversive or neutral facial reactions to this odor.[94] Second, weaning-aged infants, who had had several weeks of exposure to the flavor of carrots in either amniotic fluid or mothers' milk, consumed significantly more of a carrot-flavored cereal and were perceived by their mothers as enjoying the carrot-flavored cereal more than plain cereal.[95] In contrast, control infants, whose mothers avoided carrots during pregnancy and lactation, exhibited no such preference. Thus these very early flavor experiences may provide the foundation for cultural and ethnic differences in cuisine.

Early experiences may also result in the generation of olfactory memories through associative learning processes, as suggested by a study in children who were between the ages of 3 and 6 years.[137] Children's hedonic responses to the odor of alcohol were related to the emotional context in which parents experience alcohol and the parents' frequency of drinking. In other words, children of a parent or parents who drank alcohol to change their state of mind or to reduce dysphoric feelings ("escape drinking") were significantly more likely to judge the odor of beer as unpleasant than were similarly aged children whose parents did not drink to escape. This difference between the groups was odor specific: children in the two groups were similar in their preference for the bubble gum and rejection of the pyridine odors. These data support the hypothesis that associative learning in the context of emotionally salient conditions is a powerful mechanism by which odors acquire personal significance and that the emotional context in which children experience an odor can influence subsequent behaviors.

Clearly, experience is important in mediating affective and behavioral responses to odors in infancy and childhood. It has even been argued that all odor preferences and aversions are learned through associational learning processes; even the smell of a skunk would be perceived as pleasant if experienced under appropriate conditions.[130,138] This view is primarily based on several studies that failed to find adultlike odor preference patterns in children younger than 5 years of age.[139,140] For example, 3- to 4-year-old children have been reported to be as likely to say they like the odors of synthetic sweat and feces as they are to say that they like the smell of amyl acetate (resembling banana or pear).[139] Even 6- to 7-year-old children may differ from adults in their hedonic experience of odors. Although adults and 6- to 7-year-old children have been shown to exhibit similar rank-order preferences for odors,[141-143] children this age were less consistent than the adults in (1) selecting preferred odors in a pair-wise comparison paradigm[141] and (2) classifying odors as "liked" or "disliked."[142]

Methodologic difficulties could contribute to these apparent age-related differences. For example, children as old as 4 years tended to answer questions about odors in the affirmative, saying "yes" whether they were asked whether an odor was pleasant or unpleasant.[131] Perhaps some of the foregoing developmental findings, based on opinion polling, reflect this response bias in young children, rather than developmental changes in olfactory preferences. Furthermore, any method relying on sustained attention or placing demands on memory could yield spurious age differences.

Studies using more age-appropriate methods provide partial support for this hypothesis. Essentially adultlike odor preference patterns were obtained for a set of nine odorants (carvone, phenylethylmethyl carbinol, methyl salicylate, C-16 aldehyde, eugenol, amyl acetate, androstenone, butyric acid, and pyridine) when 3-year-old children were asked to give "good smells" to a likeable television character (Big Bird) and "bad smells" to a grouchy character (Oscar the Grouch).[113] Although children and adults in this study did differ in their distributions of hedonic ratings for some odorants, the similarities outweighed the differences. Using a similar dichotomous forced-choice task in which children pointed to a smiling face or a frowning face to indicate their odor preferences, Strickland and associates[144] also demonstrated adultlike hedonic classifications of two other odorants (benzaldehyde and dimethyl disulfide) in children as young as 3 years. Together, these studies do not support the conclusion that all odor preferences are learned relatively late in the preschool period and suggest experimental reconsideration of the view that some odors may be inherently pleasant or unpleasant.

SECTION XXIII Orthopedics

173 The Growth Plate: Embryologic Origin, Structure, and Function

Jennifer Frances, Bulent Erol, and John P. Dormans

Skeletal formation and growth occur as a process of sequential morphologic and biochemical events that occur during fetal development. During development, bone tissue is formed and grows through one of two processes. Bone can form directly from mesenchymal tissue, which is called *intramembranous ossification.* This occurs at the periosteal surfaces of all bones as well as in parts of the pelvis, scapula, clavicles, and skull. Alternatively, bone tissue can form by replacement of a cartilaginous model, which is referred to as *endochondral ossification.* Endochondral ossification occurs at the base of the skull, the vertebrae, and at the growth plates of the appendicular skeleton.

Proliferating cartilage constitutes the basis for much of the size increase of bones as organs because bone tissue itself does not grow interstitially. In the long bones of the limbs the proliferating cartilage is located at the ends, in the form of a *growth plate,* or *physis.* The cartilage in the growth plate has a unique zonal structure, biochemistry, process of matrix mineralization, and blood supply that differs markedly from hyaline or articular cartilage. Other areas of the body that have proliferating cartilage of various configurations include the skull (sutures and the base), the spine (end plates and synchondroses), the pelvis (triradiate cartilages), and the carpus and tarsus. Discussions of the growth plate and cartilage growth usually focus on the typical long bone growth plate, such as the distal femur because of its highly organized histology and great activity.

DEVELOPMENT OF THE GROWTH PLATE

Limb development has been studied in various organisms. Chick studies provided a wealth of information in the past because of the accessibility of the limb bud in ovo. However, molecular studies have focused largely on the mouse embryo. In addition, cross-species transplants have indicated that many of the same signals control limb formation in both organisms. Additional information about limb patterning has been derived from the study of regenerating amphibian limbs.

The formation of the developing limb bud in vertebrates is initiated by the mesenchyme. Somites give rise to all the limb muscle cells, whereas the lateral plate mesoderm gives rise to connective tissue and cartilage and thus determines the primary limb pattern.[1,2] In the absence of somites, the lateral plate mesoderm forms a limb with normal skeletal structure and tendons, devoid of any musculature.

The embryonic limb bud formation is initiated during the fourth week of gestation by the lateral plate mesoderm as a small projection on the ventrolateral body wall.[3] This mesenchymal projection is covered by ectoderm, the tip of which thickens and becomes the *apical ectodermal ridge* (AER) (Figure 173-1), which drives limb outgrowth and proximodistal patterning. Underlying the AER are rapidly proliferating, undifferentiated mesenchymal cells that form the *progress zone* (PZ). Proliferation of these cells causes limb outgrowth. The events in upper and lower limb buds are similar in character and sequence. There is, however, a slight craniocaudal time gradient, with the upper limb bud appearing and progressing 1 to 2 days before the lower limb bud. The molecular interaction between the AER and the underlying undifferentiated mesenchymal cells (PZ) drives limb development. Once the process of differentiation of all limb elements is complete, the AER disappears.

As the limb bud grows, three major limb axes appear at different times and by different mechanisms (Figure 173-2). The limb bud develops asymmetries along the proximodistal (flank to digit tip), anteroposterior (thumb to small finger), and dorsoventral (back of hand to palm) axes. Some of the important signals for initiating and maintaining these axes have been worked out in detail. The genes that initiate and potentiate signals in different axes often interact and feed back with each other, resulting in effects in multiple planes of growth.

Limb Bud Outgrowth (Proximodistal Patterning)

Limb bud outgrowth (proximodistal patterning) is dependent on signals emanating from the AER. Fibroblast growth factors (FGFs) produced in the AER stimulate cell proliferation in the underlying mesenchyme in the progress zone. The expression of FGF-10 and FGF-8 is necessary to *initiate* limb bud outgrowth, and the expression of each supports and promotes the expression of the other.[4] This FGF-8/FGF-10 loop is mediated by Wnt-2b, a mammalian homologue of *Drosophila* segment polarity gene-wingless and WNT-8c proteins, through a β-catenin (WNT/β-catenin pathway).[5] FGF-2, FGF-4, and FGF-8 are expressed in the AER, and each is able to *sustain* limb bud outgrowth. A graft of an AER to an ectopic site on the bud leads to extra limb growth in the ectopic location. Removal of the AER stops limb bud growth and leads to limb truncation. However, limb bud outgrowth can be sustained after excision of the AER, if FGF-impregnated beads are inserted in place of the AER.[6,7]

Cell growth and proliferation of the mesenchyme are maintained through a regulatory loop, with FGFs and a protein called sonic hedgehog (shh), which maintains the integrity of the AER. The formin gene, which encodes several proteins that function as cytokines, is required to establish this Shh/FGF-4 feedback loop. Bone morphogenic proteins (BMPs), members of the transforming growth factor-β (TGF-β) superfamily, play a complex role in the regulation of the AER (also in dorsoventral patterning).[8,9] BMPs are necessary to the induction of the AER.[8] However, BMP signaling must moderated by Gremlin

(a BMP antagonist) in order to maintain the Shh/FGF-4 feedback loop necessary for limb outgrowth and patterning.[10] The activation of Gremlin is dependent on the expression of the formin gene.[11]

Anteroposterior Axis Determination

Anteroposterior axis determination is under the control of the *zone of polarizing activity* (ZPA), which is an area of tissue in the posterior aspect of the limb bud (see Figure 173-1). Early chick studies showed that when tissue from this posterior area was transplanted to the anterior portion of another wing bud, a mirror image digit pattern developed.[12] The number of these additional digits developed depended on the strength (number of cells) and duration of transplant (16 hours for 2 digits, 20 hours for 3 digits). This observation led to the development of the morphogen gradient model, whereby anteroposterior patterning was determined by diffusion of a signal. The sonic hedge hog *(Shh)* gene is an important regulator of anteroposterior patterning.[13] Although early studies showed that exogenous application of retinoic acid to the anterior border of a normal limb could mimic results from ZPA transplant studies, this effect is now thought to be via activation of the *Shh* gene.[14] *Shh* represses Gli3R activity in the posterior limb bud, thus affecting the precise balance of Gli3A and Gli3R, which may be the basis for the graded response to Shh signaling.[13]

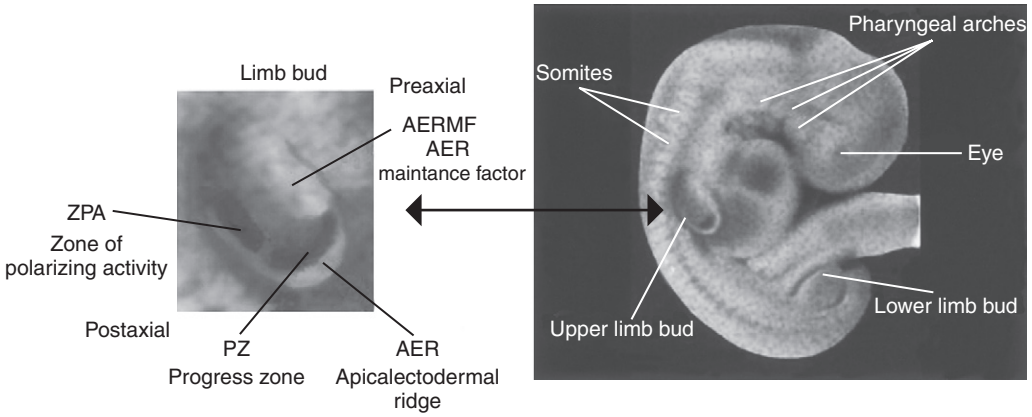

Figure 173-1 A 5-week-old human embryo and enlargement of the upper and lower limb buds. The limb bud at this time is a jacket of ectoderm (apical ectodermal ridge [AER]) covering undifferentiated mesenchymal cells (progress zone [PZ]). The zone of polarizing activity (ZPA), which is involved in anteroposterior patterning of the limb, is localized in a small area of mesoderm along the posterior border of the limb bud.

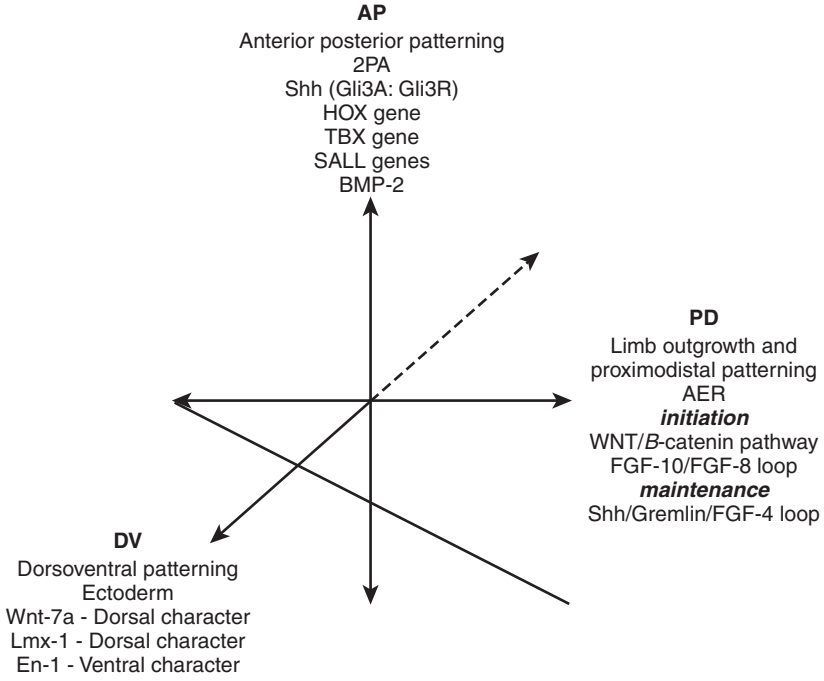

Figure 173-2 Three major limb axes. As the limb bud grows it develops asymmetries along the proximodistal (PD), anteroposterior (AP), and dorsoventral (DV) axes. The genes encoding the important signals that initiate and maintain these axes often interact and feed back, resulting in effects that are not confined to one direction of growth. *AER,* Apical ectodermal ridge; *BMP,* bone morphogenic protein; *En,* engrailed; *Fgf*, fibroblast growth factor; *GLI3A,* GLI3 activate; *Gli3R,* GLI3 repress; *Hox,* homeobox-containing gene; *Shh*, sonic hedgehog; *SALL,* Sal-like gene; *TBX,* T-bBox genes; *Wnt,* wingless; *ZPA,* zone of polarizing activity.

Other genes important in AP patterning under investigation include the 5'Hoxd genes, Tbox, and Sall family genes (specifically Tbx2, Tbx3, Sall1, and Sall4),[15,16] and defects in these genes cause digital alterations in humans.[17]

Dorsoventral Axis Determination

The dorsoventral axis is under the control of both the mesoderm and ectoderm of the limb bud at different stages of development. The mesoderm specifies the axis initially, but very early after limb bud formation, the ectodermal orientation becomes prominent. Evidence suggests that WNT-7a, a secreted signaling protein, confers the dorsal character to the ectoderm and stimulates Lmx-1.[18] Lmx-1 is a HOX gene that encodes a transcription factor (LMX-1) that dorsalizes mesoderm. The ventral limb expresses a transcription factor called engrailed (EN-1), which suppresses Wnt-7a expression, thereby limiting such expression, and consequently LMX-1 activity to the area of the dorsal mesenchyme.[19] Studies on BMP function have shown that BMP signaling is both necessary and sufficient to regulate EN1 expression, and consequently plays a role in dorsoventral patterning.[8]

Both the AER and the ZPA activate *HOXA* and *HOXD* genes. *HOX* genes have specifically been shown to affect the growth of cartilage and precartilaginous condensations. They are likely important in determining the length, segmentation, and branching of limb elements. *HOX* genes are not expressed strictly along anteroposterior or dorsoventral axes, and their position of expression differs in various areas of the limb.

Bone and Growth Plate Development

The first sign of future potential bone formation occurs in the early embryonic period as a localized condensation of the mesenchyme. Cellular condensations arise as a result of either increased mitotic activity or an aggregation of cells drawn toward a specific site.[20] As the mesenchyme begins to condense, the cells become more rounded, concomitant with a reduction in the amount of intercellular substance. This stage is referred to as the *precartilage blastema.* As the tissue continues to mature, the mesenchymal condensations differentiate into chondrocytes that form a template, or anlagen (skeletal anlagen), of the future bone (Figure 173-3). This transformation occurs during the sixth week of gestation. The expression of some specific molecular markers, such as aggrecan and type II collagen, distinguishes differentiating chondrocytes from the undifferentiated mesenchymal cells remaining at the periphery of the skeletal element that form a structure called the *perichondrium.*[21] During the seventh week of gestation, the innermost chondrocytes of the anlagen further differentiate into hypertrophic chondrocytes. At the same time as the chondrocytes hypertrophy, perichondrial cells start to differentiate into osteoblasts to form, around the cartilaginous core, a mineralized structure, termed the *bone collar*.[22,23] Once fully differentiated, hypertrophic chondrocytes become surrounded by a calcified extracellular matrix that, through a vascular endothelial growth factor–dependent pathway, favors vascular invasions from the bone collar. This process brings in chondroblasts that will degrade the extracellular matrix surrounding the hypertrophic chondrocytes and provides progenitors of osteoblasts derived from the bone collar.[24] The osteoblasts produce an osteoid matrix on the surfaces of the calcified cartilaginous bars and form the primary trabeculae; this process is called endochondral ossification. This initial site of ossification is known as the *primary ossification center,* and most of these appear in the late fetal period (Figure 173-4).

This sequential process of chondrocyte proliferation, hypertrophy, and replacement by osteoblasts becomes organized into the growth plate at each end of the expanding bone. The growth plates are apposed to the metaphyses at either end of the long bone. The histologic elements of the growth plate are well defined. Chondrocyte division is well organized into zones that can be demonstrated autoradiographically using tritiated thymidine.[25-27] Once the growth plate has been formed, longitudinal growth of the bone occurs by appositional growth of cells from within the growth plate, and new bone is formed in the metaphyseal side of each growth plate through a process that recapitulates the stages that occurred in the central portion of the original cartilaginous anlage. The rate at which this growth occurs is different at different anatomic positions; proliferating cartilage is arranged differently at different anatomic locations.[28] This process continues until closure of the growth plates at skeletal maturity.

At specific times in the postnatal development of each long bone, a secondary center of ossification (epiphysis) forms at the end of each bone. The secondary center of ossification is another zone of proliferating cartilage beneath the articular cartilage and is responsible for growth of the chondroephiphyseal cartilage

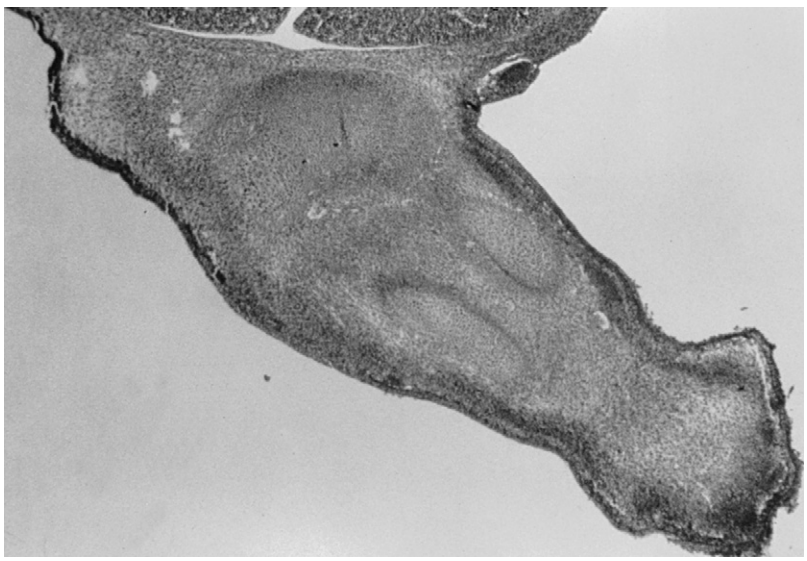

Figure 173-3 Longitudinal section of the developing hindlimb from a 13-day mouse embryo (H&E, ×40). Mesenchymal condensations of the skeletal anlagen have begun to form.

surrounding the epiphysis (Figure 173-5).[29] The processes of chondrocyte proliferation and hypertrophy, matrix calcification, vascular invasion, and osteoblastic new bone formation occur in the same sequence as in the growth plate associated with the primary ossification center. However, the epiphyseal end of the long bone enlarges as a result of radial apposition of cells around the secondary ossification center.

The Molecular Biology of Chondrocyte Differentiation

The growth plate is made up of highly organized chondrocytes at different stages of differentiation. Nonhypertrophic chondrocytes reside in the resting and proliferative zone and contribute to the replenishing of stem cells and growth through cell division. Hypertropic cells in the hypertropic zone contribute to longitudinal growth by an increase in their size and excrete factors that lead to the transformation of cartilage and matrix into bone.[30] Several growth factors control nonhypertrophic chondrocyte differentiation. The FGF receptor-3 (FGFR3) inhibits growth by restraining chondrocyte division.[31] A genetic mutation leading to constitutive activation of FGFR3 is the cause of achondroplasia, a dwarfing condition in which short stature is the result in FGFR3 continuous inhibition of chondrocyte proliferation in the growth plate.[32,33] Indian hedgehog (Ihh) promotes nonhypertrophic chondrocyte proliferation.[22] An interesting link between the Ihh pathway and the FGF pathway is indicated by data showing that FGFR3 signaling can inhibit Ihh expression.[31]

The hypertrophic chondrocytes comprise two subpopulations: the prehypertrophic chondrocytes and the fully differentiated hypertrophic chondrocytes. Parathyroid hormone (PTH)–related peptide (PTHrP) binds to the PTH/PTHrP receptor present in prehypertrophic chondrocytes, and it plays a critical role in

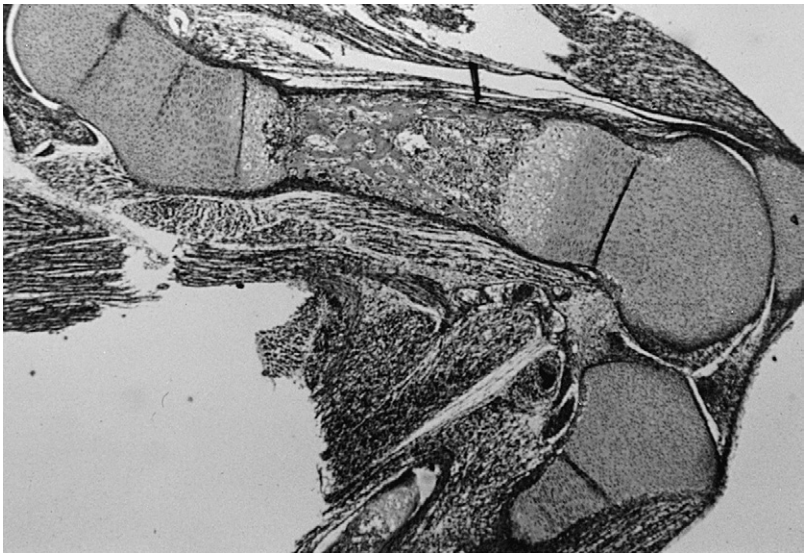

Figure 173-4 Longitudinal section of the femur and proximal tibia from an 18-day mouse fetus (H&E, ×40).The primary center of ossification has formed at the midshaft of the femur.The proximal (*left,* hip) and distal (*right,* knee) chondroepiphyses are visible, as are part of the cartilaginous patella and the proximal tibial chondroepiphysis.

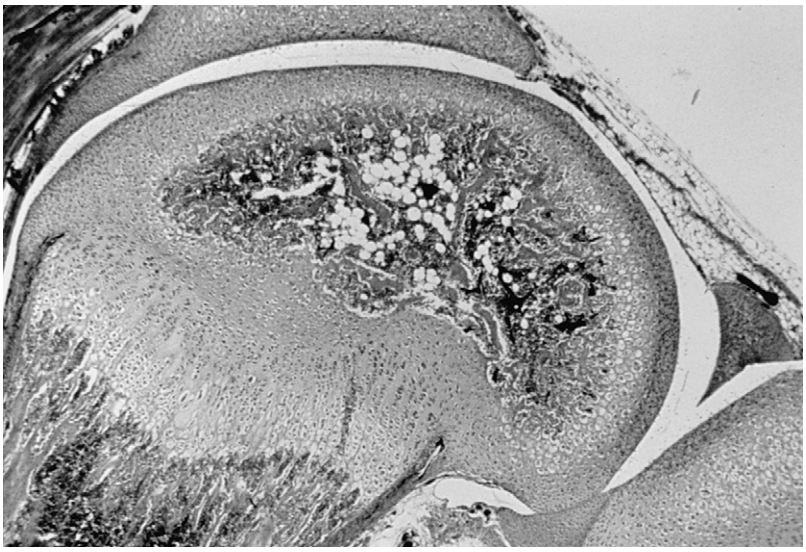

Figure 173-5 Longitudinal section of the distal femur from a 10-day postnatal mouse (H&E, ×40).The secondary center of ossification has formed within the distal femoral chondroepiphysis.The growth plate or physis is clearly defined between the secondary center of ossification and the metaphysis.

regulating hypertrophic chondrocyte differentiation, by delaying chondrocyte maturation and in doing such ensures the supply of proliferating chondrocytes necessary for skeletal growth. PTHrP expression is under the control of Ihh; Ihh up-regulates the synthesis of PTHrP by prehypertrophic chondrocytes, thereby indirectly slowing down the process of chondrocyte hypertrophy, and promoting chondrocyte proliferation.[22,34] Wnt signaling also plays an important role in the regulation of hypertrophic chondrocyte biology. Studies have shown that misexpression of Wnt-4 accelerates the transition from nonhypertrophic chondrocyte to hypertrophic chondrocyte, and in doing so results in slightly advanced ossification, whereas misexpression of Wnt-5a causes a delay in the transition from prehypertrophic to hypertrophic chondrocyte and results in a mild delay in ossification.[31]

Runx2, also called Core-binding factor-α subunit 1 (CBFA1), is a member of the runt family of transcription factors, and is necessary for osteoblast specific gene expression.[34] Runx2 is expressed in prehypertrophic chondrocytes and its constitutive expression in nonhypertrophic chondrocytes induces differentiation to hypertrophic chondrocytes, Ihh expression, and, eventually, endochondral bone formation.[35] These functions, along with its role during osteoblast differentiation and vascular invasion, identify CBFA1 as the most pleiotropic regulator of skeletogenesis.

GROWTH PLATE

The growth plate of a long bone provides an exceptional correlation among histology, ordered cytodifferentiation, molecular biology, and physical function. The growth plate is composed of a cartilaginous component that is surrounded by a fibrous component and bounded by a bony metaphyseal component. Each component has a unique structure, biochemistry, and function; together, these result in longitudinal and latitudinal growth and remodeling of the developing skeleton. The vascular supply of the growth plate results in unique biochemical properties and is integral to normal function.

Vascular Supply

The normal growth and development of a bone are inextricably linked to its vascular, and in particular its arterial, supply. In fact, the onset and maintenance of ossification depend on a constant supply of nutrients. There are three major vascular suppliers to the growth plate: the epiphyseal arteries, the nutrient arteries, and the perichondrial arteries (Figure 173-6). The epiphyseal arteries are derived from periarticular vascular arcades that form on the nonarticular bone surfaces. These arteries send branches through the cartilaginous epiphysis within cartilage canals to supply the reserve and proliferative zones of the growth plate.[36] Thus the overall viability of the growth plate to maintain normal bone growth and development depends on the integrity of these vessels. Any damage to these arteries will result in growth arrest.

The metaphyseal supply is primarily derived from the nutrient arteries, also known as diaphyseal arteries. The nutrient arteries are generally derived from an adjacent major systemic artery. A nutrient artery enters a bone through its nutrient foramen, which leads into a nutrient canal, and once the vessel reaches the medullary cavity, it divides into ascending and descending medullary branches.[36,37] The ascending and descending medullary branches anastomose with the metaphyseal collaterals at the metaphyseal zone. The metaphyseal supply induces blood-borne precursors that promote ossification and remodeling at the hypertrophic zone (HZ) of the growth plate.[36,38] The physeal cartilage itself maintains a separation between these two circulations throughout normal human growth. The perichondrial arteries supply the ring of LaCroix and the groove of Ranvier. Capillaries from this system communicate with the epiphyseal and metaphyseal capillaries in addition to the vessels of the joint capsule.

Cartilaginous Component

Within the growth plate the various subpopulations of chondrocytes (zones)—reserve (resting), proliferative (proliferating), hypertrophic—are arranged in columns (see Figure 173-6). These

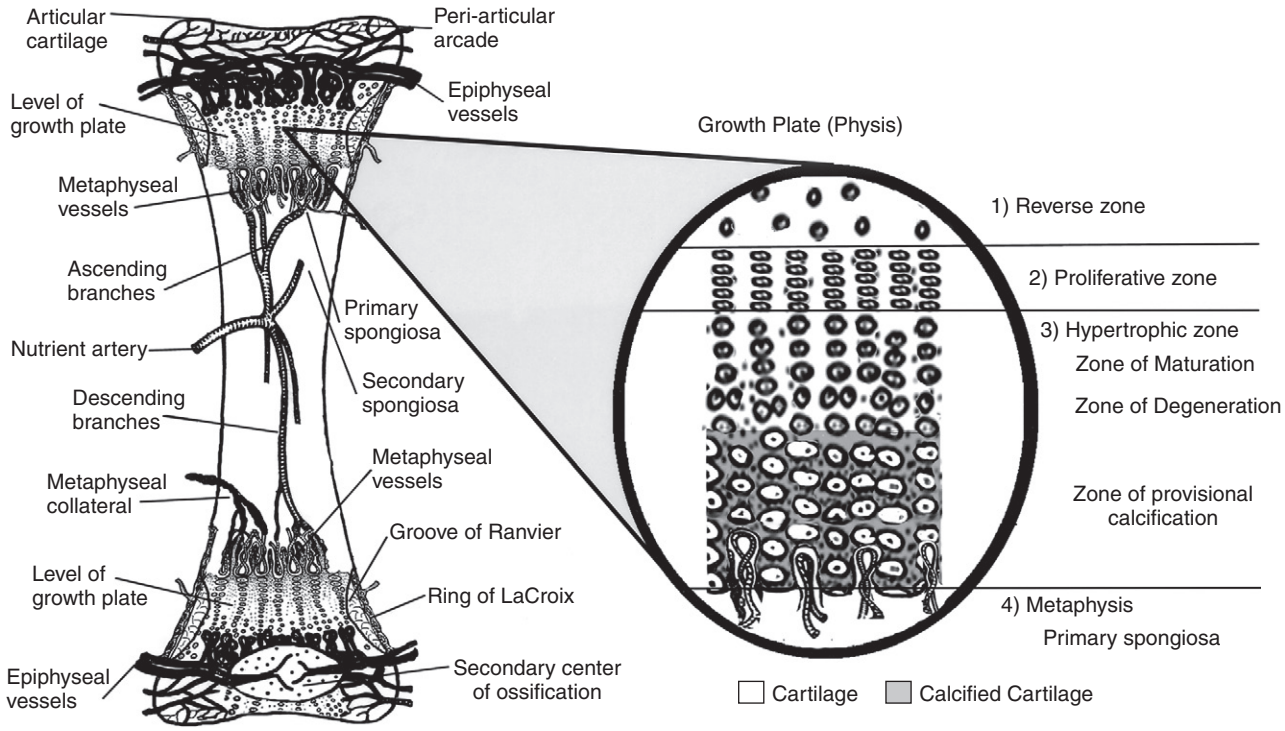

Figure 173-6 Diagrammatic illustration of the blood supply and zones of the growth plate. *(Modified from Scheuer L, Black S: Bone development. In Scheuer L, Black S [eds]:* Developmental Juvenile Osteology. *London, Academic Press, 2000, pp 18-31.)*

chondrocytes regulate longitudinal growth of the skeleton until their disappearance at the end of puberty in humans. Each zone has characteristic histologic and biochemical features that define its formation. The zone farthest away from the diaphysis and closest to the epiphysis is the *reserve zone* (RZ). In this zone the chondrocytes are small, round, and randomly distributed. The chondrocytes in the RZ replicate rarely; the ratio of matrix volume to cell volume is the highest of any layer of the growth plate.[39] The matrix contains randomly oriented fibrils of type II collagen, which inhibits calcification and acts as a barrier to the advancing front of the secondary center of ossification.[21] The chondrocytes in this zone receive a vascular supply from the epiphyseal vessels; however, the epiphyseal vessels do not actually arborize in the RZ, and hence the oxygen tension in this zone is relatively low. The precise function of the RZ remains ill defined. Two likely functions are (1) physical separation between the osseous tissue of the secondary center and the remainder of the growth plate and (2) synthesis and storage of nutrients and raw materials (i.e., glycogen, lipid, and protein) that will be used by other chondrocytes in the lower zones of the growth plate.

In the adjacent *proliferative zone* the chondrocytes are tightly bound in columns parallel to the axis of the length of the bone. The cytoplasm contains glycogen stores and is rich in endoplasmic reticulum, features suggesting a rich source of nutrients for aerobic glycolysis and a high capacity for protein synthesis. Of the three zones this zone has the highest rate of proteoglycan synthesis and turnover. The proteoglycans (aggrecans) in this zone are large aggregates consisting of glycosaminoglycans attached to core proteins.[40] Such aggregates inhibit calcification. The chondrocytes replicate rapidly in the proliferative zone, and they become flattened and slightly irregular in shape. The rate of duplication of cells is closely regulated and usually constant.[41] The binding matrix is contiguous with the matrix of the RZ and has the same biochemical composition. The type II collagen fibrils are oriented longitudinally, surrounding the columns of chondrocytes. The epiphyseal vessels that crossed the RZ terminate in the proliferative zone, thereby resulting in the highest oxygen concentration in the growth plate. The presence of rich glycogen stores and a high oxygen tension supports aerobic metabolism in the proliferative zone chondrocyte. The functions of the proliferative zone—matrix production and cellular division—together contribute to longitudinal growth.

The HZ has traditionally been divided into two parts: the upper, or zone of maturation; and the lower, or zone of degeneration. The lowest portion of the HZ is also called the zone of provisional calcification. In the zone of maturation the chondrocytes start to hypertrophy. There is a change in the proteoglycans of the matrix in this zone, with the size of the aggrecan decreasing. This decrease results from an active degradation mediated by physeal enzymes, including metalloproteases (i.e., collagenase, stromelysin, and neutral growth plate proteases).[42,43] There is also a marked decrease in type II collagen synthesis. In moving down the cellular column and away from the epiphyseal vessels, the chondrocytes are exposed to an environment of increasingly lower oxygen tension.

The major energy source for production of adenosine triphosphate (ATP) in the HZ chondrocytes is anaerobic glycolysis of glucose from endogenous glycogen stores. Glycogen is stored in the RZ and proliferative zone and is then consumed in the HZ. Metabolic activity in the HZ cells differs from that in most animal cells. In most cell types, glucose is oxidized to pyruvate in the cytoplasm, and the pyruvate then enters the mitochondria (by glycerol phosphate shuttle) to be further oxidized by the Krebs cycle. The Krebs cycle is an important additional energy source for most cells. In the growth plate pyruvate continues to enter the mitochondria but at a much reduced rate, and glycerol phosphate does not enter the mitochondria because the growth plate zones lack the glycerol phosphate shuttle. Thus even in the presence of oxygen, the growth plate cartilage metabolizes glucose relatively anaerobically. The mitochondria of the chondrocytes in the proliferative zone are capable of conducting the Krebs cycle and generating ATP. However, in the HZ, owing to lower oxygen tension, there is a switch in the function of the mitochondria from ATP production to calcium accumulation. These mitochondrial stores allow buffering of the ionized intracellular calcium in the already high concentrations of the HZ.[44]

In the zone of degeneration is a further diminution in proteoglycan size. The proteoglycan, which in aggrecan form is an inhibitor of calcification, no longer serves such a role because it is increasingly degraded.[42,43] Biochemical analysis shows that the chondrocytes in this zone are very active metabolically. They synthesize alkaline phosphatase, neutral proteases, and type X collagen, thereby participating in matrix mineralization. The mitochondria of the chondrocytes here begin to disgorge the calcium previously accumulated. This calcium apparently is packaged in vesicles of cellular membrane and is deposited into the surrounding matrix.[45] The hypertrophic chondrocytes do not synthesize type II collagen in the lower HZ, but instead synthesize type X collagen, a unique protein associated with endochondral ossification.[46,47] Active changes in chondrocytic activity occur at this site and lead to degeneration and cell death at the last intact transverse septum forming the interface with the metaphysis.[48] The longitudinal septa begin to calcify in this region of the growth plate; hence this zone is also termed the *zone of provisional calcification.* This is where the last transverse septa are ultimately degraded.

Metaphysis

The metaphysis begins distal to the last intact transverse septum of each cartilaginous cell column of the HZ (see Figure 173-6). It functions in the removal of the mineralized cartilaginous matrix of the HZ and in the formation of the primary spongiosa. Bone formation begins with the invasion of the hypertrophic lacunae by vascular loops, bringing with them osteoblasts that begin the synthesis of bone. The osteoblasts progressively lay down bone on the cartilage template. Subsequently, the initial woven bone and cartilage bars of the primary spongiosa are resorbed by osteoblasts and are replaced by lamellar bone to produce the secondary spongiosa.[49]

Perichondrial Ring of LaCroix and Groove of Ranvier

Surrounding the periphery of the physis are a wedge-shaped structure, the *groove of Ranvier,* and a ring of fibrous tissue, the *ring of LaCroix* (see Figure 173-6). The cells in the groove of Ranvier are active in cell division and contribute to an increase in the diameter, or latitudinal growth, of the growth plate. The basic structure of the perichondrial ring of LaCroix is a fibrous collagenous network that is continuous with the fibrous portion of the groove of Ranvier and the periosteum of the metaphysis. The perichondrial ring functions as a strong mechanical support at the bone-cartilage junction of the growth plate.

GROWTH AND ITS CONTROL

The endocrine control of the growth plate is a complex and important aspect of growth. Numerous factors have been identified as important regulators of bone and cartilage (Table 173-1). Some of these factors (systemic hormones, vitamins, and growth factors) are produced at a site distant from the growth plate and therefore act on the chondrocytes through a classic endocrine mechanism. Other factors both are produced and act within the growth plate and therefore function as paracrine or autocrine factors.[30] Each zone of the growth plate may be specifically targeted by one or more agents to affect a particular stage in the cell maturation phenomenon.

Growth hormone (GH) is a peptide hormone secreted by the pituitary gland, and its absence leads to pituitary dwarfism. GH acts throughout the growth plate and primarily stimulates cellular proliferation. GH does not directly stimulate the growth plate; rather, it stimulates production of a group of peptide growth factors termed *somatomedin* or *insulin-like growth factor* (IGF). The effects of GH mainly result from the production of serum-derived IGF by the liver, but there is also a direct GH effect to induce chondrocytes to produce IGF locally (paracrine or autocrine effect). IGF-I (somatomedin C) is the potent stimulator of postnatal growth mediating chondrocyte proliferation and matrix synthesis, whereas IGF-II is the fetal somatomedin.[50] Immunohistochemical studies have localized the highest concentration of IGF-I receptors to the PZ of the growth plate.[51] IGF-I increases cellular proliferation, probably by two mechanisms: by direct IGF-I effects; and, perhaps more important, through the modulation of other growth factor effects. The synergistic interactions of IGF-I with FGF and TGF-β are specific for deoxyribonucleic acid (DNA) synthesis, a finding that confirms the central role of IGF-I on mitogenesis in the growth plate.[50] Insulin can crossreact with the IGF-I receptors and therefore may have some minor anabolic effect at physiologic insulin levels.[44]

TABLE 173-1

Growth Plate Control

Agent	Effect
Specific endocrine hormones	
Thyroid hormones	↑ Chondrocyte proliferation, ↑ chondrocyte maturation
Growth hormones	Secreted by pituitary, converted to somatomedin (IGF-I); IGF-I interacts with local factors
IGF-I	↑ Chondrocyte proliferation
Insulin	Interacts with IGF-I receptor, ↑ chondrocyte proliferation
PTH-related peptide	Binds to PTH receptor → ↑ cAMP → ↑ chondrocyte proliferation and matrix synthesis, also works through inositol triphosphate and protein kinase C
Androgens	Anabolic but pharmacologic doses may promote growth plate closure
Estrogens	Inhibit bone resorption but may be important agent in plate closure
Local agents	
Growth factors	
Cytokines	
Other small molecules	
Autocrine, paracrine	
Fibroblast growth factor	↑ Chondrocyte proliferation, interacts with IGF-I
Transforming growth factor-β	Relatively weak and variable effects depending on other agents present, ↑ chondrocyte proliferation and maturation
Interleukin-1	↑ Matrix degradation through metalloproteinases
Prostaglandin	↑ Proteoglycan, ↓ collagen, alkaline phosphatase
Vitamins	
Vitamin A	Required for chondrocyte maturation
Vitamin C	Necessary cofactor for collagen synthesis
Vitamin D and metabolites	Required for calcification of matrix, deficiency leads to failure of calcification and marked elongation of the hypertrophic zone (rickets)

↑, Up-regulates; ↓, down-regulates; *cAMP,* cyclic adenosine monophosphate; *IGF-I,* insulin-like growth factor-I; *PTH,* parathyroid hormone.

The thyroid hormones, thyroxine and triiodothyronine, are peptide hormones produced by the thyroid gland. The thyroid hormones act on the PZ and upper HZ chondrocytes through a systemic endocrine mechanism and promotes chondrocyte maturation.[34] Thyroxine enhances cartilage growth by two functions: (1) it increases DNA synthesis in cells from the proliferative zone and (2) it increases glycosaminoglycan and collagen synthesis and alkaline phosphatase activity. Its effect on cartilage growth is mediated by synergy between thyroxine and IGF-I. These two agents together restore both growth and maturation. Triiodothyronine also increases cartilage growth by interacting with IGF-I. It promotes the cytodifferentiation from a proliferative to a hypertrophic chondrocyte, independently from IGF-I, however.

PTH is produced by the parathyroid glands. It acts primarily on the proliferative zone and upper HZ chondrocytes, and it has a direct agonist role in the cellular metabolism of the growth plate. There is a complex relationship among PTH, the intracellular calcium concentration, and regulation of growth plate.[52] In the growth plate chondrocyte, PTH stimulates the production of inositol triphosphate from phosphoinositol 4,5-biphosphate. Inositol triphosphate induces the release of calcium from an intracellular store, which causes a transient increase in the cytosolic ionized calcium concentration. PTH also mediates an increase in proteoglycan synthesis through the breakdown of membrane phosphoinositides and subsequent activation of protein kinase C. The regeneration of membrane phosphoinositides can result in the stimulation of prostaglandin synthesis, which also appears to have a small stimulatory effect on proteoglycan synthesis.

The effects of sex steroids (androgens and estrogens) on proliferating cartilage are complex. Although androgens and estrogens may increase chondrocyte division, they may also interact with adrenal steroids and many other factors. Androgens function primarily in the lower portion of the growth plate to stimulate mineralization. Their anabolic effect is manifested as an increased deposition of glycogen and lipids in cells and an increase in proteoglycans in cartilage matrix.[44] Androgens can also stimulate DNA synthesis in chondrocytes. Supraphysiologic doses of androgens depress growth and accelerate growth plate closure. Estrogen signaling is necessary for normal skeletal maturation and growth plate closure, but premature exposure to high levels of estrogen (precocious puberty) causes premature growth plate closure and short stature.[30]

Besides FGFs (see the earlier discussion of the development of the growth plate), several other growth factors have been demonstrated to contribute to the regulation of growth plate development. Platelet-derived growth factor stimulates DNA synthesis and cell replication of chondrocytes as well as protein synthesis. TGF-β is a multifunctional peptide that controls cell replication and differentiation. It is involved in cartilage formation during the first step of endochondral bone formation. Release of TGF-β is stimulated by PTH, but the overall effect of TGF-β appears to depend on constituent growth factors in the cell. Therefore its effects may be stimulatory or inhibitory, depending on the hormonal environment when TGF-β is introduced to the chondrocytes.[44] For example, TGF-β can inhibit progression of growth plate chondrocytes to the full hypertrophic phenotype, although this can be overcome by the thyroid hormones which drive maturation.[28] On the other hand, TGF-β is a potent inhibitor of a lymphocyte-activating factor called *interleukin-1,* which induces degradation in growth plate chondrocytes.[53]

Several vitamins are required for normal growth plate function.[54] The active metabolites of vitamin D (1,25- and 24,25-dihydroxyvitamin D) are produced in the liver and kidney. Vitamin D deficiency results in an elongation of the cell columns of hypertrophic zone. This effect is cause by a vitamin D–induced

decrease in systemic calcium and phosphorus and the subsequent inhibition of mineralization. The vitamin D metabolites are bound to cells in all growth plate zones except the HZ. The highest levels are found in the PZ. A deficiency state leads to rickets, which at the histologic level of the growth plate manifests itself as a failure of calcification of the matrix and marked elongation of the HZ. Histologically the RZ and PZ are normal, but the HZ is greatly expanded, and this results in widening of the growth plate.[30,55] Vitamin C is a necessary cofactor for the synthesis of collagen. Deficiency of vitamin C leads to scurvy. The greatest deficiency in collagen synthesis is seen in the metaphysis. The microscopic appearance of the cartilaginous portion of the growth plate is normal, but that of the metaphysis is quite abnormal. The physeal-metaphyseal junction is particularly disrupted, with persistence of calcified cartilage and sparse bony trabeculae. Vitamin A is essential for epiphyseal cartilage cell metabolism. A deficiency state results in impairment of the chondrocyte maturation.

CORRELATED CLINICAL CONDITIONS

It is interesting to review the causes of some skeletal dysplasias (osteochondrodysplasias), a group of genetic disorders characterized by generalized disorders of growth and development of bone and cartilage. The generalized disturbance in the development of the skeleton affects the skull, spine, and extremities in varying degrees resulting in disproportionate short stature (short-trunk or short-limb dwarfism). The pathogenesis of many of these conditions is slowly being discovered, teaching us little by little about the growth of the skeleton (Table 173-2). Future research in this area may lead to the development of therapeutic agents that target the genetic abnormalities that cause the previously mentioned pathologies.[56]

TABLE 173-2

Molecular Basis of Some Abnormalities of the Growth Plate

Condition	Molecule	Human Chromosome Location
Achondroplasia	Fibroblast growth factor receptor-3 (FGFR3)	4
Hypochondroplasia		
Thanatophoric dysplasia		
Diastrophic dysplasia	Diastrophic dysplasia sulfate transporter	5
Stickler syndrome	Type II collagen	12
Spondyloepiphyseal dysplasia congenita		
Kniest dysplasia		
Pseudoachondroplasia	Cartilage oligomeric matrix protein (COMP)	19
Multiple epiphyseal dysplasia		
Jansen metaphyseal chondrodysplasia	PTH-PTHrP receptor	3

PTH, Parathyroid hormone; *PTHrP,* parathyroid hormone–related protein.

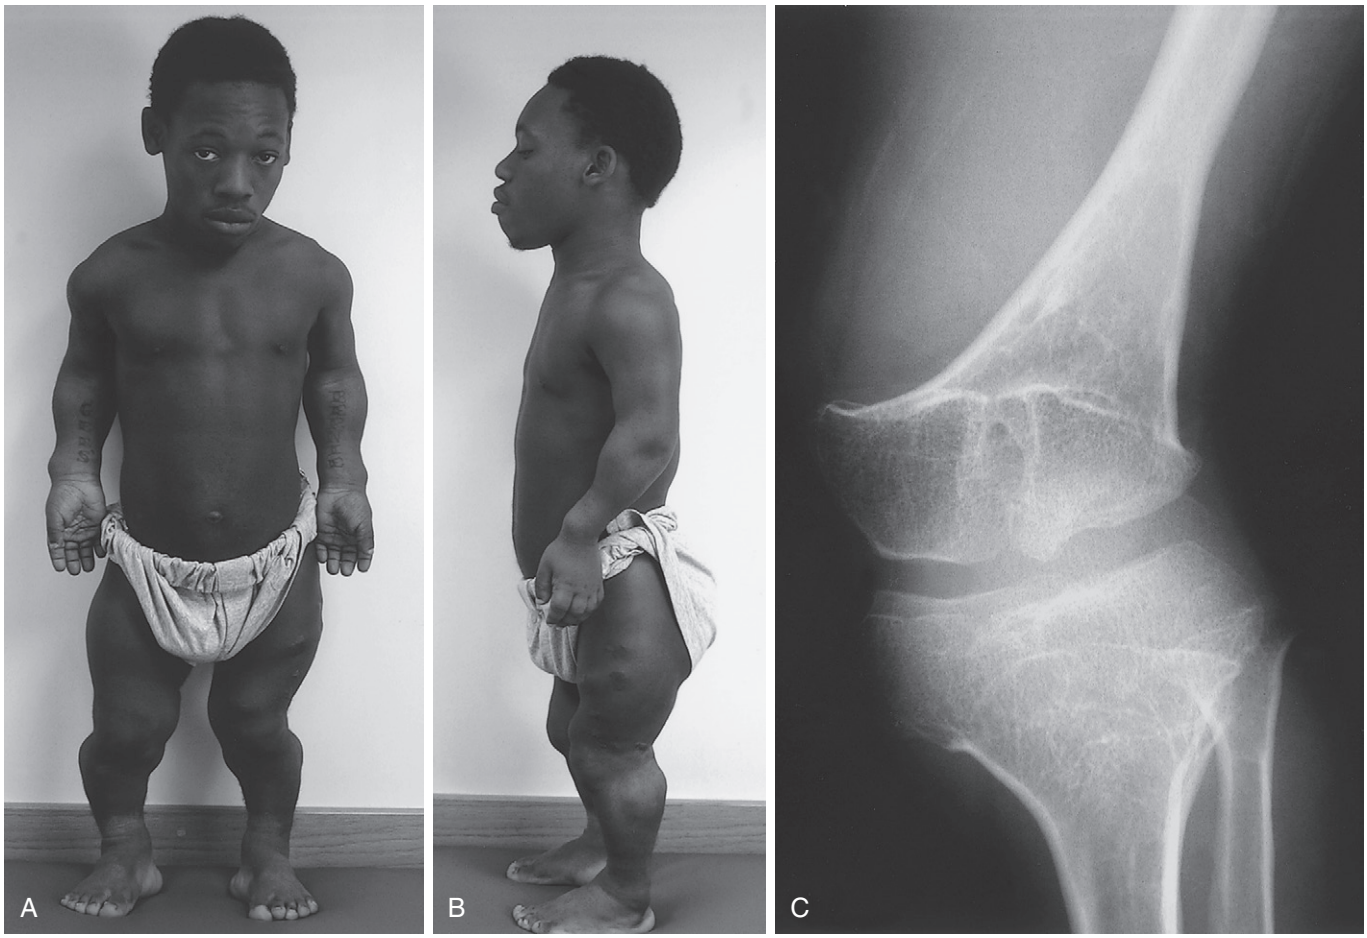

Figure 173-7 A 19-year-old patient with spondyloepiphyseal dysplasia congenita. **A** and **B,** Note the markedly short stature with short trunk and limbs. There are angular deformities of the lower limbs. **C,** An anteroposterior radiograph of the knee shows abnormally flattened and broad femoral and tibial epiphyses, causing angular deformities.

Achondroplasia, the most frequent form of short-limb dwarfism, is an autosomal dominant condition, although two thirds of cases arise by spontaneous new mutations that have been mapped to chromosome 4, in a region encoding *Fgfr-3*.[32,33] The activating mutations in the *Fgfr-3* gene lead to a retardation in chondrocyte proliferation resulting in abnormal endochondral ossification. *Hypochondroplasia* is an autosomal dominant allelic variant of achondroplasia with similar phenotypic and genotypic features, and the mutation in the *Fgfr-3* gene occurs in a different region (in the tyrosine kinase domain, in contrast to the transmembrane domain in achondroplasia).[33] A mutation in *Fgfr-2* underlies the *Crouzon syndrome,* in which the cranial sutures are disrupted.[57] In the *Pfeiffer* and *Jackson-Weiss syndromes* (both of which are characterized by craniosynostoses and limb defects) are mutations in both *Fgfr-1* and *Fgfr-2*.[58] The coordination of the various *Fgfr*s and receptors appears to be responsible for proportional growth.

Diastrophic dysplasia is a rare autosomal recessive condition characterized by short-limb dwarfism with spinal deformities and specific hand, foot, and ear abnormalities. The responsible gene has been mapped to chromosome 5 and encodes a sulfate transporter protein (diastrophic dysplasia sulfate transporter).[59] Impaired function of this protein is thought to lead to undersulfation of proteoglycans in the cartilage matrix, thus affecting hydration of cartilage.

Mutations in the gene encoding type II collagen, the predominant protein of cartilage, underlie several skeletal dysplasias: Stickler syndrome, spondyloepiphyseal dysplasia congenita, Kniest dysplasia, and Langer-Saldino achondrogenesis.[60,61] These conditions are characterized by short-trunk dwarfism and severe involvement of the vertebrae and epiphyseal centers (Figure 173-7). The gene defect has been linked to a deletion in the *COL2A1* gene on chromosome 12.

Pseudoachondroplasia and *multiple epiphyseal dysplasia* are frequent autosomal dominant disorders characterized by short-limb dwarfism and epiphyseal and metaphyseal changes. The gene responsible for these disorders has been localized to chromosome 19 and appears to encode the cartilage oligomeric matrix protein, a glycoprotein found in matrix surrounding chondrocytes.[62]

Jansen metaphyseal chondrodysplasia is a rare autosomal dominant disorder characterized by abnormal growth plate maturation and laboratory findings that are indistinguishable from hyperparathyroidism. This disorder is caused by activating mutations in PTH/PTHrP receptors.[63] This receptor is important both in calcium metabolism and in regulation of chondrocyte maturation.[64] By somatic cell hybrid analysis, the mutations in the PTH receptor gene have been mapped to chromosome 3 in humans.

Developmental Basis of Congenital Limb Differences

OVERVIEW

The phenotypic manifestations of abnormalities in limb development previously have been referred to as *deformities* or *anomalies,* but the term *congenital limb differences* is now considered more appropriate.[1,2] Although the focus of this chapter is on the developmental basis of congenital limb differences in the upper limb, similar principles and pathways apply to the lower limb.[3] The molecular regulation of limb identity is discussed next.

The embryonic upper limb begins as a small bud protruding from the body wall (somatic lateral plate mesoderm) at approximately 26 days gestation.[4] Over a period of 25 days, a complex of genetic signals controls the molecular pathways that result in a limb with the correct size, orientation, and number of digits.[5]

The bud initially is composed of morphologically homogeneous mesenchyme cells that are covered by a layer of ectoderm.[6] The mesenchymal cells are of two separate origins: Cells from the somites migrate into the limb to form muscles,[7] whereas the mesenchymal cells derived from the lateral plate mesoderm give rise to the skeleton (cartilage then bone), tendon, ligament, dermis, and other connective tissues.[8] The ectoderm gives rise to the epidermis.

Bone formation begins when mesenchymal cells form condensations.[9] This process requires bone morphogenetic protein (BMP) signaling.[10] Mesenchymal condensations in the limb differentiate to form chondrocytes, which are characterized by the expression of *Sox9.*[9] A subset of chondrocytes, the hypertrophic chondrocyte, signals to adjacent perichondrial cells to become osteoblasts. Hypertrophic chondrocytes then undergo apoptosis leaving a cartilage matrix for subsequent osteoblast migration and ultimately replacement by bone.[9]

Initial formation of tendons occurs autonomously with respect to muscle; however, further tendon development requires the presence of muscle.[11] The development of tendons also occurs in close association with that of cartilage and bone. Early in mouse limb development, tendon precursors (expressing *scleraxis*) have been observed in the mesenchymal tissue surrounding skeletal primordia, but with continued limb development, *scleraxis* expression segregates to the interface between muscle and skeletal primordia.[12]

Blood vessels are present in the limb bud from the very earliest stages except for an avascular zone subjacent to the ectoderm.[13] The vascular system undergoes extensive remodeling characterized mainly by regression and branching.[14] With time, the initial capillary network transforms into a segmental arterial supply. Regression of all but the major axial artery (called the primary subclavian artery) is followed by branching of this vessel to form the mature arterial pattern. Veins undergo two main phases of development: Initially,

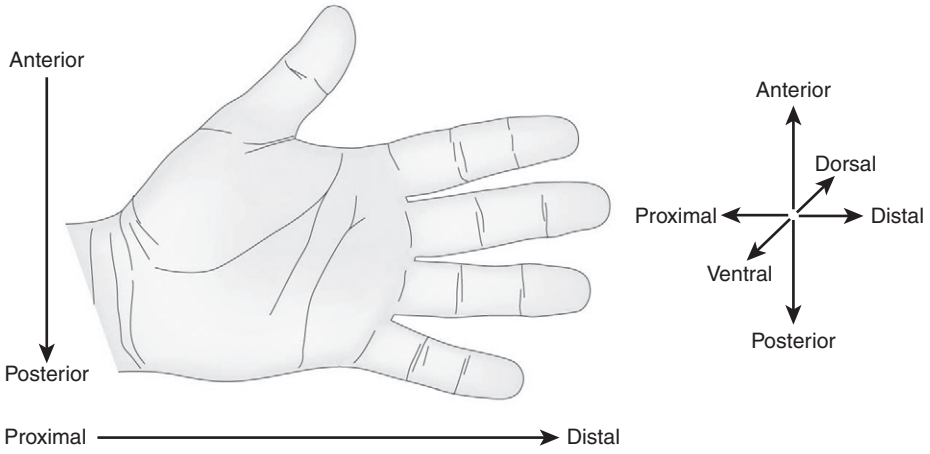

Figure 174-1 The three main axes of the human hand: proximodistal (P-D), anteroposterior (A-P), and dorsoventral (D-V). Tightly regulated processes during embryonic development ensure that the thumb arises at one edge of the hand, whereas the little finger arises at the other.[20]

the veins are located superficially along the anterior border, posterior border and apex of the limb (anterior marginal vein, posterior marginal vein, and marginal sinus). The marginal sinus subsequently regresses, and the anterior marginal vein becomes the cephalic vein and the posterior marginal vein becomes the basilic vein. Later in limb development (at approximately week 6), the deep veins that accompany the arteries become more prominent.

Nerves enter the upper limb in week 5 of development along the same planes as for the blood vessels and are in close physical proximity to them.[14] Positional signaling from the mesoderm appears to control the pattern of blood vessels and nerves.[15-17] Although not required for nerve ingrowth into the limb, muscles and skin are required for subsequent peripheral nerve branching.[18,19]

The limb bud grows along three primary axes: proximodistal (P-D), from shoulder to finger tips; anteroposterior (A-P), from thumb to little finger; and dorsoventral (D-V), from the back of the hand to the palm[20] (Figure 174-1). By day 33 of development, a paddle-shaped hand plate has formed; it is not until day 56, however, that the major morphologic features of the upper limb are complete.[4]

Limb growth is predominantly along the P-D axis during the early stages of limb development and is characterized by the sequential condensation of mesenchyme along this axis.[21] These mesenchymal condensations segregate into three main areas: the stylopod (from which will form the humerus, or upper arm), the zeugopod (from which will form the radius and ulna, or forearm), and the autopod (from which will form the carpus, or wrist, and hand).[6]

The concept of *positional information* has been used to explain how the limb pattern arises. According to this concept, mesenchymal cells are informed of their position in the three-dimensional matrix of the limb bud, and correct interpretation of this positional information results in differentiation of that cell to form the appropriate structure.[20] The pervading view of limb development was that this cellular differentiation occurred sequentially along the P-D axis.[22] In this view, the progressive specification of different parts of the limb was controlled by a timing mechanism that exerted its effect on a group of undifferentiated mesenchymal cells located in a region subjacent to the distal ectodermal cap called the *progress zone.*[23] The length of time cells spent in this progress zone specified the P-D information, and the positional value acquired as a result was fixed at the time the cells leave the zone.[22] More recent evidence, however, has challenged this concept, suggesting instead that cell fate may be specified earlier than was previously thought and by a different mechanism.[24] Differences between the early specification and progress zone models are illustrated diagrammatically in Figure 174-2.

Limb initiation is dependent on the activity of fibroblast growth factor 10 (FGF10) in the lateral plate mesoderm. *Fgf10* expression is itself downstream of WNT signaling (WNT-2b in the prospective upper limb region and WNT-8c in the prospective lower limb region). The precise craniocaudal location of limb outgrowth from the lateral aspect of the body wall is thought to be determined by the physical expression pattern of *Hox* genes.[25] Deletion of *Fgf10* in the mouse results in the absence of limbs[26,27] because FGF10 signaling in the limb mesenchyme is required to induce and maintain normal *Fgf8* expression in the *apical ectodermal ridge* (AER), which is essential for normal limb outgrowth. FGF8 and FGF10 reinforce each other through a positive feedback loop.[3]

In both *early specification* and *progress zone* models, further limb outgrowth is essential for normal patterning in the P-D axis.[22] Growth in the P-D axis is mediated by the AER. The AER is a strip of specialized epithelium, which forms at the junction between the dorsal and ventral ectoderm.[6] The key signals that mediate AER function are members of the FGF family.[22] Disruption of the AER results in limb truncation. Earlier disruptions to the AER during limb development result in more proximal limb truncations.[28] Of note, although the AER provides a permissive signal (through FGFs) enabling the realization of the P-D pattern,[6] the information for P-D patterning is intrinsic to the mesenchyme.[29] Removal of the AER is associated with cell death in the subjacent mesenchyme,[24] whereas persistence of the AER results in additional tissue outgrowth (e.g., extra phalanx).[30]

A specialized zone of mesenchyme located along the posterior border of the limb called the *zone of polarizing activity* (ZPA) is responsible for limb patterning along the A-P axis.[6] The activity of the ZPA is mediated by a molecule called Sonic hedgehog (*Shh*). If *Shh* is inappropriately expressed in the anterior portion of the limb mirror image, digit duplications result.[31] Conversely, loss of *Shh* results in loss of limb structures along the A-P axis.[32] The three GLI proteins, GLI1, GLI2, and GLI3, are the transcriptional effectors of SHH signaling.[20] In the absence of SHH, GLI2 and GLI3 repress SHH target genes. In the presence of SHH, GLI1 and GLI2 function as activators to induce the expression of SHH target genes.[20] Normally the anterior portion of the limb has high levels of the repressive GLI3,[33] which acts to prevent radial polydactyly.

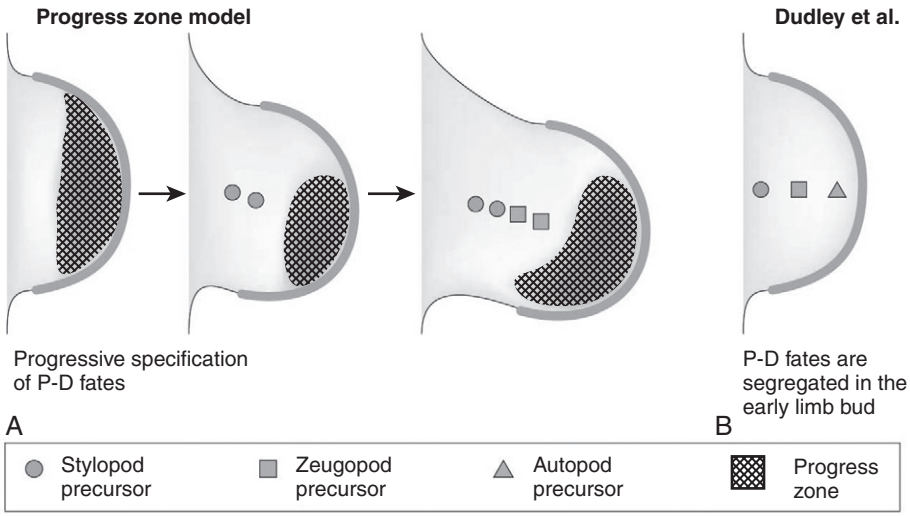

Figure 174-2 Graphical comparison of the progress zone and early specification models. The progress zone model proposes progressive proximodistal (P-D) specification that depends on the apical ectodermal ridge (AER), in which proximal fate is specified first, followed by progressively more distal specification. The early specification model stipulates that all P-D fates are established within the early limb bud.[6]

It is thought that the main role of SHH signaling is to derepress GLI3 in the posterior portion of the limb to allow digit formation to occur.[20] SHH is particularly important in autopod development.[6] High concentrations of SHH specify more posterior-type digits (e.g., little finger).[22] This property of SHH may be mediated by BMP-2,[34] because SHH signaling persists only until the digit primordia appear.[22] BMP activity in the interdigital mesenchyme appear to be the downstream vestiges of SHH activity.[22] For example, the phenotype of the individual digits appears to be determined by BMP signaling in the tissue of the interdigital space posterior to it.[35] Although BMPs appear to act in concert with SHH with regard to digit identity, they appear to antagonize SHH function with regard to digit number.[36] The number of digits is directly related to the A-P length of the apical ridge,[37] and AER length can be increased by BMP antagonists such as Noggin and Gremlin.[36] Of interest, expression of *Gremlin* has been shown to be dependent on SHH signaling.[38]

Patterning of the limb in the D-V axis is intrinisic to the mesenchyme before limb bud formation. This information subsequently is transferred to the overlying ectoderm.[39] Expression of *Wnt-7a* in the dorsal ectoderm induces the mesenchymal expression of *Lmx1b*, which confers dorsal characteristics to the limb.[40] *En-1* is expressed in the ventral ectoderm and promotes ventral limb characteristics.[40]

Apoptosis and skeletal segmentation also play important roles in further sculpting and refining, respectively, the developing limb.[41,42] Interdigital cell death occurs by caspase-dependent[43,44] and caspase-independent[45] mechanisms around 6 to 8 weeks of development.[46] WNT-14 has an inductive role in joint formation,[47] and growth and differentiation factor-5 (GDF-5) has been shown to repress chondrogenesis in regions of prospective joint formation.[48] BMPs play an important role in regulating differential phalangeal growth.[49]

Normal growth of the limb is dependent on reciprocal signaling between the ectoderm and the underlying mesenchyme.[22,50] For example, if the AER is absent or defective, SHH signaling is not induced in the mesenchyme.[51] SHH signaling maintains *Fgf4* expression in the AER.[38] FGFs, BMPs, and SHH all regulate Hox gene expression,[52] and expression of specific sets of *Hox* genes correlates with the formation of specific segments of the developing limb.[53] *Hoxa13* and *Hoxd13* play important roles in digital development, and *Hoxa11* and *Hoxd11* in forearm development.[22] The relationship between congenital limb differences and human Hox genes has been summarized by Goodman.[54]

Gene deletion and misexpression studies have demonstrated that *Tbx5,Tbx4,* and *Pitx1* have fundamental roles in the specification of limb type identity (e.g., upper limb versus lower limb).[3] *Tbx5* is required for upper limb development, and *Tbx4* is required for lower limb development. *Tbx5*$^{-}$ mutant mouse embryos demonstrate a spectrum of deformities ranging from absent upper limbs[55] to absent digit I.[56] Ectopic expression of *Tbx5* in the developing chick lower limb can partially transform its identity to that of an upper limb.[57,58] TBX5 is thought to achieve this transformation by repressing the expression of lower limb–specific genes such as *Tbx4* and *Pitx1*.[57,58] Conversely, misexpression of *Tbx4* or *Pitx1* in the upper limb transforms its identity to a lower limb.[58,59]

Congenital limb differences can be classified in many ways.[60-62] The classification system most commonly used by reconstructive surgeons treating these conditions initially was proposed by Swanson[63] and was revised by the Congenital Anomalies Committee of the International Federation of Societies for Surgery of the Hand (IFSSH).[64] The following section incorporates current knowledge about the developmental biology of the limb within the relevant parts of this classification system. A summary of the molecular basis of the many syndromes that manifest with congenital limb differences, as described next, is presented in Table 174-1.

FAILURE OF FORMATION OF PARTS

Transverse Arrest

The most common levels of transverse arrest are at the proximal forearm and the midcarpal, occurring in 1 in 20,000 live births.[2] These deficiencies commonly are associated with hypoplasia of structures more proximal in the limb. This pattern is consistent with a disruption to the AER early in development causing cell death of the underlying mesenchyme and failure of further P-D outgrowth.[24] Complete amelia is consistent with a failure of FGF10 or WNT-2b signaling in the prospective upper limb region.

TABLE 174-1

Molecular Basis of Limb Patterning

Gene		Associated Human Condition(s)
Genes Encoding Cell-Cell Signaling Molecules in the Limb and Molecules Involved in Signal Transduction		
Fibroblast growth factor (FGF) genes	FGF receptors	
Fgf8	*Fgfr*1*	Pfeiffer syndrome
Fgf4	*Fgfr2**	Apert, Pfeiffer, Jackson-Weiss syndromes
Fgf9	*Fgfr3**	Achondroplasia
Fgf10		
Wnt (wingless/Int) genes	Frizzleds (receptors)	
Wnt7a		
Wnt3a		
Wnt5a		
Hedgehog genes	*Patched* (receptor)	
Shh: Signal transduction	*Smoothened*	
Ihh: Cartilage		
	Hip (Hedgehog-interacting protein)	
	Gli3*	Greig cephalosyndactyly, Pallister-Hall syndrome
Bone morphogenetic protein (BMP) genes†	BMP receptors	
Bmp2		
Bmp4		
Bmp7		
Genes Expressed in Response to Signals in the Limb		
Hox genes		
Hoxa9 to *Hoxa13**		Hand-foot-genital syndrome
Hoxd9 to *Hoxd13**		Polysyndactyly
*Spalt**		Townes-Brockes syndrome
Meis		
*Lmx1**		Nail-patella syndrome
T-box genes		
*Tbx3**		Ulnar-mammary syndrome
Tbx4		
*Tbx5**		Holt-Oram syndrome

Data from Tickle C: Molecular basis of vertebrate limb patterning, *Am J Med Genet* 112:250-255, 2002.

*Direct association with named pathologic condition(s).

†Part of the TGF-β superfamily.

TGF-β, Transforming growth factor-β.

Longitudinal Arrest

Generally, longitudinal arrest may result from local absence of the AER at some point along the A-P axis or attenuation of the ZPA (so that posterior structures are missing).[25]

Preaxial

Radial Deficiency

Longitudinal radial deficiency occurs in 1 in 30,000 to 1 in 100,000 live births.[2] The most common syndromic associations are Fanconi anemia, thrombocytopenia–absent radius (TAR) syndrome, Holt-Oram syndrome, and the VACTERL association (*v*ertebral anomalies, *a*nal atresia, *c*ardiovascular anomalies, *t*racheoesophageal fistula, *e*sophageal atresia, *r*enal and/or radial anomalies, *l*imb defects). With the exception of that for Holt-Oram syndrome, the pathogenic mechanism for this deficiency is not known. Mutations in *Tbx5* cause the autosomal dominant form of Holt-Oram syndrome, which is characterized by a variety of thumb abnormalities (e.g., hypoplastic thumb) and heart defects (e.g., atrial septal defect [ASD]).[65] In severe cases, radial aplasia may be a feature. *Tbx5*-knockout mice have defects in digit I.[56] TBX5 activity is thought to be upstream of *Wnt2*b and *Fgf10*; accordingly, down-regulation of *Tbx5* is associated with a concomitant down-regulation of *Fgf10* and *Fgf8* in the anterior limb.[3]

Central

Central Ray Deficiency

Ectrodactyly is a central reduction of the hands and feet that occurs in approximately 1 in 18,000 births.[66] It can be associated with the ectrodactyly–ectodermal dysplasia–cleft lip or palate (EEC) syndrome, limb-mammary syndrome, or nonsyndromic split hand–split foot syndrome (SHFM). SHFM is a congenital limb difference involving the central rays of the autopod and manifests with syndactyly, median clefts of the hands and feet, and aplasia or hypoplasia of the phalanges, metacarpals, and metatarsals.[67] Digit loss can result from failure to maintain the AER locally, as occurs in the mouse mutant dactylplasia (Dac), with central loss of digits.[68] Dac homozygotes therefore lack hands and feet except for malformed single digits, whereas heterozygotes lack phalanges of the three middle digits. Dac resembles the human SHFM. The area of mapping of SHFM3 on 10q24 shows conservation of synteny with the Dac region on mouse chromosome 19; thus SHFM3 may be due to disruption of the human homologue of Dac. Mutations in p63 have been found to be associated with EEC syndrome and rarely in SHFM, which is more commonly associated with mutations in the *dactylin* gene.

Postaxial

Ulnar Deficiency

Tbx3 is one of the targets of ZPA signaling. *Tbx3* haploinsufficiency has been linked with ulnar-mammary syndrome, in which predominantly posterior defects occur in the upper limb.[22] Loss of the most posterior digit occurs as a consequence of loss of ZPA signaling. Such deficiency is a feature of mouse mutations involving *Wnt-7a,* a molecule that usually is involved in maintaining the ZPA.[69,70]

Intercalated

Phocomelia is characterized by the absence of proximal limb elements to various degrees combined with the presence of distal limb structures (e.g., autopod). Historically, this condition was associated with thalidomide ingestion during pregnancy. However, many congenital syndromes can manifest with phocomelia (e.g., Holt-Oram, TAR, Roberts, and Schinzel syndromes).[2] The *progress zone* model of limb development attempts to explain the pathogenesis of this condition by stating that proximal limb structures are relatively more sensitive to global insults than distal limb structures.[71] The *early specification* model counters this view with the notion that the progressive determination of distal fates limits the regulative ability of undifferentiated tissue in the developing limb.[24] Other theories suggest that thalidomide mediates its teratogenicity by inhibiting blood vessel growth.[72]

FAILURE OF DIFFERENTIATION (SEPARATION) OF PARTS

Soft Tissue

Cutaneous Syndactyly

Cutaneous syndactyly is described as *complete* when no regression of the interdigital tissue has been achieved (i.e., the tissue extends to the tips of the fingers) and *incomplete* when some regression of the interdigital tissue has occurred.[73] Interdigital mesenchyme normally is eliminated by apoptosis during embryonic

development. The regulation of cell death is complex. In summary, BMPs induce cell death[74,75] inhibitors of BMP signaling (e.g., Gremlin, Noggin, overexpression of dominant-negative BMP receptors) inhibit cell death,[75-77] and FGF signaling antagonizes BMP-induced cell death.[78] As stated earlier, molecules involved directly in caspase-dependent apoptosis (e.g., Bak, Bax, Dad (*d*efender *a*gainst *d*eath), APAF1 [*a*poptotic *p*rotease-*a*ctivating *f*actor-1]) also are crucial for interdigital cell death.[43,44,79]

Mouse models of cutaneous syndactyly involve either interference with cell death[43,44,77,79-82] or physical disruption of the ectodermal-mesodermal junction.[83] Most disruptions to the ectodermal-mesodermal junction result in acrosyndactyly, which is described in more detail further on. Mouse mutants with cutaneous syndactyly may have concomitant abnormalities in the AER (e.g., widening or delayed regression) secondary to inhibition of BMP signaling.[77,81,84]

Connexin 43, encoded by *GJA1,* is a gap junction protein. At later stages of limb development, *GJA1* is expressed in the AER. Mutations in *GJA1* are found in type III syndactyly (involving digits IV and V) in association with oculodentodigital syndrome.[85]

Skeletal Involvement

Osseous Syndactyly (Complex)

Interdigital tissue has the capacity to form cartilage. This observation has led to the concept that the chondrogenic potential of interdigital tissue before the onset of cell death must be actively repressed.[86] This repression may be mediated by FGF-FGFR2 signaling from the overlying ectoderm.[87] Mouse models suggest that osseous or complex syndactyly can arise as a result of abnormalities in the AER,[88,89] abnormal patterning in the mesenchyme (e.g., synpolydactyly caused by mutations in *HoxD13*),[90] or failure of bone growth (e.g., brachydactyly), described further on. Again, many of these defects trace back to defective AER maintenance. This is observed in the limb deformity *(ld)* mouse mutant, in which Gremlin activity is absent, allowing unrestrained BMP activity, which in turn prevents *Fgf4* expression in the AER.[38]

Acrosyndactyly

Acrosyndactyly is a particular type of syndactyly in which the distal portions of the fingers are joined.[73] Acrosyndactyly can arise sporadically as a result of constriction ring syndrome (secondary to physically encircling of the part by a band of amnion). It also is commonly associated with Apert syndrome.[91] Apert syndrome is an autosomal dominant condition caused by an activating mutation of FGFR2—either S252W or P253R. The syndactyly in both the hands and the feet is more severe in patients with the P253R mutation. An activating mutation of FGFR2 is consistent with the notion that FGF signaling is antagonizing BMP-induced cell death. Acrosyndactyly also is observed in a number of mouse mutants characterized by disruption of the ectodermal-mesenchymal junction.[92,93]

Synostosis

The secreted polypeptide Noggin binds to and inactivates members of the transforming growth factor-β (TGF-β) superfamily of signaling proteins, such as BMP4. Dominant mutations in human *noggin* have been found in a family segregating multiple synostoses (joint fusion) syndrome.[94]

Radioulnar synostosis is a feature of certain chromosome abnormalities, notably the triple X–Y syndrome (XXXY).[95] Mouse models of synostosis are characterized by an inhibition of BMP signaling. Murine Noggin (an inhibitor of BMP signaling) is expressed in condensing cartilage and immature chondrocytes, as are many BMPs. In mice lacking *noggin,* cartilage condensations initiate normally but subsequently become hyperplastic, and initiation of joint development fails as measured by the expression of *Gdf-5*. Excess BMP activity in the absence of Noggin antagonism may enhance the recruitment of cells into cartilage, resulting in oversized growth plates. Chondrocytes also are refractory to joint-inducing positional cues, producing synostosis.[96] The relationship of the triple X–Y syndrome to the BMP signaling pathway is not known.

Symphalangia

Symphalangism is characterized by failure of joint formation at the proximal interphalangeal joint. Proximal symphalangism syndrome (SYM1) also is associated with fusion of the carpal bones and sometimes the metacarpophalangeal joints. Dominant mutations in the gene encoding Noggin (the BMP antagonist) have been found in SYM1.[94]

DUPLICATION

When ZPA activity is abnormally present along the anterior border of the limb (e.g., as demonstrated by grafting posterior limb bud tissue to the anterior limb margin), mirror-image symmetric limbs develop.[97] Factors such as the location, concentration, and duration of the ectopic signal (e.g., Shh) and the stage of limb development will determine the extent to which duplication occurs (e.g., whole-limb duplication versus digital duplication).

Polydactyly

Polydactyly has been associated with mutations in 39 genes, not all of which fit into the current understanding of limb development. However, abnormalities in the GLI3 transcription factor are responsible for four or five phenotypes. A summary of disorders that include polydactyly as a clinical feature and their genetic basis is available in a review by Biesecker.[98]

Ulnar Polydactyly

As previously discussed, GLI3 has a repressive role in the SHH pathway. Missense mutations in *GLI3* (R625W) are associated with Greig cephalopolysyndactyly syndrome, which is characterized by, among other features, postaxial polydactyly.[99]

Central Polydactyly

Synpolydactyly (SPD), a condition of autosomal dominant inheritance, is characterized by syndactyly between digits III and IV with an extra digit in between.[90] The correlation between phenotype and the size of the polyalanine expansion tract suggests that expansion of the tract leads to a specific gain of function in the mutant HOXD13 protein.[100] These severe phenotypes are correlated with abnormal *Hoxd13* expression during the second phase of *Hoxd13* expression in the developing limbs of chicks and mice,[53] which occurs during specification of the autopod. During this phase, *Hoxd13* has the largest expression domain relative to the other 5 *Hoxd* genes and also is the first to be expressed. Mice homozygous for a triple deletion of *Hoxd11, Hoxd12,* and *Hoxd13* have phenotypes similar to those of SPD heterozygotes (presence of an extra central digit fused to digit III or IV) and SPD homozygotes.[101] HOXD13 is thought to play a dominant role by controlling mesenchymal proliferation,[102,103] and it is this that appears to be perturbed in SPD.

Mice homozygous for a mutation in *Gli3* show central polydactyly.[104] This finding is consistent with the central polydactyly phenotype in Pallister-Hall syndrome.[105] The distribution of polydactyly contrasts with that found in Greig cephalopolysyndactyly, as described.

Radial Polydactyly

Radial polydactyly may arise from abnormalities of the BMP pathway (repression) or the hedgehog pathway (activation). This is because Gremlin (BMP antagonist) usually is repressed by GLI3 (inhibitor of hedgehog pathway).[38] Expansion of the AER occurs with repression of BMP signaling. Mouse embryos null mutant for

Bmp7[106,107] or heterozygous for a null allele of *Bmp4*[108] display radial polydactyly. This observation is consistent with the concept that anterior expansion of the AER mediated by BMP repression may cause radial polydactyly. Signaling by ectopic Indian hedgehog (IHH)—which is functionally similar to SHH—in the distal anterior part of the limb results in radial polydactyly,[109] and *Gli3*$^{-/-}$ mouse mutants also have radial polydactyly.[110] Intraflagellar transport proteins have been implicated in the hedgehog pathway, and mutants of these proteins also are associated with radial polydactyly.[111]

UNDERGROWTH

Brachydactyly

Brachydactylies are a group of congenital limb differences characterized by shortening of the digits secondary to abnormal development of the phalanges or the metacarpals.[112] IHH is a member of the hedgehog family of secreted ligands and is closely related to SHH.[9] IHH activity is expressed in both prehypertrophic and early hypertrophic chondrocytes and is a regulator of chondrocyte proliferation. *Ihh*$^{-/-}$ mice have abnormalities of bone growth secondary to premature exit of chondrocytes from the proliferative pool. *Ihh*$^{-/-}$ mice fail to synthesize parathyroid hormone–related protein (PTHrP). PTHrP acts primarily to keep chondrocytes proliferating, and its signaling is downstream of IHH.[9] Mutations in the gene encoding *Ihh* are present in patients with brachydactyly type A1.[113,114] This type is associated with hypoplasia or aplasia of all middle phalanges, sometimes with joint fusions between the middle and proximal phalanx (i.e., symphalangism). These findings are consistent with experimental data showing that ectopic SHH induces ectopic phalanges.[36] In this scenario, SHH may interfere with an endogenous signaling system, possibly based on IHH, that controls the morphogenesis of each individual digit.

Receptor tyrosine kinase ROR2 is required for proper expansion of chondrocytes and growth plate organization in distal limb bones.[115] Brachydactyly type B is associated with aplasia or hypoplasia of the terminal phalanges and nails and is caused by mutations in the receptor tyrosine kinase gene *ROR2*.[116]

BMPs have multiple roles during bone formation.[9] GDF-5 is necessary and sufficient for both cartilage development and the restriction of joint formation to the appropriate location.[117] *GDF5*$^{-/-}$ mice have abnormalities in digit formation that involve failure of extension of mesenchymal condensations that lead to digit formation. Brachydactyly type C is characterized by shortening of the middle phalanges (brachymesophalangia) of digits II, III, and V. Heterozygous frameshift or nonsense mutations affecting *GDF-5* have been identified in persons with brachydactyly type C.[118]

BmpR1b is expressed in cartilage condensations during limb development. The formation of cartilage condensations is inhibited by overexpression of the BMP antagonist Noggin in chick limbs.[10] Overexpression of the protein encoded by a mutant *BmpR1b* in the chick embryo also causes shortening or aplasia of the phalanges.[112] A mutation in this gene has been found to be responsible for brachydactyly type A2, which is characterized by shortening and lateral deviation of the index fingers.[112]

GENERALIZED SKELETAL ABNORMALITIES

In addition to their role in limb patterning, FGFs are critical to subsequent bone growth.[119] Proliferating chondrocytes express *Fgf* receptor-3 (FgfR3), prehypertrophic or hypertrophic chondrocytes express *FgfR1,* and perichondrial cells express *FgfR2*.[9] In vitro data support the notion that FGF signaling is mediated by the suppression of *Ihh* expression.[120] FGF signaling through FGFR3 inhibits proliferation of chondrocytes. This mechanism is supported by gain- and loss-of-function mutation mouse models.[121,122]

Apert syndrome is characterized by craniosynostosis with complex syndactyly. It is caused by increased FGFR2 affinity for FGF ligands in the mesenchyme.[119] Pfeiffer syndrome is characterized by broad first digits and craniosynostosis and is due to a mutation in *FgfR1*. Variable mutations in *FgfR3* give rise to achondroplasia, hypochondroplasia, thanatophoric dysplasia, and a syndrome of severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN syndrome). All of these conditions are characterized by limb shortening.

As described earlier, SHH signaling from the ZPA is the primary determinant of A-P polarity in the vertebrate limb field. An active signal is produced by an autoprocessing reaction that covalently links cholesterol to the amino-terminal (N-terminal) signaling moiety N-SHH(p), tethering it to the cell membrane. Thus cholesterol modification is essential for the normal range of signaling.[123] Smith-Lemli-Opitz syndrome is caused by defects in 7-dehydrocholesterol reductase (DHCR7), an enzyme catalyzing the final step of cholesterol biosynthesis. It is characterized by generalized skeletal abnormalities including short, proximally placed thumbs and postaxial polydactyly.[124] SHH not modified by the cholesterol moiety has an increased propensity to spread long distances, causing ectopic SHH pathway activation in the anterior limb mesoderm.[125] These findings suggest that the congenital limb differences found in Smith-Lemli-Opitz syndrome may result from defects in DHCR7 leading to derepression of SHH signaling.[126]

175 Ontogenesis of Striated Muscle

Harvey B. Sarnat

HISTORICAL BACKGROUND

Embryology is the basis for understanding the intimate relation between structures in different organ systems such as the nervous system and muscle and is primordial for understanding disorders of development that in the human may present as one of the congenital myopathies. The timing and sequence of striated muscle maturation are as precise and predictable as in the nervous system. Interest in neuromuscular ontogeny began with the studies of MacCallum in the late 19th century.[1] The account of histologic changes in developing human muscle published in 1917 by Tello in Spain[2] remains as accurate and valid today as any subsequent studies by light microscopy. Ultrastructural studies of developing muscle by transmission electron microscopy began in the 1950s and were supplemented by the use of the scanning electron microscope two decades later. Histochemical techniques to demonstrate biochemical constituents and enzymatic activities in developing muscle were introduced in the 1960s and 1970s; the 1980s were a decade for the introduction

of immunocytochemistry to identify other molecules of subcellular components. The late 1980s and early 1990s saw a major breakthrough in the understanding of muscle differentiation by the discovery of myogenic regulatory genes and their transcription products. Studies of the complex interactions of these genes, their translated proteins, and the role of various trophic factors continue to be the focus of current investigations in muscle ontogenesis. Modern embryology, an integration of classic descriptive morphogenesis and the molecular genetic regulation of myogenesis, is the foundation for understanding the pathogenesis of congenital myopathies.[3]

EMBRYONIC ORIGIN OF MUSCLE

Muscle originates even before the three definitive germ layers are differentiated from the gastrula. The epiblast, the uppermost layer of the bilayered blastula, contains primordial mesodermal cells. Epiblastic cells migrate toward a line formed between parallel ridges that converge at one end; this line is known as the *primitive streak,* and the convergence of the parallel ridges is designated "anterior" and termed the *primitive node.* The axis thus formed establishes bilateral symmetry and a cephalocaudal gradient as the fundamental body plan.

From the primitive node and streak, epiblastic cells stream into the space between the two layers to form paired columns of prospective mesoderm. The primitive node is the future notochord. It is positioned beneath the future neural plate, which is of ectodermal origin. The mesodermal columns are composed of undifferentiated mesenchymal cells extending the entire length of the primitive streak. These cells migrate laterally and rostrally to fill the space between the overlying surface ectoderm, which includes the neural plate, and the deeper endodermal layer, except for an area on either side of the notochord beneath the neural plate.

Further development subdivides the layer of primitive mesenchyme. A thickened band of mesoderm condenses on either side of the primitive streak, from which primordial somites will differentiate. The myotomal plates within these still-unsegmented somite columns are anatomically distinct from the broad lateral expanse and a smaller intermediate strip of mesoderm. Elongation of the embryo is accompanied by regression of the primitive node (notochordal process) and streak caudally. As the node moves posteriorly, paired blocks of somites become segmentally condensed from the originally continuous somitic plate on either side of the developing neural tube. In addition, the lateral mesoderm splits into two layers: the upper or *somatopleure* forms the body wall, and the lower or *splanchnopleure* forms the mesenteries of the internal organs. A lateral palisading of paraxial mesenchyme against the lateral aspects of the notochord precedes overt segmentation, but, once formed, the boundaries between somites are stable and provide no opportunity for cellular mixing.[4]

Segmentation of the myotomal plate occurs along a rostrocaudal gradient. As the more caudal segments are still in the process of separating, segregated anterior somites are already changing in size and arrangement. In transverse section, the somites are composed of high columnar cells arranged radially around a small central cavity. The dorsal part of the somite, the *dermatome*, retains this columnar structure and forms a flat plate beneath the surface ectoderm. Cells of the ventral portion of each somite disperse to form a loose network known as the *sclerotome*. The small myocele cavity of the somite is transitory and becomes obliterated by cellular proliferation.

The myotome that differentiates at the medial end of the dermatome as a ventral extension near the neural tube differentiates into the axial (i.e., paraspinal) muscles and also into the muscles of the extremities as the limb buds form. The contractile elements of the developing muscle are of somitic origin, whereas the tendons, interstitial connective tissue, blood vessels, and epimysial sheaths are somatopleural derivatives.

The notochord and floor plate ependyma of the neural plate synthesize retinoic acid[5] and express a gene known in vertebrates as *Sonic hedgehog (SHH)*.[6] These factors are important in the dorsoventral patterning not only of the developing neural tube but also of the somites. Overexpression of these factors has a powerful ventralizing influence so that an ectopic length of notochord or a section of neural tube floor plate transplanted ventral to the newly formed segmental somite causes the excessive differentiation of sclerotome (the ventral part of the somite) and deficient formation of the myotome and dermatome, the dorsal part of the somite.[6-9] As the fetus matures, the loss of balanced antagonism between ventralizing genes, such as *SHH*, and dorsalizing genes, such as those of the *bone morphogenetic protein (BMP)* and *paired homeobox (PAX)* families, may result in segmental amyoplasia at the level of the notochordal or floor plate implant, a disturbance of *somitic induction*. Notochordal signals also regulate the transcriptional cascade of myogenic bHLH genes in the somite for myoblastic differentiation.[10] In a genetic mutant mouse in which somites form after notochordal degeneration, apoptosis of epaxial myotomes is accelerated.[11]

MYOGENIC REGULATORY GENES

A family of four proto-oncogenes directs the differentiation of striated muscle from any undifferentiated or incompletely differentiated mesodermal cell by blocking the methylation of DNA.[12] The molecular mechanism of myoblast differentiation requires the activation and suppression of specific genes in a temporal and spatial sequence controlled by a complex array of regulatory transcription factors. Each of these genes can activate the expression of another and, under certain circumstances, can autoactivate as well.[13-16] The four myogenic regulatory genes are a "family" not only because of their closely related functions in myogenesis but also because they all share encoding transcription factors of the *basic helix-loop-helix* (bHLH) protein, a molecular structure so fundamental in evolution that it is even found in some bacteria. These four genes or *myogenic regulatory factors (MRFs)* that control the specification and differentiation of striated muscle lineage are *Myf5, myogenin, MRF4* (also known as *herculin* and *Myf6*), and *myoblast-differentiating factor*, also known as *MyoD* or *MyoD1*.[13,17-25] Several other genes influence these MRFs or interact with them in ways that augment or impair their expression. *Myogenin* mainly mediates myoblast fusion, and, without this factor, an abundance of myoblasts may form but they do not fuse to form myotubes. The expression of *Myf5* and *MRF4* is transient in early ontogenesis and returns much later in fetal life to persist into adult life.[23]

One of the most remarkable and complex features of all myogenic genes is their intimate interactions with one another. After the discovery of this family of genes, initially it was thought that they all were redundant and any could substitute for another if one were deleted. Some indeed do have overlapping functions, such as *Myf5* and *MyoD*, that allow normal muscle development if one, but not both, of these two is defective.[26,27] A similar overlap or redundancy exists between *MRF4* and *MyoD*.[28] In general, despite these partial redundancies, each gene regulates a different aspect of myogenesis, however, and they do not easily compensate for each other either in the embryo and fetus or in myoblast precursor cells in adults for the regeneration of muscle.[29] *MyoD* cannot compensate for an absence of myogenin expression.[30] *MRF4* has functions similar to those of myogenin but not of *MyoD*[31] and can substitute for myogenin early in development.[32] *Myf5* similarly may be redundant with myogenin but less efficiently.[33,34] In *MRF4*- or myogenin-deficient mice, particularly severe impairments exist in the development of the thoracic myotomes for intercostal muscle development, and rib

fusions and sternal defects result, but these are probably secondary because neither of these two genes is expressed in rib cartilage or sternum.[35] Immunoreactivity of *MyoD* is now available for application to human fetal and neonatal muscle and is useful for some diagnoses of congenital disorders such as segmental amyoplasia.

Myogenic factor 5 (Myf5) is the earliest muscle-specific bHLH gene activated in the developing embryo.[14,19] Its expression is restricted to the medial aspect of the myotome, adjacent to the least mature myocytes.[9] *Myf5* alone cannot support myogenesis without the other three bHLH genes, however.[36] *Myf5* also seems to be mitogenic in inducing the proliferation of myoblast precursors. *Myf5* requires some activation by *MRF4*, and murine *MRF4*-null mutants show extremely reduced expression of *Myf5*, similar to *Myf5* knockout mice.[27] *Myogenin* can substitute for *Myf5* but is less efficient in this function.[33]

Myogenin does not serve a proliferative function in the genesis of myoblasts but is essential to myoblast fusion in the formation of myotubes, and it is expressed before fusion begins.[37] *Myogenin* inactivation in mice results in a normal number of myoblasts, but they become arrested in terminal differentiation.[27] Wild-type myoblasts can rescue *myogenin*-null myoblasts and cause them to fuse in vivo.[38] *Myogenin* is a specific transcriptional target of mitochondrial activity, unlike *Myf5* and *MyoD*.[39] *Myogenin* can be demonstrated by immunoreactivity in sections of human fetal and neonatal muscle (Figure 175-1).

MyoD1 is the last of the genes to become activated.[23,24] *Myf5* expression is normally suppressed by *MyoD*.[26] Despite its late expression, fetal mouse myoblasts express both *myogenin* and *MyoD* on day 1 in culture, but adult myoblasts (satellite cells) have a delay in expression of these genes and of myoblast fusion.[40] However, satellite cells coexpress proliferating cell nuclear antigen and *MyoD* on entering the mitotic cycle, and *MyoD* is critical for the programming of satellite cells into *myogenin*-differentiating cells.[41] The transition from proliferation to differentiation is delayed in mice lacking *MyoD*. Though coexpressed, *MyoD* and *Myf5* act at different times in the cell cycle: *Myf5* is maximally expressed in the G2 phase and is minimal in G1; *MyoD* is maximal in G1 and minimal in S-phase; it is reexpressed in G2 but not as strongly as in G1.[42] Another bHLH muscle–restricted transcription factor, *MyoR*, which antagonizes *MyoD*, has been recently identified.[43] *MyoD* and *myogenin* are expressed not only during fetal ontogenesis but also in adult life and are essential to the function of myogenic stem cells (i.e., satellite cells) in normal adults and also in the regenerating muscle in muscular dystrophies.[44,45] The myogenic regulatory genes, particularly *MyoD*, are so dominant that they are able to convert fibroblasts, chondroblasts, and other partially differentiated mesodermal lineages into myoblasts.[46]

The human locus of the *MyoD1* gene is on chromosome 11, very near the domain associated with embryonal rhabdomyosarcoma.[25] The genes encoding *Myf5* and *MRF4* are on chromosome 12 and that for *myogenin* is on chromosome 1. *MyoD* and *myogenin* are strongly expressed in human rhabdomyosarcoma cell lines.[47-49]

In addition to the family of four bHLH genes, *Pax3* has important interactions. It is redundant with *Myf5*: an absence of both *Pax3* and *Myf5* in embryonic mice results in generalized total amyoplasia and death; an isolated *Myf5* mutation causes milder, partial amyoplasia. Up-regulation of *Pax3* in chick embryos, by contrast, leads to precocious muscle development and arrested migration of myoblast precursor cells. *Pax3* and *Lbx1* both induce myoblast proliferation.[50] Other genes that *Pax3* induces include *Dach2, Eya2*, and *Six1*.[51,52] *Myogenin* is another key regulator of *Six1*.[53] *Pax3* is essential for the migration but not differentiation of limb muscle precursors.[54] Additional important functions of *Pax3* are the development of the eyes and the differentiation and maintenance of Bergmann glial cells of the cerebellum.

Other important genes or gene families that influence the bHLH myogenic genes are BMP2, which inhibits terminal differentiation of myogenic cells by suppressing *MyoD* and *myogenin*,[55] and LIM protein, which promotes myogenesis by enhancing the activity of *MyoD*.[56] Wnt signaling also plays a role in regulating the functions of *MyoD* and *myogenin*.[57]

Myostatin is a negative regulator gene of muscle maturation.[58,59] It is a member of the transforming growth factor β (TGF-β) family, similar to BMP. It has the latest expression in somites, after all other myogenic genes and desmin are already expressed. It also is coexpressed with *MyoD* but has a wider extent, also involving nonmuscular tissues such as the dermis. *Myostatin* inhibits transition from proliferation to differentiation but does not destroy myoblasts or alter mitotic cycling. *Myostatin* has recently

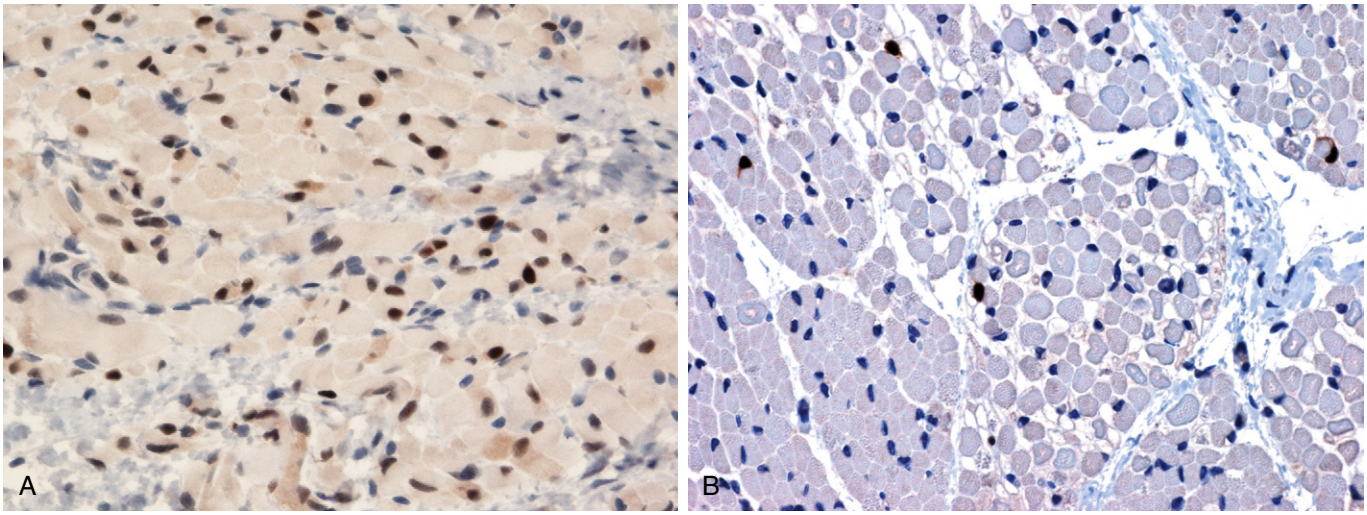

Figure 175-1 Intranuclear *myogenin* immunoreactivity in **(A)** full-term human neonate, and **(B)** 5–month-old boy with severe Duchenne muscular dystrophy. Normal neonatal muscle exhibits only occasional scattered nuclei that are marked; these are myoblasts or resident stem cells enclosed within the same basal lamina as their associated myofibre, also known as satellite cells in adult muscle. In muscular dystrophy, these myoblasts increase to attempt to regenerate muscle; such extensive distribution as in this child resembles an 8-10 week fetus. (Original magnification ×250.)

received attention in the lay press because of its potential use to enhance athletic performance.[60,61] A commercial interest in it to augment the muscular bulk of cattle and swine also exists.

In later stages of muscle ontogenesis, the selective accumulation of *MyoD1* and *myogenin* messenger RNA transcripts is not purely under genetic control but is modulated and modified by innervation of the muscle and by hormonal influences.[62-64] These effects begin earlier than the stage of histochemical differentiation of muscle fiber types at midgestation. Insulin-like growth factor (IGF) regulates normal *myogenin* expression[65] and influences muscle differentiation both upstream and downstream of *myogenin*.[66] IGF also augments proliferation that precedes differentiation.[67] Basic fibroblast growth factor (BFGF) similarly has a regulating influence on myoblast proliferation and differentiation.[68] Tumor necrosis factor-α, a cytokine, and BFGF differentially inhibit IGF-I–induced expression of *myogenin* in myoblasts.[69,70] IGF-I has early inhibitory and late stimulatory effects on *myogenin* transcription.[71] Other families of genes the transcription factors of which influence myodifferentiation include the POU homeodomain,[72] RHO proteins,[73] and SOX proteins.[74] A small number of neuroepithelial cells of the mouse neural tube coexpress neuronal markers and also *Myf5* and myosin in vitro, suggesting a potential for myogenesis from the neural tube itself.[75]

Micro-RNA expressions to detect the posttranscriptional modulation of cellular phenotypes in muscle and particularly in some of the congenital and degenerative diseases of muscle (muscular dystrophies) in humans are now feasible and promise to resolve many questions about the genetic regulation of muscle development, as well as the pathogenetic mechanisms of several developmental myopathies.[76] RNA interference (RNAi) libraries are being established in simple animals, such as the fruit fly *Drosophila*, which have genes that are phylogenetically conserved and include those of sarcomere formation in mammals.[77]

Other genes essential to muscle development and maintenance are the several genes that program sarcolemmal ion channels, particularly calcium channels. These channels form before innervations of the myofibre at 9 weeks gestation.

CYTODIFFERENTIATION OF MUSCLE CELLS

Structural and Contractile Proteins

The presumptive myoblast is a morphologically undifferentiated mesenchymal cell that divides mitotically, lacks the distinctive myofilaments of muscle cells, and does not fuse with neighboring cells of the same type.[78] The myoblast differs from its precursor, the presumptive myoblast, by synthesizing myosin and actin and assembling these proteins into thick and thin myofilaments, indicating a commitment to further differentiation as a muscle cell.[79] Although sarcomeres do not form in myoblasts, irregularly scattered clusters of myofilaments are loosely organized into interdigitating arrays. The cytoplasm of myoblasts is sparse. Adjacent myoblasts fuse by extending their contractile myofilaments across the plasma membranes of both cells and aligning the myofilaments produced by a row of several fused myoblasts (Figure 175-2). Myoblast fusion is enhanced by isoforms of the neural cell adhesion molecule that mediates interactions of apposed plasma membranes.[80]

The multinucleated syncytium of the row of fused myoblasts forms the myotube. Early myotubes continue to fuse with myoblasts and also with other early myotubules[81] (Figure 175-3). Circumferentially distributed myofilaments align themselves parallel to the longitudinal axis of the row of fused myoblasts as the filaments grow in length to extend through several fused myoblasts. Myotubular nuclei are enclosed within the center of the newly formed myotube as a single row within a central core of cytoplasm containing the membranous organelles and cytoplasmic particles. Cytoplasm is abundant, and contractile myofilaments are sparse in myotubes in comparison with more mature myocytes, but myofilaments and myofibrils are much more numerous in late myotubes than in early myotubes. Early myotubes predominate until the time of innervation at approximately 11 weeks gestation, and late myotubes are dominant during the second half of the myotubular stage from 11 to 16 weeks gestation.

Intermediate filaments, thinner but longer than the contractile myofilaments, appear in fusing myoblasts and myotubes.[82] These intermediate filaments, such as vimentin and desmin, are

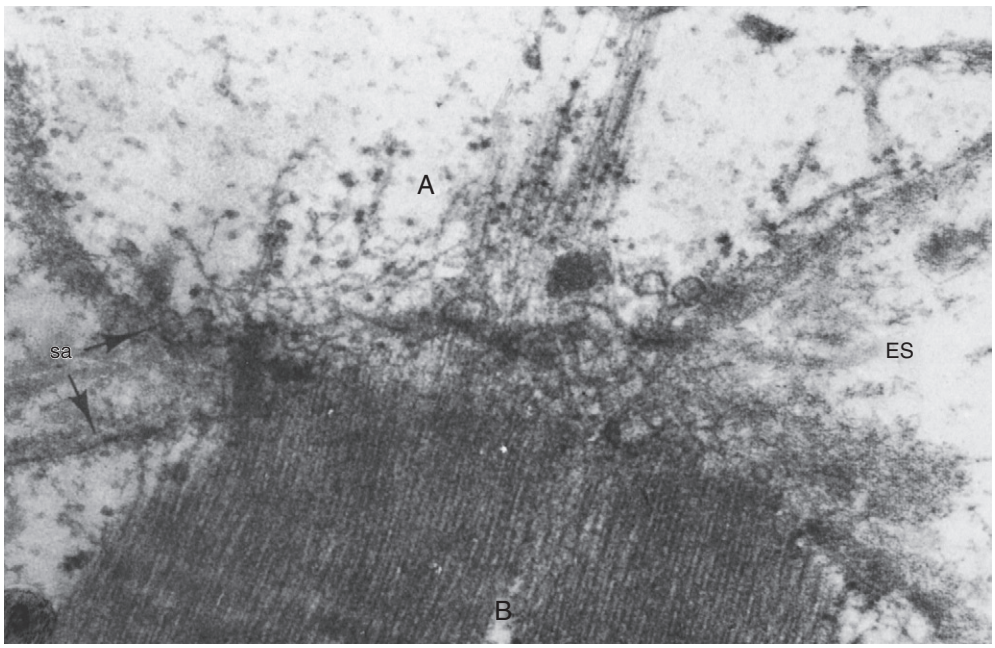

Figure 175-2 Myoblast (A) fusing with early myotube (B) in the vastus lateralis muscle of a 12-week fetus. Filaments from the myotube are seen extending into the neighboring cell. *ES,* Extracellular space; *sa,* sarcolemma. (Original magnification ×50,000.) *(From Tomanek RJ, Colling-Saltin AS: Cytological differentiation of human fetal skeletal muscle,* Am J Anat *149:227, 1977.)*

cytoskeletal proteins that help organize the cytologic structure of the muscle cell and spatial relationships of organelles, including the orientation and alignment of myofilaments (see later).

A basal lamina (i.e., basement membrane) appears as an indistinct, electron-dense thickening around the developing myotube. It usually encloses several myotubes and a number of less-differentiated myoblasts and presumptive myoblasts in the vicinity.[78,82,83] Mast cells, fibroblast-like cells, and other "unclassified" cells also may be included within the basal lamina.[84] Isolated myoblasts lack a basal lamina.[83] In this regard, they are similar to isolated fibroblasts and mast cells within the perimysium.

Further maturation of the myotube to become a myocyte involves the synthesis of more contractile myofilaments and more numerous myofibrils, displacing the central nuclei to the peripheral subsarcolemmal region and dispersing the sarcoplasm (i.e., cytoplasm) and its organelles between myofibrils. The Z-bands of several myofibrils within each maturing myotube are not "in register" with each other and do not become aligned consistently until approximately 30 weeks gestation.[78] The sarcotubular system begins forming in the late myotube but is not mature until after 30 weeks gestation.

After the myofiber achieves morphologic maturity in the relative positions and orientations of the various subcellular components, the next phase consists of the myofiber achieving greater length, an increase in the number of myofibrils in a cross-sectional field of the myofiber, and the development of histochemical fiber types. Although the number of myofibers and their morphologic maturation are mainly genetically determined, metabolic differentiation into fiber types is principally under neural control. Metabolic fiber types also exhibit subtle morphologic differences in the relative number of mitochondria and glycogen granules and in variation in the width of the Z-band.

Spindle-shaped mononucleated cells with abundant polyribosomes and endoplasmic reticulum persist in close apposition to the myotube and myocyte (i.e., multinucleated myofiber) enclosed within the same basal lamina. Such cells are presumptive myoblasts (Figure 175-4). In mature muscle, they are redesignated *satellite cells* (Figure 175-5). Although they are dormant and inactive, they are capable of mitotic proliferation and myogenesis even in the adult and are the basis of regeneration of injured muscle.[85-89]

No stage of fetal muscle development is "pure" in the sense of muscle cells exhibiting the same degree of maturation uniformly. Transitions among periods of development are gradual. At 5 to 8 weeks gestation, presumptive and true myoblasts predominate, but scattered myotubes are already evident at 6 weeks gestation. The period of 8 to 16 weeks gestation is regarded as the myotubular stage of development, and myotubes are indeed the most numerous types of muscle cells. However, many myoblasts are still identified, presumptive myoblasts frequently undergoing mitosis are encountered, and a few maturing myocytes beyond the myotubular stage are scattered during the latter weeks of this period. From 16 to 20 weeks gestation, a progressive maturation of myotubes to the cytologic structure of the mature myocyte takes place, but a few myotubes persist. Histochemical differentiation of muscle occurs mainly between 20 and 30 weeks gestation. From 30 weeks gestation to term, myofibers undergo several more subtle morphologic adjustments to maturity, such as alignment of Z-bands of adjacent myofibrils to attain "register" and further development of the sarcotubular system.

A 427-kilodalton cytoskeletal protein known as *dystrophin* is encoded by a large gene at the Xp21.2 locus. This subsarcolemmal protein attaches to the sarcolemmal membrane overlying the A-band and M-band of the myofibrils and consists of four distinct regions or domains: the amino terminus (N terminus) contains 250 amino acids and is related to the binding site of α-actinin; the second domain is the largest with 2800 amino acids and contains many repeats, giving it a characteristic rod shape; a third domain is rich in cysteine and is related to the carboxyl-terminus (C terminus) domain of 400 amino acids, unique to dystrophin and to a dystrophin-related protein encoded by chromosome 6.[90] Dystrophin may be demonstrated in striated muscle by its immunoreactivity, either by immunoperoxidase reaction (Figure 175-6) or by fluorescence microscopy, and is detected in developing human fetal muscle at 11 weeks gestation.[91,92] Dystrophin messenger RNA normally is detected in cardiac and smooth muscle in striated muscle and in the brain. The dystrophin gene encodes a 14-kilobase messenger RNA of approximately

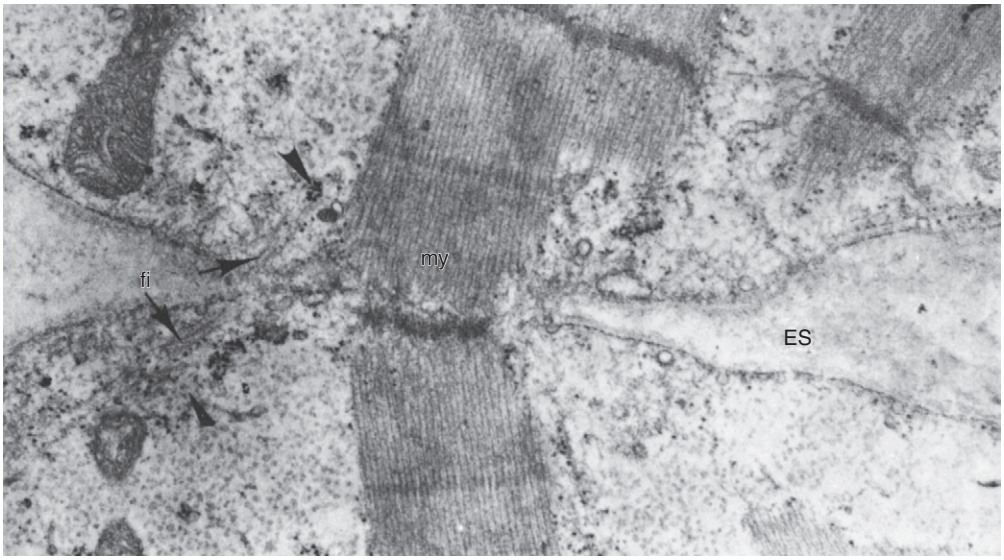

Figure 175-3 Fusion of two myotubes, more advanced in development than the myocytes shown in Figure 175-1, from the soleus muscle of a 16- to 17-week fetus. A well-formed myofibril *(my)* extends between two cells, which are joined by a narrow channel of sarcoplasm. Polyribosomes *(arrowheads)* and unassembled filaments *(fi)* are present in both cells. *ES,* Extracellular space. Figure 175-4 Presumptive myoblast *(pmb)* associated with a myotube *(mt)* in the quadriceps femoris muscle of a 14-week human fetus. An extensive rough endoplasmic reticulum and many free ribosomes are present, but no contractile filaments or T tubules are developed. Mitochondria also are seen, both in the presumptive myoblast and in the central core of sarcoplasm of the adjacent myotube. (Electron micrograph, original magnification ×12,000.)

Figure 175-5 Satellite cell of fully mature myofiber from quadriceps femoris muscle in a 7-year-old girl. As with the presumptive myoblast of fetal muscle (see Figure 175-3), the satellite cell contains mitochondria, rough endoplasmic reticulum, and free ribosomes but no contractile proteins or T-tubules and is enclosed within the same basal lamina *(arrowheads)* as the adjacent myofiber. The satellite cell is capable of mitosis and differentiation to become a true myoblast and then mature further and is the cell responsible for regeneration of injured muscle at any age. (Electron micrograph, uranyl acetate and lead citrate, original magnification ×20,000.)

80 exons. Defective dystrophin is the biologic basis of Duchenne and Becker muscular dystrophies.

Several dystrophin-related glycoproteins also form in this same general period. Alpha-sarcoglycan (formerly *adhalin*) becomes expressed before 14 weeks gestation. The other sarcoglycans (β, γ, δ) are expressed shortly thereafter. Dysferlin and caveolin-3 are other sarcolemmal membrane proteins at different sites from dystrophin and the sarcoglycans. Dysferlin deficiency is the basis of a well-documented progressive myopathy in children and adults, but dysferlin overexpression in striated muscle also can produce a progressive myopathy; hence the genetic regulation of expression, including its binding proteins, must be precise.[93] Caveolin-3 is first detected on day 10 in developing human somites.[94]

α-Dystroglycan is another sarcolemmal region protein. O-glycosylation of this protein may be altered by mutations of several genes during development, and hypoglycosylation is the molecular basis for some of the congenital muscular dystrophies.[95]

The precise timing of earliest expression of most sarcolemmal region proteins is uncertain, but collagen VI, which is deficient in a congenital muscular dystrophy known as Ullrich disease, probably is first detected at approximately 10 to 12 weeks,[96] similar to other proteins that attach to the sarcolemma. The principal source of collagen VI synthesis in striated muscle is the interstitial resident fibroblasts in the muscle.[97] It is noteworthy that this timing of appearance of sarcolemmal regional proteins coincides with the time of innervation of muscle at 9 to 11 weeks gestation. Knowledge of this timing is important in medicine because fetal muscle biopsies may now be performed during the course of pregnancy. Therefore, if a fetus is at risk for one of these diseases because of involvement of a sibling, for example, and the family wishes to know whether the present fetus is similarly involved, an accurate diagnosis can be confirmed as early as possible by immunoreactivity of sections of the fetal muscle or by haplotype analysis.[96] The various sarcolemmal regional proteins of striated muscle and their genetic defects in various myopathies were recently reviewed by Sewry.[98]

Cadherins are another group of transmembrane proteins that mediate calcium-dependent cell-cell adhesion by means of homophilic binding; M (muscle)-cadherin is a recently detected cell type–specific member of this family. In regenerating muscle and in developing fetal muscle, reactivity for M-cadherin is restricted to the plasma membrane of myoblasts and satellite cells and is most intense at the membrane areas facing adjacent myotubes or myofibers.[99-101] M-cadherin is genetically expressed but appears to be neurally regulated[102]; it is not expressed in denervated muscle.[100] The mechanism by which increased cadherin promotes early steps in muscle differentiation is by up-regulation of *myogenin*.[103,104]

Merosin is an extracellular matrix protein forming the heavy chain of the skeletal muscle basement membrane protein *laminin* and is important for maintaining the integrity of the sarcolemma. Defective merosin is implicated in the pathogenesis of one form of congenital muscular dystrophy,[105-107] and the chromosomal site of the disease gene is at the 6q2 locus.[107] The merosin (laminin-M) gene maps to chromosome 6q22-23.[108] Merosin may be detected before birth in the human placenta.[109] Type XIX collagen is a transient extracellular matrix protein that contributes to the formation of fetal basal lamina and closely follows the expression of *Myf5*.[110] Extracellular matrix is required for muscle differentiation and for the fusion of myoblasts to form myotubes, independent of *myogenin*.[111] Inhibition of fibrillar collagen production in avian and mammalian embryos results in abnormal somite formation and perturbed myogenesis.[112-114]

The innervation of muscle fibers occurs at approximately 11 weeks gestation, in the middle of the myotubular stage. Muscle spindles and Golgi tendon organs form after the myotubular stage as the general fascicular organization of the muscle evolves.

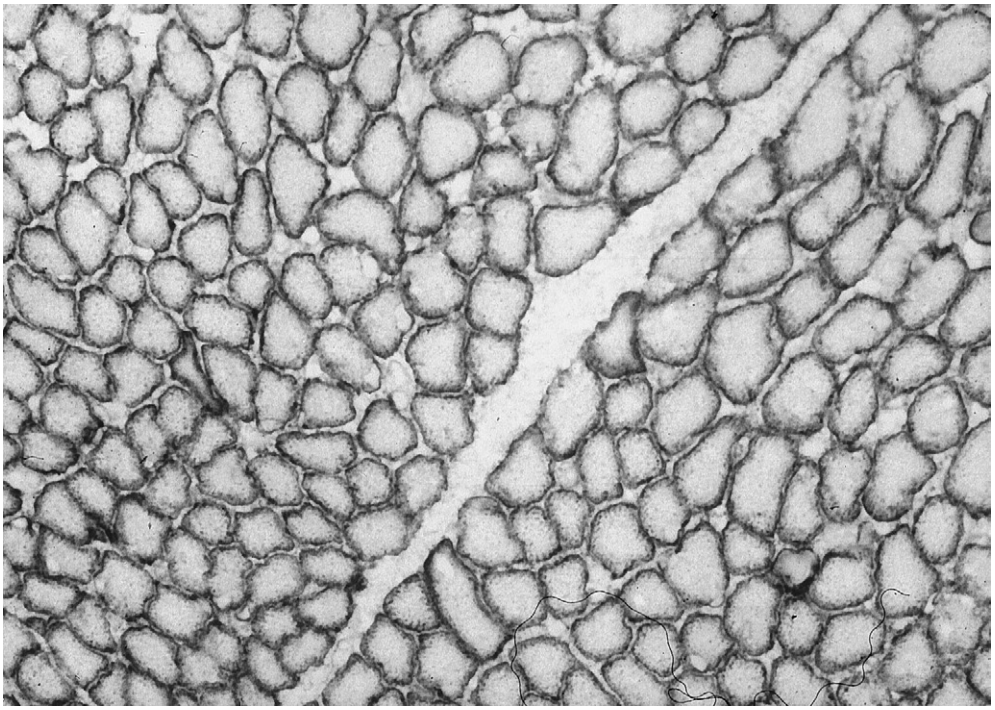

Figure 175-6 Immunocytochemical stain demonstrating dystrophin outlining the sarcolemma of normal quadriceps femoris muscle fibers in a biopsy specimen of a term male neonate. The monoclonal antibodies shown are specific for the rod domain of the dystrophin molecule; other antibodies demonstrate only the C terminus or N terminus. Dystrophin immunoreactivity is first detected in developing human muscle at 11 weeks gestation. (Original magnification ×250.)

The development of joints in the extremities begins at approximately 5 weeks gestation within the early mesenchymal condensations of precartilaginous bone. Joint spaces are already apparent by 7 weeks. Motion is probably essential for the development of joints, and some articular motion is evident as early as 8 weeks, before myotubes are innervated. These small-amplitude movements probably result from spontaneous contractions of newly formed sarcomeres. Active fetal movements are well established after 11 weeks, with the innervation of skeletal muscle, and increase progressively in both force and range of motion around articulations until birth.

Chaperone Proteins in Muscle Development

In addition to the various structural proteins of the myofiber and especially of the sarcolemma, certain "chaperone proteins" are essential for intracellular folding and assembly of polypeptides to achieve the final molecular structure of cellular structural proteins. However, they remain chaperones because they do not themselves become incorporated into the molecular structure of the protein they regulate in development. One of the most recognized of these chaperone proteins is the small heat shock protein α-B-crystallin, closely related to heat shock protein-27, which is found in all tissues and is phylogenetically very old, expressed even in bacteria and simple worms. It is demonstrated in both cytoplasm and nucleoplasm. It inhibits aggregation and precipitation of denatured proteins[115] and is up-regulated in a variety of tissues during various adverse or stressful conditions, such as fever, chronic ischemia, acidosis, x-irradiation, and exposure to toxins, and in epileptic activity in the brain.[116,117] A close association of α-B-crystallin with the Z-band of striated muscle implies that it is particularly important in protecting the Z-band from the disintegration that results in myofibrillar breakdown and also protects myosin from thermal denaturation.[118]

In muscle, the natural form of α-B-crystallin is overexpressed in myofiber atrophy, associated with a decrease in the amount of the cytoskeletal microtubule protein tubulin.[119] It also is overexpressed, but as a mutant form, in certain diseases of muscle known as myofibrillar myopathies[120] and may cause severe weakness and muscle stiffness leading to early infantile death.[121] The α-B-crystallin may have an additional role in muscle in regulating connective tissue proliferation, as it does in the dermis of the skin during wound healing.[122] In normal human fetal muscle, this protein is not demonstrated by immunoreactivity at any gestational age, perhaps because concentrations are too low to detect by this method (Sarnat HB, unpublished observations).

MORPHOLOGIC STRUCTURE OF MYOTUBES AND MYOCYTES

Sarcolemmal Nuclei

Myoblasts and myotubes have large, vesicular, ovoid nuclei. The chromatin is finely dispersed throughout the nucleoplasm, with a thin condensation against the nuclear membrane. One or often two prominent nucleoli are present (Figure 175-7). Ultrastructurally, the ribonucleoprotein of these nucleoli forms coarse, electron-dense strands (nucleolonemata) rather than the more massive nucleolar sphere of the mature sarcolemmal nucleus (Figure 175-8). These features of the nucleoli and of the finely dispersed DNA are characteristic of active transcription of RNA needed for the synthesis of contractile proteins. The nuclei of regenerating myofibers of children and adults have a similar appearance. The nuclear membrane of fetal myotubes contains pores, similar to the mature state. In the term neonate, some sarcolemmal nuclei are still vesicular and ovoid as are seen in less-mature stages, but most nuclei have acquired the elongated shape with dense chromatin that characterizes the mature state (Figure 175-9). The nuclei of myotubes are arranged in a single-file row within the central core of sarcoplasm. Nuclei may be tightly packed and in contact with neighboring nuclei, or they may be separated by intermediate segments of sarcoplasm of variable lengths (Figure 175-10). Both arrangements

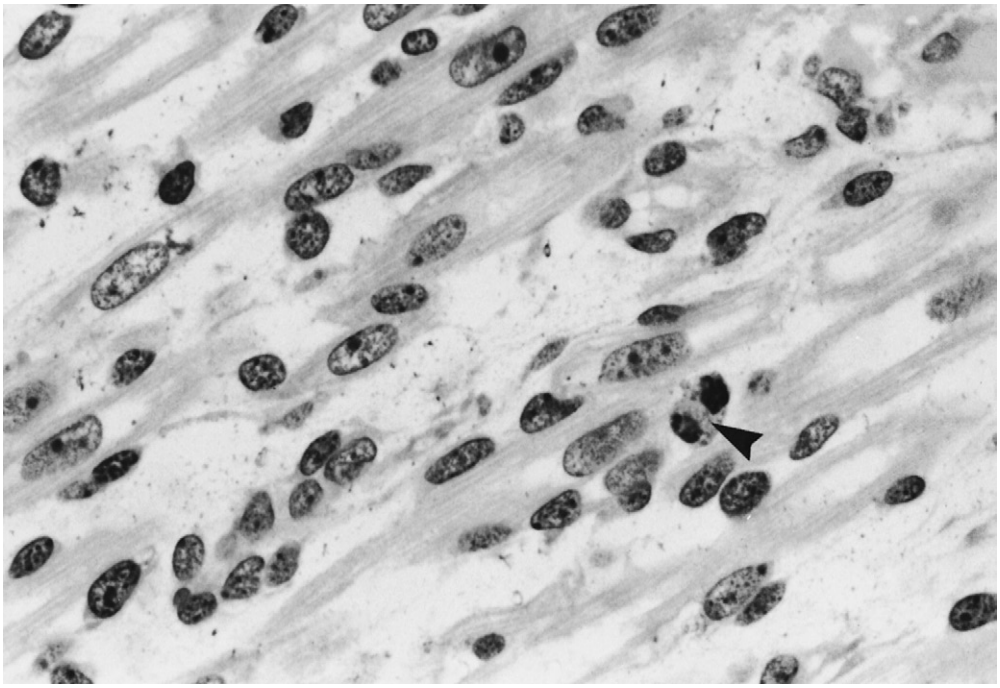

Figure 175-7 Myotubes in the quadriceps femoris muscle of a 14-week human fetus. Nuclei are large and vesicular with finely dispersed chromatin and one or two prominent nucleoli. Mitotic figures of presumptive myoblasts *(arrowhead)* are common. (Hematoxylin-eosin, original magnification ×1000.)

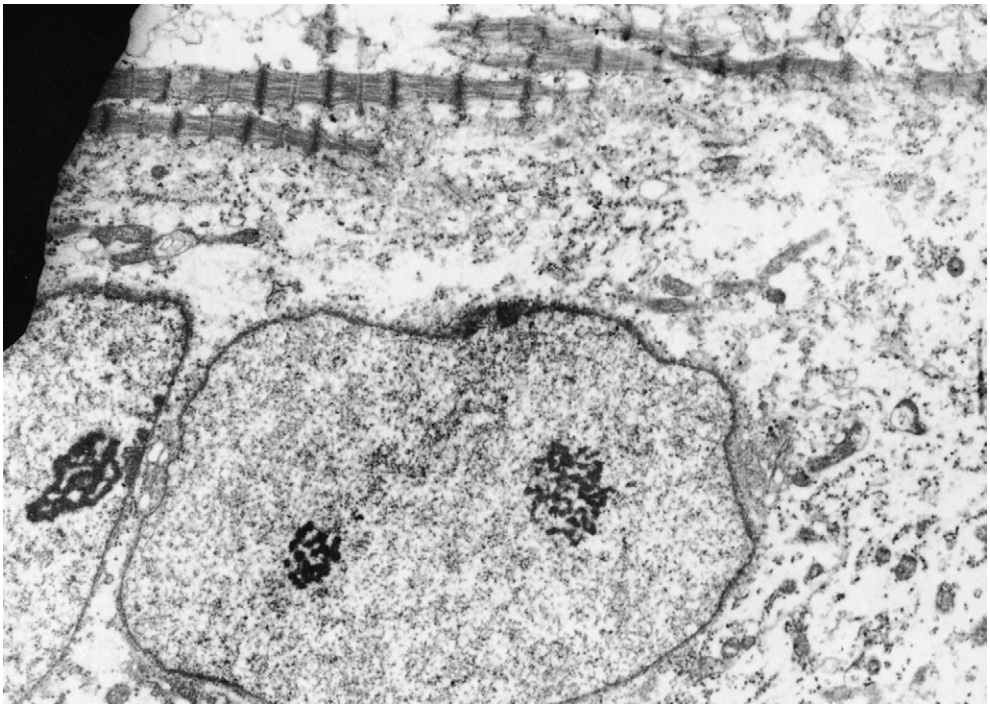

Figure 175-8 Myotube in the quadriceps femoris muscle of a 14-week human fetus. Nuclei exhibit finely dispersed chromatin and strands of ribonucleoprotein-forming nucleoli. Newly formed sarcomeres of contractile proteins are seen at the *top* of the figure. The sarcoplasmic core contains many mitochondria. (Electron micrograph, uranyl acetate and lead citrate, original magnification ×10,000.)

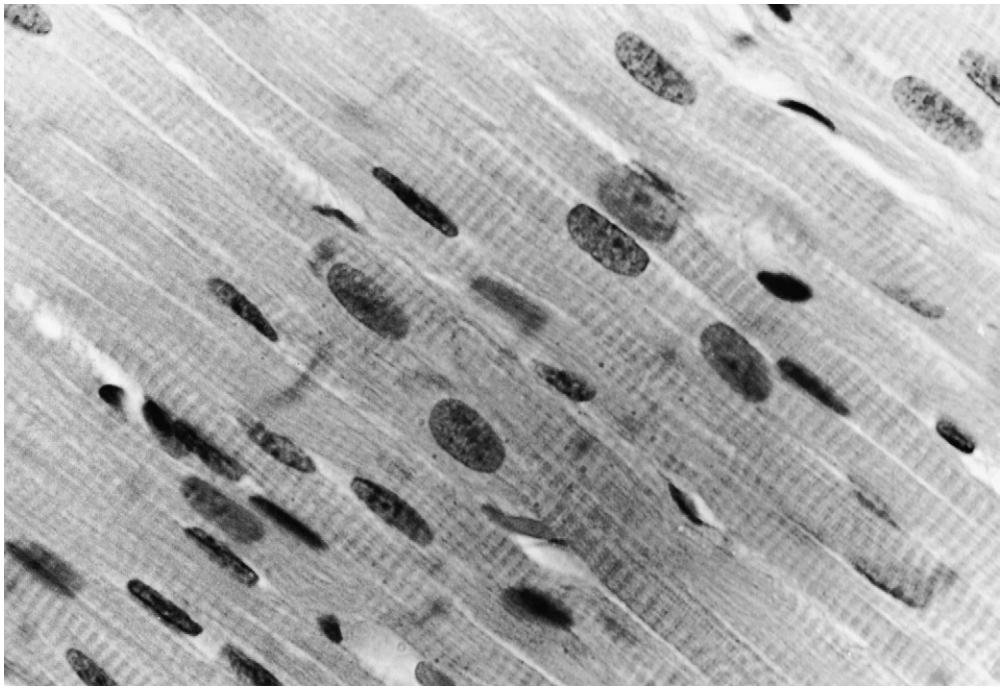

Figure 175-9 Longitudinal section of the quadriceps femoris muscle from a term neonate. Many sarcolemmal nuclei retain the ovoid, vesicular appearance of the immature myofiber, but others are elongated and hyperchromatic, characteristic of mature myocytes. (Hematoxylin-eosin, original magnification ×1000.)

occur simultaneously within the same muscle, and contiguous as well as widely spaced nuclei occur within different segments along the same myofiber. Closely spaced nuclei are generally more characteristic of early myotubes than of late myotubes. Intranuclear lamin A/C is expressed in differentiating myoblasts.[123] Lamin A/C, lamin B1, and emerin are defective in certain hereditary myopathies, highlighting the importance of myonuclear membrane proteins, as well as sarcolemmal plasma membranes, in the integrity of normal muscle development and maintenance.

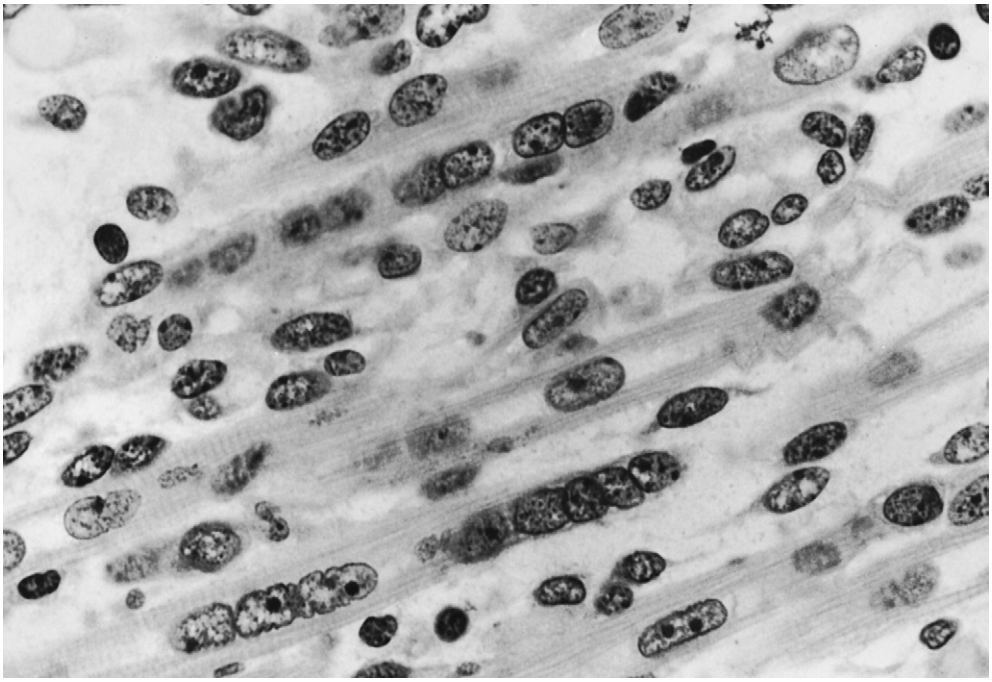

Figure 175-10 Myotubes in the quadriceps femoris muscle of a 12-week human fetus. The spacing of central nuclei is variable. Rows of closely spaced, contiguous nuclei without intervening sarcoplasm are seen, or segments of internuclear sarcoplasm, often several nuclear diameters in length, are found. (Hematoxylin-eosin, original magnification ×1000.)

Sarcoplasmic Organelles

The abundant sarcoplasm (i.e., cytoplasm) within the core of the myotube between and around nuclei contains membranous organelles. These are mitochondria with well-formed cristae, Golgi apparatus generally at the end of a nucleus, and single-membrane vesicles. Most vesicles have dense cores and probably are lysosomes. Notably lacking from the core of sarcoplasm in myotubes are transverse tubules and sarcoplasmic reticulum (SR) (i.e., endoplasmic reticulum), including their diads and triads that are so common in the intermyofibrillar sarcoplasm of more mature myocytes. Mitochondria are almost the only organelles found in the subsarcolemmal sarcoplasma of myotubes. The septae of sarcoplasm that separate the myofibrils of myotubes contain few organelles, unlike the intermyofibrillar sarcoplasm of mature myofibers, although mitochondria may already begin to redistribute themselves between myofibrils of late myotubes.[83]

Glycogen

Free glycogen particles are numerous in the central core of sarcoplasm and in the subsarcolemmal region of myotubes but are less concentrated between myofibrils. In older fetuses (after 30 weeks gestation) and in the first postnatal month, double-membrane vesicles or membranous fragments containing glycogen are commonly seen in the intermyofibrillar sarcoplasm. These vesicles are probably derived from lysosomes. Free glycogen particles are notably lacking from the regions of vesicle-enclosed glycogen.[78]

Contractile Myofilaments

In the myoblast, randomly oriented thin and thick myofilaments occur sparsely in the cytoplasm without parallel alignment or evidence of even rudimentary sarcomere formation. Z-band material is not condensed. The early myotube shows poorly aligned thin myofilaments in the periphery of the cytoplasm, near the inner cell membrane; clusters of thick myofilaments with their associated ribosomes are in close proximity.[78] Lattice formation involving alternating thick and thin filaments in a hexagonal array and Z-bands become evident with the synthesis of even a small number of myofilaments. Haphazardly oriented thin filaments are peripheral to the lattice structure, suggesting their assembly even as new myosin filaments are synthesized. However, filament assembly and lattice formation may not depend on the presence of Z-band material because clusters of thin and thick filaments without associated Z-material are commonly encountered. The Z-bands that are seen always show fine filaments extending in either direction, and the earliest appearance of Z-bands is consistently observed in foci of thin filament formation.[78] Z-material may form when thick myofilaments are either present or lacking, and it appears to be unrelated to myosin.

Thick filaments are synthesized in different sites of the early myotube cytoplasm than are thin filaments. Although thin filaments first appear in the periphery of the cytoplasm, thick filaments appear nearer the central core of sarcoplasm. Thin filaments also appear earlier than thick filaments.[124] Ribosomes are attached along the thick filaments but decrease in number as these myosin filaments are incorporated into the lattice structure of the sarcomere.

As more thin and thick myofilaments are assembled into a lattice structure, and repeating sarcomeres form as the myotube lengthens, the contractile filaments form a denser tubular structure enclosing the core of sarcoplasm and central nuclei (Figure 175-11). The wall of this tube of contractile filaments thickens, and the diameter of the myotube increases. Progressive conversion of the myotube to a mature myofiber involves continued synthesis and arrangement of myofilaments, encroachment on the central sarcoplasmic core, and squeezing of the sarcoplasm between groups of myofilaments as the septa that isolate groups of myofilament lattices from adjacent groups. In addition, the central nuclei "migrate" between the forming myofibrils to the subsarcolemmal position that they occupy in the mature myofiber.

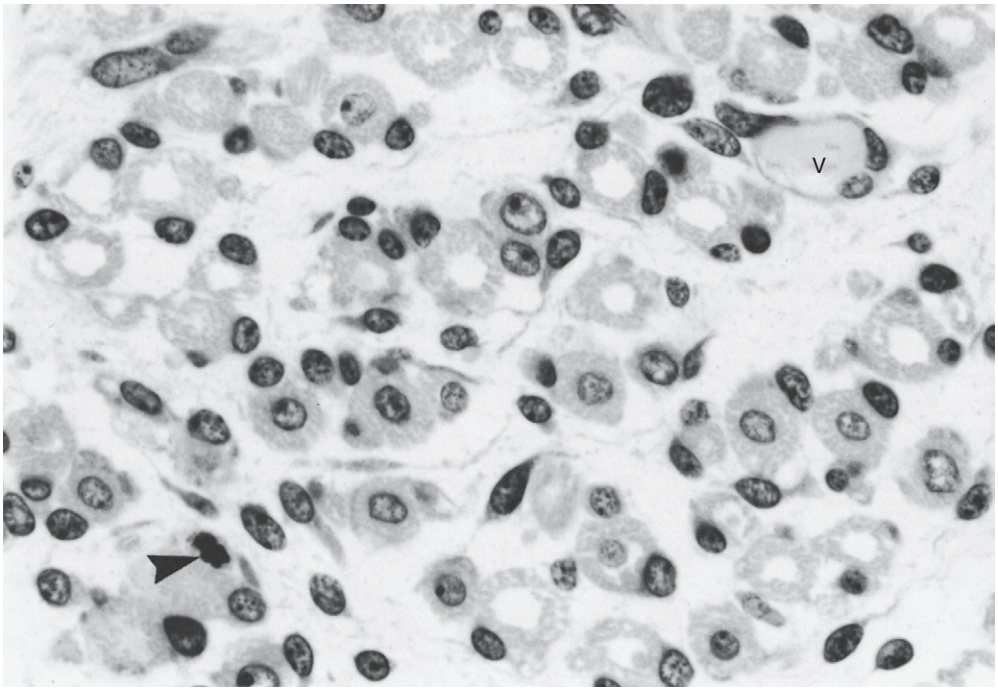

Figure 175-11 Transverse section of the quadriceps femoris muscle in a 12-week human fetus. Late myotubes are a thick cylinder of myofibrils, surrounding central nuclei and the central core of sarcoplasm, seen as a clear space at levels between nuclei. Early myotubes have much thinner cylinders of myofibrils. The peripheral nuclei associated with some myotubes are myoblasts or presumptive myoblasts; one of the latter is undergoing mitosis *(arrowhead)*. Blood vessels *(V)* are a thin endothelium without smooth muscular walls. (Hematoxylin-eosin, original magnification ×1000.)

Growth of the myofiber near term and after birth involves mostly a continued synthesis of contractile proteins and an increased number of myofibrils, associated with a corresponding increase in the amount of sarcoplasm and organelles, as well as the addition of more sarcomeres as the muscle grows in length.

Intermediate Filaments

Intermediate filaments are fibrous cytoskeletal polymers intermediate in size between 6-nm actin filaments and 23-nm microtubules that form the structural framework of nearly all eukaryotic cells. These scaffold proteins anchor cells against mechanical stress and function as bridges between linkage proteins and other cytoskeletal components.[124,125] Perinuclear regions of myotubes characteristically include nonoriented filaments, intermediate in diameter to thick 15-nm and thin 8-nm contractile filaments and measuring 10 to 12 nm.[78,82] Muscle intermediate filaments also are found distal to regions of sarcomere formation. These intermediate filaments are cytoskeletal proteins that help maintain the positions of nuclei and organelles in all cells and help organize the alignment of contractile elements but are not contractile themselves. They may be important in determining the polarity of the early myotube.

Intermediate filament proteins have specific immunoreactivity in differentiating cells and mature cells of various types. The development of intermediate filaments has been less studied in muscle than in the nervous system, and most studies have focused on maturing muscle in tissue culture rather than on animal or human fetuses in vivo. Vimentin is largely a transitory fetal intermediate protein that disappears from most cells with maturation. In the fetal central nervous system, vimentin is demonstrated in primitive neuroectodermal cells but is replaced by either neurofilament protein or glial fibrillary acidic protein in cells differentiating along neuronal or glial lines, respectively. Vimentin is prominent in myoblasts,[126-129] and some investigators find that it disappears after myoblast fusion.[128] It continues to be expressed in fetal myotubes and has stronger immunoreactivity in late myotubes than in early myotubes (Figure 175-12), but it is not demonstrated in mature striated muscle (see Figure 175-12). However, even in adult life it persists in smooth muscle cells, including the muscular walls of blood vessels.

Another important muscular intermediate filament, desmin, is responsible for maintaining the register of Z-bands between adjacent myofibrils by forming links between Z-bands.[130] Desmin is thus the third protein, in addition to actinin and actin, to be localized at the Z-band with use of immunocytochemical techniques. Desmin synthesis is initiated at the time of myoblast fusion and is prominent in fetal myotubes, especially late myotubes (Figure 175-13, *A*), having the same distribution as vimentin.[126,127] Early myotubes contain three times as much desmin as vimentin,[129] but this is difficult to demonstrate in mature muscle by immunocytologic reaction (see Figure 175-13, *B*). Desmin filaments begin to redistribute transversely at the time of sarcomere formation.[128] Nevertheless, desmin is still demonstrated in adult muscle by electrophoretic and special immunologic methods.[127-133] The sparse strands of desmin in adult muscle connect myofibrils at the level of the Z-bands to adjacent sarcolemma, mitochondria, and nuclei to maintain the relative positions of these structures, but they do not attach to the T-tubule systems.[133] Desmin also is associated with the neuromuscular junction site.[134] Immunocytochemical analysis demonstrates both vimentin and desmin in human striated muscle fibers until approximately 36 weeks gestation, although neither is as strongly expressed as in myotubes.[135] In the term neonate, vimentin is not normally demonstrable in myofibers but is prominent in the endothelial cells of blood vessels. Desmin shows only trace or no immunoreactivity in myofibers unless incubated with highly concentrated antibodies (1:50 dilution used for tumors is not appropriate; 1:1200 dilution should be employed).[136] As with vimentin, desmin continues to be strongly expressed by immunocytochemical methods in mature smooth

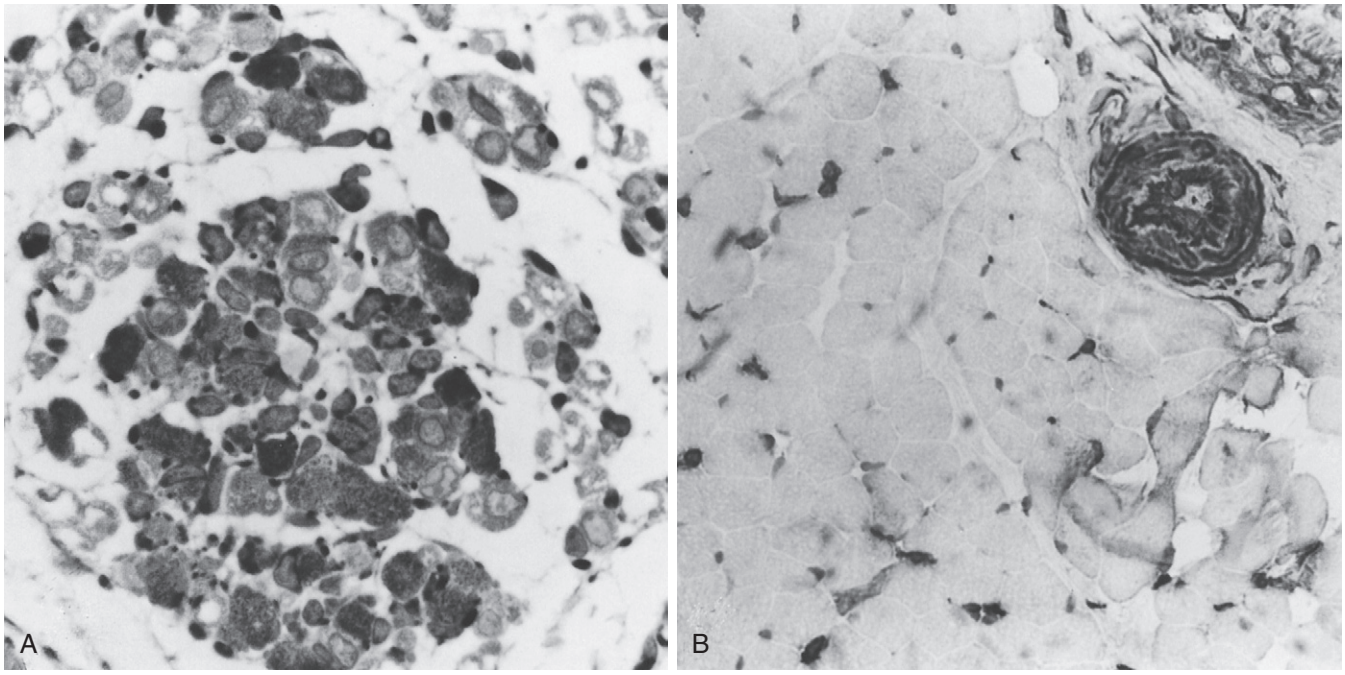

Figure 175-12 Vimentin, a transient intermediate filament protein, is strong in fetal myotubes (dark-staining immunoreactive product), particularly late myotubes, but is no longer seen in striated myofibers of the term neonate, although it is still strongly reactive in smooth muscle of vascular walls and also in endothelial cells. **A,** 14-week fetus. **B,** Term neonate. (1:200 dilution; original magnification ×1000.)

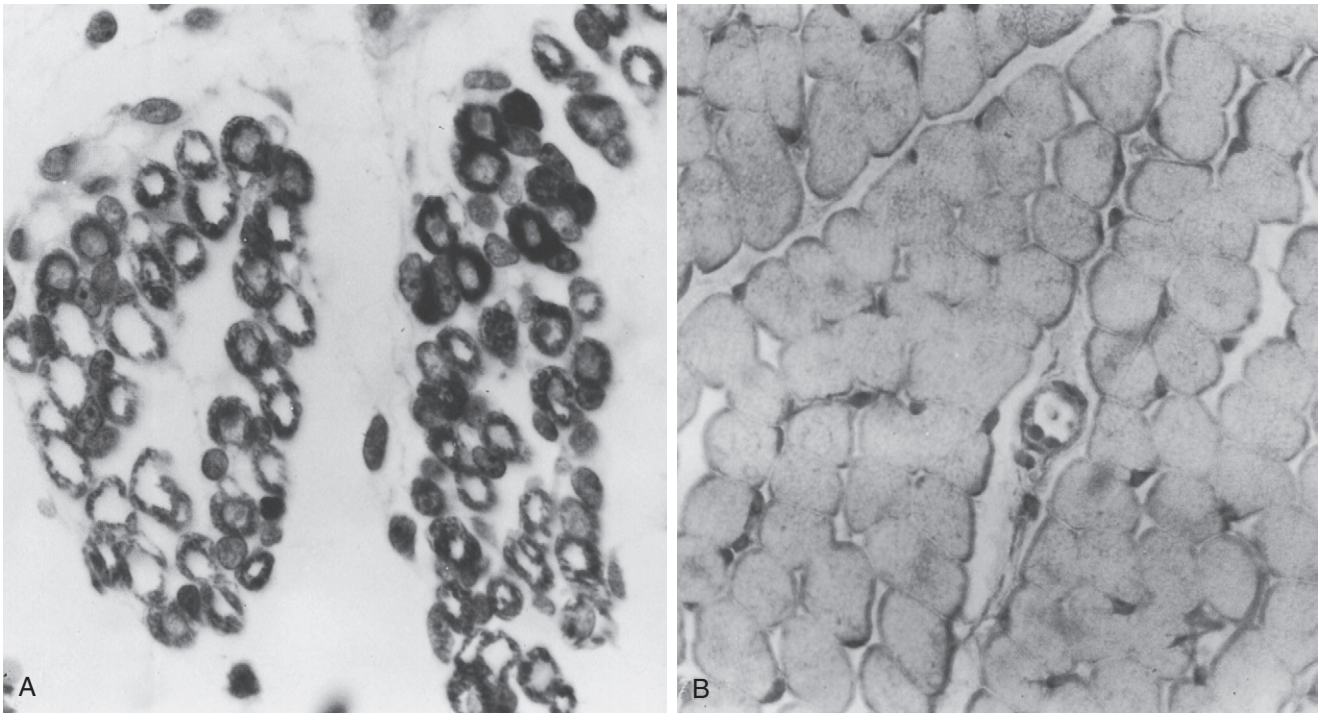

Figure 175-13 Desmin (dark-staining product) is abundant in myotubes and has the same distribution as vimentin. It is no longer demonstrated by immunoreactivity in term neonatal muscle, although it persists in small amounts to maintain the registry of adjacent Z-bands. **A,** 14-week fetus. **B,** Term neonate. (1:800 dilution; original magnification ×1000.)

muscle cells, in which these intermediate filaments appear to be associated with the plasma membrane but are not connected to either the actin or myosin filaments.[137] Desmin is closely associated with α-B-crystallin and is augmented in certain human myopathies in a general category as "myofibrillar myopathies."[138]

Microtubules

Microtubules that are approximately 25 nm in diameter are characteristic in regions of myofilament synthesis and early assembly, but they are lacking in regions of more advanced myofibril

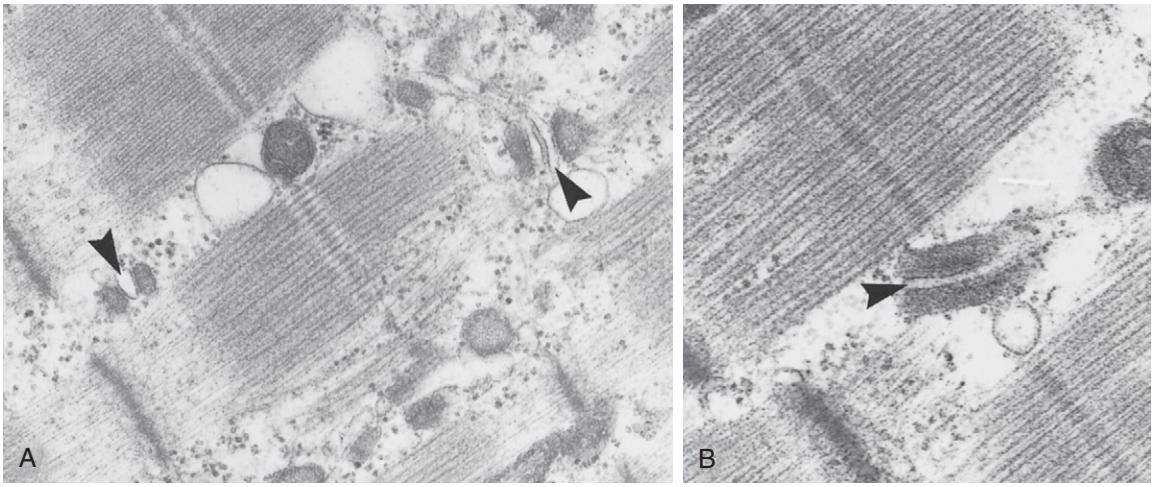

Figure 175-14 Triad formation in term neonatal muscle. The triads *(arrowheads)* are formed by a T-tubule with a pair of dilated terminal cisternae of sarcoplasmic reticulum. They generally occur at or near the Z-band and are perpendicular to the long axis of the myofiber in the mature state **(A),** although they initially have a more parallel orientation in relation to the myofiber axis **(B)** until approximately 28 weeks gestation. (Electron micrographs, uranyl acetate and lead citrate. **A**, Original magnification ×25,000. **B**, Original magnification ×35,000.)

formation.[78] Their orientation is usually oblique, and they are situated near the ends of developing sarcomeres. A microtubular network is present in both mononucleated myoblasts (in which they radiate from a juxtanuclear center toward the cell periphery) and multinucleated myotubes, in which microtubules are numerous and are arranged in parallel longitudinal orientation.[130,131]

Ribosomes

Ribosomes are abundant in regions of myofilament assembly and sarcomere formation.[82] They may be single and free in the cytoplasm, may occur in clusters as polyribosomes, or may be membrane associated. Ribosomes are structurally related to the formation of thick myosin filaments but not to the formation of thin filaments. Polyribosomes of approximately 15 individual ribosomes are consistently clustered near both ends of the thick filaments, nearest to the I-band, and single ribosomes also occur along the length of the myosin filament.[64] Ribosomes decrease in number and virtually disappear as the sarcomeres form, and they are rare in mature muscle. They reappear in regenerating myofibers at any age. The high RNA content in fetal myotubes and regenerating myofibers of injured mature muscle and the lack of demonstrable RNA in mature normal myocytes are well demonstrated by acridine orange fluorochrome studies.[139]

Sarcotubular System

In myotubes and mature myofibers, the endoplasmic reticulum of less-differentiated myoblasts and presumptive myoblasts is called the SR. Early myotubes exhibit multiple vesicular structures that probably are a primordial stage in the formation of SR. Irregular tubules show branching as the myotube matures, and these tubules are found in regions of cytoplasm containing myofilaments and forming sarcomeres. Numerous Z-bands are in continuity with the SR, but this is not a constant feature. Some studies suggest that the SR tubules completely encircle the Z-band,[83] but my observations agree with those of Tomanek and Colling-Saltin[78] that this is an inconsistent feature. The SR does not appear essential in the assembly of myofilaments; however, the alignment of Z-bands in register with those of adjacent myofibrils, a late development after 30 weeks gestation, may be a function of SR tubules associated with Z-bands.[78] The SR of both developing and mature myocytes is mostly smooth, without attached ribosomes. Short segments of rough endoplasmic reticulum are also encountered in myotubes but not in mature myofibers.

The T-system develops by invaginations of the sarcolemma (i.e., cell membrane) of the myotube in cultured chick embryonic muscle.[140] Observations of human fetal muscle suggest a similar process of T-tubule formation.[78] Diads, a close association of an SR tubule and a T-tubule, and triads, a T-tubule between a pair of dilated terminal cisternae of SR, are seen only in the periphery of myotubes, often associated with the sarcolemmal membrane[78,140-142] (Figure 175-14). Diads and triads occur in deeper regions of the myofiber only after sarcoplasmic septa separate the myofibrils as the central core of cytoplasm becomes dispersed with advanced maturation of the myotube. Membranes of SR and T-tubules first become apposed with no visible structure between them; tenuous connections next traverse the space between apposed membranes, and well-developed bridges finally form.[142] Cisternae of the SR expand to form their characteristic structure after contacting T-tubules.[140] SR cisternae contain electron-dense material that consists of mucopolysaccharides or glycoproteins to provide sites for calcium binding.

The observation that during early fetal development SR cisternae seldom show connections to other SR components suggests either that they develop independently or that they form on short fragments of SR that eventually unite with other SR tubules.[78] Triads have a predominantly longitudinal orientation relative to the long axis of the myofiber until approximately 28 weeks gestation, after which time they rotate to the mature transverse orientation (see Figure 175-14).[140-143]

Spherical vesicles with bristles on their outer surface in the periphery of the myotube are probably components of SR terminal cisternae rather than T-tubules because they also are found in satellite cells. Presumptive myoblasts of fetal muscle and satellite cells of mature muscle possess an extensive endoplasmic reticulum, but T-tubules are not evident and do not appear until the myotubular stage of development.[78]

Mitochondria

The mitochondria of striated muscle are similar to those in other types of cells but generally larger than in most cells and are very numerous because of the need to continuously generate energy.

In the myotube, mitochondria are located in the central core of the myofiber between the row of central nuclei. With reorganization of the fiber after 15 weeks gestation and relocation of the nuclei to the subsarcolemmal region, mitochondria become redistributed into the intermyofibrillar sarcoplasm throughout the fiber and in the subsarcolemmal region. They become particularly numerous and tightly clustered in the regions of motor end plates. Little difference is seen ultrastructurally between the cristae of mitochondria in immature and mature muscle. Because muscle is such a rich source of mitochondria, muscle biopsy often is performed as the tissue of choice for the study of mitochondrial histochemical and ultrastructural features, for biochemical assay of respiratory chain enzymes, and for the study of mitochondrial DNA in suspected systemic mitochondrial diseases.

PHYSIOLOGIC CELL DEATH OF MYOTUBES

Degenerating myotubes occur singly or in small groups among normal myotubes in fetuses of 10 to 14 weeks gestation.[144-146] Mononuclear phagocytic cells may be numerous around degenerating myocytes. Electron microscopy reveals nonartifactual extensive necrotic and degenerative changes in both nuclei and sarcoplasm, loss of cell membranes, amorphous condensation of myofibrils, and extrusion of cellular contents into the endomysial extracellular space. This process of physiologic cell death is similar to that observed in the central nervous system and other body systems. An even earlier phase of apoptosis occurs among myoblasts still in the somitic myotome, before migrating into the sites of axial and appendicular muscles.[11]

GROWTH OF MYOFIBERS

The size of an individual muscle is determined by the number and size of its constituent myofibers and also by the amount of connective tissue that forms septa separating fascicles (i.e., perimysium). The diameter of individual muscle fibers is affected by many factors, including age, nutrition, exercise, and the effects of hormones, drugs, and disease. However, the number of muscle fibers in a particular muscle is relatively constant after birth and is genetically programmed.[147,148] A few studies have suggested a postnatal increase in total myofibers of particular muscles such as those of mastication.[147] Protein-calorie malnutrition during fetal development may alter the final number of muscle fibers in animals,[149] but this phenomenon has not been adequately studied in human infants who have had intrauterine growth restriction or who are born to undernourished mothers. In contrast, the ratios of histochemical fiber types within the muscle are under neural control and are altered in either fetal or adult life by abnormal innervation patterns (see later). The average cross-sectional diameter of muscle fibers in the term neonate is 15 μm; the adult mean diameter of 65 μm is achieved at approximately 13 years of age. A standard curve plotted in 1969 for quantitative measurement in muscle biopsies of children remains valid and widely used by pathologists.[150]

Between 9 and 16 weeks gestation in the human embryo, myotubes contain approximately 35 myofibrils in a transverse section of the tube of contractile filaments. Mature muscle fibers each contain approximately 80 to 110 myofibrils in transverse section. Initially, myotubes are larger in cross-sectional diameter than other myofibers, but the situation is later reversed; as myotubes lengthen, their diameter actually decreases. Although the ratio of myotubes to maturing myofibers reverses, hypertrophy of individual myofibers replaces hyperplasia (i.e., increased number of myofibers) as the principal factor contributing to the total increase in the transverse area of the whole muscle.

Myofibril number is not related to myotube size, although it does increase at a declining rate. The total proliferation in number of sarcolemmal nuclei with longitudinal growth of the myofiber is accomplished by mitosis of presumptive myoblasts and their conversion to true myoblasts, rather than by proliferation of existing sarcolemmal nuclei, because the latter are incapable of mitosis. This process slows in late gestation.[146]

Between 20 and 24 weeks gestation, approximately 10% of total myofibers in a cross-sectional field are noted to be approximately twice as large as the remaining 90%. These hypertrophic fibers are scattered uniformly throughout the fascicles and are never grouped. They were first identified by Wohlfart in 1937 and were designated by him as b-fibers; the majority population of smaller fibers were termed a-fibers,[151] a terminology still used. The Wohlfart b-fibers were also later shown to be distinguishable from the a-fibers (see later) by histochemical reactivity. Between 24 and 30 weeks gestation, as histochemical differentiation proceeds, the Wohlfart a-fibers increase in diameter to achieve the same size as the b-fibers that do not grow as fast, until the two populations of myofibers can no longer be distinguished by size after 30 weeks.

Growth of myofibers during late gestation is mainly in length rather than diameter, but the latter accelerates in the postnatal period. Some increase in the number of myofibers in late gestation and after birth may occur because of longitudinal splitting; an explanation of this splitting down the middle of the growing myofiber is that, when a fiber achieves a critical size, the oblique pull of peripheral actin filaments is strong enough to cause the Z-band to rupture.[152] After birth, linear growth of skeletal myofibers is greatest in the first 2 years and is accomplished mainly by adding sarcomeres rather than by extending the distance between Z-bands.

METABOLIC DIFFERENTIATION OF MYOFIBERS

After nearly all fetal myotubes have become myocytes with peripheral sarcolemmal nuclei and an intermyofibrillar distribution of sarcoplasm and organelles, the next major maturational development is the differentiation of the uniform population of myofibers into a heterogeneous population of two distinct metabolic types and at least one subtype. Neural influence is first expressed in muscle maturation in the further growth and morphologic reorganization of myotubes and plays no role in the fusion of myoblasts to become myotubes. However, the expression of metabolic differences between muscle fibers is strongly controlled by innervation, and myofibers retain the capacity to change metabolic type with changes in innervation, as with denervation-reinnervation of muscle. This mutability is retained in human striated muscle not only during fetal life and infancy but also in the adult.

Metabolic differences between myofibers are expressed as relative differences in various enzymatic activities of the oxidative and glycolytic pathways, differences in calcium-mediated myofibrillar adenosine triphosphatase (ATPase) isozymes that are expressed maximally at various pH ranges, in heavy-chain myosin, and in relative numbers or concentrations of mitochondria, lipid droplets, and glycogen particles within the sarcoplasm. These features are well demonstrated in frozen tissue section by histochemical methods and, more recently, by immunocytochemical reactivity for heavy-chain myosin that distinguishes fiber types in formalin-fixed, paraffin-embedded sections.[153]

The period of histochemical differentiation is between 20 and 30 weeks gestation in humans, but some differences among myofibers in their metabolic profiles may be seen as early as 18 weeks. Before that time, all myofibers appear histochemically uniform with all enzymatic stains; with use of myofibrillar ATPase stains, they correspond to IIc fibers, which are considered the least differentiated subtype in mature muscle.

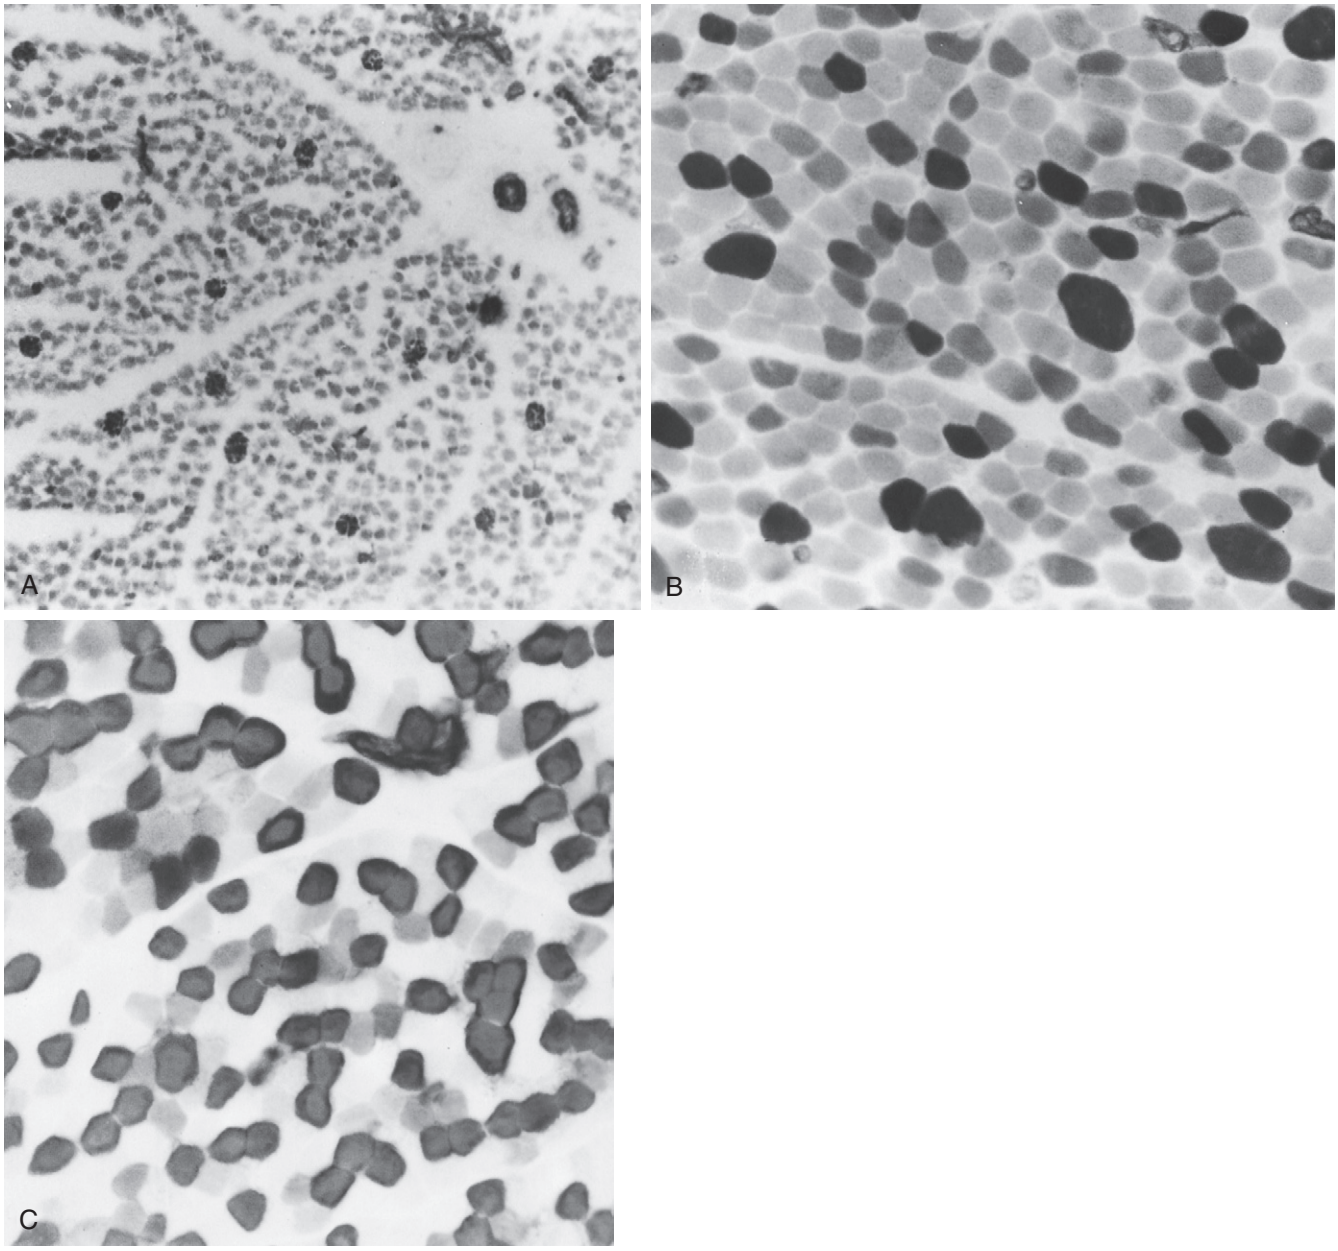

Figure 175-15 Myofibrillar ATPase stain, preincubated at pH 4.3, in human fetuses at 24 weeks gestation **(A),** 27 weeks gestation **(B),** and 40 weeks gestation (term) **(C).** In the early histochemical stage of development **(A),** approximately 10% of myofibers become larger than the others, are scattered in distribution and never grouped, and react as type I fibers, the "Wohlfart b-fibers." As maturation proceeds, more type II fibers become converted to type I **(B),** until a relatively equal number of the two types exist at term **(C).** Still a greater proportion of subtype IIc fibers (intermediate intensity of staining) exist at birth than in the adult. (Original magnification ×250.)

The early phase of histochemical differentiation, generally 20 to 24 weeks, coincides with the appearance of Wohlfart b-fibers, the 10% of total myofibers that are larger than the rest and that are scattered evenly throughout the fascicles without being grouped.[151,154] These Wohlfart b-fibers are uniformly type I (i.e., strong ATPase activity at acid pH of preincubation, strong oxidative enzymatic activity and weaker glycolytic activity, less glycogen than type II); the 90% remaining Wohlfart a-fibers react histochemically as type II (i.e., strongest ATPase activity at alkaline pH of preincubation, weaker oxidative and stronger glycolytic enzymatic activity, and more glycogen than type I) and correspond almost exclusively to subtype IIc of mature muscle (Figure 175-15).

As maturation proceeds, and especially during the later phase of histochemical differentiation from 24 to 30 weeks gestation, progressive conversion of many type II fibers (Wohlfart a-fibers) to type I fibers occurs; *however,* growth of the population of smaller fibers at a greater rate than growth of the Wohlfart b-fibers obliterates the distinction of these populations by either size or their reactivity as type I. By 30 weeks gestation, most muscles of the human body have relatively equal numbers of types I and II myofibers, and they are distributed in a mosaic or checkerboard pattern without large groups of either type, although small groups of three to five fibers of the same type may occur. Type II fibers may predominate in the single line of myofibers along the edges of fascicles.

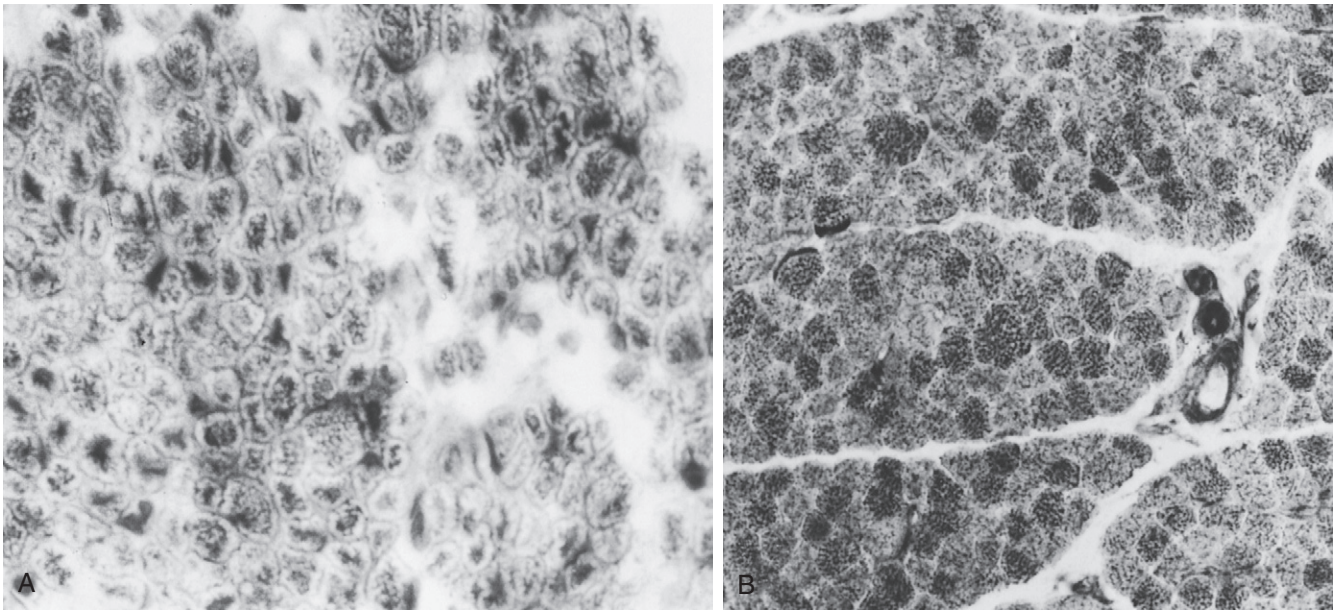

Figure 175-16 A, Oxidative enzymatic (mitochondrial) activity has a characteristic histochemical distribution in myotubes: intense staining confined to the central core of sarcoplasm and a thin rim in the subsarcolemmal region, the cylinder of myofibrils remaining unstained. Fiber types cannot be distinguished. **B,** In term neonatal muscle, the oxidative enzymatic activity is now redistributed uniformly in the intermyofibrillar sarcoplasm. Dark points of activity are mitochondria. The darker-staining fibers are type I, and the lighter-stained fibers are type II, as in the adult. (Nicotinamide adenine dinucleotide, tetrazolium reductase [NADH-TR]: **A**, original magnification ×1000; **B,** original magnification ×250.)

During the later period of histochemical differentiation (after 30 weeks gestation), type II fibers become distinguished by myofibrillar ATPase stains as subtypes defined by their degree of inhibition of reaction at varying pH of preincubation.[154] Thus, at high pH, such as 9.8 or 10.4, all type II fibers are uniformly stained darker than type I fibers. At pH 4.6 or 4.7, type I fibers are dark, whereas some type II fibers are intermediate in intensity and others are totally inhibited and unstained. The inhibited fibers are designated IIa, and the intermediate fibers are designated IIb and IIc. At a still lower pH of preincubation (4.3), IIa fibers remain completely inhibited, IIb fibers are either totally inhibited or very light, and IIc fibers are intermediate—darker than IIb fibers but not as dark as type I fibers. At maturity, approximately 65% of total type II fibers are designated IIa, 30% are designated IIb, and only 5% are designated IIc. In the term neonate, however, 15% to 20% of type II fibers are IIc or "undifferentiated" fibers (see Figure 175-15).[154-156] Differentiation of the soleus muscle, with a higher percentage of type I fibers, is not complete until 9 to 12 months of age in the human infant and is accompanied by slowing of contractile properties that correspond to the functional use of this muscle as the infant stands more and prepares to walk.[156]

The oxidative enzymatic activity of the mitochondria and SR has a characteristic histochemical distribution with use of stains of the electron transport chain (e.g., nicotine adenine dinucleotide [reduced form]–tetrazolium reductase) and of the tricarboxylic acid (Krebs) cycle (e.g., succinate dehydrogenase, malate dehydrogenase, isocitrate dehydrogenase). In myotubes, the activity follows the distribution of mitochondria and is seen only in the central core of sarcoplasm and in the subsarcolemmal region (Figure 175-16, *A*). As the myofiber matures, the mitochondria become redistributed in the intermyofibrillar sarcoplasm. Therefore type I fibers, which have more mitochondria than type II fibers, appear darker (see Figure 175-16, *B*). Oxidative enzymatic stains used to be regarded only in relative ratio of activity to glycolytic enzyme stains, but it is now recognized that each is a marker for the specific mitochondrial respiratory chain complexes, and they have assumed an even greater value in interpreting some muscle biopsy results, as well as in developmental studies of muscle.

Myophosphorylase activity also may be histochemically demonstrated in unfixed frozen sections of striated muscle. A fetal form of myophosphorylase is replaced by the mature form of the enzyme after birth. In addition to myophosphorylase, phosphofructokinase and other enzymes of the glycolytic Embden-Meyerhof pathway may also be demonstrated in fetal muscle as early as the late myotubular stage. Distinction between histochemical fiber types is not evident until after 24 weeks gestation, however. The myogenic genes may also play a role in muscle fiber–type differentiation, even though this phase of ontogenesis is considerably later than the primary period of expression of these genes. In transgenic mice, myogenin induces, or at least accompanies, a shift from glycolytic (type II fibers) to oxidative (type I fibers) metabolism.[157,158] With aging in adult life, changes in levels of expression of *myogenin* and *MyoD* proteins in muscle also occur.[159]

FASCICULAR ORGANIZATION OF DEVELOPING MUSCLE

As the paired longitudinal somitic plates on either side of the neural plate begin to segment into somites, the space between somites contains looser, less densely cellular mesenchyme than the more compact somites. The mesenchymal cells in this looser tissue differentiate into fibroblasts and soon secrete collagen into the intercellular space as the more compact mesenchymal cells of the somites predominantly become myoblasts and primordial dermal cells. During growth of the limb buds, the individual muscles of the extremities are derived from the somites, whereas the collagenous muscle capsules (i.e., epimysium), blood vessels, and tendons are somatopleural derivatives.

Individual muscles consist of loose arrays of presumptive and true myoblasts and differentiating myotubes without the

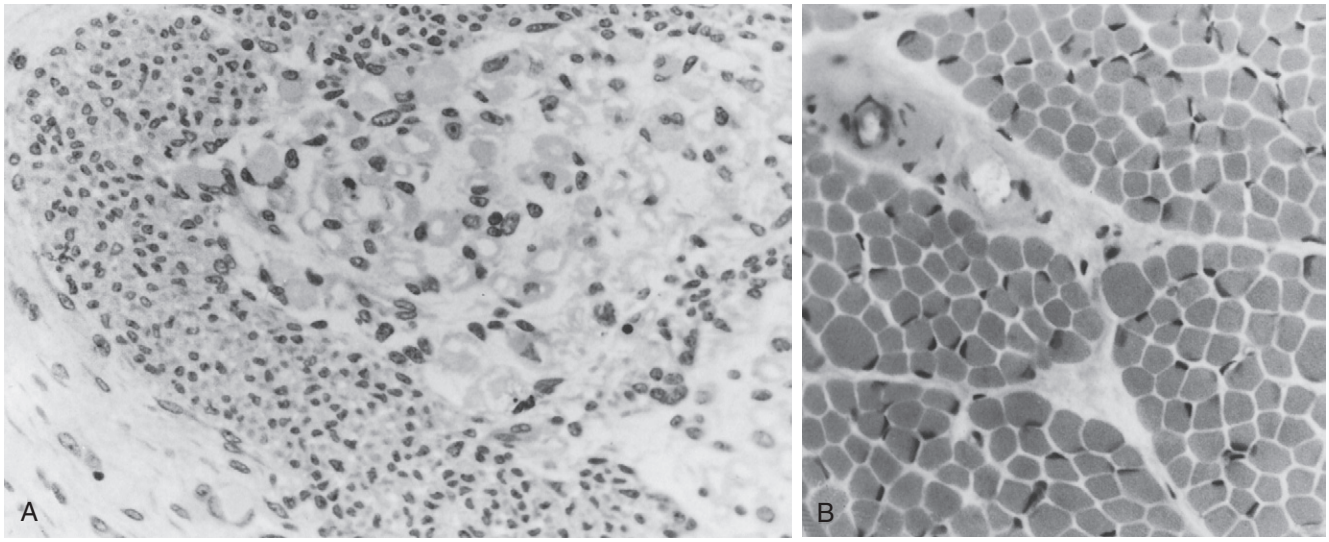

Figure 175-17 A, Soleus muscle of 12-week human fetus. Early myotubes and myoblasts tend to predominate at the periphery, and late myotubes are more frequent in the interior of the muscle. Perimysial connective tissue septa have not yet developed. **B,** Term neonate, quadriceps femoris muscle. The fascicular organization of the muscle is well developed, with a well-defined perimysium that includes arterioles, venules, and intramuscular nerves. (Hematoxylin-eosin; **A,** original magnification ×400; **B,** original magnification ×250.)

connective tissue septa that subdivide more mature muscle into fascicles. During the myotubular stage of myogenesis, myotubes and myoblasts cluster in small groups of three to as many as eight cells, but mostly three to five myotubes, surrounded by a single common basal lamina.[155,160] Single myotubes enclosed within their own individual basal lamina and isolated myoblasts without a basal lamina also appear.[78] Independent myotubes become more numerous in later stages of development, and, by the end of the myotubular stage, clusters of myotubes within a common basal lamina are no longer seen, although single myotubes continue to be closely associated with myoblasts and presumptive myoblasts.[160] Myoblasts and early myotubes tend to predominate at the periphery of the developing muscle, and maturation of the myotubes in the center of the muscle is more advanced (Figure 175-17, *A*).

Fibroblasts also are included within developing muscle and produce delicate reticular and collagen fibers. Thin collagenous septa (i.e., perimysium) divide the muscle into fascicles, particularly in association with the growth of blood vessels. This process begins in the late myotubular stage, occurring mainly as myotubes are converted to myocytes with peripheral nuclei and continuing during the early phase of histochemical differentiation. By 30 weeks gestation, the fascicular organization of muscle is well established. Perimysial connective tissue then thickens and includes all arterioles, venules, and nerves that penetrate the muscle (see Figure 175-17, *B*). Endomysial collagen fibers between individual myofibers within a fascicle are thinner, sparser, and much more delicate in the term neonate than in the older child; the endomysium mainly develops after birth.

Blood vessels within developing muscle are seen as early as 6 weeks gestation in humans. During the myotubular stage of development, vessels consist of delicate channels or sinuses with thin endothelial cells and wide lumina (Figures 175-18 and 175-19). With growth of the perimysium, the feeding vessels develop smooth muscular walls and a thicker endothelium. The capillary network becomes denser as myofibers mature and contraction becomes more forceful. By term, both capillaries and larger arterioles and venules are well developed (see Figure 175-17, *B*).

Several resident inflammatory cells are seen scattered in the perimysium of muscle. At least two distinct populations of macrophages (M1 and M2) have differing roles in necrosis and regeneration in development and in myopathies.[161] Mast cells and scattered T- and B-lymphocytes also are present, even in fetal muscle, and can increase when signaled to do so. In addition, hematogenous arrival of additional inflammatory cells in response to injury occurs.

MUSCLE SPINDLES AND TENDON ORGANS

Intrafusal fibers are already forming during the myotubular stage of development, but they are difficult to recognize histologically because they closely resemble extrafusal fibers at this time. The distinctive connective tissue capsule of the spindle does not form until later.[162-164] Spindles may be readily identified after 20 weeks gestation in humans, and they appear fully mature at 30 weeks, including well-developed nuclear bag and nuclear chain forms of intrafusal fibers (Figure 175-20) with their mature histochemical characteristics.

Because intrafusal fibers enclosed by a delicate collagenous capsule may be recognized as early as 14 weeks gestation in human fetuses, spindles actually begin forming late in the myotubular stages.

In the rat, the earliest detectable spindles in hind limb muscles are seen less than 2 days before birth and consist of a single myotube bearing simple nerve terminals of the large primary afferent axon from nearby unmyelinated intramuscular nerve trunks. The capsule forms by an extension of the perineurium of the supplying nerve fasciculus and is confined initially to the innervated zone.[162-165] Myoblasts are present within the capsule of the spindle throughout its development and fuse to form a smaller and less-differentiated myotube. This myotube matures in close association with the initial fiber, and by birth it has formed the smaller, intermediate nuclear bag fiber identified in the adult. Nuclear chain fibers develop in the same way, but myoblast fusion forms satellite myotubes in apposition to more mature fibers within the same basal lamina. By 4 days after birth, the adult complement of four intramuscular muscle fibers is present. Fusiform innervation begins at birth and is not complete until the 12th postnatal day (rat) when the myofibrillar ultrastructure is fully mature.[164] The periaxial space appears at the same time. The afferent innervation thus precedes the efferent nerve supply

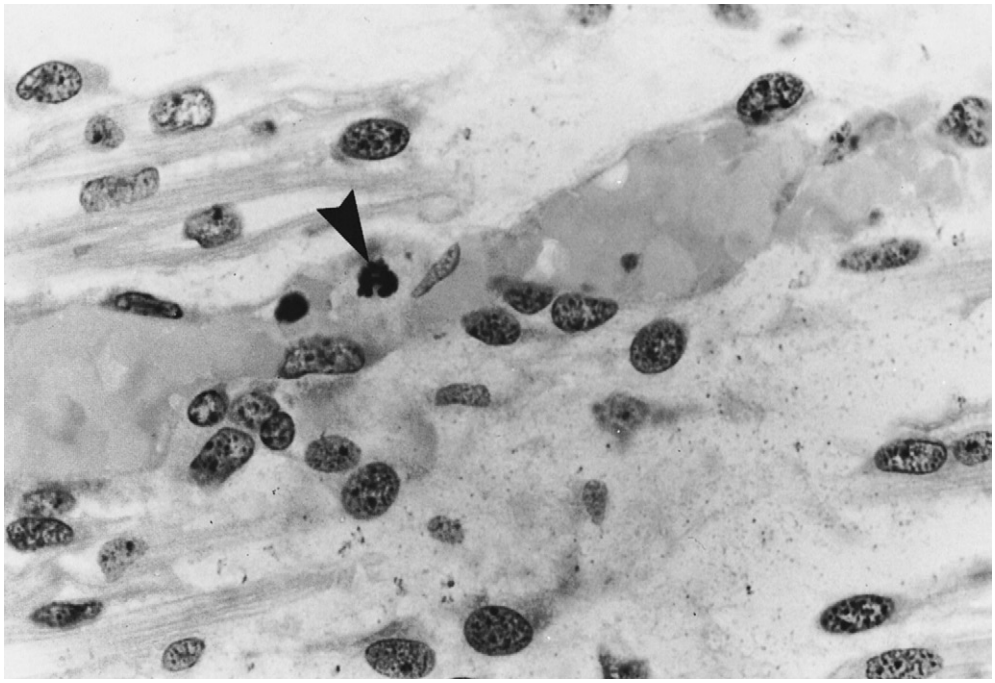

Figure 175-18 Intramuscular blood vessel in quadriceps femoris muscle of a 14-week fetus. The vessel is thin walled, and the lumen is wide and dilated. The mitotic figure *(arrowhead)* may be an endothelial cell or a presumptive myoblast. (Hematoxylin-eosin, original magnification ×1000.)

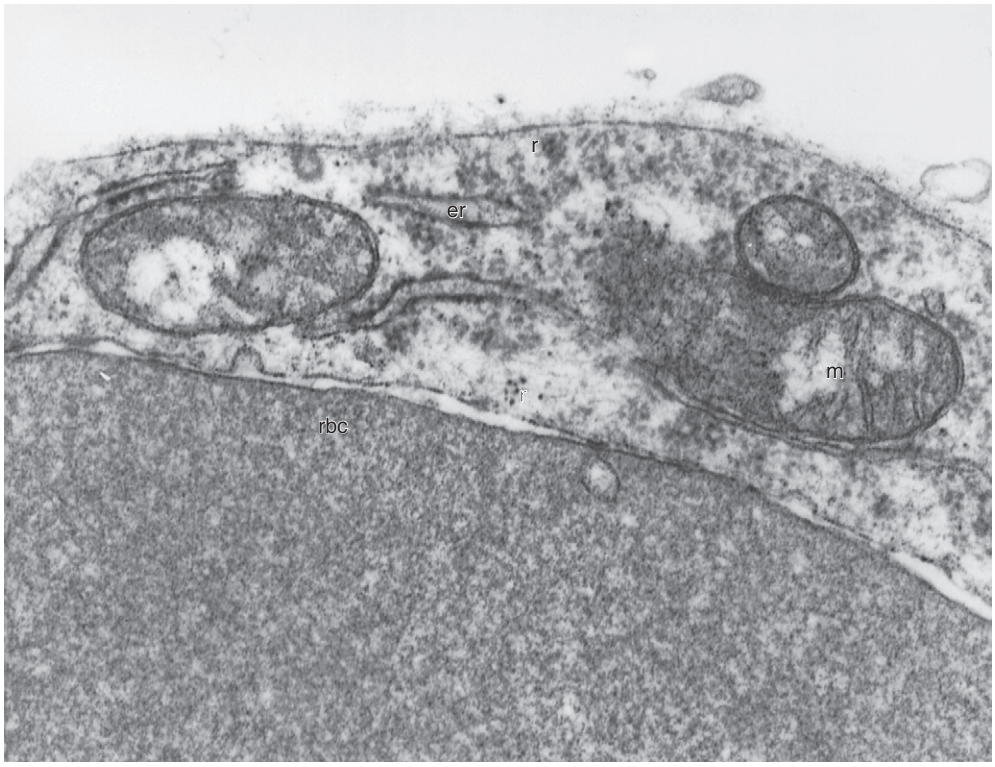

Figure 175-19 Endothelial cell of intramuscular blood vessel of a 14-week fetus. Mitochondria *(m),* rough endoplasmic reticulum *(er),* and free ribosomes *(r)* are seen in the cytoplasm. A red blood cell *(rbc)* is seen in the lumen of the vessel. (Electron micrograph, uranyl acetate and lead citrate, original magnification ×25,000.)

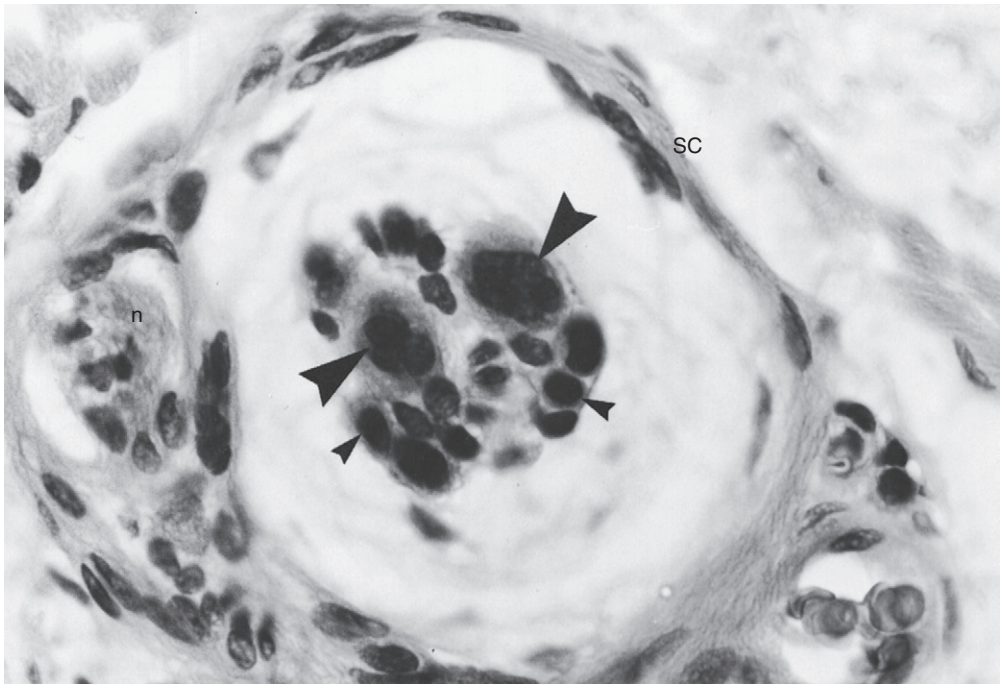

Figure 175-20 Muscle spindle within the quadriceps femoris muscle of a term neonate. Both nuclear bag fibers *(large arrowheads)* and nuclear chain fibers *(small arrowheads)*, as well as the spindle capsule *(SC)* and associated nerve *(n),* are well developed at birth. (Hematoxylin-eosin, original magnification ×1000.)

to the intrafusal spindle fibers. Morphogenesis of the rat muscle spindle is complete at 25 days after birth.[165]

As with the differing morphologic features between extrafusal and intrafusal muscle fibers, mature intrafusal fibers exhibit histochemical characteristics that are unique and do not correspond to the histochemical types of extrafusal fibers.[166-169] These histochemical subpopulations appear somewhat later than the differentiation of fiber types of extrafusal myofibers, with some overlap.

Golgi tendon organs are stretch receptors found between muscle and tendon and less frequently within the tendon itself. They also are distributed in the intermuscular connective tissue and in the capsules of joints. Tendon organs are almost as numerous as muscle spindles, although infrequently seen in muscle biopsy specimens.[170] Because tendon organs lie in series with the main mass of muscle, they are sensitive to any sudden change in muscle length, active or passive, or to a summation of active and passive stretch. Their afferent nerve fibers all belong to group Ib, with widespread central connections that allow for patterned and sequential engagement of synergistic and antagonistic muscles as integrated movements. Golgi tendon organs develop after the myotubular stage and are well formed by 28 weeks gestation. Numerous pacinian corpuscles similar to those of the dermis also occur near the myotendinous junction, mainly within the tendon (Figure 175-21), but they also occur in the perimysium between muscle fascicles at distal ends of muscles.

Unlike extrafusal myofibers that characteristically undergo atrophy and disappear after loss of their motor nerve supply, intrafusal spindle fibers continue to develop normally during the first 3 weeks after deefferentation of immature neonatal rat muscle, but only if their afferent sensory nerve supply and dorsal root ganglia are preserved (even if the spinal cord segment is extirpated). Intrafusal fibers then actually proliferate at 3 to 5 weeks after denervation with the supernumerary fibers forming from the fusion of myoblasts derived from activated intrafusal satellite cells and also from longitudinal splitting of preexisting intrafusal myofibers.[170-174] New intrafusal fibers originate from both nuclear bag and nuclear chain fibers but mainly from the latter.[171] The ratio of myosin heavy chain isoforms is altered under these circumstances.[167,174] The total efferent and afferent denervation of muscle spindles, by contrast, results in atrophy and numeric reduction of intrafusal myofibers.[174,175] In sum, intrafusal muscle fibers are much more dependent on sensory than on motor nerve supply to preserve their integrity, and they proliferate as a delayed response to deefferentation, rather than undergo atrophy.[166]

TENDON DEVELOPMENT

Tendons are dense fibrous bands that attach striated muscles to bones, as either the proximal origin or the distal insertion of the muscle. In *traction tendons*, in which the line of action corresponds to that of the muscle, few blood vessels are uniformly distributed within the tendon tissue. In *gliding tendons*, which change their direction of pull, an avascular zone normally forms in the region where the tendon wraps around the pulley.[176] The angiogenic peptide vascular endothelial growth factor is present in both endothelial cells and tenocytes (a fibroblast derivative) of human fetal tendons exposed to traction, but not in the avascular zone of gliding tendons that are predominantly exposed to compressive and shearing forces. The avascular zone of tendons might be caused by a mechanically induced down-regulation of vascular endothelial growth factor expression.[177] Tendons begin forming at the time of the differentiation of the fascicular organization of muscle. The transitional zone is a mixture of perimysial fibrous bands and myofibers that may show cytoarchitectural differences from the same fibers in the main belly of the muscle and hence can easily be misinterpreted as myopathic findings in muscle biopsy samples taken too near the insertion, as during "heel cord" (Achilles tendon)–lengthening procedures.

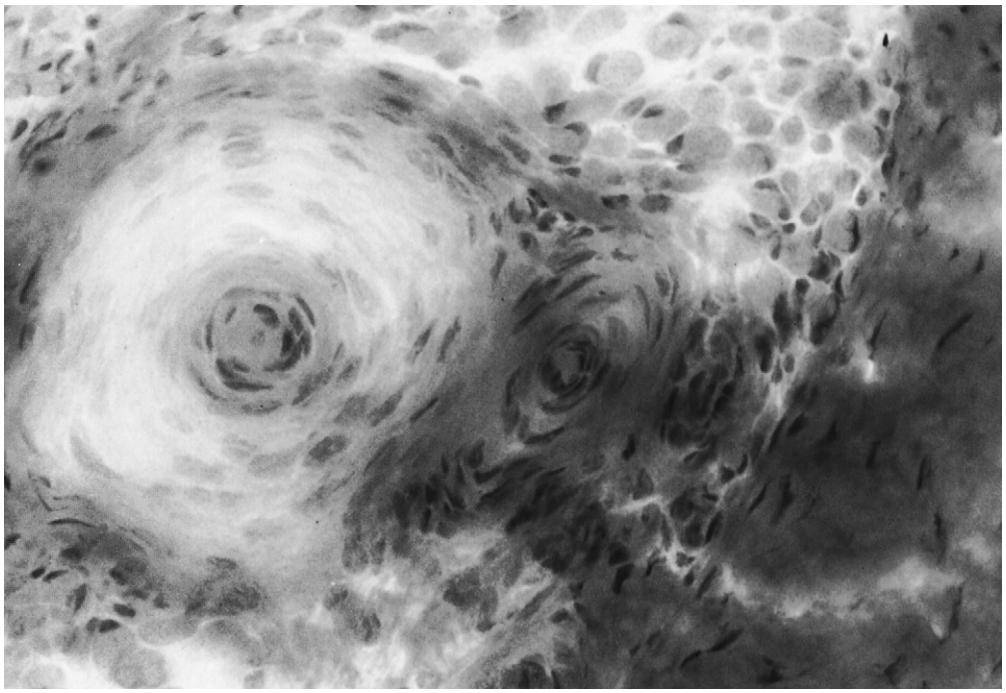

Figure 175-21 Pacinian corpuscle near myotendinous insertion of the quadriceps femoris muscle in a 36-week premature infant. The fibrous epimysial muscle capsule is seen on the *right.* (Gomori trichrome, original magnification ×1000.)

MEMBRANE EXCITABILITY AND INNERVATION OF FETAL MUSCLE

The resting membrane potential of mature muscle, approximately 90 mV, is actively maintained by continuous energy production derived from Na^+,K^+-ATPase (calcium-mediated ATPase and creatine kinase are the energy sources for the contractile mechanism of myofibrils). This energy-generating system for maintaining membrane excitability develops early in myogenesis; even early myotubes already have a continuously polarized membrane. Spontaneous subthreshold potentials may be recorded anywhere along the sarcolemmal membrane, but their site of origin is in the middle of the fiber at the point at which end plates are eventually formed.[177] They resemble the miniature end-plate potentials of adult fibers but occur at a lower frequency and with a slower time course. The plasma membrane of myoblasts also is excitable, although it may easily fatigue. The compound that most strongly and consistently provokes membrane depolarization is acetylcholine (ACh), the transmitter secreted at the neuromuscular junction of mature striated muscle in humans, all vertebrates, and some invertebrates.

ACh receptors are among the first membrane proteins to appear during the development of striated muscle. In the larval amphibian *Xenopus*, functional ACh receptors begin to form within 2 hours after the myotomes begin to appear, which is much earlier than nerve contacts muscle.[178,179] In the rat, peripheral nerves and functional ACh receptors both appear when developing muscle cells are first identified,[180] but functional innervation is not required for the development of ACh receptors, and myoblasts isolated in tissue culture continue to develop them.[181] The expression of ACh receptors in living rat embryos is unaltered after destruction of their motor neurons.[182]

Although innervation is not essential for the initial formation of functional ACh receptors, innervation of muscle leads to a major redistribution of receptors, eventually resulting in their aggregation at the points of nerve contact.[179,182,183] After the concentration of receptors at the synapse point, a decrease occurs in the density of receptors in portions of the sarcolemmal membrane not directly contacted by nerve endings.[179,184,185] The decreased density of ACh receptors is accompanied by a low sensitivity of nonsynaptic membrane to ACh, a characteristic of adult muscle fibers. Aggregates of synaptic junction receptors remain after denervation; removal of the nerve results in a return of high levels of extrajunctional receptors.[186,187]

Innervation of human striated muscle occurs in the middle of the myotubular stage of development, maximally at approximately 11 weeks gestation, but motor end plates begin to form as early as 9 weeks gestation and continue to develop and mature until 20 weeks gestation.[188] The primitive motor end plate contains a few axons always covered by one Schwann cell. It does not change either in number or in structure between 10 and 20 weeks gestation, although continuous modification of the postsynaptic membrane is observed throughout this period.[189] The axon contains a few synaptic vesicles and is in close contact with the unfolded plasma membrane of the primary myotube. The first morphologic change indicative of end-plate formation is seen at the junction of the sarcolemma with the axolemma, the former having a distinct thickening in the small junctional zone. This thickening of the postsynaptic membrane may already be evident when the axon is 20 to 30 nm away from the muscle cell.[189] At the mature myotubular stage, at approximately the 14th week of gestation, synaptic gutters and primary synaptic clefts form. Secondary synaptic clefts are first seen in the 16th week of gestation. The characteristic convolutions of the mature postsynaptic membrane are thus well established by midgestation and are fully mature at birth.

Myotubes initially are innervated from several nerves. The mature single-nerve supply to each myofiber results from retraction of all but one nerve as development proceeds. Fidziańska found several synaptic axonal terminals grouped together and filled with synaptic vesicles at the motor end plate of human fetuses of 10 to 20 weeks gestation; these axonal terminals did not seem to change in either ultrastructural appearance or number during this period and were always covered by a single

Schwann cell.[189] Silver impregnations of nerve fibers also show a single motor end plate on each fetal myofiber supplied by more than one axon.[190] It may be concluded from these data that each developing myofiber has just one end plate but that this end plate is supplied by two or more axons. This conclusion is consistent with other electrophysiologic and morphologic data indicating polyneural innervation of fetal muscle fibers. Scanning electron microscopy of nerve-muscle cultures also confirms that a single embryonic muscle fiber may be contacted by as many as five different nerves arising from different motor neurons.[191] Physiologic cell death of a spinal neuroblast is unrelated to the change from polyneuronal to mononeuronal innervation of muscle,[192] but functional neuromuscular innervation is probably one factor that regulates the natural process of cell death among embryonic motor neurons of the spinal cord, because the number of motor neurons undergoing natural cell death is closely related to muscular activity.[193]

"Myotube satellite cells" with long cytoplasmic processes extending beyond the basal lamina into the endomysial space are seen in developing extraocular muscles. They contact free cells of similar appearance, as well as axon-surrounding Schwann cells, often forming an extensive network. These myotube satellite cells resemble Schwann cells in all respects except for the lack of an associated axon, and they may be Schwann cells disposed to promote axonal growth toward differentiating myofibers not yet innervated.[194]

Spinal motor nerve roots begin their myelination cycle at approximately 16 weeks gestation, and roots and peripheral nerves are well myelinated by late gestation.[195] In the phrenic nerve, one and a half turns of myelin are seen around nerve fibers at 15 weeks gestation[196]; the vagal nerve begins its myelination cycle at approximately 24 weeks gestation in humans[197] and at a corresponding age in fetal lambs.[198] Myelination of axons innervating extraocular muscles is reported by some investigators as early as 18 weeks gestation.[199]

SUPRASEGMENTAL NEURAL INFLUENCES ON MUSCLE MATURATION

The importance of innervation to muscle fiber maturation beyond the myotubular stage is well demonstrated both in vivo and in vitro. Neonatal neurectomy in rats prevents further development of the myocyte.[200] In humans, the effects of perinatal denervation on the morphologic features of muscle are well demonstrated in progressive spinal muscular atrophy, a degenerative motor neuron disease beginning in fetal life and continuing after birth.[201]

Suprasegmental centers in the cerebrum, cerebellum, and brain stem may alter the discharge pattern of motor neurons and change the course of muscle maturation. Classic studies document that excessive nerve stimulation experimentally causes a conversion of type II fibers to type I in the rat,[202,203] and abnormal suprasegmental stimulation of lower motor neurons in the human fetus may have a similar influence on histochemical differentiation.

Histochemical abnormalities in the muscle biopsy specimens from infants with cerebral malformations have been noted by several researchers.[204-207] Similar aberrations in the sizes and ratios of histochemical fiber types occur in the muscles of neonates with congenital contractures after fetal immobilization (i.e., arthrogryposis multiplex congenita).[207] Prospective study of the muscles of infants with various types of cerebral dysgenesis documented by imaging procedures or by postmortem examination demonstrates that three categories of disorders in muscle maturation may be identified: (1) delayed maturation in term infants, the muscle being morphologically normal but incompletely differentiated histochemically; (2) fiber-type predominance of more than 80% of either type I or type II fibers; and (3) the classic "congenital muscle fiber-type disproportion," defined as a predominance and uniform hypoplasia of type I fibers, often with secondary hypertrophy of type II fibers.[208,209]

An equally dramatic finding is the presence of normal and histochemically mature neonatal muscle in infants with normal spinal cords but severely hypoplastic brains, or with such severe dysplasias that few if any descending pathways exist to relay suprasegmental impulses.[208] This finding in the human is supported by observations in the stage 13 or 14 (day 2) chick embryo that extirpation of several cervical segments of spinal cord does not alter the development of motor end-plate distribution or histochemical differentiation by ATPase of muscles innervated by more caudal segments.[210] The relatively isolated human spinal cord with normal muscle maturation demonstrates that the motor unit is capable of maturing normally without cerebral influence, and the aberrant patterns found in infants with cerebral dysgenesis suggest that abnormal descending upper motor neuron influences may alter the course of muscle ontogenesis, probably by interfering with the discharge pattern of the lower motor neuron.

The most common malformation of the brain associated with abnormal muscle development is cerebellar hypoplasia as an isolated anomaly or in conjunction with cerebral dysplasias.[208,209] Abnormal development of brain stem structures is also associated with aberrant muscle maturation, but congenital lesions confined to suprasegmental structures, even when severe, do not seem to affect muscle development. Descending brain stem pathways become myelinated during the period of histochemical differentiation of muscle, between 20 and 30 weeks gestation,[195] and are functional during this period. The corticospinal tract, by contrast, is unmyelinated until much later, after muscle maturation is complete, and probably subserves several functions in the term neonate.[211,212] It is therefore likely that suprasegmental influences on muscle maturation are mediated more by the numerous small bulbospinal (i.e., "subcorticospinal") pathways, such as the tectospinal, rubrospinal, olivospinal, vestibulospinal, and reticulospinal tracts, than by the much larger but late-myelinating corticospinal tract.

SECTION XXIV

Endocrine Function

176

Adda Grimberg and Jessica Katz Kutikov

Hypothalamus: Neuroendometabolic Center

Enabled by its strategic anatomy, the hypothalamus uniquely serves the interface between the neural and endocrine systems. It is at the same time a part of the brain, an intrinsic component of neural pathways, and an endocrine gland, specially connected to the pituitary gland to form the "master gland" unit of the body. The multiple functions of the hypothalamus ultimately involve regulation of the body's energy status and the maintenance of *homeostasis,* or bodily equilibrium. It has been long understood that, to refine this regulation, the hypothalamus responds to information from the brain and to the levels of the peripheral hormones and body fluids it is controlling. An appreciation is growing that the hypothalamus also receives input from the gut and fat stores, in essence closing the loop of metabolic regulation. All these incoming factors are compared with intrinsic set points, and outgoing messages are then released to enact modifications that will match the body to the appropriate set point. We have reviewed pediatric disorders of the neuroendocrine system, both congenital and acquired, elsewhere[1]; this chapter focuses on normal anatomy, embryology, and physiology of the hypothalamus.

ANATOMY

Despite the importance of the hypothalamus for multiple homeostatic functions, the structure is less than 1% of human brain volume; its various parts total approximately 4 g of the 1200 to 1400 g of an adult human brain.[2] Many of the borders of the hypothalamus are difficult to distinguish and are semiarbitrary. The hypothalamus lies at the base of the third ventricle, immediately posterior to the optic chiasm.[2-4]

Because of its many eminences, the hypothalamus is an irregular structure that roughly forms a diamond. It is composed of four main structures[2]: the tuber cinereum, the median eminence, the infundibulum, and the mamillary bodies. The tuber cinereum lies centrally on the inferior aspect of the hypothalamus. The median eminence, a central swelling located on the tuber cinereum, forms the floor of the third ventricle. The infundibulum is a stalk that connects the median eminence to the posterior lobe of the pituitary, and the mamillary bodies are two round protuberances at the posterior end of the inferior surface of the hypothalamus.[4]

The hypothalamus can be difficult to describe because of its lack of landmarks. Of the many systems devised to divide the hypothalamus into discrete areas, two are particularly helpful. One describes nine zones, determined by their mediolateral and anteroposterior locations[2,3]; it is shown in Figure 176-1. The second system defines discrete clusters of cell bodies (nuclei) that have characteristic anatomic positions and functions (Table 176-1). Hypothalamic nuclei are not well circumscribed in adult brains. Examination of developing brains, in which cell groups are more discrete, has led to a greater understanding of hypothalamic architecture. Nonetheless, this schema is also semiarbitrary and is divided in many ways, depending on the source.

An area of particular controversy involves reports of sexual structural differences in several hypothalamic nuclei.[5] In both rats and human adults, the sexually dimorphic nucleus of the preoptic area is larger in males than in females.[6,7] Another preoptic cell group was found to be larger in men.[8-10] The bed nucleus of the stria terminalis is male predominant,[5,11] whereas the massa intermedia (interthalamic adhesion) is female predominant.[12] Age-related changes in neuronal health and sex hormone activity can affect these differences. For example, because the cell loss of human senescence in the sexually dimorphic nucleus of the preoptic area follows different time courses in men and women, the magnitude of the structural difference is age dependent.[5,13] Sexual functional differences have also been shown in the hypothalamus by immunocytochemistry staining for various neuronal products (e.g., somatostatin and vasopressin) and hormone receptors (e.g., androgen and estrogen receptors).[5] Speculation and controversy surround the implications for sexually dimorphic behaviors and psychological phenomena. Most relevant to neonatologists is the debate about imprinting of the brain by androgens in utero and its consequences for therapeutic outcomes in patients with various intersex conditions including ambiguous genitalia.[14]

A final anatomic feature that is integral to hypothalamic functioning is its blood supply. The hypothalamus communicates with the anterior pituitary gland through a special portal circulation that not only is fenestrated (the exception to the blood-brain barrier) but also transmits information bidirectionally. This feature enhances the ability of the hypothalamus to receive both signals from the general circulation and feedback from the pituitary. Furthermore, the hypothalamohypophysial portal system ensures that high concentrations of hypothalamic factors reach the pituitary, often at concentrations that far surpass those in the general circulation.[15]

EMBRYOLOGY

Early in nervous system development, three primary brain vesicles form from the neural tube: the prosencephalon or forebrain, the mesencephalon or midbrain, and the rhombencephalon or hindbrain.[16] Secondary vesicles then form from the prosencephalon during the fourth to fifth weeks of gestation. The secondary vesicles are termed the telencephalon, or endbrain, and the diencephalon. The telencephalon grows to cover all other brain structures and eventually becomes the cerebral hemispheres. The diencephalon also grows, forming a roof plate and two alar plates. During the sixth embryonic week, neuroblasts in the inferior portion of the alar plates of the diencephalon proliferate, forming the human hypothalamus.[16,17] Hypothalamic development occurs in two main stages: forebrain induction by early signals before or during gastrulation and then cell type differentiation by ventralizing and rostralizing signals from the axial mesendoderm. Axial mesendoderm induction of hypothalamic

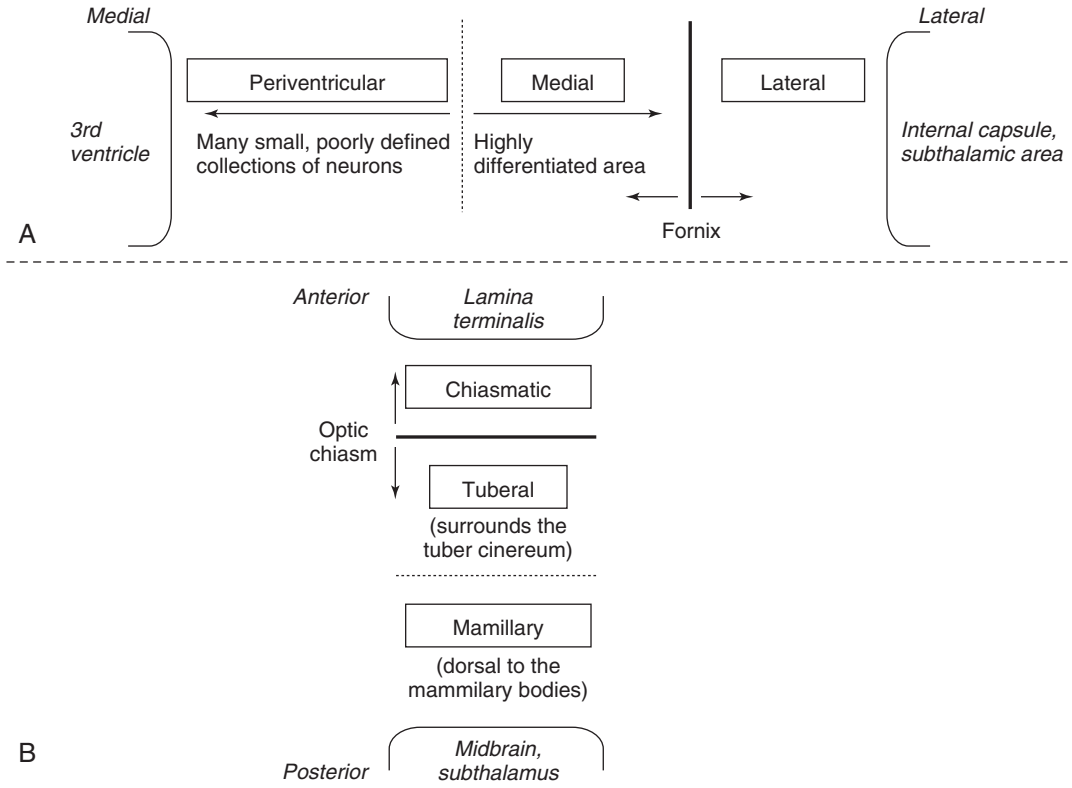

Figure 176-1 Nine anatomic areas of the hypothalamus. Three mediolateral **(A)** and three anteroposterior zones **(B)** form a grid that divides the hypothalamus into nine anatomic areas. Defining features and boundaries of each zone are shown.The chiasmatic region can be further subdivided into preoptic (anterior to optic chiasm) and supraoptic (superior to optic chiasm) areas.

TABLE 176-1

Hypothalamic Nuclei

Anteroposterior region	Nuclei	Anatomy	Function
Chiasmatic	Preoptic area	Small nuclear groups, anterior to optic chiasm	Controls blood pressure, body temperature, hormonal release, reproductive activity
	Suprachiasmatic nucleus	Midline nucleus above optic chiasm	Sets circadian rhythm and sleep-wake cycles, regulates body temperature, hormonal control
	Paraventricular nucleus	Medial half = parvocellular neurons; lateral half = magnocellular neurons	Produces oxytocin and antidiuretic hormone (magnocellular neurons); regulates anterior pituitary function (parvocellular neurons); regulates autonomic responses
	Supraoptic nucleus	Superior to optic chiasm; also contains magnocellular neurons	Produces oxytocin and antidiuretic hormone
	Anterior nucleus	Between the paraventricular and supraoptic nuclei	Less differentiated; role ill-defined
Tuberal	Dorsomedial nucleus	Dorsal part of medial zone; projects locally and to periaqueductal gray matter	Feeding, growth, maturation, reproduction; parvocellular neurons regulate anterior pituitary function
	Ventromedial nucleus	Ventral part of medial zone; projects locally and to periaqueductal gray matter	Feeding, growth, maturation, reproduction; parvocellular neurons regulate anterior pituitary function
	Arcuate nucleus	Basal portion of tuber cinereum	Parvocellular neurons regulate anterior pituitary function; dopaminergic neurons
	Lateral hypothalamic nucleus	Large neurons lateral to ventromedial nucleus	Signals hunger
Mamillary	Posterior nucleus	Prominent nucleus, medial	Controls autonomic function
	Mamillary nuclei	Complex of three or four nuclei	Hippocampus → mamillary nuclei → thalamus; Papez circuit possibly involved in emotion and memory

development is necessary for eye separation, and its failure causes holoprosencephaly.[18]

Distinct cell groups are easier to distinguish in the fetal hypothalamus than in the adult hypothalamus. The fetal hypothalamic nuclei become recognizable between 6 and 12 weeks gestation. At this same time, the hypothalamic fiber tracts develop, and many hypothalamic factors become detectable.[19] For example, somatostatin, dopamine, and thyrotropin-releasing hormone are detectable as early as the 10th week of gestation.[17] At 9 to 10 weeks gestation, little differentiation of the hypothalamic nuclei has taken place. By 24 to 33 weeks, the hypothalamus contains an increased number of better-defined structures and more closely resembles an adult hypothalamus. By the immediate postnatal period, the neonatal hypothalamic cell groups are remarkably similar to those structures in a mature adult.[20]

Information about the embryology of the hypothalamohypophysial portal system is limited. Evidence exists that the primary plexus begins to develop as early as 11.5 weeks gestation.[17] Capillary penetrance of the median eminence is not evident until more than 16 weeks gestation.[21] Further development throughout gestation is indicated by the greater number of capillary loops and the more mature vasculature present at birth.[17]

Our understanding of hypothalamic embryology has progressed from the morphologic to the genetic level. Development of the hypothalamus and pituitary gland is coordinated through parallel actions of genes expressed in both organs; extrinsic signals activate repertoires of transcription factors in a well-defined spatiotemporal pattern that lead to cellular differentiation into the various cell types that assume the distinct functions of the mature organs.[18,22,23] Some of these genes are summarized in Table 176-2.[18,22-25]

NEUROLOGIC FUNCTIONS

Like other brain centers, the hypothalamus participates in neural pathways by synthesizing and secreting neurotransmitters, chemical messengers used for synaptic transmission, signaling, and neuromodulation. Different pathways control various functions of the hypothalamus, although for some functions, discrete areas or nuclei are not identifiable as the control centers. Some of the neurotransmitters are summarized in Table 176-3. Other neurotransmitters are also involved in hypothalamic functioning, such as the excitatory amino acids in a pathway connecting to the hippocampus and limbic system, but their actions are less well understood.

Circadian Rhythms

The suprachiasmatic nucleus sets the clock for the body's circadian rhythms, adaptations to the reproducible 24-hour day-night cycle of life on earth.[26] Neurons of the suprachiasmatic nucleus oscillate in a synchronized fashion in vitro with a period close to 24 hours.[27] In vivo, these oscillations become entrained to the solar day-night cycle by light; signals from the retina are transmitted by the retinohypothalamic tract to the suprachiasmatic nucleus. In the suprachiasmatic nucleus, these signals affect gene expression for at least four transcription factors that act in a transcription-transduction feedback loop to determine the oscillations.[26,27] Suprachiasmatic neurons contain somatostatin, vasoactive intestinal polypeptide, vasopressin or antidiuretic hormone (ADH), and neurotensin. Efferent pathways, including one that controls pineal function, then regulate various endocrine, cardiovascular, temperature, and behavioral circadian rhythms.[2,26,28]

In humans, the suprachiasmatic nucleus is recognized by midgestation and the retinohypothalamic tract by 80% gestation.[26,29] Fetuses show 24-hour rhythms in hormones, cardiovascular function, and behavior. Rather than being synchronized with the time of day, their rhythms are set by maternal signals, including the maternal cortisol rhythm.[26] Although the circadian system is responsive to light at premature stages in human and other primate infants, the system progressively matures after birth to achieve full entrainment after 2 months of age.[30]

The daily sleep-wakefulness cycle is the most obvious behavioral manifestation of the suprachiasmatic nucleus's activity and circadian rhythms. Human evolution as hunter-gatherers has led to the coordination of sleep with metabolic homeostatic mechanisms; hunger, vigilance, and food-seeking behaviors occur primarily during daylight hours whereas satiety and somnolence occur together for periodic rest.[31,32] Hypocretin (also called orexin) neurons in the lateral hypothalamus respond to metabolic signals of the body's nutritional status and to dark-light cues from the suprachiasmatic nucleus pacemaker to stimulate both alertness and appetite and feeding behaviors. Hypocretin deficiency, in both humans and animal models, causes narcolepsy.[33] Disturbances of the circadian cycle and chronic sleep deprivation have been implicated in hyperphagia and obesity, mainly via the hypocretin system,[31] and, with further contributions from unbalanced autonomic nervous system activity,[34] in the metabolic syndrome (visceral obesity, type 2 diabetes mellitus, dyslipidemia, and hypertension).

Autonomic Nervous System Function

A topographic arrangement of autonomic function exists in the hypothalamus; parasympathetic control stems mainly from anterior and medial regions, whereas the lateral and posterior areas control sympathetic responses. Parasympathetic activity results in slowing of the heart rate, peripheral vasodilation, and increased gastrointestinal motility. Alternatively, sympathetic stimulation results in pupillary dilation, increased heart rate and blood pressure, and other responses associated with increased emotional stress.[2]

Heart rate, heart rate variability, and other cardiac measures are often used as markers when assessing fetal and neonatal autonomic function.[35,36] Fetuses at 20 weeks of gestational age demonstrate heart rate stability and differences among individuals. Fetal heart rate, beginning at 24 weeks of gestation, may be predictive of postnatal heart rate, but fetal heart rate variability does not become predictive of postnatal heart rate variability until 6 weeks later. This finding likely reflects a later maturation of the neuroregulatory system that controls heart rate variability.[35] The reduction in heart rate variability in fetuses with increasing gestational age also suggests that the autonomic nervous system continues to develop throughout gestation.[36]

Autonomic activity in fetuses varies over the course of a day. For instance, in normal fetuses, the fetal autonomic activity that controls heart rate follows a 12-hour cycle, as opposed to the maternal 24-hour rhythm. This 12-hour rhythm disappears immediately after birth, although the 24-hour circadian rhythm does not become established until 2 to 4 weeks later.[37]

Temperature Regulation

Like autonomic control, temperature regulation occurs regionally, rather than in discrete nuclei. The preoptic anterior hypothalamus contains thermosensitive neurons that detect increases in blood temperature and cool the body by heat dissipation, whereas the posterior hypothalamus conserves heat when decreased body temperature is detected.[2,38] The temperature control centers of the hypothalamus coordinate behavioral, autonomic, and endocrine responses of the body to regulate body temperature, including panting and peripheral vasodilation in response to increased body temperature, shivering and peripheral vasoconstriction in response to decreased body temperature,[39] and modulation of thyroid hormone–stimulated thermogenesis.[40,41] Hypothalamic injury can produce prolonged hypothermia resulting from

TABLE 176-2

Genes in Hypothalamic Development

Gene	Normal function	Consequences of mutation or deletion
Rpx/Hesx1	Expressed during gastrulation in the midline endoderm-mesoderm (prechordal plate precursor), to induce anterior head structures Afterward, expression is restricted to Rathke's pouch Ventral → dorsal down-regulation of expression coincides with pituitary cell differentiation	Deletions: Absence of infundibulum and Rathke's pouch (most severe); hypothalamic floor expansion and abnormal bifurcation of Rathke's pouch Homozygous missense mutations (R53C) cause septo-optic dysplasia, which is frequently associated with hypothalamic or pituitary dysfunction
Shh (sonic hedgehog)	Expressed by oral ectoderm Induces its own expression and that of other genes (e.g., *Nkx2.1*) in ventral midline neural cells Suppresses *Pax6* expression in the midline Required for resolution of the single retinal field into two separate primordia	Holoprosencephaly Hypothalamic or pituitary absence or dysfunction
Six3	Transcription factor Expressed in Rathke's pouch and hypothalamus Involved in early induction of the pituitary gland	Holoprosencephaly Hypothalamic or pituitary absence or dysfunction
Gli3	Represses *Shh* signaling	Pallister-Hall syndrome (hypothalamic hamartomas)
Nkx2.1/Tebp/TTF-1	Dorsoventral gradient of expression (higher in ventral region and posterior pituitary; none in Rathke's pouch) Required for development of Rathke's pouch	Absence of entire pituitary gland Absence of selective hypothalamic nuclei (premamillary nucleus, arcuate nucleus, mamillary body, supramamillary nucleus)
Brn-2	Coexpressed with *Brn-4* in presumptive paraventricular and supraoptic nuclei Required for terminal differentiation and survival of magnocellular and parvocellular neurons in these nuclei	Magnocellular and parvocellular neurons fail to project axons into the posterior pituitary Complete loss of posterior pituitary
Sim1	Expressed in paraventricular and supraoptic nuclei	Paraventricular and supraoptic nuclei fail to express *Brn-2,* oxytocin, antidiuretic hormone, thyrotropin-releasing hormone, corticotropin-releasing hormone, somatostatin Homozygous deletion: perinatal lethal from complete development defect of paraventricular nucleus Haploinsufficiency: isolated hyperphagia, early onset obesity, increased linear growth, no decrease in energy expenditure
Nhlh2	Expressed in developing hypothalamus Expressed in both embryonic and adult pituitary	Hypogonadism and progressive adult obesity Reduction of pro-opiomelanocortin–producing cells in the arcuate nucleus (increased leptin resistance)
SF-1/Ftz-F1	Expressed in developing adrenal glands, gonads, and diencephalon Regulates both androgens and müllerian inhibiting factor (i.e., male differentiation)	Absence of adrenal glands Absence of gonads Absence of pituitary gonadotropes (no luteinizing hormone, follicle-stimulating hormone, and gonadotropin-releasing hormone)
Gsh-1	Binds to growth hormone–releasing hormone promoter	Hypoplastic pituitary gland Dwarfism; growth hormone deficiency (from absence of growth hormone–releasing hormone in arcuate nucleus) Sexual infantilism and infertility
Necdin	Paternal monoallelic expression in developing hypothalamus	Decreased number of oxytocin-producing cells in paraventricular nucleus Decreased number of gonadotropin-releasing hormone–producing cells in preoptic region Mutant mice show neonatal lethality with reduced penetrance Maps to the critical region of Prader-Willi syndrome
Peg3	Paternal monoallelic expression in developing hypothalamus	Decreased number of oxytocin-producing cells in paraventricular nucleus Abnormal maternal behavior leading to perinatal lethality of offspring mice
Sox2	Expressed in the developing central nervous system and placodes	Heterozygous mutations in humans: bilateral eye defects, anterior pituitary hypoplasia and hypogonadotropic hypogonadism, variable defects affecting the corpus callosum and mesial temporal structures, hypothalamic hamartoma, sensorineural hearing loss, esophageal atresia
Sox3	Expressed in infundibulum	X-linked hypopituitarism, infundibular hypoplasia, variable learning difficulties

Data from Kioussi C, Carrière C, Rosenfeld MG: A model for the development of the hypothalamic-pituitary axis: transcribing the hypophysis, Mech Dev 81:23, 1999; Michaud JL: The developmental program of the hypothalamus and its disorders, Clin Genet 60:255, 2001; Kelberman D, Rizzoti K, Avilion A, et al: Mutations within Sox2/SOX2 are associated with abnormalities in the hypothalamo-pituitary-gonadal axis in mice and humans, J Clin Invest 116:2442, 2006; and Woods KS, Cundall M, Turton J, et al: Over- and underdosage of SOX3 is associated with infundibular hypoplasia and hypopituitarism, Am J Hum Genet 76:833, 2005.

TABLE 176-3

Hypothalamic Neurotransmitters

Category	Neurotransmitter	Pathway	Function
Monoamines			
Catecholamines	Dopamine	Incertohypothalamic tract Mesencephalic tract Tuberoinfundibular tract Median eminence	Influences secretion of pituitary hormones Primary inhibitor of PRL L-DOPA stimulates GH release
	Norepinephrine	Lateral tegmental system Dorsal tegmental system Can be localized to all hypothalamic nuclei; highest concentrations in the arcuate nucleus and median eminence	Regulates emotional and motivated behavior Stimulates GH and gonadotropin release Inhibits secretion of oxytocin, vasopressin, and ACTH
	Epinephrine	Cell bodies near the locus ceruleus	Inhibits secretion of vasopressin and oxytocin
Indolamines	Serotonin	Most of the hypothalamic nuclei	Involved in cyclic release of some hypothalamic hormones
		Highest concentrations in the arcuate and suprachiasmatic nucleus	Stimulates GH and PRL release
	Histamine	Tuberomamillary nucleus in the posterior lateral hypothalamus	May help maintain arousal Stimulates oxytocin, vasopressin, and GH release
Cholinergic	Acetylcholine	Large amount present in median eminence	Stimulates secretion of vasopressin, oxytocin, ACTH, and gonadotropin release Inhibits somatostatin; stimulates GH release Inhibits TSH release
Amino acids (inhibitory)	γ-Aminobutyric acid	Synthesized from glutamate Basal ganglial system	In anterior hypothalamus, helps induce sleep Inhibits oxytocin, vasopressin, ACTH, PRL, and TSH release Stimulates GH and gonadotropin release
Peptides	Angiotensin II	Renin (from kidneys) cleaves angiotensinogen (made by liver) to angiotensin I; angiotensin I cleaved by angiotensin-converting enzyme in lungs in angiotensin II	Stimulates secretion of vasopressin Stimulates ACTH and luteinizing hormone and inhibits PRL and GH release Induces thirst, drinking behavior Involved in regulation of water balance
	Atrial natriuretic peptide	Left atrium	Opposes vasopressin secretion
		Anterior tip of third ventricle Many neuronal endings in the median eminence	Involved in regulation of water balance
	β-Endorphins	Arcuate nucleus and basal tuberal area in the rat Project through the anterior hypothalamic area and innervate the median eminence	Released during stress Stimulate ACTH, PRL, and GH release

ACTH, Corticotropin; *GH,* growth hormone; *L-DOPA,* levo-3,4-dihydroxyphenylalanine; *PRL,* prolactin; *TSH,* thyroid-stimulating hormone.

alterations in the temperature set point or defects in heat production mechanisms. Fever results from an elevation of the temperature set point by inflammatory cytokines, such as interleukin-1, that raise prostaglandin E levels in the hypothalamus; normal physiologic mechanisms then maintain body temperature at this elevated set point.[38]

The fetal environment is stable at approximately 37° C. The temperature gradient, wherein fetal temperature is approximately 0.5° to 1.0° C higher than maternal temperature, results in fetal heat dissipation. Heat loss occurs through the placenta, fetal skin, amniotic fluid, and uterine wall. The hypothalamus most likely controls this higher fetal temperature in utero. After birth, the neonate has tremendous heat losses through the skin that require functioning thermoregulatory mechanisms to prevent hypothermia. Premature infants are often unable to maintain appropriate body temperature and behave like poikilotherms rather than homeotherms. How the hypothalamus matures to the environmental conditions after birth is still unknown.[42]

Emotional Expression and Behavior

Selective stimulation or lesions of various areas in the hypothalamus elicit different behavioral and emotional responses such as aggression, anger, fear, pleasure, and sexual gratification. Although the hypothalamus is important for integrating and expressing emotion, other areas of the brain, including the cortex, limbic system, and thalamus, interact with the hypothalamus to bring about the varied types of responses.[2,43,44]

The hypothalamus participates in the two physiologic stress response systems, the sympathetic-adrenal-medullary system and the hypothalamic-pituitary-adrenal system. The sympathetic-adrenal-medullary system causes the well-known stress-induced release of epinephrine. Sympathetic-adrenal-medullary activation, which is dependent on characteristics of both the situation and the individual, occurs in response to challenges with a faster onset than activation of the hypothalamic-pituitary-adrenal axis.[45] Hypothalamic-pituitary-adrenal axis function culminates in cortisol release, which is described in detail in Chapters 180 and 181. Stress induction of the hypothalamic-pituitary-adrenal axis is active in newborns. When neonates are exposed to noxious stimuli (e.g., circumcision, heel stick blood sampling), cortisol levels rise and can be associated with how much the infant cries. Once the noxious stimulus is removed, healthy neonates quickly return to basal cortisol concentrations. Soothing procedures such as the use of a pacifier can reduce crying in response to noxious stimuli, but they do not affect the hypothalamic-pituitary-adrenal response to the stimuli.[46]

ENDOCRINE FUNCTIONS

The hypothalamus also serves as an endocrine organ, synthesizing and releasing hormones into the circulation to effect changes in target tissues. Hypothalamic endocrine activity can be divided

into two distinct categories as established by the anatomy of the hypothalamopituitary unit. Because the posterior pituitary gland, or neurohypophysis, is composed of axonal projections from the hypothalamus, the hormones released into the circulation by the posterior pituitary are actually made in cell bodies of the hypothalamus. In contrast, the anterior pituitary gland, or adenohypophysis, is a distinct gland. The hypothalamus secretes various releasing and inhibiting factors that regulate anterior pituitary hormone synthesis and release. These factors are made in hypothalamic neurons and are carried down axons to the median eminence. They then reach the anterior pituitary by the special hypothalamohypophysial portal circulation, whereas the anterior pituitary hormones reach their target organs by the peripheral circulation.[28]

Hypothalamic hormone production and release are primarily regulated by humoral feedback. Three levels of feedback regulation to the hypothalamus exist. *First-order feedback* involves one hormone, as exemplified by oxytocin and ADH. These hormones act on target cells (breast, uterus, kidney) but do not stimulate the release of secondary hormones. Oxytocin and ADH levels, together with nonhormonal signals (e.g., plasma osmolality and hypovolemia or hypotension for ADH), directly regulate their own production and release. Close proximity of oxytocin and ADH neurons and co-localization of receptors for the hormones on the neurons that produce those hormones allow local concentrations of oxytocin and ADH within the supraoptic and paraventricular nuclei to refine further activity of the neurons that produce them.[47-49] *Second-order feedback* involves a second hormone produced by the pituitary, such as prolactin (PRL). Hypothalamic hormones stimulate or inhibit anterior pituitary release of a hormone, and the circulating levels of the pituitary hormone feed back to regulate hypothalamic hormone release. For example, increases in circulating PRL concentrations stimulate hypothalamic secretion of dopamine (PRL-inhibiting factor) into the hypothalamohypophysial portal circulation to prevent excessive PRL release by the pituitary; high PRL levels also inhibit hypothalamic release of vasoactive intestinal polypeptide, a hormone that stimulates PRL release.[50] In a *third-order feedback* loop, a third endocrine gland (e.g., adrenals, gonads, thyroid) is involved in addition to the hypothalamus and pituitary. Within a third-order feedback pathway, multiple types of feedback loops exist: long, short, and ultrashort feedback. Long-loop feedback occurs when hormones from peripheral endocrine target cells or substances from tissue metabolism influence the production of hypothalamic hormones. This type of feedback is most often negative, although it can be positive. Short-loop feedback is second-order feedback within a third-order feedback system. For instance, certain pituitary hormones (e.g., corticotropin, luteinizing hormone, thyroid-stimulating hormone) not only stimulate target gland hormone production, but also feed back to limit or terminate hypothalamic releasing hormone production (corticotropin-releasing hormone, gonadotropin-releasing hormone, and thyrotropin-releasing hormone, respectively). When hypothalamic hormone release affects its own synthesis, ultrashort feedback has occurred. This is similar to first-order feedback within a third-order system. The mechanism of this ultrashort feedback is either through neurotransmission between two cells in the hypothalamus or through pituitary tanycyte release of the hormone into cerebrospinal fluid, which can regulate hypothalamic activity because the hypothalamus is located at the base of the third ventricle.[28] The growth hormone pathway (reviewed in detail elsewhere[51,52]) is an excellent example of a third-order system and is shown in Figure 176-2.

Two neurosecretory systems produce hypothalamic hormones (summarized in Table 176-4): magnocellular and parvocellular. The *magnocellular system* consists of specialized, large-celled (magnocellular) neurons, the hypothalamoneurohypophysial tract, and the neurohypophysis (posterior pituitary). Its principal products are ADH and oxytocin. Most of the magnocellular neurons are located in the supraoptic and paraventricular nuclei, but additional small nuclei also contain these neurons.[3] Apart from projections to neurohypophysis, some magnocellular neurons project to the median eminence and some ADH-containing fibers project to the choroid plexus in the lateral ventricles and brain stem regions.[15]

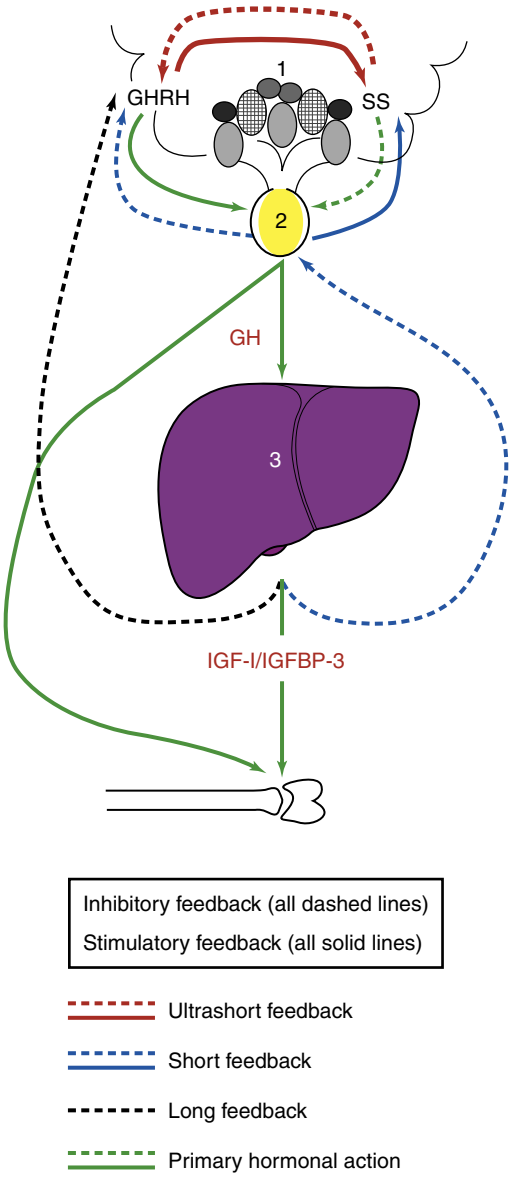

Figure 176-2 The growth hormone (GH) axis exemplifies a third-order feedback loop. A third-order feedback loop involves hormonal production by three endocrine glands: *(1)* the hypothalamus produces growth hormone–releasing hormone (GHRH) and somatostatin (ss); *(2)* the pituitary gland produces GH; and *(3)* the liver acts as an endocrine gland, producing insulin-like growth factor-I (IGF-I) and its binding protein (IGFBP-3). Stimulatory feedback is depicted as a *solid arrow,* inhibitory feedback as a *dashed arrow.* Ultrashort feedback is colored in *red,* short feedback in *blue,* and long feedback in *black.* Primary hormonal action is shown in *green.* Among the final end-organs of this system is the growth plate of growing bones.

TABLE 176-4

Hypothalamic Hormone Axes

Neurosecretory system	Hormone	Hormone gene locus	Hypothalamic nucleus of origin	Secondary pituitary hormone	Pituitary action	Final axis gland	Axis function
Magnocellular	ADH	20p13	Supraoptic and paraventricular	NA	V1b receptors: stimulate ACTH release	NA	Enhances renal free water retention; vasoconstriction
	Oxytocin	20p13	Supraoptic and paraventricular	NA	NA	NA	Stimulates uterine contractions at parturition; milk let-down reflex for lactation
Parvocellular	GHRH	20q11.2	Arcuate	GH	Stimulatory	Liver	Somatic growth
	ss	3q28	Paraventricular; also in neocortex, basal ganglia, limbic system; endocrine pancreas and gut (D cells)	GH, PRL, TSH, ACTH	Inhibitory	Liver	Regulation of pituitary function, especially somatic growth; neurotransmitter; gut function and pancreatic endocrine regulation (locally produced ss)
	CRH	8q13	Paraventricular	ACTH	Stimulatory	Adrenals	Maintenance of normal blood pressure and glucose; stress response
	TRH	3q13.3-q21	Paraventricular	TSH	Stimulatory	Thyroid	Regulates overall metabolic rate; effects on heart, bone, gut, and other organ functions
	GnRH	GnRH1 = 8p21-p11.2; GnRH2 = 20p13	Arcuate	LH, FSH	Stimulatory	Gonads	Reproduction
	Dopamine	—	Arcuate	PRL	Inhibitory	NA	Lactation

ACTH, Corticotropin; *ADH,* antidiuretic hormone or vasopressin; *CRH,* corticotropin-releasing hormone; *FSH,* follicle-stimulating hormone; *GH,* growth hormone; *GHRH,* growth hormone–releasing hormone; *GnRH,* gonadotropin-releasing hormone; *LH,* luteinizing hormone; *NA,* not applicable; *PRL,* prolactin; *ss,* somatostatin; *TRH,* thyrotropin-releasing hormone; *TSH,* thyroid-stimulating hormone (thyrotropin).

In contrast, the *parvocellular secretory cells* are small neurons, mostly in the region of the tuber cinereum below the third ventricle, that produce the hypophysiotropic hormones.[3] The parvocellular neurons are found in various hypothalamic nuclei, including the arcuate and paraventricular nuclei, and project to the median eminence.[28] Their hormonal products (all peptide hormones except dopamine) are carried by the hypothalamohypophysial portal system to the anterior pituitary, where they regulate adenohypophysial function. Because the hormonal systems of the anterior pituitary are reviewed in detail in other chapters of this book, we focus on the magnocellular system.

Adult numbers of oxytocin- and ADH-producing cells in the supraoptic and paraventricular nuclei exist as early as the second half of gestation, which is earlier than development of some other nuclei.[53] Oxytocin and ADH can be detected as early as the 10th gestational week. Vasopressinergic neurons appear 1 week earlier in the supraoptic than in the paraventricular nucleus. Although an adult organization of vasopressinergic neurons can be identified early in the second trimester, the number of those neurons seems to increase until the 26th week of gestation. The vasopressinergic system of neurons is also highly active in the perinatal period.[54]

The synthetic pathways of oxytocin and ADH are very similar.[55] Both are synthesized from protein precursors (prohormones) that are encoded by single-copy genes located near each other on chromosome 20. Both genes are composed of three exons; the entire mature hormone is encoded within the first exon. The remainder of the oxytocin gene encodes neurophysin I, whereas the longer ADH gene also encodes neurophysin II and the glycoprotein, copeptin.[56] The prohormones are transported down the axons and are stored in colloid-filled vesicles. Proteolytic enzymes in these neurosecretory granules cleave oxytocin and ADH from the neurophysins, which are presumed to primarily serve as their carriers during axonal transport. When the magnocellular cell bodies are properly stimulated, oxytocin, ADH, and the neurophysins are released from the axonal terminals by calcium-dependent exocytosis.[3] In addition to oxytocin and ADH, magnocellular secretory granules contain many other peptides but in much smaller amounts. These include dynorphin, enkephalins, galanin, and cholecystokinin, and, although they are secreted along with oxytocin and ADH, the role of many of these peptides is unknown.[57]

Oxytocin

Oxytocin secretion is prompted by mechanical vaginal distention and, in lactating women, by suckling and nipple stimulation; no recognized stimulus exists for its secretion in men. Cholinergic and α-adrenergic fibers carry the stimulatory inputs, whereas β-adrenergic fibers provide inhibition of oxytocin release. Oxytocin serves two physiologic functions: it aids in parturition by stimulating uterine contractions, and it facilitates nursing by stimulating contraction of myoepithelial cells in the lactating mammary gland (milk "let-down" reflex). In fact, nursing cannot occur without oxytocin, and maternal and fetal stress during labor and delivery can reduce oxytocin release, thereby impairing

lactation.[58] Oxytocin action at parturition is primed by two major changes. Oxytocin release, which occurs in brief secretory bursts, increases in both the fetus and the mother during labor.[59,60] Meanwhile, the increase in uterine oxytocin receptors at term makes the uterus particularly sensitive to the hormone.[59] Oxytocin secretion is suppressed by relaxin, an ovarian peptide that suppresses uterine contractions and relaxes pelvic connective tissue during parturition.[61] Therapeutically, oxytocin and its analogues are used to induce labor (or to augment labor in uterine dysfunction), to prevent postpartum uterine atony or hemorrhage, and to promote milk let-down in lactation.

Antidiuretic Hormone

The two names of this hormone, vasopressin and ADH, reflect its two main actions, which are mediated by two different classes of receptors. V1 receptors stimulate vasoconstriction, glycogenolysis, platelet aggregation, and vascular smooth muscle hypertrophy. A subclass of V1 receptors (V1b) is located in the anterior pituitary and stimulates corticotropin release. V2 receptors increase water permeability of the renal collecting ducts by inducing aquaphorins; this results in greater water retention and decreased urine volume. Neural input for ADH secretion can elicit newly synthesized hormone within 30 minutes, but it also exhibits fatigue with high frequencies or prolonged duration.[62] The main stimulus for the antidiuretic effects of ADH is an elevation in plasma osmolality, primarily the extracellular fluid concentration of sodium chloride, as detected by osmoreceptor cells within the hypothalamus. Baroreceptor (carotid sinuses, aortic arch, cardiac atria, and great veins) sensing of hypovolemia or hypotension leads to ADH levels superseding those required for maximal urine concentration and causes vasoconstriction.[15] In most cases, the two mechanisms act in concert; dehydration leads to both hypernatremia and hypovolemia. However, the two ADH responses may become dissociated in disease states involving intravascular volume depletion despite total body fluid overload and hyponatremia (e.g., congestive heart failure, cirrhosis, and nephrotic syndrome).[63] Deficiency of ADH hormone production and resistance to ADH action cause central and nephrogenic diabetes insipidus, respectively[64]; both disorders are characterized by polyuria, polydipsia, and a tendency to dehydration. In contrast, the syndrome of inappropriate ADH secretion is characterized by diminished urine output and free water intoxication.

During development, ADH aids in regulating the proliferation and morphogenesis of target cells in the brain, pituitary, kidney, and liver. Because the fetus contributes significantly to modulation of fluid fluxes among the maternal, fetal, and amniotic fluid compartments, fetal ADH action is an important component of adaptive responses to changes in the environment in utero.[65] The ADH system also plays an essential role in fetal adaptation to the stresses of labor.[54,65] In the perinatal period, ADH is integral in establishing body fluid homeostasis, by providing the brain, pituitary, heart, and adrenals with increased blood flow and aiding in regulation of the cardiovascular system, water reabsorption, gluconeogenesis, and glycogenolysis after delivery.[54]

METABOLIC REGULATION

The hypothalamus plays a crucial role in regulating the body's metabolic state by controlling both feeding behavior and energy expenditure rates. The regulation is so precise that, under reasonably steady-state conditions, deflections in the body weight and fat mass of mammals remain within 0.5% to 1%.[66] The importance of the hypothalamus to this system has long been appreciated because of the hyperphagia and obesity syndromes that result from hypothalamic lesions. The ventromedial nucleus of the hypothalamus has been identified as a satiety center, whereas the lateral hypothalamic area stimulates feeding.[2,19] More recent investigations have focused on the peripheral hormones that feed metabolic information back to the hypothalamus.

Leptin

The *OB* gene, located on chromosome 7q31.1 and encoding the hormone leptin, was cloned and sequenced in 1994.[67] Leptin is produced by white adipose tissue and is secreted into the circulation in proportion to the body's fat mass.[68,69] Circulating both freely and protein bound, leptin crosses the blood-brain barrier and binds to leptin receptors in the central nervous system. Many of these receptors are located in the hypothalamus and control pathways involved in the regulation of appetite and thermogenesis.[68] Thus leptin serves as the hypothalamic index of body fat mass.[69,70] Leptin has other neuroendocrine functions, including regulation of fertility and the secretion of growth hormone, corticotropin-releasing hormone, thyrotropin-releasing hormone, and PRL.[68,69]

The exact mechanism of leptin uptake into the central nervous system has yet to be elucidated, though it is inhibited by hypertriglyceridemia.[71] One possibility involves the neurons of the median eminence, which not only project outside the blood-brain barrier but also express leptin receptors. Once inside the central nervous system, leptin can bind to receptors present in many hypothalamic nuclei, especially the arcuate, dorsomedial, ventromedial, and ventral premamillary nuclei.[72] Leptin binding to its receptor signals the body's energy status to two opposing classes of neurons. Pro-opiomelanocortin (POMC) neurons (catabolic pathways) are stimulated by leptin, whereas neuropeptide Y (NPY) neurons (anabolic pathways) are inhibited.[70]

Leptin directly stimulates POMC neurons, which are located in the arcuate nucleus, as well as outside the hypothalamus in the nucleus of the tractus solitarius. POMC is a precursor to many polypeptides termed melanocortins, including α-melanocyte–stimulating hormone. When the hypothalamic melanocortin receptors MC3-R and MC4-R are stimulated by α-melanocyte–stimulating hormone, food intake is decreased and energy expenditure is increased.[66,70] Agouti gene–related peptide (AGRP) is an endogenous melanocortin system antagonist that is also expressed in the arcuate nucleus.[73]

AGRP messenger RNA is highly co-localized with messenger RNA of NPY,[74] the system opposing POMC. A member of the pancreatic polypeptide family, the anabolic, orexigenic hormone NPY is widely distributed in the human brain. NPY potently stimulates feeding, is capable of overriding the body's satiety and weight control mechanisms,[66] and reduces energy expenditure by decreasing nonshivering thermogenesis in brown adipose tissue.[66,68] Leptin inhibits NPY activity. NPY can inhibit POMC neurons directly at the cell body or postsynaptically through the release of AGRP.[66] Thus leptin stimulates POMC neurons both directly and indirectly, by eliminating the POMC inhibition by NPY,[70] and the two opposing systems are coordinated toward an overall negative effect on energy balance. Many other substances have been implicated in energy homeostasis, but not all are understood as well as the POMC-NPY systems. Those also under leptin regulation include orexins,[66] cocaine- and amphetamine-regulated transcript, glucagon-like peptide-1, melanin-concentrating hormone, and cholecystokinin.[68,72]

Leptin is secreted in a rhythmic pattern that correlates with meals (leptin levels are reduced by fasting). Leptin's actions on the hypothalamus probably serve a long-term regulatory system that sets a point of satiety; short-term regulatory systems that control single meal intake are more likely determined by leptin actions on the brain stem. Obesity more frequently results from leptin resistance than from leptin deficiency.[75] Leptin levels in females are almost double those in males with the same body mass index or fat reserve. This finding not only has implications for leptin physiology but also supports the role of leptin in

reproductive and gonadal function.[68] The gender difference in leptin levels is found at birth, which suggests that the process begins in utero.[68,76] Circulating leptin levels are also higher during gestation than in nongravid individuals, and disturbances in leptin production have been found in several pathologic pregnancy states that alter fetal growth.[77]

The role of leptin in the fetus is unknown. Leptin has been identified in fetal cord blood in the 18th week of gestation. Adipose tissue development occurs during the second trimester, and, consistent with this finding, leptin levels dramatically increase at 34 weeks gestation.[73] Leptin is also produced by the placenta but in very small amounts that are unlikely to contribute significantly to cord blood levels.[76] The level of leptin for body weight is disproportionately high in neonates.[68,76] The reason for this is unknown, but it normalizes toward adult levels around 2 weeks of life.[68] Neonatal leptin levels have been shown to predict weight gains in infancy.[68,78]

Ghrelin

Ghrelin is an orexigenic peptide that was first identified in 1999 as the endogenous ligand for the growth hormone secretagogue receptor (GHSR).[79] Its central role in the stimulation of feeding was not appreciated until 2001.[80] Ghrelin is produced primarily in the stomach (X/A-like cells of the oxyntic glands) but also in the duodenum, jejunum, pituitary, kidney, placenta, and hypothalamus.[81] Although it is accepted that ghrelin-producing neurons exist in the hypothalamus, it is still controversial whether ghrelin is produced there in physiologically relevant amounts.[80,81] Regardless of the source, ghrelin can reach the mediobasal and mediolateral hypothalamus through the general circulation. It is unknown whether peripherally produced ghrelin can reach areas of the hypothalamus protected by the blood-brain barrier. Once ghrelin reaches the hypothalamus, the peptide targets ghrelin receptors present in various hypothalamic nuclei. Ghrelin then exerts its energy homeostatic effects through a central mechanism involving NPY[81,82] and AGRP.[81]

The effects of ghrelin on body metabolism are opposite to those of leptin. However, ghrelin appears to be regulated more acutely, unlike the more chronic regulation of leptin. During food deprivation, leptin levels fall, POMC production decreases, NPY and AGRP levels rise, and ghrelin levels increase.[83] In this situation, ghrelin serves as a hunger signal, trying to restore the body to a state of positive energy balance. On eating, increases in lower intestinal osmolarity (rather than direct effects of nutrients in the foregut) and insulin surges suppress postprandial ghrelin release.[84] Ghrelin levels drop after feeding, are decreased in obesity (though high in Prader-Willi syndrome), are increased in anorexia nervosa, and are low after gastric bypass surgery.[81,84,85] Ghrelin suppresses reproductive function, both centrally and through direct gonadal effects, in times of nutritional stress,[86] whereas leptin plays a permissive role during times of nutritional plenty.[87]

Apparently independent of its orexigenic effects, ghrelin stimulates growth hormone release. Because they work through different receptors (GHSR and growth hormone–releasing hormone receptor, respectively), ghrelin and growth hormone–releasing hormone stimulation of growth hormone secretion are synergistic.[88] The GHSR type 1a is a G-protein–coupled receptor that is mainly expressed in the pituitary and hypothalamus and mediates ghrelin's endocrine functions. Various related receptor subtypes are widely distributed in the central and peripheral tissues and mediate ghrelin's nonendocrine actions.[89] Short stature in two unrelated families segregated with a missense mutation that decreased cell-surface expression of GHSR and selectively impaired GHSR constitutive activity without losing its ability to respond to ghrelin.[90] GHSR-null mice accumulated less body weight and adiposity than control mice when fed a high-fat diet,[91] similar to ghrelin knockout mice.[92]

Other Adipokines

Leptin has become the prototypic member of the adipokine family, a group of hormones produced primarily by adipose tissue that regulate energy homeostasis and affect other functions such as the reproductive, neuroendocrine, cardiovascular, and immune systems. Adipokines are reviewed extensively elsewhere.[93-96] Central actions, especially involving the hypothalamus, have been described as contributing mechanistically to adipokine effects on energy balance.[96] The most abundantly produced adipokine is adiponectin, a collagen-like molecule that decreases weight, fat, and eating; increases insulin sensitivity; and exerts antiatherogenic, antiangiogenic, and antitumor actions.[95-98] It was also found to regulate pituitary function, namely inhibiting growth hormone and luteinizing hormone secretion in vitro.[99] The role of adiponectin in modulating pregnancy-related insulin resistance, fetal growth, and the metabolism of newborns and children is now being studied.[100,101]

DETERMINANT OF FUTURE, AS WELL AS CURRENT, HEALTH

The current obesity epidemic has spurred keen interest in the identification of precedent risk factors and the interplay between genetic and environmental traits in influencing human physical and metabolic development throughout the life span. In particular, nutritional status during the in utero and neonatal periods has been found to affect adiposity and the metabolic syndrome later in life, even in adulthood.[102-104] A body of literature has emerged under the rubric of fetal origins of adult disease, extending beyond obesity and its comorbidities,[105,106] and the hypothalamus plays a prominent role. Because the hypothalamus integrates the various neuroendometabolic functions described in this chapter to maintain homeostasis, hypothalamic adaptations to in utero conditions mold the programming (i.e., set points and responsiveness) that will govern the homeostatic mechanisms throughout life.

Growth Factor Regulation of Fetal Growth

Growth during fetal life is characterized by an early period of cell division and formation of the major organ systems, followed by a more prolonged period of growth and refinement of organ development. *Growth factors* are peptides or proteins that serve as key regulators of cell proliferation and differentiation. They exert their effects by binding to specific receptors, which mediate signal transduction across cell membranes. The binding triggers a cascade of responses, including those involving second messengers, which ultimately result in cell mitogenesis or differentiation. Over the past decade the scientific literature has witnessed an explosion of information regarding the physiology of these agents. It is evident that a variety of growth factors are expressed in diverse tissues during embryonic life, and they may have endocrine as well as autocrine-paracrine effects.

INSULIN-LIKE GROWTH FACTOR AXIS

The primary regulator of postnatal somatic growth is growth hormone (GH). In the liver and other target cells, GH induces the production of insulin-like growth factors (IGFs), IGF-I and IGF-II.[1] The IGFs, particularly IGF-I, have direct, endocrine effects on somatic growth and on the proliferation of many tissues and cell types. Both IGF-I and IGF-II are expressed during fetal development in a GH-independent fashion. In addition to their anabolic effects, IGFs also are thought to be significant autocrine-paracrine factors involved in cellular and tissue function.[2,3] Locally produced IGFs have been demonstrated in nearly all tissue types, where they are considered to be responsible for cell growth and differentiation. GH is thought to play only a minor role in fetal growth, limited to the third trimester. This chapter presents evidence that the IGFs and their regulatory proteins play a central role in the regulation of fetal growth.

Insulin-like Growth Factors

IGF-I and IGF-II are two closely related peptide hormones approximately 7 kDa in size that share a high degree of structural similarity with proinsulin.[3] Like proinsulin, they are composed of A, B, and C domains; however, they also include a D domain. Together, these components form the mature IGF peptide. The IGFs are synthesized with an additional extension peptide known as the *E peptide,* which is removed during posttranslational processing. Both IGF-I and IGF-II are encoded by a single gene each, which by alternative splicing results in several messenger RNA (mRNA) species. The *IGF1* gene spans 95 kilobases (kb) on the long arm of chromosome 12 and contains 6 exons; the *IGF2* gene has a total genomic size of 35 kb and is made up of 9 exons. *IGF2* is located on the short arm of chromosome 11 (near the insulin gene), in an area that is paternally imprinted in all mammalian species. This paternal imprinting phenomenon is related to the fact that IGF-II is a major fetal growth factor.

Insulin-like Growth Factor Receptors

The IGFs interact with specific receptors, designated type 1 and type 2 IGF receptors, as well as with the insulin receptor, which can bind IGF-I and IGF-II, but with much lower affinity than for insulin.[3] The type 1 IGF receptor binds IGF-I with high affinity, IGF-II with slightly lower affinity, and insulin with low affinity. This receptor mediates the known mitogenic effects of the IGFs. The type 1 IGF receptor and the closely related insulin receptor

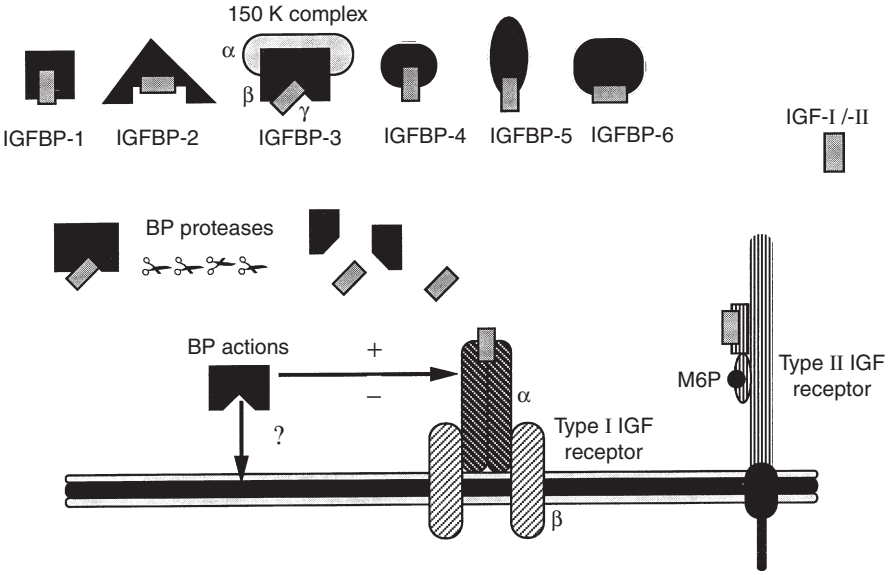

Figure 177-1 The insulin-like growth factor axis, including the IGFs, IGFBPs, and IGFBP proteases. The relationship of the components of the IGF axis is depicted in this figure. *IGF,* Insulin-like growth factor; *IGFBP,* IGF-binding protein.

are heterotetramers composed of two pairs of α and β subunits, the result of posttranslational processing of a single gene product of a single gene that encodes for the entire receptor. The two α subunits, which are involved in ligand binding, are linked by disulfide bonds and are primarily extracellular (Figure 177-1). The β subunits are connected to the α subunits by disulfide bonds and function as intracellular tyrosine kinases. On ligand binding, they undergo a conformational change that enables them to bind ATP and become autophosphorylated. Subsequently, these kinases phosphorylate cytoplasmic molecules known as the *insulin receptor substrates* (IRS-1 and -2), which are involved in mediating many of the effects of insulin and IGFs.[4] IRS proteins couple insulin and IGF receptors to the phosphoinositide 3-kinase (PI3-kinase) and extracellular signal-regulated kinase (ERK) cascades. Products of PI3-kinase, including phosphatidylinositol-3,4-biphosphate and phosphatidylinositol 3,4,5-triphosphate, attract serine kinases to the plasma membrane, including the phosphoinositide-dependent kinase (PDK1 and PDK2) and at least three protein kinases B (PKB)/AKT isoforms. During co-localization at the plasma membrane, PDK1 or PDK2 phosphorylates and activates PKB-1,-2, or -3. The activated PKB/AKT phosphorylates many substrates to control various biologic signaling cascades, including glucose transport, protein synthesis, glycogen synthesis, and cellular proliferation and survival in various cells and tissues.[5]

The insulin receptor itself exists in two isoforms in humans, produced by tissue-specific alternative splicing of exon 11 of the insulin receptor gene, *IR.*[6,7] Relative expression of the different insulin receptor isoforms, the type A insulin receptor (IR-A) and type B insulin receptor (IR-B), is not only tissue-specific but also developmentally regulated, with IR-A preferentially expressed in fetal tissues.[8] In addition, in cell transfection experiments, IR-A was found to bind IGF-II with an affinity equal to that for insulin. Whereas insulin binding to IR-A stimulated the metabolic effects of insulin receptor activation, IGF-II binding to IR-A more effectively stimulated mitogenic processes.[8]

The type 2 IGF receptor is structurally distinct from the type 1 receptor and the insulin receptor; it primarily binds IGF-II.[2] Unlike the insulin receptor and the type 1 IGF receptor, the type 2 IGF receptor is not a tyrosine kinase. Instead, it is a monomeric receptor with a large extracellular domain made up of 15 repeat sequences and a small region homologous to the collagen-binding domain of fibronectin. The type 2 IGF receptor is 270 kDa in size and functions also as the cation-independent mannose-6-phosphate receptor.[9] The receptor does not have a signaling domain and is thought to be recycled between the plasma membrane and intracellular compartments. It also has been suggested that the type 2 IGF receptor targets excess IGF-II for lysosomal destruction during fetal life. The type 2 receptor is maternally imprinted in mice but not in humans.[10]

Additional members of the class of receptors for the IGF-insulin family are less well characterized. One such receptor is composed of an insulin receptor α-β heterodimer binding to a type 1 IGF receptor α-β heterodimer and thus has been labeled the hybrid receptor.[11] Analysis of tissues in which this receptor appears to be common (such as placenta) and transfection experiments in cell lines have demonstrated two isoforms of this hybrid receptor—a hybrid receptor containing insulin receptor isoform A (Hybrid-Rs^A) and one containing insulin receptor isoform B (Hybrid-Rs^B). Hybrid-Rs^A has biologic properties intermediate between those of the insulin and the type 1 IGF receptor: It binds both insulin and IGFs with high affinity and stimulates cell proliferation and migration.[12] (By contrast, Hybrid-Rs^B binds IGF-I with high affinity but IGF-II with only low affinitiy, whereas insulin has little to no affinity at all.) The complementary DNA (cDNA) for an additional receptor has been cloned, and because of its high homology with the insulin receptor, it has been designated the *insulin receptor–related receptor* (IRR).[13] IRR is an orphan receptor of the insulin receptor family that does not bind insulin or insulin-like peptide and can be expressed as variably spliced isoforms. IRR may have a role in fetal development, because its expression occurs specifically in developing renal and neural tissues. IRR also is expressed in pancreatic islets, but the lack of this receptor in mice does not affect beta cell development and function.[14] An additional atypical IGF receptor with altered ligand binding also has been described.[15] This may represent a posttranslationally modified type 1 IGF receptor of unclear function.

Insulin-like Growth Factor Binding Proteins

The IGF-binding proteins (IGFBPs), a family of proteins with high affinity for the IGFs, have been shown to be involved in the modulation of the mitogenic effects of IGFs on cells. In vivo, the IGFs are bound to this family of six structurally and evolutionarily related IGFBPs (IGFBP-1 to IGFBP-6). In serum, a majority

(70% to 80%) of IGFs exist in a 150-kDa complex composed of one IGF molecule, IGFBP-3, and the acid-labile subunit (ALS). A smaller proportion (approximately 20%) of the IGFs are associated with other serum IGFBPs within a 50-kDa complex, and less than 5% of the IGFs are found in the free form of 7.5 kDa. ALS is a protein that binds to the IGF/IGFBP-3 binary complex, primarily in serum, prolonging the $t_{1/2}$ of serum IGFs and facilitating their endocrine actions. These IGFBPs appear to regulate the availability of free IGFs for interaction with the IGF receptors, as well as to interact directly with cell function.[16] They are part of a superfamily that comprises six high-affinity IGFBPs and at least four other low-affinity IGF binders, termed insulin-like growth factor–binding protein-related proteins (IGFBP-rPs).[17] In addition, limited evidence suggests that the cell surface proteoglycan glypican-3, mutations of which cause the overgrowth syndrome known as Simpson-Golabi-Behmel syndrome type 1, also binds IGF-II and may modulate its function.[18]

IGFBP-1 is a 25-kDa protein that is found in high concentrations in amniotic fluid; it also is secreted by hepatocytes under negative regulation by insulin. IGFBP-2 is a 31-kDa protein found in serum, cerebrospinal fluid, and seminal plasma. It is expressed in many fetal and adult tissues. IGFBP-3 is the major binding protein in postnatal serum and is synthesized by hepatocytes and other cells. In plasma, IGFBP-3 is found as part of a 150-kDa complex, which also includes an ALS and an IGF molecule, all of which are GH-dependent. IGFBP-4 is a 24-kDa protein that has been identified in serum, seminal plasma, and numerous cell types. IGFBP-5 appears to be an IGF-enhancing protein that is found in cerebrospinal fluid and serum. It also is observed in rapidly growing fetal tissues. IGFBP-6 has relative specificity for IGF-II over IGF-I. It is found in cerebrospinal fluid and serum and is produced by many cells. The six cloned cDNAs for the IGFBPs show a high degree of structural similarity and sequence conservation across species. IGFBPs are tightly regulated by various endocrine factors and are uniquely expressed during ontogeny.[19]

Three possible models for the interaction of the IGFBPs with the IGFs and their receptors have been proposed.[20] The first is that these molecules limit the availability of free IGFs for interaction with the IGF receptors. For example, the addition of IGFBPs to many cell cultures in vitro results in the inhibition of IGF actions within these experimental systems.[21] In other systems, however, IGFBPs have been demonstrated to enhance IGF action, under circumstances that may involve cellular processing of the IGFBPs.[16] Finally, as has been shown in several in vitro systems, IGFBPs may inhibit cell growth in an IGF-independent fashion, acting through their own receptors.[20,21]

IGFBP-3 is a mediator of apoptosis under the control of a number of cell cycle regulators.[22] In studies using specific antisense oligonucleotides and neutralizing anti-IGFBP-3 antibodies to block IGFBP-3 expression and action, IGFBP-3 was identified as the mediator of apoptosis induced by retinoic acid and transforming growth factor-β (TGF-β) in multiple cell types.[23-26]

Insulin-like Growth Factor–Binding Protein Proteases

A group of enzymes that are capable of cleaving IGFBPs have been recognized as potential modulators of IGF action.[27] First identified in pregnancy serum, IGFBP-3 proteolytic activity is responsible for the disappearance of intact IGFBP-3 from the serum of pregnant women, with no change in IGFBP-3 immunoreactivity and an increase in lower-molecular-weight fragments.[28,29] IGFBP proteases also have been reported in the serum of severely ill patients in a state of cachexia, in critically ill neonates, in patients with GH receptor deficiency, and in patients with in prostate cancer and other malignancies.[30-32] Prostate-specific antigen was the first kallikrein protein demonstrated to be an IGFBP protease.[33] Subsequently, it has been determined that other members of the kallikrein family, such as nerve growth factor (NGF), also serve as specific IGFBP proteases.[34] Cathepsins are another class of IGFBP proteases that have been shown to be active in acid pH.[35] Finally, matrix metalloproteinases, which are known to cleave collagen and other extracellular matrix components, are a group of IGFBP proteases.[36] It has been speculated that the IGFBP proteases are important modulators of IGF bioavailability and bioactivity through their modification of the IGF carrier proteins. The proteolytic activity may play a role in regulating IGF availability at the tissue level by decreasing the affinity of the binding proteins for the growth factors, thereby releasing free IGFs and allowing increased receptor binding.[33,36,37] Together, all of these interrelated molecules act in coordinated fashion to control growth and differentiation. This system of molecules has been termed the *IGF axis* and is summarized in Figure 177-1.

ADDITIONAL GROWTH-REGULATING PEPTIDES

Fibroblast Growth Factor Family of Peptides and Receptors

Fibroblast growth factors (FGFs) are a family of peptide cytokines that are important in the regulation of many tissues. To date, 23 different FGFs have been identified, including the best-characterized acidic FGF (aFGF), or FGF1; basic FGF (bFGF), or FGF2; and keratinocyte growth factor (KGF), or FGF7. The FGFs exert their actions by binding to one of a family of four membrane-bound FGF receptors, FGFR1 to FGFR4, and a heparin sulfate proteoglycan co-receptor to form a three-part signaling complex.[38] FGFs appear to have primarily autocrine-paracrine functions in organ growth and differentiation, bone formation, and cell differentiation and migration, as well as in carcinogenesis. The role of FGF in osteogenesis and growth initially was demonstrated by the discovery of a gain-of-function mutation in *FGFR3* as the cause of achondroplasia in humans.[39,40] Subsequently, other forms of chondrodysplasia as well as other skeletal dysplasias were found to be caused by mutations in the FGFRs, further emphasizing the importance of FGF signaling in bone formation.[41]

Nerve Growth Factors

The complex array of cells that make up the nervous system is under the regulatory influence of specific growth factors, such as nerve growth factor (NGF), neurotensin, and the neural-derived growth factors (NDGFs). NGF is synthesized in peripheral cells and transported in retrograde fashion up the neuronal axis to the cell body—a process which suggests that NGF is a neurotropic agent directing neurons to sites of innervation.[42] NGF exerts its effects on cells derived from the neural crest, including central nervous system and peripheral nervous system neurons, and some non-neurons, such as immune cells and endocrine cells. NGF stimulates mitosis in some cell types and is capable of inducing differentiation events in neural tissue. NGF synthesis is controlled in part by hormones, such as testosterone and thyroxine. It also has been demonstrated that the γ subunit of NGF serves as an IGFBP protease.[34] Further research will help elucidate the interactions between NGF and the IGF axis components in the regulation of cellular growth.

Epidermal Growth Factor System

Epidermal growth factors (EGFs) and their receptors are widespread in many tissues and participate in specific developmental processes such as neonatal eyelid opening and tooth eruption. EGFs have potent mitogenic actions that have been extensively explored in cell culture systems. The receptor for EGFs was characterized as a prototype model for signal transduction involving tyrosine kinases. EGFs have been identified in most body fluids of mammals, and extensive in vitro data indicate multiple cellular functions of EGFs. Members of the EGF family may have a role in

embryogenesis and fetal growth, because receptors have been identified in fetal tissues. The mouse fetus expresses EGF receptors from 12 days onward,[43] and targeted mutation of the EGF receptor demonstrated its significance in fetal development and growth.[44] EGFs can induce tracheal branching morphogenesis in chick lung rudiments and stimulate epithelial maturation in the lung and other tissues in rabbits.[45] Although EGF transcripts have not been detected in the fetus, it is maternal EGF that appears to play a role in fetal growth, because maternal EGF deficiency leads to hypoglycemia and intrauterine growth restriction (IUGR) in offspring—an effect that is corrected by EGF administration.[46,47] Transforming growth factor-α (TGF-α) is a peptide that displays 30% homology with EGF and also exerts effects through the EGF receptor.[44,48] It has been shown to be expressed in preimplantation mouse embryos and decidua of rat and may therefore be important in fetal development.[49-51]

Other Growth-Promoting Peptides

An increasing number of growth factors are being recognized as having growth-promoting activities in certain cell types. In general, these molecules appear to play important autocrine-paracrine as well as endocrine roles. Notable among these are groups of growth factors that have tissue-specific effects. Endothelin, platelet-derived growth factor (PDGF), and vascular epithelial growth factor (VEGF) regulate angiogenesis and other vascular processes, in addition to modulating the function of numerous cultured cells. PDGF acts in sequence with other growth factors to regulate entry into the cell cycle.[52] A variety of hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF), erythropoietin, and thrombopoietin promote the growth of the different lineages of the precursor cells in the bone marrow. Growth of immune system cells is stimulated by an array of cytokines, including interleukins and interferons. Other growth factors, such as hepatocyte growth factor (HGF), that have been attributed to specific tissues are being recognized as having general growth-promoting effect in numerous tissues.

Growth Inhibitory Peptides

A particularly interesting class of cytokines that can negatively modulate cellular growth is the TGF-β family, members of which are structurally distinct from TGF-α. TGF-β can either act to mediate cellular growth and malignant transformation or act as a growth inhibitory substance with the potential for arresting the growth of normal and neoplastic cells. TGF-β transcripts have been detected in preimplantation embryos.[50] This peptide is involved in mesodermal differentiation and organogenesis. It may stimulate some mesenchymal mitosis while inhibiting the proliferation of epithelial cells.

TGF-βs have both autocrine and paracrine effects. The response depends on the origin of the cell: In some cell types (e.g., hepatocytes, hematopoietic cells), cell growth is stimulated, whereas in other cell types (e.g., osteoblasts, granulocytes), growth is inhibited. During pregnancy, TGFs are important in the regulation of trophoblast invasion, decidualization, and placentation.[53] Mutations in the TGF-β family ligands are responsible for a number of human diseases, including hereditary chondrodysplasia.[54] Retinoic acid and other steroid hormones also have been shown to have inhibitory effects on cell growth. Tumor necrosis factors (TNFs) and other compounds have been described to have similar effects. These molecules may regulate the entry of cells into programmed cell death (apoptosis).

GROWTH FACTORS IN FETAL GROWTH: ANIMAL MODELS

In this section, comparisons are made with corresponding human mutations when appropriate.

Insulin-like Growth Factor Axis Expression

The embryo establishes its own IGF axis very early in gestation, providing evidence that this axis plays a functional role in fetal growth. The mRNAs for IGF-II, the type 2 IGF receptor, and IGFBP-2, -3, and -4 are among the earliest of fetal mouse transcripts and are detectable in two-cell murine embryos by reverse transcriptase–polymerase chain reaction analysis.[55-57] These transcripts become more abundant as gestation progresses. The distribution of the type 2 IGF receptor in tissues corresponds to that of IGF-II mRNA. IGF-I expression occurs somewhat later, by 7 to 8 days gestation in mouse embryos.[51] The type 1 IGF receptor is expressed in the eight-cell rat embryo, and its mRNA is widely distributed in various tissues by midgestation.[58]

Regulation of IGF expression in fetal life is not fully defined. Postnatal IGF synthesis is controlled by GH and by nutritional status, but IGF regulation in intrauterine life is less well understood and does not appear to be GH-dependent. Furthermore, evidence suggests that IGFs not only stimulate proliferation but also can induce differentiation events in some cells during organogenesis in an autocrine or paracrine manner. With regard to organ differentiation, these actions, probably are tightly regulated within specific tissues and developmental stages during intrauterine life.

Overexpression of the Growth Hormone–Insulin-like Growth Factor Axis in Transgenic Animals

Overexpression of Growth Hormone and Insulin-like Growth Factor-I and -II

The creation of transgenic mice overexpressing GH-IGF axis molecules has furthered the understanding of the control of IGF-I secretion and actions in fetal and postnatal growth (Table 177-1). Mice with GH overexpression display increased postnatal linear growth and dramatic weight gain to as much as twice the normal body weight with selective organ hypertrophy.[59,60] Acceleration of growth correlates with the onset of GH-dependent

TABLE 177-1

Physical and Biochemical Features of Various GH/IGF-I Transgenic Mouse Models

Transgene Model	Postnatal Growth (% normal)	GH	IGF-I	IGFBP-3	Brain Size	Liver Size
GH	200	⇈	⇈	—	Normal	⇈
IGF-I	130	↓	↑	↑	⇈	↑
GH^-	60	⇊	⇊	⇊	↓	⇊
$GH^-/IGF\text{-}I^+$	Normal	↓	Normal	Normal or ↓	↑	↓
IGFBP-3	80	—	⇈	⇈	↓	↑

IGF-I expression during the second to third postnatal week, suggesting that the growth-promoting properties of the transgene are mediated through the induction of IGF-I expression postnatally. IGF-I transgenic mice also are larger than normal, but their weight increase (to 30% over that of control mice), which occurs after 4 to 6 weeks of postnatal life, is more modest than that in the GH transgenic mice, which probably is related to the lower IGF levels seen with the former.[61] The brains and other organs of these animals demonstrate a large increase in weight relative to overall growth. IGF-I levels in these mice are elevated but are lower than those seen in the GH-transgenic mice; endogenous GH and hepatic IGF-I expression are suppressed by 60% to 75% (see Table 177-1).[62] IGF-II transgenic mice are not bigger than normal, but in the existing models, the major portion of IGF-II expression occurs postnatally.[63]

To separate out more completely the effects of endogenous GH and IGF-I expression, IGF-I transgenic mice were mated with a GH-deficient mouse strain.[64,65] The offspring displayed normal body weight and linear growth. Some non–GH-dependent effects of IGF-I were present, including a disproportionate increase in brain weight, implying that these are local effects of IGF-I. The livers of these mice were hypoplastic (an effect seen in GH-deficient mice), an abnormality that was only partially corrected with IGF-I. Overall, the transgenic animal data confirm the role of GH and IGF-I in postnatal growth and suggest that IGF-I mediates a majority of GH effects, but that variations in local expression IGF-I can result in altered growth of specific tissues.

Overexpression of IGFBPs

Mice overexpressing IGFBP-1 are similar in size to (or slightly smaller than) the wild type at birth.[66,67] Brain weights are decreased in these transgenic mice compared with wild type mice.[68] It is generally thought that IGFBP-1 functions to inhibit IGF-I action and thus may contribute to the impaired fetal brain development seen in these transgenic animals. Overexpression of IGFBP-2 in mice did not result in a different birth weight and was associated with a reduction of body weight gain only after the age of 3 weeks.[69]

In two different IGFBP-3 transgenic mouse models, transgene expression resulted in a 10% reduction in birth weight, as well as organomegaly in body regions different from the major expression sites.[70-72] Total body weight in transgenic mice overexpressing IGFBP-4 is indistinguishable from that in control animals.[73]

Insulin and Insulin-like Growth Factor Axis–Null Mutations

Studies of null mutations (knockouts) created by homologous recombination in the genes encoding insulin, IGF-I, IGF-II, and the IGF receptors have enabled investigators to explore the role of the IGF axis in fetal growth. In all of the null mutations, body proportions are qualitatively normal.

Insulin-like Growth Factors and Insulin-like Growth Factor Receptor Mutations

Mice in which the IGF-II gene has been eliminated by targeted disruption exhibit severe growth restriction, to 60% of normal size at birth, with small placentas.[74,75] After birth, however, survival is normal, and the mice grow at a near-normal rate, although they remain small relative to normal littermates. In the heterozygous state, the IGF-II knockout can manifest itself only if the paternal allele is targeted, elegantly demonstrating the paternal imprinting of the IGF-II gene.[76] IGF-I gene–targeted mice also are small (60% of normal) at birth, whereas the placentas are of normal size.[74,77,78] Furthermore, they display dramatic growth arrest postnatally (30% of normal). These mice also are more likely to die during the neonatal period; the increased death rate may be related to poor development of diaphragm and lung.

Postnatal development of surviving IGF-I–knockout mice has been analyzed in detail. At 2 months of age, IGF-I–deficient mice show extensive reductions in brain size, consistent with a role for IGF-I in axon growth.[79] Morphologic and morphometric analyses of long bones in mice lacking IGF-I indicate that IGF-I promotes bone development by increasing cellular proliferation, without affecting differentiation. The growth plates are uniformly affected, with reductions in the resting, proliferative, and hypertrophic chondrocytes. As a result, the formation of secondary ossification centers is delayed.[80] Other reports have described homozygous IGF-I mutations in humans, manifesting as severe prenatal and postnatal growth failure, sensineural deafness, and mental retardation.[81-83] Mice with null mutations of both IGF-I and IGF-II also displayed more severe IUGR (to 30% of normal size), and all of these mice died after birth from respiratory failure. Thus IGF-I and -II appear to have independent growth-promoting activities that are compounded when both are absent. The results of the studies confirm that both IGF-I and IGF-II appear to be critical for fetal growth, whereas IGF-I promotes postnatal growth as well. IGF-II signaling may dictate the size of the placenta, thereby affecting fetal size.

Liver IGF-I–deficient (LID) mice grow normally despite a 75% reduction in serum IGF-I levels.[84] In these mice, expression of IGF-I in nonhepatic tissues is normal, suggesting that the normal growth exhibited by these animals may be mediated by autocrine-paracrine actions of IGF-I, as well as by some nonhepatic sources of circulating IGF-I. Similarly, ALS-knockout (ALSKO) mice demonstrate only a 10% reduction in body weight despite a 65% reduction in circulating IGF-I levels.[85] More recent reports of human ALS mutations show similar findings: markedly reduced circulating total IGF-I levels, undetectable ALS, but only mildly affected prenatal and postnatal growth.[86,87] These findings are consistent with the idea that locally synthesized IGF-I plays a prominent role in somatic growth. LID + ALS double-knockout mice showed serum levels of IGF-I reduced to approximately 10% to 15% of normal levels.[88] In these animals, GH levels were markedly increased and linear growth was severely attenuated (for a 30% reduction in body length and weight starting at the age of 2 to 3 weeks). Thus the double-gene-disruption LID + ALSKO mouse model demonstrates that a threshold concentration of circulating IGF-I is necessary for normal growth.

Gene targeting of the type 1 IGF receptor results in severe IUGR, with a phenotype similar to that seen in double–IGF-I/IGF-II gene targeting.[77] These mice also die after birth, apparently from inadequate respiration. The results indicate that the mitogenic effects of IGF-I and IGF-II are mediated primarily through the type 1 IGF receptor. Although no humans have been identified with homozygous mutations, a handful of patients have been described with heterozygous mutations of the IGF-IR or the IGF-IR proreceptor, all with IUGR progressive postnatal growth failure.[89-91]

Although mice with disruption of the type 1 IGF receptor displayed growth failure, only the mice missing IGF-II displayed decreased placental growth. Indeed, placenta-specific IGF-II represents a major regulator of placental growth.[92] By controlling placental growth and ability to transport vital amino acids and glucose to the fetus, placental IGF-II in turn affects fetal growth, especially in late gestation.[93,94] Furthermore, the fact that genetic IGF-II deficiency has a phenotype independent of that associated with the type 1 and type 2 receptors suggests that an additional receptor mediates IGF-II actions in fetal life. Gene targeting of the type 2 receptor results in mice that are 30% larger than littermates—a finding compatible with its negative growth-modulating effect.[95] This gene is maternally imprinted in mice but not in humans. Thus those mice inheriting the maternal 2R allele lack functional 2R receptors and die shortly after birth. The levels of lysosomal enzymes in amniotic fluid are increased, and selective organ enlargement is apparent.

It has been hypothesized that mice lacking the type 2R accumulate toxic levels of IGF-II.[95]

These studies provide supportive evidence that the IGF-II/mannose-6-phosphate (Man-6-P) receptor may function primarily to degrade and remove IGF-II from the extracellular environment. The opposite imprinting of IGF-II and the type 2 IGF receptor may modulate fetal demand and maternal supply of nutrients.[96] The phenotype of mice lacking both type 1 IGF receptor and type 2 IGF receptor provides evidence for the ability of IGF-I to signal through the insulin receptor, because these mice exhibit normal embryonic and postnatal growth. It has been shown that mice lacking the type 2 IGF receptor are rescued from perinatal lethality and undergo near-normal postnatal development when they carry null mutations of the type 1 IGF receptor. Triple mutants lacking IGF-II and both IGF receptors exhibit only approximately 30% of normal weight, phenotypically indistinguishable from double mutants lacking IGF type 1 receptor and IGF-II (see Table 177-2).[97] Genetic evidence indicates that the receptor supporting somatic growth of the type 1– type 2 IGF receptor double mutants is the insulin receptor, because mice lacking all three genes (insulin receptor, type 1 IGF receptor, type 2 IGF receptor) are nonviable dwarfs that attain only 30% of normal size.[98]

To address the issue of the role of GH and IGF-I in growth, Lupu and colleagues[80] have generated mice lacking both IGF-I and GH receptor. Double-knockout mice exhibit a greater degree of growth restriction (to 17% of normal size) than that seen in mice lacking either gene alone, indicating that the two genes act both independently and synergistically to promote growth. Whereas IGF-I promotes both prenatal and postnatal growth, GH appears to be required exclusively for postnatal growth, because the growth defect in GH receptor–deficient mice becomes apparent only after postnatal day 20.

Insulin and Insulin Receptor Mutations

The generation of mice bearing insulin receptor mutations has been instrumental in delineating the pathogenesis of insulin resistance, diabetes, and obesity. In terms of somatic growth, mice lacking the insulin receptor are born at term with slight growth retardation (approximately 10%)[98]; inactivation of the two insulin genes also results in a slight impairment of embryonic growth, with a 15% to 20% decrease in birth weight.[99] The growth impairment observed in mice lacking the insulin genes indicates that the effect of insulin to promote mouse embryo growth is paltry compared with that of IGF-I and IGF-II. Mutations of the insulin receptor in humans are phenotypically heterogeneous in terms of the metabolic consequences. As in mice, lack of the insulin receptor in humans is compatible with embryonic development and term birth. Most strikingly, however, human infants lacking the insulin receptor demonstrate severe growth restriction at birth and gain little if any weight thereafter.[100] The most likely explanation of the difference between insulin receptor–deficient mice and children is that embryonic growth in humans and that in rodents follow different patterns. During the last trimester of human gestation, corresponding to the first weeks of postnatal life in mice, a significant increase in adipose mass is seen. The adipose organ is exquisitely sensitive to insulin, as demonstrated by the excessive adiposity of fetuses exposed to high insulin concentrations in utero who are born large for gestational age (LGA) as a result of maternal diabetes[101,102] or hyperinsulinism.[103,104] Thus, in contrast with its role in mice, insulin is a fetal growth factor in humans. Null mutations of the human insulin gene have not been reported.

Insulin-like Growth Factor–Binding Protein Mutations

When the knockout approach was applied to the IGFBPs, the results were surprisingly subtle: In IGFBP-2–knockout mice, a reduction in spleen weight of adult males was the only morphologic alteration.[104] IGFBP-4 mutants appear to be slightly smaller than their normal counterparts, and the genetic ablation of IGFBP-6 has not resulted in any apparent phenotypic manifestation.[105] A recently described IGFBP-3/IGFBP-4/IGFBP-5 triple-knockout mouse was shown to have a modest reduction in birth weight, similar to that for the IGFBP-4 single-gene mutant, and a moderate reduction in postnatal growth (78% of wild type).[106] It has been speculated that functional compensation by other members of the IGFBP family (including IGFBP-rPs) may prevent the appearance of dramatic phenotypes.[107]

Insulin Receptor Substrate and AKT Mutations

The two IRS proteins, IRS-1 and IRS-2, mediate many insulin and IGF responses, especially those associated with somatic growth and carbohydrate metabolism. The IRS-1 branch of the pathway plays a significant role in mediating the effects of IGF-I on growth. Deletion of the *IRS1* gene in mice reduces embryonic and neonatal growth,[108] whereas deletion of *IRS2* barely reduces prenatal and early postnatal growth by 10%.[109] The *IRS1*-knockout mouse has been described as having a phenotype of fetal growth restriction to 50% to 70% normal size in the homozygous state.[108] Postnatally, these mice remain small (at 50% to 70% of normal weight), and catch-up growth does not occur. The offspring display no obvious developmental abnormalities and have normal bone development. Gene targeting of *IRS1* results in impairment of both growth and carbohydrate metabolism, compatible with its role in mediating both insulin and IGF-I effects.[108,110] Growth is reduced 40% in *IRS2*-null mice that are also haploinsufficient for IRS-1, whereas growth is reduced 70% in *IRS1*-null mice also haploinsufficient for *IRS2*.[111] Thus IRS-2 cannot fully replace IRS-1 in this process. *IRS2*-null mice also exhibit a diabetic phenotype with peripheral insulin resistance and panceatic beta cell failure.[109]

Downstream from IRS, *AKT1* and *AKT2* gene deletions also result in different phenotypes. Although *AKT2*-null mice exhibit insulin resistance,[112] at birth *AKT1*-null mice have a 20% reduction in body weight compared with wild-type mice.[113] The decrease in body weight in AKT-1–deficient mice persists throughout postnatal development regardless of sex, and glucose tolerance is normal.[113] These data demonstrate that AKT-1 is more important to the growth of the organism, both in utero and after birth, whereas AKT-2 is critical to insulin-dependent control of carbohydrate metabolism.

IGF axis gene knockouts are summarized in Table 177-2.

GROWTH FACTORS IN HUMAN FETAL GROWTH

Pregnancy

During pregnancy, circulating levels of IGFs rise in maternal serum and significantly in fetal serum.[114,115] Placental GH, human placental lactogen (HPL), and nutritional factors may regulate maternal IGF-I levels during pregnancy.[116,117] Placental GH is not detected in the fetus, but HPL stimulates IGF-I and IGF-II production in fetal tissue.[118] Maternal IGFBP-1 levels rise 5- to 10-fold during gestation,[29,114] probably as a manifestation of the insulin resistance of pregnancy. IGFBP-1 levels are substantial in amniotic fluid, where they may have a fetal renal or hepatic source. A negative correlation exists between term IGFBP-1 levels in maternal serum or IGFBP-1 levels in amniotic fluid at 16 weeks gestation and fetal weight.[119] Thus the elevated IGFBP-1 concentrations (10 to 100 ng/L) in amniotic fluid may modulate fetal IGF action. It also has been suggested that elevated maternal IGFBP-1 levels may limit trophoblast invasion, thereby negatively affecting placental growth.

Pregnancy-associated IGFBP-3 protease activity, which has been shown to appear after 6 weeks gestation, is responsible for the decrease in and progressive disappearance of intact IGFBP-3 on Western ligand blot analysis (without a change in IGFBP-3 immunoreactivity) and the appearance of lower-molecular-weight

TABLE 177-2

Physical and Biochemical Features of the Various GH/IGF1–Knockout Mouse Models

Knockout Model	Birth Weight (% of normal)	Other Features	Postnatal Course
IGF-I	60	Normal placenta; decreased brain size	Slow growth; death before adulthood
IGF-II	60	Small placenta	Normal growth rate
IGF-I + IGF-II	30	Small placenta; no respirations	Immediate postnatal death
LID	Normal	75% reduction in serum IGF-I	Normal growth
ALSKO	Normal	65% reduction in serum IGF-I	10% reduction in body weight
LID + ALSKO*	Normal	85-90% reduction in serum IGF-I; increased GH levels	30% reduction in body weight and length
IGF-I receptor	45	No respirations	Immediate postnatal death
IGF-II receptor	130	Edema, large placenta	Death in utero
IGF-I receptor + IGF-II receptor	100	Large placenta	Normal growth rate
IGF-I receptor + IGF-II	30	Small placenta	
IGF-II receptor + IGF-II	80	Small placenta	
IGF-I receptor + IGF-II receptor + IGF-II	30	Small placenta	
IGF-I + GH receptor	17		Postnatal growth retardation
IRS-1	50-70	Insulin resistance	Survival with normal growth rate, but persistent small size (no catch-up growth)
IRS-2	90	Insulin resistance, pancreatic beta cell failure	Development of diabetes
AKT-1	80	Normal glucose tolerance	Neonatal death in some animals Persistent small size in surviving pups
Insulin genes (Ins1 + Ins2)	80-85	Diabetes	Normal growth rate; early death from diabetes
Insulin receptor	90	Diabetes; hypotrophy of subcutaneous fat	Normal growth rate; early death from diabetes

fragments of IGFBP-3 with a lower affinity for IGFs.[29,120,121] It has been demonstrated that IGFBP-2, IGFBP-4, and IGFBP-5 also undergo proteolysis during pregnancy.[29,122] The significance of the pregnancy-associated protease remains unclear. Some investigators have postulated that IGFBP proteolysis may play a role in facilitating trophoblastic invasion.[123] It has been demonstrated that the pregnancy serum protease may play a role in regulating IGF bioactivity by making IGFs more available to the cells.[124] It is possible, therefore, that this proteolytic activity could affect placental and, consequently, fetal growth by releasing free IGFs and allowing increased receptor binding.

Insulin-like Growth Factor Axis Expression by the Fetus

Available data regarding the earliest expression of the IGF axis in the human embryo are limited. In the trophoblast, however, *IGF2* mRNA is detected by days 12 to 18,[125,126] and soon after, mRNA encoding the type I and II receptors also can be found.[127] The animal data demonstrating IGF-II expression before that of IGF-I indicate the importance of IGF-II in early embryogenesis. Expression of IGFs is widespread in all human tissues during the second trimester.[128] Western immunoblotting techniques have demonstrated that type II IGF receptors are present in most human fetal tissues at 23 weeks.[129] The widespread expression and action of IGFs in embryogenesis are mostly autocrine-paracrine in nature and GH-independent. Although the control of IGF levels in the fetus is not well understood, IGF actions are thought to occur in concert with other hormones and growth factors and to be greatly influenced by the presence and distribution of IGFBPs. Techniques of immunocytochemistry, in situ hybridization, and Northern blot analysis have identified IGFBP-1 through IGFBP-6 in most fetal tissues.[130,131] Synthesis and secretion of IGFBPs are tissue-specific.[129]

In the third trimester, fetal serum IGF-I concentrations steadily increase, correlating with the time of peak fetal weight gain. Although fetal serum IGF-I levels are lower than those in adults, several investigators have reported that maternal and fetal cord serum IGF-I levels correlated with birth weight,[132-135] suggesting co-regulation by nutritional factors. This correlation, however, has not been a consistent finding in every study.[114] Insulin levels appear to affect IGF levels as well, although this effect may be secondary. Fetal IGF-II levels have shown a correlation with birth weight in some studies but not in others.[132,135] The animal studies presented in the previous section indicate that IGFs are not under endocrine control prenatally and that GH deficiency, although affecting postnatal growth, does not result in significant prenatal growth retardation. Nevertheless, data from humans with hypopituitarism do support a role of GH in third-trimester fetal growth, because these infants, although demonstrating overall growth still within the normal curves, often have mean birth lengths 0.8 to 1.7 standard deviation scores below the mean.[136,137] Furthermore, neonates with GH insensitivity (resulting in Laron syndrome) also are small at birth (–1.59 mean standard deviation score [SDS] for height), and their serum levels of IGF-I and IGF-II are low at birth as well.[138] The phenotype of severe IUGR in patients with mutations of the *IGF1* gene proves that IGF-I plays a critical part in human fetal growth, independently of GH.[81-83]

The IGFBP profile for cord serum differs from that for adult serum. IGFBP-3 is low, with relative predominance of IGFBP-2.[134] Furthermore, IGFBP-1 levels in cord serum are up to 10 times higher than levels seen in adults and decline markedly during the first week of life. IGFBP-1 levels show a negative correlation with birth weight. In addition, correlation between IGFBP-1 and insulin level has been demonstrated both in infants who are born LGA and those with IUGR. In LGA infants born to nondiabetic mothers, significantly elevated insulin levels are associated with decreased IGFBP-1 levels; an opposite trend is seen in IUGR infants.[139]

Intrauterine Growth Restriction

IUGR is defined by a birth weight or length 2 or more standard deviations below the mean (i.e., –2 SD) for gestational age and gender, a cutoff that corresponds approximately to the 3rd

percentile for gestational age. A total of 4,112,052 infants were born in the United States in 2004; of these, approximately 94,600 infants were affected with IUGR, as determined using an overall prevalence rate of 2.3%.[140]

IUGR may result from diverse genetic and environmental influences on the developing fetus: chromosomal defects, maternal nutrition, genetics, or decreased uteroplacental blood flow. Disproportional IUGR can result from circulatory changes in the fetus that favor redistribution of blood flow to the heart and brain. In severe IUGR, head size is compromised as well. Endocrine factors appear to play a role in the pathogenesis of IUGR. Decreased levels of placental GH and maternal IGF-I have been demonstrated in IUGR.[141] In both preterm and full-term infants, low birth weight is associated with low cord serum IGF-I, IGF-II, and IGFBP-3 and high IGFBP-1.[134,135,139,142,143] Some investigators, however, have demonstrated more variable IGF levels in infants with IUGR,[114] indicating that this single marker may underestimate the complexity of this condition and the heterogeneity of its causes. IGFBP-2 levels may be higher, similar to those seen in hypopituitary patients postnatally.[139] The increase in IGFBP-1 (mostly of hepatic origin) appears to be the result of inadequate nutrient supply, with resultant hypoinsulinemia.

It has been speculated that the elevated IGFBP-1 levels in these infants may induce sequestration of IGFs, thereby restricting fetal growth. Not only are alterations in IGF levels seen in children with IUGR, but the IGF type 1 receptor affinity also was reduced in a subgroup of patients with IUGR.[144] The finding of a homozygous deletions of *IGF1* in a handful of patients with severe IUGR[81-83] implicates IGF-I in the etiology of this disorder, but larger studies looking for *IGF1* mutations in larger groups of children born with IUGR have failed to identify them, suggesting that these mutations are not a common cause of IUGR.[145-147] Conversely, an association between a polymorphism of the *IGF1* gene and low serum IGF-I levels was found in a study involving children with short stature born small for gestational age (SGA), suggesting that genetically determined low serum IGF-I levels may lead not only to reduction in birth length, weight, and head circumference but also to persistent short stature.[148] TGF-β also has been implicated in the pathogenesis of IUGR. TGF-β cord blood levels were found to be significantly lower in pregnancies complicated by IUGR than those in "control pregnancies," in which children were born at a weight appropriate for gestational age (AGA).[53]

A majority of children born with IUGR will experience adequate catch-up growth in length during the first 2 years of life. Postnatal catch-up growth usually begins immediately after birth, and in fact, most of the increases in SDS for height occur by 6 months of age.[149,150] McCowan and co-workers[151] showed that 40 of 203 infants (20%) born SGA remained short and 31 (16%) remained light at 6 months. Around 2 years of age, most children born SGA tend not to exhibit further catch-up growth, and approximately 10% will remain at –2 SD or below for height throughout childhood and adolescence and into adulthood, indicating a persistent failure to achieve normal linear growth. In one study of a large population of neonates with follow-up to adulthood, height was measured at the age of 20 to 21 years. Compared with an AGA control population, the SGA subjects were 4 to 6 cm shorter as adults.[152]

In 2001, the use of recombinant human GH was approved by the U.S. Food and Drug Administration (FDA) for the long-term treatment of growth failure in children born SGA who fail to manifest catch-up growth by age 2 years. Multiple studies have demonstrated the efficacy of GH therapy in promoting catch-up growth in children born with IUGR.[153-157] Some of these studies also have demonstrated positive effects of GH therapy on body composition, blood pressure, and lipid metabolism.[158-161,137-139] Although decreased insulin sensitivity has been reported in SGA children on GH treatment, glucose tolerance remained normal,[162] and fasting insulin and glucose levels returned to the levels in control subjects after the discontinuation of treatment.[158] Thus far, the evidence suggests that GH therapy in short children born SGA is safe and efficacious.[158,162]

Growth restriction during the fetal period has been associated with a higher prevalence of such conditions as hypertension, cardiovascular disease, and type 2 diabetes in adult life.[163] These findings constitute the basis for the fetal origins of the adult disease hypothesis, which proposes that insults in utero lead to "reprogramming" of the endocrine system, which in turn predisposes infants born with IUGR to adverse health outcomes in adulthood. Lifelong programming of the IGF system by the intrauterine hormonal and nutritional environment has been suggested to be a key mediator of the link between small size at birth and cardiovascular disease in adulthood.[142] An increased prevalence of metabolic syndrome (consisting of obesity, cardiovascular disease, hypertension, and type 2 diabetes) has been reported among adults who were born SGA.[164] In addition to risk factors associated with IUGR, increasing evidence suggests that rapid postnatal catch-up growth further enhances risk for development of obesity and the metabolic syndrome.[165,166] Insulin resistance has been linked to thinness at birth followed by obesity in adulthood.[167,168]

Macrosomia

Alterations in the IGF axis also have been demonstrated in infants who are LGA, including those born to diabetic mothers (see Figure 177-2 and Table 177-3). In these infants, IGF-I, insulin, and IGFBP-3 levels are increased, whereas IGFBP-1 levels are significantly decreased.[139] Fetal hyperinsulinemia secondary to maternal diabetes mellitus results in increased body fat, with a more modest increase in body length. Insulin promotes fetal growth by permitting nutrient uptake, and increased IGF-I production may be a result of the nutritional state of these infants.[169] The alterations in IGFBP-1 also appear to be secondary to the higher insulin levels, but IGF-I levels and nutritional status also may play a role. It has been speculated that the lower IGFBP-1 levels result in less inhibition of IGF-I effects, resulting in greater growth.

Infants with the Beckwith-Wiedemann syndrome have a doubling in *IGF2* gene dosage as a result of alterations at chromosomal locus 11p15.5. These infants are macrosomic and often demonstrate evidence of congenital hyperinsulinism. Placental hypertrophy is seen as well.[170] In the limited studies that have been performed, levels of IGF-II are not increased in cord serum in these infants, but it is possible that *IGF2* gene dosage may increase fetal growth through the stimulation of placental growth.[123] These infants also are predisposed to the development of IGF-II–dependent neoplasms, such as Wilms tumor. In fact, in an analysis of birth weights for more than 1800 patients with Wilms tumor, the mean was significantly greater than the national average, especially for those with Beckwith-Wiedemann syndrome or hemihypertrophy, suggesting the presence of systemic growth effects of IGF-II on both fetal size and the development of Wilms tumor.[171] Of interest, single-nucleotide polymorphisms in *H19,* a maternally imprinted gene implicated in translational regulation of *IGF2,* when identified in either offspring or maternal DNA, have been associated with elevated cord blood IGF-II levels and higher birth weight.[172] This evidence suggests a role for *H19* in controlling fetal growth restraint through regulation of IGF-II.

SUMMARY

In recent years, the medical and scientific literature has witnessed an explosion of information regarding the physiology of growth and growth factors in prenatal life, and the various components of the IGF axis in particular. Local IGFs and IGFBPs are of prime importance in fetal and placental growth. Genetic manipulations of IGF axis components in fetal mice have further clarified the

roles of these agents. Undoubtedly, the coming years will bring even more new information on the physiology and pathology of these key cellular regulators. These discoveries are likely to lead to the increasing use of diagnostic tests and to the recognition of genetic mutations of the GH-IGF axis in cases of IUGR, as well as to therapeutic applications of these agents.

Growth Hormone and Prolactin

This chapter examines the roles of the diverse and varied functions of growth hormone (GH) and prolactin (PRL) in fetal development and the perinatal period.These are evolutionarily related hormones of the lactogenic superfamily, and, although their concentrations are high in fetal life, the functional significance of these high concentrations remains uncertain.The placenta is also a rich source of somatogenic and lactogenic hormones secreted into the maternal circulation, where they are believed to play an important role in maternal metabolic adaptations to support pregnancy and in preparation of the mammary gland. Although high levels of circulating GH and PRL in the fetus and neonate are universal in mammals, much more diversity exists in the nature of placental hormone production, reflecting gene duplications of either the GH or placental lactogen (PL) ancestral genes (see later discussion). This chapter focuses on the roles of GH, PRL, and the PL hormones during fetal development and the perinatal period.

THE DEVELOPMENT OF HYPOTHALAMOPITUITARY CONTROL

The differentiation of adenohypophyseal cell lineages within Rathke's pouch is dependent on a series of transcriptional factors that generate spatial and temporal patterns of gene expression (for review, see reference 1). Gene deletions or mutations of some of these signaling molecules (i.e., Pit-1, Six6, and Pax6) have been shown to result in pituitary abnormalities or altered numbers of pituitary cell types. Pit-1, in particular, is required for the development of somatotrophs, lactotrophs, and thyrotrophs.[1] Dominant and recessive mutations in Pit-1 lead to

absent or diminished GH, PRL, and thyroid-stimulating hormone secretion. Pit-1 regulates the respective transcription of GH, PRL, and thyroid-stimulating hormone, acting as a gene activator or repressor, depending upon in which cell type these genes are expressed. Pit-1 interacts with cell type–specific transcriptional co-regulators, and this interaction may be determined by slight structural changes in their otherwise highly homologous 5′ flanking regions. A 2-bp sequence variation in the Pit-1 binding site of the GH promoter can induce a conformational change in the DNA structure that may be critical to the transcriptional machinery distinguishing between the GH and PRL regulatory regions. Thus several mechanisms are in place to ensure specificity of pituitary cell-type transcriptional control.

In mice, differentiation of the thyrotrope occurs around embryonic day 12.5 (E12.5),[1] making thyroid-stimulating hormone one of the first pituitary gene products observed. Somatotrophs and lactotrophs develop last (in mice, approximately E16), and can comprise up to half of the pituitary cell-type population.[1,2] In sheep, in which brain development is largely completed before birth, both somatotrophs and lactotrophs can be identified by 60 days postconception; term is 146 days).[3] In humans, GH is first detectable in the fetal pituitary by immunocytochemistry at 8 weeks postconception. PRL-secreting cells can be detected by 12 weeks postconception, but their number is low until after 26 weeks postconception, when a considerable hyperplasia of lactotrophs is observed.[4]

Some pituitary tumors secrete both GH and PRL from a single cell, and it has been suggested that there may be a common bihormonal-secreting precursor. In studies of primary pituitary cultures derived from neonatal rats[5] and cultured human fetal pituitary cells,[6] one third of the GH- or PRL-synthesizing cells secrete both GH and PRL simultaneously. As PRL secretion inevitably commences at a later stage of development than GH secretion, it has been suggested that lactotrophs may be derived from this putative somatomammotroph.[6] Indeed, it has been shown that an immortalized cell line—GHFT[7]—has properties of somatomammotrophs and is able to differentiate to PRL-secreting lactotrophs after treatment with FGF-2.[8]

The development of the hypothalamic-pituitary adenohypophyseal circulation has been reviewed elsewhere.[9,10] The portal circulation matures early in development and is not a rate-limiting step in the development of functional control of adenohypophyseal secretion in fetal life. Instead, the development of neuroregulatory control over hypothalamic release and inhibitory factors, as well as the development of hormone receptors, makes way for negative feedback loops to appear. Additionally, the unique milieu of the fetus exposes it to placental neuromodulators, such as prostanoids and estrogen, which play a part in the changing pattern of circulating fetal and perinatal hormone concentrations.

The mechanisms for GH release and inhibition develop progressively from early gestation. Somatostatin, which is inhibitory to GH release, is detectable in the human fetal hypothalamus by 11 weeks postconception,[11,12] and somatostatin-staining neurons terminate in the median eminence by 16 weeks.[13] GH-releasing hormone–staining neurons are detected in the median eminence by 18 weeks.[14] Less is known of the development of the other hypothalamic GH-releasing factor, ghrelin (discussed later). The dominant stimulator of PRL release is the tripeptide, thyrotropin-releasing factor. However, in contrast to GH release, which is low in the absence of hypothalamic influences, PRL release is under tonic inhibition by dopamine of hypothalamic origin.[15] Dopamine is present in the human fetal hypothalamus by 10 weeks gestation, at concentrations higher than those observed in the adult hypothalamus.[16,17] Dopaminergic regulation of PRL release can be demonstrated in the fetal sheep by the beginning of the third trimester. Additionally, dopamine inhibition may derive from nonneuronal sources.[15,18,19]

GROWTH HORMONE

Growth hormone (GH) promotes postnatal somatic growth by stimulating paracrine and endocrine production of IGF-1 and also has IGF-1 independent effects on metabolism. The pulsatile release of pituitary GH is primarily due to the opposing influences of hypothalamic GH-releasing hormone and somatostatin. Circulating GH and IGF-1, in turn, can influence their own expression by negative feedback mechanisms to the hypothalamus and pituitary.

GH is detectable in human fetal plasma by at least 10 weeks postconception.[20] In species with long gestations, such as the human and sheep, high levels of GH relative to postnatal concentrations are established by midgestation. The pattern of secretion can be shown to be pulsatile in utero with both elevated peaks and nadirs and sexually dimorphic.[21] Concentrations fall gradually in late gestation and precipitously within hours of birth.[21] This pattern appears to be due to early maturation of responsivity of the fetal somatotroph to GH-releasing hormone, plus later development of inhibitory control accelerated by endocrine and metabolic events surrounding birth. The release of somatostatin and GH-releasing hormone is under control of a variety of neuromodulators and neurotransmitters. These include dopamine, which is inhibitory[22]; opiates[23]; serotonin[24]; γ-aminobutyric acid (GABA)[25]; and β-adrenergic stimuli.[26] The development of these neurotransmitter controls appears progressively during the late phase of pregnancy.[21] Immaturity of inhibitory control by somatostatin and IGF-1[9,27] contribute to the high concentration of GH observed in the fetus. Both somatostatin and GH-releasing hormone influence the sheep fetal pituitary from at least 75 days postconception,[28,29] although the data suggest that in vitro and in vivo somatostatin is less effective in inhibiting GH secretion prenatally than it is postnatally.[30,31] IGF-I levels are low in the fetal circulation because of the relative immaturity of GH receptors (GHR), thus failing to induce the negative feedback loop that would prevent GH hypersecretion.[32] Hence the fetal pituitary is "gated" to remain in a hypersecretory state.

Ghrelin, an endogenous ligand for the GH secretagogue receptor, has potent GH-secreting properties.[33] Ghrelin is primarily produced in the stomach but is also detected in the pituitary, hypothalamus, and placenta.[33] Several reports suggest a role for ghrelin in pregnancy. Ghrelin levels are higher in women with pregnancy-induced hypertension than in normotensive pregnant women,[34] which is supported by observations of ghrelin-binding studies in heart and blood vessels.[35] Its effects on fetal development are less clear—knockout mice models show that it is not essential for embryonic or fetal development under normal nutritional conditions, suggesting that its role is largely related to postnatal regulation of energy balance via appetite modulation.[36] Neverthess, ghrelin levels are high in the neonate, in whom it may have a role in the initiation of feeding and protection against neonatal hypoglycemia.[37] Ghrelin also has been detected in fetal and infant lung, where its expression peaks in the first 18 weeks gestation and decreases thereafter.[38] The role of ghrelin in controlling fetal GH secretion, however, is unknown.

In humans, GH levels are high at birth but decline rapidly within days and then progressively during the following months.[39,40] The mechanism of this decline has been studied in detail in the sheep. Free fatty acid infusions inhibit GH secretion almost totally by a direct action on the somatotroph.[27] Free fatty acid concentrations are low until birth, when they rise rapidly within a few minutes owing to the onset of nonshivering thermogenesis. In a series of experiments in which the individual events of birth have been mimicked without delivering the fetus, it has been possible to show that the initiation of nonshivering thermogenesis is dependent on oxygenation of the fetus and removal of a presumed placental inhibitor.[41,42] Data in other species are limited, but in the human term infant, thermogenesis is initiated soon after birth[43]

and increases more slowly in the premature infant, offering one explanation for the slower GH decline in preterm infants.[44]

The functional significance of elevated GH concentrations in the fetus remains uncertain—the phenotype of the child with isolated GH deficiency is rather unremarkable: generally tending to have hypoglycemia, micropenis, and perhaps a small reduction in birth length. Indeed, it has generally been considered that GH had no significant role in promoting fetal skeletal growth, and recent work has also found that in the neonate, growth is dependent on increased bioavailability of IGF-1, which is probably directly regulated by nutrition.[45] It has been postulated that the low responsiveness is due to low levels of the GHR and related signaling components.[46] In line with this, the small effect of GH in late gestation on linear growth in clinical studies[47] has been linked to the late appearance of the GHR in musculoskeletal tissues.

The physiology of the GHR has been reviewed in other publications.[48-50] Data suggest that the concentration of GHR in hepatic tissue is low until after birth, as determined in sheep,[51,52] bovine,[53,54] pig,[55] and rat,[56] and GHR appears to be induced by the peripartum glucocorticoid surge.[57] If extrapolated to the human, it would suggest that GH-dependent growth first appears after the week 34 of pregnancy.

Pantaleon and colleagues[58] have reported that transcripts encoding GH, GHR, and GH-binding protein have been detected in mouse preimplantation embryos from E1 to E4, followed by detection of GH protein at the two-cell stage. GHR is presumed to be functional at this stage in that exogenous GH administration to blastocysts promotes glucose transport and glycogen breakdown and increases protein synthesis.[58] Waters and Kaye[59] suggest that the increased glucose transport and glycogen breakdown promote the formation of ATP that fuels the Na^+ pumps and ionic gradients required for blastocoele formation and resulting cell proliferation. Reports have shown immunoreactive GHR in the human fetus from as early as 8.5 weeks fetal age.[60,61] Whether GHR is fully functional at these early developmental stages remains to be determined. GHR can be alternatively spliced to give rise to transcript variants, although not much is known about their function.[62] One common variant is an individual-specific polymorphism that leads to deletion of exon 3.[63,64] This polymorphism is associated with increased postnatal growth velocity, but interestingly, it is also associated with decreased fetal growth.[65]

GH may play a role in fetal metabolism. The hypophysectomized fetal lamb retains excess adiposity, and this is reversed by the administration of GH.[66] Similarly, GH has been shown in the fetal lamb to affect glucose/insulin metabolism[67] in a manner analogous to its postnatal diabetogenic action. In the rabbit, GH has been suggested as a stimulator of fetal hepatic glycogen synthesis.[68,69] This may be the basis of the hypoglycemia seen in human neonates with isolated GH deficiency.[70,71] Based on rodent studies, a more speculative role for embryonic/fetal GH has been proposed in relation to neural development.[72,73] GH promotes neuronal differentiation, neurogenesis and gliagenesis in the fetal rat, possibly via IGF-1 induction.[74] In line with this, GH-deficient mice show hypomyelination and microcephaly. GH also displays antiapoptotic properties in neonatal rat brains subjected to hypoxic ischemic injury. However, human studies are more equivocal on the functional role of GH; individuals with congenital GH deficiency or an abnormal GHR (and hence GH insensitivity) have apparently normal cognitive function.

PROLACTIN

Prolactin (PRL) is synthesized by lactotrophs in the pituitary, but it may also be produced in other tissues (i.e., mammary gland, ovary, decidua, pancreas, kidney, osteoblasts, lymphocytes, and so on) where it is synthesized locally (for review, see references 75, 76, and 77). In the mother, PRL is best understood for its role in milk secretion, but it has also been associated with the development of maternal behavior in rodents.[19] In the fetus, PRL has been associated with lung maturation and may have osmoregulatory properties.[19] The *PRL* gene is present as a single copy on human chromosome 6.[19] Several transcriptional and translational modifications of PRL have been described that may contribute to its ability to mediate diverse functions.

PRL is detected in both the maternal and fetal circulation. In the first trimester of human pregnancy, maternal PRL levels begin to rise in response to increasing estrogen and by term reach a level ten times that of a nonpregnant woman.[78] As PRL does not cross the placenta, the fetus produces its own PRL from early on in gestation.[79,80] PRL is first detected by 12 weeks postconception,[81-83] when levels are low; after 26 weeks postconception, they rise sharply. PRL in cord blood is markedly elevated at 170 ng/mL compared with less than 20 ng/mL in adults. A positive correlation exists between cord blood PRL levels and gestational age.[84,85] PRL levels decline by more than 60% in the first week after birth,[86] and this decline is delayed in premature infants.[87]

A similar pattern is observed in experimental animals. In sheep, PRL levels rise by 135 days gestation (term = 146 days) and decline after birth.[88,89] Data are similar for the rhesus.[90] However, in most altricial species such as the rat, plasma PRL is low at birth, and levels do not rise until 15 days after birth and peak before puberty.[91,92]

Estrogen is the primary contributor to the prenatal rise in PRL levels. Estrogen acts directly on the pituitary to promote the synthesis and release of PRL.[19] It increases the number of TRH-binding sites on the lactotroph and reduces dopamine secretion and antagonism of dopamine action.[93-96] A temporal correlation between the rise in PRL and estrogen levels late in gestation shows a lag in the rise in PRL compared with estrogen in both humans[6] and sheep. Further, at least in sheep, the interanimal variation in PRL concentrations and the seasonal and diurnal variations are difficult to reconcile, with a dominant role for estrogen in short-term regulation of fetal PRL secretion. It seems likely that estrogen exerts a long-term tonic influence on the maturation of the lactotroph and synthesis of PRL, rather than having short- or intermediate-term regulatory effects. It may be that chronic exposure to estrogen is the mechanism by which the pituitary in the second half of gestation switches from secreting virtually no PRL to maintaining a significant and progressive hyperprolactinemia.

PRL levels are also influenced by seasonal patterns.[19] They fluctuate in fetal sheep according to the length of the photoperiod, with higher concentrations secreted in longer, rather than shorter, photoperiods. It has been determined that maternal melatonin during the dark phase plays a key role in relaying this information to the sheep fetus.

PRL exerts its biologic activity by binding to the PRL receptor (PRLR), which like GHR, is a member of the cytokine receptor superfamily.[75] PRLR protein can detected in the human fetus as early as 7.5 weeks gestation, and like PRL, it is distributed in nearly all tissues.[97] Structurally, the receptor transverses the cell membrane, once with a single, short transmembrane domain, and extracellular and intracellular domains that are conserved across the cytokine receptor superfamily.[75] A single gene *(PRLR)* encoding hPRL is localized to chromosome 5 in close proximity to the *GHR* gene.[75] Human GH and PL (to be described) also bind to the hPRLR with high affinity,[98] in contrast to many other species. The PRLR is alternatively spliced to generate several short (s) and one long (l) variant, differing by length and sequence in their cytoplasmic tail.[75] In general, binding to PRLR causes activation of the JAK/STAT cell-signaling pathways and STAT-1 and -5 are directly activated by PRL.[75] The l-PRL receptor transmits a complete intracellular signal, whereas the s-PRL receptor may be a clearance form.[75] It is interesting that s-PRLR may act in a dominant negative fashion over PRLR dimerization by forming inactive s- and l-PRL heterodimers.[99] PRLR expression is modulated by

glucocorticoids[100]—cortisol stimulates the expression of l- and s-PRLR in fetal sheep,[101] and corticosterone exerts the same effect on l-PRLR in pregnant and lactating mice.[102]

It has been suggested that PRL plays a role in the development of brown fat. In placentally restricted sheep, the l-PRL receptor is reduced in fetal adipose tissue,[103] which may have an impact on nonshivering thermogenesis after birth, whereas enhanced maternal nutrition results in increased levels of l-PRL receptor in adipose tissue, as well as an increase in uncoupling protein-1 (UCP-1), a protein involved in thermoregulation.[104]

Lower levels of fetal/neonatal PRL correlate with increased risk of respiratory distress syndrome, and PRL may play a role in enhancing fetal lung maturation.[84,85,105] Lactogenic receptors are present in the fetal lung,[106] although a group has reported an inability of labeled hPRL to bind human lung preparations.[107] Infusion of PRL alone to the fetal rabbit or lamb did not appear to alter surfactant production.[108] However, PRL is synergistic with cortisol and thyroid hormones in promoting lung maturation in the sheep in vivo,[109] and this is supported by in vitro data.[110]

PRL has long been recognized as an osmoregulatory hormone in teleost fish and amphibia.[19,111] Fetal PRL secretion is dramatically affected by changes in the osmolality of fetal cerebrospinal fluid,[112] and it has been suggested that the perinatal changes in PRL secretion relate to changes in sodium homeostasis.[113] Manipulation of PRL levels in the newborn rabbit suggests that PRL enhances water retention, and that the loss of total body water in the first few days after birth could be due to the decline in plasma PRL concentrations.[114] Decidual PRL has been suggested to play a role in the regulation of amniotic fluid volume and osmolarity,[115] and it can be demonstrated to alter the permeability of the human fetal membranes to water.[116,117]

It has also been suggested that in the rodent, PRL may regulate somatic growth in the early neonate,[118,119] but no comparable data exist in larger mammals.

PLACENTAL LACTOGENIC HORMONES

The placentas of all species secrete multiple members of the lactogenic family, suggesting an important role in maintaining pregnancy. However, this role is poorly understood. In humans, members of this family include a variant form of GH and an evolutionarily and structurally related class of hormones, the PLs. In humans, the genes encoding pituitary GH *(GH-N),* placental GH *(GH-V)* (see later), and PL (*PL-A, PL-B,* and PL-like *[PL-L]*) are clustered on the same chromosome, 17q22-24. This reflects their evolutionary origin from a single somatolactogenic gene, which had also duplicated to give rise to the *PRL* gene that is now located on chromosome 6.[120] *PL-A* and *PL-B* have slightly divergent cDNA sequences, but after processing of their respective prehormones, they give rise to an identical PL hormone product. *PL-L* codes for a variant of PL that is spliced into a much shorter form, and transcripts from all three PL genes can be detected at varying abundance in the placenta.[121]

However, many species have differences in relation to the evolution of this so-called GH gene cluster, and this in turn determines the species-specific presence of PLs. Most nonprimate mammals, and the prosimian primates, possess only one GH-like gene that encodes pituitary GH.[122] However, GH (and PRL) were subjected to a period of rapid, adaptive evolutionary change in the lineage leading to higher primates.[122] The rapid evolution of GH was followed by gene duplication events that cumulatively led to the development of a complex locus for GH genes, and in humans this process enabled the emergence of placental GH and PL genes.[123] Comparative genomic studies on primates have demonstrated that the GH cluster in New World monkeys and humans arose from independent gene duplication events, and the cluster shows high variability even among New World monkeys.[124] Among ruminants, GH gene duplication has been found in sheep and goats but not cattle.[125] With respect to PRL, no similar evidence for gene duplication is available for higher primates and humans. In contrast, rodents and ruminants possess a large family of highly divergent, PRL-like genes. These clusters are less well characterized, but are known to express PLs and a broad range of placental lactogenic hormones as such proliferins.[126]

PL is detected in both the maternal and fetal circulation, but its role in fetal development is largely unknown.[121,125] In humans, PL is first detected in the maternal circulation beginning at 6 weeks gestation where its levels progressively rise to a concentration range of 200 to 300 nM at term. In a species-specific fashion, PL is functionally similar to PRL or GH: In sheep, PL is primarily somatotropic; in humans, it is primarily lactogenic. PL stimulates mammogenesis and promotes maternal insulin resistance and, thus maternal lipolysis, to ensure adequate reserves of glucose and free fatty acids for the fetus.[121] PL may also enhance maternal appetite.[127] In sheep, PL levels rise in response to maternal starvation, leading some to suggest that it stimulates repartitioning of maternal nutrients to the fetus and stimulates the fetus to use its own substrates.[128-130] In the fetus, PL may indirectly promote growth by stimulating amino acid uptake, DNA synthesis, and IGF-1 production.[121]

Although hPL is functionally more like hPRL, its sequence is similar to that of hGH. In humans and primates, the PL and GH gene families are clustered on the same respective chromosome. Human PL has more sequence identity to hGH-N (85%) than to hPRL (17%).[121] In contrast, PL in rodents and ruminants is most similar to PRL. Analogous to humans, the mouse and ovine (o) PL genes are contiguous with their PRL counterpart and share more sequence similarity with the PRL coding region than with GH (oPL versus oPRL: 48% homology; oPL versus oGH: 27% homology).[131,132] Mice also have two variants of PL—mPL-1 and mPL-2—that can substitute for pituitary PRL secretion during pregnancy. mPL-1 is first detected after implantation, when pituitary PRL expression ceases, where it assumes maintenance of the corpus luteum. By midgestation, mPL-1 expression declines and is replaced by mPL-2 for the remainder of pregnancy.[133,134] This redundancy of function bears some resemblance to the onset of hGH-V, another unique placental hormone (see later discussion).

The search for a specific PL receptor has uncovered another example of redundancy of function within the GH-PL-PRL family. No evidence is definitive for a distinct PL receptor.[135] Instead, PL is capable of binding to either homodimers or heterodimers of GH and PRL receptors. In sheep, oPL binds the GH receptor with higher affinity than oGH.[51,136,137] It has been shown in mice that mPL-1 and -2 exert their biological activity by binding to PRLR,[138-140] whereas in sheep, oPL stimulates heterodimerization between GHR and PRLR.[141] It is unknown whether an analogous heterodimer of GHR and PRLR occurs in humans.

A second gene for GH encodes a variant form found only in the placenta. Placental GH (GH-V) is synthesized by syncytiotrophoblasts beginning at around 24 weeks postconception, and in the mother gradually replaces GH expression from the pituitary (for review, see references 142 and 143). GH-V is synthesized by the placenta until term and is secreted in a continuous fashion, unlike pulsatile pituitary GH secretion. However, it would appear that unlike PL, secretion of GH-V is solely into the maternal circulation.[142,143] GH-V is not subject to regulation by GH-releasing hormone but is suppressed by elevated maternal glucose.[142,143] GH-V exerts its biologic activity by binding primarily to the GH receptor, as it does not have the Zn^+ binding site required for interaction with the PRL receptor.[144] A clear definitive role for GH-V has not been determined,[145] but in pregnancies complicated by intrauterine growth retardation, GH-V levels are decreased.[142,143] GH-V may, like PL, have a part in inducing insulin resistance in the mother to ensure adequate glucose reserves for the fetus, thereby contributing indirectly to fetal growth.[142,143]

Luteinizing Hormone and Follicle-Stimulating Hormone Secretion in the Fetus and Newborn

The pituitary gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), influence the function of the differentiated gonad in utero and regulate gonadal function in later life. LH and FSH are secreted by the same pituitary cell, the gonadotroph, under the influence of hypothalamic and other hormones. Both LH and FSH are glycoprotein hormones, as are thyroid-stimulating hormone (TSH) and human chorionic gonadotropin (hCG). All are dimers composed of two noncovalently associated protein subunits α and β. The α subunits are identical, but the β subunits are unique and confer biologic specificity. The biologic specificity of hCG, a placental glycoprotein, is similar to that of LH.

Gonadotropin-releasing hormone (GnRH; also known as LHRH or LRF) is the main hypothalamic factor controlling the secretion of LH and FSH. The major role of LH is to control steroidogenesis in the gonad and that of FSH to control gametogenesis. Congenital abnormalities or mutations in the regulation of LH and FSH can therefore lead to abnormalities of phallic development, puberty, and fertility.

This chapter reviews the anatomic development of key components of the gonadotropin regulatory axis (including the hypothalamus, pituitary, and portal circulation), the role of gonadotropins in the fetus and neonate, the factors that control gonadotropin secretion, and disorders in the development of the gonadotropin regulatory system.

DEVELOPMENT OF THE HYPOTHALAMUS AND PITUITARY

Hypothalamus

The hypothalamus (Table 179-1) develops from the primitive forebrain (prosencephalon). By approximately the fifth week after conception, the forebrain differentiates into the cerebral hemispheres and the diencephalon; the ventral aspect of the diencephalon then develops into the hypothalamus. By 14 to 16 weeks gestation, hypothalamic nuclei and fiber tracts have differentiated.[1-5]

GnRH, the major secretagogue of pituitary LH and FSH is a decapeptide released by specific neurosecretory cells in the hypothalamus and is carried by portal circulation to the pituitary.

Most studies of fetal hypothalamic GnRH content have involved fetuses from a relatively brief developmental window during early gestation to midgestation, and thus comprehensive developmental trends have been difficult to establish. The hypothalamic content of GnRH has been reported by some investigators[6,7] to increase during the first half of gestation, although others report little relationship to gestational age during this period.[8-10] Hypothalamic GnRH content generally has been reported to be similar in male and female fetuses,[6-8,11] with some exceptions.[9] Little is known about the early postnatal development of hypothalamic GnRH in humans, although Bugnon and

colleagues[12] noted an increase in immunoreactive GnRH neurons in hypothalami of human neonates compared with those of late gestational fetuses.

The GnRH gene is expressed and the protein found in the hypothalamus during early stages of development. GnRH protein has been detected by radioimmunoassay of whole brain extracts as early as 4.5 weeks gestation.[10] GnRH has been identified within the hypothalamus by 8 to 13 weeks gestation.[7,10-13] By 16 weeks gestation, GnRH-containing neurons are known to terminate on portal vessels.[14]

Several aspects of GnRH ontogeny are noteworthy. First, GnRH neurons originate in the embryonic olfactory placode as early as 5.5 weeks gestation[15] and undergo a unique pattern of axophilic migration across the terminal nerve to their ultimate location in the hypothalamus by midgestation.[16-18] Then they extend axonal processes into the median eminence to establish neurovascular connections.

Second, GnRH neuronal migration is complex and is influenced by many genes, proteins and nuclear transcription factors. Pax6, Otx1, Otx2[19,20] are a few of the transcription factors that have been implicated in this process. They may also activate pathways essential for cell survival, growth, and differentiation. Subsequently, transcription factors such as Pax6 and Gsh2 determine brain migration route, switch on GnRH gene expression, and determine final cell position in the brain. The chemical guidance for axonal routing and GnRH neuron migration is provided by various axonal guidance molecules, extracellular matrix proteins, growth factors and neurotransmitters. Molecular pathways involved in GnRH cell migration include the Rho GTPase family, PI3K, MAPK and Ras family. (For detailed review of this process, see references 19 and 20.) The various transcription factors and other molecules that influence GnRH neuronal cell migration are summarized in Table 179-2. Studies on human GnRH cells in long-term cell cultures have shown that GnRH can also modulate the differentiation and migration of GnRH-secreting neurons in an autocrine fashion.[21] Various genes that have been implicated in GnRH neuronal migration include the product of the Kallmann syndrome gene (KAL1) located on Xp22.3 region, KAL 2 (fibroblast growth factor receptor-1[FGFR-1]),[22-24] and GPR 54 (G-protein coupled receptor).

The KAL1 gene and its product Anosmin[25] are implicated in the X-linked form of Kallmann syndrome, whereas FGFR-1 is implicated in autosomal dominant hypothalamic hypogonadism seen in males and females.[22,23,26] FGFR-1 is a member of the receptor tyrosine kinase superfamily and also regulates cell proliferation, migration differentiation, and survival. Hence, mutations in FGFR-1 are associated with other congenital malformations in addition to hypogonadotropic hypogonadism and may explain some forms of Kallmann syndrome that are not associated with anosmia. GPR 54, a G-protein coupled receptor and its ligand Kisspeptin have been described as major neuromodulators of the gonadotropic axis.[26-28] Mutations in the GPR 54 gene have been found in consanguineous families with high incidence of hypogonadotropic hypogonadism.[27,28]

Third, complex molecular mechanisms are responsible for tissue-specific transcriptional activity of the GnRH gene. The human GnRH gene (GnRH-I), located on 8p21-p11.2 and comprised of three exons encoding a protein of 92 amino acids,[29,30] is the form found in hypothalamic neurons and regulates pituitary gonadotropins. A second gene, GnRH-II encodes a decapeptide neurotransmitter in the midbrain. Other GnRH genes have been described in mammals and non mammalian vertebrates.[31] Available evidence indicates that the GnRH-I gene is targeted to hypothalamic neurons by enhancer and promoter elements acting in concert with transcription factors Otx2, Brn-2, and Oct-1[32,33] and the POU domain of transcription factors, SCIP, Pct-6 and Tst-1. A variety of hormones and second messengers also influence GnRH gene expression.[34] Also evidence shows that the orphan nuclear receptors DAX-1 and SF-1 are important for the proper development and function of the entire hypothalamic-pituitary-gonadal axis.[35,36]

Pituitary

The pituitary gland arises from ectoderm, with the adenohypophysis (anterior pituitary) originating from oral ectoderm and the neurohypophysis (posterior pituitary) deriving from the neuroectoderm.[37] Pituitary development starts on embryonic day 8.5 in the mouse. In humans, terminal differentiation of cells is completed in the first trimester, whereas in mice the process continues until after birth. Pituitary development has been identified in the human fetus by the third week of pregnancy with Rathke's pouch, the precursor of the anterior pituitary, developing as an evagination of the primitive stomodeum at the fourth week of gestation, with subsequent separation from the stomodeum by the fifth week of gestation.[38-40] The floor of the sella turcica forms by the seventh week of gestation, and, by the eighth week, the connection of the pouch with the oral cavity fully disappears.[41]

The anterior pituitary is eventually populated by at least five highly differentiated cell types that emerge in a temporally and spatially specific fashion and include the corticotrophs (which secrete adrenocorticotropic hormone), the somatotrophs (which secrete growth hormone), the lactotrophs (which secrete prolactin), the thyrotrophs (which secrete TSH), and the gonadotrophs (which secrete LH and FSH).[37,42] Intense investigation has focused on the molecular mechanisms responsible for the differentiation of the specific cell types, and two important principles have emerged from these ongoing studies: the differentiation of specific cell types in the pituitary follows a highly ordered sequence, and the coordinated expression and down-regulation of homeodomain transcription factors plays a critical role in controlling the differentiation.[37,42,43] For example, rodent studies indicate that differentiation of all cell types requires transient expression of Rpx (also called Hesx1) and Pitx, but then, on approximately embryonic day 10, the cells divide into Lhx3 dependent and independent lineages (Figure 179-1).[37,44] The main population of corticotrophs is Lhx3 independent and appears by embryonic day 12 or 13; the other cell lineages appear to be Lhx3 dependent. Under the influence of Prop-1, the Lhx3 dependent lineage further bifurcates into Pit-1 dependent and independent pathways. The Pit-1 dependent pathway leads to the differentiation of somatotrophs, lactotrophs, and thyrotrophs by embryonic day 16. The Pit-1 independent pathway, under the influence of other factors, including steroidogenic factor-1 (SF1), leads to differentiation of the gonadotrophs by embryonic day 17. In addition to intrinsic pituitary factors, evidence shows that, at distinct developmental stages, inductive processes from adjacent tissue are also important for proper cell differentiation and expansion of pituitary cell lineages.[41] In animal models, other signaling molecules such as GnRH2, ACVR2, BMP4, FGF, Wnt, and SHH have been found to be critical for pituitary development. (See references 37, 42, and 44 for detailed discussion of this complex developmental sequence.) The importance of these basic components of pituitary development to human physiology is emphasized by identification of human mutations that cause predictable phenotypes.[42]

Once formed, the gonadotroph secretes LH and FSH early in embryogenesis. The fetal pituitary secretes LH and FSH in culture at 5 to 7 weeks gestation.[45,46] LH and FSH have been detected in the pituitary by immunoassay and immunocytochemistry as early as 9.5 to 11 weeks gestation.[47-51] The pituitary content of LH and FSH then rises sharply, with pituitary LH and FSH content peaking at 25 to 29 weeks gestation in female fetuses and at 35 to 40 weeks gestation in males.[50] The pituitary content of LH and FSH is higher in female fetuses than in males between approximately 10 and 25 weeks gestation, as assessed by radioimmunoassay[48,50-52] and immunocytochemistry.[53] This sexual dimorphism may reflect testosterone production by the male fetus, with resulting inhibition of pituitary gonadotropin production.[54]

Early in gestation, the predominant pituitary glycoprotein fraction is the α subunit.[12,49,55] As gestation progresses, the relative amount of β subunit and intact gonadotropin appears to increase.[12,53,56] Relatively little is known about postnatal pituitary gonadotropin development. Kaplan and colleagues[8] found that the content and concentration of pituitary LH and FSH in 2- to 6-month-old infants were higher than in late gestational female fetuses.

It is not clear to what extent GnRH normally contributes to the functional development of the gonadotroph. In vitro, GnRH can stimulate differentiation of fetal rat gonadotrophs[57,58] and LH synthesis in cultured fetal human pituitary cells.[59] Human anencephalic fetuses have reduced pituitary gonadotropin content[8] as well as persistent predominant secretion of the α subunit of glycoproteins,[55,56] suggesting that GnRH normally contributes to gonadotroph development and function. The fetal pituitary also has potential for some differentiation in the absence of direct hypothalamic influences,[60] as suggested by studies on anencephalic fetuses[61-63] and transplanted rat pituitary.[64,65]

Portal Circulation

Work using vascular casts suggests that the hypothalamic pituitary portal system is intact by 11.5 to 12 weeks gestation,[66] earlier than originally estimated.[67-69] It has been suggested that

local diffusion may allow communication between the hypothalamus and pituitary before that time.[8]

ROLE OF PITUITARY GONADOTROPINS IN THE FETUS AND NEONATE

Fetal pituitary LH and FSH are not required for sexual and gonadal differentiation. Pituitary gonadotropins, however, are required for normal function of the differentiated gonad. Because hCG can activate LH receptors, placental hCG leads to production of testosterone early in gestation,[54,70] and this testosterone production leads to normal formation of male external genitalia by 12 to 14 weeks gestation. However, later in gestation, testosterone production by the fetal testes depends on fetal LH, and this LH-induced testosterone production is responsible for growth of the formed phallus during the later stages of pregnancy. The increased incidence of normally formed but small phallus (microphallus) and cryptorchidism in male infants with anencephaly or gonadotropin deficiency[71-73] supports the concept that pituitary gonadotropins influence testicular growth and function later in gestation, as does the finding that the testes of anencephalic fetuses are hypoplastic, with decreased numbers of testicular Leydig cells.[73-75] In females, anencephalic fetuses have been reported to show small ovaries with hypoplasia of the primary follicles.[75] Some reports suggest that the ovaries are relatively normal until 34 to 36 weeks gestation and only later show evidence of maldevelopment.[76]

REGULATION OF PITUITARY LUTEINIZING HORMONE AND FOLLICLE-STIMULATING HORMONE SECRETION IN THE FETUS AND NEONATE

Factors That Regulate Pituitary Luteinizing Hormone and Follicle-Stimulating Hormone Secretion in Adults

In adults, the secretion of pituitary LH and FSH involves the finely balanced interplay of several regulatory agents (Figure 179-2). The major elements involved in this interplay are the hypothalamus, pituitary, and gonad (a unit referred to as the hypothalamic-pituitary-gonadal axis). The main stimulus for pituitary gonadotropin secretion is the hypothalamic decapeptide, GnRH. More than 16 GnRH molecules and several GnRH receptors have been identified in mammals and nonmammalian vertebrates.[77,78] The function and tissue specificity of these various molecules is still being elucidated, but the regulation of LH and FSH secretion seems to reside primarily with the originally identified molecular species.[77] At least two forms of GnRH and two GnRH receptors are expressed in humans.

Many afferent neurotransmitter systems from the brain stem, limbic system, and other areas of the hypothalamus convey information to the GnRH neurons. They may contain norepinephrine, dopamine, serotonin, γ-aminobutyric acid (GABA), glutamate, endogenous opioid peptides, neuropeptide-Y, galanin, and other neuropeptides.[79-81] Glutamate and norepinephrine are stimulatory, whereas GABA and endogenous opioid peptides are inhibitory (see Figure 179-2). Secretions from surrounding glial cells such as transforming growth factor-α can also stimulate GnRH release.[79,82] Steroid hormones such as estradiol and testosterone can also alter the pattern of GnRH secretion by binding to steroid hormone receptors in the hypothalamus and pituitary, providing negative feedback. It is important to note that GnRH neurons themselves lack steroid hormone receptors; hence the negative feedback of steroids at the level of the hypothalamus is mediated via actions on other neural systems that, in turn, input to the GnRH neurons.[79] In addition, glucose, thyroxine, glucocorticoids, leptin, and exogenous factors such as stress, health, exercise, and nutritional factors can also influence GnRH secretion.[83]

The normal pulsatile secretion of LH is believed to be mediated directly by episodic release of GnRH. The pulsatile release of GnRH is critical for the maintenance of gonadotropin secretion in adults. Animal studies have shown that different pulse frequencies of GnRH can lead to differential ratios of FSH and LH.[79,84] Continuous administration of exogenous GnRH to adults leads to an initial increase in gonadotropin secretion, followed by prolonged suppression of gonadotropin secretion owing to down-regulation of the pituitary gonadotroph.[57,84,85] The rate of pulsatile GnRH secretion, along with ovarian hormone feedback, also influences the degree of glycosylation of LH and FSH, which can profoundly influence the physiologic function and stability of these hormones in circulation.[86,87]

GnRH travels through the hypophysial portal blood system to the anterior pituitary, where it binds to GnRH receptors on the cell surface of gonadotrophs to stimulate gonadotropin release.[79,88] The human GnRH receptor gene is localized on chromosome 4q21.2. The GnRH receptor belongs to a family of G-protein coupled receptors, and binding of the GnRH to its receptor initiates several intracellular signaling pathways including phospholipase C, inositol 1,4,5 triphosphate (IP3), protein kinase C, mitogen activated protein kinase-1 (MAPK1), calcium influx, and calcium release from intracellular stores.[89] The mobilization of intracellular calcium affects the initial burst of LH secretion and the influx of extracellular calcium maintains sustained gonadotropin secretion.[90]

Another G-protein coupled receptor, GPR54 and its ligand kisspeptin, have generated intense research.[91-95] Kisspeptin is encoded by the Kiss-1 gene. Current understanding from mouse studies indicates that Kisspeptin stimulates GnRH secretion by a direct effect on GnRH neurons, most of which express GPR54. Estradiol and testosterone inhibit Kiss-1 mRNA expression in the arcuate nucleus, whereas these steroids induce Kiss-1 mRNA expression in the anteroventral periventricular nucleus.[93,94]

Gonadal secretions are also major physiologic regulators of LH and FSH secretion in adults. Gonadal steroids exert negative feedback (inhibitory) effects on gonadotropin release. In mature premenopausal women, estrogens can also exert positive feedback, mediating the ovulatory surge of gonadotropins. In addition to steroids, the gonads produce peptides, such as inhibins A and B, that selectively modulate FSH-secreting cells. Although other regulators, such as activins and follistatin, are present in the peripheral circulation, these factors probably act in an autocrine or paracrine fashion, with activin stimulating FSH release and follistatin inhibiting FSH release by binding to activin. (For complete reviews of the regulation of gonadotropin secretion in adults, see references 79 and 96). In developing animals, the roles of the various components of this complex system are not fully understood. In the next section, each of these regulatory influences in the fetus and newborn infant is reviewed.

Factors That Regulate Pituitary Luteinizing Hormone and Follicle-Stimulating Hormone Release in the Fetus and Newborn Infant

Gonadotropin-Releasing Hormone (GnRH)

GnRH is present in the human fetal hypothalamus by 8 to 11 weeks gestation.[7,10-13,97] The secretory pattern of GnRH during human fetal and early neonatal development is not known. However, GnRH neurons from nonhuman primates secrete their peptide in a pulsatile manner in vitro, suggesting that early intrinsic pulsatile secretion of GnRH may be independent of non-GnRH neuronal synaptic input.[81,98]

GnRH appears to influence gonadotropin release early in gestation. The human fetal pituitary in vitro releases LH, FSH, or both, in response to GnRH by approximately 13 to 19 weeks

gestation (Figure 179-3 to 179-6).[99-101] By the second trimester, pretreatment with estradiol enhances the sensitivity of human fetal pituitaries to GnRH.[102] GnRH appears capable of influencing LH synthesis as well as secretion at this period of development.[59]

The human fetal pituitary releases gonadotropins in response to exogenous GnRH in vivo by the second trimester, and the increment in LH and FSH levels after GnRH administration is greater in the second than in the third trimester.[103] These findings are supported by studies in monkeys[52,104,105] and sheep[106] that show the fetal gonadotroph to be responsive to GnRH, with a declining response as gestational age advances.[106,107]

In human neonates[102,103,108] and infants,[108-111] exogenous GnRH also stimulates gonadotropin release. Limited data suggest that the responsiveness of the gonadotroph to GnRH varies with age during infancy. Tapanainen and colleagues[111] administered GnRH (50 μg/m^2 intravenously) to infant boys who had undescended but palpable testes and who ranged in age from 3 to 390 days.[111] GnRH stimulated LH and FSH release in all age groups, but peak gonadotropin release occurred at 1 to 3 months of age, with a subsequent decline from 3 to 12 months of age. A similar age-dependent change in LH response to GnRH was found in infant monkeys.[104]

Gonadotropin secretion is episodic in rhesus monkey [112] and ovine[113] fetuses, as well as in human, ovine,[114] and rhesus[115] infants. In the ovine fetus, administration of a GnRH antagonist decreases LH pulse frequency.[113] Because pulsatile secretion of LH is believed to depend on pulsatile release of GnRH, these

findings also suggest a role for endogenous GnRH in the regulation of LH release in the perinatal period.

The ontogeny of gonadotroph GnRH receptors in humans is not known. However, the observation that the fetal pituitary releases gonadotropins in response to GnRH by the second trimester[99,101,103,116] suggests the presence of hypophyseal GnRH receptors by that time. Animal studies on zebra fish indicate that GnRH receptors mRNA may be present as early as 36 to 56 hours postfertilization.[117] In rats, pituitary binding sites for GnRH have been detected by 13 days gestation (term = 22 days)[118] with the pituitary GnRH receptor number increasing in the late prenatal and early postnatal period.[119] Postnatally, the concentration of GnRH receptors in rodents is highest between 15 and 20 to 30 days of age and decreases thereafter to reach adult levels by approximately 60 days of age.[88] Although GnRH has been detected in the placenta,[77,120] the role of the placental material in the physiologic regulation of pituitary gonadotropin release is uncertain. Anencephalic and gonadotropin-deficient fetuses are deficient in hypothalamic—but presumably not in placental—GnRH. That these infants generally have subnormal quantities of pituitary gonadotropins,[8,121] suggests that placental GnRH may not be an important factor for the normal regulation of gonadotropin release in utero. The overall influence of neurotransmitters on gonadotropin release in the human fetus and neonate is not known, although some animal studies suggest that specific neurotransmitters such as endogenous opioids may be involved.[122]

Taken together, the available data indicate that the pituitary gonadotroph is responsive to hypothalamic GnRH during fetal life, and that endogenous GnRH stimulates gonadotropin release in the fetus and neonate.

Gonadal Steroids

From animal studies, evidence is indirect that the capacity of gonadal steroids, especially testosterone, to inhibit gonadotropin release is present during fetal development. For example, castration of male rhesus fetuses at approximately midgestation results in elevation of gonadotropin levels,[81,123,124] and early testosterone or dihydrotestosterone replacement prevents the increase of gonadotropins after castration.[124] These results suggest that functional negative feedback between the testes and the hypothalamic-pituitary axis is present by midgestation in rhesus fetuses. The role of fetal ovarian estrogen in regulating gonadotropin secretion is less clear, in part because both male and female fetuses develop in an environment that is rich in estrogens of fetoplacental origin. In female rhesus fetuses, gonadectomy has had variable results on gonadotropin secretion.[123-125] Estradiol infusions blunt LH release in the late gestational ovine fetus.[126] Gonadotropin levels, which increase in the early postnatal period, may reflect, in part, a release from negative feedback as sex steroids are removed from the fetal circulation.

By the newborn period, gonadal steroids appear to suppress gonadotropin secretion in both sexes. Castration of newborn female rhesus monkeys results in elevation of FSH and, to a lesser extent, LH levels.[127] Orchiectomy of male monkey neonates also results in elevation of LH and FSH, suggesting that testosterone may influence early postnatal gonadotropin secretion in male.[125,127-129] The specific gonadotropin secretion pattern differs between neonatal castrated male and female monkeys, and it has been suggested that this reflects intrinsic sexual dimorphism of hypothalamic GnRH secretion.[127] Similarly, gonadal failure in human neonates leads to elevated gonadotropin levels,[130] indicating that gonadal products normally suppress gonadotropin secretion even in the neonatal period. Further evidence for negative feedback by gonadal steroids derives from the observation that administration of estrogen and progesterone to extremely premature female infants suppresses LH and FSH secretion.[131]

Castration-induced elevation of circulating gonadotropins, however, is not fully sustained into late childhood, and gonadotropin levels in both experimental orchiectomy and in naturally occurring gonadal failure decline during infancy or early childhood (only to rise again in the peripubertal period).[125,128,130] However, the gonadotropin levels do not reach levels as low as those in children with normal gonads.[132] Together, these findings suggest that although gonadal steroids influence gonadotropin secretion in neonates, they are not the sole mediators of changing gonadotropin levels in infancy. The eventual decline in

gonadotropin levels in late infancy and early childhood is due primarily to extragonadal and presumably central hypothalamic-pituitary factors, in combination with some gonadal derived inhibition.[125,128,129]

Inhibin

Inhibins are polypeptides secreted by the Sertoli cells in the testis and by the granulosa cell in the ovary, which inhibit the release of FSH but not LH from the pituitary. Inhibin is also synthesized by the placenta.[133] Biologically active inhibin is present in the fetus, and administration of inhibin suppresses serum FSH.[134]

Studies have shown inhibin B in male and female fetuses at midgestation, with higher levels in males than females (Figures 179-6 to 179-8). Circulating inhibin levels are higher in premature than in term infants.[135] Inhibin B levels are higher in boys than in girls after birth.[136-138] In boys, levels peak at approximately 3 to 12 months of age and remain elevated until approximately 15 months of age.[137] The production of inhibin during the first month of life may be enhanced by the postnatal surge in gonadotropins.[50,54] Although the precise role of inhibins in the fetus and neonate is not clear, these findings suggest that endogenous inhibin may play a physiologic role in suppressing FSH in fetal and neonatal animals.[134]

PLASMA GONADOTROPINS IN THE FETUS AND NEONATE

General Pattern

Little is known about plasma gonadotropin levels in human fetuses before 10 to 14 weeks gestation. Circulating immunoreactive FSH is detectable by the 10th to 13th week of gestation in human fetuses and increases to peak levels at approximately midgestation (see Figures 179-3 to 179-6).[50,54] At that time, FSH concentrations are comparable with those of castrated animals. FSH levels then decline; by birth, FSH levels are low, similar to those of prepubertal children.[8,50,139,140] Circulating LH concentrations in the fetus follow a similar pattern.[50,51,54,140] Studies in premature infants are consistent with studies in fetuses and show a decline in serum LH and FSH levels with advancing gestational age.[135]

Soon after birth, LH and FSH levels rise (see Figure 179-5). Although reported patterns vary somewhat, this increase is sustained for weeks to months and is followed by a decline to prepubertal levels (see Figures 179-5, 179-7, and 179-8).[123,141,142] The specific patterns also differ between boys and girls, as discussed in detail later.[138,142-144]

Pulsatile secretion of gonadotropins is a hallmark feature of the mature hypothalamic-pituitary axis. Studies in the primate[112] and ovine[113,145] fetuses suggest that pulsatile secretion of gonadotropins may develop in utero. Evidence shows that gonadotropin secretion in the 1- to 3-month-old human infant is also episodic.[146,147]

Circulating hCG, the placental glycoprotein, declines from high levels at 13 to 17 weeks gestation to low levels at term (see Figures 179-3 and 179-4)[50,51,103] and falls to undetectable levels by the fifth postnatal day.[103,144] The α glycoprotein subunit is the predominant glycoprotein component in fetal plasma and cord blood and in the pituitary gland. Plasma levels of free α subunit are high at midgestation and decline near term.[55,56,148] The α glycoprotein hormone subunit may originate from cells that secrete LH, FSH, hCG, or TSH. The finding that α subunit declines postnatally[49,149] whereas plasma LH and FSH increase suggests that most of the α subunit that circulates in the fetus is derived from hCG.

Sexual Dimorphism

Sexual dimorphism characterizes both the prenatal and postnatal patterns of gonadotropin secretion.[150] In the fetus, FSH levels peak at midgestation in both sexes, but FSH levels at this time are higher in female fetuses than in male fetuses (see Figures 179-3to 179-6).* LH levels have also been reported to be higher at midgestation in females than in males[51,140,148] but not in all studies.[50,103] The subsequent decline in LH and FSH levels with advancing gestational age occurs in both sexes, and by term, the low FSH levels are similar in males and females (see Figures 179-3 to 179-6). Cord blood concentrations of both LH and FSH are low.[54,150,151]

Reports of gonadotropin levels in the postnatal period and early infancy have varied somewhat, but some generalization seems valid. After birth, FSH levels increase markedly in girls to peak at approximately 3 months of age and usually decline to prepubertal levels by 6 to 9 months,[81] although elevated levels can persist up to 2 years.[136] In contrast, FSH levels of male infants have been reported to rise less briskly, peak at 1 week to 3 months of age at levels lower than those of females,[81,98,138,144,152] and more uniformly decline to prepubertal levels by 4 to 9 months after birth.[136,144] LH peaks in boys at approximately 1 to 3 months of age and declines to prepubertal levels by 4 to 9 months.[136,144,153] Girls exhibit a similar pattern, but, in contrast to FSH, peak LH levels are generally lower than those of boys.[144] Similar patterns of gonadotropin secretion have been found in the ovine fetus[154] and in neonatal subhuman primates.[144,155,156]

Mechanisms Postulated to Be Responsible for Characteristic Patterns of Gonadotropin Levels in the Fetus and Neonate

The mechanisms underlying the characteristic changes in gonadotropin levels in the fetus and neonate are not fully elucidated. In the fetus, it has been suggested that rising levels of LH and FSH at midgestation reflect autonomous or unrestrained release of gonadotropins.[50,54] The later decline in gonadotropin levels with advancing gestational age may reflect increased sensitivity to the inhibitory effects of gonadal steroids (especially in males)[50,54]; increasing levels of circulating fetal estrogen in both sexes[54]; and reduced GnRH secretion owing to central neuroinhibitory influences, maturation of sensitivity to sex steroids, or both.[54] Data from the study of 46,XY infants with androgen insensitivity syndrome suggest that the withdrawal from the negative feedback of androgens during the neonatal transition may play a critical role in the postnatal LH and testosterone surge.[57] In a longitudinal study, infants with partial androgen insensitivity syndrome mounted the expected postnatal surges, but LH and testosterone levels failed to increase in infants with complete androgen insensitivity syndrome.[157] The early postnatal rise in gonadotropin levels had been postulated to reflect the loss of the negative feedback effect previously exerted by maternal estrogens. This mechanism now seems less likely in 46,XY infants, but the roles that estradiol and androgens play in regulation of the postnatal surge in 46,XX infants remains unclear.[158] After the postnatal surge, the reproductive endocrine axis enters a long period of relative, but not absolute, quiescence (often referred to as the "juvenile pause") until GnRH secretion re-emerges, leading to pubertal maturation. The factors causing the postnatal decline in gonadotropin levels are not clear. Several regulatory processes likely are involved, including central neuroinhibitory processes[128,129] and the potentially increased sensitivity of the hypothalamus and pituitary to the negative feedback effect of gonadal steroids.[54] Factors that may mediate the central inhibition include the relative predominance of γ-aminobutyric acid versus glutamate neurotransmitter activity and the inhibitory action of neuropeptide-Y.[81,159] Although not fully understood, it is becoming increasingly likely that the factors responsible for the juvenile pause are not simply the mirror image of the factors that lead to reactivation of GnRH secretion with puberty.

CONDITIONS ASSOCIATED WITH ABNORMALITIES OF GONADOTROPIN SECRETION IN THE FETUS AND NEONATE

Anencephaly

Anencephaly is a severe defect of neural tube development that is incompatible with long-term survival. Major portions of the nervous system are absent, usually including the hypothalamus. The pituitary gland is present but small. Although the number and size of pituitary cells appear normal at week 17 or 18 of gestation, by term gonadotrophs are almost absent.[160] The pituitary content of LH and FSH appears reduced,[8,121] and is comparable with that of 10- to 20-week fetuses.[8] The α subunit appears to be the dominant glycoprotein factor.[56,121]

Anencephalic male infants often have normally formed but small external genitalia and undescended testes. This likely reflects reduced testosterone synthesis in the latter part of gestation owing to gonadotropin deficiency. The testes have reduced numbers of Leydig cells, and the epididymis is underdeveloped.[73,74] Anencephalic female fetuses have normal external genitalia, consistent with the concept that gonadotropins and ovarian secretion products are not essential for female sexual differentiation. The ovaries are small, with reduced numbers of primary follicles.[75] In anencephalic newborn infants, basal plasma LH and FSH levels are generally low compared with normal neonates,[8,151] and, in a limited number of studies, LH and FSH levels failed to increase after administration of exogenous GnRH.[8,161,162]

Together, these characteristics of infants with anencephaly suggest that pituitary differentiation may occur even in the absence of normal GnRH production, but that full activity and maintenance of the immature gonadotroph normally requires endogenous GnRH.

Congenital Hypothalamic and Pituitary Abnormalities

Hypogonadotropic hypogonadism can be caused by genetic defects at the level of the hypothalamus or pituitary. At the hypothalamic level defects of GnRH neuronal migration or defective hormone synthesis and secretion can cause disorders in hypothalamic GnRH function.

Kallmann syndrome is a genetically heterogeneous disorder of hypogonadotropic hypogonadism with hyposmia or anosmia. Various reports have indicated autosomal dominant, autosomal recessive and X-linked transmission.[23] Mutations in the KAL-1 gene have been found in 14% of familial and 11% sporadic cases of hypogonadotropic hypogonadism in males. Other phenotypic features in males with KAL-1 mutations include delayed puberty, variable degrees of anosmia or hyposmia, as well as mirror movements and unilateral renal agenesis.[30,163] Female carriers have no specific phenotypic abnormalities. Another gene implicated in Kallmann syndrome is the fibroblast growth factor receptor gene (also known as FGFR-1 or KAL2),[22,23] Heterozygous nonsense and missense mutations and small deletions of FGFR-1 have been described in familial (autosomal dominant) and in sporadic cases of Kallmann syndrome. Phenotypic features are variable and may include anosmia, delayed puberty, dental agenesis, and cleft palate.

The GPR54 gene and its ligand, kisspeptin, are important in the regulation of gonadotroph function.[28] At least four different mutations have been described in patients with autosomal recessive hypogonadotropic hypogonadism of this type, including homozygous deletion, missense, and nonsense mutations. The phenotypic features include normal sense of smell as well as other manifestations of hypogonadism.[30]

At the pituitary level, GnRH receptor mutations have been described in familial autosomal recessive, normosmic hypogonadotropic hypogonadism. They are predominantly missense mutations and result in loss of receptor function.[30]

Mutations in various pituitary transcription factors (Table 179-3) can cause gonadotropin deficiency which is usually associated with other pituitary hormone deficiencies. The reader is referred to references [42,72] for detailed descriptions.

Mutations in other genes such as the SNRPN (small nuclear ribonucleoprotein polypeptide), leptin, leptin receptor, and DAX1 have also been implicated in hypogonadotropic hypogonadism (see Table 179-3). In syndromes such as CHARGE[164] or Noonan, that are associated with hypogonadotropic hypogonadism, the exact molecular mechanism is not yet clear.

Many features of gonadotropin deficiency will not be apparent in the neonatal period. At birth, girls with congenital GnRH or gonadotropin deficiency have normal external genitalia because, as noted, female sexual differentiation does not appear to require GnRH, LH-FSH, or ovarian hormones. Males with congenital GnRH or gonadotropin deficiency (whether isolated or associated with other pituitary hormone deficiencies), tend to have microphallus and undescended testes[72] (see Table 179-3). Infants with Kallmann syndrome and other forms of gonadotropin deficiency have been reported to show low basal gonadotropin levels and subnormal gonadotropin responses to GnRH.[8,71,165] Male infants with LH receptor abnormalities are unable to fully stimulate testosterone production in response to LH or hCG signaling and can present with phenotypes ranging from complete failure of virilization to hypospadias and/or microphallus.[35] Of note, because

TABLE 179-3

Examples of Genetic Disorders Associated With Hypogonadotropic Hypogonadism

Gene	Phenotype (Inheritance; Clinical characteristics in addition to hypogonadotropic hypogonadism)
Hypothalamus	
KAL1	X-linked; Kallmann syndrome anosmia/hyposmia, renal agenesis
FGFR-1 (fibroblast growth factor receptor-1; KAL2)	Autosomal dominant; Kallmann syndrome with anosmia/hyposmia, cleft lip/palate
GPR54 (KiSS1 derived peptide receptor)	Autosomal recessive
Pituitary	
GnRH receptor	Autosomal recessive
HESX 1 (RPX)	Recessive; CPHD with septooptic dysplasia Dominant; IGHD
PROP 1 (POU 1 F1)	Recessive; CPHD
LHX3	Recessive; CPHD, rigid cervical spine
LHX4	Dominant; CPHD with defects in sella turcica and cerebellar tonsil
GLI 2	Dominant; CPHD with variable holoprosencephaly features
PHF 6	X Linked; CPHD; Borjeson-Lehmann syndrome, mental retardation
Other	
SNRPN (small nuclear ribonucleoprotein polypeptide SmN)	Lack of function of paternal 15q11-q13 region or maternal uniparental disomy; Prader Willi syndrome, obesity
Leptin	Autosomal recessive; obesity
Leptin receptor	Autosomal recessive; obesity
DAX1	X linked recessive; Adrenal hypoplasia

Animal models of several of these genetic defects have been described.[30,42]

CPHD, Combined pituitary hormone deficiency; *IGHD,* isolated growth hormone deficiency.

neonates with congenital growth hormone and adrenocorticotropic hormone deficiency are prone to develop hypoglycemia, the association of hypoglycemia and microphallus—particularly in a full-term infant—should alert the physician to the possibility of congenital panhypopituitarism.[72]

Gonadal Failure

Gonadal differentiation and its abnormalities are described in another chapter. In this section, we refer to gonadal failure as absence of normal gonadal development or inability of the gonad to produce sex steroid, and we discuss the effects of such failure on gonadotropin secretion.

Elevated circulating levels of gonadotropins have been found in neonates and infants with gonadal failure.[130,132] In these conditions, the elevation of gonadotropins represents an appropriate response to the primary deficiency of gonadal products. For example, in the syndrome of gonadal dysgenesis (Turner syndrome), levels of FSH, and, to a lesser extent, LH are elevated above the normal range during infancy.[130] This finding is consistent with the concept that the negative feedback loop between the gonad and the hypothalamic-pituitary unit is intact in the newborn infant. In Turner syndrome, gonadotropin levels decline somewhat after age 4 years, even despite continuing gonadal failure,[130] suggesting that both central processes and gonadal factors contribute to the inhibition of gonadotropin secretion in the prepubertal child.

Similarly, elevation of basal and stimulated gonadotropin levels has been described in male infants with anorchia, rudimentary testes,[166] and other forms of primary testicular failure.[167] Interpretation of the normality of basal gonadotropin levels must be related to the age of the child. Boys with anorchia have elevated concentrations of basal gonadotropins, particularly FSH, from infancy to 4 years. The levels of gonadotropins then decrease somewhat until 9 years of age, at which time they rise and remain elevated during adulthood. The levels of FSH are lower than those seen in girls with gonadal dysgenesis. This may be attributable to the effect of fetal testosterone on the fetal hypothalamus.[168] Male infants with certain forms of androgen resistance may have elevation of LH.[169] Although many congenital disorders are associated with ambiguous genitalia or hypogonadism, information regarding associated perinatal gonadotropin secretion is often lacking.

Prematurity and Small-for-Gestational Age Status

The effects of prematurity on gonadotropin secretion are not fully understood. In preterm females, cord blood levels of LH and FSH were found to be elevated and declined with advancing gestational age to term.[170,171] For the first 10 postnatal weeks, serum levels of LH and FSH are higher in premature infant girls than in full-term girls; no difference in gonadotropin levels between premature and term male infants has been noted.[170,172] Hypersecretion of FSH has been reported in infants born small for gestational age.[172,173]

Development of the Corticotropin-Releasing Hormone–Corticotropin System in the Mammalian Fetus

Since the publication of the last edition of this chapter, advancements in understanding the importance of adrenocorticotropic hormone (ACTH) or corticotropin in the maturation of the adrenal cortex have been significant. In a large part, this has been due to the application of gene manipulation approaches that have enabled study of the effects of selective deletion of proopiomelanocortin (POMC; the precursor of ACTH) and the impact of replacement of ACTH on adrenal function. In addition, the impact of prenatal manipulations on the corticotropin-releasing hormone (CRH)-ACTH-adrenal axis in adulthood (i.e., "programming") has become an area of intense interest. Consequently, this chapter focuses on the CRH-ACTH system, and we refer readers to earlier versions of the chapter for information pertaining to β-endorphin during development. However, it should be noted that immunoreactive β-endorphin is frequently secreted with ACTH and appears to be under similar regulatory control. Also, when reviewing the information presented in this chapter, it is important to remember that antibodies used in the standard immunoassays employed for ACTH measurement frequently crossreact with other peptides derived from POMC, which contain similar amino acid sequences to corticotropin. Thus immunoreactive ACTH values reported in the literature may not always reflect only the fully processed and bioactive form of ACTH, namely ACTH[1-39].

A general scheme of the regulation of the brain-pituitary-adrenal axis is shown in Figure 180-1. The primary secretagogues that stimulate secretion of ACTH from corticotropes in the anterior pituitary are CRH and arginine vasopressin (AVP). These peptides are released from neurons in the paraventricular nucleus, nerve endings of which abut the hypothalamopituitary portal vessels. The peptides are carried in the portal blood to the anterior pituitary, where they stimulate the corticotropes. The release of CRH and AVP is governed by a variety of inputs into the paraventricular nucleus. From a developmental standpoint, an anatomical maturation of the system as well as maturation of the physiological regulation occurs. In general, corticotropes release ACTH in response to stimulation from early in development, but the ability of ACTH to stimulate adrenal glucocorticoid secretion appears relatively later in gestation.

The primary precursor of ACTH is POMC (Figure 180-2). This peptide undergoes a series of enzyme-induced cleavages resulting in the formation of several peptides that vary depending upon the site of origin. For example, in the anterior-pituitary corticotropes, both pro-ACTH and β-lipotropin are formed from POMC via the action of the enzyme prohormone convertase 1 (sometimes called prohormone convertase 3). Pro-ACTH is then further cleaved to yield other peptides as well as ACTH. The enzymatic processing of pro-ACTH to ACTH appears to require hypothalamic input to the pituitary as it is abolished by lesions

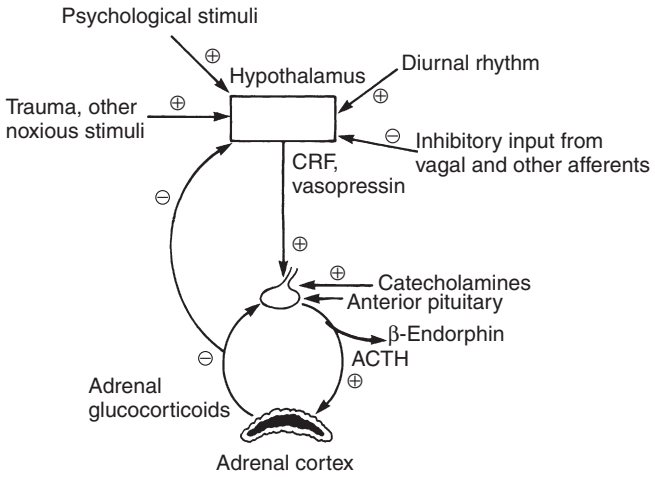

Figure 180-1 Diagram of regulation in the corticotropin-releasing factor *(CRF)*/corticotropin *(ACTH)* axis. *(Modified from Gannog W:* Review of Medical Physiology, *ed 13, Norwalk, CT, 1987, Appleton & Lange, p 314.)*

destroying the paraventricular nucleus in the hypothalamus.[1] In the anterior lobe, ACTH[1-39] is a terminal product, whereas in the melanotrophs of the intermediate lobe, ACTH is further cleaved to α-melanotropin, which can act on receptors distinct from the adrenal ACTH receptor (melanocortin-2 receptor). However, because the role of melanocortin in development is not clear at this time, it will not be discussed in this chapter.

DEVELOPMENT

During the course of pregnancy, significant changes occur in both the maternal and fetal CRH-ACTH systems. These changes play critical roles in the process of fetal maturation.

Corticotropin-Releasing Hormone

The neurovascular link between the hypothalamus and pituitary is first apparent at 12 weeks gestation (G; 0.30 G = 40 weeks) in the human fetus. By 16 weeks (0.40 G), nerve fibers in the rostral region of the median eminence are weakly stained by CRH antiserum. These CRH positive fibers increase in number between 18 and 30 weeks gestation and terminal dilatations in perivascular areas can be observed by midgestation. Cell bodies containing CRH are difficult to identify and have not been detected before 19 weeks (0.48 G).[2]

CRH-containing neurons have been identified in the ovine fetus at a stage comparable with that in humans (0.38 G versus 0.34 G). Both CRH peptide and mRNA levels are increased close to term in the fetal sheep hypothalamus. Further, specific changes in CRH mRNA expression within the paraventricular nucleus have been noted. In other regions of the fetal brain (hippocampal-amygdala complex and frontal cortex), CRH mRNA expression remains relatively constant, whereas peptide levels increase in late gestation. In the brainstem, where CRH is important for autonomic functioning, CRH mRNA expression does not change markedly with advancing gestation; however, increased polyadenylation of CRH mRNA in the hypothalamus is apparent.[2] The physiological significance of this increase in poly(A) tail length is not completely understood, but may relate to increased stability or translatability of the message.

Studies in fetal sheep indicate that hypothalamic CRH peptide and gene expression appears to be regulated by glucocorticoid-mediated negative feedback, as is the case in adults. However, the efficacy of this feedback may decrease with increasing gestational age. This would explain how, in spite of high prevailing plasma cortisol levels, the hypothalamic drive stimulating ACTH secretion does not decrease in the late gestation fetus.

CRH mRNA is present in the human placenta, where expression increases in the last 5 weeks gestation.[3,4] The CRH gene is found on chromosome 8 in humans. Substantial similarity between species related to conservation of the promoter region,[3,5] which contains regulatory elements for cyclic adenosine monophosphate (cAMP), half-estrogen response elements, and ecdysone. The cAMP element appears functional because both forskolin (which increases cAMP) and the cAMP analogue 8-Br-cAMP increase CRH expression in syncytiotrophoblast cells. Conversely, deletions or mutations of the consensus cAMP regulatory element in placental cells transfected with the CRH promoter lead to a decreased cAMP response.[3] Glucocorticoids, progesterone, and possibly estrogen may play roles in regulating placental CRH expression. Immunoreactive and bioactive CRH-like activity has also been detected in sheep placenta, where immunoreactive CRH is localized in the syncytiotrophoblast and intermediate trophoblast layers.[2,3]

In human maternal plasma, CRH concentrations remain at nonpregnant levels (<50 pg/mL) for much of gestation, before increasing dramatically (approximately 20-fold) close to term. This increase is a consequence of corresponding heightened placental, as well as decidual and fetal membrane secretion,[6] and decreased plasma CRH-binding protein levels. After delivery, maternal plasma CRH levels decline rapidly.[7] Maternal plasma CRH concentrations increase earlier in preterm delivery, intrauterine growth restriction, and preeclampsia. This suggests that maternal plasma CRH levels may reflect fetal well-being.

Human fetal plasma CRH concentrations are elevated compared with neonatal levels, but do not appear to change with advancing gestation, and are lower than maternal concentrations.[8,9] CRH concentrations are higher in the umbilical vein than artery. CRH in the fetal circulation is thought to be almost exclusively of placental origin.[8] The disparity between maternal and fetal plasma CRH concentrations during gestation suggests that differential regulation of CRH production and secretion in the maternal and fetal components of the placenta occurs.[8] Fetal

plasma CRH-binding protein levels decrease between midgestation and term.[10]

CRH exerts its effect by binding to CRH-R1 and CRH-R2 receptors, both of which have specific isoforms. As in the pituitary, CRH receptors are expressed in the placenta.[7] CRH-R2 receptors have also been detected in myometrium from pregnant, but not nonpregnant, individuals.[7] Cytokines, glucocorticoids, neurotransmitters, and peptides stimulate CRH release, but nitric oxide and progesterone inhibit release from placental tissues.[11]

Corticotropin

Human maternal plasma ACTH concentrations increase moderately in late gestation as do cortisol concentrations.[6,12] The extent of increase, however, is disproportional to the massive increase in circulating placental-derived CRH.

ACTH is detected in human fetal plasma by 16 weeks of gestation.[2] Some reports suggest that plasma concentrations tend to increase slightly with advancing gestation[9] (Figure 180-3); others have indicated that change is little or none. Given that fetal plasma cortisol concentrations tend to increase in the same period, it would seem logical for ACTH concentrations also to be elevated, at least to some extent. Indeed findings from comprehensive animal studies (see later discussion) have revealed that ACTH concentrations (specifically bioactive ACTH) increase significantly in late gestation. Fetal plasma ACTH levels are typically equal to, or higher than, maternal plasma concentrations.

Study of human anencephalic fetuses (in whom plasma ACTH is not detectable) suggests that all ACTH circulating in fetal plasma is of pituitary origin.[2] ACTH does not appear to readily cross the placenta from mother to fetus.[2]

In general, study of ovine fetuses has revealed that although plasma immunoreactive ACTH levels do not change markedly during gestation, an increase in bioactive ACTH$^{1\text{-}39}$ close to term is significant, coinciding with the plasma cortisol surge.[13] Moreover, the ratio of bioactive ACTH to ACTH precursors (including POMC and pro-ACTH) is elevated. This altered processing of POMC would appear to be related to changes in prohormone convertase 1 distribution and expression in the anterior pituitary. The percentage of anterior pituitary cells expressing prohormone convertase 1 increases significantly in the final 20 days gestation in keeping with the heightened bioactive ACTH concentrations evident at this time.[1]

Various manipulations in fetal sheep have demonstrated the importance of hypothalamic input in the control of ACTH secretion. Both surgical isolation of the fetal pituitary from hypothalamic influence (hypothalamic pituitary disconnection) and paraventricular lesioning interfere with the ontogenic increase in bioactive ACTH, the ratio of bio- to immunoactive ACTH, and cortisol.[1,14,15] These findings underline the importance of hypothalamic secretagogues in regulating POMC processing and ACTH secretion in the late gestation fetus. Further, it appears that AVP plays a critical role in mediating the late gestation increase in the ratio of bio- to immunoactive ACTH as pituitary responsiveness to AVP increases while responsiveness to CRH decreases close to term in the fetal sheep.[16,17]

Studies With CRH, CRH-R1, and POMC knockout mice

Mice genetically manipulated to lack expression of CRH, CRH-R1, and POMC (knockouts; CRH−/−, CRH-R1−/− and POMC−/−) offer insight into the importance of these peptides for general and HPA axis development in the fetus. When mice heterozygous for the CRH gene (CRH+/−) are mated, the resultant CRH−/− fetuses develop normally, and indeed when born are indistinguishable from CRH+/+ and CRH+/− littermates.[18] These mice do, however, exhibit impaired adrenal responsiveness to stress.[18,19] POMC expression is not different between CRH−/− and CRH+/+ fetuses in late gestation,[20] which suggests that CRH is not required for corticotroph development. CRH−/− fetuses in CRH−/− dams die soon after birth due to fetal glucocorticoid insufficiency unless exogenous glucocorticoids are provided to sustain fetal lung development.[18] For similar reasons, CRH-R1−/− progeny from CRH-R1−/− dams also die within 48 hours after birth.[21] These findings not only reflect the importance of glucocorticoids for fetal lung maturation, but also CRH (especially maternal) in mediating glucocorticoid synthesis during pregnancy.

Mouse POMC−/− offspring derived from POMC heterozygous parents are also viable and fertile, indicating that POMC and its derived peptide are not essential for fetal survival.[22,23] These mice are born with completely dysfunctional adrenal glands, as evidenced by the lack of corticosterone (and other adrenal steroid) production.[24] In adult POMC−/− mice, it has been demonstrated that chronic exposure to exogenous ACTH can fully restore adrenal functionality, morphology, and size.[25] In contrast, POMC alone exerts no such restorative effects. Although similar "replacement/rescue" interventions have not been applied during pregnancy, one would presume that exogenous ACTH should promote normal adrenal development in the POMC−/− fetus. Evidence favoring the singular importance of ACTH in regulating fetal adrenal maturation is also apparent in the findings of studies in which fetal sheep are subjected to hypothalamopituitary disconnection. These fetuses have low plasma levels of bioactive ACTH and their adrenals at term display reduced ACTH receptor expression and steroidogenic capacity, resembling adrenals in 120-day-old fetuses. Treatment of these fetuses with ACTH alone fully restores adrenal cortisol production, thereby demonstrating the primary importance of ACTH in fetal adrenal development.

REGULATION

A number of studies have examined the changing ratios of POMC-derived peptides, such as N-POMC$^{1\text{-}77}$ and pro-ACTH (as well as POMC itself) to ACTH$^{1\text{-}39}$ as a function of gestational age and stimulation by CRH or AVP. The increase in total immunoreactive ACTH, which may occur toward term, is paralleled by a small but definite increase in the concentration of ACTH$^{1\text{-}39}$ relative to either N-POMC$^{1\text{-}77}$ or the biosynthetic precursors POMC

and pro-ACTH. A complementary finding has been observed in vitro with fetal sheep anterior pituitary slices secreting increasing amounts of $ACTH^{1-39}$ relative to precursors as a function of gestational age. These findings suggest that the capacity of pituitary corticotrophs to synthesize, process, and secrete $ACTH^{1-39}$ increases as development progresses. Indeed, when a sensitive bioassay is used to measure ACTH activity in fetal plasma, levels increase between 100 and 140 days of gestation.[13]

A definite change in ACTH responsiveness to secretagogues occurs during development. Cultures of pituitary cells from immature sheep fetuses (100 to 115 days gestation) respond robustly to CRH, and very modestly to AVP. In contrast, cultured cells from mature fetal pituitaries respond less dramatically to CRH but markedly to AVP. This developmental change in the capacity of these secretagogues to stimulate ACTH release is not evident in cells from mature fetuses adrenalectomized at approximately 120 days gestation. These cells show a pattern of secretion resembling that of cells from immature fetuses. A probable explanation for these observations is that the increase in cortisol normally seen at the end of gestation promotes the change in ACTH secretory responses to CRH and AVP; when the cortisol increase does not occur late in gestation, corticotrophs maintain an immature profile of responsiveness.[16]

The developmental changes in the overall secretory pattern are universal at the single cell level. CRH causes more corticotrophs to secrete ACTH in pituitaries from immature fetuses, whereas AVP stimulates a greater number of cells to secrete ACTH in mature pituitaries.[17] Also, in the immature fetal pituitary, ACTH-secretory responses to CRH or AVP can be totally accounted for by the recruitment of erstwhile nonsecreting cells to secrete. However, in term pituitaries the response to AVP involves both recruitment and an increase in the average amount of ACTH secreted per cell.[17] This change in CRH-responsiveness is probably due to decreased pituitary CRH receptor expression considering that CRH-R1 receptor mRNA and protein decrease throughout late gestation and in response to cortisol treatment.[26]

Age related changes in responsiveness have also been detected in vitro, with the largest increments in ACTH release occurring in pituitary cells from earlier gestation fetuses. It is noteworthy that fetal sheep pituitaries isolated at 0.43 gestation exhibited ACTH responses to CRH. This approximates the period of development when CRH can first be shown to exert an effect on ACTH release in human fetal pituitary cells.

For glucocorticoids to affect activity of the CRH-ACTH axis, glucocorticoid receptors should be expressed in the fetal pituitary or in brain regions thought to be important for regulation of the system. The presence of specific glucocorticoid binding sites has been reported in cytosolic preparations of fetal pituitary, hypothalamus, and hippocampus. Receptors are expressed as early as midgestation in all three tissues, and the concentration of binding sites does not vary uniformly with gestational age. However, receptor levels are higher in the fetus than in the adult. The association constants calculated by Scatchard analysis of the data indicate a high affinity binding site and sucrose density gradient profiles of the ligand-binding site complex that are characteristic of a glucocorticoid receptor. Thus at least a portion of the biochemical machinery essential for glucocorticoid modulation of the CRH-ACTH system is present by 0.5 gestation.[2]

Incubation of pituitary cells in the presence of dexamethasone for 24 hours results in suppression of basal ACTH release and CRH-induced ACTH secretion. These observations suggest ACTH secretion in the early gestation human fetus is primarily regulated by CRH and that adrenal glucocorticoids exert negative feedback on ACTH secretion. Plasma immunoreactive ACTH levels in the fetal sheep remain relatively low during the last third of gestation. However, in the 24 to 48 hours preceding parturition, a marked increase in ACTH occurs. This increase in ACTH is unique because it occurs in spite of the high prevailing plasma cortisol concentrations apparent at this time. The explanation for this increment in ACTH is currently unknown but may be related to the aforementioned increase in pituitary responsiveness to AVP, and associated changes in postreceptor signal transduction. Specifically, evidence suggests that the amount of second message (inositol trisphosphate) generated upon AVP/AVP-R binding increases with advancing gestational age (Figure 180-4).

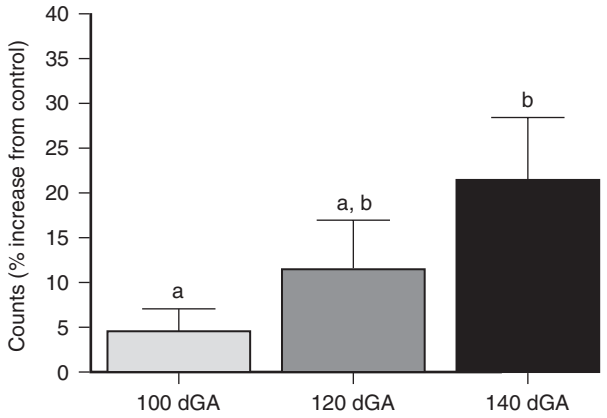

Figure 180-4 Ontogeny of inositol trisphosphate *(IP3)* formation in ovine pituitary cells after stimulation with arginine vasopressin *(AVP).* Cells were isolated from fetuses at 100, 120, and 140 days gestational age (dGA). Control cells were unstimulated. Groups with different letters are significantly different ($p < .05$), n = 5-7 fetuses per group. *(Modified from Carey LC, Tatter SB, Rose JC: Ontogeny and effects of hypothalamic pituitary disconnection on formation of inositol trisphosphate in fetal sheep pituitary cells,* Endocrinology *148:1440, 2007.)*

Consistent with the ability of glucocorticoids to inhibit ACTH secretion is the observation that cortisol infusion blocks CRH-induced ACTH release in the sheep fetus. The ACTH response to AVP has also been demonstrated to be impaired by synthetic glucocorticoids in the ovine fetus, and dexamethasone inhibits ACTH release after the simultaneous injection of CRH and AVP. The ability of glucocorticoids to inhibit CRH and vasopressin-stimulated release of ACTH in vivo has been confirmed in vitro.[2] These findings, however, appear inconsistent with the previously noted increase in pituitary responsiveness to AVP close to term that occurs in the presence of high endogenous plasma cortisol concentrations. Why such changes are not apparent after administration of synthetic glucocorticoids earlier in gestation is unclear, but this may be related to acute versus chronic exposure and/or naturally occurring as opposed to synthetic glucocorticoids.

FETAL PROGRAMMING AND THE HYPOTHALAMUS-PITUITARY-ADRENAL AXIS

Timely activation and inhibition of the hypothalamus-pituitary-adrenal (HPA) axis plays a key role in coordinating the development and maturation of various organs. Probably as a consequence of that role, the timing of HPA activity is an essential element of *fetal programming*. Programming is the process whereby early adaptation to adverse environments results in permanent physiological changes that may be beneficial during fetal life but are less advantageous postnatally. However, because programming is associated with both precocious exposure to glucocorticoids before birth and elevated HPA axis activity after birth, it remains an important aspect of investigation of the regulation of the HPA axis in fetuses. Accordingly, this chapter includes descriptions of some of the most relevant research models used to simulate the conditions associated with altered activation of the fetal HPA axis. Although a comprehensive review of all the research into

TABLE 180-1

Representative Studies Using Models of Fetal Programming That Demonstrate Altered Hypothalamus-Pituitary-Adrenal Axis Activity During Development or in Postnatal Life

Model	Species	Timing of the Finding(s)	Broad Finding(s)
Smoking	Human	Birth	Increased ACTH in umbilical blood of tobacco-exposed neonates[70]
Long term hypoxia	Sheep	Late gestation	Slightly elevated or unchanged plasma ACTH levels; increased adrenal sensitivity to ACTH[53-59]
Exposure to glucocorticoids	Rat	Birth	Decreased plasma ACTH and corticosterone; decreased mRNA for CRH in PVN[48]
	Sheep	105 days gestation	Previous exposure to dexamethasone blocks ACTH and cortisol responses to acute hypoxia[49]
		128 days gestation	2 days after exposure to glucocorticoids, basal plasma cortisol increased and an increased ACTH response to acute hypoxia[50]
		6 to 12 months postnatal	Prenatal exposure to betamethasone blunts the increase in the ACTH response to CRH and AVP that ordinarily occurs between ages 6 and 12 months[71]
		130 days gestation	Increased mRNA for GR and MR in the hippocampus[72]
	Guinea pig	52 days gestation	After exposure to dexamethasone on days 50 and 51, increased plasma cortisol and increased mRNA for GR and MR in the hippocampus of female fetuses; male fetuses have decreased plasma cortisol[51]
IL-6 exposure	Rat	As adult offspring	Increased basal plasma ACTH and corticosterone; decreased mRNA for MR and GR in PVN; increased mRNA for CRH receptor in pituitary[73]
Multiple pregnancy	Sheep	130 days gestation	Twins have lower basal cortisol and cortisol responses to acute hypoxia[38]
Undernutrition (periconceptional)	Sheep	Birth	Precocious activation of HPA axis; premature delivery[60]
Undernutrition early in pregnancy	Sheep	Age 85 days	Increased basal plasma cortisol[74]
		126-129 days gestation	Decreased ACTH, cortisol responses to acute hypoxia[61]
		113-127 days gestation	Decreased ACTH, cortisol responses to CRH and AVP at 113-116 days and decreased cortisol response at 126-127 days[40]
Undernutrition late in pregnancy	Rat	Neonate	Decreased adrenal weights and decreased mRNA for GR and MR in hippocampus[42]
Ethanol	Rat	Age 45 and 60 days	Increased HPA responses to immunological challenges[75]
	Rat	Age 22 days	Increased ACTH response to stress; possibly not mitigated by neonatal handling[76]

NOTES: This table is not meant to be comprehensive in terms of models or experimental findings. Rather, it is intended to illustrate the breadth of models and findings that relate changes in fetal HPA axis activity to programming.

Gestation in sheep is approximately 145-150 days, in guinea pigs 70 days.

ACTH, Adrenocorticotropic hormone; *AVP,* arginine vasopressin; *CRH,* corticotropin-releasing hormone; *GR,* glucocorticoid receptor; *HPA,* hypothalamus-pituitary-adrenal; *IL,* interleukin; *MR,* mineralocorticoid receptor; *PVN,* paraventricular nucleus.

the fetal HPA axis and programming is far beyond the scope of this chapter, it focuses on a few of the key, recent lessons learned from that research (Table 180-1).

Generally, in acute situations, the fetal HPA axis responds similarly to its postnatal counterpart. For example, hypoxia or hypoglycemia will be detected in the central nervous system leading to activation of the HPA cascade and resultant elevated glucocorticoid levels. Acute responses would appear to be part of the ordinary developmental process and not associated with programming. In contrast, adaptations to chronic situations may be different. It is possible that these are associated with programming not only because of the temporal element but because they potentially contribute to establishing a trajectory for growth. For example, prolonged hypoglycemia at a vulnerable time might signal a trajectory for growth in a nutritionally challenged environment, with the consequence of altering mechanisms for the uptake of glucose with increased efficiency. The HPA axis is a fetal organ system that also responds differently to chronic stimuli and, in doing so, contributes to the programming process.

Among the most important animal models developed for this research are those in which metabolic substrates, such as oxygen or protein, are restricted during gestation. For various, obvious reasons, numerous species have been used, with the most common being rats and sheep. These models include those of global substrate reduction, accomplished by placental embolism,[27,28] placental restriction through the surgical excision of attachment sites,[29-31] uterine artery ligation,[32,33] cord occlusion,[26,34] or multiple pregnancy (in monovulatory species).[35-38] In another important category of models of programming, specific substrates are limited. These include decreasing maternal food or protein intake,[39-42] insulin-induced hypoglycemia,[43] and decreased oxygen availability via gestation at altitude,[44] or decreasing the fraction of maternal inspired oxygen.[45,46]

In addition to limiting substrates during gestation, other models of programming include those that mimic ill-timed exposure of fetuses to elevated levels of glucocorticoids. This is generally accomplished by either direct administration of glucocorticoids to mother and/or fetus, inhibition of 11β-hydroxysteroid dehydrogenase (the placental enzyme that ordinarily shields the fetus from excursions in the levels of maternal glucocorticoids) or by stimulating endogenous production of maternal or fetal glucocorticoids, such as by maternal ethanol ingestion or smoking.[47-52] The administration of glucocorticoids has direct clinical relevance as well because glucocorticoid treatment is frequently used to stimulate lung development in cases of anticipated premature delivery.

Among the more interesting fetal adaptations are those that occur in response to prolonged hypoxemia. This has been typically studied in sheep and accomplished in a number of experimental ways. In contrast to the acute response to hypoxemia, which is an increase in HPA activity, both before and after birth, chronic fetal hypoxemia is associated with plasma ACTH levels that are indistinguishable from control levels or only slightly increased.[53-57] An additional, interesting adaptation to long-term hypoxia is that the adrenal apparently becomes somewhat more sensitive to increases in ACTH. Acute stimulation of the HPA axis by cord occlusion or

other means, when superimposed on chronic hypoxemia, tends to produce an attenuated ACTH response and potentiated cortisol response compared with the normal acute response.[55-59] The reasons for the increased adrenal responsiveness are not clear because many of the adrenal molecules involved in responses to ACTH are unchanged or decreased, although it should be noted that the plasma ratio of ACTH[1-39] to ACTH precursors (see previous discussion) is increased in with chronic hypoxia.[53]

Maternal undernutrition is another important model used to study programming and the role of the HPA axis therein. Of particular significance are studies that involve early or periconceptional undernutrition. In these cases, the undernutrition would be expected to have no or negligible impact on the fetus by virtue of limiting substrate; yet the effects can be quite profound. The effect on the developing HPA axis is therefore expected to be more likely due to altering the greater environment in early gestation and/or influencing the developmental trajectory. In two models of ovine periconceptional undernutrition, evidence shows precocious activation of the HPA axis. In one, periconceptional (−60 to +7 days relative to mating), but not subsequent, undernutrition was associated with elevated ACTH levels in twin, but not singleton, fetuses late in gestation.[36] In another study, more severe nutrient restriction from days −60 to +30 relative to mating resulted in premature delivery in half of the fetuses, associated with precociously elevated ACTH and cortisol levels.[60] In contrast, results from other studies in which maternal nutrient intake was restricted early in gestation, but not *before* mating, are consistent with negligible effects on the HPA axis, or possibly even some blunting of the adrenal response to ACTH.[40,61] Although the results are not consistent, they have shed an entirely new light on the regulation of the fetal HPA axis and the influence of the maternal environment around the time of conception thereupon.

Perhaps less surprisingly, undernutrition late in gestation, when fetal metabolism is nearing the limits of available substrate, is also associated with elevated plasma levels of ACTH. Interestingly, evidence suggests that the effects of early undernutrition in a sheep model is independent of maternal glucocorticoids,[62] whereas late undernutrition in another model in rats may be an indirect effect, mediated by maternal glucocorticoids.[42] If so, this could be considered counterintuitive because any periconceptional glucocorticoid effect would have to be maternal, whereas late in gestation, the fetal HPA axis is fully active and can act independently.

Evidence that alterations of fetal HPA activity have long-lasting, if not permanent, effects on the function of the axis come from studies in which animals subjected as fetuses to the above conditions have been followed after birth and from studies in which the direct effects of fetal exposure to glucocorticoids on various regulatory systems have been documented postnatally. For example, treatment of pregnant vervet monkeys with dexamethasone daily from gestation until delivery resulted in an enhanced cortisol response to stress in offspring at 8 months of age.[63] Although the precise mechanisms by which elevated or precocious activity in the fetal HPA axis leads to altered regulation of the axis postnatally have yet to be elucidated, much interest is focused on the setpoint of feedback regulation. During development it is likely that some increased aspects, representing HPA activity, trigger permanent changes to establish that level of activity as normal. Some evidence shows that elevated levels of glucocorticoids alter brain physiology, including the down-regulation of glucocorticoid receptors in the hippocampus, which may decrease sensitivity to negative feedback.[64,65] This remains an area of intense research.

The widespread use of antenatal glucocorticoid therapy in humans to enhance fetal lung maturation has also prompted investigators to assess whether prenatal steroid exposure programs changes in activity in the HPA axis after birth. The available data suggest this is the case. In one of the first prospective studies examining this issue, the plasma ACTH and cortisol values in response to stimulation by CRH were measured in 137 very-low-birth-weight infants at 7 and 14 days of age. Comparisons were made between infants whose mothers received betamethasone treatment before delivery and those whose mothers did not. Although the ACTH responses were similar in the groups that received steroid and those that did not, the plasma cortisol responses were significantly attenuated at 7 days in the infants whose mothers received antenatal corticosteroids. However, at 14 days of age the differences in cortisol responses to CRH had disappeared. These data suggest that one or two doses of antenatal corticosteroids are capable of attenuating the adrenal response to stimulation in the newborn.[66] Other studies have demonstrated that prenatal betamethasone treatment modulates the stress response in healthy premature infants. In a small study, salivary cortisol production after heelstick blood sampling was monitored in nine newborns whose mothers had antenatal betamethasone treatment and in nine infants from untreated mothers. All the infants were born at 33 to 34 weeks gestation and studied within 3 to 6 days of delivery. The cortisol response to heelstick was blocked in the infants exposed to betamethasone prenatally.[67] A similar comparison was subsequently made in infants 4 to 6 weeks after exposure to the steroid. At that time, the cortisol response to the stress of a heelstick remained blocked.[68] Similarly, the salivary cortisol response to immunization at 4 months of age is attenuated in preterm babies whose mothers received either betamethasone or dexamethasone before delivery.[69] These data are reasonably consistent and suggest that programming of the HPA axis in fetal life can occur as a result of prenatal glucocorticoid exposure. The impact of such programming persists for at least 4 months after birth.

The association of the fetal HPA axis in general, and regulation of ACTH secretion in particular, with both normal coordination of the maturation of various organs and with fetal programming places the axis in an intriguing place both physiologically and as a subject of current interest. Clearly, timing is critical and alterations to the environment that signal a less favorable progression thorough gestation are often associated with altered ACTH secretion or adrenal sensitivity to ACTH. However, the mechanisms involved in this altered regulatory function referred to as programming have not been identified.

SIGNIFICANCE

It now seems reasonably clear that a primary role for the CRH-ACTH system is related to its essential nature in promoting the maturation of adrenal steroidogenesis in fetal life. This can be seen in a variety of animal models that have as their end result impairment of CRH synthesis, the capacity of CRH to stimulate ACTH release, or the ability of the pituitary to synthesize ACTH. Thus targeted disruption of the CRH gene or the CRH-R1 receptor results in animals that lack the ability to secrete adrenal glucocorticoids and that cannot survive for prolonged periods after birth unless replacement steroid is provided. Likewise, animals lacking the POMC gene have dysfunctional adrenals and suffer the consequences of a profound lack of circulating glucocorticoids. Even if disruptions of the CRH-ACTH system occur in the last half of pregnancy, the ability of the fetal adrenal to secrete corticosteroids is almost completely lost. Because the normal development of multiple organ systems in the fetus, especially the lung, have an absolute requirement for glucocorticoids to be present in fetal circulation the normal development of the CRH-ACTH system is essential for preparing the fetus for extrauterine life.

The recognition that activity in the fetal CRH-ACTH-adrenal axis is susceptible to the effects of programming by various

stimuli adds a new layer of complexity for understanding the interactions among the factors that regulate normal development of this hormonal system. The observations in humans that prenatal events can program alterations in responses to stress by the brain-pituitary-adrenal axis after birth also suggest that the normal development of this system has important ramifications for well-being in adulthood. Clearly, additional research is needed on the normal development of this system to better understand its impact on prenatal and postnatal health.

Fetal and Neonatal Adrenocortical Physiology

The adrenal cortex undergoes remarkable growth and unique metamorphosis during the fetal and neonatal period. Its morphology, functions, and secretory product profiles are distinctly different during fetal versus postnatal life. The major products of the fetal adrenal cortex, the weak androgens dehydroepiandrosterone (DHEA) and its sulfate (DHEAS), disappear almost completely after birth, reappearing years later at the onset of adrenarche. The functions of the adrenal cortex during fetal life—participation in the maintenance of pregnancy and initiation of parturition, as well as secretion of cortisol to promote organ maturation before birth—also change postnatally to maintenance of homeostasis, particularly in the presence of stress, and modulation of inflammatory challenges.[1]

The cumulative work of many investigators has demonstrated that the structural and functional organization of the fetal adrenal cortex of humans and higher primates is unique.[2] In addition, a major regulator of fetal adrenal development, placental corticotropin-releasing hormone (CRH), is present only in humans and closely related primates.[3] Thus, although insights can be obtained from other animal models, caution must be exercised in applying such findings to human physiology. Wherever possible, this chapter focuses on studies of humans and other primates.

DEVELOPMENTAL HISTOLOGY

The primordial adrenal gland is first evident in humans as a distinct cluster of cells at 33 days postconception.[4] By 50 to 52 days postconception, steroidogenic activity can be detected within the nascent fetal zone.[5] The gland then grows exponentially, increasing 10-fold between 8 and 10 weeks postconception,[5] equaling the kidney in weight at 20 weeks of gestation, then doubling in size between 20 and 30 weeks and doubling again by term, reaching a combined weight of about 8 grams (Figure 181-1).[6] After birth, the gland quickly involutes, shrinking to a combined weight of about 2 grams by 1 year of age before beginning to grow again.

This remarkable growth during fetal life occurs through a combination of hyperplasia, hypertrophy, and reduced apoptosis. During the embryonic period, mitotic activity has been observed throughout the fetal adrenal cortex.[6] The cortex then quickly differentiates into two distinct zones: an outer definitive zone, composed of a thin layer of tightly packed small, basophilic cells with ultrastructural characteristics consistent with cellular proliferation, and a much larger inner fetal zone, containing large, eosinophilic cells with a steroid secreting phenotype.[7-10]

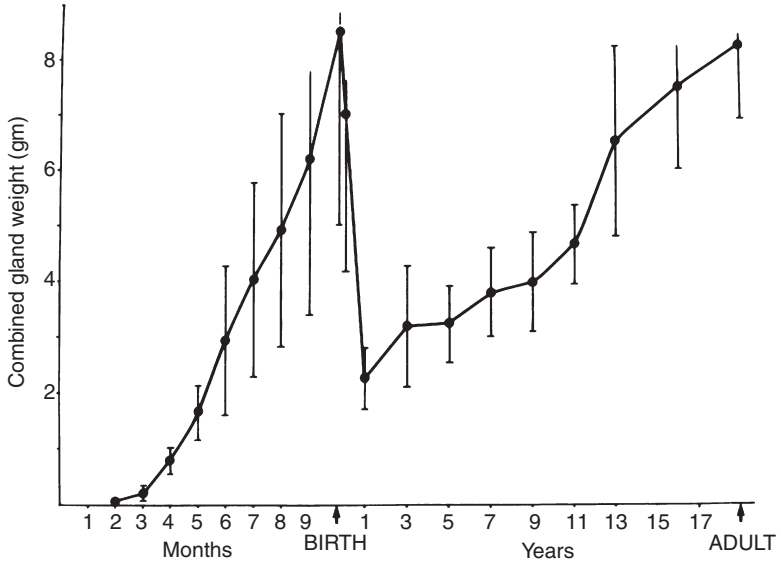

Figure 181-1 Adrenal gland weights during human development. *(From Neville AM, O'Hare MJ:* The Human Adrenal Cortex, *Berlin, 1982, Springer-Verlag, p 12.)*

The ultrastructural appearance of these two zones led investigators to conclude that cells in the fetal zone did not divide. Using newer techniques, however, investigators have identified mitotic figures throughout the fetal zone, suggesting that it grows by hyperplasia as well as hypertrophy.[8] Because the mitotic index in the definitive zone exceeds that in the fetal zone, however, proliferation appears to occur predominantly in the definitive zone, with new cells migrating toward the center, where they hypertrophy and terminally differentiate into steroid producing cells.[8]

At the intersection of these two zones, a transitional zone appears and begins to secrete cortisol at week 22 to 24 of pregnancy.[11] This transitional zone expands through the latter part of gestation and becomes the cortisol-secreting zona fasciculata by term, and the outer, definitive zone becomes the zona glomerulosa, which secretes the mineralocorticoid aldosterone.[11]

Apoptotic nuclei have been identified primarily at the center of the cortex.[8] These nuclei are present in low but increasing numbers during gestation.[8] After birth, maximal apoptosis is observed in the fetal zone, which subsequently disappears.[8] Several years later, the zona reticularis will appear at the site of the earlier fetal zone and begin to secrete DHEA and DHEAS, regulating the onset of adrenarche.[1]

ENZYMES AND SECRETORY PRODUCTS

The major secretory products of the adrenal cortex include weak androgens (DHEA and DHEAS), cortisol and aldosterone. As shown in Figure 181-2, steroidogenesis requires a series of enzymatic steps, including four cytochrome P450 oxidase enzymes.[1] Two of these are located in the mitochondria—cholesterol side chain cleavage enzyme (P450scc) and 11β-hydroxylase (P450C11)—and two are found in the endoplasmic reticulum: 17α-hydroxylase/17,20 lyase (P450C17) and 21-hydroxylase (P450C21).[12] The first, rate-limiting step in the synthesis of steroid hormones is the conversion of cholesterol to pregnenolone by P450scc, which is dependent on delivery of cholesterol to the mitochondrion by the steroidogenic acute regulatory protein.[12,13] Absence of this regulatory protein impairs adrenal and gonadal steroidogenesis and is clinically manifested as congenital lipoid adrenal hyperplasia.[14] The critical branch point enzymes regulating steroidogenesis are 3β-hydroxysteroid dehydrogenase (type 2 isozyme, 3βHSD2) and P450C17. These two enzymes compete for substrate.[15] In tissues in which 3βHSD2 is highly expressed, cortisol is produced preferentially; low 3βHSD activity in conjunction with high P450C17 promotes DHEA production.[15,16]

After the embryonic period, the enzymes and secretory patterns of each zone within the adrenal cortex are distinct, and the specific steroidogenic enzymes within each zone determine the type of steroid produced in that zone[2,9,11,17] (Figure 181-3). The fetal zone contains P450C17, but lacks 3βHSD2, and therefore secretes DHEA and DHEAS in massive amounts—up to 200 mg/day during the third trimester.[18] These adrenal androgens serve as substrates for placental aromatases, which convert them to the estrogens estriol, estradiol, and estrone[19,20] (Figure 181-4). This process appears to be fundamental to the normal maintenance of pregnancy, as reviewed later in this chapter.

The transitional zone, which appears at 22 to 24 weeks gestation, contains 3βHSD2 and can therefore synthesize cortisol de novo from cholesterol[1,17] (see Figures 181-2 and 181-3). Before the appearance of the transitional zone, however, cortisol may be produced by the fetus using placental progesterone as a substrate[9,21] (see Figure 181-4). The outer, definitive zone of the cortex also begins to express 3βHSD2 toward the end of gestation, but this zone lacks P450C17 and therefore secretes the mineralocorticoid aldosterone[9,11,17] (see Figures 181-2 and 181-3). The zona reticularis, which will not become morphologically apparent until adrenarche, appears to be analogous to the fetal adrenal cortex in that it lacks 3βHSD2 and secretes DHEA and DHEAS.[1]

The expression of these critical branch point enzymes very early in gestation and their effects on early development have been unclear. 3βHSD2 was generally believed to be absent from the human fetal adrenal cortex in the undisturbed pregnancy until 22 to 24 weeks gestation. However, one immunohistochemical study found transient staining for 3βHSD in numerous definitive zone and occasional fetal zone cells very early in development, which disappeared by 14 weeks postconception.[22] A recent study confirmed this transient expression of 3βHSD2, as well as its regulatory orphan nuclear receptor (nerve growth factor–induced clone B, or NGFIB), in human adrenal cortex during the embryonic period, and additionally documented a brief spike in adrenal cortisol content and secretion during this time.[5] Biosynthesis was maximal at 8 to 9 weeks postconception, after which 3βHSD immunoreactivity and cortisol content decreased quickly, declining by half at 10 weeks and to undetectable levels

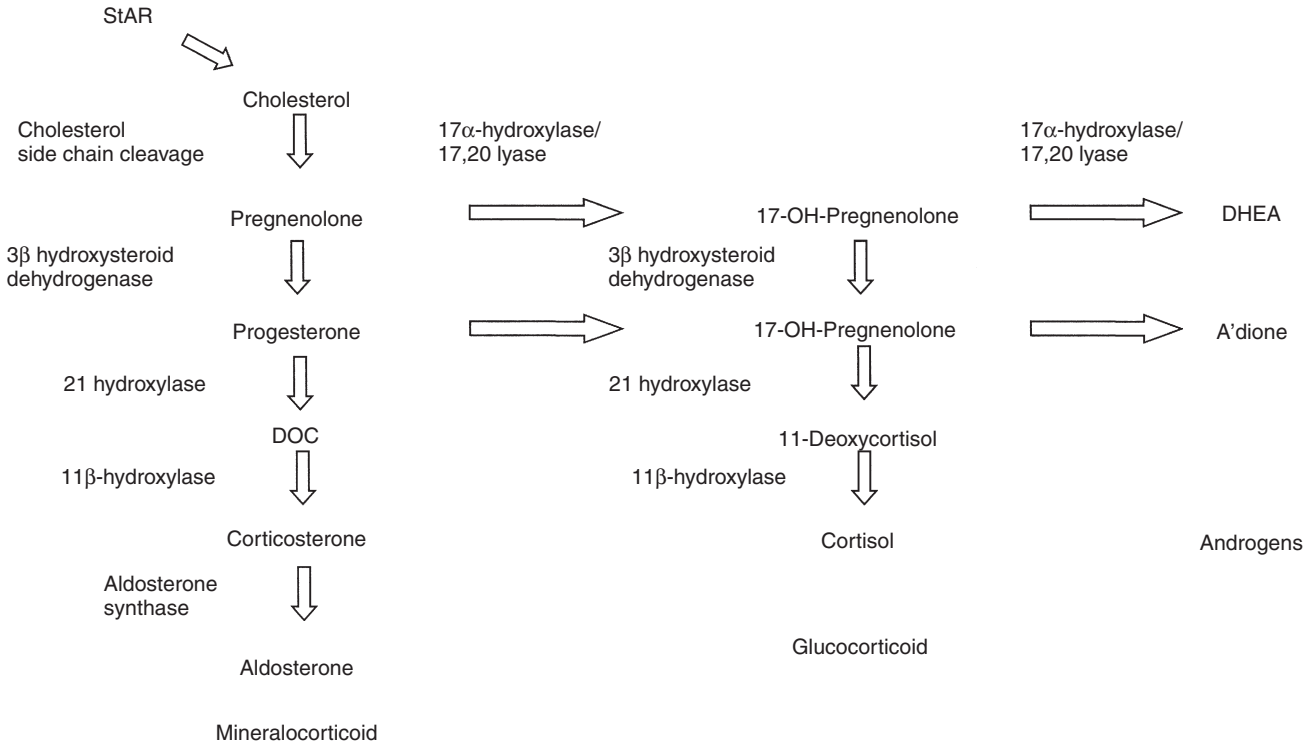

Figure 181-2 Adrenal steroidogenesis. After the steroidogenic acute regulatory *(StAR)* protein-mediated uptake of cholesterol into mitochondria within adrenocortical cells, aldosterone, cortisol, and adrenal androgens are synthesized through the coordinated action of a series of steroidogenic enzymes in a zone-specific fashion. *A'dione,* Androstenedione; *DHEA,* dehydroepiandrosterone; *DOC,* deoxycorticosterone. *(From Stewart PM: The adrenal cortex. by 14 weeks postconception. This early, transitory cortisol production was coincident with the detection of adrenocorticotropic hormone (ACTH) in the same fetuses. Additionally these adrenocortical cells were responsive to ACTH, strongly suggesting that even at this early stage adrenal cortical cells are regulated by ACTH secretion.[5]

This thought-provoking new work may solve the puzzle of how female fetuses affected by P450C21-deficient congenital adrenal hyperplasia become virilized very early in gestation, at a time before the fetus had been thought to produce cortisol. Virilization occurs in congenital adrenal hyperplasia when the cortisol biosynthesis pathway is stimulated by ACTH, but cortisol production is blocked by the absence of P450C21 (see Figure 181-2). This block in cortisol synthesis removes the normal negative feedback of cortisol to the pituitary and results in increased ACTH secretion. In this situation, continuing stimulation of the cortisol synthesis pathway leads to an accumulation of cortisol precursors, which are shunted into increased production of DHEA and DHEAS (see Figure 181-2). Later in gestation, these increased fetal androgens will be converted to estrogens by placental aromatases (see Figure 181-4), thus preventing accumulation in the fetus.[5,19] At this early stage of gestation, however, placental aromatase activity is low, resulting in an accumulation of androgens and virilization of the external female genitalia during differentiation, a process that occurs at 8 to 10 weeks postconception.[5]

REGULATION OF FETAL ADRENAL DEVELOPMENT

As befits an organ involved in the vital functions of maintaining the pregnancy, initiating parturition, and maturing fetal organs for extrauterine existence, the fetal adrenal cortex is regulated by an intricate web of factors from fetus, placenta, and mother. These factors combine to shield the fetus from premature exposure to excess cortisol early in gestation and then to stimulate the increased cortisol production essential for preparation for extrauterine survival. Normal fetal cortisol concentrations are low until well into the third trimester of pregnancy (Figure 181-5).[23] The profound effects of premature exposure of the fetus to increased glucocorticoid concentrations have been well documented in animal models, and include decreased body, brain, and organ weights.[24,25]

Fetal Factors

Adrenocorticotropic Hormone

Stimulation of the adrenal cortex by ACTH from the fetal pituitary is necessary for its normal morphologic development and steroidogenic function. The effects of a lack of ACTH in the human are demonstrated in the anencephalic fetus. Stereologic studies of adrenal cortex structure in anencephalic fetuses have shown a striking decrease in both cell number and total volume of the fetal zone and transitional zone (zona fasciculata), with less effect on the zona glomerulosa.[26,27] Although ACTH has been detected in placental tissue,[28] outcomes such as this would suggest that placental ACTH is not sufficient for normal human adrenocortical growth and development.

The specific effects of ACTH on adrenocortical cells have been documented in primate models. In vivo increasing fetal ACTH either by directly administering ACTH or by suppressing cortisol synthesis with metyrapone results in hypertrophy of the transitional zone and early appearance of 3βHSD message in both the transitional and definitive zones.[29,30] Conversely, administration of betamethasone to suppress fetal ACTH secretion eliminates

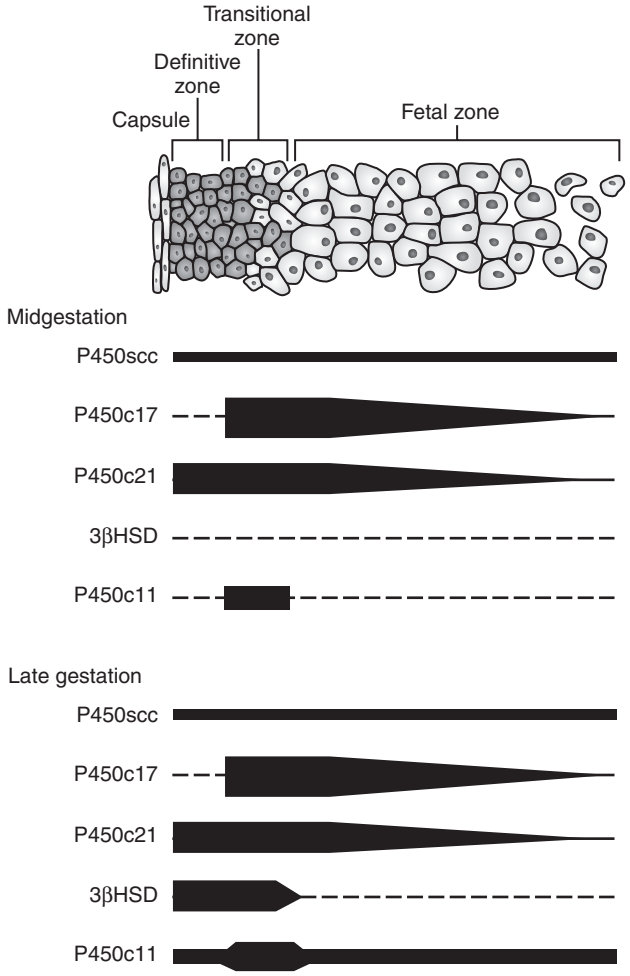

Figure 181-3 Schematic representation of the localization of expression of P450scc, P450c17, P450c21, 3βHSD, and P450c11 in the primate fetal adrenal cortex during mid- and late gestation. Thickness of the line indicates relative abundance of expression. *Dashed line* indicates lack of expression. Note the lack of P450c17 expression in the definitive zone at all stages of gestation and the ontogenetic expression of 3βHSD only in the definitive and transitional zones late in gestation. *(From Mesiano S, Jaffe RB: Developmental and functional biology of the primate fetal adrenal cortex,* Endocr Rev *18:385, 1997).*

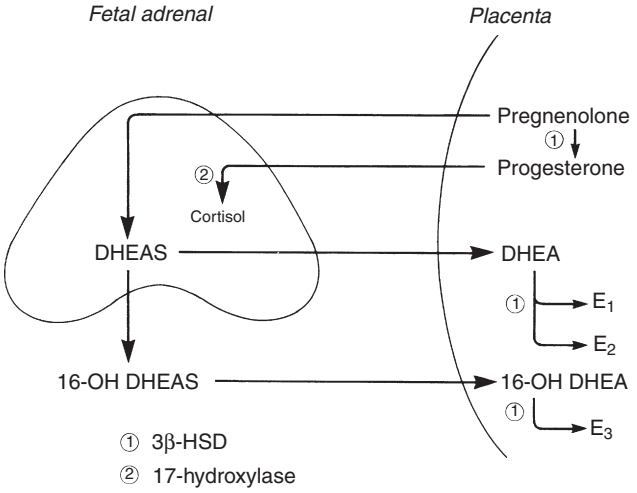

Figure 181-4 Diagrammatic representation of the fetoplacental unit composed of the fetal adrenal cortex and the placenta. The placenta is deficient in 17-hydroxylase activity and cannot synthesize estrogens from progesterone. The fetal adrenal cortex has low 3βHSD and Δ4,5 isomerase activity and cannot synthesize progesterone. Sulfokinase activity is high in fetal adrenal tissue, and steroid sulfatase activity is high in placental tissue. Thus the placenta produces progesterone, which is predominantly converted to DHEA by the fetal adrenal cortex; the DHEA can be sulfated to form DHEAS. Part of this is 16-hydroxylated by the fetal liver, and both DHEA and DHEAS are used by the placenta as substrates for estrone *(E_1)* and estradiol *(E_2)* synthesis, respectively. Placental sulfatase converts DHEAS and 16-hydroxy-DHEAS to DHEA and 17-hydroxy-DHEA. The 16-hydroxy-DHEA is used for estriol *(E_3)* synthesis. *(From Fisher DA: Endocrinology of fetal development. In Larsen PR, Kronenberg HM, Melmed S, Polonsky KS, editors:* Williams Textbook of Endocrinology, *Philadelphia, 2003, Saunders, 2003, p 813.)*

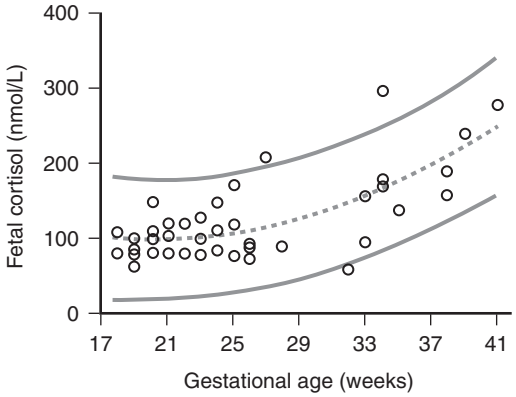

Figure 181-5 Individual values and reference range (mean and 95% confidence intervals) of fetal serum cortisol throughout pregnancy. the transitional zone and decreases mRNA expression of both 3βHSD and the ACTH receptor.[29,31] Suppression of ACTH with betamethasone at midgestation also resulted in decreased adrenal weight and cell size, cellular disorganization, increased apoptosis, and reduction in expression of mRNA for the P450scc and P450C17 enzymes, effects that were reversed by concomitant treatment with ACTH.[32]

The expression of the ACTH receptor in the adrenal cortex increases through midgestation, then decreases substantially by term.[33] Additionally the responsiveness of the fetal and the developing transitional zones to ACTH appear to diverge during the second half of gestation. In the fetal zone, a selective decrease in ACTH receptor expression and a consequent decreased responsiveness to ACTH occurs; in the emerging transitional zone an increase in ACTH receptor density and 3βHSD expression is seen.[33,34] The decline in ACTH-responsiveness in the fetal zone may be due to suppression by increasing estrogen concentrations (see later discussion).[35] In contrast to the effects of ACTH on the fetal and transitional zones, the outer definitive zone, the future zona glomerulosa, may be less affected by exogenous ACTH or betamethasone.[29] This is consistent with findings in human anencephalic infants, in whom the growth of the zona glomerulosa is relatively unaffected by the absence of fetal ACTH.[26,27]

ACTH exerts its effects on adrenal cells at least in part through local growth factors, particularly insulin-like growth factor (IGF) II. A polypeptide growth factor important in the regulation of fetal growth,[36] IGF-II is highly expressed in the fetal adrenal cortex, and its expression is stimulated by ACTH.[37,38] In turn, IGF-II stimulates proliferation of fetal adrenal cortical cells, increases steroid production, and augments expression of steroidogenic enzymes.[38-41] IGF-II appears to act through the IGF-I binding protein, possibly in concert with other polypeptide growth factors that have been shown to be mitogenic for human fetal adrenal cells, particularly basic fibroblast growth factor and epidermal growth factor.[38,39,41-44]

Transcription of ACTH effect on the fetal adrenal cortex appears to be modulated by members of the nuclear receptor superfamily. Several nuclear receptors essential for human adrenal cortex development have been implicated in transcription of ACTH effect, and more will likely be identified. The orphan nuclear receptor steroidogenic factor (SF) 1 is expressed throughout the adrenal gland and participates in the activation of numerous enzymes in the steroid biosynthetic pathway.[45] Activation of ACTH-dependent signaling cascades has been shown to lead to the cyclical recruitment of SF-1 and multiple rounds of transcription.[45] Human mutations of SF-1 produce adrenal failure, indicating its importance in adrenal development.[46] Another orphan nuclear receptor responsive to ACTH stimulation is NGFIB. NGFIB shows differential expression in the different fetal adrenal zones, and may play a crucial role in functional adrenal zonation by up-regulating 3βHSD2 gene transcription in the transitional and definitive zones.[16] A third nuclear receptor, DAX-1 (dosage-sensitive sex reversal, adrenal hypoplasia congenita, critical region on X-chromosome, gene 1) appears to be an important negative modulator of ACTH-stimulated glucocorticoid synthesis, repressing SF-1–dependent activation.[47] ACTH has been shown to down-regulate DAX-1 as well as stimulate SF-1, a potential mechanism for modulating cortisol production by the adrenal cortex.[48] Deletion or mutation of DAX-1 results in X-linked adrenal hypoplasia congenita, a disorder with profound hormonal deficiencies.[49]

Angiotensin II

Angiotensin II has been implicated in apoptosis of fetal adrenal cells, acting through its type 2 receptor (AT_2).[50] This receptor is most strongly expressed at the center of the fetal zone, which is also the location with the highest density of apoptotic figures. In cells cultured from second trimester human adrenal glands, stimulation with angiotensin II produced changes consistent with apoptosis, including DNA fragmentation, interruption of the DNA repair mechanism, and reorganization of the actin cytoskeleton, leading to the hypothesis that angiotensin II–related apoptosis contributes to the involution of the fetal zone seen after birth.[50]

Local Microenvironment/Extracellular Matrix

The regulation of zonal expression of enzymes within the adrenal cortex has been a major area of curiosity. That is, if the cells primarily originate from the definitive zone and then migrate inward, why do they express different enzyme profiles in different zones, resulting in the functional zonation observed in the gland?[11,51] Comparing in vivo with in vitro cellular function has strongly implicated a local regulation of the phenotype. For example, human fetal zone cells do not express 3βHSD in vivo; however, these cells quickly begin to produce 3βHSD in response to ACTH in vitro.[52] This functional zonation of the cortex may be regulated in part by the extracellular matrix of the local microenvironment, in particular type IV collagen, laminin, and fibronectin. Type IV collagen is present throughout the adrenal cortex and has been shown to promote cellular proliferation, as well as increase cortisol secretion in response to ACTH.[53,54] Laminin is found primarily at the periphery of the gland and causes increased proliferation and decreased apoptosis in cultured human fetal adrenal cells.[54] In contrast, the fetal zone is rich in fibronectin, which does not promote proliferation, but facilitates migration and apoptosis, enhances DHEAS secretion, and decreases cortisol secretion in cell culture.[53,55] Additionally, type IV collagen and fibronectin both have been shown to modulate the intracellular localization of DAX-1, likely affecting the function of this negative regulator of steroidogenesis.[56]

Placental Factors

A unique interactive relationship between placenta and adrenal cortex in the primate pregnancy appears to be vital to the maintenance of pregnancy, the development and maturation of the adrenal gland—and consequently other organs, such as the lung—and possibly the initiation of parturition. In addition the interrelationship of the placenta and adrenal cortex serves to shield the fetus from premature exposure to excess cortisol.

Estrogen

Pepe and Albrecht[57-59] proposed a central integrative role for estrogen in regulating the maturation of both the placenta and the fetal hypothalamic-pituitary-adrenal axis (HPA axis). Their extensive studies of the baboon pregnancy demonstrated both the model's relevance to human pregnancy and the effects that estrogen exerts by (1) acting directly on the adrenal cortex, (2) regulating the expression of 11βHSD in the placenta, and (3) affecting placental progesterone production. Because fetal androgens are the primary substrate for placental estrogen production, the fetal adrenal cortex is central to these functions.

Estrogen appears to have a direct effect on the fetal adrenal cortex. In the baboon model, estrogen receptors-α and -β are expressed throughout the fetal adrenal cortex.[60] In this model, estrogen administration suppresses DHEA but not cortisol production in response to ACTH at midgestation.[60-62] Conversely, suppression of placental estrogen production during the second half of pregnancy significantly increases DHEA secretion and the size of the fetal zone, effects that are reversed by concomitant treatment with estradiol.[35] These findings are consistent with an inhibitory effect of estrogen on the fetal zone during the latter half of gestation. In these experiments, no such effect was observed in the transitional or definitive zone.[35] These results suggest that placental estrogen provides a feedback mechanism to restrain the growth of the fetal zone during the second half of pregnancy, thus providing a consistent, but not deleteriously high estrogen exposure.[35]

Numerous studies have shown that estrogen also modulates the maturation of the primate fetal adrenal cortex through its regulation of the expression of placental 11β-hydroxysteroid dehydrogenase (11βHSD)[59] (Figure 181-6). This enzyme is widely distributed in the body and is thought to modulate local exposure to cortisol in many tissues, including lung and kidney.[63] 11βHSD exists in two forms: 11βHSD1, which converts biologically inactive cortisone to active cortisol, and 11βHSD2, which transforms cortisol into cortisone.[59] At midgestation 11βHSD1 predominates in the placenta, allowing transfer of some maternal cortisol to the fetus, suppressing the fetal HPA axis.[64,65] Late in gestation, however, 11βHSD2 predominates, transforming most maternal cortisol into the biologically inactive cortisone, thus releasing the fetal HPA axis from negative feedback and stimulating its maturation.[65,66] Estrogen appears to regulate this increase in the relative concentration of 11βHSD2 to 11βHSD1 by late gestation; suppression of placental estrogen synthesis with an aromatase inhibitor significantly decreases 11βHSD2 expression.[67]

The two different forms of 11βHSD also appear to localize to different membrane fractions of the syncytiotrophoblast: 11βHSD1 is abundant in the membranes closest to the maternal circulation,

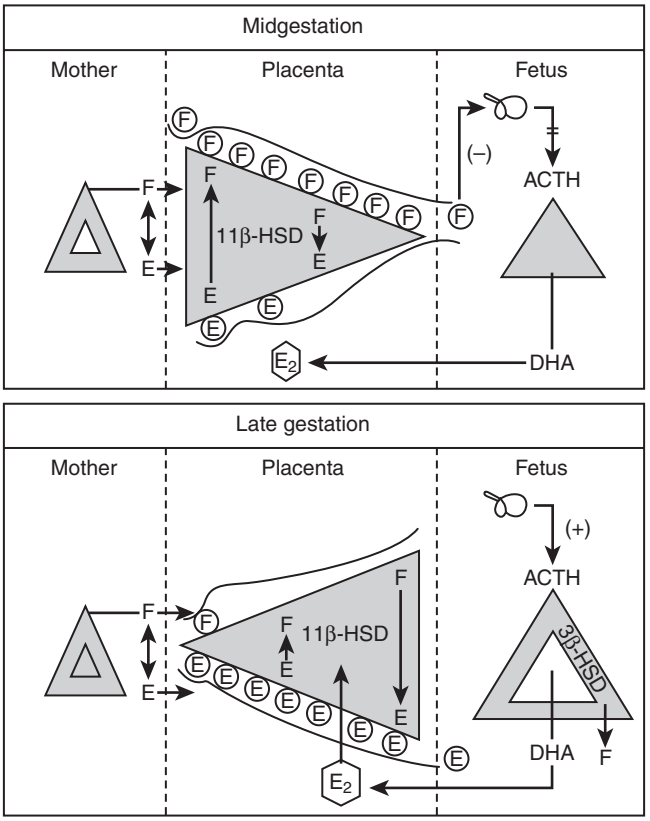

Figure 181-6 The role of estrogen *(E_2)* on placental 11βHSD-catalyzed metabolism of cortisol *(F)* and cortisone *(E)* and regulation of the fetal pituitary-adrenocortical axis at mid-and late gestation in the baboon. *(From Albrecht ED, Pepe GJ: Central integrative role of oestrogen in modulating the communication between the placenta and fetus that results in primate fetal-placental development,* Placenta *20:133, 1999.)*

and 11βHSD2 is concentrated in the membranes facing fetal vasculature.[66] This organization creates a gradient favoring metabolism of maternal cortisol to cortisone as gestation progresses. One group of investigators has reported that during the final few days of baboon gestation the expression of placental 11βHSD2 again decreased, possibly providing brief exposure to additional maternal cortisol to further mature the fetus for delivery.[68]

This changing pattern of placental 11βHSD expression would serve to first limit the exposure of the fetus to cortisol during most of the gestational period, permitting the necessary intense fetal growth and cellular proliferation, then subsequently stimulate the increased fetal adrenal cortisol production needed for maturation of vital organ systems before birth.[69,70] The importance of placental 11βHSD2 in limiting early fetal exposure to cortisol is supported by several findings in the human. First, placentas from pregnancies complicated by intrauterine growth restriction show decreased expression and activity of 11βHSD2, consistent with a role for placental 11βHSD2 in limiting exposure of the fetus to cortisol.[71-73] In addition, fetal growth restriction has been correlated with higher cortisol but lower ACTH concentrations in the fetus, as well as decreased response to ACTH stimulation in the preterm infant.[74,75] These findings are consistent with an increased exposure of the fetus to maternal cortisol in the face of decreased 11βHSD2 activity, with resulting passive suppression of the fetal HPA axis.

Estrogen also may play a part in maintaining pregnancy by increasing progesterone synthesis in the placenta. Estrogen promotes low density lipoprotein uptake and P450scc activity by the placenta, rate-limiting steps for progesterone production.[76-78] Suppression of estrogen production has been shown to decrease placental uptake of low density lipoprotein, placental P450scc activity, and peripheral progesterone concentrations in a dose-dependent manner.[76-78] However, when pregnant baboons were treated with a specific nonsteroidal aromatase inhibitor that substantially decreased maternal estrogen concentrations, maternal concentrations of progesterone were not different from untreated animals, leaving the effect of estrogen on progesterone concentrations in vivo open for further investigation.[79]

Placental Corticotropin-Releasing Hormone

Corticotropin-releasing hormone (CRH) is produced by the placenta and fetal membranes in increasing amounts during gestation, with exponentially increased production during the last 6 to 8 weeks of pregnancy.[80-83] A premature rise in CRH in maternal serum has been associated with preterm delivery, leading to its putative role as a "placental time clock" for human gestation, although the cellular basis for this mechanism is not known.[84] The magnitude of the increase in CRH during human pregnancy is much greater than in other primates,[85] which may limit the value of such models in describing this facet of human physiology.

Placental CRH stimulates the fetal HPA axis to increase fetal cortisol production.[86] However, in contrast to the hypothalamus, in which CRH production is inhibited by cortisol, placental CRH production is stimulated by glucocorticoids.[82,87] This cortisol-stimulated increase in placental CRH further stimulates fetal adrenal cortisol production, creating a "feed-forward" loop that may contribute to the onset of parturition and the maturation of the fetal adrenal cortex.[83,86] CRH has also been shown to stimulate DHEAS secretion, possibly increasing its availability for estrogen production.[88] In concert, increasing expression of placental 11βHSD2 late in gestation reduces the transmission of maternal cortisol to the fetus, releasing the fetal HPA axis from negative feedback, further stimulating increased production of fetal steroids and, in turn, estrogen and CRH production (Figure 181-7),[84] until the upward spiral ends in parturition.

FUNCTIONS OF THE FETAL ADRENAL CORTEX

The fetal adrenal cortex appears to partner with the placenta to maintain pregnancy and initiate parturition and to provide the late term cortisol surge necessary for maturation of organ systems in preparation for extrauterine life.

Maintenance of Pregnancy and Initiation of Parturition

As reviewed earlier, the fetal zone of the adrenal cortex secretes increasing amounts of DHEA and DHEAS through gestation, which serve as substrates for synthesis of placental estrogens. Estrogen appears critical to the maintenance of primate pregnancy. In humans, a 50% spontaneous abortion rate has been reported in women who have a mutation of the estrogen receptor gene,[89] and in baboons administration of an aromatase inhibitor to suppress placental estrogen production resulted in miscarriage in 50% of the pregnancies.[79] Although human pregnancies complicated by very low estrogen levels have resulted in term pregnancies, the authors of this study suggest that in such pregnancies estradiol is maintained in a low but bioactive range.[79]

In contrast to its actions in sheep, the increase in cortisol concentration at term does not initiate labor in the primate.[69,70] However, through its unique relationship with the placenta, the fetal adrenal cortex appears directly involved in the cascade of events leading to parturition. In the rhesus monkey, infusion of androstenedione increases placental estradiol synthesis and induces premature labor.[85,90] Conversely, when synthesis of estrogen from androstenedione is blocked by an aromatase

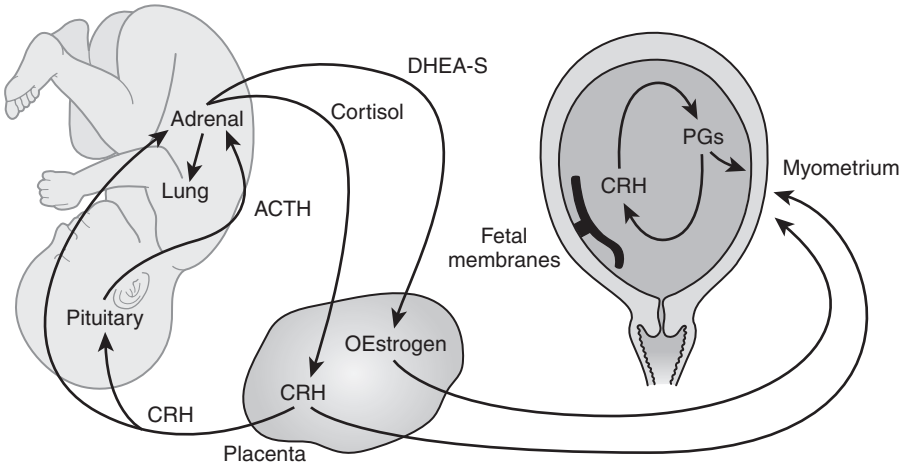

Figure 181-7 Interacting positive-feedback hormonal loops in the fetal, amniotic, and maternal compartments that may promote the progression of fetal maturation and initiation of parturition in humans. Each of the *arrows* represents a stimulatory action of the indicated hormone. *PGs,* Prostaglandins. *(From McLean M, Smith R: Corticotrophin-releasing hormone and human parturition,* Reproduction *121:496, 2001.)*

inhibitor, the androgen-induced preterm labor is prevented.[91] Interestingly in this model, peripheral infusion of estrogen to the dam increased myometrial activity but did not result in fetal membrane changes or preterm birth, implicating a paracrine function of placental estrogen in the initiation of parturition.[91] Cortisol may also participate in the initiation of labor indirectly by competing with progesterone for binding with placental glucocorticoid receptors. Progesterone binding of the glucocorticoid receptor inhibits placental CRH production; as fetal cortisol concentrations rise late in gestation, cortisol can displace progesterone from the glucocorticoid receptor, removing this inhibition.[92,93]

Maturation of Organs and Enzyme Systems

During most of gestation, low fetal cortisol concentrations permit necessary cellular growth and proliferation. Late in gestation, however, cortisol concentrations rise, promoting the cellular differentiation and organ maturation necessary to sustain independent existence[69] (see Figure 181-5). A large body of literature supports the role of cortisol in regulating numerous maturational processes, particularly lung structure and function, kidney function, glycogen accumulation and gluconeogenesis in the liver, triiodothyronine and catecholamine production, regression of lymphoid tissue in spleen and thymus, and increased β-adrenergic receptor density in numerous tissues.[69]

NEONATAL ADRENAL CORTICAL FUNCTION

The sudden loss of placental and maternal protection at birth requires that the newborn provide its own homeostasis, for which the hormones of the adrenal cortex are essential. Cortisol regulates protein, carbohydrate, lipid, and nucleic acid metabolism, maintains cardiac and vascular response to vasoconstrictors, regulates extracellular water and promotes free water excretion, suppresses the inflammatory response and decreases capillary permeability during inflammation, and modulates central nervous system processing and behavior.[94,95] Aldosterone regulates fluid and electrolyte homeostasis; deficiency produces hypovolemia, hyponatremia, and hyperkalemia.[96] In the absence of an enzyme deficiency that blocks glucocorticoid synthesis, the adrenal cortex of the newborn infant should be able to respond to ACTH stimulation with an appropriate rise in cortisol concentration. However, two circumstances may be exceptions to that statement: the first several days of transition to extrauterine life and prematurity.

Transition to Extrauterine Life

After the surge of cortisol normally engendered by parturition,[20] cortisol concentrations in well infants may fall to very low levels without apparent clinical compromise.[97] However, several small studies have suggested that in the first days of life, apparently normal term infants may be unable to respond to critical illness with production of sufficient cortisol to maintain cardiovascular stability, resulting in a relative adrenal insufficiency similar to that seen in other critically ill patients.[98-105] One preliminary report showed that critically ill term and near-term infants had low ACTH levels and low cortisol concentrations, but their cortisol response to exogenous ACTH stimulation was indistinguishable from that of well term infants.[106] These data suggest that the observed low cortisol concentrations may result from a lack of hypothalamic stimulation of the pituitary or a lack of pituitary response to CRH.

One possible reason for this finding of inadequate response to stress but adequate response to ACTH is the sudden withdrawal of the very high concentrations of CRH produced by the placenta at term. As reviewed earlier, CRH concentrations are low in nonpregnant individuals but reach very high concentrations in both maternal and fetal plasma before term or preterm delivery.[81,84] At birth, the major source of this CRH—the placenta—is removed, and maternal plasma concentrations again fall to undetectable levels within 24 hours.[80] A blunted ACTH response to CRH stimulation has been documented in women during the postpartum period.[107] It is not known whether the same phenomenon may exist in newborns, leading to a transient decrease in their ability to respond to stress.

Preterm Infants

From the review of fetal adrenal cortical development, it would seem reasonable to postulate that very preterm infants may not have sufficient functional adrenal capacity to respond to postnatal stress. In the undisturbed pregnancy, the transitional zone only begins to appear at 22 to 24 weeks gestation, and 3βHSD expression then increases gradually until term.[9] However, most preterm deliveries result from disordered pregnancy, which may alter adrenal development. For example, a large autopsy series

found that premature infants exposed to prenatal inflammation from chorioamnionitis had larger adrenal glands than those not exposed, suggesting an effect of inflammation on adrenal development.[108] Consistent with those findings, infants exposed to chorioamnionitis have elevated cortisol values early in life.[109]

In the baboon model, a significant percentage of extremely preterm neonates have decreased cortisol production early in life, with associated cardiovascular dysfunction that can be reversed by hydrocortisone supplementation.[110] In human infants, a developing literature has shown that although well preterm infants, similar to term infants, may have low serum cortisol values without apparent clinical compromise,[97] these infants also may not respond to critical illness with sufficient cortisol production. Sick preterm infants and those receiving vasopressor support for hypotension have lower cortisol concentrations than well infants, a reversal of the expected pattern of higher cortisol values with increasing illness.[111-114] Hydrocortisone treatment of infants with vasopressor-resistant hypotension results in amelioration of hypotension and weaning of vasopressor support.[115,116] Lower cortisol values have also been reported in sick preterm infants who died, compared to survivors.[117] Additionally, extremely preterm infants have elevated cortisol precursors, consistent with a limited enzymatic capacity to synthesize cortisol.[118-120] Several studies have linked lower cortisol values or decreased cortisol response to ACTH to the development of bronchopulmonary dysplasia, but others have not, likely due to differing populations and the multifactorial etiology of bronchopulmonary dysplasia.[113,121-126]

These data support the possibility of a developmental adrenal insufficiency in the extremely preterm infant with clinical consequences. The preponderance of these data might suggest a benefit to cortisol replacement in the extremely preterm infant; however, even low-dose hydrocortisone therapy in such infants was associated with a serious adverse effect: spontaneous gastrointestinal perforation.[127,128] Although this effect may have been due to an interaction with concurrent indomethacin or ibuprofen therapy, it emphasizes the need for caution in approaching the treatment of infants who, were they still in utero, would be exposed to a much lower level of cortisol. It is clear that extrauterine existence requires the extremely preterm infant to respond to significant stress and that both adrenal insufficiency and glucocorticoid excess are detrimental to homeostasis and neurologic development[94,95]; however, neither the most appropriate measures of adrenal function nor the most beneficial supportive therapies for preterm infants have been elucidated.

Fetal and Neonatal Thyroid Physiology

EMBRYOGENESIS AND HISTOLOGIC DEVELOPMENT OF THE THYROID GLAND

The human *thyroid gland* is a derivative of the primitive buccopharyngeal cavity.[1-3] It develops from contributions of two types of anlagen: a midline thickening of the pharyngeal floor (median anlage) and paired caudal extensions of the fourth pharyngobranchial pouch (lateral anlagen). All these structures are discernible by day 16 to 17 of gestation; by 24 days gestation, the median anlage has developed a thin, flasklike diverticulum, extending from the floor of the buccal cavity down to the fourth branchial arch. At 40 days gestation, the median and lateral anlagen have fused, and, by 50 days gestation, the buccal stalk has ruptured. During this period, the thyroid gland migrates caudally to its definitive location in the anterior neck, helped in part by its relationship with developing cardiac structures.

The early histologic development of the thyroid gland has been divided into three phases: (1) precolloid (7 to 13 weeks gestation), (2) early colloid (13 to 14 weeks gestation), and (3) follicular (>14 weeks gestation) phases.[4] In the precolloid phase, the thyroid cells contain an intracellular canaliculus derived from

the smooth endoplasmic reticulum. As these canaliculi mature, they migrate toward the cell apex and begin to discharge their contents extracellularly. In the early follicular stage, these canaliculi fuse, and desmosomes define the borders of these spaces, thus allowing for the central accumulation of colloid. At this time (approximately 70 days gestation), iodide concentration and thyroglobulin synthesis can be demonstrated within the gland. During the final follicular phase, a further increase in the size of the colloid spaces occurs, as well as progressive cell growth and accumulation of thyroid hormones.

The *parathyroid glands* develop between 5 and 12 weeks gestation from the third and fourth pharyngeal pouches. The third pouches encounter the migrating thyroid anlage, and the parathyroid anlagen are carried caudally with the thyroid gland. They finally come to lie at the lower poles of the thyroid lobes as the inferior parathyroid glands. The fourth pouches encounter the thyroid anlage later and come to rest at the upper poles of the thyroid lobes as the superior parathyroid glands. The individual parathyroid glands increase in size from less than 0.1 mm diameter at 14 weeks to 1 to 2 mm at birth. The fifth pouches contribute paired ultimobranchial bodies that become incorporated into the developing thyroid gland as the parafollicular C cells, the calcitonin-secreting cells.[5,6]

Hypothalamic maturation proceeds from the fifth week through 30 to 35 weeks gestation.[2] Most of the hypothalamic nuclei and fibers of the supraoptic tract are visible histologically by 12 to 14 weeks. Thyrotropin-releasing hormone (TRH) is detectable in hypothalamic tissue by 10 to 12 weeks. Between 10 and 35 weeks, continuing histologic maturation of the hypothalamus takes place.

The anterior *pituitary gland* is a derivative of the primitive buccal cavity (Rathke pouch), and its embryologic development parallels that of the thyroid anlagen.[2] By the fifth week in the human embryo, the Rathke pouch makes contact with a funnel-shaped ventral diverticulum of the third cerebral ventricle, the infundibular process. By 12 weeks, the buccal connection is obliterated by the developing sphenoid bone, and the pituitary gland becomes partially encapsulated within a bony cavity, the sella turcica. Between 9 and 12 weeks, many pituitary cell types appear, each more or less specialized for secretion of one of the anterior pituitary hormones. Secretory granules can be identified within these cells at 10 to 12 weeks, and thyrotropin (TSH) is identifiable by bioassay and immunoassay at this time.

Abnormalities of hypothalamic or pituitary gland embryogenesis can be associated with TSH deficiency and secondary hypothyroidism. Developmental abnormalities of the thyroid gland usually represent defects in early morphogenesis resulting from aberrant thyroid tissue migration. The most common anomaly is the persistence of the thyroglossal duct. This is not usually associated with altered thyroid status in the newborn, but it may present in later life as an infected fistulous tract. Abnormalities of thyroid embryogenesis (thyroid dysgenesis) include agenesis or ectopic tissue in sublingual, cervical, mediastinal, or even intracardiac locations. Failure of fusion of median and lateral anlagen may produce cystic masses of cells in various locations in the neck. Although ectopic thyroid tissue may manifest some function, infants with these anomalies usually exhibit some degree of hypothyroidism. Calcitonin deficiency also is present in children with congenital hypothyroidism.[7] Hypoparathyroidism, however, is not associated with thyroid dysgenesis, although the parathyroid glands may be ectopic.

THYROID HORMONE SYNTHESIS

Circulating plasma iodide enters the thyroid follicular cells and is combined with tyrosine through a series of enzymatically mediated reactions to form the active thyroid hormones 3,5,3′-triiodothyronine (T_3) and thyroxine (T_4). The steps in synthesis and release of thyroid hormones include the following:

1. Active transport of inorganic iodide from plasma to thyroid cell.
2. Synthesis of tyrosine-rich thyroglobulin, which acts as the intermediate iodine acceptor.
3. Organification of trapped iodide as iodotyrosines.
4. Coupling of monoiodotyrosines (MIT) and diiodotyrosines (DIT) to form the iodothyronines, T_3 and T_4, with storage of iodotyrosines and iodothyronines in follicular colloid.
5. Endocytosis and proteolysis of colloid thyroglobulin to release MIT, DIT, T_3, and T_4.
6. Deiodination of released iodotyrosines within the thyroid cell with reuse of the iodine. These steps and their inhibitors are outlined in Table 182-1 and are pictorially represented in Figure 182-1.

Iodide Concentration

The first and rate-limiting step in the synthesis of thyroid hormones involves the concentration of iodide by the thyroid follicular cell. The thyroid iodide transporter is located in the follicular cell plasma membrane.[8,9] Extrathyroidal tissues (gastric mucosa, salivary gland, mammary gland, choroid plexus, placenta, and skin) also concentrate iodide but are not able to organify iodide. Iodide transport requires energy and is inhibited by dinitrophenol or ouabain, implying requirements for oxidative metabolism and phosphorylation. Iodide transport is linked to sodium (Na^+) transport and to Na^+, potassium–adenosine triphosphatase (Na^+,K^+-ATPase) activity, but the actual mechanism of transport remains uncertain. In basal conditions, the thyroid-serum ratio of iodide is 30 to 40:1. This ratio reaches several hundred-fold in circumstances of iodine deficiency and TSH stimulation.

Thyroglobulin Synthesis and Iodide Organification

Thyroglobulin contains the tyrosyl residues that provide the substrate for organification of iodide.[10,11] It is a large glycoprotein (molecular weight 660,000 daltons, sedimentation coefficient of 19 S) with two subunits, each of which is composed of several peptide chains. Thyroglobulin is the predominant protein in thyroid colloid, and approximately 3% of the thyroglobulin protein is composed of tyrosine residues. Iodination of these tyrosyl residues requires an activated, reactive iodine molecule. This is provided via a thyroid peroxidase enzyme complex that produces hydrogen peroxide as the oxidizing agent. The iodination occurs at the cell-colloid interface and is linked to the process of exocytosis of thyroglobulin. These processes of oxidation, iodination, and exocytosis are rapid; half the intracellular iodide is incorporated into thyroglobulin colloid within 2 minutes after the iodide

is trapped by the follicular cell.[10,11] Thyroid peroxidase also is involved in the coupling of MIT and DIT to form T_3 and T_4. The peroxidase enzyme complex is inhibited by the antithyroid drugs propylthiouracil and methimazole. A defect in the iodide trapping process, a defect in thyroglobulin synthesis, or a defect in the peroxidase enzyme complex can produce hypothyroidism.

Coupling of Iodotyrosines

Although it is not known whether T_4 formation in vivo involves predominantly intramolecular or intermolecular coupling of MIT and DIT residues, the coupling process itself has been well characterized. As indicated earlier, thyroid peroxidase also catalyzes the coupling of MIT and DIT residues, although nonenzymatic coupling is theoretically possible. The relative proportions of T_3 and T_4 formed depend on the influence of several factors, including TSH and iodine availability, which modulate the relative proportions of MIT and DIT. Under basal conditions, in the absence of iodine deficiency or excessive TSH stimulation, 70% of the total thyroglobulin iodoprotein is in the form of iodotyrosines, with the remainder as iodothyronines in a T_4 to T_3 ratio of 10 to 20:1.[10,11] Hypophysectomy and iodine deficiency are known to impair the efficiency of coupling, probably by decreasing the efficiency of thyroglobulin iodination. The thioureylene drugs (propylthiouracil, methimazole, carbimazole), through their action as thyroid peroxidase inhibitors, act to decrease both iodination and iodotyrosine coupling in the thyroid. Propylthiouracil also inhibits the peripheral metabolism of thyroid hormones. It is not clear whether specific defects in the coupling process lead to clinical disease. Most of the patients for whom coupling defects have been proposed are either iodine deficient or have organification defects that lead to inefficient coupling.

Thyroglobulin Proteolysis and Thyroid Hormone Secretion

Thyroglobulin, stored in colloid after iodination at the apical thyrocyte cell membrane, must reenter the cell and undergo proteolysis to release the bound and stored thyroid hormones.[10,11] This process, which is modulated to a great degree by TSH, involves endocytosis of colloid as phagosomes, fusion of phagosomes with lysosomes to form phagolysosomes, and subsequent proteolysis. Hydrolyzed free MIT, DIT, T_3, and T_4 are then released from the lysosomes into the follicular cell cytoplasm from which T_3 and T_4 can diffuse into thyroidal capillary blood. The follicular cell also contains an outer (phenolic) ring iodothyronine deiodinase that converts T_4 to T_3. Activity of this deiodinase is under TSH control such that the amounts of secreted T_3 and T_4 in relation to the ratio of T_3 to T_4 stored in thyroglobulin increase during TSH stimulation. Thyroid-stimulating antibodies may mimic these effects of TSH and contribute to the increased levels of T_3 secretion seen in patients with Graves' disease.

Microtubular function is necessary for proper transport of vesicles within the follicular cell.[11] Thus colchicine and cytochalasin B have inhibitory effects on the secretion of thyroid hormones. High doses of iodide also inhibit the release of thyroid hormones, at least in part via endocytosis and colloid resorption; in addition, an inhibiting effect on lysosomal protease activity may exist.

Evidence is ample to indicate that exposure of neonates to relatively high concentrations of iodide or organic iodine-containing compounds can produce transient hypothyroidism.

Iodotyrosine Deiodination and Recycling of Intrathyroidal Iodide

Although proteolytic cleavage of thyroglobulin results in the liberation of free iodotyrosines, as well as iodothyronines, only small amounts of MIT and DIT leave the follicular cell.[11] Thyroid follicular cells contain an iodotyrosine deiodinase, which catalyzes the rapid deiodination of MIT or DIT. This enzyme is inhibited by dinitrotyrosine. The iodide generated from deiodination of iodotyrosines is principally reused for iodination of thyroglobulin, although some diffuses from the thyrocyte (the so-called *iodide leak*).

Ontogenesis of Thyroid Hormone Receptors

The principal actions of thyroid hormones in target tissues are regulated principally through interaction with specific nuclear receptors functioning as transcription factors, both stimulating and inhibiting target gene expression.[12] Generally, the receptors show a much higher affinity for T_3 as a ligand than T_4. Four principal thyroid hormone receptors (TRs) have been identified and characterized: TR alpha 1 and 2, as well as TR beta 1 and 2. However, many more transcripts that bind T_3 as a ligand have been demonstrated, some of which also bind DNA. In humans, the gene encoding the alpha subtype has been mapped to chromosome 17 and that for the beta subtype to chromosome 3. Alternative splicing gives rise to the multiple subtypes. The interaction of these subtypes is complex. Several of the alpha variants indeed do not bind T_3 (TR alpha 2, as well as TRv alpha 2 and 3); these may act in a negative fashion to inhibit the binding of other TRs to their respective DNA sites. The TRs generally exist as monomers, homodimers, or heterodimers, typically associated with other nuclear proteins such as the retinoid-X receptors.[12]

As might be expected, the various TRs are differentially expressed in a wide variety of tissues, as well as being developmentally regulated. TR beta 1 expression is abundant in liver and kidney with some messenger RNA expression in a wide variety of other tissues. TR beta 2 expression is highest in pituitary tissue. The TR alpha variants are generally widely distributed.[13,14]

The maturation of TRs typically follows the pattern of thyroid hormone effects during development. Expression in pituitary, brain, and bone occurs before expression in liver and brown adipose tissue. The expression of the alpha family typically precedes that of the beta subtypes. This has been shown in rodent, ovine, and human species. Generally, brain and pituitary tissues exhibit the earliest expression of alpha 1 and 2 activity followed later by messenger RNA and protein products in liver, kidney, and brown adipose tissue.[14,15]

FETOPLACENTOMATERNAL THYROID INTERACTION

The relative independence of the maternal and fetal hypothalamic-pituitary thyroid hormone systems is suggested by several clinical observations. The placenta is impermeable to TSH and is largely impermeable to the thyroid hormones. These data are summarized in Table 182-2.[16] Direct evidence of placental transfer of thyroid hormones is provided by studies using various thyroid hormone analogues and tracers, as well as observations under various maternal and fetal conditions. Interspecies differences are important in the interpretation of these data. Prenatal and postnatal maturation varies widely between precocial and altricial species. Placental types differ among the most common species used for perinatal thyroid studies: rodents, sheep, and humans, each species having varying numbers of tissue layers separating maternal and fetal circulations, as well as differing degrees of monodeiodinase activities. Human studies have shown limited transfer from mother to fetus in the euthyroid state. Large doses of T_4 given to women produced only minor changes in cord serum concentrations of hormonal iodine.[17] Supraphysiologic doses of T_3 administered on a long-term basis to pregnant women several weeks before delivery significantly increased maternal serum T_3 levels but only minimally lowered fetal T_4 values.[18,19] Studies in rats have shown low but significant levels of thyroid hormones in fetal tissues before the time of fetal thyroid hormone production.[20,21] These observations have been elegantly reconfirmed in a transgenic rodent model.[22] However, maternally derived T_4 may have implications during pathologic states such as severe fetal hypothyroidism. For example, infants with certain iodide organification defects incapable of synthesizing thyroid hormones still have demonstrable albeit quite low levels of T_4 immediately after birth.[23] In areas of endemic cretinism resulting from low environmental iodide levels, a relationship between maternal thyroid function and subsequent fetal thyroid function can be shown.[24] The early ability of decreased fetal T_4 to markedly increase brain type 2 monodeiodinase levels,[25] as well as the timing and type of brain thyroid hormone receptors on ultimate tissue thyroid-dependent effects, have also been noted.[26,27] These complex and interrelated relationships likely underlie the relative neurodevelopmental sparing of athyrotic neonates. In addition, the inability to consistently diagnose congenital hypothyroidism on a clinical basis in the immediate neonatal period may reflect a maternal contribution to fetal thyroid system homeostasis in the hypothyroid state.

The thioureylene antithyroid drugs cross the placenta and may compromise fetal and neonatal thyroid function.[28,29] The placenta also is permeable to selected synthetic thyroid hormone analogues such as 3′,5′-dimethyl,5-isopropyl thyronine. No rationale currently exists for use of these analogues, however, because of their low biologic activity. Finally, the placenta is permeable to the hypothalamic peptide TRH. Both primate and human fetuses early in the third trimester respond to pharmacologic doses of exogenous TRH with an increase in serum TSH.[30,31] Little endogenous TRH is normally detected in adult humans, because of the presence of TRH-degrading enzyme systems in the blood. Although the sera of pregnant women contain somewhat lower levels of these enzymes than do nonpregnant sera, the nearly immeasurable levels of TRH in the maternal circulation have little effect on fetal thyroid function.[28]

The unique fetal environment, by contrast, includes many extrahypothalamic sources of TRH. Fetal gut tissues, particularly pancreas, produce TRH, and this pancreatic TRH has been isolated and found to be identical to hypothalamic TRH. In newborn rat pups, pancreatectomy, but not encephalectomy, is associated with reduced circulating TRH levels.[32] The placenta also

produces an immunoreactive TRH, which appears to be identical to hypothalamic pyroGlu-His-ProNH_2.[33] Other forms of TRH that have TSH-releasing activity have been reported in the placenta.[34] These substances presumably derive from alternative cleavage of the prepro-TRH molecule. The high circulating level of TRH in the fetus results from increased production in extrahypothalamic tissues and from low or absent levels of TRH-degrading activity in fetal blood.[35,36] Human cord values of TRH are also elevated.[37] Administration of anti-TRH antibodies to neonatal rats does not alter serum TSH levels, a finding suggesting that TRH is not required for TSH secretion at this early stage of thyroid development.[38] The significance of TRH in human cord blood is not clear.

In addition to TRH, the placenta produces substances with TSH-like activity. The α-subunit of TSH is identical to that of human chorionic gonadotropin (hCG), and the β-subunit of hCG has structural homology with the β-subunit of TSH; thus, hCG has some TSH-like bioactivity.[39,40] The biologic potency of hCG, however, is only approximately 0.01% that of TSH, and hCG normally has little influence on fetal thyroid system development or function. The large increase in maternal serum hCG activity that occurs early in pregnancy may account for the slight, transient suppression of maternal TSH levels seen early in the first trimester.[39,40]

Placental permeability to maternal molecules may be a factor affecting fetal thyroid function as a result of maternal pathophysiologic states (acute iodide administration, autoimmune thyroid disease, pharmacotherapy of thyrotoxicosis). The fetal pituitary-thyroid axis, however, normally develops independently of maternal thyroid axis influence. The placenta and selected fetal tissues may serve as a source of TRH, but the extent of this influence on fetal thyroid function is uncertain. The demonstrated maternal-fetal transfer of thyroid hormones may be important for fetal development, particularly brain growth and differentiation, in circumstances of fetal hypothyroidism.

CONTROL OF THYROID HORMONE PRODUCTION

The pattern of human perinatal thyroid hormone secretion is shown in Figure 182-2. Maturation of thyroid system control can be considered in three phases: hypothalamic, pituitary, and thyroidal. Changes in these systems are complex and are superimposed on the increasing production and increasing serum concentration of serum thyroid hormone–binding globulin (TBG), as well as the changing pattern of fetal tissue iodothyronine deiodination during gestation. Maturation of these latter systems is described in the next section.

Although the fetal thyroid gland is able to concentrate iodide and to synthesize thyroglobulin at 70 to 80 days gestation, little thyroid hormone synthesis occurs until approximately 18 weeks gestation. At this time, thyroid follicular cell iodine uptake increases, and T_4 becomes measurable in the serum. Both total and free T_4 concentrations then increase steadily until the final weeks of pregnancy.[41,42] This pattern differs from the pattern of development of serum T_3 levels in the fetus. The fetal serum T_3 concentration is low (<15 ng/dL) until 30 weeks and then increases slowly in two distinct phases: a prenatal and a postnatal phase. Before birth, serum T_3 increases slowly after 30 weeks gestation to reach a level of approximately 50 ng/dL in term cord serum.[41-44] After birth, both T_3 and T_4 serum concentrations increase four-fold to six-fold within the first few hours of life, and they peak 24 to 36 hours after birth. These levels then gradually decline to adult values over the first 4 to 5 weeks of life. The prenatal increase in serum T_3 seems to be largely the result of progressive maturation of hepatic type I (phenolic) outer ring iodothyronine deiodinase activity and increasing hepatic conversion of T_4 to T_3, although other tissue sources of deiodinase such as brown fat and kidney may be involved.[44]

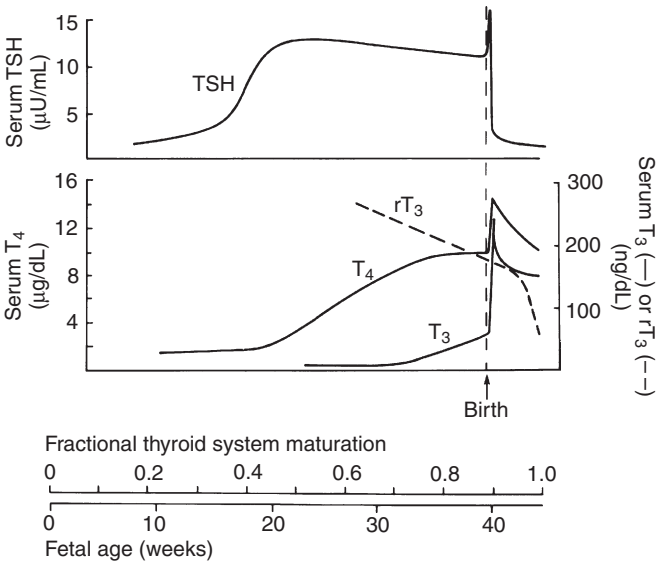

Figure 182-2 Patterns of circulating levels of thyroid-stimulating hormone *(TSH),* reverse triiodothyronine *(rT_3),* thyroxine *(T_4),* and triiodothyronine *(T_3)* in the human fetus.

Fetal serum TSH increases rapidly from a low level at 18 weeks to a peak value at 24 to 28 weeks gestation, and then it gradually declines until term.[41,42] At the time of parturition, partly in response to cold stress, an acute release of TSH (the TSH surge) occurs, resulting in an elevated level by 30 minutes of life.[45] The level of circulating TSH remains modestly elevated for 2 to 3 days after birth. The increases in thyroid hormone that occur immediately after birth are not totally dependent on TSH and may represent other influences on the thyroid gland at the time of parturition. The high postnatal T_3 level in the days after birth results from TSH stimulation of thyroidal T_3 secretion, as well as further rapid maturation of tissue outer-ring monodeiodinase activity in the neonatal period.[46,47]

Progressive increases in fetal serum T_4, free T_4, and TSH take place during the latter half of gestation, with an increasing free T_4–TSH ratio.[42,43,48] The pituitary gland contains a type II outer-ring iodothyronine deiodinase that converts T_4 to T_3, which, in turn, binds to the nuclear T_3 receptor to modulate TSH production. In most circumstances, it is circulating T_4 that is most important in TSH control. Thus, even when the circulating T_3 level is low (as in midgestation), negative feedback control (by T_4) of pituitary TSH secretion may be significant. The progressive increase in the free T_4–TSH ratio in the late-gestation fetus, however, results more from the increase in free T_4 than from a decrease in TSH; a progressive maturation of thyroidal response to TSH has been shown in fetal sheep and seems likely in the human fetus.[43,48] An additional cause of the progressive increase in the free T_4-TSH ratio with a minimal change in TSH is a progressive increase in feedback sensitivity of the pituitary to thyroid hormone inhibition of TSH production. The mechanism for this is not yet clear. Changes in pituitary thyrotroph T_3 or TRH receptors, a decrease in thyrotroph outer-ring iodothyronine deiodinase activity, or decreasing T_3 receptor action on TSH biosynthesis may be involved.

The ontogeny of TRH secretion and function in the fetus remains somewhat obscure. TRH immunoactivity is detectable in the hypothalamus by midgestation, and it increases markedly in the third trimester after the peak in serum TSH activity is noted. The premature infant (<30 to 32 weeks gestation) is characterized by low levels of T_4 and free T_4, a normal or low level of TSH, and a normal or prolonged TSH response to TRH, indicating a

state of physiologic TRH deficiency.[49,50] The term human fetus responds to pharmacologic maternal doses of TRH with a somewhat prolonged increase in TSH, a finding suggesting a degree of relative hypothalamic (tertiary) hypothyroidism.[31] Peripheral sources of TRH (placenta and pancreas) probably contribute to the elevated circulating levels of fetal and cord blood TRH and presumably account for the high circulating TSH level characteristic of the midgestation fetus. This TRH may be responsible for the high fetal serum TSH level before the increase in hypothalamic TRH concentration. The significance of ectopic TRH to the development of thyroid system control, however, remains to be investigated.

The control of fetal thyroid hormone secretion can be characterized as a balance among increasing hypothalamic TRH secretion, increasing thyroid follicular cell sensitivity to TSH, and increasing pituitary sensitivity to thyroid hormone inhibition of TSH release.[42,47,50] The fetus progresses from a state of both primary (thyroidal) and tertiary (hypothalamic) hypothyroidism in midgestation through a state of mild tertiary hypothyroidism during the final weeks of pregnancy and to fully mature thyroid function in the perinatal period.

FETAL THYROID HORMONE METABOLISM

The thyroid gland is the sole source of T_4, whereas most of the T_3 that circulates in the adult is derived from conversion of T_4 to T_3 via monodeiodination in peripheral tissues.[16,51,52] Deiodination of the iodothyronines is the major route of metabolism, and monodeiodination may occur either at the outer (phenolic) ring or the inner (tyrosyl) ring of the iodothyronine molecule. Outer-ring monodeiodination of T_4 produces T_3, the active form of thyroid hormone with greatest affinity for the nuclear receptor. Inner-ring monodeiodination of T_4 produces rT_3, an inactive metabolite. In mature humans, 70% to 90% of circulating T_3 is derived from peripheral conversion of T_4, and 10% to 30% results from direct glandular secretion. Nearly all the circulating rT_3 derives from peripheral conversion, with only 2% to 3% coming directly from the thyroid gland. T_3 and rT_3 are progressively metabolized to diiodinated, monoiodinated, and noniodinated forms of thyronine, none of which possesses biologic activity.

Two types of outer-ring iodothyronine monodeiodinase (5′-MDI) have been described. Type I 5′-MDI, predominantly expressed in liver and kidney, is a high-dissociation constant (K_m) enzyme, inhibited by propylthiouracil, and its activity is stimulated by thyroid hormone. Type II 5′-MDI, predominantly located in brain, pituitary, and brown adipose tissues, is a low-K_m enzyme insensitive to propylthiouracil, and its activity is inhibited by thyroid hormone.[51] Type I 5′-MDI activity in liver and perhaps kidney and muscle probably accounts for most of the circulating T_3. Type II 5′-MDI acts primarily to increase local intracellular levels of T_3 in the brain and pituitary and is important to brown adipose tissue function during the immediate postnatal period. The outer-ring iodothyronine deiodinase also deiodinates reverse T_3 to diiodothyronine.

Both type I and type II 5′-MDI are present in third-trimester fetuses.[25,52-54] In sheep, a species in which thyroid hormone system maturation closely resembles that in humans, hepatic type I 5′-MDI activity increases three-fold to four-fold, and brain type II 5′-MDI activity increases approximately 50% over the last third of gestation.[52] Both deiodinase enzymes are thyroid hormone responsive. Hepatic type I 5′-MDI activity, however, becomes thyroid hormone responsive (e.g., activity decreases with hypothyroidism) only during the final weeks of gestation. Brain type II activity, in contrast, is responsive (activity increases with hypothyroidism) throughout the final third of gestation.[25,55] Thus type II deiodinase probably plays an important role to provide a source of intracellular T_3 to those tissues (e.g., pituitary and, in some species, brown fat and brain) dependent on T_3 during fetal life, whereas the ontogeny of the type I enzyme (to provide increased serum T_3 levels) increases only during the final weeks of gestation and during postnatal life.[32]

TABLE 182-3

Average Iodothyronine Production Rates in Fetal Sheep

rT_3, Reverse triiodothyronine; *rT_3S,* reverse T_3 sulfate; *T_3,* triiodothyronine; *T_4,* thyroxine; *T_3S,* T_3 sulfate; *T_4S,* T_4 sulfate.

An inner (tyrosyl)-ring iodothyronine monodeiodinase (type III 5′-MDI) has been characterized in most fetal tissues, including the placenta.[31,52] This enzyme system catalyzes the conversion of T_4 to rT_3 and T_3 to diiodothyronine. The maturation of these enzyme systems has been studied primarily in the rodent and sheep. Fetal thyroid hormone metabolism is characterized by a predominance of type III enzyme activity, particularly in liver, kidney, and placenta, and this accounts in part for the increased circulating levels of rT_3 observed in the fetus.[51-53] Placental type III deiodinase contributes to amniotic fluid rT_3 levels and presumably also contributes to circulating fetal rT_3.[16] The persistence of high circulating rT_3 levels for several postnatal weeks in the newborn, however, indicates that type III 5′-MDI activities expressed in nonplacental tissues importantly contribute to the maintenance of high circulating rT_3 levels.[16]

Studies have shown high concentrations of sulfated iodothyronine analogues in human and ovine fetal serum.[56-60] These include T_4 sulfate (T_4S), reverse T_3 sulfate (rT_3S), T_3 sulfate (T_3S), and T_2 sulfate (T_2S). Average production rates, calculated as the product of basal hormone concentrations and clearances, are shown in Table 182-3. The sulfate conjugates and rT_3 have low affinity for the nuclear T_3 receptors and minimal biologic activity.[61] Thus the production of inactive thyroid hormone analogues in the fetus (rT_3,T_4S, rT_3S = 29 μg/kg per day) greatly exceeds the production of active T_3 (2 μg/kg per day). Clearly, most of the T_4 in the fetus is metabolized to inactive metabolites via the type I and type III iodothyronine monodeiodinase and sulfotransferase enzyme systems in fetal tissues. Evidence is suggestive that T_3S can be metabolized in vivo to T_3.[62] T_3S production is quite limited, however, and the combined average production rate for T_3 and T_3S (4 μg/kg per day) in the fetal sheep is low. It appears from these data that peripheral thyroid hormone metabolism in the sheep fetus, in contrast to the adult, is shunted to inactivation, rather than to the production of active hormone.

The alanine side chain of the inner ring of the iodothyronines also may undergo decarboxylation or transamination.[63] Although the acetic acid derivatives of T_4 have some biologic activity in vitro, their rapid degradation in vivo precludes much physiologic significance. Pyruvate and lactate derivatives also have been isolated, both with minimal biologic activity. Thyroid hormones also are excreted as both free and glucuronide or sulfuronide conjugates in urine and stool; some of these forms can undergo hydrolysis and enterohepatic recirculation. In general, gut excretion accounts for less than 15% of the total amount of metabolized T_3 or T_4 after birth.

Both T_3 and T_4 in blood are associated with various plasma proteins, including TBG, T_4-binding prealbumin (TBPA), and albumin.[63] TBG serves as the primary transport protein for both T_3 and T_4; approximately 70% of the total T_4 and 40% to 60% of total T_3 are bound to TBG. The remaining thyroid hormones are distributed about equally between TBPA and albumin. The binding affinities of these proteins are such that adult free T_4 and T_3 concentrations are approximately 0.03% and 0.3% of the total hormone concentrations. TBG, TBPA, and albumin are produced by the liver, and production of these proteins increases progressively during the final half of gestation. Hepatic TBG production is stimulated by estrogen, and the increasing levels of estrogens during pregnancy account, at least in part, for the T_4 concentration, which increases progressively from midgestation until 34 to 35 weeks gestation.[16,43] The free T_4 level, however, also increases, because of progressively increasing T_4 production.[43,47] The T_3 concentration also increases, from a barely detectable level before 30 weeks gestation to 50 ng/dL in the term fetus, and the free T_3 concentration probably increases in parallel.

Fetal thyroid hormone metabolism is largely oriented to production of inactive metabolites via production of sulfate conjugates and predominant T_4 inner-ring monodeiodination to rT_3. The type 2 deiodinase activity in fetal brain and brown adipose tissues serves to protect these tissues in the event of fetal T_4 deficiency.

Thyroid System Effects and Adaptation to Extrauterine Life

In general, much of the fetal thyroid development is preparatory, providing for the relatively large amounts of thyroid hormones required for normal postnatal development. The production of active thyroid hormones is markedly increased in association with the events of parturition (see Figure 182-2). During the first hours after birth, an abrupt three-fold to six-fold increase occurs in circulating T_4 and T_3 levels, coincident with an increase in serum TSH concentration.[42] The initial increases in circulating thyroid hormone levels largely result from increased hormone secretion from the thyroid gland.[45,46] The TSH surge (which is likely a response to the thermal stimuli coincident with birth), however, can be obtunded in the neonatal sheep by warm bath immersion without complete inhibition of the increments in T_3 or T_4.[3] A postnatal increase in serum catecholamine concentrations also occurs at the time of parturition,[64] and the thyroid gland is adrenergically innervated. Stimulation of thyroidal adrenergic receptors may augment TSH-induced changes in the T_4-T_3 ratio of secreted thyroid hormones. Because TBG concentrations remain relatively constant throughout the newborn period, free T_4 and T_3 levels rise abruptly after birth in association with increases in hormone production rates. The cold-stimulated TSH surge is short-lived, and the decrease in TSH that follows during the 72 to 96 hours after birth results from feedback inhibition by T_4 at either the hypothalamic or the pituitary level (or both).[42,47] The serum TRH concentration is elevated in cord blood and falls in the days after birth. A clear increase in the serum TRH value coincident with the increase in TSH after parturition has not been reported, but the parallel increases in both TSH and prolactin levels in the early hours after birth support the view that the TSH surge is mediated by TRH.[42,47] Thyroid hormone levels in the newborn gradually return to adult levels by approximately 1 month of age. The high level of circulating rT_3 characteristic of the fetus persists after birth and gradually declines to the adult range by 4 to 6 weeks of age.[54]

The metabolic significance of the neonatal thyroid hormone surge is not entirely clear. Physiologic processes known to be modulated by thyroid hormone in adults, such as thermogenesis and cardiovascular responses, clearly are important in the transition from intrauterine to extrauterine life, and it is tempting to link these with the changes in thyroid hormone metabolism that occur during transition. Several studies have attempted to establish such a link. Brown adipose tissue is the major site for newborn thermogenesis.[65] Hypothyroidism induced during the final weeks of gestation is associated with impaired brown adipose tissue thermogenesis, largely because of the effects of T_4 on brown adipose tissue iodothyronine monodeiodinase activity and mitochondrial uncoupling protein (thermogenin).[66] Obtundation of the postnatal T_3 surge (by acute thyroidectomy in newborn sheep), however, does not accentuate transient neonatal hypothermia, a finding indicating that the prenatal T_4 level is more important in neonatal thermogenesis than is the early postnatal T_3 surge.[46]

A similar relationship between thyroid system function and neonatal cardiovascular adaptation has been described in neonatal sheep; normal fetal thyroid function in the final weeks of gestation is required for the increases in myocardial performance associated with the transition to extrauterine life. Obtundation of the acute increase in serum T_3 at birth, however, does not alter neonatal cardiovascular adaptation.[67] These observations support the view that, in the sheep, the level of thyroid function during the final weeks of gestation is more important than the neonatal increases in T_3 and T_4 for successful neonatal transition. The situation in the human neonate may be somewhat different. Neonates with congenital thyroid agenesis have few, if any, signs or symptoms of thyroid hormone deficiency, and their postnatal environmental adaptation usually is not impaired.[42,68] The fetal sheep is relatively more mature at birth, presumably accounting for this difference. The precise timing of maturation of thyroid hormone effects on thermogenesis and cardiovascular function in the human neonate has not been defined. It is clear that most (95%) infants with congenital hypothyroidism at birth have few manifestations of thyroid hormone deficiency and develop normally when replacement therapy is begun in the neonatal period. Serum TSH levels are elevated, and a 3- to 6-week delay in bone maturation may occur.[42] The posterior fontanelle may be relatively large, and the physiologic hyperbilirubinemia of the newborn may be more marked and prolonged. Growth is not impaired, however, and other metabolic alterations usually are not evident.

The ontogenesis of various thyroid actions has been characterized in rodents. These include tissue thermogenesis, carcass and muscle growth, skeletal maturation, skin and brain maturation, and hormone and growth factor production and action. Some of these effects represent thyroid hormone actions on specific gene products, mediated via thyroid hormone receptor control of gene transcription.[52,69] Other thyroid hormone actions represent complex events, the mechanisms of which are not yet understood, such as the effects on growth, skeletal maturation, and brain development.

The thyroid hormone dependency of these growth and metabolic events in rodents is manifest in the postnatal period, in general during the second and third postnatal weeks. Nuclear thyroid hormone receptors appear in most rodent tissues during the last week in utero and the first postnatal week.[70] Thus there is a discrepancy between the timing of appearance of selected thyroid hormone actions and the appearance of thyroid nuclear receptors, and it is possible that at least some of the variation in timing of appearance of thyroid hormone actions in the rodent relates to maturation of events beyond the step of T_3 binding to the nuclear receptors. Other thyroid hormone receptors have been identified, including mitochondrial and plasma membrane receptors, but the significance of these is not yet clear.[69] Most of the effects described previously are thought to be mediated via the nuclear receptors.

A similar delay in appearance of selected thyroid hormone actions has been observed in developing sheep.[52,69] The sheep, like the human and in contrast to the rodent, is a precocious

species and is relatively mature at birth. In fetal sheep, effects of thyroid hormones on various parameters of brain development appear as early as 0.5 to 0.6 of fractional thyroid system development. Thyroid effects on skin maturation and growth also appear relatively early in gestation, whereas effects on heart, lung, kidney, and liver are delayed until the final few weeks before birth. In the sheep, as in the rodent, the appearance of selected thyroid hormone actions late in gestation, such as the effects on hepatic malic enzyme activity and hepatic epidermal growth factor receptor concentrations, is not accounted for by the appearance of thyroid hormone nuclear receptors; hepatic receptors are present by 0.5 (on the fractional thyroid system maturation scale) of gestation.[52] The effect of thyroid hormone on lung β-adrenergic receptor binding also occurs well after the appearance of thyroid hormone nuclear receptors in the lung.[71] Thus the timing of maturation of thyroid hormone actions is variable in both rodent and sheep species and relates to the ontogenesis of nuclear thyroid hormone receptors, as well as to maturation of postnuclear mechanisms.

In humans, thyroid nuclear receptors have been reported in fetal lung, brain, heart, and liver at 13 to 19 weeks gestation.[15,72] The only thyroid hormone actions that have been characterized in the fetus are the effects of hypothyroidism on serum TSH and bone maturation. Most effects of thyroid hormone on perinatal developmental processes occur after birth (Figure 182-3).

Thyroid hormones affect important developmental processes, including growth, thermogenesis, and development. The largely successful transition of athyrotic infants to extrauterine life reflects the limited importance of fetal thyroid hormones in all but the final weeks of gestation. An exception to this may be the fetal brain, a major site of type II iodothyronine monodeiodinase activity in the fetus. The presence of this enzyme system in the brain early in development and its demonstrated response to fetal hypothyroidism in the rat and sheep suggest that intracellular conversion of T_4 to T_3 in the brain is important in these species for normal development and differentiation of the central nervous system. The critical period for this effect in the sheep is the last trimester of gestation; in the rat, the critical period is the first 3 postnatal weeks. Precise data are not available for the human fetus, but early treatment of congenital hypothyroidism in the neonate prevents subsequent mental retardation, a finding suggesting that the period of thyroid dependency of the human brain extends into the postnatal period. Early and adequate postnatal thyroid hormone replacement in athyrotic infants also normalizes growth and development.

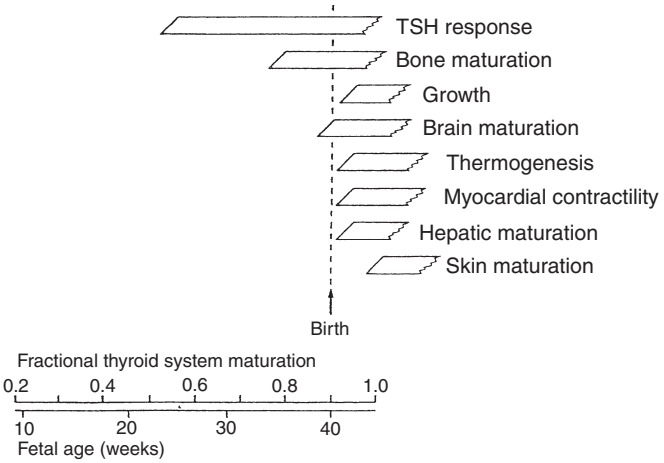

Figure 182-3 Onset of actions of thyroid hormone in the developing human. The *left edge of the bar* indicates the initiation of thyroid hormone responsiveness of the indicated parameter. *TSH,* Thyroid-stimulating hormone.

Low-T_3 Syndrome in Premature Infants

In the preterm infant, changes in thyroid function parameters during neonatal adaptation are qualitatively similar to those in term infants but are quantitatively obtunded.[42,43] The neonatal TSH surge and the neonatal T_4 and T_3 peak responses decrease with decreasing gestational age, and the transient low-T_3 state that follows probably is related to the state of relative undernutrition in the neonatal period.[42] Premature infants have an increased susceptibility to neonatal morbidity, including birth trauma, acidosis, hypoxia, hypoglycemia, hypocalcemia, and infection, all superimposed on feeding disorders and relative malnutrition. All these factors tend to inhibit conversion of T_4 to T_3 in the neonatal period and aggravate the extent of the low-T_3 state characteristic of prematurity.[42,73-75] Serum T_3 values may remain low in these infants for 1 to 2 months.

Features of the *low-T_3 syndrome* in premature infants include a low serum T_3 concentration resulting from a decreased rate of conversion of T_4 to T_3, variable but usually elevated serum rT_3 levels, and normal or low total serum T_4 concentrations.[42,43] Free T_4 levels usually are in the range of values for healthy premature infants of matched gestational age and weight. TSH values are low in these infants. Preterm infants presenting with low or borderline-low thyroid hormone levels and elevated TSH values should be carefully evaluated for hypothyroidism, including assays of thyroid-blocking immunoglobulins. A trial of T_4 replacement therapy may be warranted in these infants.

Concerns remain regarding ultimate cognitive function in preterm infants with low thyroid hormone values. Early (first week of life) low T_4 levels have been associated with neurologic dysfunction at 5 years of life and poor school performance at 9 years of age.[76] This finding has prompted several studies examining the effect of T_4 supplementation in very preterm infants. Randomized, placebo-controlled T_4 replacement in preterm infants less than 30 weeks gestation resulted in improved neurologic function in very preterm infants (25 to 26 weeks gestation) but worsened cognition and behavioral development in infants born after 29 weeks gestation.[77] Review of thyroid hormone augmentation for preterm infants fails to demonstrate improved neurodevelopmental outcome in treated infants.[78] Moreover, results from various antenatal TRH exposure trials (preterm fetuses exposed to maternal TRH treatment in an attempt to improve subsequent postnatal lung function) also suggest that early alterations in thyroid system function may be associated with deleterious intellectual outcomes.[79,80] Thus the use of thyroid hormones in nonhypothyroid preterm infants should be restricted to those infants enrolled in approved studies.

SECTION XXV

Ovary and Testis

183

Stan R. Blecher and Robert P. Erickson

Genetics of Sex Determination and Differentiation

The classical paradigm of mammalian, including human, sexual development postulates an initially "indifferent" (sexually undifferentiated) state that is transformed, in two major stages, into the sexually dimorphic male and female forms. The two stages are called *primary,* relating to the gonad, and *secondary,* referring to all other genital organs.[1]

In the first stage, *primary sex determination,* specific sex determining genetic factors, present from conception, drive the development of the gonad. The primordial, indifferent gonad is situated in the gonadal ridge region of the intermediate mesoderm of the fetus. In genetic males, the indifferent gonad is induced to become a testis, under the influence of (a) male-determining gene(s). In the female, with no such genes present, the gonad remains uninduced and an ovary develops. Mesenchymal cells of the gonadal (genital) ridge and the neighboring metanephros give rise, in males, to androgen-producing Leydig cells of the testis or, in females to the theca cells of the ovary and to connective tissue. The adjacent celomic epithelium grows into the mesodermal mass to produce the Sertoli cells of the testicular seminiferous tubules, or the follicle cells of the ovary. In addition, primordial germ cells migrate to the developing gonad to give rise to sperm or egg cells.

In the second stage,[2] *secondary sexual differentiation,* all other features of sexual dimorphism are established. In this concept, all features of both internal and external sexually dimorphic structures other than the gonads develop from the action of hormones produced in males by the testis, lack of these hormones (or production of other hormones) in females, and independently of the sex-determining gene(s).[1] This paradigm is known as the Jost Principle.

Although current understanding builds on this framework, our knowledge has advanced considerably in recent years, leading to some modifications of the original paradigm. It is now known that "genetic maleness" in mammals is normally dependent on the presence of a sex- determining region of the Y chromosome and "genetic femaleness" on its absence. The identity of the testis-determining gene on the Y chromosome is known, as is the fact that the effect of this gene in formation of the testis is not direct, but rather is mediated by other, so-called downstream genes. Some of the latter have been identified. Also, the action of the Y-chromosomal region is preceded by "upstream" gene action that is evidently prerequisite for the Y-chromosomal function in gonadal determination. Furthermore, some sex specific, including Y chromosomal (male-specific) gene action itself, appears to influence sexual phenotype, either before gonadal development (i.e., at a "pregonadal" juncture) or later, but independently of hormonal action. Finally, we now better understand the development of the ovary as being not merely a passive, uninduced state, but also dependent on specific gene action. These findings necessitate modification of the Jost paradigm.

A large number of genetic pathways interact in a complex and, in part, overlapping and redundant manner, to execute the genetic control of sexual development. In this chapter, we describe this dynamic, sequential program as occurring in four stages. These are: sex-chromosomal assignment of sex, established at conception; pregonadal sexual development and sexual dimorphism; gonadal development; and secondary sexual differentiation.

Y-CHROMOSOMAL SEX DETERMINATION

Sex-Determining Role of the Mammalian Y Chromosome

In 1923 it was demonstrated cytologically that humans have X and Y chromosomes.[3] By analogy with *Drosophila,* it was assumed that sex determination in mammals would be mediated by the ratio of the number of X chromosomes to the number of sets of autosomes (i.e., chromosomes other than the sex chromosomes). However, in 1959, it was discovered that an XO sex chromosome karyotype (i.e., absence of the Y chromosome) produced a basically female phenotype both in humans (Turner syndrome)[4] and mice,[5] and XXY produced predominant maleness in humans (Klinefelter syndrome).[6,7] These observations demonstrated that the presence of a Y chromosome, independent of the number of X chromosomes, resulted in the development of a predominantly male phenotype, and the absence of the Y chromosome resulted in the development of a predominantly female phenotype. Thus the Y chromosome appeared to possess a gene or genes the presence or absence of which determined the destiny of the bipotential gonad as a testis or ovary, respectively, and, through this, the development of the dimorphic secondary sex characteristics.[1] In the human, the hypothetical Y-chromosomal gene was named *TDF* (testis-determining factor), and in mice *Tdy* (testis-determining gene on the Y). (In accordance with standard convention, gene symbols are italicized; gene product symbols are not. Because of a high degree of homology [genetic equivalence] between mouse [and other mammals] and human and of accessibility to experimentation especially in mice, modern human genetic research relies extensively on murine studies, from which much can be extrapolated to humans. Human genes are indicated by uppercase letters whereas their mouse homologues are in lower-case, except that for dominant genes the first letter is capitalized.) The minor deviations of Klinefelter and Turner syndromes from normal male and female phenotype, respectively, are probably due to the influence of other (non-*TDF*) sex-chromosomal factors (see later section) on the sex differentiation pathway.

Early Y-Chromosomal Candidate Sequences: H-Y antigen, *Bkm* Sequences, and *Zfy*

Many candidate genes for *TDF* have been studied, taking into account biochemical differences between males and females and the evolutionary conservation that would be expected in genes involved in sex determination. It was proposed that the

highly conserved, male-specific molecule, H-Y antigen (originally identified in skin transplantation experiments), was the product of *TDF*.[8] For more than 10 years this proposal was considered valid. However, the findings of phenotypically male XX*Sxr* male mice that did not express H-Y[9] and of XY humans of female phenotype who were H-Y positive,[10] excluded this hypothesis. Another candidate for *TDF* was the repetitive sequence *Bkm* ("Banded krait minor") originally isolated from the snake *Bungarus fasciatus*[11] and which, in some vertebrates, was found only in the sex chromosomes. This hypothesis was rejected because in the human these sequences are dispersed in the genome and are not concentrated in the sex specific region of the Y chromosome.[12]

The discovery that 46,XX males usually have translocations (transfers of chromosomal material) of Yp (where p indicates the short arm of a chromosome and q the long arm) to one of their Xps was a major breakthrough in mapping *TDF* on the Y chromosome.[13,14] The X and Y chromosomes have homologous (genetically equivalent) segments at the ends of their respective p arms, and these segments pair at meiosis. Because of genetic exchange between these segments, genes located in this region produce phenotypes that appear to be neither X- nor Y-linked (i.e., appear to be inherited as if on autosomes). Accordingly, these regions are called *pseudoautosomal.* The occurrence of abnormal crossovers adjacent to the pseudoautosomal region can result in the illegitimate transfer of *TDF* to the X chromosome.[15,16] Molecular analyses in such patients permitted the construction of a deletion map of the Y chromosome[17,18] and showed that a small region of Yp adjacent to the pseudoautosomal region is essential for testicular differentiation. Finer mapping continued, and one candidate gene was mistakenly identified: Page and colleagues[19] found a highly conserved sequence that seemed to map with a male-determining Y fragment and named it *ZFY*. However, one of their XX males did not have *ZFY*, and the finding of more such patients[20,21] suggested that *ZFY* could not be *TDF*.

The *SRY* Gene

The resumed search for *TDF* was targeted on 35 kilobases (kb) of DNA between the proximal (i.e., toward the centromere of the chromosome) limit of the pseudoautosomal region of the Y chromosome and the breakpoint in XX males lacking *ZFY*. A subclone selected for its male specificity in mammals was found to encode a protein containing an 80-amino-acid segment that was homologous to the mating-type protein in *Schizosaccharomyces pombe* and to a conserved 80-amino-acid, DNA-binding motif present in the HMG1 (High Mobility Group 1) transcription-regulating proteins.[22] Further analyses of a variety of tissues disclosed a transcript of this gene, only in the testes. It was proposed that this gene, designated *SRY* (sex-determining region, Y chromosome), was *TDF*.[22] Soon thereafter, mutations in the *SRY* were found in some cases of XY, pure gonadal dysgenesis.[23–26] The mouse *Sry* gene was cloned at the same time as *SRY*.[27] Much information on human *SRY* has been obtained indirectly from studies on mouse *Sry*. In the following, these symbols are used specifically for their respective species, or *SRY/Sry* is used for situations applying to both.

Some mice transgenic (i.e., in which a gene has been artificially transferred) for a fragment containing *Sry* showed 40,XX sex-reversal—that is, mice otherwise destined to be female had a male appearance (although they were sterile).[28] Testes of these mice were histologically similar to those of human XX males. However, sex reversal did not always occur. This incomplete penetrance may be related to the influence of genetic background on *Sry* transgene expression.[29] Genetic modifiers may also be the explanation for the multiple phenotypes seen with particular mutations in *SRY*. Interestingly, the human gene *SRY* does not cause sex reversal in transgenic mice; it is not nearly as conserved in function as some human genes, a few of which can work even in *Drosophila*. The HMG boxes of *SRY* and its mouse homologue, *Sry*, are examples of so-called generalized HMG boxes.[30] It has been demonstrated that the SRY HMG box binds to synthetic DNA fragments of the sequence AACAAAG,[31] but also to cruciform DNA structures irrespective of their sequence. Both targets adopt similar conformations in solution, in which state binding of SRY induces a large conformational change in the DNA. Some mutations in the SRY HMG box alter the DNA contact sites in such a way as to preclude the usual deformation of the DNA.[32,33]

The principle evidence in favor of *SRY/Sry* being *TDF/Tdy* is the following:

1. It is localized in the smallest region of chromosome Y capable of inducing testicular differentiation in humans[22] and mice.[27]
2. Some cases of XY, pure gonadal dysgenesis present de novo mutations in the *SRY* gene.[23–26]
3. In the mouse, *Sry* expression correlates with the initiation of testicular determination in the gonadal ridge[34] and, in both mouse and man, its expression in the blastocyst corresponds to the more rapid growth of the Y-bearing blastocyst (see later discussion).[35–38]
4. A fragment of DNA that includes the mouse gene is able to induce male-type development in some transgenic XX mice.[28]
5. It is an evolutionarily conserved gene on the Y chromosome of metatherian and eutherian mammals.[22,39]

PREGONADAL SEXUAL DEVELOPMENT AND SEXUAL DIMORPHISM

In humans, although the sex chromosome complement, and therewith the sex-determining genes, are established at fertilization, it is not until about 42 days that differentiation of the indifferent gonads into testes in the male or, slightly later, their development into ovaries in the female, can be detected. However, very early male and female embryos, and possibly even zygotes, do differ phenotypically. In a previous edition of this book, we argued that differential gene expression at pregonadal stages influences or sets the scene for subsequent gonadal sex determination and differentiation and that this warrants the inclusion of a Pregonadal Stage in the sequence of sexual developmental events. Sex differences that are evident in early developmental stages, but for which the detailed genetic basis is not yet determined, include the time of occurrence of the first cleavage division, the rate of early embryonic cell division, the rate of accumulation of proteins, and differences in external genitalia. Now evidence exists that pregonadal expression of genes upstream to *Sry* influence the sex determining pathway. Some of these upstream genes are autosomal although, as discussed later, pregonadal Y-chromosomal gene expression, including expression of *Sry* itself, also occurs.

Phenotypic Pregonadal Sexual Dimorphism for Which Specific Genes Have not yet Been Identified

First Cleavage Division of the Zygote

In studying in vitro fertilized and cultured bovine embryos, Yadav and colleagues[40] found that early cleaving embryos were significantly more likely to be male than female. This sexual dimorphism suggests the possibility that differential expression of Y or X-linked genes is present in the zygote shortly after fertilization.

Rates of Cell Division in Early Embryos

Scott and Holson[41] reported that male rat fetuses are larger than female and have higher protein content at 12.5 days postcoitus. Preimplantation XY mouse embryos have been reported to be

more advanced than XX[42] as have cattle embryos.[43,44] Thornhill and Burgoyne[45] argued that the paternal X has a retarding effect on postimplantation mouse embryos. However, Burgoyne[46] found an accelerating effect of the Y chromosome on preimplantation mouse embryos, although the trait appeared to be polymorphic. Peippo and Bredbacka[47] found that in day 3 *in vivo* mouse embryos, females were more advanced; during a subsequent 24-hour *in vitro* culture period the increase in cell number was greater in male embryos. These authors proposed that previous results suggesting increased rates of cell division in male embryos might be an artifact of in vitro culture. Ursula Mittwoch has long maintained[48] that fast growth rate actually leads to testis formation and slow rate to ovary formation.

Pregonadal, Genetically Determined Development of Male External Genitalia

An important brick in the structure of our current understanding of pregonadal expression of sex-determining genes emerged from studies on some marsupials, such as the tammar wallaby. In these animals some features of sexual dimorphism, including the scrotum in the male and the mammary glands in the female, appear before development of the gonads and independently of hormones.[49] Although these organs develop mainly under hormonal influence in true (eutherian) mammals, evolutionary conservation of some pregonadal sex-determining gene expression has been shown to occur in mice. The XX*Sxr* pseudomale mouse is a chromosomal female (XX) that is masculinized by transposition of *Sry* and neighboring genes to an X, but which lacks the rest of the Y chromosome. The anogenital space, the size of which is a measure of masculinization (and which is also the region in which the scrotum develops) is smaller in prepubertal and adult pseudomales than in their normal, XY brothers.[50] Interestingly, XX*SXr* pseudomale mice, in which testosterone levels are as high as or higher than in normal males, have abnormal epididymides that lack the important initial segment,[51] and the abnormality is present before the pubertal androgen surge.[52] However, XO*Sxr* mice, with equivalent levels of testosterone, have normal epididymides. According to the Jost Principle, epididymal development should be solely dependent on androgens, but these data suggest an effect of a noninactivated X-chromosomal gene, independent of hormonal action, on this secondary sex organ.[51,52]

These examples in tammar wallabies and mice illustrate the existence of secondary sexually dimorphic gene expression patterns in pre- or postgonadal embryos that are independent of gonadal hormonal action, contrary to the Jost Principle. Some candidate genes that could account for such pregonadal gene activity[53] and a possible model molecular mechanism[54] is discussed later.

Genes Known to be Transcribed Pregonadally

Early Transcription of Zfy and SRY

Transcripts of *Sry* and *Zfy* are present in the mouse embryo at the blastocyst stage,[35] and, in the human embryo, *SRY* and *ZFY* have been found to be transcribed at the one cell stage—the earliest genes yet found to be transcribed in the human embryo.[36,37] These data suggest that *SRY/Sry* could be involved in the initiation of the genetic cascade that leads to sex determination.[55]

Expression of H-Y Antigen by Early Embryos

As mentioned earlier, evidence for the existence of (a) male-specific molecule(s), subsequently named H-Y, originally emerged from skin transplantation experiments in inbred mice. One epitope of human H-Y, called *SMCY*, has been cloned.[56] A serologically detectable counterpart of H-Y, now called SMA (serologically detected male antigen) has been extensively used as a method of exploring genetic sex. Studies on early embryos have shown that H-Y antigen is detectable as early as at the eight-cell stage in mice.[57] Although the genetics of sex-specific antigens is far from clear, this finding further underscores the fact that sex-specific gene expression commences at an early stage in embryogenesis.

Genes Functioning Upstream of SRY/Sry

For the orderly function of the sex-determining gene *SRY/Sry*, normal operation of two other sets of genes must first occur. These two sets are those genes controlling the establishment of the cells and tissues that are precursors of the gonads and those genes that directly influence *SRY/Sry*.

Genes That Act on Precursor Cells and Tissues

Several genes of this type are known. Some of these are expressed at early developmental stages, and others are expressed in the gonadal ridge shortly before the activation of *SRY/Sry* that immediately precedes gonadal differentiation.

Of genes that function at early stages of development, members of the *Lhx* family may be near the "top" of the cascade. *Lhx* refers to the LIM homeobox gene family, which contains transcription factors.[58] Genetic "knockout" (KO) (experimental inactivation) of the mouse gene *Lhx1*, which has a role in gastrulation, causes absence of kidneys and gonads.[59] KOs of *Lhx-9* also fail to form gonads because somatic cells of the genital ridge fail to proliferate. *Fgf-8* and *Wnt-4* are upstream of *Lhx-1*,[60,61] and *Lhx-9* and *Wt-1* both activate *Sf-1*[62] (see next section). Mice with KO of *Emx-2* lack kidneys, ureters, gonads, and genital tracts.[63]

Gene action in the gonadal ridge before sex-specific gonadal differentiation includes steroidogenic factor-1 (*SF-1/Sf-1*), which is homologous to the *Drosophila* gene Fushi tarazu 1 (*Ftz-F1*). A key regulator of steroidogenic enzymes in adrenocortical cells,[64] it is expressed in the urogenital ridge at embryonic day 9 to 9.5 in the mouse. This is before the time of expression of *Sry*[65]; this result was confirmed in humans.[66] KO of *Sf-1* resulted in mice that died 8 days after birth.[67,68] The knockout mice lacked adrenal glands and gonads and had a resulting deficiency in corticosterone that was the likely cause of death.

Erickson and colleagues[69] predicted that human mutations in *SF-1* would lead to "a phenotype associated with predominantly female appearance and severe neonatal problems due to lack of steroid hormones." Such a patient was reported in 1999: A 46,XY female with adrenal failure at two weeks of life was found to have a heterozygous, adjacent two-base pair mutation.[70] Three other such patients have now been described. The region of 9q33 to which *SF-1* maps[71] has not yet been associated with cytogenetic abnormalities and problems of sexual differentiation. Evidence has accrued that SF-1 may have a role in co-stimulation of the Müllerian-inhibiting substance (MIS) promotor.[72,73]

Other genes that are expressed in mouse gonadal ridge at day 9.5, before *Sry* and before sexual determination becomes evident, may have a role in preparing the gonad for sexual differentiation. These include *Dmrt-1* and *-2* and *Wt-1*. *DMRT-1* and *DMRT-2*, mammalian homologues of a gene shared between *C. elegans* and *Drosophila*, map to distal 9p (toward the tip of the chromosome arm).[74,75] It has long been known that deletions at distal 9p are frequently associated with 46,XY sex reversal. *Dmtr-1* is expressed in the mouse genital ridge at day 9.5.[76] Expression is initially equal in genital ridges of both sexes but gradually it becomes limited to expression in the 40,XY gonad. The avian homologue of *DMRT-1* is also expressed in the genital ridge and Wolffian duct (a precursor of internal sex organs) before sexual differentiation in the avian embryo; the same is not true of the *SRY* homologue.[76] Thus, as might be expected for a gene with homology to a *C. elegans* and *Drosophila* gene involved in sex determination, *DMRT-1* may have a more conserved role in sexual determination in vertebrates than does *SRY*. The association between the Wilms tumor 1 (*WT-1*) gene and testis development was recognized from investigations into the Denys-Drash and the WAGR syndromes. In Denys-Drash syndrome, caused by point

mutations of the *WT-1* gene, complex nephropathy and sexual ambiguity is present. Male (XY) patients with Denys-Drash syndrome may have female or ambiguous external genitalia with dysgenic gonads. WAGR syndrome, caused by deletions of chromosomal band 11p13, consists of Wilms tumor, aniridia, genitourinary anomalies, and mental retardation. Patients with the WAGR syndrome may have undescended testes and hypospadias, both of which are abnormalities of secondary sexual development. The occurrence of deletions suggested the presence in this region of a tumor suppressor related to Wilms tumor.[77] It has been proposed that the *WT-1* gene is involved in mesenchymal-epithelial interactions[78]—for example, between Sertoli cells and Leydig cells in the testis. Such interactions are crucial not only in the developing gonad but also the kidney. *WT-1* has at least 24 different isoforms (different forms of the gene) simultaneously present in individuals, which arise through alternative splicing of the messenger RNA of the gene. Of these many isoforms, particular interest has focussed around two that are highly conserved in evolution[79] and that are due to alternative splice donor sites at the end of exon 9 of the gene. The two isoforms respectively either possess, or lack, the three amino acids K (lysine), T (threonine) and S (serine). Children with Frasier syndrome, a variant of Denys-Drash, who frequently show partial or complete XY sex-reversal, mostly have a mutation in the splice site that creates the KTS insertion and thus a deficiency in the +KTS isoform.[80] Homozygous mice lacking the *Wt-1* +KTS isoforms also show a complete XY sex reversal due to a dramatic reduction of *Sry* expression.[81] Some conflicting data exist, however; thus, although interactions between *Sry* and *Wt-1* in the developing mouse gonad are clearly important, their relative roles in control of sexual determination are not yet clear.

Genes That Directly Influence *SRY/Sry*

Two known mutants in mice suggest the possibility that chromatin changes could be the initial stage in sex determination. One possible mechanism for this might be "release" of *SRY* from an autoinhibition that this gene may normally undergo through a receptor on the gene to which the gene's own product can bind. The gene *M33* is the mouse homologue of the *Drosophila* gene *Polycomb*, which regulates chromatin structure. KO of *M33* caused failure of growth of the primordial gonad at the normal time of *Sry* expression, suggesting that *M33* maybe upstream of *Sry*. The mutants show hermaphroditism with intersex genitalia or complete male-to-female sex reversal.[82] In addition, the gene for the syndrome ATR-X (*a*lpha-*t*halassemia [sometimes], mental *r*etardation, mapping to the *X*), which also shows sexual ambiguity,[83] interacts with heterochromatin proteins and modifies DNA. The Wt-l +KTS isoform could possibly also be involved in alterations of chromatin structure.

Fibroblast growth factor 9 (*Fgf-9*) may be an important mediator of *SRY* action.[84] The *Fgf-9* KO shows deficient mesonephric cell migration into the gonad, deficient mesenchymal proliferation, decreased Sertoli cell function, and frequent sex reversal. Male to female sex-reversal, with reduced expression of *Sry* (and *Sox-9*; discussed later) is found in triple KO of three insulin receptor genes.[85] Gonadal anlages were small, supporting the notion of a relation of gonadal cellular proliferation and *Sry* expression.

GONADAL DEVELOPMENT

The data on transcription of *SRY* in human and mouse blastocysts, discussed earlier, suggest the possibility that earlier events have set in motion biochemical pathways related to the visible event of gonadal ridge differentiation. Furthermore, for normal female sex-determination to occur and the primitive gonad to differentiate to an ovary, homozygosity of at least one X-chromosomal locus appears to be essential. Relatively little is known about genetic control of ovarian development. A possible candidate gene for a role is *DSS*[86] (discussed later).

The components of the human bipotential gonadal primordium were described in the introduction to this chapter. Migration of the primordial germ cells is completed in the sixth week of gestation, when the embryonic female or male gonads are indistinguishable. Absence of primordial germ cells is not compatible with ovarian differentiation but does not prevent testicular seminiferous tubule morphogenesis.[87] Evidence suggests that the initial stages of gonadal differentiation are realized in the supporting cells (pre-Sertoli or prefollicular),[88] but cell to cell interactions are critical for the function of *SRY* and, in general, for gonadal differentiation.[89] In the next section, we discuss the development of the testis and review recent data on genes involved in ovarian differentiation.

Development of the Testis: Genes Acting Downstream of *SRY/Sry*

Although *SRY/Sry* appears to be the Y-chromosomal sex-determining *switch*, recent work has made clear that it is not the ultimate, masculinizing gene of the sex determination pathway. A strong candidate for the latter is *SOX-9/Sox-9*. Because no evidence for a role of *SRY/Sry* in *SOX-9/Sox-9* expression has emerged, current thinking is that the masculinizing gene is inhibited by a hypothetical "gene *Z*,"[90] and that testicular induction occurs when gene *Z* is itself suppressed by *SRY/Sry*. In the following paragraphs, we develop this concept and consider candidates for gene *Z* and possible modifying factors of it.

That *SRY/Sry* is not the ultimate masculinizing gene is suggested by the following evidence. First, it is not essential in all mammals; the males of several species of voles[91] and spinous country rats[92] develop appropriately without it. Second, investigations into the XX true hermaphrodites frequently seen among South African Bantus have also not detected Y chromosomal sequences.[93] Thus mammalian male sex determination can certainly occur in the absence of *SRY*, and, in normal human development, several genes downstream of *SRY* are involved.

It has been proposed that the HMG domain of the gene product SRY binds to regulatory DNA sequences of the hypothetical negative regulator of male sex determination, gene *Z*.[90] Interaction of SRY with the *Z* gene is postulated to inhibit the regulatory effect of *Z,* resulting in a male phenotype. One possible inhibitor of male development, and target for *SRY*, is *SOX3*,[94] a member of the *SOX* gene family, to be described below. *Sox-3* is more abundantly expressed in female than in male genital ridges.[95]

Gene *Z* was postulated to be located on Xp21.[90] A number of 46, XY individuals with sex reversal have partial duplications of Xp and an intact *SRY* gene. They usually have female external and internal genitalia with partial gonadal dysgenesis.[86] Bernstein and colleagues[96] presented two cases and concluded that "testis-determining genes of the Y chromosome may be suppressed by regulatory elements of the X." The X-homologue of *ZFY*, *ZFX*, which escapes inactivation, may be one candidate.[97] XXY (Klinefelter syndrome) individuals do develop testes but they are not normal, and these patients do have partially feminized phenotypes. Furthermore, some XXY triploids have shown sexual ambiguity;[98] lack of X-inactivation in the triploids may be the cause.[99] Bardoni and colleagues[86] hypothesized a single gene in the Xp region of interest, and named it *DSS* (*d*osage *s*ensitive *s*ex reversal). This region includes *DAX-1* (*d*osage sensitive sex reversal, *a*drenal hypoplasia congenita gene on the *X* chromosome gene *1*), gene defects of which cause adrenal hypoplasia.[100,101] *DAX-1* is a candidate for *DSS*. Capel and colleages[102] have argued that an increased dosage of *DAX-1* would override the *SRY* signal for testis development. Indeed, *DAX-1* is normally down-regulated in the developing testis, whereas its expression persists in the developing ovary.[103] Overexpression in *Dax-1* transgenics delays testicular development and

can result in sex reversal in the presence of a weak-functioning (hypomorphic) *Sry*.[104] Another gene involved in dosage-dependent 46,XY sex reversal is *WNT-4*, which maps to distal 1p, duplications of which sometimes cause male pseudohermaphroditism.[105] The *Wnt-4* KO does not affect male sexual development but the females are masculinized.[106] Interestingly, overexpression of *WNT-4* (in transfection—i.e., transgenic—experiments with cultured Sertoli and Leydig cells) appears to result in up-regulation of *DAX-1*, linking these two dosage-dependent, female sexual development program-enhancing pathways.[107]

Genes that are functionally downstream of *Sry* in gonadal development, and possible mediators of its action, include nexin 1 and *Fgf-9*, involved in cell proliferation and migration. KO of the latter can lead to decreased function of Sertoli cells and sex reversal. Desert hedgehog (*DHH*) is expressed in Sertoli cells and is required for spermatogenesis.

A family of genes with homology greater than 60% to the HMG box of *SRY* was discovered, and designated *SOX* (*SRY* box-related) genes.[108,109] These genes are evolutionarily very conserved. The relationship between *SRY* and the *SOX* genes has aroused great interest from the point of view of the origin and evolution of *SRY* in mammals.[110] *SOX3* and *SOX-9* have been mentioned previously in this chapter, the former as a possible inhibitor of masculinization and target of *SRY*. *SOX-9/Sox-9* is a candidate for the ultimate masculinizing gene. This is supported by some evidence. In camptomelic dysplasia, due to haploinsufficiency of *SOX9*, partial sex reversal of XY individuals may occur.[111] Increased dosage of *SOX9*, due to a chromosomal duplication, strongly masculinized an XX fetus.[112] In mice, *Sox9* transgenics develop a normal male appearance in the absence of *Sry*,[113] and 40,XX, *Sry*− mice (i.e., genetic females) carrying the deletion *Odsex* (which maps about 1 million base pairs upstream of *Sox9*) up-regulate *Sox9* expression in fetal gonads and develop as phenotypic males.[114] *Sox-9* is only expressed in Sertoli cell precursors.[115] Prostaglandin D2 signaling, induced by *Sry*, may recruit Sertoli cells to express *Sox-9*.[116] Controlled KO of *Sox-9* in the gonadal anlage results in complete XY sex reversal.[117] *SOX8* is also expressed in the developing testis and may function redundantly with *SOX-9*.[118] Inhibition of nuclear export of SOX-9 that had been transfected into granulosa precursor cells of XX mouse gonadal anlage induced AMH production, a sex reversal phenotype (see later section).[119] Nuclear localization of this molecule normally occurs only in the male gonad.[120,121]

It has been shown that the HMG box of SRY recognizes the promoter elements of the gene for MIS (discussed in a later section), but this binding is insufficient to regulate transcription in in vitro systems. It also binds to the promoter of aromatase P450.[122] Thus SRY could contribute, with SOX-9, to transcription of these target genes. Because no evidence for a role of *SRY* in *SOX-9* expression has come to light, *SRY* is postulated to be the deinhibitor of a yet to be identified inhibitor of *SOX-9* in mammals. MIS is a presumptive target of *SOX-9* regulation in these species.[123] The relationships of *SOX-9/Sox-9* and MIS may be different in *SRY*-negative male mammals and in nonmammalian species. Co-stimulators, with SOX9, of MIS may include SF-1, WT-1, and other gene products. MIS and testosterone, both of which are produced in the testis, appear at this time to be the major, downstream masculinizers in the sex differentiation pathway. Other genes that are downstream of *SOX-9* include vanin 1.[124] However, no downstream target of *SOX-9* that has a specific function in testicular development has been identified.

Development of the Ovary

As indicated in the introduction for this chapter, the idea that the ovary arises solely as an outcome of an "uninduced state" is being replaced, as new data emerge that elucidate the existence of genes specifically involved in ovarian differentiation. As noted earlier, overexpression of *WNT-4* (in transfection experiments with cultured Sertoli and Leydig cells) causes up-regulation of *DAX-1*, thus suggesting a correlation between these two genes such that each, in various circumstances, appear to promote ovarian development. Lack of *Wnt-4* gives rise to masculinization of the XX gonad, though a recent study has shown that *Wnt-4* also has a specific but different role in male gonadal development.[125] Nef and colleagues[53] used microarrays to compare gene expression patterns of XX and XY Sf-1 positive gonadal cells and found that cyclin-dependent kinase inhibitors were overexpressed in XX gonads, a finding that could relate to the known difference in proliferation rates of XX and XY gonads, discussed in an earlier section. Jorgensen and Gao[126] demonstrated a six-fold ovary-specific enhancement of *Irx-3* (Iroquois homeobox gene family member 3) at days 12 to 13.5 of murine development. This finding was independent of the presence of germ cells.

The female to male sex reversal seen in polled (hornless) goats (Polled Intersex Syndrome [PIS]) has long been the subject of much interest, partly because the reversal trait occurs only in animals homozygous for the mutation (i.e., is inherited as an autosomal recessive), whereas the trait of absence of horns behaves as an autosomal dominant. Recent research reviewed by Baron and colleagues[127] has revealed some fascinating insights and brought to light the existence of another gene involved in ovarian development in mammals, including humans.

The polled mutation in goats turns out to be a ~12 kb deletion from a *cis*-regulating region, at band q43 on goat chromosome number 1, that controls the expression of three contiguous genes.[54] One of these three, *FOXL-2*, which is highly conserved in vertebrates, appears to be an ovary-determining gene. Another of the three—*PISRT-1* (*PIS*-related *t*ranscript, gene *1*)—is a regulatory element necessary for *FOXL-2* expression in the ovary. In XY males, *SRY* evidently blocks *PISRT-1* and thus prevents gonadal expression of *FOXL-2* (and hence ovarian induction). However, *PISRT-1* evidently also inhibits *SOX-9*, thus suppressing testis formation, as proposed for the hypothetical gene *Z*, discussed in a previous section. Fetal gonads of the Polled goat (i.e., animals carrying the *PIS* deletion) show complete repression of both *FOXL-2*, the ovarian inducer, and *PISTR-1*, the suppressor of testis inducing *SOX-9*,[54] thus accounting for the observed sex-reversal phenotype.

The genetics of the polled trait itself illuminates another intriguing feature of sexual development: the independence from hormonal influence of a feature of secondary sexual maturity. In wild-type fetuses the PIS cis-regulating element suppresses the expression of the three adjacent genes in skin surrounding the future horn buds. The function of at least one of these is evidently to limit horn growth.[54] Other examples, in the XX*Sxr* pseudomale mouse and in the tammar Wallaby, of such exceptions to the Jost Principle were given in an earlier section. The polled situation in which the PIS cis-regulating element controls the expression of adjacent genes[54] might be a model to account for those other Jost principle exceptions.[49–51]

In humans, band q23 on chromosome 3 is homologous to the *FOXL-2/PISRT-1* region (q43) of caprine chromosome 1. FOXL-2 protein has been detected in the nuclei of human fetal granulosa cells, but not in fetal or adult testes. Loss of function mutations in *FOXL-2* in humans can be responsible for a syndrome of eyelid dysmorphism and ovarian dysgenesis that causes primary amenorrhea in 46,XX women.[128]

The mutual interrelationships of the different genes recently shown to be involved in ovarian development remain to be elucidated, but it is clear that clarification of this central piece of the sex determination paradigm is imminent.

SECONDARY SEXUAL DIFFERENTIATION

The classical paradigm of sexual development introduced at the beginning of the chapter was formulated in principle by Alfred Jost[1] at the end of the 1940s to explain the results of his

observation that extirpation of the gonads (ovaries or testes) of rabbits before sexual differentiation had occurred invariably resulted in the development of a basic, female-type pattern in the fetuses.[129] This and subsequent research established that although sex-determining genes are evidently responsible for directing the development of the gonad, secondary sexual differentiation of internal duct systems and external genitalia is under hormonal control in eutherian mammals, including humans.

Indifferent (bipotential) external structures are initially present in males and females. The testis produces androgens, which masculinize the labioscrotal folds to form a scrotum, and the genital tubercle to form the penis. In the absence of the testis, and therewith of high levels of androgen molecules, the labioscrotal folds do not fuse and form labia, and the genital tubercle becomes the clitoris. Internally, the mesonephric (Wolffian) and paramesonephric (Müllerian) ducts will develop into male or female structures respectively. Testicular androgen promotes development of the Wolffian ducts into epididymides, vasa deferentia, and seminal vesicles, and absence of androgens leads to degeneration of the Wolffian ducts. Also produced in the testis is MIS, which causes disintegration of the Müllerian duct. In the female, in absence of MIS, the Müllerian ducts become the uterine tubes, uterus, and upper part of the vagina. The possible place of the gene for MIS in the sequence of events downstream of *SRY*[130] was discussed earlier.

Information on genes controlling female secondary sexual development can be obtained from studies on patients with pseudohermaphroditism. In this group of conditions the patient's primary and secondary sexual features are discordant. Thus in male pseudohermaphroditism a genetic male, having a testis, shows female or ambiguous external and/or internal genitalia.

For example, Androgen Insensitivity Syndrome (AIS), an X-linked condition also known as Testicular Feminization, occurs in XY individuals, and illustrates the above description of the main features of secondary sexual differentiation. In AIS the Y-chromosomal testis-determining mechanism is intact, and testes are present, but because the X-linked mutation renders tissues insensitive to androgens, the external genitalia fail to develop in masculine direction. Instead, they retain the basic female configuration, and the individual gets diagnosed as a girl at birth. The Wolffian ducts also do not develop and, because the testis produces MIS, the Müllerian ducts regress, so the individual does not have uterus, tubes, and the upper part of the vagina. At pubertal age menarche fails to occur.

In female pseudohermaphroditism, individuals have ambiguous or male-type external genitalia with female gonads and karyotype. Perloff and colleagues[131] and others[132–135] have described a distinct form of female pseudohermaphroditism associated with malformations of the internal genital, urinary, and gastrointestinal tracts. They may occur in the apparent absence of testosterone or *SRY*.[136] Possible causes include a disturbance of a specific caudal developmental field,[133] a primary defect in the cloacal membrane[135] or failed fusion of the urorectal septum with the cloacal membrane.[137] Some cases of penoscrotal transposition[138,139] and some cases of prune belly sequence and of bilateral renal agenesis[132,140] have similar patterns of caudal malformations. Furthermore, this pattern of dysmorphism, but without female pseudohermaphroditism, is found in the MURCS (*Mu*llerian duct aplasia-*r*enal aplasia, *c*ervicothoracic *s*omite dysplasia) association. This condition usually occurs sporadically in families. In most cases, the cause is unknown.

The role of growth factors in the differentiation of the genital tubercle has been explored in mice. The possible role of *Fgf-9* in gonadal differentiation was mentioned earlier. *Fgf-8* and *-10* are implicated in external sexual differentiation; KO of *Fgf-10* results in marked sexual ambiguity.[141] A pathway initiated by Sonic hedgehog (*Shh*), and interactions of its product with a number of these factors, has been studied in organ cultures of murine genital tubercles.[142] *Shh* KO embryos showed no external genitalia at 12.5 days gestation and showed down-regulation of *Fgf8*. Cultured genital tubercle explants treated with antibody to Shh also showed no external genitalia at 12.5 days gestation and marked down regulation of *Fgf-10*. Recently it has been shown that *Fgf-8* also has a role upstream of *Shh*[143] and downstream of androgens.[144]

These findings are also relevant to the hypospadias seen in Smith-Lemli-Opitz syndrome; the developmental defects seen in this cholesterol synthesis deficiency may in part be due to altered Shh signaling. Holoprosencephaly, sometimes seen in Smith-Lemli-Opitz syndrome, occurs with *Shh* haploinsufficiency, whereas hypospadias does not. Shh is also required for prostate development.[145] In contrast, Desert hedgehog is required to maintain germ cells in the testis.[146]

Although, as mentioned previously, *Wnt-4* is implicated in gonadal differentiation, *Wnt-5a* has also been implicated in genital tubercle development.[147] Furthermore, the role of MIS in development seems dependent on the signaling molecule *Wnt-7a*. In *Wnt-7a* KO males fail to undergo regression of the Müllerian duct, and females show abnormal oviduct/uterine development.[148,149] MIS-receptor is not expressed in the males[148]; thus *Wnt-7a* is essential for MIS function.

Multiple *Hox* genes, including the *Hoxa* and *Hoxd* groups, are involved in sexual differentiation. For example, compound double homozygous deficiency of *Hoxa-13* and *Hoxd-13* showed a complete absence of external genitalia.[150] Haploinsufficiency of the *HOXD* complex caused genital anomalies of a small phallus and no palpable testes in one case, and penoscrotal transposition with micropenis with multiple limb and other abnormalities in another.[151] Hand-foot-genital syndrome with male cryptorchidism and hypospadias is due to mutations in *HOXA-13*.[152]

CONCLUSION

The classical paradigm of Jost, formulated in the 1940s, provides a starting point for present-day consideration of sexual development in humans. However, recent research requires modification of that framework. Although Jost regarded the establishment of genetic sex that occurs at conception, and the determination of the fate of the gonad, to constitute a single step, it is now known that much transpires between these two events. Furthermore, the Jost Principle envisioned active induction of the testis only; the ovary developed by default in the absence of testis determining factors. However, the existence of ovary determining genes has now been established. The new paradigm, formulated here, proposes that primary sex determination comprises the three steps of sex chromosomal (X or Y) assignment of sex; pregonadal sexual development and sexual dimorphism; and gonadal (testicular or ovarian) development. Furthermore, the Jost Principle envisioned that all development of sexual dimorphism other than that of the gonads was due to hormones and independent of genetic sex. It is now clear that the situation is more complex. The new paradigm recognizes that some features of secondary sexual differentiation are directly influenced by gene action that is independent of testicular (or ovarian) hormones.

The sex determination pathway, like most developmental pathways, has a strong tendency to maintain its function (i.e., is homeostatic). Redundancy in pathways may be part of the mechanism by which the homeostatic continuation of sexual development occurs. One can surmise that a number of genes in the pathway might be up- or down-regulated to compensate for deficiencies in other members of the pathway. Further understanding of the sex determination pathway will come from studies of altered gene expression in deficient states and the location and identification of modifier genes that alter the pathway.

Differentiation of the Ovary

DEVELOPMENT OF A FUNCTIONAL OVARY

The follicle—the functional unit of the ovary—consists of an oocyte in the late prophase of the first meiotic division surrounded by granulosa cells and enclosed by a basement membrane that in turn is surrounded by theca cells.

Three major events are prerequisites for the development of a functional ovary, namely, initiation of meiosis, formation of follicles, and differentiation of steroid-producing cells. In the human, as in many other mammalian species, these events begin during fetal life, at a time when germ cells and somatic cells have populated the ovarian anlage.

In both sexes, the human gonads are closely connected to the mesonephros throughout early differentiation. Mesonephric cells, as well as cells from the ovarian surface epithelium, migrate simultaneously with the primordial germ cells to form the future gonadal tissue at the ventrocranial aspect of the mesonephros.[1,2] In the fetal mouse, cells from mesonephros form an *adrenogenital primordium* characterized by activity for steroidogenic factor 1.[3] This primordium may be the progenitor of the hormone-producing somatic cells of the differentiated gonad of both sexes and of the adrenal gland. SF-1 depends on the action of the ribonuclease Dicer1. Interestingly, knockout of Dicer1 results in complete degeneration of the testis, whereas the ovary proceeds through differentiation in the mouse.[4]

Meiosis and follicle formation are interrelated processes, the first being the prerequisite for the second, which, conversely, secures survival of the oocyte. The steroid-producing theca cells form later, around the growing follicles, whereas differentiation of steroid-producing cells in the stroma may be unrelated to the foregoing two events.[1]

Within the follicle, a unique micromilieu forms that secures oocyte growth and maturation. However, intraovarian and interovarian regulatory mechanisms, as well as systemic interrelationships, participate in controlling the fate of female germ cells.

Gonadal Sex Determination

In contrast to some other vertebrate classes (e.g., amphibians and fish), spontaneous sex reversal has never been reported in mammals.[5] In most vertebrate classes, gonadal differentiation is the result of the genetic sex. In mammals, the testis is formed when a Y chromosome is present, and an ovary develops if this chromosome is absent, irrespective of additional sex chromosomes.[6] During the 1970s and 1980s, a testis-determining region of the Y chromosome was located in smaller and smaller parts of the chromosome. In 1990, the sex-determining region Y—a single gene—was found.[7-9] It is thought that if the *Sry* gene is not activated, ovarian development will take place (for review, Wilhelm and colleagues[10]). However, in addition to the *Sry* numerous other genes are involved in the control of sex determination and early gonadal and sex duct formation and differentiation.[11,12] Edson and colleagues[13] provided an excellent review on genes and other factors involved in gonadal sex differentiation.

Early Ovarian Differentiation

In the human, the migration of primordial germ cells from the primitive gut to the gonadal ridge is guided by autonomic nerves and completed around the ninth week of fetal life.[14,15] Simultaneously invading mesonephric cells accumulate in the central part of the ovary and form the intraovarian rete in the medulla (Figure 184-1). The expanding medulla gradually pushes the germ cells toward the periphery, forming in the cortex a high density of germ cells (Figure 184-2).

By morphologic criteria the ovary is usually recognizable at a later stage of gonadal differentiation than the testis. The first signs signifying that the indifferent gonad is becoming a testis are the formation of the testicular cords enclosing the germ cells[16] and the rounding up of the organ.[17] In the human testis, these events take place at the sixth week of fetal life.

Cords enclosing the germ cells are, however, also seen at early stages of ovarian differentiation in some mammalian species

†Deceased

(e.g., the pig and the sheep). In other species (e.g., the mouse and the hamster), the germ cells are more evenly distributed throughout the ovary. These different patterns of germ cell location within the ovary are closely related to the onset of meiosis. In species in which germ cell cords are formed, meiosis is delayed by a "delay period" (delayed meiosis) until the cords dissolve, whereas, in species without cord formation, meiosis proceeds immediately (immediate meiosis).[18] During the delay period, transitory ovarian steroidogenesis takes place (see later). This is analogous to early testicular differentiation, in which steroidogenesis begins immediately after testicular cords are formed.[19,20] It has been proposed that enclosure of germ cells into specific germ cell compartments, either as temporarily formed cords or as follicles, is a prerequisite for the start of steroid production in the developing gonads.[18]

Morphologically and functionally, the human fetal ovary represents an intermediate type between immediate and delayed meiosis. Although germ cells appear in clusters during fetal life, well-defined cords are not formed (Figure 184-3; see Figure 184-2).[21] Nonetheless, the delay period lasts for a relatively long time, from the onset of sex differentiation at approximately the 6th week of fetal life until the 9th week, when meiosis starts.[22,23] Although the aromatizing enzyme system is present by the sixth week of fetal life few or no steroids are produced by human ovaries during the delay period.[24] Interstitial cells with ultrastructural resemblance to steroid-producing cells have been recognized from the 13th week of fetal life (Figure 184-4).[25]

The origin of the somatic cell population of the cortex is uncertain, and different theories have been proposed. Generally, the following sources for their origin have been suggested: the surface epithelium,[26] the mesonephros, or a combination of the two.[21,27] In vitro experiments attempted to trace the origin of gonadal somatic cells by culturing fetal mesonephric tissue from one mouse strain carrying a cellular marker together with fetal gonads from another strain without a marker[28,29] and vice versa.[30] However, results of the first studies indicated that mesonephric cells almost entirely migrated to the testis, not to the ovary, whereas the later study showed that cells moved in both directions in both sexes. Thus the origin of the somatic cells of the gonads remains uncertain.

MEIOTIC PROPHASE OF OOCYTES

By the end of the 10th week of gestation, the human ovarian cortex contains numerous mitotically dividing *oogonia*. When the oogonia stop dividing and enter meiosis, they are termed *oocytes*. The first oocytes in the human ovary are seen during the 11th week of gestation.[23] The term *oogenesis* denotes the

transformation of an oogonium into an oocyte, and maturation into a fertilizable oocyte.

The number of oogonia increases exponentially by mitotic division from approximately 20,000 in the 6-week-old human fetus to approximately 250,000 in the 10th week,[23,31] and it reaches a maximum of 7 million in the 20th week (Figure 184-5).[32,33] Genes and transcription factors involved in multiplication of the oogonia include *DAX-1*[34] and expression of Kit protein.[35,36] Extensive degeneration, however, reduces the number of germ cells drastically during the rest of fetal life, leaving only 1 to 2 million oocytes in the ovaries of the newborn girl.[32,37]

Process of Meiosis

Meiosis begins with premeiotic DNA synthesis, followed by the transitory stages of the first meiotic prophase: preleptotene-leptotene-zygotene, and pachytene to arrest in diplotene stage. When the diplotene stage is reached, the process is arrested (Figure 184-6). During this first meiotic prophase, the maternal and paternal genes are exchanged between the homologous chromosomes. The diplotene stage, sometimes named the dictyate stage, is maintained until the oocyte resumes meiosis (just before ovulation) or degenerates. Some oocytes may thus last for the whole fertile life span. Oocyte degeneration may occur at any time during development. At resumption of meiosis, the first meiotic prophase is completed, and the oocyte proceeds through the first meiotic division, the reduction division, in which the homologous chromosomes are separated into the daughter cells, now each containing 1n chromosomes and 2c (i.e., copy) DNA. The second meiotic division, which in the human takes place by fertilization, is not preceded by the usual DNA synthesis, and the DNA content is therefore halved to 1c. In the human, the meiotic divisions result in gametes with 23 chromosomes (1n) and 1c DNA.

The Meiotic Prophase: Morphologic Features and Genetic Control

The different transitory stages of meiosis are identifiable by the configuration of the chromosomes. In the preleptotene and leptotene stages, the chromosomes condense and appear as thin, coiled threads, each thread consisting of identical sister chromosomes. The chromosomes coil increasingly during progression through the zygotene to pachytene stages. The synaptonemal complexes begin to form in the zygotene and are completed in the pachytene stage. These complexes represent the pairing of homologous chromatids. It seems that proper formation of the synaptonemal complexes ensures normal chromosome segregation in the reduction division of meiosis.[38] Passing into the diplotene stage, the chromosomes decoil, and chiasmata or crossing-over may be recognized. At this stage, the paternal and maternal chromatids exchange gene material. The amount of exchanged gene material can be evaluated in the metaphase of the second meiotic division after labeling of premeiotic oogonia in S phase with bromine deoxyuridine.[39] During the diplotene stage, the oocyte and its nucleus enlarge. The chromosomes decondense, thus making the nucleus faintly stainable.

Numerous genes with functions specific for the early meiotic processes are known. One of these is *DAZL 1,* which encodes for a protein with RNA-binding element and is found in human oogonia.[40] *Dazla*-deficient mice are infertile because the oocytes are lost when passing through meiosis.[41] Other genes such as *Scp1-3* and cohesin proteins are needed for the structural organization of chromosomes during assembly of the synaptonemal complexes and recombination.[42-45]

As discussed earlier, meiosis begins with premeiotic DNA synthesis and ultimately leads to the 4c DNA content of the leptotene stage.[46,47] This DNA must last until ovulation ceases, which in the human can occur up to 50 years later. In other mammalian species, it has been shown by DNA labeling that no neoformation of oocytes takes place later in life; that is, the entire pool of oogonia is transformed into oocytes before or around birth.[48-51] An exception to this rule was demonstrated in the ovaries of adult prosimians (lower primates) showing DNA synthesis in oogonia-like germ cells.[52,53] However, the concept that neoformation of mammalian oocytes does not occur later in life has recently been challenged and is still debated.[54-57]

In the early stages of fetal ovarian development, oogonia and oocytes are often interconnected by cytoplasmic bridges[58] forming so-called *germ cell cysts*.[59] These bridges may be important for exchange of intercellular signals and may explain why groups of germ cells divide synchronously and enter meiosis in clusters (see Figure 184-6).[60]

Initiation and Regulation of Meiosis

The time of onset of meiosis in the female varies among different mammalian species but occurs always at an early stage of development, often in fetal life. In the testis, by contrast, initiation of meiosis is postponed until puberty in all species. These discrepancies have led to the hypothesis that an internal clock of the germ cells determines the onset of meiosis, independent of external factors.[61] However, the male germ cells can be induced to enter meiosis prematurely, for example, if the cells are located in the adrenal gland of the human fetus[62] or if they are exposed to a meiosis-inducing substance before the testis is sex differentiated.[18] Thus it seems uncertain whether a germ cell clock governs the switch from mitosis to meiosis or it is triggered by paracrine or other external stimuli (see later).

Meiosis-Regulatory Substances

A characteristic feature of the developing mammalian ovary is that the germ cells first entering meiosis are those situated in the central part of the ovary,[63] in close connection with the mesonephric-derived rete ovarii.[27] It has therefore been proposed that the mesonephric-derived cells in the ovary trigger the onset of meiosis.[27] In vitro experiments with gonads of fetal mouse[64] and hamster[65] suggest that the mesonephros produces a substance that promotes and induces meiosis in male, as well as in female, germ cells. This substance was termed *meiosis-inducing substance* and is probably a lipid.[66,67]

The presence of meiosis-inducing substance in gonads, in which meiosis is initiated, and its role in this process have been questioned. One study showed that fetal male mouse germ cells are "passively" entering meiosis when they are mixed and cultured with lung cells.[68] However, recent research in fetal mouse gonads shows that retinoic acid, an active derivative of vitamin A, stimulates the *Stra8* gene (*Stimulated by Retinoic Acid Gene* 8), which is required for the transition into meiosis in both female and male germ cells.[69] Therefore the fact of retinoic acid being a lipid is in accordance with the original proposal 25 years ago that meiosis-inducing substance is a lipid.[67] Retinoic acid is secreted by mesonephros in both sexes, but in the developing testis it is transformed by the enzyme CYP26B1 to inactive products; in the ovary, this enzyme is inactive, and

retinoic acid can stimulate its receptor which, in turn, will result in meiotic entry.[69]

FOLLICULOGENESIS

Folliculogenesis is the process during which the diplotene oocyte becomes surrounded by a single layer of granulosa cells and enclosed by an intact basal lamina, thus forming a specific germ cell compartment (Figure 184-7). Whether a follicular arrangement of granulosa cells and basal membrane can occur without the presence of an oocyte has been disputed, because it has not yet been possible to create gonads completely devoid of germ cells, such as by selective destruction by drugs.[70]

The separation of the diplotene oocyte from the surrounding tissue secures its survival and creates a unique micromilieu, which sustains further growth and differentiation. If the oocyte in the diplotene stage fails to be enclosed in a follicle, it invariably degenerates. Some follicles die as a result of specific programmed cell death, or *apoptosis*.[71-73] In the fetal human ovary, *naked oocytes* (diplotene oocytes without a granulosa layer) are often seen, but they always appear to be degenerating. Such oocytes are never seen later in life.[74]

The first follicles are encountered in the human ovary at approximately the 14th week of fetal life, and folliculogenesis is completed immediately after birth.[75] The appearance and growth of the first follicles coincide with the increase of fetal gonadotropins. Whether these two events are causally related is uncertain. Recent research has shown that genes expressed in the germ cells, such as *Figla, Nobox, Kit,* and *Ntrk2,* as well as genes expressed in the surrounding cells, such as *Foxl2, Kitl,* and *Ngf,* are important for folliculogenesis.[76] A study on mouse reproduction reports that the gene PTEN (phosphatase and tensin homolog deleted on chromosome 10) has a profound influence on follicle growth activation.[77] In mice lacking PTEN, small follicles are induced to grow, resulting in: 1) depletion of the follicle pool early in life, and 2) sterility.

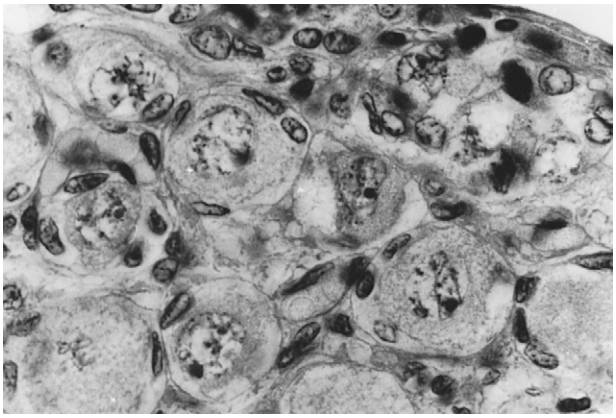

Figure 184-7 Primordial follicles in the ovarian cortex of a 30-week-old human fetus. (Original magnification ×560.)

Formation of the Granulosa Layer

The first follicles are formed in the inner part of the cortex, where oocytes first reach the diplotene stage.[78] In the newborn mouse ovary, programmed breakdown of the germ cell cysts may serve as a prerequisite for follicle formation.[79] It has been observed that the granulosa cells of the first and always centrally placed follicles are initially connected with the intraovarian rete cords.[80] This finding supports the assumption that granulosa cell precursors are of mesonephric origin. In fact, transplant experiments of fetal mouse ovaries showed that when invasion of mesonephric cells into the ovary is prevented, follicles are not formed.[81] It has also been proposed that the surface epithelium may give rise to granulosa cells, because proliferation of this epithelium into the cortex takes place during early stages of ovarian differentiation, before folliculogenesis.[27] One morphologic study of the formation of ovarian follicles during fetal sheep development suggested that almost all granulosa cells originate from the ovarian surface epithelium.[82] It is thus possible that mesonephric-derived cells, as well as cells of the surface epithelium, contribute to the granulosa cell population. In the mouse, the enclosure of the oocyte with the first granulosa cells is dependent on the action of FIGLA (factor in the germ line alpha).[83] In the human, *FIGLA* is only expressed in the oocytes from week 12 of fetal life, just before follicle formation takes place. However, a multitude of genes are probably involved in this important process.

Across mammalian species, the first generation of follicles appears to differ from later ones, exhibiting a different pattern of growth and differentiation (Figure 184-8).[84] The granulosa cells of these follicles seem to arise as a result of migratory processes of the extraovarian rete cells into the intraovarian rete that are

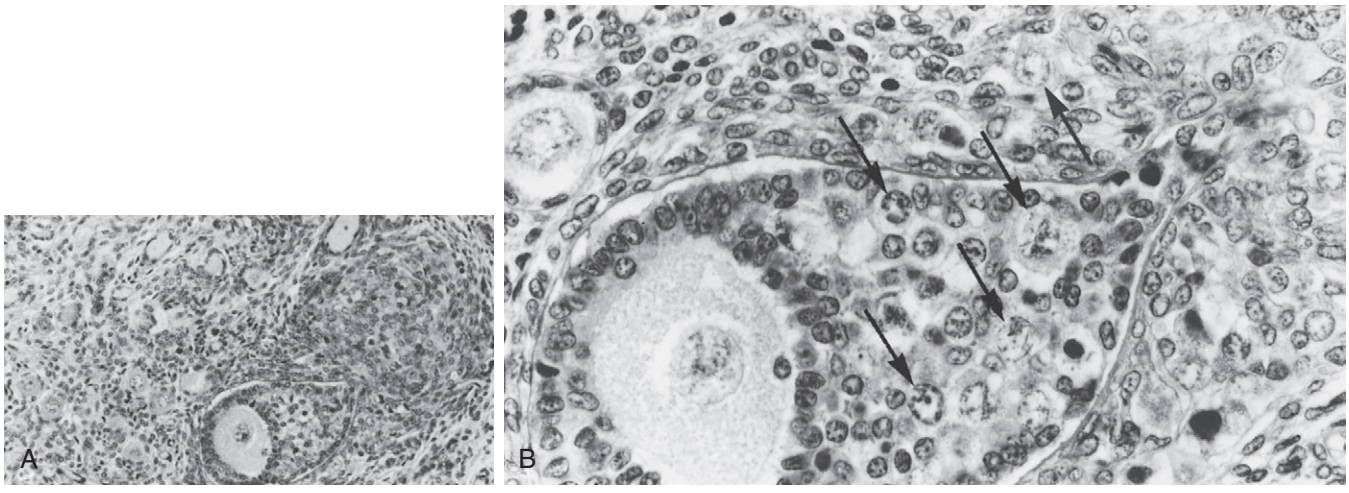

Figure 184-8 Abnormal follicle of a human fetal ovary, 33 weeks old. A, Besides a large oocyte, the granulosa layer contains numerous small oocytes and oogonia, some of which are degenerating. The granulosa layer opens up into a "nest" of small oocytes tightly packed with somatic cells. (Original magnification ×400.) **B,** Higher magnification of **A.** The arrows point at some of the small oocytes.

in contact with the oocytes.[81,85] Growth of later generations of follicles, which are no longer connected to the intraovarian rete, depends on proliferation of the fixed population of granulosa cells already enclosed in the follicle.[86,87]

The granulosa layer of the first generation of follicles that starts to grow in the inner part of the cortex and in the developing medulla often differs compared with later generations. The basal membrane does not always enclose the granulosa layer. It forms a tail-like extension (see Figure 184-8), which is sometimes connected to the intraovarian rete tubules. The first generation of follicles in the human fetal ovary may contain several oocytes of varying size and even oogonia that express genes characterizing primordial germ stem cells, such as CKIT, OCT4, and SSEA4.[57,88] Sometimes one oocyte is larger than the others (see Figure 184-8, *B*). Small oocytes—not enclosed in follicles—may also be seen in clusters densely packed with somatic cells (see Figure 184-8). In conclusion, it seems that early in development the interaction between the oocyte and the granulosa cells is not fully established, which results in abnormal follicles. Shortly after birth, however, these abnormal follicles disappear.

Initiation of Follicular Growth

As soon as follicles are formed, some of them begin to grow. From that time it has been estimated that approximately 10 to 20 primordial follicles are recruited daily for growth.[89] Thereafter initiation of follicular growth from the pool of small resting follicles continues until the pool is exhausted at menopause.[90] It is not certain whether follicular growth is initiated in the oocyte, in the granulosa cells, or simultaneously in both. In the immature mouse ovary, the number of granulosa cells of small follicles increases before the oocyte begins to grow.[91] At the same time, the oocyte nucleolar RNA polymerase activity increases,[91] and the nucleus enlarges.[92] Therefore it seems that initiation of growth in the oocyte and the granulosa cells is closely related.[93]

Once initiated, follicular growth continues until the follicle either ovulates or degenerates.[94] It is unknown what events trigger the initiation of growth. Exogenous gonadotropins have been reported to initiate follicular growth in the infant mouse ovary.[95] Follicular growth is also sustained by gonadotropins in vitro, as well as in vivo.[96-98] Moreover, retardation of follicular growth is seen in hypophysectomized fetal monkeys,[99] in anencephalic human fetuses,[75] and in infant mice treated with antigonadotropins.[100] Conversely, follicles begin to grow in cultures of fetal mouse[96,101] and hamster[97] ovaries, even in the absence of gonadotropins and steroid hormones.

It is therefore likely that factors other than gonadotropins control initiation of follicular growth. In the 1990s, numerous growth factors and other local acting factors or hormones, as well as their receptors, were identified in the mammalian ovary during early stages of folliculogenesis. However, folliculogenesis and early follicle growth seem to be controlled differently in different species. In primates, androgens stimulate insulin-like growth factor-I of the small oocyte and initiate follicular development, but this process does not occur in rodents.[102] Growth differentiation factor-9, a distant member of the transforming growth factor-β superfamily, is specifically expressed in the oocyte of all sizes in different species,[103-105] and mice with inactivated growth differentiation factor-9 are infertile and lack growing follicles.[106] Whether growth differentiation factor-9 is also needed for early follicular growth in other species is not yet clarified. In the human fetal and adult ovary, transforming growth factor-β and its receptor are expressed in granulosa cells of nongrowing follicles and may be involved in growth initiation.[107] It was recently found that the human ovarian medulla from early childhood through fertile life contains groups of small primordial and early growing follicles.[108] Thus, the dogma that all small, nongrowing follicles are confined to the cortex is invalid.

OVARIAN STEROIDOGENESIS

Early Steroid Production by the Ovary

In species with delayed meiosis, such as the sheep,[109] rabbit,[110] and cow,[111] considerable amounts of estradiol are secreted during a limited premeiotic period (the delay period) of fetal life. In the rabbit, it has been shown by quantitative cytochemistry that the intraovarian rete cells of the medulla exhibit activity of 3β-hydroxysteroid dehydrogenase during the delay period.[112] It is likely that these cells are responsible for the synthesis of the steroids.[113] However, in other species (i.e., those with immediate meiosis), steroid production is low or undetectable during early stages of development. In the human, no ovarian estradiol synthesis can be detected until late in fetal life.[114,115] This is striking considering the following: (1) the human fetal ovary possesses aromatizing enzyme systems for conversion of androgens to estrogens beginning with the eighth week of gestation[21]; (2) cells with ultrastructural characteristics of steroid production potentials are noted from the 12th week of gestation[1]; and (3) the activity of 3β-hydroxysteroid dehydrogenase is present in such cells from the 20th week of fetal life.[113] In the human, the early interstitial cells are located in the inner part of the ovarian cortex close to the developing follicles, but they never make contact with the oocytes (see Figure 184-4).

The mechanisms that trigger differentiation of the steroid-producing cells and initiation of steroid production are unknown. In the human fetal pituitary gland, the production of luteinizing hormone and follicle-stimulating hormone reaches a peak between the 16th and 20th weeks of gestation and then levels off and remains low until puberty.[116,117] Thus the peak production of gonadotropins occurs several weeks before the start of ovarian steroidogenesis. Moreover, once started, a slight increase of ovarian steroidogenesis (i.e., estrogen production) is seen throughout late fetal life when fetal gonadotropin secretion decreases. It therefore seems unlikely that pituitary gonadotropins control onset of fetal ovarian steroidogenesis.

Formation of the Theca Layer and Early Follicular Steroidogenesis

In the human ovary from late fetal life and until follicles are exhausted from the senile ovary, theca cells differentiate around the late preantral or early antral follicles (Figure 184-9).[86] Spindle-shaped

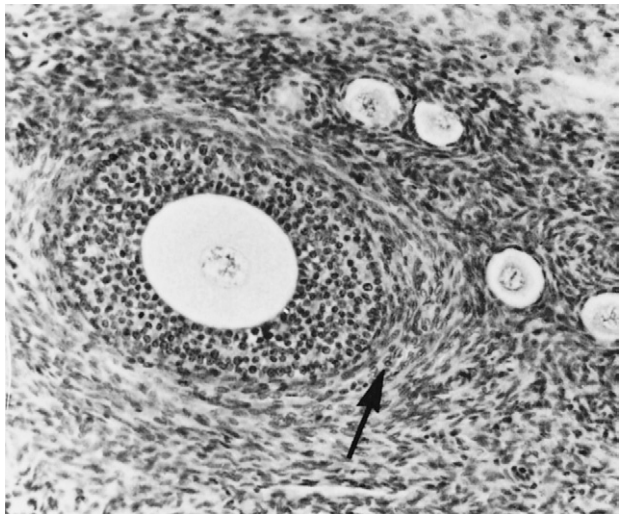

Figure 184-9 Inner part of the ovarian cortex of a 32-week-old human fetus showing a growing preantral follicle with a differentiating theca layer *(arrow)* and some primordial follicles. (Original magnification ×450.)

Figure 184-10 Cortex of an ovary from a 4-year-old child. Many small oocytes populate the area below the dense tunica albuginea. Remnants of a collapsing antral follicle occupy the lower part of the figure. (Original magnification ×280.)

hypotrophic cells encircle the basement membrane delineating the follicle together with blood vessels and nerves. Soon the theca cells acquire the ultrastructural and biochemical characteristics of steroid-producing cells. The origin of the theca cells is not established, but a pool of cells with potential for differentiating into theca cells must be present at all times, because every growing follicle sooner or later during its development requires a theca layer.

In the adult ovary, estrogen production by the follicle is the result of a synergism between the theca cells and the granulosa cells.[118] As soon as the theca cells differentiate around the follicle, the granulosa cells acquire 3β-hydroxysteroid dehydrogenase activity,[113] and by that time the follicular unit should be able to produce steroids, for example, by expressing P450c17 protein, the important steroidogenic enzyme involved in the conversion of pregnenolone and progesterone to androgens.[119] The late fetal ovary and the ovary during childhood contain numerous small antral follicles with well-differentiated theca cells. However, throughout childhood, serum levels of estrogens and other steroids remain low, probably because of lack of sufficient gonadotropic stimulation during this period.

FORMATION OF THE OVARIAN STROMA

During early fetal life, the main cell types that contribute to the ovarian stroma are mesenchyme and fibroblasts. Later in development, remnants of degenerating small follicles add to the stroma mass. Although some cells, for example hilus cells, are equipped with enzymes necessary for steroidogenesis, it is uncertain to what extent these cells participate in ovarian hormone production.[119] In fact, typical luteinized interstitial tissue is not seen until after the first ovulation has occurred.

FOLLICULAR GROWTH DURING CHILDHOOD

Birth itself is not a landmark in ovarian development and differentiation. Follicular growth starts in the early midtrimester, and antral follicles are often seen 1 month before birth. Therefore the ovaries of the female newborn infant contain preantral and antral follicles, at different stages of growth and atresia, in addition to a large pool of primordial follicles.[37] Follicular growth is the normal

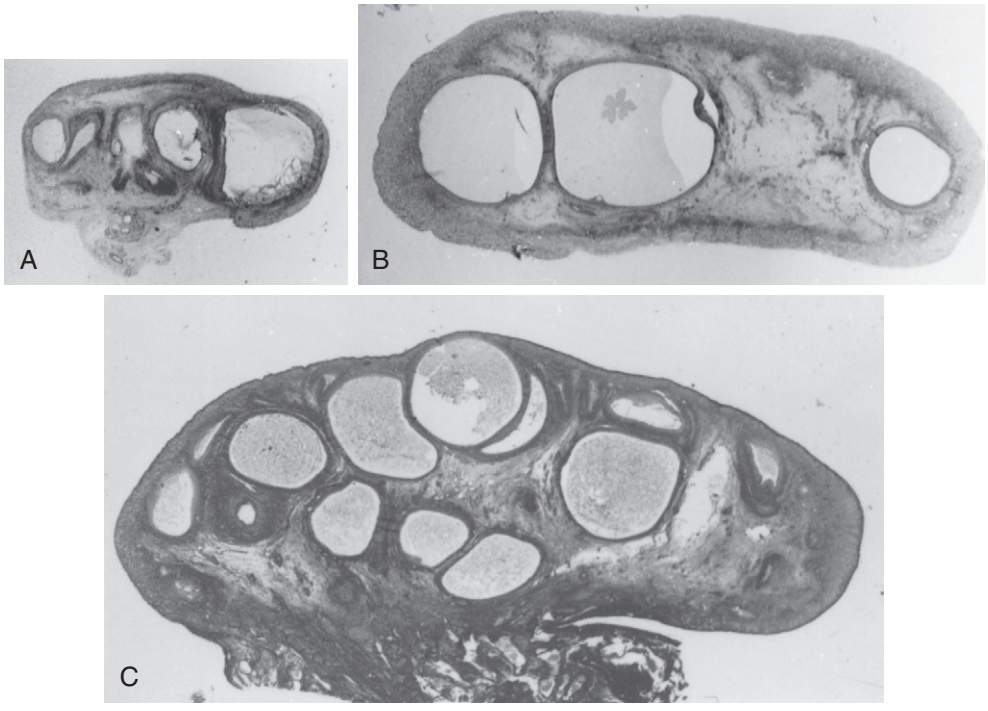

Figure 184-11 Human ovaries of young children, all with several antral follicles, none of which exceed 6 mm in diameter. (Original magnification ×5.) **A,** 2 months old. **B,** 4 years old. **C,** 7 years old.

finding in the ovary of the newborn infant (see Figure 184-8, *B*).[74,120] Absent or retarded growth of follicles at the time of birth is seen only in ovaries of children with disease.[121] The perinatal and postnatal increases in human gonadotropins, which decline only after the third month of age, sometimes cause development of ovarian cysts a few months later. If the cysts are larger than 5 cm in diameter, intervention may be needed to prevent adnexal torsion.[122] In addition to gonadotropins and steroids, small antral follicles accumulate anti-Müllerian hormone (AMH) in very high concentrations (twofold to threefold higher than in circulation). This suggests that these hormones also play important intrafollicular functions in follicles from the ovaries of young girls.[123]

All follicles that start to grow during childhood are destined to undergo atresia at some stage of development, because no ovulations occur before menarche (Figure 184-10). Although follicles may reach 6 mm in diameter during childhood, the size of the largest healthy, growing follicle does not generally exceed 10 mm.[124] The number of antral follicles also increases with age. In the newborn infant, three to five follicles larger than 1 mm in diameter may be present, whereas, in 8-year-old girls, the number is often 10 or more (Figure 184-11). This increase in the number of antral follicles is probably caused by the simultaneous increase in the basal levels of follicle-stimulating hormone and luteinizing hormone.[125]

185 Testicular Development and Descent

Mary M. Lee

The testis originates as a bipotential gonad during sexual differentiation. Although chromosomal or genetic sex (46,XX or 46,XY) is established at the time of fertilization, the gonads and genitalia are initially similar morphologically with the capacity for differentiation to either a phenotypic male or female. The expression of *SRY* (the sex-determining region Y gene) is a key determinant for development of the embryo along a male-specific pathway. SRY activation initiates a series of transcriptional events that lead to testis determination, a critical step in sexually dimorphic sex differentiation.[1,2] Subsequently, the somatic cells of the testis secrete testosterone and Müllerian-inhibiting substance (MIS)—also known as anti-Müllerian hormone (AMH)—to elicit male-specific differentiation of the internal and external genitalia. This classic model for sexual differentiation was proposed by Professor Alfred Jost after he demonstrated in a series of grafting experiments that two discrete testicular hormones are needed for development of the male phenotype.[3] Jost hypothesized that testicular hormones direct differentiation along the male pathway; in the absence of a testis, female development was the default pathway.[4] This paradigm has been challenged in recent years with the recognition that specific gene signaling is also required for ovarian formation and development of female genitalia.[5]

TESTIS DETERMINATION

Three to four weeks after conception, primitive germ cells are visible in the dorsal endoderm of the yolk sac. These germ cells migrate to the hind-gut epithelium, then spread dorsally along the mesentery and the body wall mesenchyme in response to chemotactic signals to populate the primitive gonad in the urogenital ridge.[2,6,7] Epithelial cells delaminate from the coelomic epithelium, enter the urogenital ridge, and enclose the germ cells as they reach the urogenital ridge to form the primary sex cords. The germ cells actively divide during their migration from the yolk sac endoderm to the urogenital ridge. Although germ cells along the migratory pathway that fail to reach the ridge degenerate, residual primitive germ cells at these extragonadal sites are thought to be the origin of teratomas.[8] Transcription factors such as steroidogenic factor-1 *(SF1),* homeobox genes (*Lhx-9, Lim1,* aka *Lhx1,* and *Emx2*), and the Wilms tumor suppressor gene *(Wt1)* play key roles in early gonadal formation.[5,9-12] In mice with targeted mutations of these genes, an indifferent gonad is formed initially but fails to develop further and degenerates. Some of the genes critical for testis development also play a role in other aspects of fetal development. *WT1* gene mutations result in several syndromes associated with gonadal dysgenesis and renal impairment, whereas *SF1* mutations manifest as adrenal and gonadal dysgenesis.[9,11,13-15] At later developmental stages, *SF1* is a sexually dimorphic gene that is repressed in the ovary and up-regulated in the differentiating testis to control somatic cell differentiation and induce steroidogenic enzyme expression.[16]

The gonad remains undifferentiated until 6 weeks gestational age when activation of *SRY* in 46,XY embryos initiates the male developmental pathway[1,6,7] (Figure 185-1, *A*). *SRY* is a member of the SOX family of transcription factors that all share a high mobility group DNA-binding motif.[17] Activation of a transient but precise spatiotemporal pattern of expression of SRY in pre-Sertoli cells up-regulates the expression of *SOX9* (17q24.3-25.1), a key autosomal sex determining gene.[18,19] *SOX9* is initially expressed in the supporting cell lineage of both male and female gonads. After *SRY* activation, *Sox9* expression increases in males and shifts from a cytoplasmic to nuclear distribution.[20,21] In females, in the absence of SRY, *SOX9* expression is down-regulated. Patients with loss of function mutations in either *SRY* or *SOX9* genes have varying degrees of testicular dysgenesis.[22-26] In the mouse, the desert hedgehog gene *(Dhh)* and its receptor *Patched 1 (Ptch1)* are also expressed in male gonads soon after *Sry* is activated; *Dhh* localizes to Sertoli cell precursors and *Ptch1* to peritubular cells and Leydig cell precursors.[27,28] The expression of *Dhh* is not essential for initial testicular determination, but is critical for subsequent testicular differentiation and morphogenesis. Targeted deletion of *Dhh* disrupts early cord formation and severely impairs spermatogenesis and fetal Leydig cell differentiation. Other, as yet unidentified, autosomal genes located within chromosomal deletions, such as 9p24 and 10q that are associated with sex reversal or partial gonadal dysgenesis, may also play critical roles in testicular differentiation.

Sry expression in pre-Sertoli somatic cells stimulates their proliferation and differentiation to the Sertoli cell lineage denoted by expression of MIS and other Sertoli cell-specific genes.[6,7] *Sry* also stimulates migration of peritubular myoid cells and endothelial cells from the mesonephros into the ridge—an essential step in the formation of testicular cords.[29] Shortly after Sertoli cell differentiation, male specific vascularization of the gonad occurs with organization of the gonad into discrete cords (see Figure 185-1, *B*). The coelomic vessel is formed with a network of branching capillaries restricted to the interstitial space. These capillaries eventually drain into venules in the mesonephros and are thought to be important for rapid distribution of testicular hormones into the systemic circulation. Concurrently, fetal Leydig cells differentiate from the interstitial mesenchymal cells between the testicular cords. The interstitium also contains endothelial cells, macrophages, and fibroblasts. The Leydig cells are the steroidogenic cells of the testis that produce androgens necessary for virilization of the male genitalia and internal reproductive tract. The testicular cords start to separate from the overlying epithelium as a dense layer of fibroblastic cells forms the tunica albuginea. During this period, the primordial germ cells within the testicular cords continue to differentiate and proliferate, increasing from 3000 to 30,000 in number by 9 weeks gestation.[30] In contrast to ovarian development, however, the presence of germ cells is not necessary for testicular morphogenesis to proceed. By the ninth week, the rete testis, the anastomosing ends of the cords near the hilus of the testis, extends into the mesonephric ridge and later connects to the remaining mesonephric tubules to eventually form the ductus deferens.

INTERNAL REPRODUCTIVE TRACTS AND EXTERNAL GENITALIA

The urogenital ridge arises from the intermediate mesoderm as bilateral thickenings at the ventrolateral surface of the mesonephros. The wolffian ducts, the anlagen of the male internal

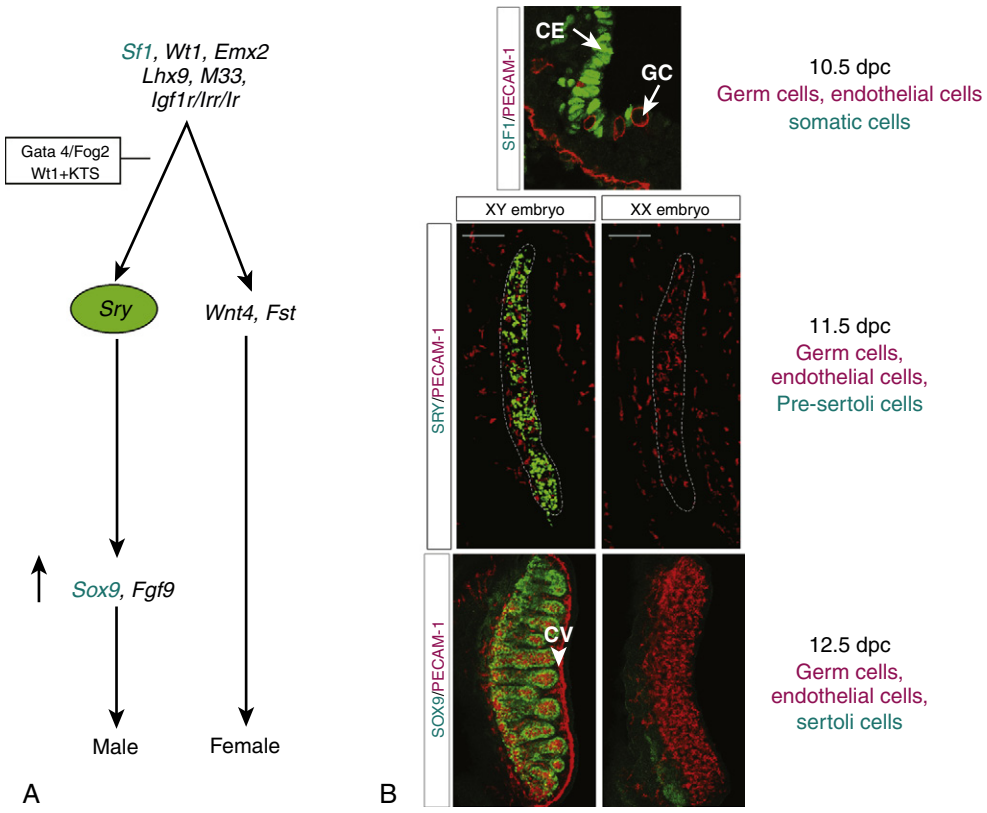

Figure 185-1 The mammalian sex determination pathway. A, The genes activated during gonad determination as a testis or ovary. **B,** Confocal images showing the sex-specific changes in gonadal morphology and gene expression during this early stage of gonadal development. *(From Polanco JC, Koopman P: Sry and the hesitant beginnings of male development,* Dev Biol *302:13, 2007.)*

reproductive tract, and the Müllerian ducts, the precursors of female structures, are present in all embryos.[4,5] The Wolffian duct arises as the caudal extension of the pronephric excretory duct. During gonadogenesis, the Müllerian (paramesonephric) duct develops in close proximity to the wolffian duct by invagination of the coelomic epithelium to form a tube surrounded by mesenchymal cells. The undifferentiated urogenital ridge has the capacity for developing male or female internal reproductive tracts depending on the local hormonal milieu. A number of genes that are critical for formation of the bipotential gonad are also essential for formation of the urogenital ridge. Mice with null deletions of *Lim1, Lhx9 and Emx2* manifest defects in urogenital ridge development as well as absent gonads.[10,12,31] In mice with *Pax2* deletions, the gonads form normally, but the genital ducts fail to develop, suggesting a specific role for *Pax2* in controlling differentiation of the intermediate mesoderm.[32] *Pax2* may also have a secondary role in wolffian duct differentiation as it localizes to the duct at later stages of genital tract development.

Paracrine hormones from the testis play key roles in mediating the sexually dimorphic differentiation of the wolffian (male) and Müllerian (female) internal genital ducts.[4,5,7] To achieve normal male differentiation of the internal and external genital structures, MIS and testosterone must be secreted by the fetal testis at the correct developmental stages and their downstream signaling pathways must be intact. A number of genes, including *SRY, SOX9s, SF1, GATA-4,* and *WT1* have been shown to act cooperatively or synergistically *in vitro* to transactivate MIS expression in Sertoli cells as an early event in testicular determination.[33,34] MIS, a 140 kDa glycoprotein in the transforming growth factor (TGF) β family of cellular growth and transcription factors, is produced as a prohormone requiring proteolytic cleavage to generate a bioactive hormone.[35-37] MIS binds to cell surface serine-threonine kinase receptors to signal through the Sma and Mad related proteins (SMAD) pathway. Although MIS receptors localize to the *mesenchymal* cells surrounding the Müllerian duct, epithelial-mesenchymal interactions culminate in apoptotic cell death of the adjacent epithelial cells.[38] MIS-induced regression of the Müllerian ducts starts by 8 weeks and is complete by 12 weeks gestation, leaving a vestigial remnant that persists as the prostatic utricle. Androgens have no independent effect on the Müllerian duct but act synergistically with MIS to promote full regression, whereas estrogens inhibit the actions of MIS on duct involution.

Testosterone-stimulated differentiation and growth of the Wolffian structures (epididymis, vas deferens, seminal vesicles) occurs between 9 and 14 weeks of embryonic life.[2,7,18] *SF1* induces the expression of the genes in the steroidogenic pathway: acute steroidogenic regulatory protein, the cytochrome P450 steroid hydroxylases, and 3β-hydroxysteroid dehydrogenase to initiate testosterone biosynthesis in Leydig cells.[16] Virilization of the external genitalia is also androgen dependant but requires additional reduction of testosterone to its more active metabolite, dihydrotestosterone by 5α-reductase, an enzyme present on genital skin. During the early stages of sex differentiation, fetal Leydig cell differentiation and synthesis of testosterone is gonadotropin-independent. Later in gestation, however, human chorionic gonadotropin or luteinizing hormone (LH) stimulation is needed for the continued synthesis of testosterone and completion of fetal masculinization.

LEYDIG CELLS

The Leydig stem cells are believed to migrate from either the mesonephrogenic mesenchyme or coelomic epithelium to the gonadal ridge where they localize to the interstitial space of the developing testis.[2,6,39] The initial differentiation of fetal

Leydig cells and onset of androgen production at 7 to 8 weeks occurs before the onset of pituitary LH production and testicular LH receptor expression, thus is considered LH independent.[40,41] Although the specific signal(s) triggering fetal Leydig cell differentiation remain uncertain, several genes are known to be critical for development of the Leydig cell lineage. Disruption of the GATA/FOG-2 interaction results in decreased expression of male-specific genes in the somatic cell lineages and in aberrant Leydig cell differentiation.[42] Sertoli cell secreted factors such as desert hedgehog (DHH) and genes expressed in Leydig cell precursors such as the Pdgf receptor-α and GATA-4 play key roles in modulating further differentiation of fetal Leydig cells.[6,18,27,28,39] *SF1,* a gene expressed downstream of Sry, has a pivotal role in gonadal and adrenal organogenesis as well as being a transcriptional activator of steroid hydroxylases and other genes that are essential for androgen biosynthesis.[16]

Fetal Leydig cells progressively increase in abundance to reach a maximum number at 48×10^6 cells per pair of testes at week 14, then remain stable until week 24 when they start to decline in number.[39,43,44] The increase in Leydig cell numbers is attributed to proliferation of the precursor cells because differentiated steroidogenic Leydig cells do not divide. From weeks 12 to 18, the Leydig cells appear hyperplastic and comprise the largest relative percentage of the testicular volume during fetal development. The fetal Leydig cells are at their most active phase of testosterone production and serum testosterone concentrations reach peak levels during this period (Figure 185-2). In the third trimester, fetal Leydig cells decline in number and mass through degeneration to reach their lowest numbers at 18×10^6 cells per pair of testes just before birth. The decrease in Leydig cell numbers during the latter part of gestation is accompanied by a parallel decline in androgen production.[41]

Androgen biosynthesis and secretion by fetal Leydig cells is essential for virilization of the internal and external genitalia. The hallmark of a terminally differentiated Leydig cell is the acquisition of steroidogenic capacity.[39,44] As the testis organizes into cords, 3β-hydroxysteroid dehydrogenase starts to be expressed in somatic interstitial cells that are identifiable as Leydig cells by ultrastructural features of steroidogenic cells. The synthesis of testosterone commences at weeks 7 to 8 and thereafter increases markedly to reach peak rates at 14 to 16 weeks. During the critical window of sex differentiation from week 8 to 12, the abundant production of testosterone and its conversion to the more active metabolite, dihydrotestosterone, are believed to be gonadotropin independent.[39-41,44] By the second trimester, androgen biosynthesis becomes gonadotropin-dependent as Leydig cells start to express the LH receptor, which is responsive to the high concentrations of placental human chorionic gonadotropin in the intrauterine environment. In concert with the induction of LH receptor expression, pituitary secretion of LH increases during the latter half of gestation.[41] Fetal Leydig cells are not subject to negative feedback by LH and have a greater response to its stimulatory effects, in contrast to robust negative feedback of the postnatal adult Leydig cells by LH. Thus the steroidogenic capacity per fetal Leydig cell is higher than that of adult Leydig cells.[44] Nevertheless, before birth the steroid content per fetal Leydig cell decreases (perhaps as a result of inhibitory paracrine hormones) and circulating testosterone concentrations are much lower because of the reduced numbers of Leydig cells.

Discrepancies exist in the data on the effects of other hormones and paracrine factors on steroidogenesis in fetal Leydig cells. Fetal Leydig cells have been shown to be insensitive to the inhibitory effects of estrogens, a property that would enable the fetus to circumvent the high concentrations of maternal estrogens that might be present in the intrauterine milieu.[45,46] Conversely, studies have also shown that estrogens inhibit testosterone production in cultured Leydig cells and decrease Leydig cell numbers. Other negative regulators of fetal steroidogenesis include two paracrine factors, MIS and TGF-β, that both have inhibitory effects on androgen biosynthesis.[44,47] In addition to hormones and growth factors, extracellular matrix components and structural interactions may have modulatory influences.[39]

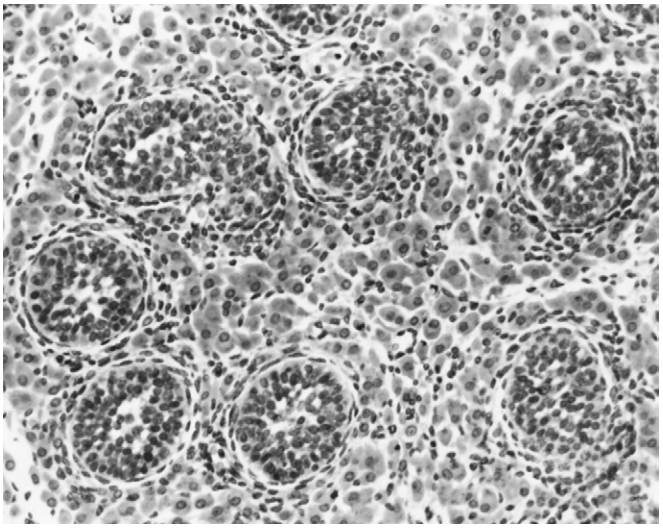

Figure 185-2 Human fetal testis histology. In Polin RA, Fox WW, Abman SH [eds]:* Fetal and neonatal physiology, *ed 3, Philadelphia, 2004, WB Saunders, pp 1956-1960.)*

After birth, a transient neonatal activation of the hypothalamic-pituitary-gonadal axis at 2 to 4 months of age stimulates an increase in Leydig cell numbers and a robust rise in androgen production.[48] This is followed by dedifferentiation and/or degeneration of the fetal Leydig cells and a marked decline in androgen production to the low levels that persist until the onset of puberty.[43] Very few differentiated Leydig cells are present in the prepubertal testis. The interstitial space contains predominantly mesenchymal cells that are precursors of the postnatal adult Leydig cells. These "infantile" Leydig cells have a multilobed nucleus and minimal smooth endoplasmic reticulum. The mesenchymal cells proliferate and increase in number during childhood, then differentiate to adult steroid-secreting cells with a large polygonal configuration, eccentric nuclear position, abundant smooth endoplasmic reticulum, pleomorphic mitochondria, and well-developed Golgi apparatus at puberty.[39] LH, in concert with other hormones that stimulate androgen production, promotes maturation of the steroidogenic enzyme pathway to progressively increase androgen production. The secretion of testosterone during puberty is needed to achieve spermatogenesis and secondary sexual maturation. In the adult, the terminally differentiated Leydig cells produce testosterone abundantly. Morphologically, the adult Leydig cells can be distinguished from fetal Leydig cells by the presence of Reinke crystals, which are of unknown function but specific to mature Leydig cells. The number of mature Leydig cells in the adult testis is relatively static as the terminally differentiated cells do not divide, although a limited number of Leydig cells may arise de novo from mesenchymal precursors in the interstitial space.

SERTOLI AND GERM CELLS

As the primordial germ cells migrate to the urogenital ridge, they are enclosed by fetal Sertoli cells and organized into seminiferous cords (see Figure 185-1 and Figure 185-3). The Sertoli cells

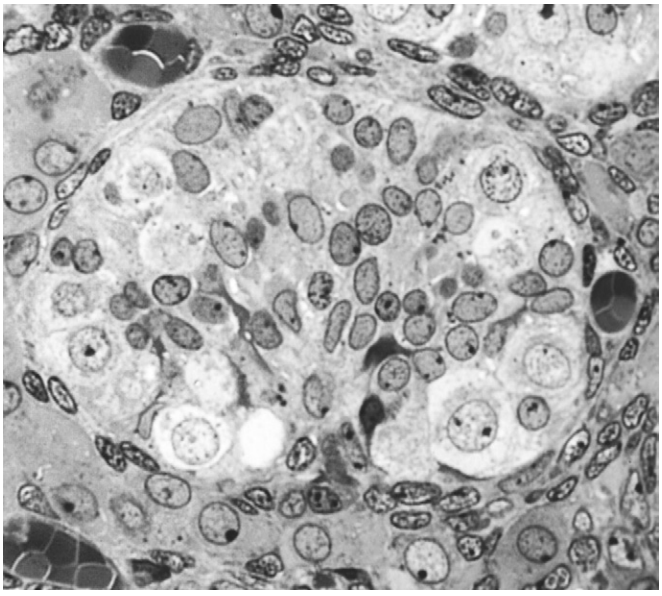

Figure 185-3 Seminiferous cords in human fetal testis with Sertoli cells and round immature germ cells at the periphery. (toluidine blue, ×500). *(Reprinted with permission from Aslan AR, Kogan BA, Gondos B: Testicular development. In Polin RA, Fox WW, Abman SH [eds]:* Fetal and neonatal physiology, *ed 3, Philadelphia, 2004, WB Saunders, pp 1956-1960.)*

are considered the "nurse" or supporting cells for the germ cells and regulate many germ cell functions. A deficiency in Sertoli cell number will impact the number and quality of sperm in the mature testis. The relative numbers of Sertoli and germ cells within the seminiferous tubules vary throughout the stages of reproductive development.[49] Initially predominantly Sertoli cells exist, but the high fetal testosterone concentration from weeks 8 to 22 gestation stimulates proliferation of the germ cells to reverse the ratio of germ cells to immature Sertoli cells. As testosterone production declines during the third trimester, however, germ cell mitotic activity also declines, resulting in a lower ratio of germ cells to Sertoli cells, which is sustained until puberty. After birth, germ cells proliferate transiently during the neonatal minipuberty, then stop dividing until the peripubertal years when a higher mitotic activity equalizes the number of germ cells and Sertoli cells in the pubertal testis. During early childhood, the Sertoli cells divide rapidly until the onset of puberty when they differentiate, form tight junctions, and no longer undergo cell division.[50]

In the immature testis, round to oval gonocytes are located centrally within the tubules. As they mature to prespermatogonia, they shift to the periphery of the tubules near the basal lamina. The prespermatogonia are connected by residual cytoplasmic bridges that remain after incomplete cytokinesis during mitosis. These interconnections between differentiating spermatogonia enable synchronized maturation of adjacent germ cells. Each germ cell division replenishes the spermatogonial pool as well as generates germ cells that undergo spermatogenesis. Spermatogonia are classified by their morphology, maturational stage, position within the germinal epithelium, and variations in nuclear chromatin precipitation.[51] More immature spermatogonia are found along the basement membrane whereas mature forms are present closer to the tubular lumen. Type A spermatogonia, divided into Ad (dark type A) and Ap (pale type A) groups are considered part of the spermatogonia stem pool. Progressive differentiation to B type spermatogonia represents the first step of spermatid formation. Sequential stages of spermatogenesis can be identified within a testis, including, from the least to the most mature forms: Ad spermatogonia, Ap spermatogonia, type B spermatogonia, primary spermatocytes (leptotene, zygotene, and pachytene), secondary spermatocytes, Sa, Sb1, Sb2, Sc, Sd1, and Sd2 spermatids, and mature spermatozoa. One group found that in men who had orchidopexy before the age of two years old, the risk for infertility correlates with the presence of Ad spermatogonia at the time of orchidopexy; they have proposed that increased testosterone during the minipuberty of infancy may be essential for transformation of germ cells to Ad spermatogonia.[52]

The development of germ cells occurs in parallel with the maturation of Sertoli cells. Fetal Sertoli cells have round to elliptical nuclei and small nucleoli. They have a minimal smooth endoplasmic reticulum, but abundant ribosomes and rough endoplasmic reticulum.[53] At puberty, the immature Sertoli cells develop tight junctions and acquire differentiated characteristics. The presence of tight junctions between adjacent cell membranes creates the blood-testis barrier. This unique characteristic enables the Sertoli cells to create a microenvironment for controlling the biochemical milieu within the cords as well as to facilitate the migration of germ cells within the seminiferous tubules.

Although the Sertoli cell number does not change during pubertal maturation, they occupy a relatively smaller area of the tubules as the tubules elongate and enlarge due to active germ cell proliferation.[53] The Sertoli cells have a critical role in the production and secretion of various proteins, some of which act as endocrine and paracrine hormones. During testis determination, the first hormone secreted by the Sertoli cell is MIS, the hormone responsible for inducing regression of Müllerian duct structures in males during normal embryogenesis. Mutations of MIS or its type II receptor cause retention of Müllerian structures in males, a condition termed the persistent Müllerian duct syndrome. Although Müllerian duct regression is complete by the second trimester, MIS continues to be abundantly produced throughout gestation and even after birth.[54] In addition to its role in Müllerian duct regression, MIS may also have paracrine modulatory actions on germ cell maturation and Leydig cell development in males.[44,55]

The Sertoli cells also secrete inhibin, a related hormone in the TGF-β family that acts via negative feedback on the pituitary to downregulate follicle-stimulating hormone secretion.[56] Like the other members of this gene family, inhibin consists of two subunits—inhibin A and inhibin B—and undergoes proteolytic processing. Inhibin indirectly regulates spermatogenesis through its modulation of follicle-stimulating hormone but is also believed to have direct paracrine effects on spermatogenesis.[57]

BLOOD-TESTIS BARRIER

The Sertoli cells develop tight junctions that create a physical barrier between the bloodstream and the testicular tubules.[58] In rats, the blood-testis barrier does not fully develop until puberty; in humans, the age at which the barrier becomes fully functional is not known. The blood-testis barrier helps maintain the microenvironment of the apical adluminal compartment of the seminiferous tubules. Experimental data show that the tight junctions prevent passage of large tracers from the basal compartment, that is, the interstitium to the apically located tubular lumen, whereas smaller tracers are not completely excluded.[58,59] This physical separation enables the Sertoli cell to control the special microenvironment of the tubular lumen to facilitate spermatogenesis. The blood-testis barrier is also thought to provide some immuno-protection and prevent autoimmune destruction of differentiating germ cells. Some of the mechanisms by which Sertoli cells maintain the barrier have been elucidated and a number of extracellular matrix proteins and ectoplasmic specialization proteins are critical for its structural and functional integrity. In the rat testis, inhibitors of protein phosphatase disrupt the barrier,

whereas pretreatment with protein tyrosine kinase inhibitors can prevent this effect. Similarly, both protein kinase A activator and protein kinase C inhibitors also perturb the Sertoli cell tight junctions, indicating a regulatory role for protein kinases. Formation of the barrier can be disrupted by administration of certain toxins, hormonally active compounds such as diethylstilbestrol, and heavy metals such as cadmium.

More immature spermatogonia (spermatogonia and preleptotene spermatocytes) are located close to the basement membrane, whereas more mature, differentiating spermatocytes and spermatids are found in the adluminal compartment. During spermatogenesis, at the time of meiosis, the intercellular junctions are remodeled to enable migration of the preleptotene and leptotene spermatocytes across the barrier into the adluminal compartment. From the apical side of the tubules, the spermatogonia complete maturation and are released from the seminiferous epithelium. The regulation of this process is not fully understood, but cytokines are known to have a role in the restructuring of the tight junctions that is essential during spermatogenesis.[60]

PERITUBULAR STRUCTURES

Although the organization of the interstitial cells varies among species, the peritubular structures uniformly help impart structural integrity to the seminiferous tubules. In humans, the lamina propria in humans contains five to seven layers separating the seminiferous tubules from the interstitium.[59] The outer one to two layers consist of fibroblastic cells that form the adventitia and provide structural support for the tubules. The middle layers contain myoid cells that have fibroblastic characteristics and help create the blood-testis barrier. These myofibroblasts have contractile ability and may therefore have a significant role in movement of spermatozoa through the tubules to the rete testis. In experimentally created cryptorchidism, there is thickening of the peritubular structures that may interrupt the movement of the differentiating germ cells and contribute to the associated infertility. The collagen-rich innermost layer is immediately adjacent to the basal membrane of the tubules. This cellular layer produces extracellular matrix proteins, which are needed for structural support of the basement membrane, and secrete paracrine growth factors, such as peritubular factor that modulates sertoli cell function (PModS) and TGF-α, that help regulate Sertoli cell function and differentiation.

A better understanding of testis development has revealed the complex cell-to-cell interactions and the diverse signaling pathways that are utilized to establish the organizational structure of the testes and achieve the maturational processes that are needed for virilization of the genitalia and reproductive competence. The descent of the testes from an intraabdominal to a scrotal position is a key developmental step to attain reproductive competence.

REGULATION OF TESTICULAR DESCENT

In conjunction with *in utero* testicular development and somatic and germ cell differentiation, the testis undergoes anatomic changes in its position during the second half of gestation. Insights on the process of testicular descent from an abdominal to scrotal position have been gained by investigating this event in animals. Differences among species in timing, anatomy and final testicular position, and hormonal milieu, however, limit the ability to fully extrapolate observations in animal models to human testicular descent. For example, in contrast to the late fetal timing of human testicular descent, testes in rats do not descend until puberty and move easily into the scrotum due to the formation of a pouch-like processus vaginalis. Aside from animal studies, clinical investigations that may include comprehensive hormonal and radiologic assessment and surgical or autopsy explorations with pathology specimens have helped clarify this process in humans.

The current model consists of a biphasic process comprising two distinct phases—a transabdominal and an inguinal-scrotal step[61] (Figure 185-4). When testes develop from the mesonephros, they are attached to the posterior abdominal wall by the cranial suspensory ligament and caudally by the genitoinguinal ligament (or the gubernaculum).[62,63] During the transabdominal phase of descent, the cranial suspensory ligament regresses, whereas the caudal end of the gubernaculum enlarges in a "swelling reaction" to form an outgrowth. The testes are anchored by the gubernaculum to the abdominal wall near the site of the future inner ring of the inguinal canal. Consequently, as the abdominal cavity enlarges, the testes remain in the lower abdomen and eventually assume a position lateral to the inferior pole of the kidneys.

The key hormone responsible for the transabdominal phase of testicular descent is insulin-like factor 3 (INSL3), also known as relaxin-like factor, a member of the insulin-like superfamily produced in Leydig cells.[64] INSL3 signals through its receptors (leucine-rich repeat-containing G protein–coupled receptor 8) on gubernacular cells to stimulate gubernacular differentiation and growth. In humans, the gubernaculum increases in size from 15 to 24 weeks gestation. This gubernacular outgrowth ("swelling") is characterized by hyperplasia and hypertrophy of the mesenchymal cells due to an increase in glycosaminoglycans and hyaluronic acid that promotes water retention and makes the

gubernaculum gelatinous.[63] Male mice with a null mutation of *Insl3* have a poorly developed gubernacular bulb, intact cranial suspensory ligament,[65,66] and undescended testes, whereas overexpression of *Insl3* in females leads to descent of the ovaries to the inguinal region.[67] Although mutations in *Insl3* and its receptor, leucine-rich repeat-containing G protein-coupled receptor 8, have been implicated in patients with cryptorchidism, the phenotype is more variable.[64] Moreover, the etiology of undescended testes in humans appears to be more complex and multifactorial because only a small subset of patients with cryptorchidism are found to have *INSL3* gene and promoter mutations.[68]

The cranial suspensory ligaments regress in males during the transabominal phase of testicular descent but remain intact in females, suggesting that their regression is needed for full abdominal descent. This process is thought to be under androgen control. In rodent models, prenatal antiandrogen treatment prevents complete regression of the cranial suspensory ligaments and prenatal androgen treatment induces regression of the ligaments and partial descent of ovaries.[69,70] In the absence of androgen action, such as with androgen-insensitive testicular feminizing mice and patients with androgen insensitivity syndrome, the cranial suspensory ligaments do not regress and the gubernacular bulb is smaller.[63,71,72] In patients with androgen insensitivity syndrome, the testes are located either in the inguinal region (suggesting that the transabdominal phase of descent occurs even in the absence of androgen action) or midway down the abdomen (suggesting that androgens may play a supportive role in this process).[73] These data confirm that androgens have only a minor role in the transabdominal phase of testicular descent; their predominant role is to mediate the movement of the testes from the inguinal region through the inguinal canal into the scrotum during the second inguinal-scrotal phase of testicular descent.

During the inguinal-scrotal phase of descent from weeks 25 to 32 of gestation, the testes move from within the abdominal cavity at the level of the anterior iliac spine through the internal and external rings of the inguinal canal into the scrotal sacs.[61-63,71,74,75] The period of gubernacular outgrowth during the transabdominal phase is followed by protrusion of the bulb through the developing scrotal sac and formation of the processus vaginalis that facilitates movement of the testes through the inguinal canal. Subsequent shortening of the proximal gubernaculum and involution of the caudal bulb also promotes movement of the testes from the external inguinal ring to the bottom of the scrotal sacs.

The actions of androgens are essential for the inguinal-scrotal phase of testicular descent. Cryptorchidism is a cardinal feature of a number of animal models and human disorders associated with either inadequate androgen action or perturbation of the hypothalamic-pituitary-gonadal axis.[61,71,73,74,76] Patients with hypothalamic hypogonadism or other forms of hypopituitary dysfunction have a much increased rate of inguinal testes. As described previously, cryptorchidism is also seen commonly in infants with androgen insensitivity syndrome or defects in testosterone biosynthesis that results in insufficient androgen action.

A number of animal studies have explored the dependency of testicular descent on androgens as well as the adjunct role of other hormones on this complex process. In rodents, testicular descent into the scrotum occurs at puberty rather than in utero; thus models manipulating the postnatal hormonal environment are not directly applicable to human testicular descent. For example, in postnatal rats, removal of the salivary glands, the major source of epidermal growth factor compromises testicular descent at birth and administration of epidermal growth factor reverses cryptorchidism induced by flutamide, but whether epidermal growth factor modulates testicular descent in humans is unknown.

Administration of estrogenic agents, endocrine disrupting compounds, and antagonists or antibodies that block LH, INSL3, and testosterone action can all inhibit testicular descent (reviewed in references 71, 74, and 75). Several models of experimentally induced cryptorchidism can be reversed by administration of exogenous testosterone, confirming its critical role for this developmental event.[77] Although 5α-reductase activity is present in the rat gubernaculum, finasteride, a 5α-reductase inhibitor, has little effect on testicular descent. The conversion of testosterone to dihydrotestosterone, therefore, does not appear to be essential, and testosterone itself is the primary hormonal mediator of inguinal-scrotal descent.

Clinical studies have examined differences in gonadal and pituitary hormones between children with cryptorchidism and those with normal testicular descent.[78] Boys with cryptorchidism have been reported to have lower MIS values, lower inhibin, and higher follicle-stimulating hormone values; normal, lower, or higher LH values; and lower or normal testosterone values than controls.[78-83] These discrepant findings may reflect differences in the patient population investigated and the heterogeneity in the etiology of cryptorchidism. Nevertheless, these data are consistent with the role of androgens as the primary determinant of the inguinal-scrotal phase of testicular descent.

The effects of androgens on testicular descent are mediated both directly through androgen receptors expressed on mesenchymal cells found between the smooth muscle cells and also indirectly via androgen actions on the genitofemoral nerve.[61,71] The key role of the genitofemoral nerve was recognized via experiments demonstrating that transection of the genitofemoral nerve early in gestation inhibited gubernacular development and left the testes in an inguinal position.[63] Although this was initially thought to be due to loss of motor innervation of the cremasteric muscle, later studies suggested that this manipulation was interfering with secretion of an androgen stimulated neuropeptide, calcitonin gene–related peptide (CGRP), by sensory neurons in the genitofemoral nerve. The role of the genitofemoral nerve and CGRP has subsequently been further clarified by this group.[61,63] They propose a model in which androgens masculinize the sensory neurons in the genitofemoral nerve to stimulate synthesis and release of CGRP into the gubernaculum. Receptors for CGRP are expressed on embryonic myotubules found within the gubernacular cells in the area of the developing cremasteric muscle. CGRP stimulates rapid rhythmic contractions of the gubernaculum that may be important for its migration to the scrotum. In vitro, CGRP has been shown to act as a chemotactic and proliferative signal for gubernacular cells at its caudal end. Exogenous treatment with a synthetic CGRP antagonist (CGRP 8-37) has been shown to delay testicular descent in rats, whereas administration of CGRP stimulated testicular descent in cryptorchid pigs. The data supporting a role of CGRP in human testicular descent are limited to evidence that CGRP is able to stimulate fusion of inguinal hernia sacs in organ culture.[84] Although indirect, this serves as a model for one of the events that occur during testicular descent, the obliteration of the processus vaginalis.

THE DIAGNOSIS AND INCIDENCE OF CRYPTORCHIDISM

Clinical disorders of testicular descent are the most common minor congenital abnormality in male newborns.[85] The term for this condition, *cryptorchidism,* is derived from the Greek words *kryptos* and *orchis* for "hidden gonad." Most commonly, the undescended testes are found in the inguinal region, stemming from a disruption of the more complex inguinal-scrotal phase of descent, especially involving the slower process of migration from the external ring to the scrotum. The testes, however, can be asymmetrically positioned and found anywhere along the path of embryologic testicular descent, even in ectopic locations (Figure 185-5).

The etiology of cryptorchidism is unknown in the majority of cases and appears to be multifactorial.[71,74,75,86] Only a minority

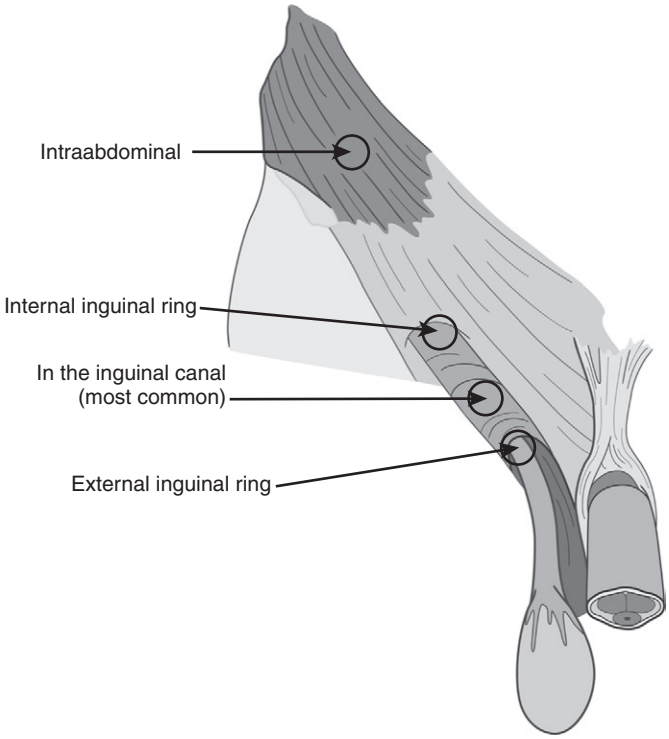

Figure 185-5 Common locations of the cryptorchid testis. *(From Christensen JD, Dogra VS: The undescended testis,* Semin Ultrasound CT MR *28:307, 2007.)*

of cases are identified as being caused by a specific genetic or endocrine disorder, although the likelihood of finding a specific etiology increases if associated anomalies are present. Epidemiologic studies have demonstrated geographic differences in the prevalence of cryptorchidism and other male reproductive disorders, such as hypospadias and decreased fertility, suggesting that underlying genetic, lifestyle, or environmental factors may play a causative role.[75,85,87] Some studies also report an increase in the incidence of these conditions in the past century.[75] A unified hypothesis of a testicular dysgenesis syndrome due to embryonic disturbance in testicular formation or function has been proposed to explain these findings.[88]

One of the major impediments to determining the exact prevalence of cryptorchidism is the lack of specificity in the diagnosis. Although the distinction between a completely nonpalpable, intraabdominal testis and a scrotal testis is readily appreciated, the difficulty lies in distinguishing inguinal undescended testes from those that are retractile. This becomes even more difficult later in infancy and childhood when the cremasteric reflex is more active and can have a high interobserver variability.[89] The cremasteric reflex is easily triggered during an examination when the scrotum is exposed to cold and the child is apprehensive, leading to potential misdiagnosis of a normally descended testis as being undescended. The erroneous classification of a retractile testis as cryptorchid and the different criteria used by investigators to define a cryptorchid testis may account for inconsistencies in the prevalence data among centers. Moreover, the lack of standardization in the diagnosis of cryptorchidism and the potential for misdiagnosis also contribute to the ambiguity on the efficacy of different modes of management.

A recent systematic review of the literature found a rate of undescended testes that varied from 1.0% to 4.6% in newborn infants with birth weight greater than 2.5 kg, and a rate of 1.1% to 45.35% in preterm infants weighing less than 2.5 kg.[85] At 1 year of age, the rate of undescended testes in the term infants had decreased to 1.0% to 1.5%, consistent with previous reports of spontaneous descent in the first year in 50% to 75% of cases, with most occurring in the first 3 months. Prevalence rates in school aged children were more variable—6-year-olds had a rate of 0% to 2.6% and 11-year-olds had a rate of 0% to 6.6%. In one longitudinal study, Scorer[90] reported that the majority of cryptorchid testes underwent spontaneous descent by 9 months of age with an incidence at birth of 2.7% decreasing to 0.8% by 1 year of age. An increase in prevalence, however, is noted in some school studies that has been attributed to acquired ascent of the testes during childhood as a result of inadequate elongation of the spermatic cord.[91,92] Prematurity and low birth weight are both significant risk factors for cryptorchidism, and a family history of cryptorchidism also increases the relative risk for cryptorchidism. A recent study showed that relative risk was 10.1% for twins and 3.52% for siblings.[93] Therefore familial as well as developmental or environmental factors may incur risk for the occurrence of cryptorchidism.

pulmonary
endothelium-dependent, 808
nitric oxide-mediated, 807–813, 811f–814f, 815–816
undernutrition and altered, 804
Vasopressin
adrenocorticotropic hormone secretion and, 1988, 1990–1991, 1991f
antidiuretic effects of, 1955
blood pressure and, 794
calcium homeostasis and, 1375
hypothalamic control of, 1953–1955, 1954t
lung liquid transport and, 912
placental circulation and, 125
renal blood flow and, 1325
for shock, 860
urinary concentration and, 1392–1393, 1398t, 1399–1400
fetal, 1319, 1400–1402, 1401f
neonatal, 1403–1405, 1405t
Vasoregulation
peripheral, shock and, 858
pulmonary, nitric oxide-mediated, 807–808, 809f
VEGF. *See* Vascular endothelial growth factor.
Veins
development of, 701–702
differentiation of, 708–709, 709f
Velocimetry
Doppler, uteroplacental, 838
fetal, changes in, 303–305, 304f–305f
umbilical artery, 842
Venous hemorrhagic infarction, 1820, 1834
Ventilation. *See also* Liquid ventilation; Mechanical ventilation.
bag and mask, 850, 850f
in bronchopulmonary dysplasia, 1057–1058
distribution of, 967, 967b
in hyaline membrane disease, 1030–1031
Ventilation-perfusion relationships, 960
assessment of, 960–963
assumptions about, 963

Ventilation-perfusion relationships *(Continued)*
carbon dioxide gradient in, 962–963
nitrogen gradient in, 962
oxygen gradient in, 960–962, 961f–962f
pulse Doppler oximetry in, 963
trace inert gases gradient in, 963, 963f–964f
factors regulating, 964–967
distribution of ventilation and, 967, 967b
hypoxic pulmonary vasoconstriction and, 965–966, 965f–966f
nitric oxide and, 967, 968f
pulmonary arterial pressure and, 964–965
vasoactive mediators in, 966–967
liquid ventilation and, 1067–1068
perinatal transition in, 964, 964f
Ventricles
of brain, embryonic development of, 1751
cardiac
action potential of, 736f, 738f
congenital heart disease and function of, 779, 781f, 783f, 785, 787, 787f of, 782–784
myocardial and septal development in, 698–699
Ventricular septal defect, 757–758, 786
Ventriculoinfundibular flange or ridge, 698
Vernix, 680–683, 683f–684f
Very-low-birth-weight infants
glucose metabolism in, 529–530
skin of, 688–689, 688f, 689b
Very-low-density lipoproteins, 441, 442f, 511, 511f
Vesicles, transsyncytial movement of, 137
Vestibular system, 1883f
Villi, placental, 110–116, 110f, 134t
anchoring, 108, 116
development of, 108–109, 109f
fetal endothelium and, 110
fetoplacental angioarchitecture and, 113f, 114
intervillous space of, 116
maternofetal barrier integrity and, 113
trophoblast of, 110–113, 112f
types of, 111f, 113–114, 113f–114f
Villous stroma, 110, 112f
Villous trees, 111f, 114–116, 114f–115f
Vimentin, 1934–1935, 1935f
Viruses
host defense against, 1570
adaptive, 1570, 1570t, 1580
B cells, antibody, and complement in, 1588–1589
CD28/CD80-86 co-stimulation in, 1586–1587
CD4 T cell–mediated, 1581–1584, 1581b, 1583f
CD8 T cell–mediated, 1584–1585, 1584t, 1586f
chemotactic and homing receptor expression in, 1587
γδ T cells in, 1587–1588
natural killer T cells in, 1588
T cells in, 1580–1581, 1580f
complement in, 1588–1589, 1646–1647
herpes simplex as prototype of, 1570–1571
innate, 1570–1572, 1570t
cellular mechanisms of, 1577
chemokines in, 1577
cytokines in, 1575–1577
interferons in, 1573–1575
pattern recognition receptors in, 1572–1573, 1572t, 1573f
surfactant proteins in, 1577
intrauterine infection by, 156–157, 157t
Visceral and craniofacial malformations, 56, 57t
Visual attention, 504
Visual cortex, 1779, 1779f, 1781
Visual function
fatty acids and, 464, 497, 500–503
maternal marijuana use and, 279
Visual system, 1883f
Vitamin A, 409–415. *See also* Retinoic acid; Retinol.
brain development and, 1864
bronchopulmonary dysplasia and, 881, 1056
deficiency of, 412–413
digestion and absorption of, 412, 412f
enteral nutrition and, 411–412
fetal acquisition of, 409–410
forms of, 409, 410f
guidelines for, 413
lung growth and, 890
metabolism of, 409, 410f–411f
parenteral nutrition and, 412
plasma status at birth, 410–411
plasma transport of, 409
toxicity of, 413
Vitamin B_{12}, 1864
Vitamin C, 429–431
Vitamin D
brain development and, 1867
for breast-fed infants, 324–325
calcium homeostasis and, 356–358, 357f, 386–387, 388f, 1374
calcium transport and, 367–368, 389–392, 391f
lung growth and, 890
magnesium homeostasis and, 389
magnesium transport and, 398
phosphorus homeostasis and, 388
phosphorus transport and, 369, 394–395
Vitamin D receptor, 358, 367–368
Vitamin E, 415–435
for anemia of prematurity, 1513t–1514t, 1515
antioxidant function of, 417
deficiency of, 417–418
excretion of, 418
fetal accumulation of, 423, 424f, 425t
functional requirements for, 417–418, 423, 424f, 427–432
future directions for, 427
history of, 416–417
hyperlipidemia of pregnancy and, 422, 424–426, 424f, 426f–428f, 426t–427t
intestinal absorption of, 418
membrane content of, 418, 423–424, 425f
non-antioxidant function of, 417
nutritional role of, 419–420
plasma lipids and lipoproteins in newborn and, 421–423, 422t, 423f
plasma lipoproteins and, 420–421, 421f
plasma transport of, 420
sources and activity of, 416t, 417f, 418–419, 419t
Vitamin K, 435–440
blood coagulation and, 435–436
forms of, 436, 436f
function and metabolism of, 436–437, 436f–437f
γ-carboxylation system and
maturation of, 437–438, 437f–438f
regulation of, 438–439, 439f
in human milk, 331
supplemental, 234–235, 324–325
Vitamins
for anemia of prematurity, 1513t–1514t, 1515
growth plate control by, 1914–1915, 1914t
in human milk, 324–325, 324t, 327t
placental transfer of, 234–235, 241
Vitelline arteries, 773
Vitelline veins, 701, 773–774
Vitronectin, 1644
Volume loading, responses to, 1442
Volume of distribution
body water, 1445–1446, 1446f
drug, 213, 226
fetal, 260–261
in tracer studies, 518
Volume-pressure loops in pulmonary graphics monitoring, 1019–1022, 1020f–1021f
Volume reserve of neonatal heart, 786
Volutrauma, 1042
Volvulus, gastric, 1189
von Willebrand factor, 1538, 1540t, 1542t
cord platelets and, 1544
procoagulant properties of, 1548–1549, 1548f

W

Waardenburg syndrome, 674, 674t, 1750
Warfarin
breast-feeding and, 295
placental transfer of, 239
protein binding of, 238–239
vitamin K and, 436–437, 437f
Warm shock, 858
Water. *See also* Body water; Lung liquid.
placental transfer of, 138, 1402, 1438
urinary excretion of, 1412–1415, 1414f
urinary reabsorption of, 1392–1396, 1393f
fetal, 1400–1401, 1401f
neonatal, 1410, 1410f
Weaning
pancreatic secretion and, 1234
urinary concentration and, 1404, 1404f
Weight. *See also* Birth weight; Low-birth-weight infants.
fetal, 47f, 585, 585f–586f, 586t–587t
maternal, multiple pregnancy and, 201
neonatal
body composition and, 342, 343t
breast-feeding and, 325–326
loss of, 1439
measurement of, 311, 343–344
Western blotting, 12
White blood cell count, fetal, 1489t. *See also* Leukocyte(s); *specific cell type.*
White matter
cerebral, hydrocephalus and injury to, 1841
periventricular
injury to, 1840
lesions of, 1835t
Whole-body plethysmography, 1013
Wilms tumor suppressor gene, 2031, 2032f
Window current, 735
Withdrawal reflex, 1870–1871, 1873
Wnt7b gene, 714–715, 760, 764f
WNT-4/Wnt-4 gene, 2018–2019, 2029
WNT/Wnt proteins
brain development and, 1307–1308, 1863
growth plate development and, 1908, 1909f, 1910–1912
renal development and, 1311
Wohlfart a- and b-fibers, 1937–1939, 1938f
Wolffian ducts, 2031–2032
WT-1/Wt-1 gene, 2016–2017

X

Xanthines for apnea, 1006–1007, 1007b
X chromosome, 1, 2014
Xenon clearance techniques for cerebral blood flow measurement, 1827–1828
X-linked disorders, 8f, 9–10

Y

Y chromosome, 1, 2014–2015, 2022
Yolk sac
  cholesterol from, 449–450
  erythropoiesis in, 1495, 1496f
  hematopoiesis in, 1470–1471, 1486
  megakaryocytopoiesis in, 1526
Yolk sac placenta, 134t
Young and Laplace, law of, 1097–1099, 1103

Z

Z-bands of striated muscle, 1936, 1936f
Z-disk of cardiac sarcomere, 718–720, 720f, 726
Zero-order kinetics of drug elimination, 220, 226
ZFY/Zfy gene, 2014–2016
Zinc, 403–408
  biochemistry and biology of, 403–404
  deficiency of, 406–407
  homeostasis of, 405–406
  metabolism of, 404–405
  premature infant requirements for, 407
  supplements of, 325
Zinc-containing neurons, 404
Zinc finger motif, 404
Zona pellucida, 34–37, 35f, 37f
Zone of progression, 85
Zone of provisional calcification, 1913
Zones of polarizing activity
  in limb growth, 85, 1909, 1909f, 1918–1919
  in neural plate, 1864
Zygosity, 198
Zygote, 37, 2015
