During labor, an increase in fetal blood pressure (e.g., caused by a compression of umbilical cord) leads to bradycardia by initiating a vagal nerve reflex. Fetal hypoxemia can have a direct depressing effect on the function of the central nervous system and fetal myocardium, which can result in a decrease in, or even loss of, FHR variability. The complex effects of hypoxemia and developing acidemia on chemoreceptors of the fetus result in an increase of blood pressure and bradycardia.[98] During labor, signals of fetal heart action can be detected either transabdominally by using a Doppler ultrasound transducer or, after rupture of membranes, transcervically with a fetal scalp electrode. From the measured beat-to-beat intervals, FHR is calculated and recorded simultaneously with the signals of uterine activity as a cardiotocogram. Uterine activity is recorded either with an external tocodynamometer or with an intrauterine pressure catheter. Cardiotocography is widely used today as the preferred method for monitoring fetal health in labor.

FETAL ELECTROCARDIOGRAM IN LABOR

Fetal electrocardiogram (ECG) signals are easily obtained from the fetal scalp during labor. The early interest of researchers in revealing information on fetal myocardial function from the ECG was hampered by difficulties in obtaining signals of good quality and performing accurate waveform analysis.[99] Technologic developments have made it possible to design computerized techniques for improved isolation and analysis of fetal ECG signals.

In studies on animal fetuses, it has been shown that the ECG waveform is changed in a characteristic fashion with fetal hypoxia.[100,101] When the oxygen supply is insufficient to satisfy the energy needs of fetal myocardium, myocardial energy balance becomes negative, metabolism changes to anaerobic, and acidosis occurs. When the fetus compensates for hypoxia by

additional glycogenolysis, an elevation occurs in the ST segment of the waveform and an increase in the height of the T wave. This change can be quantified by calculating a ratio between the amplitude of the QRS complex and the T wave (T/QRS ratio), which in noncompromised fetuses does not exceed 0.25. In normal fetuses, a direct correlation exists between the PR interval and FHR. This relationship is inverted and the PR interval shortens[102] with fetal acidosis, which might enable distinction between FHR decelerations of various origins. The first studies in human fetuses during labor reported promising results, suggesting that changes in the fetal ECG waveform may be an early sign of fetal hypoxia.[103] The clinical usefulness of this new method of fetal surveillance during labor was demonstrated in two large randomized controlled trials.[104,105] In the Swedish trial comprising 4966 parturients, the cardiotocography plus automatic analysis of fetal ST-segment was shown to reduce both the cord artery metabolic acidosis rate and the rate of operative delivery for fetal distress.[105] In addition, it was shown that cardiotocography plus ST analysis provides information on intrapartum hypoxia, thus allowing for intervention in time and prevention of intrapartum asphyxia and neonatal encephalopathy.[106]

76 Physiology of Resuscitation

Ola Didrik Saugstad

Of the approximately 130 million annual births globally, it has been estimated that 5 to 7 million newborn infants need some kind of intervention immediately after birth; of these, 1.3 million require more extensive resuscitation.[1-5] To perform an optimal resuscitation procedure, it is important to understand the physiologic events that occur as the fetus makes the transition from intrauterine to extrauterine life and the physiologic changes that occur during asphyxia and resuscitation.

It has been estimated that 50% to 70% of infants who require resuscitation at birth come from high-risk pregnancies, and therefore the need for resuscitation often can be predicted.[6] Nonetheless, at least 30% of babies who require resuscitation with endotracheal intubation come from apparently low-risk situations, a finding demonstrating the need for attendance by expert personnel after birth.

BASIC PHYSIOLOGIC CHANGES

Our basic knowledge of the physiologic changes during peripartum asphyxia and resuscitation comes from animal experiments in the early 1960s.[7] However, newer techniques, such as near-infrared spectroscopy and proton spectroscopy, have taught us more about the sequence of biochemical and physiologic changes during and after an asphyxial event.

The classic data from Dawes and associates from experimental studies with rhesus monkeys are presented in Figure 76-1.[4,5,7] This illustration represents the basis for our current understanding of the physiology related to asphyxia and resuscitation. These data also describe changes in pulse, respiration, and blood pressure and emphasize the difference between primary and secondary apnea.

In this model, rhesus monkeys were delivered by cesarean section, the umbilical cord was immediately tied, and the animals were prevented from breathing by immediately sealing their heads in a bag of saline solution. After a few shallow breathing movements, respiratory efforts stopped, and the animals developed primary apnea, which, in some cases, lasted for up to 10 minutes. However, after 1 to 2 minutes of primary apnea, gasping movements often started and progressed with increasing vigor and frequency. These respiratory efforts were accompanied by thrashing movements of the extremities. In this period, spontaneous ventilation could still be induced by appropriate sensory stimuli. The heart rate decreased from 200 beats/minute in the normal fetal rhesus monkeys to 100 beats/minute. After 4 to 5 minutes, a series of spontaneous deep gasps occurred that gradually became weaker until the last gasp after approximately 8 minutes. Cardiac activity continued for 10 minutes or more before cardiac arrest. The period between the last gasp and cardiac arrest is known as secondary or terminal apnea.

Blood pressure initially increased during primary apnea, but it then abruptly decreased and reached a plateau before declining during secondary apnea. The longer the period before the initiation of ventilation, the greater was the delay until the animal took its first spontaneous gasp. For every minute of delay in establishing assisted ventilation, the time to first gasp was delayed by 2 minutes, and the time to spontaneous rhythmic ventilation was delayed by 4 minutes (Figure 76-2).[8]

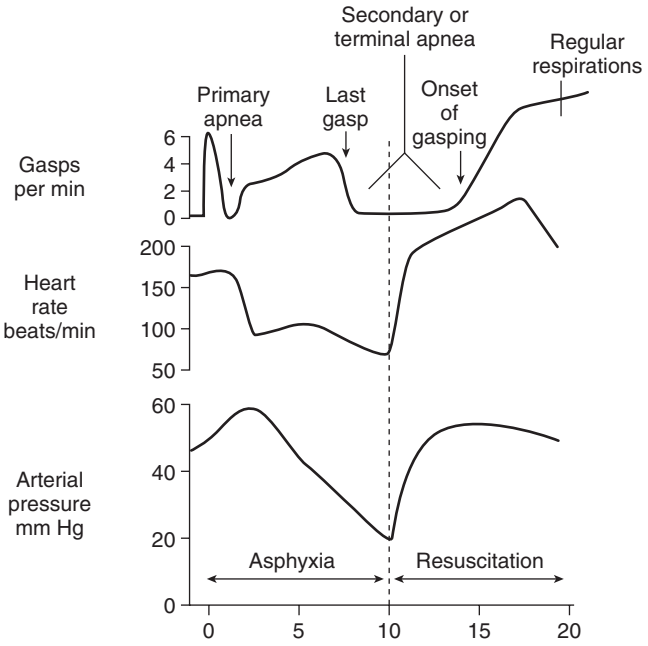

Figure 76-1 The relation between heart rate, blood pressure, and respiratory efforts in rhesus monkeys during asphyxia and resuscitation. *(From Dawes GS, Jacobson HN, Mott JC, et al: The treatment of asphyxiated, mature foetal lambs and rhesus monkeys with intravenous glucose and sodium carbonate,* J Physiol (Lond) *169:167, 1963.)*

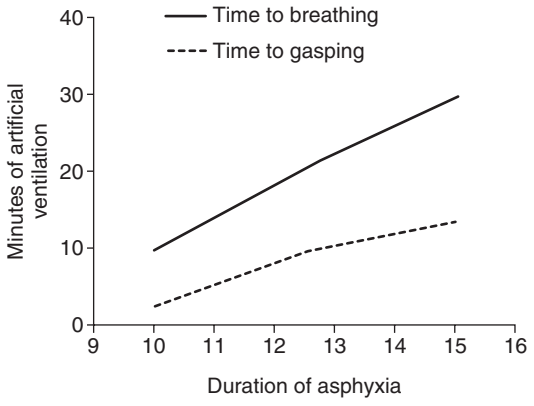

Figure 76-2 The relation between the duration of asphyxia and artificial ventilation until the first gasp and breath are detected. *(Data from Adamsons K Jr, Behrman R, Dawes GS, et al: Resuscitation by positive pressure ventilation and tris-hydroxymethylaminomethane of rhesus monkeys asphyxiated at birth,* J Pediatr *65:807, 1964.)*

TABLE 76-1

Changes in Apgar Scores during the First 10 Minutes of Life

1-min Apgar	5-min Apgar	10-min Apgar
4 (1-7)	7 (3-9)	8 (4-9)
40%*	6%*	3.4%*
94%†	29%†	13%†

Values are median (5th to 95th percentile) Apgar scores in 600 newly born infants needing resuscitation.
*Percentage with Apgar score <4.
†Percentage with Apgar score <7.

During severe asphyxia, the pH drops from 7.30 to 6.80 within 5 minutes, which is primarily the result of an increase in arterial carbon dioxide tension of 10 mm Hg (1.3 kPa) per minute. By the end of secondary apnea, arterial carbon dioxide tension can exceed 100 mm Hg (>13 kPa), and serum potassium level can rise to 15 mmol/L or more.[4]

The physiologic changes that occur with asphyxia and resuscitation were also assessed in a newborn piglet model in which hypoxia was induced by exposure to 8% oxygen (O_2), followed by 20 minutes of active resuscitation with different O_2 concentrations.[9-11] Although this model differs in several ways from human intrauterine asphyxia, it likely describes general principles in the physiologic response to neonatal asphyxia and reoxygenation. In this model, arterial oxygen tension (Pa_{O_2}) typically decreases to 20 to 30 mm Hg (3 to 4 kPa) within 5 minutes, with severe hypotension and lactic acidosis.[9-11]

Another model includes repetitive episodes of intrauterine hypoxia in animals. This causes global neuronal, cortical, midbrain, and cerebellar damage. Damage to the watershed areas between the areas of blood vessels supplying the cerebral cortex is commonly observed.[4] This is an important model because the human fetus may have recurrent episodes of acute, total, or partial asphyxia before the start of labor, with recovery of biochemical abnormalities. Thus severe asphyxial damage may occur without a decrease in fetal pH, and the child may have a normal Apgar score after delivery.[4]

RESPONSE TO RESUSCITATION

A newborn infant who does not breathe may have had birth asphyxia. However, apnea can also be caused by central nervous system depression resulting from maternal drugs, central nervous system injury, septicemia, anemia, primary muscular or neurologic disease, or congenital malformations obstructing the airways. Premature infants may not initiate respirations at birth because of muscular weakness or poorly compliant lungs.[4] These babies are often in need of immediate intervention, and a great need exists for a quick and easy way to assess the response of the resuscitative efforts.

Apgar Scoring

The Apgar scoring system is not the best means to assess the acute response of resuscitation, because it is taken first at 1 minute and then at 5 minutes. Moreover, most babies with an umbilical cord pH lower than 7.10 have normal Apgar scores; only when the pH is less than 7.00 are low Apgar scores commonly observed.[12] The five components of the Apgar scoring system (heart rate, respiration, muscle tone, reflex responsiveness, color) are indicators of different physiologic responses and therefore carry different significance. Heart rate and respiration are obviously more important than reflex responsiveness. Muscle tone represents higher cerebral function, whereas the other components, including heart rate, respiration, and reflex responsiveness, are brain stem responses.[4] Color is dependent on both respiration and heart rate. Rapid achievement of higher Apgar scores has, traditionally, been considered the hallmark of a successful resuscitation, and persistent low Apgar scores may be related to poor prognosis.[13,14]

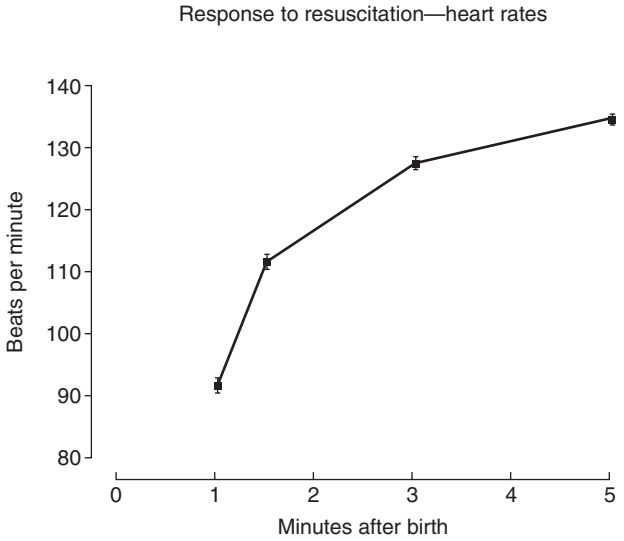

Figure 76-3 Heart rate development in newborn infants requiring resuscitation at birth. *(Data from Saugstad OD, Ramji S, Rootwelt T, Vento M. Response to resuscitation of the newborn: early prognostic variables,* Acta Paediatr *94:890, 2005.)*

In a clinical study in 600 newborn infants who required resuscitation at birth because of bradycardia (heart rate <80 beats/minute) or apnea, the median 1-minute Apgar score increased from 4 to 8 within 10 minutes.[15] Table 76-1 shows the median Apgar scores in this population and the percentage with an Apgar score of less than 4 and less than 7, respectively. However, a controversy has arisen over whether resuscitation with room air is preferable, and in one study the Apgar score was, in fact, higher in those resuscitated with room air compared with pure O_2.[15]

Heart Rate

The best way to assess the response to resuscitation is to count the pulse. This can be done by listening to the heart by stethoscope or by palpating the pulse at the base of the umbilical cord. In infants with a 1-minute Apgar score higher than 6, the median heart rate at 1 minute was more than 130 beats/minute. Figure 76-3 shows heart rate responses, between 1 and 10 minutes of life, in a population of 600 newborn infants who required resuscitation.[15] Median heart rate was restored from approximately 90 to 114 beats/minute at age 60 to 90 seconds. From 3 minutes onward, heart rate remained stable (>130 beats/minute). The lower the Apgar score, the lower was the initial heart rate. When the Apgar score was less than 4 at 1 minute, the median heart rate was 80 beats/minute at 60 seconds and 100 beats/minute after 90 seconds. However, after 3 minutes, the median heart rate returned to a normal range. Table 76-2 shows median heart rates the first 10 minutes of life related to Apgar score at 1 minute.

In the population noted earlier, only 1.7% had a heart rate lower than 60 beats/minute after 3 minutes of resuscitation, and 1% after 5 minutes. In patients with persistent bradycardia, chest compressions are recommended, according to the current resuscitation guidelines of the American Heart Association, the American Academy of Pediatrics, and the International Liaison Committee on Resuscitation.[16,17] In the study population described earlier, chest compressions were performed in nearly 20% of cases, even though this approach was indicated in only

TABLE 76-2

Heart Rate and Arterial Oxygen Saturation in Relation to 1-minute Apgar Score

	Min	1-min Apgar ≥7	1-min Apgar <7	1-min Apgar <4
HR	1	136 (85-156)	86 (40-140)	80 (10-131)
	1.5	140 (110-156)	110 (60-150)	100 (50-158)
	3	142 (120-167)	130 (80-163)	128 (69-160)
	5	142 (136-164)	140 (100-168)	139 (80-168)
	10	142 (120-169)	140 (110-170)	140 (100-174)
Sa_{O_2}	1	75 (57-82)	65 (40-82)	60 (40-81)
		57/79	*67*/60	*65*/58
	3	90 (65-98)	85 (59-92)	80 (41-94)
		65/90	*85*/85	*82*/78
	5	93 (84-98)	90 (68-95)	87 (62-96)
		86/95	*90*/90	*87*/85
	10	94 (88-96)	92 (80-97)	90 (72-97)
		88/95	*92*/90	*90*/90

Values are median and 5th to 95th percentiles for heart rate (HR, beats/minute) and arterial oxygen saturation (Sa_{O_2}, %) according to 1-minute Apgar score the first 10 minutes after birth in 600 newborn infants requiring resuscitation at birth. Median values for Sa_{O_2} are given separately also for *room air*/100% O_2 resuscitated, respectively. (From Saugstad OD, Rootwelt T, Aalen O: Resuscitation of asphyxiated newborn infants with room air or oxygen: an international controlled trial: the Resair 2 study, *Pediatrics* 102:1, 1998.)

1% to 2% of the infants, a finding suggesting an inappropriate and overly aggressive approach in many cases.

Time to First Breath

The time to first breath and first cry (and to a normalization of the breathing pattern) is another simple means to assess the response to resuscitation. It has been reported that time to first breath is approximately 10 seconds in healthy term infants after vaginal delivery and 15 seconds after cesarean section.[18]

In the population of 600 infants noted previously, those with 1-minute Apgar score higher than 6 took their first breath at a median time of 42 seconds. No differences were seen between term infants and preterm infants (>1000 g birth weight). Those resuscitated with ambient air took their first breath and cried significantly earlier than infants given pure O_2.[15] In term babies, median time to first breath increased to 90 seconds when the 1-minute Apgar score was <7 and 120 seconds if the 1-minute Apgar score was <4. Time to first breath was approximately three times longer when the heart rate at 1 minute was <60 versus 80 beats/minute. Table 76-3 shows the median time to first breath and cry related to 1-minute Apgar scores and heart rates at 1 minute. Data for room air, as well as infants resuscitated with 100% O_2, are given.

In another series of normal babies, the mean time to first audible cry was 36 seconds (with a SD of 24 seconds). In asphyxiated babies needing resuscitation, first cry occurred in mean at 72 seconds with room air resuscitation and at 102 seconds for those resuscitated with pure O_2. The mean time to establish a regular, spontaneous respiratory pattern with effective respiratory movements (allowing a maintenance of heart rate and arterial O_2 saturation [Sa_{O_2}] greater than 90%) was less than 1 minute in normal, nonasphyxiated term infants, 4.6 minutes with room air resuscitation, and 6.6 minutes for infants resuscitated with 100% O_2.[19,20] Therefore, as in studies in animals, pure O_2 inhibits respiratory activity in the newborn infant.[21,22]

Oxygen Saturation

Another means to assess the response to resuscitation is to follow Sa_{O_2} by pulse oximetry. Normal Sa_{O_2} values for term infants during the first 10 minutes after birth have been reported.[23]

TABLE 76-3

Time to First Breath and First Cry in Relation to 1-minute Heart Rate and Apgar Score

	1-min HR ≥80	1-min HR <80	1-min HR <60	1-min Apgar >6	1-min Apgar <4
First breath	1.0 (0.25-5.0) *1.0*/1.33	1.5 (0.25-27.4) *1.5*/2.0	3.0 (1.0-44) *2.5*/3.0	0.75 (0.25-2.1) *0.64*/0.75	2.0 (0.6-30) *2.0*/2.5
First cry	2.0 (0.5-14.9) *1.5*/2.0	2.1 (0.5-1032) *1.8*/3.0	3.5 (1.5->) *3.0*/4.3	1.0 (0.5-2.4) *1.0*/1.0	3.5 (1.0->) *3.0*/4.0

Values are median and 5th to 95th percentile time in minutes after birth to first breath and cry according to heart rate (HR, beats/min) at 1 minute after birth in 600 newly born infants requiring resuscitation at birth. Median values are given also for *room air*/100% O_2 resuscitated, respectively, >, An upper limit could not be established based on these data. (From Saugstad OD, Rootwelt T, Aalen O: Resuscitation of asphyxiated newborn infants with room air or oxygen: an international controlled trial: the Resair 2 study, *Pediatrics* 102:1, 1998.)

TABLE 76-4

Changes in Arterial Oxygen Saturation According to 1-minute Heart Rate

Min	1-min HR ≥80	1-min HR <80	1-min HR <60
1	70 (39-82)	60 (40-75)	45 (40-99)
3	85 (41-94)	85 (60-93)	76 (60-94)
5	90 (72-96)	90 (69-95)	80 (60-93)
10	93 (70-97)	90 (80-97)	90 (76-99)

Values are median Sa_{O_2}, % (5th to 95th percentiles) in the first 10 minutes of life according to heart rate (HR, in beats/min) at 1 minute after birth in newly born infants requiring resuscitation at birth. (From Saugstad OD, Rootwelt T, Aalen O: Resuscitation of asphyxiated newborn infants with room air or oxygen: an international controlled trial: the Resair 2 study, *Pediatrics* 102:1, 1998.)

For infants with a 1-minute Apgar score higher than 6, the median Sa_{O_2} value increased from 75% (at 1 minute) to 90% after 3 minutes and to 93% and 94% after 5 and 10 minutes, respectively. When the 1-minute Apgar score was less than 4, Sa_{O_2} values increased from 60% at 1 minute to 80% at 3 minutes and to 87% and 90% at 5 and 10 minutes of life, respectively (see Table 76-2). Surprisingly, the Sa_{O_2} was identical with use of either room air or 100% O_2 for resuscitation—paradoxically, with a tendency to higher Sa_{O_2} in room air–resuscitated infants. However, in children with a 1-minute Apgar score >6, Sa_{O_2} was significantly higher in those given 100% O_2 (90% vs. 75% at 3 minutes and 95% vs. 86% at 5 minutes, with no differences at 10 minutes). Supplemental O_2 therefore does not elevate Sa_{O_2} faster than room air during the first 10 minutes of life in depressed infants, but it does in nondepressed infants. Table 76-4 shows the development in Sa_{O_2} during the first 10 minutes of life according to 1-minute Apgar score. Figure 76-4 depicts the changes in Sa_{O_2} in asphyxiated and nonasphyxiated term infants during the first 10 minutes of life.[24]

METABOLIC CHANGES

The changes in base deficit (BD) during hypoxia and reoxygenation in newborn piglets are shown in Figure 76-5.[11] The increase in BD exhibited a linear relationship with the duration of hypoxia. Hypoxia induced by the breathing of 8% O_2 resulted in a rise in BD of 0.4 mmol/L/minute compared with a rate rise of 0.67 mmol/L/minute when animals breathed 6% O_2. During reoxygenation, BD continued to increase or plateau during the first 5 minutes or so, most likely because of vasodilatation in peripheral tissues with release and washout of lactic acid and

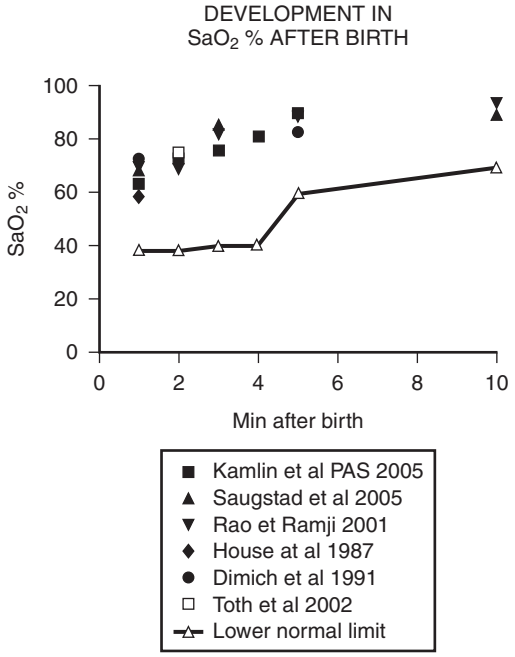

Figure 76-4 Development in arterial oxygen saturation in nonasphyxiated newborn infants. *(From Saugstad OD: Oxygen saturations immediately after birth,* J Pediatr *148:569, 2006.)*

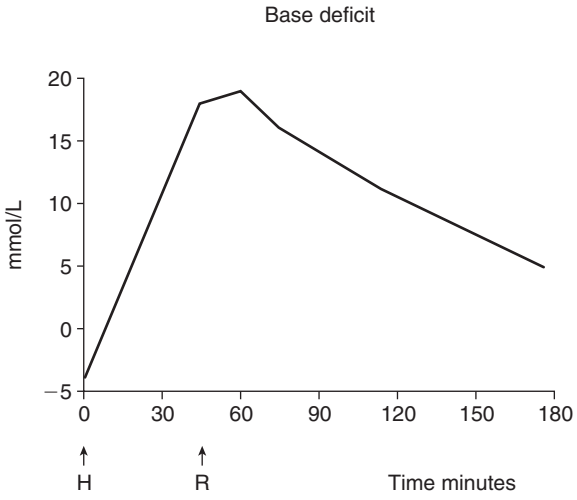

Figure 76-5 Development in base deficit in newborn piglets during hypoxemia *(H)* (inspired oxygen fraction, 0.08) and during reoxygenation *(R). (Data from Medbo S, Yu XQ, Asberg A, Saugstad OD: Pulmonary hemodynamics and plasma endothelin-1 during hypoxemia and reoxygenation with room air or 100% oxygen in a piglet model,* Pediatr Res *44:843, 1998.)*

other metabolites. This phase was followed by a steady decrease of BD with a typical rate of approximately 0.17 mmol/L/minute between 30 and 60 minutes and 0.12 mmol/L/minute between 60 and 90 minutes after onset of reoxygenation.[10-12] These data indicate that, depending on the severity and duration of the hypoxemia, it takes 2.5 to 4 times the duration of hypoxia to normalize BD. A similar pattern and relationship have been observed for arterial hypoxanthine.

Figure 76-6 shows the changes in heart rate compared with BD in newborn infants requiring resuscitation.[25] The decrease of BD

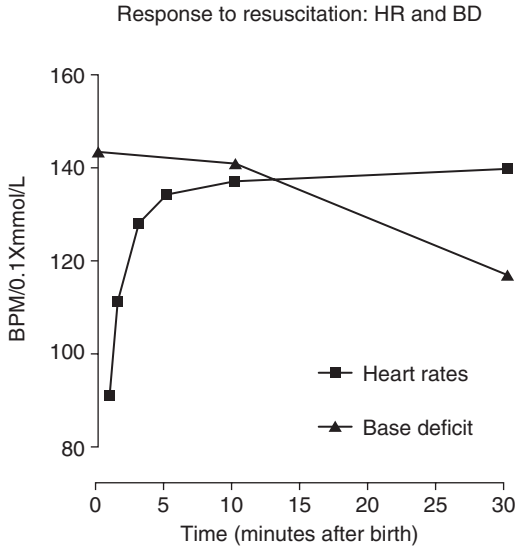

Figure 76-6 The change in heart rate *(HR)* compared with base deficit *(BD)* in newborn infants requiring resuscitation. *(From Saugstad OD: Resuscitation with room-air or oxygen supplementation,* Clin Perinatol *25:741, 1998.)*

in human infants follows the same pattern and rate as in piglets, decreasing 6 to 7 mmol/L/hour. It can be inferred from this figure that heart rate changes represent a rapid response to successful resuscitation, whereas metabolic changes are slower indicators of the success of resuscitation.

In the brain, excitatory amino acids such as glutamate and aspartate increase in the striatum during hypoxemia, and the concentrations double during the first minutes of resuscitation before a rapid decline. Normalization is reached within 15 minutes after start of resuscitation, but a secondary peak in these amino acids may be found several hours after asphyxia.[26]

The concentration of nitric oxide decreases in the brain during hypoxia and increases rapidly during reoxygenation, exceeding basal levels by approximately 40% (more so in infants resuscitated with 100% O_2 than in those resuscitated with room air).[27] Hydrogen peroxide in lymphocytes in the sagittal sinus also increases during reoxygenation, although not when room air resuscitation is used.[28]

REGULATION OF BREATHING

Breathing in fetal life is controlled by several factors. It is inhibited at the brain stem level by humoral factors such as endogenous opioids, prostaglandins, and adenosine, and it is stimulated by carbon dioxide, during active sleep. Hypoxemia completely inhibits breathing. During parturition, breathing movements are completely inhibited; however, severe asphyxia can induce gasping movements, resulting in the aspiration of meconium during delivery.[29]

The first breaths normally are vigorous, a finding suggesting a strong respiratory drive. Breathing is triggered by numerous mechanisms, such as removal of placental humoral inhibitory factors, cooling, catecholamine surge induction of genes encoding for substances important for breathing (e.g., substance P), and rising carbon dioxide concentrations. Because the set point for Pao_2 oxygen tension is relatively low after birth, it seems counterintuitive that a high O_2 concentration during resuscitation would delay the time to first breath. It takes 2 to 3 days until the set point of the peripheral chemoreceptors is increased to adult levels.[29]

EFFECTS OF FIRST INFLATIONS

Insufflation Pressure

The insufflation pressure needed to open the lungs after birth varies, but an opening pressure greater than 10 cm H_2O is rarely needed. In most babies, air enters the lungs as soon as the intrathoracic pressure begins to fall. In more than 80% of newborn infants needing artificial ventilation, this is satisfactorily achieved by bag and mask.[30]

When resuscitation is performed, one should use only the minimal pressure needed to achieve small chest wall excursions. Generally, peak intrathoracic pressures of 20 to 30 cm H_2O are sufficient. However, an occasional infant may require pressures of 40 to 50 cm H_2O if air entry is poor.[31]

When positive pressure ventilation is applied to intubated newborn babies in need of ventilatory support immediately after birth, various reactions have been described. The most common response to lung inflation is the generation of a large positive intrathoracic (intraesophageal) pressure (≤82 mm Hg, 11 kPa). Head's paradoxical reflex is also commonly seen during bag and mask ventilation. This means that the inflation triggers an inspiratory effort, creating a negative esophageal pressure; levels up to 48 cm H_2O have been described. Such inspiratory efforts often produce a fall in inflation pressure. Occasionally, no change in esophageal pressure is observed.[32,33]

Poor Efficacy of Bag and Mask Ventilation

The efficacy of face mask respiration has been questioned. Tidal volume exchange can be less than one third of that noted with endotracheal intubation. Even when very high pressure is used, (≤40 cm H_2O) mean tidal exchange is less than in babies with endotracheal intubation. Face mask ventilation is helpful in establishing a functional residual capacity. Figure 76-7 shows expiratory tidal exchange with the first three breaths in infants receiving ventilation by face mask versus those who had intubation. For the first breath, expiratory tidal exchange by face mask is only one fifth of that measured in infants with endotracheal intubation.[34]

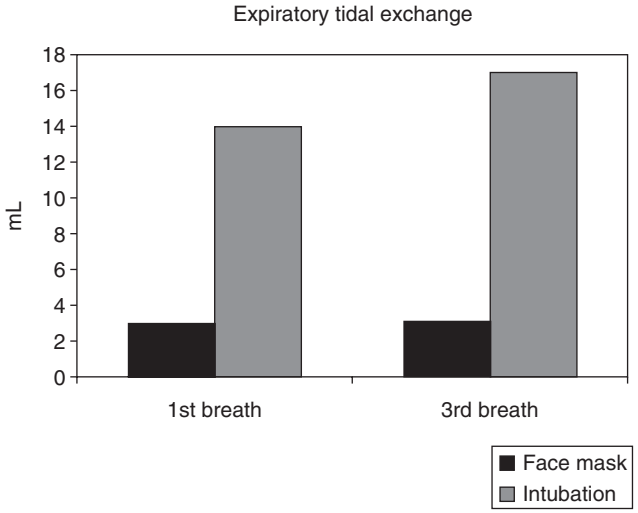

Figure 76-7 Tidal exchange in the first three breaths in term newborn infants receiving ventilation with bag and mask versus intubation. *(Data from Milner AD, Vyas H, Hopkin IE: Efficacy of facemask resuscitation at birth,* BMJ *289:1563, 1984.)*

First Inflations in Premature Infants

The patterns described previously are probably not relevant for premature infants. In the smallest babies, heart rate and blood pressure quickly decline with the onset of hypoxemia. Furthermore, the response to resuscitative efforts in the preterm infant is affected by the state of surfactant sufficiency or deficiency. A few manual breaths with a high tidal volume (30 to 40 mL/kg) in premature, surfactant-deficient newborn lambs can induce lung injury. Large inflations at birth also cause an uneven surfactant distribution and may compromise the effect of surfactant. Therefore it is extremely important to initiate ventilation gently in these babies.[35] In newborn infants less than 29 weeks gestational age who received surfactant before the first breath, the median inspiratory pressure needed was 20 cm H_2O. Fewer than one fifth of these infants needed more than 20 cm H_2O, and none needed more than 30 cm H_2O. The use of high inspiratory pressures may contribute to an increased risk of chronic lung disease.[35-37]

HEMODYNAMIC CHANGES

Systemic Blood Flow and Myocardial Function

Blood pressure follows a typical pattern during hypoxia and resuscitation, as described by Dawes and colleagues.[7] In the newborn piglet model, hypoxia increases mean arterial blood pressure initially from basal levels of approximately 70 mm Hg before it starts to fall[9-11] (Figure 76-8). During resuscitation with either

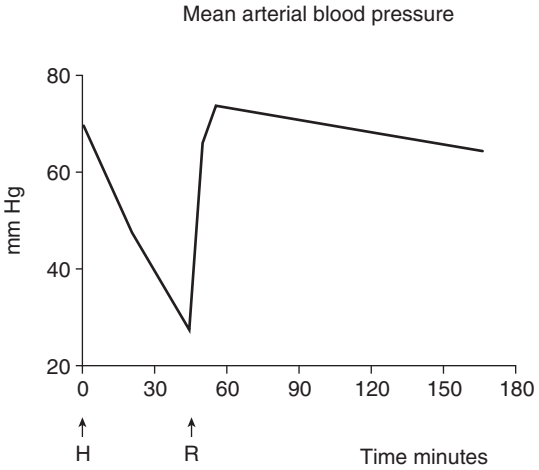

Figure 76-8 Change in blood pressure in newborn piglets exposed to hypoxia *(H)* and reoxygenation *(R). (Data from Medbo S, Yu XQ, Asberg A, Saugstad OD: Pulmonary hemodynamics and plasma endothelin-1 during hypoxemia and reoxygenation with room air or 100% oxygen in a piglet model,* Pediatr Res *44:843, 1998.)*

room air or 100% O_2, a rapid restoration of blood pressure was observed within 5 to 10 minutes; however, a secondary decline in blood pressure often occurred.[11] In this model, 2 hours after reoxygenation was initiated, some piglets needed inotropic support because of myocardial insufficiency, and markers of myocardial damage were found.[38]

Cardiac output follows a pattern similar to that of arterial blood pressure, with a 50% to 60% initial increase followed by a rapid decline, approximately 20 minutes after hypoxemia occurs. At the start of resuscitation, cardiac output was only approximately 50% of basal levels. However, resuscitation restored cardiac output quickly, and it reached levels approximately 30% higher than the basal levels (approximately 180 mL/kg/minute). Subsequently, a relatively rapid decline was observed, to 30% lower than basal levels 2 hours after start of resuscitation. Relatively speaking, the blood pressure is maintained better than cardiac output during

this period.[11] Systemic vascular resistance decreased by 25% to 50% during hypoxemia and increased to 75% to 90% of the basal level within 5 to 10 minutes after start of resuscitation.[11]

Pulmonary Blood Flow

Pulmonary artery pressure and vascular resistance also follow a biphasic pattern during hypoxia and reoxygenation, with a rapid increase in pulmonary vascular resistance during the first few minutes of hypoxemia, followed by a slower increase until a peak is reached at 50% higher than basal levels.[11] Pulmonary arterial pressure declines in parallel with cardiac output until the start of resuscitation. At that point, a rapid restoration of pulmonary arterial pressure is observed, sometimes even to higher than basal values (Figure 76-9). Within 2 to 3 hours, normalization of the pulmonary arterial pressure is found. However, in newborn infants who have inadequate responses to resuscitation, pulmonary arterial pressure may not decrease.

Pulmonary vascular resistance (Figure 76-10) immediately rises (approximately threefold) from basal values during hypoxia, but it returns to basal levels within 5 minutes of resuscitation in piglets. In this model, the pulmonary vascular resistance does not differ whether 21% or 100% O_2 is used during resuscitation.[11]

Cerebral Blood Flow

Cerebral blood flow in newborn piglets, as measured by radiolabeled microspheres, increases initially during hypoxemia, but then it declines with persistent hypoxia. During successful resuscitation, cerebral blood flow is quickly restored.[39] Blood flow in the microcirculation quickly falls to zero both in the cortex and in the striatum of hypoxic newborn piglets.[27,28,40] During resuscitation, blood flow in the cerebral circulation is restored; however, it can take substantial time, and sometimes it never reaches baseline. Resuscitation with 100% O_2 in piglets restored cerebral blood flow more efficiently than 21% O_2 when normocapnia was maintained. However, when resuscitation was performed in moderately hypercapnic animals, this difference was diminished.[40]

Premature infants randomly assigned to receive either 80% or 21% O_2 a few minutes after birth had a 20% reduction in cerebral blood flow in 80% O_2 compared with babies breathing 21% O_2.[41] It is still unknown whether rapid or slower restoration of cerebral blood flow is best for the preterm infant. However, restoration of cerebral blood flow that is too slow may not be beneficial.

BRAIN OXYGENATION

Brain oxygenation can be assessed experimentally by continuous measurements with a Po_2 electrode in the brain region of interest. Clinically, near-infrared spectroscopy can be used. During hypoxia, brain Po_2 quickly falls close to zero and is gradually restored during reoxygenation.

Near-infrared spectroscopy measurements in newborn piglets showed that the so-called *oxygenation index* (change in oxygenated hemoglobin minus change in deoxygenated hemoglobin) rapidly declines to zero; however, 5 minutes after the start of reoxygenation, it is higher than baseline with use of 21% or 100% O_2. The oxygenation index is significantly higher with 100% O_2 than with room air resuscitation.[42]

After the onset of hypoxemia in newborn piglets, the Pao_2 in the sagittal sinus dropped from 40 mm Hg to zero. After reoxygenation, an overshoot was found during the first 15 to 30 minutes, more so in animals reoxygenated with 100% O_2 than in those reoxygenated with 21% O_2. Sao_2 values in the sagittal sinus also dropped to zero during hypoxemia (from an initial level of 50%) and rose to 70% and 90%, respectively, with use of 21% and 100% O_2 for reoxygenation.[42]

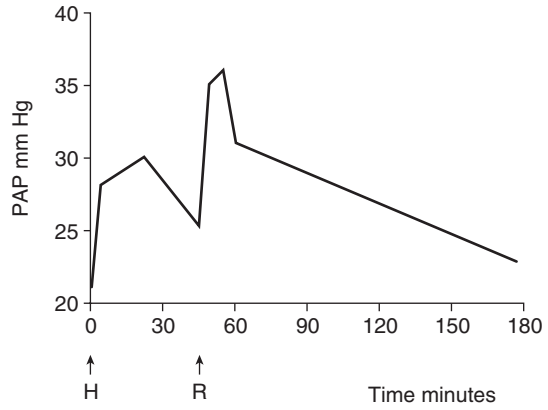

Figure 76-9 Change in pulmonary arterial blood pressure *(PAP)* in newborn piglets exposed to hypoxia *(H)* and reoxygenation *(R). (Data from Medbo S, Yu XQ, Asberg A, Saugstad OD: Pulmonary hemodynamics and plasma endothelin-1 during hypoxemia and reoxygenation with room air or 100% oxygen in a piglet model,* Pediatr Res *44:843, 1998.)*

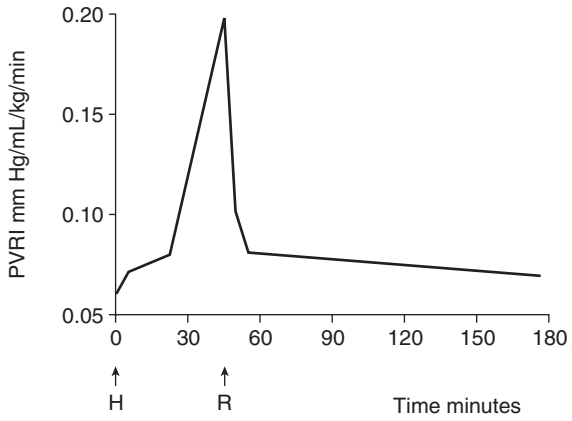

Figure 76-10 Change in pulmonary vascular resistance *(PVRI)* in newborn piglets exposed to hypoxia *(H)* and reoxygenation *(R). (Data from Medbo S, Yu XQ, Asberg A, Saugstad OD: Pulmonary hemodynamics and plasma endothelin-1 during hypoxemia and reoxygenation with room air or 100% oxygen in a piglet model,* Pediatr Res *44:843, 1998.)*

Using near-infrared spectroscopy, several investigations showed that cerebral blood volume increases markedly during hypoxia.[42,43] The blood volume of the brain continues to increase after initiation of resuscitation, and it reaches a maximum at 5 to 10 minutes, returning to baseline values after approximately 1 to 2 hours.

CEREBRAL ELECTROPHYSIOLOGIC CHANGES

The electroencephalogram (EEG) becomes isoelectric within approximately 20 minutes in newborn piglets breathing 8% O_2, but variation is great, with the 25th to the 75th percentile ranging from 7 to 37 minutes. The EEG waves reappear during resuscitation within a median time of 2 minutes in animals resuscitated

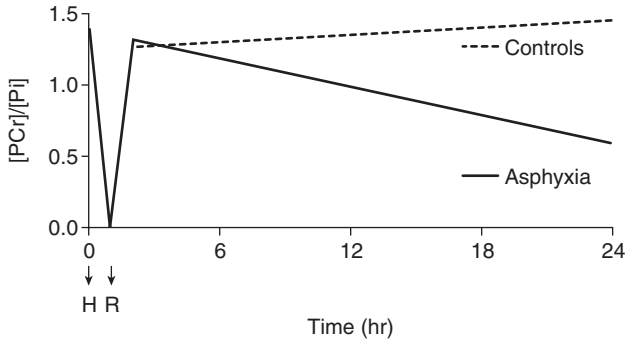

Figure 76-11 The ratio between phosphocreatinine *(Pcr)* and inorganic phosphate *(Pi)* in the newborn piglet brain assessed by proton spectroscopy during asphyxia and the postasphyxic period illustrating primary and secondary energy failure. *H,* Hypoxia; *R,* reoxygenation. *(Data from Lorek A, Takei Y, Cady EB, et al: Delayed ["secondary"] cerebral energy failure after acute hypoxia-ischemia in the newborn piglet: continuous 48-hours studies by phosphorous magnetic resonance spectroscopy,* Pediatr Res *36:699, 1994.)*

with 21% and 12 minutes if pure O_2 is used; however, those values are not significantly different. Within a 2-hour observation period, 75% of the piglets had EEG return to basal levels; of these, one third had an abnormal pattern.[44]

Somatosensory evoked potentials also disappeared during severe hypoxemia, but they reappeared in approximately 90% of the piglets during resuscitation. The amplitude increased steadily from zero at the beginning of resuscitation to approximately 25% after 30 minutes and to 50% to 60% of baseline after 60 minutes, followed by a stable plateau. No differences were found regardless of whether 21% or 100% O_2 was used for reoxygenation.[39,44]

ENERGY STATUS IN THE BRAIN

Proton magnetic resonance spectroscopy of the newborn piglet brain revealed that pH, adenosine triphosphate, and phosphocreatinine rapidly decreased during hypoxemia.[43,45] This is the so-called *primary energy failure*. However, during resuscitation, the energy status is quickly restored to normal levels. Typically, 8 to 36 hours later, a new gradual decline in the energy status of the brain occurs.[45,46] This secondary energy failure is associated with irreversible brain damage (Figure 76-11), a finding suggesting that a window for therapeutic options exists hours after restoration of the primary energy failure and before secondary failure occurs.

With use of spectroscopy techniques, it has also been established that increased intracerebral lactic acid levels are detected weeks after the initial hypoxic insult. In newborn infants with brain injury after a hypoxic ischemic episode, high lactate levels persisted more than a month after birth, in contrast to those who developed normally in spite of a hypoxic insult. Further, this high lactate level has been accompanied by persistent alkalosis. Because alkalosis accelerates lactic acid production, this may be the cause of the elevated lactic acid levels detected.[47] Possible mechanisms leading to persistent cerebral lactic alkalosis are a prolonged change in redox state within neuronal cells, the presence of phagocytic cells, the proliferation of glial cells, or altered buffering mechanisms. An early (<18 hours after birth) elevation of brain lactate seems to indicate a poorer prognosis. It is now clear that brain alkalosis is a negative marker in the newborn infant with birth asphyxia, and the prognosis is best when moderate cerebral acidosis is present.[48]

Pathophysiology of Shock in the Fetus and Neonate

Cardiovascular compromise in the fetus and neonate often leads to severe organ injury or death, and the success of therapeutic interventions is limited by difficulties with accurate and timely detection of the condition, especially in the fetus, and the sensitivity of the developing organism to alterations in blood and oxygen (O_2) supply. Studies using animal models of fetal and neonatal shock have investigated the cause-specific pathophysiologic changes in the cardiovascular system and, although in much less detail, the cardiovascular response to therapeutic interventions. However, little is known about the cellular effects of shock in the developing animal, and virtually no data exist for the human fetus and neonate. Extrapolation of animal data to humans must be done with caution, and because of the unpredictable impact of interspecies differences on organ development and maturational processes, extrapolation of data obtained in animal models of fetal and neonatal shock to the human fetus and neonate is even more prone to error.

CARDIOVASCULAR COMPROMISE IN THE FETUS

In the fetus, inadequate tissue O_2 delivery is most often caused by decreased blood flow to the uterus, the placenta, or the fetus. In addition, circulatory failure resulting from structural developmental abnormalities, infections, cardiac arrhythmias, and decreased O_2 carrying capacity of the blood also occurs, leading to development of hydrops and, unless intervention is successful, to fetal or neonatal demise. The studies on fetal shock have primarily employed experimental models of decreased blood flow or O_2 delivery, or both, to the fetus, and most of these studies have used the pregnant sheep model.

Developmental Changes in Fetal Gas Parameters

Under normal circumstances, hemoglobin O_2 saturation in the fetal umbilical artery and vein is 50% and 75%, respectively.[1] Thus, the fetus is exposed to lower levels of oxidant stress compared with the newborn. Fetal O_2 tension (P_{O_2}) and pH decrease and carbon dioxide tension (P_{CO_2}) increase with advancing gestational age.[2-4] These changes are primarily driven by the increased O_2 consumption and associated CO_2 production of the growing fetus. The fall in the pH is secondary to the higher CO_2 production as gestational age progresses. Because O_2 carrying capacity also increases, total O_2 content in the fetal blood remains stable throughout gestation. However, although disputed,[4] fetal O_2 saturation has been found to decrease with advancing gestational age.[5] The decrease in fetal O_2 saturation is thought to result from the effect of decreasing pH and increasing P_{CO_2} on the hemoglobin-O_2 dissociation curve and a drop in P_{O_2}.[5]

Oxygen Delivery, Oxygen Consumption, and Oxygen Extraction in the Fetus

Delivery of O_2 depends on blood O_2 content and cardiac output. In the fetus, regional O_2 delivery is unique because the O_2 content of blood flowing to the different organs varies significantly. Under physiologic conditions, despite the low fetal P_{O_2}, O_2 delivery exceeds the metabolic demand of the tissues. The high cardiac index and hematocrit, the increased O_2 affinity of fetal hemoglobin, and the balanced distribution of cardiac output between the placenta and fetus all contribute to ensure appropriate O_2 delivery to the fetal organs.[1] In addition, the tight regulation of uterine and umbilical blood flow plays a major role in ensuring appropriate fetal O_2 uptake. However, reductions in uterine blood flow are relatively well tolerated by the fetus, and, in the sheep, decreasing uterine blood flow by as much as 50% does not adversely affect fetal blood gas parameters.[6] The increase in O_2 extraction is an immediate and effective mechanism compensating for the decrease in O_2 delivery in cases of reduced uterine blood flow.[7] *O_2 extraction,* defined as the ratio between O_2 consumption and O_2 delivery, is about 0.3 in animal fetus.[8,9] Data obtained from umbilical vessels at the time of delivery suggest a higher extraction in human fetus (0.52 to 0.62).[5,10] Because of

lower O_2 consumption in the immature compared with the more mature fetus, O_2 extraction is significantly lower during early gestation.[5,11] When O_2 consumption is increased up to 28% higher than baseline levels by the infusion of norepinephrine or thyroid hormone in the fetus, arterial or venous blood gas values remain unaffected.[12] This finding underscores that, despite the low Pao_2, the fetus is able to adapt to conditions associated with significant increases in O_2 consumption without evidence of disturbances in oxidative metabolism in the tissues.

Fetal Response to Hypoxemia

Lactic Acidosis in Fetal Hypoxemia

Under physiologic conditions, lactate level is higher in the fetal than the maternal circulation. The mild increase in fetal lactate levels is the result of enhanced placental lactate production and decreased fetal gluconeogenic utilization of lactate.[1]

Lactic acidosis develops under pathologic conditions in which O_2 delivery decreases to the point at which compensatory increases in O_2 extraction and cardiac output have reached their limit to satisfy tissue O_2 demand. Critical O_2 delivery in fetal sheep appears to be at 12 mL/kg/minute, and decreases in O_2 delivery to less than this value are associated with impaired oxidative metabolism and the accumulation of lactic acid in the fetal tissues and blood.[13] Indeed, elevated plasma lactate has been shown to be a good indicator of fetal hypoxemia. After 4 to 5 hours of fetal hypoxemia, blood lactate reaches a plateau despite continued anaerobic metabolism. The placental clearance of lactate is responsible for this phenomenon.[7] Thus, despite the ongoing fetal anaerobic metabolism in cases of chronic and severe fetal hypoxemia, the fetal serum lactate level does not rise beyond the point of equilibrium.[7]

The fetus responds differently to various levels of severity of hypoxia. Maternal hypoxia-induced mild fetal hypoxia does not alter fetal acid-base balance when fetal arterial O_2 saturations remain in the 40% range even when the hypoxemia persists for 24 hours.[14] Conversely, when fetal hypoxia results in fetal arterial O_2 saturations of less than 30%, metabolic acidosis develops.[15] Human data are consistent with the results of animal studies indicating that arterial oxygen saturation of 30% is the threshold for developing metabolic acidosis.[16,17] Thus the *critical threshold of arterial O_2 saturation,* defined as the arterial O_2 saturation below which metabolic acidosis develops, is about 30% in the maternal hypoxia-induced fetal hypoxia model in the sheep. It appears that susceptibility of the fetus to hypoxia is developmentally regulated; the preterm fetus is less sensitive to the effects of maternal hypoxia than its term counterpart.[15,18] For instance, when maternal hypoxia results in fetal arterial O_2 saturations of less than 30%, the preterm ovine fetus develops metabolic acidosis at a much slower pace[18] than that described for the fetus near or at term.[18]

The fetus also appears to respond differently to various causes of hypoxia.[19] When fetal hypoxemia is induced by umbilical cord occlusion, the fetal response differs from that seen with maternal hypoxia.[20] When fetal hypoxemia is caused by umbilical cord occlusion, metabolic acidosis develops more rapidly compared with maternal hypoxia-induced fetal hypoxemia.[20] The lack of placental compensatory mechanisms in the cord occlusion model may be responsible for this difference. Finally, the fetal response to hypoxemia is also altered when hypoxia is caused by decreased uterine blood flow. In this model, the critical threshold of arterial O_2 saturation is lower than in the maternal hypoxia or cord occlusion models, and rapid lactate accumulation and fall in pH only occur when fetal O_2 saturation is in the 15% to 20% range.[21] This finding suggests that placental compensatory mechanisms remain effective when blood flow to the uterus is decreased. Because of interspecies differences, these findings obtained in the sheep should be translated to the human fetus with caution.

Endocrine Responses to Fetal Hypoxemia

In the fetus, acute hypoxemia is associated with an increase in the plasma concentration of several hormones, including adrenocorticotropic hormone,[22-24] β-endorphin,[25,26] vasopressin,[27-29] glucocorticoids,[22-24] norepinephrine, and epinephrine.[21,29,30] This stress hormone response facilitates fetal adaptation to hypoxemia in part by ensuring the redistribution of blood flow to vital organs.[31]

However, the effectiveness of the fetal stress hormone response is limited by the developmentally regulated immaturity of certain endocrine organs and the cellular mechanisms of end-organ responses. For instance, although the fetal adrenal glands increase cortisol secretion in response to hypoxemic stress, the increase in the cortisol level is significantly less, whereas the increase in the catecholamine levels is similar to that seen in the mature animal.[21] In addition, expression of the cardiovascular adrenergic receptors and second-messenger systems is developmentally regulated, contributing to the observed differences in the stress response between the fetus and the mature animal.

The exact mechanisms of the 50- to 1000-fold increase in fetal catecholamine release to fetal stress remain to be clarified. One study[32] investigated the effect of metabolic acidosis on adrenal catecholamine secretion. In an effort to avoid the adrenal stimulatory effect of hypoxemia associated with acidosis-induced rightward shift in oxyhemoglobin dissociation curve, 100% O_2 was administered to the pregnant ewe during the infusion of 30% lactic acid to the fetus. Under these experimental circumstances, metabolic acidosis in the absence of hypoxia did not stimulate adrenal catecholamine secretion. Conversely, studies investigating fetal catecholamine release in the presence of hypoxemia have reported increased catecholamine and vasopressin secretion in the presence or absence of associated metabolic acidosis.[27,33]

Cardiovascular Effects of Fetal Hypoxemia

In the fetus, the right and left ventricles work in parallel, and therefore the combined left and right cardiac output is considered the total cardiac output. In the fetal lamb, the combined cardiac output is 450 mL/kg/minute, to which the right and left ventricles contribute 300 and 150 mL/kg/minute, respectively.[34] Similarly, in the human fetus, the contribution of the right ventricle to the combined cardiac output is significantly higher than that of the left ventricle. Data obtained by echocardiography show the combined cardiac output in human fetus to be similar to that of fetal sheep; however, the right ventricle contributes only about 60% of the combined output.[35,36]

In the fetal lamb, the cardiovascular response to acute hypoxemia is characterized by the rapid development of hypertension, bradycardia, increased peripheral vascular resistance, and a 15 to 20% decrease in the cardiac output. The decrease in cardiac output is primarily the result of the increased peripheral vascular resistance (afterload), bradycardia, vagal stimulation, and myocardial depression. However, significant myocardial depression occurs only if the hypoxemia is severe or prolonged or is associated with metabolic acidosis.[31] In the fetus, adenosine may play an important modulatory role in the previously described cardiovascular "maladaptation" by influencing fetal autonomic and glycolytic responses to hypoxia. In the sheep, blockade of the adenosine receptors during fetal hypoxia significantly attenuates the development of hypertension (systemic vascular resistance increase), bradycardia, and metabolic acidosis.[37,38] The fetal cardiovascular response to prolonged hypoxemia is different from that seen in the acute hypoxemia models. In fetal sheep with sustained hypoxemia, cardiac output drops progressively to 38%, and, not unexpectedly, right ventricular output is compromised earlier than the left ventricular output.[39]

In response to fetal hypoxemia, distribution of cardiac output and venous return is altered in an effort to maintain perfusion and O_2 delivery to the vital organs such as the heart, brain, and adrenal glands.[8,40,41] During induced maternofetal hypoxia, the percentage of systemic venous blood recirculated to the fetal body and not sent to the placenta for oxygenation is decreased, whereas the proportion of umbilical venous blood contributing to fetal cardiac output is increased from 27% to 39%.[40] As mentioned earlier, there are differences in the fetal response, including the distribution of cardiac output, venous return, and O_2 delivery among the different models of fetal hypoxia. However, regardless of the cause of hypoxia, the blood flow and O_2 delivery to the heart, brain, and adrenal glands are maintained, and the proportion of umbilical venous blood bypassing the liver through the ductus venosus is increased in all cases.[8,40,41]

Finally, the fetal cardiovascular and endocrine response to acute hypoxemia is altered when repeated hypoxic events occur. This is important because recurrence of hypoxic insults to the fetus may not be infrequent in human pregnancies in which blood flow to the uterus, placenta, or the fetus is repeatedly compromised. It appears that prevailing hypoxemia sensitizes the cardiac and vasoconstrictor chemoreflex responses because enhanced femoral vasoconstriction and marked elevation in plasma norepinephrine and vasopressin have been demonstrated in response to acute hypoxemia in fetal sheep that were previously exposed to sustained hypoxemia.[42]

Renal Responses to Hypoxemia

Although the placentomaternal unit performs most of the effective compensatory functions,[43] the fetal kidney has the ability to contribute to the maintenance of fetal acid-base balance. For instance, ammonium excretion and hence generation of bicarbonate, as well as sodium excretion, increase during the recovery period from hypocapnic hypoxia in the fetal sheep.[44] The possible reason that the foregoing fetal renal compensatory changes only occur during the recovery period from acute hypocapnic hypoxia is the hypocapnia itself. Because fetal P_{CO_2} is low as a result of maternal compensatory hyperventilation to hypoxia in this model and because CO_2 is required for bicarbonate absorption in the proximal tubule, bicarbonate reabsorption and acid excretion in the fetus are delayed until hypoxemia subsides and maternal, and thus fetal, P_{CO_2} returns to normal.

In addition to the effects of hypoxemia on the renal compensatory mechanisms maintaining fetal acid-base balance, there are other changes in renal function induced by hypoxemia. Fractional excretion of sodium is increased by a decrease in proximal tubule sodium reabsorption.[44,45] Urine osmolality also increases, and free water clearance drops secondary to increases in vasopressin release.[44,46] Finally, like the other organs, the immature kidney is also less susceptible to hypoxemia than the mature kidney.[47] The renal response to lactic acidosis induced by acid infusion in the fetal sheep is confined to tubular adaptive responses with decreases in urine pH and increases in ammonium and titratable acid excretion without changes in glomerular filtration rate.[48]

CARDIOVASCULAR COMPROMISE IN THE NEONATE

Definition and Phases of Neonatal Shock

Shock develops when O_2 delivery to the tissues is inadequate to satisfy cellular metabolic demand. Independent of the origin, there are three phases of shock, and each phase is characterized by unique pathophysiologic changes.

In the *compensated phase*, vital organ function is maintained by intrinsic neurohormonal compensatory mechanisms resulting in distribution of organ blood flow primarily to the heart, brain, and adrenal glands and away from other "nonvital" organs. Several hormones and local factors affecting myocardial function, organ blood flow distribution, capillary integrity, systemic and pulmonary vascular resistance, and cellular metabolism are released during this phase. Stroke volume, central venous pressure, and urine output all decrease. However, blood pressure remains within normal limits because the increases in myocardial contractility and heart rate maintain cardiac output close to the normal range. Because blood pressure is the function of blood flow and systemic vascular resistance, blood pressure may not always appropriately reflect the status of organ blood flow in this phase. This observation especially concerns the nonacidotic extremely low-birth-weight preterm neonate with immature myocardium and compensated shock during the first postnatal day.[49,50] In addition, the developing cerebral cortex of the extremely low-birth-weight preterm neonate may function as a "nonvital" organ with low-priority circulation resulting in vasoconstriction and decreased cortical perfusion in cases with low cardiac output,[51] just like the vasoconstriction that occurs to maintain blood pressure in the traditional nonvital organs (e.g., skin, muscle, kidney, liver, mesenterium). Thus, in these patients, blood flow to the brain stem and not to the entire brain may be maintained only during the compensated phase of shock.

If the circulatory compromise is not recognized and treated, neonatal shock will enter the *uncompensated phase,* in which failure of the intrinsic neurohormonal compensatory mechanisms results in decreased microvascular perfusion, myocardial contractility, stroke volume, and blood pressure, with ensuing significant decreases in organ blood flow and tissue perfusion and lactic acidosis. If treatment is delayed or the condition is prone to rapid deterioration, such as in fulminant sepsis, myocarditis, or asphyxia with multiorgan failure, neonatal shock will enter the final and *irreversible phase,* in which cellular damage leading to complete organ failure dominates the clinical picture, and death occurs invariably.

Factors in the Pathophysiology of Shock at the Cellular and Molecular Level

Reactive Oxygen Species

These molecules are involved in initiation and amplification of cellular injury in shock. Under normal conditions, the redox coupling reactions generate water as a result of complete O_2 reduction with only minimal (1%) univalent O_2 reduction ($O^{\bullet}{}_2^-$).[52] However in shock, $O^{\bullet}{}_2^-$ is significantly increased.[53] Ischemia and hypoxia result in accumulation of electron donor compounds such as reduced nicotinamide adenine dinucleotide secondary to impairment of oxidative phosphorylation in the mitochondria.[53] Subsequent reperfusion then leads to enhanced reactive O_2 species production by the enhanced availability of the electron acceptor O_2.

Furthermore, because anaerobic metabolism leads to inadequate production of adenosine triphosphate (ATP), hypoxanthine and xanthine accumulate. Under normal physiologic conditions, hypoxanthine is oxidized to urate by xanthine dehydrogenase and xanthine oxidase, with the latter generating $O^{\bullet}{}_2^-$ and H_2O_2 as byproducts. During ischemia-reperfusion, cellular changes favor hypoxanthine oxidation by xanthine oxidase, with a resultant significant increase in the production of reactive O_2 species. Reactive O_2 species cause cellular injury through their adverse effects on different cellular structures that lead to polysaccharide depolymerization, lipid peroxidation,[54] alterations in the primary structure of amino acids,[55] and nucleic acid oxidation.[56] These effects impair the cellular adhesion and receptor physiology, disrupt cell membrane integrity[54] and the function of many enzymes,[55] and damage DNA,[56] respectively. The fetus and neonate are prone to develop severe cellular injury during the

ischemia-reperfusion cycle because they have immature antioxidant defenses.

Nitric Oxide

Under physiologic conditions, nitric oxide (NO) plays an important role in the regulation of vascular tone. However, under pathologic conditions, inducible NO synthase (iNOS) is upregulated by endotoxin and proinflammatory cytokines, and large amounts of NO are produced.[57,58] Overproduction of NO by iNOS has been implicated in the pathogenesis of shock in pediatric patients, including newborn infants.[59,60] Excessive production of NO then leads to hypotension, decreased vascular response to vasoconstrictor hormones, and myocardial dysfunction.[57] In addition to the adverse cardiovascular effects, NO can cause direct cellular injury through formation of reactive free radicals such as peroxynitrite[61] and by inhibiting mitochondrial respiratory function.[62]

Because excess NO is involved in the pathogenesis of shock, studies have focused on testing therapeutic modalities that inhibit NOS as a possible treatment strategy, especially in septic shock. However, the use of nonselective NOS inhibitors that inhibit both endothelial (e)NOS and iNOS has resulted in deleterious effects in immature[63] and mature animal models of shock and increased mortality in human adults with septic shock.[64,65] In contrast, selective inhibition of iNOS improves hypotension and lactic acidosis in the mature canine endotoxic shock model.[66] However, whether selective iNOS inhibition is helpful in the treatment of neonatal shock remains to be elucidated.[67]

Platelet-Activating Factor

This phospholipid mediator has been implicated in the pathogenesis of shock in both animal models[68,69] and adult subjects.[70] In animal models of septic shock, animals treated with a platelet-activating factor antagonist showed improvement in their cardiovascular status.[71,72] Although there is no study on the role of platelet-activating factor in neonatal shock, its association with necrotizing enterocolitis is well documented.[73,74]

Eicosanoids

In inflammation, arachidonic acid derived from cell membrane phospholipids is metabolized by cyclooxygenase or lipoxygenase to produce inflammatory mediators such as prostaglandins, thromboxanes, and leukotrienes. Although eicosanoids have been implicated in the pathogenesis of organ failure and shock, their exact role remains to be elucidated. Rats deficient in essential fatty acid, and thus unable to produce significant amounts of eicosanoids, are much less susceptible to endotoxic shock and have significantly improved survival rates compared with wild-type rats.

Eicosanoids, such as the predominantly vasodilator prostacyclin and prostaglandin E_2, and the vasoconstrictor thromboxane A_2, play an important role in the regulation of vascular tone. Some eicosanoids (thromboxane A_2) induce platelet and neutrophil aggregation and thus have significant proinflammatory effects, whereas others, such as prostaglandin E_2, also exert an antiinflammatory action by down-regulating cytokine release by macrophages and lymphocytes. Indeed, there are both animal and human data supporting the role of prostaglandins as both proinflammatory and antiinflammatory agents. In animals with hypovolemic shock, administration of prostacyclin and prostaglandin E_1 and E_2 improves cardiovascular status.[75,76] Conversely, in the septic human and animal, inhibition of cyclooxygenase may improve both the cardiovascular status and survival.[77,78]

Studies in animal models and humans have also shown that the levels of thromboxane B_2, a metabolite of thromboxane A_2, are increased in septic shock.[79,80] In addition to its proinflammatory and vasoconstrictor effects, thromboxane A_2 may have a direct myocardial depressant effect, and therefore it may significantly compromise cardiac output.[79]

K_{ATP} Channels

Among the various potassium channels, ATP-dependent potassium channel (K_{ATP}) has emerged as the key channel through which many modulators exert their action on vascular smooth muscle tone.These channels are located in cell membrane of vascular smooth muscle cells. In case of tissue hypoxia, reduction in ATP and increase in lactate level activate K_{ATP} channels, leading to efflux of K^+. The resultant hyperpolarization of the cell membrane decreases vascular tone by decreasing intracellular calcium through inhibition of voltage-gated calcium channels.[81]

K_{ATP} channels have been implicated in the pathogenesis of vasodilatory shock.[82] Some of the mediators of septic shock, such as nitric oxide, are known to activate K_{ATP}.[83] Animal studies have shown an improvement in blood pressure in response to K_{ATP} blockers,[84,85] but a recent small human trial failed to show any benefit of the administration of the K_{ATP} channel inhibitor glibenclamide in adults with septic shock.[86]

Other Factors

Among other factors with potential clinical importance in shock, nuclear factor-κB (NF-κB) has been suggested to have a prognostic value. In patients with septic shock, higher peripheral mononuclear cell NF-κB activity is associated with increased mortality.[87] It is not known whether this is an association or a causative relationship.

Down-Regulation of Adrenergic Receptors

Down-regulation of the adrenergic receptors and second-messenger systems in cases of critical illness and exogenous catecholamine administration,[88] as well as a relative or absolute adrenal insufficiency,[89] have emerged as probable causative factors in adults[90] and neonates[91] for the development of pressor-resistant shock. Because expression of the cardiovascular adrenergic receptors and some components of their second-messenger systems is inducible by glucocorticoids,[92] steroid administration offers a powerful clinical tool to reverse the effects of adrenergic receptor down-regulation.[90,91] These genomic effects of steroids resulting in the synthesis and membrane assembly of new receptor proteins require at least several hours to take place. However, improvement in cardiovascular function occurs within 1 to 2 hours after hydrocortisone administration to neonates.[91] This finding can be explained by the observations that steroids also exert certain nongenomic actions, which affect the cardiovascular system without delay. Glucocorticoids inhibit the catechol-*O*-methyltransferase, the rate-limiting enzyme in catecholamine metabolism, and decrease the reuptake of norepinephrine by the sympathetic nerve endings, leading to increases in the plasma concentration of catecholamines.[93] Physiologic doses of mineralocorticoids and, to a lesser degree, pharmacologic doses of glucocorticoids also instantly increase cytosolic calcium availability in myocardial and vascular smooth muscle cells by acting through putative cell membrane-bound specific steroid receptors.[93] In addition, steroids inhibit prostacyclin production and the induction of iNOS,[94] and they limit the pathologic vasodilation associated with the nonspecific or specific inflammatory response in the critically ill neonate. Finally, by improving capillary integrity, steroid administration may also increase the effective circulating blood volume in neonates with capillary leak.

Physiology of Neonatal Circulation

Cardiac Output

Under physiologic conditions, tissue perfusion is maintained by the provision of uninterrupted blood flow through the microcirculation. Normal microcirculation, in turn, depends on the organ perfusion pressure maintained by the interaction among cardiac output, preload, and afterload. *Cardiac output* is the product of stroke volume and heart rate and is determined by the amount

of blood returning to the heart (preload), the strength of myocardial contractility, and the resistance against which the heart must pump (afterload). When myocardial function is intact, cardiac output depends solely on preload and afterload, according the relationships described by the Starling curve.

Normal ranges for left and right ventricular output for preterm and term neonates have been reported between 150 and 300 mL/kg/minute.[95,96] In the transitional circulation of the newborn infant, in whom ventricular output does not consistently reflect systemic blood flow because of the shunts across the fetal channels,[96] superior vena cava blood flow can be measured and used to estimate systemic blood flow.[50] Normal values for superior vena cava blood flow in well preterm neonates range between 40 and 120 mL/kg/minute, with a median rising from 70 mL/kg/ minute at 5 hours of age to 90 mL/kg/minute at 48 hours.[50]

The strength of myocardial contractility depends on the filling volume and pressure and on the maturity and integrity of the myocardium. Thus, decreases in preload (hypovolemia, cardiac arrhythmia), as well as prematurity and hypoxic and infectious insults, all decrease contractility and lead to decreases in cardiac output.

If the systemic or pulmonary vascular resistance (afterload) is too high, the ability of the myocardium may become compromised to pump against the increased resistance, and cardiac output will fall.[97] In the neonate, significant increases in the afterload may occur with enhanced endogenous catecholamine release during the period of immediate postnatal adaptation as well as in hypovolemia or hypothermia, or when inappropriately high doses of vasopressors are administered to a patient with intact cardiovascular adrenoreceptor responsiveness. Depending on which circulation (systemic or pulmonary) is more severely affected, the high afterload can impair the function of either ventricle. However, by the ensuing decrease in blood return to the initially unaffected ventricle, the reduction in the output of one of the ventricles will influence the function of the other ventricle. In addition, in the immediate postnatal period, shunts through the patent ductus arteriosus or foramen ovale may compromise the circulation.[98] In the extremely low-birth-weight neonate, normal postnatal closure of these fetal channels frequently fails, and as the right-sided pressures fall, pulmonary edema may rapidly develop, further compromising the hemodynamic status of these critically ill patients.[98]

Systemic Blood Pressure

Systemic blood pressure is the product of systemic blood flow and systemic vascular resistance. The gestational and postnatal age-dependent normal ranges for systemic blood pressure in neonates have been described in the literature.[99,100] Although blood pressure only weakly correlates with blood flow in the critically ill extremely low-birth-weight neonate during the period of immediate postnatal adaptation,[50,97] there is an association between low blood pressure and early central nervous system injury in this patient population.[101,102] However, a recent study failed to show any association between hypotension in first 3 postnatal days (as defined by three commonly used thresholds) and brain injury diagnosed by ultrasound obtained before 10 postnatal days in preterm infants.[103] Data indicate that only when mean blood pressures in extremely low-birth-weight neonates are less than or equal to 20 mm Hg and greater than or equal to 40 mm Hg, blood pressure becomes a more accurate indicator of abnormal and normal systemic blood flow.[104] Thus, in extremely preterm neonates with mean blood pressures between 20 and 40 mm Hg in the immediate postnatal period, the state of systemic blood flow is unclear, and the situation can be clarified only with ultrasonographic evaluation of cardiac function and organ blood flow. In more mature preterm and term neonates, blood pressure and organ blood flow appear to have a better correlation. Recent studies have provided some insights into the possible lower blood pressure limit of the cerebral blood flow autoregulatory curve. In extremely low-birth-weight infants during the transitional period (first 2 postnatal days), cerebral blood flow was maintained if mean blood pressure was greater than 29 mm Hg.[105] The cerebral blood flow autoregulation became pressure-passive once mean blood pressure dropped below 29 mm Hg. Even if this cut off value holds true in larger studies, lower blood pressures do not necessarily result in ischemic cerebral injury as compensatory mechanisms provide some degree of protection. Indeed, in one study, cerebral function as assessed by electroencephalogram was affected only when mean blood pressure was below 23 mm Hg.[106]

Organ Blood Flow and Its Autoregulation

Even extremely immature preterm neonates appear to be able to autoregulate their cerebral blood flow.[102,107-109] However, organ blood flow autoregulation is impaired in some preterm neonates, especially in those with birth asphyxia, acidosis, infection, tissue ischemia, and sudden alterations in arterial P_{CO_2}, rendering these patients at higher risk for cerebral injury. As mentioned earlier, because most of the severe cerebral injuries occur in extremely low-birth-weight neonates during the immediate postnatal period, the cortical vessels of these patients may be regulated as low-priority vessels, and thus blood is shifted away from the immature cerebral cortex during periods of circulatory compromise, as it is in other low-priority organ systems such as the kidneys, muscles, skin, and the hepatic and mesenteric circulation.[8,31,40,41] Because afterload abruptly increases with delivery, the immature myocardium struggles to maintain cardiac output in these subjects. Indeed, it is likely that the development of compensated shock and relative cortical ischemia is part of the transition to extrauterine life in most extremely low-birth-weight neonates. The cortical ischemia then sets the stage for reperfusion injury (intracranial hemorrhage or periventricular white matter injury) to occur once myocardial function and organ perfusion improve.[110]

Pathogenesis of Neonatal Shock

The clinical presentation, pathophysiology, and treatment of neonatal shock are significantly affected by the primary cause of the condition.[111] Hypovolemia, myocardial dysfunction, and abnormal regulation of peripheral vascular tone are the primary etiologic factors leading to shock in the neonate. In the critically ill neonate, more than one of these factors may be involved. For instance, in a newborn with septic shock, the capillary leak–induced hypovolemia, direct myocardial injury, and abnormal regulation of vascular tone may all contribute to the development of the circulatory compromise.

Hypovolemia

Hypovolemia is an uncommon primary cause of neonatal shock, especially during the first postnatal days. In preterm newborns, there is no evidence that hypotensive babies as a group are hypovolemic.[112] Hypovolemia causes low cardiac output and hypotension by decreasing the preload. Hypovolemia can result from loss of circulating blood volume after hemorrhage (absolute hypovolemia) or from inappropriate increases in the capacitance of the blood vessels as in vasodilatory shock (relative hypovolemia). In addition, the positive intrathoracic pressure associated with positive pressure mechanical ventilation reduces venous return and hence preload and cardiac output in ventilated preterm and term neonates.[113]

Absolute hypovolemia in the neonate can be caused by intrapartum fetal blood loss resulting from a hemorrhage from the fetal side of the placenta or from acute fetomaternal hemorrhage or acute fetoplacental hemorrhage. The latter may occur in neonates with breech presentation or a tight nuchal cord in whom

the umbilical cord comes under significant pressure.[114] Postnatal hemorrhage may occur from any site and is frequently associated with endothelial damage and disseminated intravascular coagulation induced by perinatal infections or asphyxia. Acute abdominal surgical problems and conditions associated with increased capillary leak with loss of fluid into the interstitium can also lead to significant decreases in the circulating blood volume.

Myocardial Dysfunction and Structural Heart Disease

There are significant differences in myocardial structure and function between the immature myocardium of neonates and the mature myocardium of older children and adults.[111, 115] Of particular interest among the differences are the greater dependence of the immature myocardium on extracellular calcium concentration and its greater sensitivity to an increase in afterload. As for the latter, a neonate is more prone to develop myocardial dysfunction and decreased cardiac output in response to increased afterload compared with a child or an adult. Unfortunately, conditions that can lead to increase in afterload are not uncommon in the immediate postnatal period. With the cessation of low resistance placental flow after delivery, the systemic vascular resistance (SVR) increases. Such a rise in SVR can lead to an increase in left ventricular afterload, with resultant decrease in cardiac output, and to the development of shock, primarily in the more immature preterm neonate during the transitional period. In one study, about half of the preterm infants with hypotension or metabolic acidosis had myocardial dysfunction.[116] In addition, the myocardium in preterm infants with a low superior vena cava (SVC) flow (used as a surrogate of upper body blood flow) appears to be more sensitive to afterload than those with a normal SVC flow.[117] This suggests that myocardial dysfunction due to immaturity plays a potential role in developing poor organ perfusion. On the other hand, even though the myocardium takes months to mature, myocardial dysfunction associated with immaturity does not play a significant role in pathogenesis of neonatal shock beyond the transitional period.

Other than myocardial immaturity, perinatal asphyxia and prolonged septic shock are the major causes of myocardial dysfunction. Preterm infants who undergo ductal ligation may also develop subtle myocardial dysfunction in the immediate postoperative period.[118] However, this transient deterioration in cardiac function is not related to the increase in SVR, as afterload remains unchanged after ligation. The cause of this phenomenon is unknown. It is possible that the acute decrease in myocyte fiber length following sudden decrease in the left ventricular preload after ligation of the ductus arteriosus plays a role and myocardial function rapidly improves as the myocardium resets to the new loading condition.

Finally, cardiomyopathies, structural heart defects that produce duct-dependent systemic circulation (hypoplastic left heart syndrome, critical coarctation of aorta, and critical aortic stenosis), anomalous left coronary artery from pulmonary artery, and tachyarrhythmias can present in early neonatal life with cardiogenic shock.

Abnormal Peripheral Vasoregulation and Neonatal Shock with Complex Pathogenesis

Extreme Prematurity

The transitional circulatory changes in the first 12 to 24 hours after birth represent a period of unique circulatory vulnerability for the extremely preterm infant. During the period of immediate postnatal adaptation, the left ventricle has to double its output. As described in the section on organ blood flow autoregulation, the extremely premature infant has significant difficulties to adjust to extrauterine life and is prone to develop reperfusion injury in the brain.[97,110] Under these conditions, blood pressure in the low-normal to normal range does not necessarily translate into normal organ blood flow and tissue perfusion in the extremely premature neonate.[50,97]

In the transitional circulation of the preterm infant, neither right nor left ventricular output will consistently reflect systemic blood flow because of the shunts across the ductus arteriosus and foramen ovale.[96] Consequently, measurement of either ventricular output can overestimate systemic blood flow by more than 100% in some cases.[96] As mentioned earlier, superior vena cava flow can be used as a marker of total systemic blood flow,[51] and serial measurements of superior vena cava flow have been used to describe the natural history of systemic blood flow changes in preterm neonates in the early postnatal period.[110,119] At least one third of preterm neonates born before 30 weeks gestation have a period of low systemic blood flow, mostly during the first 12 hours of life.[50,110] Gestational age is the dominant predictor of the development of the low-flow state; 70% of babies born before 26 weeks gestation have a period of low systemic flow compared with about 10% at 29 weeks gestation. Thus, the development of a low-flow state with compensated neonatal shock appears to be part of the transitional adaptation process in the extremely low-birth-weight patient population immediately after birth. The low-flow state can persist for up to 24 hours but usually improves thereafter. There is a strong relationship between recovery from the low-flow state and subsequent intraventricular hemorrhage,[110] and the low-flow state itself has been identified as a significant risk factor for poor neurodevelopmental outcome.[120]

Sepsis

Endotoxin or lipopolysaccharide plays a major role in the pathophysiology of septic shock caused by gram-negative organisms. Lipopolysaccharide induces the production of proinflammatory cytokines such as tumor necrosis factor-α (TNF-α) and interleukin-1. In addition to activating the inflammatory response, TNF-α induces apoptosis.[121] NF-κB, a nuclear transcriptional factor, mediates the inflammatory response induced by TNF-α.[122] TNF-α is a potent stimulator of iNOS, and overproduction of NO causes vasodilatation, systemic hypotension, and the generation of reactive free radicals such as peroxynitrite. In gram-negative septic shock, myocardial dysfunction develops, at least in part because of the effect of up-regulated TNF-α production,[123] as evidenced by improvement in cardiac function after administration of anti-TNF-α antibody.[124] Finally, TNF-α, by up-regulating tissue factor production in endothelial cells, also activates the extrinsic coagulation pathway and contributes to the generation of thrombi in the microcirculation.[125]

The triggers of inflammation and the host response in septic shock caused by gram-positive organisms are less well defined. However, cell wall components such as peptidoglycans and lipoteichoic acid, as well as exotoxins, have been implicated in the induction of the cytokine cascade.[126]

Although clinical evidence of circulatory compromise is a feature of many infectious processes in the newborn, the hemodynamics in neonatal septic shock have not been well studied. In older subjects, two distinct hemodynamic patterns occur. *Warm shock* is characterized by loss of vascular tone, increased systemic blood flow, and low blood pressure, and it is difficult to recognize initially unless the blood pressure is closely monitored. *Cold shock,* conversely, is characterized by increased vascular tone, low systemic blood flow, and eventually falling blood pressure, and it has been well described in the newborn.[127]

Pressor-Resistant Systemic Hypotension in Neonates

As discussed in the section on down-regulation of adrenergic receptors, pressor-resistant hypotension in preterm and term infants is now a well-recognized condition.[91,128] The underlying systemic hemodynamic changes, although not well-defined, appear to be similar to those seen in adult vasodilatory shock, with normal to high systemic blood flow and possibly

supranormal cardiac output.[129] Neonates with this condition are more likely to be extremely premature (≤27 weeks) or to have been critically ill or suffered a degree of perinatal asphyxia. Potential mechanisms of the uncontrolled vasodilation include dysregulated cytokine release, excess NO synthesis, vasopressin deficiency, overactivation of the potassium-ATP channels in the vascular smooth muscle cell membrane in response to tissue hypoxia, and down-regulation of the cardiovascular adrenergic receptors.[91] In the neonate, the foregoing mechanisms may be exacerbated by immaturity, relative adrenal insufficiency,[89,130] or preceding asphyxia, or they may be secondary to the transitional circulatory failure of the extremely low-birth-weight neonate.

Treatment of Neonatal Shock

Treatment of neonatal shock must be tailored to the primary cause or pathogenesis and to the level of maturation of the critically ill neonate.[131,132]

Volume Administration

Because hypotensive neonates as a group are not hypovolemic,[112] because myocardial dysfunction frequently contributes to the development of neonatal hypotension,[133] because dopamine is more effective in normalizing blood pressure than is volume administration,[134,135] and because excessive fluid administration increases morbidity, especially in the preterm neonate,[136] fluid resuscitation should be minimized.

Concerning the type of fluid administration, isotonic saline has been shown to be as effective as 5% albumin in increasing the blood pressure.[137] In addition, albumin may cause an impairment of gas exchange, may induce a fluid shift from the intracellular compartment,[138] and may be associated with increased mortality.[139] Therefore, the use of isotonic saline has been advocated.[131,140] However, because of the unbalanced nature of normal saline, its administration in large amounts may worsen metabolic acidosis. If there is an identifiable volume loss, the type of fluid lost should be replaced.

Dopamine and Dobutamine

There is only indirect evidence that the use of these sympathomimetic amines improves neonatal mortality or morbidity. Studies in developing and mature animals showed significant age-dependent differences in the cardiovascular and renal effects of dopamine[141] and the cardiovascular effects of dobutamine.[142] However, owing to maturation-dependent and maturation-independent interspecies differences, interpolation of these findings to the human neonate may be misleading.[107,140] Although a few studies examined the developmentally regulated hemodynamic effects of dopamine[107,109,135,143,144] and dobutamine[97,129,145] in the human neonate, there is still only limited information available on the effects of dopamine and dobutamine on tissue O_2 delivery and consumption[146] and systemic blood flow in the newborn.[97]

Hemodynamic Effects

Dopamine, an endogenous catecholamine, exerts its cardiovascular actions through the dose-dependent stimulation of the cardiovascular dopaminergic receptors and the α- and β-adrenergic receptors. In addition, by stimulating epithelial and peripheral neuronal dopaminergic and adrenergic receptors, the drug exerts significant renal and endocrine effects independent of its cardiovascular actions.[140] Although dopamine affects all three major determinants of cardiovascular function, the drug-induced increases in myocardial contractility[135,140] and peripheral vascular resistance[135,140,145] are the most important factors in increasing systemic blood pressure and improving the cardiovascular status.

Animal studies on the cardiovascular effects of dopamine during development showed that the drug's positive inotropic effect and selective vasodilatory actions in the different regional circulations are maturation dependent.[147-149] However, in the human preterm neonate, clinical studies have demonstrated greater increases in stroke volume[150] and glomerular filtration rate[151,152] in response to dopamine administration than expected from the findings of the developmental animal studies. Thus, functional cardiovascular β-adrenergic and dopaminergic receptors exist, at least beyond 23 weeks gestation, in the heart and the renal circulation of the human neonate.[107,109,135,140,143,144,150] In addition, during the early phases of shock, when the cardiovascular adrenergic receptors are not yet down-regulated, dopamine increases blood pressure in preterm infants at lower doses compared with children and adults.[150-153] The increased sensitivity to the vasoconstrictive (afterload-increasing) effects of dopamine may be related to the enhanced expression of α-adrenergic receptors during early development,[154] as well as to the differences in the maturation of hepatic and renal dopamine-clearance mechanisms.[152]

The original dose range recommendation of 2 to 20 μg/kg/minute of dopamine was based on pharmacodynamic data obtained in healthy adults. However, changes in cardiovascular adrenergic receptor expression by critical illness,[93] relative or absolute adrenal insufficiency and immaturity,[89,130] and the dysregulated production of local vasodilators during severe illness decrease the sensitivity of the cardiovascular system to dopamine and result in the emergence of hypotension resistant to conventional doses of the drug.[91,128] Thus, with the advancing disease process, increased doses of dopamine and other sympathomimetic amines may be needed to exert the same magnitude of cardiovascular response. Indeed, there is no evidence that, when required to normalize blood pressure, high-dose dopamine treatment with or without additional epinephrine administration has detrimental vasoconstrictive effects.[91,128,155] However, there are no data available on changes in cardiac output and organ blood flow in response to high-dose catecholamine treatment in pressor-resistant neonatal shock.

Unlike dopamine, dobutamine is a relatively cardioselective sympathomimetic amine with significant α- and β-adrenoreceptor-mediated direct inotropic effects and limited chronotropic actions.[142,156,157] Dobutamine administration is usually also associated with a variable decrease in total peripheral vascular resistance[157] and, at least in adults, with improved coronary blood flow and myocardial O_2 delivery.[156] Furthermore, unlike dopamine,[140] dobutamine increases myocardial contractility exclusively through the direct stimulation of the myocardial adrenergic receptors. Because myocardial norepinephrine stores are immature and are rapidly depleted in the newborn and because dobutamine may decrease afterload, newborns with primary myocardial dysfunction and elevated peripheral vascular resistance are most likely to benefit from dobutamine treatment.[140,157] Although addition of dobutamine to dopamine in preterm infants with respiratory distress syndrome is effective in increasing blood pressure, this approach is associated with supranormal cardiac output states and lower systemic vascular resistance.[129] Whether the benefits of supranormal cardiac output by providing adequate tissue O_2 delivery throughout the body outweigh the risks of sustained hypercontractility potentially resulting in myocardial injury remains to be investigated. Although dopamine is effective in normalizing the cardiovascular status in most neonates with hypotension,[140] neither dopamine nor dobutamine effectively improves low systemic blood flow in extremely low-birth-weight neonates during the first 24 hours of life.[97] However, in hypotensive very-low-birth-weight (VLBW) infants, stepwise titration of both dopamine and epinephrine improves blood pressure and cerebral perfusion.[158] This finding underscores the earlier-described complexity of the cardiovascular changes during the immediate postnatal transition of the extremely low-birth-weight human neonate.

The vasodilatory dopamine receptors are primarily expressed in the renal, mesenteric, and coronary circulations.[140] Dopamine has been shown to decrease renal vascular resistance selectively[107,109] and to increase glomerular filtration rate[151,152] in preterm infants as early as 23 weeks gestation. However, dopamine decreases mesenteric vascular resistance in preterm infants only beyond the first postnatal day,[107,109,144] and the effects may be variable.[144] Similarly, there are some differences in the reported magnitude of the drug-induced increases in ventricular function, cardiac output, and systemic vascular resistance.[135,144,145] These findings may be best explained by differences in the intravascular volume status, the postnatal age, the developmentally regulated expression of cardiovascular adrenergic and dopaminergic receptors, and the severity of adrenergic receptor down-regulation among the different populations of critically ill preterm infants studied. None of the studies has, however, found evidence of a direct effect of dopamine on cerebral blood flow.[107,109,135,144] Finally, in addition to increasing afterload, dopamine also increases pulmonary vascular resistance in preterm neonates.[159] However, because the drug-induced increases in systemic blood pressure are not associated with impaired oxygenation in most neonates,[140] there is no evidence of consistent increases in extrapulmonary right-to-left shunting during dopamine treatment. In preterm neonates, dopamine also improves right ventricular performance.[160]

There are no data available on the direct renal, cerebral, or pulmonary hemodynamic effects of dobutamine in the human newborn. However, when dobutamine increases blood pressure, it may also increase mesenteric blood flow in preterm infants.[161] Because dobutamine does not stimulate the dopaminergic receptors, β-adrenoreceptor-induced selective vasodilation may be responsible for the observed mesenteric vasodilation.

Epithelial and Neuroendocrine Effects

Independent of the previously described cardiovascular effects, dopamine exerts direct renal[140,152] and endocrine[140] actions in the newborn. Through its direct effects on sodium, phosphorus, and water transport processes and sodium-potassium ATPase activity[162] in the renal tubules, dopamine increases sodium, phosphorus, and free water excretion and may increase the hypoxic threshold of renal tubular cells during episodes of hypoperfusion and hypoxemia.[140] Through its renal vascular and epithelial actions, dopamine also potentiates the diuretic effects of furosemide[163] and theophylline.[164] Among its endocrine actions, the dopamine-induced decreases in plasma prolactin and thyrotropin levels[140] may be of clinical importance. The potential impact on long-term neurodevelopmental outcome and immunologic function of the drug-induced alterations in the neuroendocrine function has not been investigated in the preterm or term neonate. Because dobutamine does not directly stimulate the dopaminergic receptors, its administration is likely to be devoid of neuroendocrine effects.

Other Sympathomimetic Amines and Hormones

Although both epinephrine and norepinephrine have been used in the treatment of hypotension in preterm infants, data in peer-reviewed literature on the cardiovascular actions of epinephrine during development are available only from studies on newborn animals.[165] Studies of the cardiovascular and renal effects of these catecholamines in the human neonate have been published only in abstract form.[166-168] The only published article shows that epinephrine, similar to dopamine, increases blood pressure and cerebral perfusion in VLBW infants.[158] It is not known whether there is a difference in the cardiovascular response or side effects with the combined use of epinephrine and dopamine compared with the use of increasing doses of dopamine beyond 20 μg/kg/minute with or without dobutamine in the human neonate. In addition to sympathomimetic amines, arginine vasopressin has been reported to improve cardiovascular function in newborns with vasodilatory shock.[169]

Steroid Administration

There is emerging evidence that brief steroid treatment stabilizes the cardiovascular status and decreases the need for pressor support in the critically ill newborn with pressor-resistant hypotension.[89,91,128,130,170,171-174] The potential mechanisms of steroid treatment in hypotensive preterm and term neonates on improving the cardiovascular status were described earlier, in the section on pressor-resistant hypotension. As for the effects on hemodynamics, hydrocortisone increases blood pressure by increasing peripheral vascular resistance without adversely affecting the cardiac output in vasopressor-treated preterm and term infants.[174] Finally, there are no data on the potential long-term neurodevelopmental side effects of the attempted physiologic supplementation with hydrocortisone or the use of low-dose dexamethasone to enhance cardiovascular stability and pulmonary function in critically ill preterm and term infants.

Supportive Measures

Maintenance of normal arterial pH and serum ionized calcium concentrations is important for optimizing the cardiovascular response to catecholamines. Because metabolic acidosis with a pH of less than 7.25 compromises myocardial function in preterm infants,[175] maintenance of the arterial pH above this range in infants with acidosis with a significant metabolic component may be warranted.[175] However, the efficacy and potential short- and long-term adverse effects of the administration of sodium bicarbonate or tromethamine have not been studied in the neonatal patient population.

SUMMARY

Treatment of hypotensive, critically ill preterm and term neonates requires the ability to monitor the most important determinants of cardiovascular function, including the blood pressure and systemic and organ blood flow; a thorough understanding of the pathogenesis and pathophysiology of neonatal shock; and knowledge of the developmentally regulated mechanisms of actions, pharmacodynamics, and potential side effects of the sympathomimetic amines and other medications used in the management of neonatal shock.

SECTION XII

The Lung

78

Susan E. Wert

Normal and Abnormal Structural Development of the Lung

The respiratory system is composed of the lung, its conducting airways, and the respiratory muscles of the thorax. These structures function together to provide oxygen from the external environment to the organism, while removing excess carbon dioxide from the blood. Appropriate anatomic development of these structures is essential for overall respiratory function in the newborn infant, along with histologic, cellular, and biochemical maturation of the lung, which is critical for proper physiologic function at birth. This chapter describes the anatomic development of the lung and its conducting airways, along with a review of associated pulmonary malformations. Selected molecular mechanisms that regulate structural development of the lung and its conducting airways are also discussed briefly. More complete and detailed discussions of these mechanisms can be found in several excellent recent reviews,[1-4] as well as in subsequent chapters of this book.

OVERVIEW OF LUNG DEVELOPMENT

Lung development can be divided into five distinct, but overlapping, chronologic stages of organogenesis, which describe the histologic changes that the lung undergoes during morphogenesis and maturation of its structural elements. These stages include *embryonic, pseudoglandular, canalicular, saccular,* and *alveolar* phases of lung development, which extend throughout gestation and into the postnatal period (Table 78-1). Human lung development is initiated in early gestation as a small, saccular outgrowth, or *diverticulum*, of the ventral wall of the foregut. During subsequent *embryonic* and *pseudoglandular* stages of lung development, formation of the conducting airways, or *tracheobronchial tree,* takes place by a process called *branching morphogenesis.* This process involves rapid growth and repetitive branching of the *primitive respiratory diverticulum* until all of the branches of the tracheobronchial tree are formed. Outgrowth, expansion, cytodifferentiation, and maturation of the alveolar, or gas-exchange, regions of the lung occur later in gestation, during the *canalicular, saccular,* and *alveolar* stages of morphogenesis. The *alveolar* stage of lung development extends into the postnatal period, during which millions of additional alveoli are formed and *maturation of the microvasculature,* or *air-blood barrier,* takes place,[5] greatly increasing the surface area available for gas exchange (Table 78-2). Although definitive alveoli can be found in the human lung by 36 weeks gestation, greater than 85% to 90% of all alveoli are formed within the first 6 months of life.[6] Overall, the number of alveoli increases by approximately six-fold between birth and adulthood, that is, from an average of 50 million (ranging from 20 to 70 million) alveoli in the term lung to 300 million (ranging from 212 to 605 million) alveoli in the adult human lung.[6-8] After the first 6 months of life, alveolar formation continues at a slower pace until approximately 2 years of age, when further growth of the lung becomes proportional to growth of the body. From birth to adulthood, the conducting airways increase in length and diameter (see Table 78-2), and the gas-exchange surface area and its diffusion capacity increase linearly with body weight up to approximately 18 years of age.[9]

Embryonic Stage (3 to 7 Weeks After Conception)

The lung is a derivative of the primitive foregut endoderm and the adjacent mesoderm. The *respiratory primordium* of the lung first appears on postconception (p.c.) day 22 as an enlargement of the caudal end of the *laryngotracheal sulcus*, which is located in the medial pharyngeal groove, an outgrowth of the ventral wall of the primitive foregut endoderm.[5] The *primitive respiratory diverticulum*, or lung bud, appears on day 26 p.c., when the embryo is only approximately 3 mm long, and begins to grow ventrocaudally into the mesoderm surrounding the foregut, that is, in a position that is anterior and parallel to the primitive esophagus. Epithelial cells of the primitive respiratory diverticulum invade the surrounding mesoderm, or *splanchnic mesenchyme,* forming tubules that undergo repetitive lateral and terminal *(dichotomous)* branching to form the proximal structures of the tracheobronchial tree. On day 28 p.c., the respiratory diverticulum bifurcates into right and left primary bronchial buds (main stem bronchi), the left bud being shorter and more horizontal than the right bud. The region proximal (or cephalad) to the first bifurcation becomes the trachea and larynx. Shortly thereafter, the trachea and the esophagus begin to separate into two distinct structures.[10] A second round of asymmetric branching occurs during the fifth week of gestation (day 33-41 p.c.) to yield three secondary bronchial buds on the right and two on the left (lobar bronchi), which become the primary lobes of the right and left lung. During the sixth week (day 41-44 p.c.), a third round of branching yields 10 tertiary bronchi on the right and eight or nine bronchi on the left, which become the bronchopulmonary segments of the mature lung. During this stage extensive proliferation occurs of both epithelial and mesenchymal cells with focal apoptosis in the mesenchyme around branch points and in regions of new bud formation.[11]

At this stage of development, the mesenchyme is composed of a loose arrangement of primitive cells that will later differentiate into progenitor cells of the future blood vessels, lymphatics, smooth muscle, cartilage, and connective tissue components. The extracellular matrix (ECM) is composed primarily of fluid, hyaluronic acid, and proteoglycans. The basement membrane underlying the epithelium contains type IV collagen and other basement membrane glycoproteins, such as laminin and fibronectin, and proteoglycans.[12] The trachea and bronchial tubules lack underlying cartilage, smooth muscle, and nerves; the pulmonary and bronchial blood vessels are not well developed; and the pseudostratified, columnar epithelium is composed of relatively primitive, undifferentiated epithelial cells. At the end of this stage, the lung resembles a small tubuloacinar gland, and separation of the trachea and esophagus is complete.[10]

TABLE 78-1

Human Lung Development and Associated Abnormalities

Stage	Major developmental events	Abnormalities and syndromes
Embryonic, 3-7 wk p.c.	Lung bud arises from ventral foregut endoderm	Laryngeal, esophageal, tracheal atresia
	Branching morphogenesis initiated	Tracheal and bronchial stenosis
	Main stem, lobar, segmental, and subsegmental bronchi form	Bronchogenic cysts
	Trachea and esophagus separate	Tracheoesophageal fistula
	Pulmonary arteries bud off sixth pair of aortic arches	Pulmonary agenesis and aplasia
	Pulmonary veins develop as outgrowths of left atrium	Extralobar pulmonary sequestration
Pseudoglandular, 5-17 wk p.c.	Formation of tracheobronchial tree complete by 16 wk	Renal agenesis and pulmonary hypoplasia
	Pulmonary arterial development parallels airway branching	Intralobar pulmonary sequestration
	Acinar tubules and buds form in peripheral lung	Pulmonary cysts
	Ciliated, goblet, neuroepithelial, and basal cells differentiate	Cystic adenomatoid malformation
	Pulmonary lymphatics appear	Pulmonary lymphangiectasia
	Cartilage, mucous glands, and smooth muscle develop	Tracheomalacia and bronchomalacia
	Pleuroperitoneal cavity closes	Congenital diaphragmatic hernia
Canalicular, 16-26 wk p.c.	Acinar tubules and buds expand	Renal dysplasia and pulmonary hypoplasia
	Air-blood barrier and capillary network forms	Alveolar capillary dysplasia
	Alveolar type I and type II cells differentiate	Respiratory insufficiency
	Lamellar bodies form in type II cells	Surfactant deficiency
Saccular, 24-38 wk p.c.	Distal air spaces continue to branch and grow	Oligohydramnios and pulmonary hypoplasia
	Air spaces expand to form saccules	Alveolar capillary dysplasia
	Mesenchyme thins and condenses	Surfactant deficiency
	Septal walls contain double capillary network	RDS
	Elastin deposited at sites of secondary septal crest formation	HMD
	Surfactant synthesized and secreted by type II cells	Apnea of prematurity
	Fetal lung fluid and fetal breathing	Transient tachypnea
Alveolar, 36 wk p.c. to 2 yr	Secondary septa form, subdividing saccules into alveoli	Lobar emphysema (overinflation)
	Alveolar septal walls thin with loss of connective tissue	Pleural effusions and fetal hydrops
	Alveolar surface area increases	Persistent fetal circulation
	Double capillary network fuses into a single network	Pulmonary hypertension
	Fibroblasts differentiate	Pneumonia
	Collagen, elastin, and fibronectin deposited	Meconium aspiration syndrome
	Surfactant production increases in type II cells	RDS, HMD, surfactant deficiency

HMD, Hyaline membrane disease; *p.c.,* post conception; *RDS,* respiratory distress syndrome.

TABLE 78-2

Postnatal Growth of the Human Lung and Conducting Airways

	Term	Adult	Fold increase
Lung weight (avg)	50 g	800 g	16
Lung volume (avg)	150-200 mL	5000 mL	25-33
Alv SA	3-4 m^2	75-100 m^2	25
SA/kg (avg)	0.4 m^2	1 m^2	2.5
Alv number (avg)	50×10^6	300×10^6	6
Alv number (range)	$17\text{-}71 \times 10^6$	$212\text{-}605 \times 10^6$	8.5-12.5
Alv diameter (avg)	150 μm	300 μm	2
Alv septal wall thickness (avg)	5 μm	2.5 μm	2
Air-blood barrier (avg)	0.6 μm	0.6 μm	0
Tracheal length (avg)	26 mm	184 mm	7
Main bronchial length (avg)	26 mm	254 mm	10

Modified from Hodson WA: Normal and abnormal structural development of the lung. In Polin RA, Fox WW, editors: *Fetal and neonatal physiology,* ed 2, Philadelphia, 1998, Saunders, p 1037.

Alv, Alveoli; *Avg,* average; *SA,* surface area.

Vascular connections with the right and left atria are established at the end of the embryonic stage, creating the primitive pulmonary vascular bed.[13,14] Pulmonary arteries arise from the sixth pair of aortic arches and grow into the surrounding mesoderm, where they accompany the developing airways, segmenting with each bronchial subdivision, and connect to the vascular plexus forming in the pulmonary mesenchyme. During fetal life, the pulmonary artery is connected to the aortic arch by the ductus arteriosus, which enables the right ventricular output from the heart to bypass the pulmonary vascular bed. The pulmonary veins develop as an outgrowth of the left atrium, which divides several times before connecting to the pulmonary vascular bed. Lymphatic vessels originate from the cardinal veins.

Developmental abnormalities that arise during the embryonic stage of lung development are related to lung bud formation, separation of the trachea and esophagus, formation of the proximal conducting airways, and initial lobe formation. These abnormalities include laryngeal, esophageal, and tracheal atresia; tracheal and bronchial stenosis; tracheomalacia and bronchomalacia; tracheoesophageal fistulas; pulmonary agenesis; ectopic lobes; bronchogenic cysts; and arteriovenous malformations (see Table 78-1).

Molecular Mechanisms Regulating Early Lung Development

Experimental studies have demonstrated that dorsal-ventral, lateral, and proximal-distal patterning of the developing lung is regulated by interactions with the surrounding mesenchyme.[1,2,15,16] These interactions involve both positive and negative signaling mechanisms that result in normal growth and organization of the lung. Molecular mechanisms that regulate the initiation of lung bud formation and early branching morphogenesis are (1) expression of nuclear DNA-binding proteins, or *transcription factors,* that are important for specification of the foregut endoderm and its derivatives; (2) endogenous, secreted polypeptides, or *morphogens,* that are important for epithelial-mesenchymal interactions in the lung and pattern formation; (3) *growth factors* that are important for cellular proliferation, migration, and cytodifferentiation; and (4) exogenous factors, such as retinoic acid (RA) (vitamin A), which

functions as a morphogen and is required for early lung bud formation.[1-4,17-20]

Transcription factors that are critical for foregut development and, by extension, early lung development include members of the FOX, GATA, and GLI families of transcription factors. FOXA2 (also known as HNF3β) is a member of a large family of nuclear transcription factors, termed the winged helix/forkhead box (or forkhead DNA-binding domain) family of transcription factors.[21,22] These nuclear proteins are involved in cell commitment, cytodifferentiation, and gene transcription in a variety of organs, including the central nervous system and derivatives of the foregut endoderm.[23,24] FOXA2 is required for formation of the foregut endoderm, as well as organogenesis and cytodifferentiation of the lung. FOXA2 regulates regional specification of cell fate, or cell commitment, in the primitive foregut endoderm and cooperates with another transcription factor, thyroid transcription factor-1 (TTF1, also known as NKX2-1, T/EBP, or TITF1) to determine epithelial cell lineages.[3,4] FOXA2 expression is detected in the pulmonary epithelium throughout lung development, and its expression is maintained in the fully differentiated adult bronchial and alveolar epithelium.[25-27] GATA6 is a zinc finger transcription factor that induces differentiation of the primitive foregut endoderm into respiratory cell lineages via its interactions with TTF1 and FOXA2. GATA6 is expressed in the foregut endoderm and in the pulmonary epithelium during lung development. Genetic ablation of *Foxa2* or *Gata6* in mice disrupts formation of the foregut endoderm and all of its developmental derivatives, including the lung.[28-30] TTF1 is a homeobox protein that is also expressed in the epithelium of the lung throughout development, as well as in the adult lung.[25,31,32] TTF1 is essential for branching morphogenesis, epithelial cell proliferation, development of distal lung structures, and expression of the surfactant proteins.[33] When *Nkx2-1* is inactivated in gene-targeted mice, lung development is perturbed, resulting in the formation of bilateral, sac-like structures that are lined with primitive epithelial cells and originate from a short, common tracheoesophageal tube.[34,35] The absence of TTF1 arrests dorsal-ventral separation of the trachea and esophagus, branching morphogenesis of the lung, and epithelial cell differentiation.

Members of the GLI family of zinc finger transcription factors, GLI1, GLI2, and GLI3, are expressed in the foregut mesoderm and are downstream transducers of sonic hedgehog (SHH) signaling.[36,37] SHH is a secreted polypeptide, or *morphogen,* that is expressed in the foregut endoderm and in the primitive epithelial cells of the lung, as well as in the notochord, the neural plate, and the brain. Its receptor, patched-1 (PTCH1) is expressed in the mesoderm of the lung. When SHH binds to its receptor, another transmembrane protein, called smoothened (SMO), is released and translocated to the nucleus where it activates the GLI2 and GLI3 genes. GLI2 and GLI3, in turn, modulate the expression of other proteins that play a role in lung development, such as GLI1, PTCH1, and FGF10.[1-4,16,17,19] Both SHH and the GLI family members are associated with induction of cellular proliferation, as well as dorsal-lateral patterning of the lung. SHH expression is found at the growing tips of the bronchial tubules, where it is thought to act as a mitogen for the adjacent, primitive, mesenchymal cells. *Shh*-null mutant mice exhibit foregut abnormalities.[38,39] Branching morphogenesis is severely impaired, resulting in extremely hypoplastic, rudimentary lungs that originate from a fused tracheoesophageal tube. Genetic ablation of *Gli2 (Gli2−/−)* in mice also causes foregut defects, including esophageal and tracheal stenosis, pulmonary hypoplasia, and lobation defects (fusion of the four right lobes into one lobe), coincident with diminished expression of PTCH1 and the GLI1 isoform.[40] Genetic inactivation of both *Gli2* and *Gli3* in compound, homozygous, *Gli2−/−;Gli3−/−* mice results in complete pulmonary agenesis, including agenesis of the trachea and the lung, as well as the esophagus. Esophageal atresia and tracheoesophageal fistula with fusion of the lung in the midline is found in compound *Gli2−/−;Gli3+/−* mice.[40] Haploinsufficiency of FOXF1, another SHH target that is expressed in the mesenchyme, also causes esophageal atresia, tracheoesophageal fistula, fusion of the right lung lobes, and pulmonary hypoplasia with altered expression of GLI3, FGF10, and BMP4.[41,42]

Growth factors that are critical for early lung formation include members of the fibroblast growth factor family (FGF) and their receptors, FGFR1, 2, 3, and 4, which induce cellular proliferation, migration, and differentiation in the developing lung.[1-4,16-19,43] One of the most critical events in the induction of early branching morphogenesis is the activation of FGF10 expression in the mesoderm. FGF10 functions as a chemoattractant, inducing growth of the bronchial buds toward regions of FGF10 expression in the mesoderm. FGF10 signaling is mediated by its receptor, FGFR2, which is a tyrosine kinase receptor expressed in the foregut endoderm and primitive respiratory epithelium. Disruption of FGF10 or FGFR2 expression in mutant mice results in the formation of a trachea but no lungs,[44-47] whereas blockade of FGFR2 signaling in transgenic mice, by using a mutant, dominant-negative, FGFR2(IIIb) receptor, completely blocks branching of all the conducting airways distal to the primary bronchi.[48] On the other hand, excision of a single copy of the FGFR(IIIc) isoform, which is expressed in the mesenchyme, resulted in a gain of function mutation with increased expression of the FGFR2(IIIb) isoform in mice.[49] This mutation resulted in kidney, lung, lacrimal gland, and skeletal defects, similar to those found in the human congenital disorders, *Apert* and *Pfeiffer syndromes,* which are caused by missense mutations in the human FGFR2 gene.[50,51] More recently, the hedgehog interacting protein, HIP1, has been shown to play a role in the control of SHH-mediated regulation of FGF10 expression. HIP1 is an integral membrane protein that binds to SHH and is expressed in the distal mesenchyme.[52] Targeted deletion of *Hip1* in mice resulted in defects in lobation and pulmonary hypoplasia, which were attributed to increased SHH signaling with repression of FGF10 expression at sites of secondary bud formation.[53]

RA signaling is required for normal development of many different organs, including the lung. RA signaling appears to be required for lung bud formation, because acute vitamin A deprivation in pregnant animals at the onset of lung development results in tracheal stenosis and pulmonary agenesis.[19] RA activity is mediated by binding to RA receptors, RAR(α, β, γ) and/or RXR(α, β, γ), to form a complex that is translocated to the nucleus, where it modulates gene transcription by binding to RA response elements in noncoding regions of its target genes. These receptors have multiple isoforms that form heterodimers with each other and are widely expressed throughout the embryo, as well as in the pulmonary epithelium and surrounding mesenchyme. Genetic ablation of RA receptors in mice causes abnormalities resembling those found in vitamin A–deficient animals, including malformations of the eyes, skeleton, limbs, aortic arch, genitourinary tract, and the lung. Disruption of RA signaling in compound *RARα1−/−;RARβ2−/−* mice results in tracheoesophageal fistula, agenesis of the left lung, and hypoplasia of the right lung.[54] Subsequent development of the lung during branching morphogenesis is associated with down-regulation of RA signaling, which increases FGF10 expression, limiting proliferation of distal epithelial structures.[55] Conversely, maintenance of RA signaling in embryonic lung cultures disrupts the formation of distal lung structures, while promoting the formation of proximal structures, most likely through up-regulation of the SHH pathway, which inhibits FGF10 signaling.[55]

RA signaling may be further mediated by interactions with the HOX family of homeodomain transcription factors, which determine anterior-posterior patterning of the body axis during development.[56] Expression of the HOX genes is regulated both spatially and temporarily during lung development and is

associated with branching morphogenesis.[57-59] In the mouse, *Hoxb3, b4,* and *b5* are expressed in the foregut endoderm where the lung buds will form. During lung development, *Hoxb3* and *Hoxb4* are expressed in the mesenchyme of the trachea, bronchi, and distal lung, whereas *Hoxa5, Hoxb2,* and *Hoxb5* are restricted to the distal mesenchyme.[59] RA up-regulates *Hoxb5* in embryonic lung cultures, resulting in abnormally elongated bronchial tubes and decreased branching,[60] whereas inhibition of *Hoxb5* expression results in short primary branches with decreased secondary branching.[60] Aberrant expression of HOXB5 has been associated with human *bronchopulmonary sequestration*[61] and *congenital cystic adenomatoid malformations,*[62] suggesting that dysregulation of the *HOXB5* gene may be involved in these pulmonary malformations. Targeted deletion of the *Hoxa5* gene in mice results in laryngotracheal malformation; reduced number of cartilaginous, tracheal, and bronchial rings; tracheal stenosis; impaired branching morphogenesis; and thickened alveolar walls.[63] Loss of HOXA5 was also associated with decreased expression of TTF1 and FOXA2, as well as their target genes, the surfactant proteins, in this experimental model.[63]

Congenital Disorders and Mutations Associated With Early Pulmonary Malformations

Pulmonary agenesis, lung lobation defects, tracheal stenosis (dysplastic tracheal cartilage), and tracheoesophageal fistula have been observed in some patients with *Pallister-Hall syndrome,* which is associated with mutations in the human *GLI3* gene.[50,64,65] Patients with these mutations also exhibit malformations involving the central nervous system (hypothalamic hamartoblastoma, pituitary aplasia or dysplasia), craniofacial features, limbs (postaxial polydactyly), kidneys (renal dysplasia), adrenals (adrenal hypoplasia), and the heart.[50] Esophageal atresia; tracheoesophageal fistula; esophageal and tracheal stenosis (cartilaginous sleeves); laryngomalacia, tracheomalacia, and bronchomalacia; lobar atresia; and pulmonary aplasia have been observed in patients with *Pfeiffer, Apert,* and/or *Crouzon syndromes,* all of which are associated with mutations in the human *FGFR2* gene.[50,51,66-70] Patients with these mutations also exhibit varying degrees of craniosynostosis, or premature closure of the cranial sutures.

Pseudoglandular Stage (5 to 17 Weeks After Conception)

The pseudoglandular stage of lung development is so named because of the distinct glandular appearance of the lung during this period of morphogenesis; that is, the lung is composed of multiple epithelial tubules surrounded by relatively extensive regions of mesenchyme. At the beginning of this stage, the rate of cell proliferation increases, and sequential branching of the airways and vascular structures continues. Formation of the conducting airways, including the terminal bronchioles, is more or less complete by the end of this stage, with 12 to 17 generations of bronchial tubules in the upper lobes, 18 to 23 in the middle lobes, and 14 to 23 in the lower lobes.[71] Numerous *acinar tubules and buds,* which give rise to the adult *pulmonary acinus,* are also formed in the periphery of the lung by the end of this stage, arising as distal branches of the terminal bronchioles.[72,73] The pulmonary acinus includes two to four respiratory bronchioles, each ending in six to seven generations of branched alveolar ducts and sacs.

The bronchial tubules are lined initially by a pseudostratified columnar epithelium. These cells are morphologically undifferentiated and contain large pools of intracellular glycogen, deriving most of their energy needs from anaerobic glycolysis. A prominent basement membrane, rich in laminin and collagen type IV, underlies the epithelium. Mesenchymal cells adjacent to these tubules differentiate into myofibroblasts by 7 weeks p.c., aligning themselves in a circumferential orientation that is perpendicular to the long axis of the tubules. The ECM is composed of various types of glycosaminoglycans and proteoglycans, such as chondroitan, dermatan, and heparan sulfate, as well as laminin, fibronectin, tenascin, entactin, and type I and type III collagen.[12,74] These macromolecules are important for cell proliferation, migration, adhesion, and differentiation during lung development. As branching progresses, the pseudostratified columnar epithelium is reduced to a tall columnar epithelium in the proximal airways and to a cuboidal epithelium in the distal acinar tubules and buds. Cytodifferentiation of the conducting airway epithelium occurs in a centrifugal direction with ciliated, nonciliated (serous), goblet, neuroepithelial, and basal cells appearing first in the more proximal airways.[75-77] Isolated neuroepithelial cells, the first bronchial epithelial cells to differentiate, can be detected in the proximal airways by 8 to 9 weeks p.c.[78] Clusters of neuroepithelial cells, called neuroendocrine bodies, are detected by 9 to 10 weeks p.c. These are located at branch points along the bronchial tree and are innervated by sympathetic and sensory nerve fibers. Ciliated cells appear in the epithelium of the trachea by 10 weeks, in the main stem bronchi by 12 weeks, and in the segmental bronchi by 13 weeks. Mucous cells are present by 13 weeks, and mucous glands appear in the trachea by 11 to 12 weeks and in the bronchi by 13 weeks, with active mucous production by 14 weeks.[79] Cartilage appears in the trachea and bronchi by 10 weeks and in the segmental bronchi by 16 weeks.[80] By the end of this developmental stage, cartilaginous structures extend as far as the segmental bronchi and airway smooth muscle extends as far as the alveolar ducts. Spontaneous contractility of fetal airway smooth muscle can be observed in cultured human fetal lung explants at this stage of development.[81] The smooth muscle layer enveloping the conducting airways is invested by an extensive network, or plexus, of neural ganglia and nerve bundles, which is detected as early as 7.5 to 8 weeks p.c.[82] Elastic fibers are detected in the walls of the trachea and the main stem bronchi, the pleura, and the pulmonary artery.[12] Epithelial cell differentiation is initiated in the distal acinar structures with the onset of surfactant protein B (SP-B) and C (SP-C) expression. These two hydrophobic, lung-specific proteins are expressed selectively in the distal respiratory epithelium by 12 to 14 weeks p.c.[83]

The intrapulmonary arterial system develops along with the bronchial and bronchiolar tubules, branching in parallel with these airways.[13,14,84] The pulmonary veins and lymphatics take a different pathway through the lung, coursing in between the airways in the connective tissue septa that divide and surround each pulmonary segment.[85] All of the preacinar, or distal, arteries and veins are formed by the end of this period.[13,14] Formation of these structures takes place through the process of vasculogenesis, that is, by the coalescence of nascent endothelial cells, or angioblasts (derived from the mesenchyme), into endothelial tubes. These tubes gradually become invested with smooth muscle cells so that, by the end of this developmental stage, smooth muscle actin and myosin can be detected in all of the vasculature.[86-89]

A variety of congenital defects in branching morphogenesis may arise during the pseudoglandular stage of lung development, including bronchopulmonary sequestration, congenital cystic adenomatoid malformation, cyst formation, acinar dysplasia or aplasia, and pulmonary hypoplasia. The *pleuroperitoneal cavity* also closes early in the pseudoglandular period. Failure to close the pleural cavity is often accompanied by herniation of the abdominal contents leading to secondary pulmonary hypoplasia (see later).

Molecular Mechanisms Regulating Branching Morphogenesis

During the pseudoglandular stage of lung development, FGF10 signaling continues to be critical for branching morphogenesis (as discussed earlier). FGF7 (also known as KGF) is also expressed

in the mesenchyme at this time and binds to FGFR2 receptors in the epithelium. FGF7 influences branching morphogenesis by promoting epithelial growth and differentiation. Overexpression of FGF7 in transgenic mice results in the formation of large, fluid-filled, cyst-like structures,[90,91] whereas *Fgf7*-null mutants have no abnormalities, suggesting that FGF7 signaling in the lung overlaps with that of other growth factors.[92] FGF9 is also expressed at high levels during this stage of lung development, but it is synthesized in the pulmonary epithelium, not in the mesenchyme. FGF9 signaling is mediated through FGFR1 receptors, which are expressed in the mesenchyme. Targeted disruption of *Fgf9* in null mutant mice results in pulmonary hypoplasia, because of a reduction in mesenchymal tissue and decreased branching of the airways, although sacculation of the peripheral air spaces and cytodifferentiation of alveolar epithelial cells are not perturbed.[93]

Factors that tend to antagonize or limit FGF signaling, in addition to SHH, include transforming growth factor β (TGF-β), bone morphogenetic protein-4 (BMP4), and the *Sprouty* (*Spry2* and *Spry4*) genes, which may also modulate the EGF and TGF-β pathways.[1-4,16-19,43] TGF-β modulates branching morphogenesis in the lung by limiting epithelial bud formation. TGF-β accumulates in the mesenchyme adjacent to the proximal airways and at sites of cleft formation (between the branching airways), where it inhibits FGF10 expression and promotes the synthesis and deposition of ECM components. Deposition of ECM components stabilizes the proximal airways and prevents further branching at these sites. Induction of SMAD family members, downstream mediators of TGF-β, also inhibits cell proliferation, as well as FGF10 expression.

Members of the TGF-β family are also important for proximal-distal differentiation and left-right patterning in the lung. Weaver and colleagues[94] showed that disruption of BMP4 signaling in mice alters proximal-distal differentiation patterns in the developing pulmonary epithelium. BMP4 is expressed at high levels in the distal epithelium and counteracts FGF10-induced bud formation. Overexpression of the BMP antagonist, *Xnoggin,* or blockade of BMP4 signaling in transgenic mice by using a dominant-negative BMP receptor *(dnAlk6),* resulted in a reduction of distal alveolar cell types with a concomitant increase in bronchiolar cell types (ciliated cells and Clara cells).[94] On the other hand, targeted deletion of *Noggin* in homozygous null mutant mice resulted in esophageal atresia and tracheoesophageal fistula, as well as in defects in branching morphogenesis.[95] Overexpression of Gremlin, a secreted protein that binds to BMP4 and prevents it from interacting with its receptor, resulted in a similar phenotype in transgenic mice,[96] whereas reduction of Gremlin expression in cultured lungs increased branching morphogenesis, epithelial cell proliferation, and cytodifferentiation of type II cells.[97]

Left-right asymmetry is accomplished by a signaling cascade involving four other members of the TGF-β family, LEFTY1, LEFTY2, NODAL, and GDF1, as well as the *Pitx2* gene, which is a transcriptional target of Nodal-signaling.[1-4,16-19] LEFTY1 restricts the expression of LEFTY2 and NODAL to the left side. Inactivation of *Lefty1* in mice leads to bilateral expression of *Lefty2,* resulting in left pulmonary isomerism. In this condition, the lobation pattern normally seen on the right side (four lobes) is replaced by the left-sided pattern (one lobe), resulting in bilateral single, or "left," lobes.[98] In contrast, targeted deletion of *Nodal*, *Gdf1,* or *Pitx2* in mice results in right isomerism of the lung.[98-101] Other factors that may be involved in left-right patterning in the lung include RA signaling and FOXJ1 (also known as HFH4) expression. Targeted disruption of RA signaling in compound *RARα1−/−;RARβ2−/−* null mutant mice results in agenesis of the left pulmonary lobe,[54] and targeted disruption of the nuclear transcription factor *Foxj1* results in random left-right asymmetry, as well as the complete absence of cilia.[102] This phenotype is similar to that seen in the human congenital disorder, *Kartagener syndrome,* in which situs inversus, bronchiectasis, and immotile cilia are found.[50,103]

Additional growth factors that promote branching morphogenesis and growth of the lung via interaction with their respective membrane receptors include (1) FGF1 (also known as acidic FGF) and FGF2 (also known as basic FGF), which up-regulate FGF7; (2) epidermal growth factor (EGF) and TGF-α, which stimulate branching morphogenesis, cell proliferation, and cytodifferentiation; (3) hepatocyte growth factor (HGF), which is a potent mitogen; (4) insulin growth factor (IGF), which facilitates signaling of other growth factors; (5) platelet-derived growth factor (PDGF), which is a potent mitogen and chemoattractant for mesenchymal cells; and (6) vascular endothelial growth factor (VEGF), which regulates vascular growth and patterning.[19,43,104]

Molecular Mechanisms Regulating Vascular Development

Transcriptional factors thought to be involved with specification of vascular progenitor cells include the paired-related homeobox gene, *Prx1,* and the divergent homeobox gene, *Hex,* whereas the homeobox gene *Prox1* is associated with differentiation of venous endothelial cells into the primitive lymphatic vascular network.[105,106] Vascular growth and patterning is regulated primarily by VEGF, which is synthesized in the epithelium and secreted into the mesenchyme, where it binds to its receptors, VEGFR1 (also known as FLT1 in the mouse), VEGFR2 (also known as FLK1 in the mouse, or KDR in humans), and VEGFR3, found on primitive endothelial cells.[13,14,105-107] Targeted inactivation of the *Vegf* gene in mice results in impaired angiogenesis and is lethal in the fetal period,[108] and targeted mutation of *Vegfr1 (Flt1)* is also fetal lethal because of disrupted vascular formation in the embryo.[109] Ruhrberg and colleagues[110] engineered a transgenic mouse expressing an isoform of VEGF-A (Vegf120/120) that lacked heparin-binding or ECM interaction domains. Expression of this isoform in the lung impaired lung microvascular development and delayed air space maturation.[111] Lymphatic endothelial cells undergo proliferation and migration in response to VEGF-C/D signaling through the VEGFR3 receptor, which becomes restricted to lymphatic endothelial cells once lymphatic development is initiated.[105,106] Deletion of VEGF-C in mice leads to failure in migration and proliferation of lymphatic endothelial cells and results in the complete absence of lymphatic vessels,[112] and either VEGF-C haploinsufficiency or insufficient VEGFR3 signaling caused by mutation of the kinase domain results in hypoplastic lymphatic vascular networks.[112,113] Additional molecules involved in both blood and lymphatic vessel formation include members of the ephrin and angiopoietin families of proteins, along with their tyrosine kinase receptors, which are important for assembly, stabilization, remodeling, and maintenance of vessel integrity.[105,106]

Vascular development is also dependent on interactions with surrounding ECM components.[12,74] Fibronectin, which binds to endothelial cells via integrin receptors, is a component of the capillary basement membrane and is important for early capillary tube formation. Fibronectin also promotes cell migration and proliferation and prevents apoptosis, or cell death. Mice that lack the fibronectin gene fail to develop normal vasculature and die in utero.[114] Laminin, a large, noncollagenous glycoprotein, is another important basement membrane component that promotes cell attachment, migration, differentiation, cell growth, and vascular tube formation.[115] Type IV collagen, which is the major structural component of mature basement membranes, also binds to endothelial cells through specific integrin receptors and promotes cell attachment and cytodifferentiation.[12,74] Type IV collagen is expressed later than fibronectin and laminin, and its appearance coincides with a reduction in endothelial cell division, promoting tube formation and stabilizing the structure of newly formed vessels.[12]

Additional growth factors and their receptors that modulate vascular development include the platelet-derived growth factors, PDGFA and PDGFB, which function as mitogens and

chemoattractants for other mesenchymal cells that will be incorporated into the vessel wall. Once these cells contact the endothelium, they differentiate into smooth muscle cells, most likely through the activation and secretion of TGF-β, which in turn inhibits further endothelial cell proliferation and stimulates ECM deposition (elastin and collagen) by the smooth muscle cells. A similar phenomenon occurs with the recruitment of smooth muscle cells by the developing bronchial tubules. In addition to PDGF and TGF-β, endothelial cells secrete a variety of other growth factors and inhibitors that are important for cell proliferation and differentiation. These include EGF/TGF-α, FGF1, FGF2, IGF-I, and IGF-II (and their receptors), all of which stimulate cell proliferation; and TNF-α and heparin sulfate, which inhibit cell proliferation. The deposition of ECM components (collagen and elastin) appears to be stimulated by both PDGF and TGF-β, as well as by IGF-I and IGF-II.[107]

Canalicular Stage (16 to 26 Weeks After Conception)

The canalicular stage is so named because of the appearance of vascular canals, or capillaries, that multiply in the interstitial compartment to form the *air-blood barrier,* or *alveolar-capillary respiratory membrane,* the future gas-exchange surface of the lung.[5] Development of the alveolar-capillary membrane, along with the synthesis and secretion of *pulmonary surfactant,* is critical for extrauterine survival of the immature fetus, if delivered prematurely near the end of this stage. Gas exchange cannot occur in the premature infant unless these capillaries are close enough to the adjacent alveolar epithelium for optimal gas diffusion to take place across their surfaces. Rapid expansion of the capillary bed, with condensation and thinning of the mesenchyme, is the first critical step in the formation of the gas-exchange regions of the lung. During this stage of lung development, the total surface area of the alveolar-capillary membrane increases exponentially with a concomitant decrease in the mean mesenchymal wall thickness, thereby increasing the potential for gas exchange in the immature lung.[5] Disturbances in this stage of lung development result in severe hypoxemia and are not compatible with life after birth.

At the beginning of the canalicular stage, formation of the bronchial tree is complete, and the terminal bronchioles have divided into two or more respiratory bronchioles that have subdivided further into small clusters of short acinar tubules and buds lined by cuboidal epithelium. These structures undergo further differentiation to become the adult respiratory unit, or *pulmonary acinus,* consisting of alveolarized respiratory bronchioles, alveolar ducts, and alveoli. Clusters of acinar tubules and buds grow by further lengthening, subdividing, and widening at the expense of the surrounding mesenchyme. The proportion of dividing epithelial and endothelial cells increases, and the number of dividing interstitial cells (fibroblasts) falls. Apoptosis of cells in the interstitial tissue contributes to mesenchymal involution and thinning of the alveolar septa at this stage.[11] Epithelial growth drops in the larger airways, and cell proliferation occurs predominantly in the peripheral acinar tubules and buds. This peripheral growth is accompanied by the growth and development of intraacinar capillaries (derived from angioblastic cells in the interstitium), which align themselves around the air spaces, establishing contact with the adjacent epithelium to form the primitive alveolar-capillary membrane. Epithelial cell differentiation becomes increasingly complex and is especially apparent in the distal regions of the lung parenchyma, where alveolar type I and type II cells can be detected. Bronchiolar cells begin to express differentiated features and to synthesize cell-specific proteins, such as the Clara cell secretory protein (CCSP).[25,116-118] Cuboidal type II cells lining the distal tubules express increasing amounts of surfactant proteins and phospholipids.[25,83,119-125] Nascent lamellar bodies, the storage form of pulmonary surfactant, are seen in association with rich glycogen stores in cuboidal pre–type II cells lining the acinar tubules and buds.[126-129] Cells of the proximal acinar tubules become flattened and attenuated, acquiring features of typical squamous, type I alveolar epithelial cells. Type I cell differentiation occurs in conjunction with the formation of the alveolar-capillary membrane, that is, wherever endothelial cells of the developing capillary system come into contact with adjacent acinar epithelial cells. Where this occurs, the intercellular junctional complexes, originally localized around the epithelial cell apex, shift to the basolateral aspect of the intercellular cleft. The cells develop thin cytoplasmic attenuations, differentiating into squamous type I cells and losing features previously associated with pre–type II cells. By the end of the canalicular stage of lung development, the potential alveolar-capillary membrane (air-blood barrier) is thin enough to support gas exchange.

Abnormalities of lung development associated with the canalicular stage include acinar dysplasia, alveolar capillary dysplasia, and pulmonary hypoplasia. Pulmonary hypoplasia is often caused by diaphragmatic hernia or compression by thoracic or abdominal masses, by prolonged rupture of membranes causing oligohydramnios, or by renal agenesis (Potter syndrome) in which amniotic fluid production is impaired. Although postnatal gas exchange can be supported late in the canalicular stage, infants born during this period generally have severe complications related to decreased levels of pulmonary surfactant, which cause respiratory distress syndrome (RDS) and hyaline membrane disease (HMD). The administration of exogenous surfactants improves survival in these infants, but bronchopulmonary dysplasia (BPD), a complication caused by ventilatory therapy for RDS, frequently develops later. Surfactant synthesis and mesenchymal thinning can be accelerated by glucocorticoids,[130-133] which are administered to mothers to prevent RDS and HMD when a premature birth is anticipated.[134-136]

Saccular Stage (24 to 38 Weeks After Conception)

During the saccular stage of lung development, the terminal clusters of acinar tubules and buds begin to dilate and expand into thin, smooth-walled, transitory alveolar saccules and ducts, and a marked reduction, or condensation, of the surrounding mesenchymal (interstitial) tissue occurs. The lung continues to grow peripherally by branching and growth of the transitory alveolar ducts so that, by the end of this period, three additional generations of alveolar ducts ending in terminal saccules have formed. These peripheral regions of the lung also increase in size as a result of lengthening and widening of all of the segments distal to the terminal bronchioles. Intersaccular and interductal septa develop that contain delicate collagen fibers and a double capillary network.[5] Overall cell proliferation slows as a result of a sharp drop in division of the epithelial cell population. With the reduction in epithelial cell proliferation comes ultrastructural evidence of cytodifferentiation. Maturation of type II epithelial cells continues and is associated with increased synthesis of surfactant phospholipids[122,137]; the surfactant-associated proteins A, B, C, and D*; and ABCA3, a phospholipid transporter important for lamellar body formation.[141] Glycogen content is reduced, and mitochondrial enzyme activity increases, indicating a shift to aerobic oxidative pathways. Lamellar bodies increase in number and size, and increasing amounts of tubular myelin, the secretory form of pulmonary surfactant, are seen in the terminal air spaces.[126] The concentration of pulmonary surfactant is still low, however, and its phospholipid composition differs significantly from that at term.[122]

Squamous type I cells continue to differentiate and line an increasing proportion of the surface area of the distal lung.

*References 25, 83, 119, 121, 123-125, 128, 138-140.

Enlargement of the potential gas exchange surface is dependent on the development of type I cells with their attenuated, flattened, squamous cell shape. Capillaries become associated more closely with the squamous type I cells, decreasing the diffusion distance between the air spaces and the capillary bed. Basal lamina of the epithelium and endothelium fuse to form the thin-walled alveolar-capillary membrane. In the newborn and adult lung, the mean thickness of the alveolar-capillary membrane is 0.6 μm, which permits passive diffusion of oxygen and carbon dioxide between the alveolar lumen and the capillary bed.[5] Near the end of this stage, the stroma, or interstitial tissue, contains increasing amounts of ECM, and elastin is deposited in areas where future interalveolar septa will form, subdividing the terminal alveolar saccules into true alveoli. The immature lung contains relatively few elastin and collagen fibers, has little elastic recoil, and can be easily ruptured at this stage.[12]

By the beginning of the saccular stage of lung development, the conducting airways have developed both mucous cells and ciliated cells. Cartilage and submucosal glands extend as far down the airway as they do in the adult lung. The epithelial cells are capable of producing fetal lung fluid. Abnormalities associated with the saccular stage of lung development are similar to those associated with the canalicular stage of lung development, including pulmonary hypoplasia, acinar dysplasia or aplasia, alveolar capillary dysplasia, and RDS, HMD, and BPD in the premature infant.

Alveolar Stage (36 Weeks After Conception to 2 Years After Birth)

The alveolar stage is the last stage of lung development and is marked by the formation of secondary alveolar septa, which partition the terminal ducts and saccules into true alveolar ducts and alveoli, and maturation of the alveolar-capillary membrane. This process greatly increases the surface area of the lung available for gas exchange. At the beginning of this stage, the alveolar septa are relatively thick and contain a capillary network on each side of a central core of connective tissue, often referred to as a double capillary network.[5] The secondary interalveolar septa consist of short buds or projections of connective tissue that also contain a double capillary network and interstitial cells that are actively synthesizing collagen and elastin. Restructuring of the terminal saccule into a true alveolus consists of lengthening and thinning of the secondary septa, reduction of septal interstitial tissue, and remodeling of the capillary bed by fusion of the two septal capillary networks into one.[5] Pulmonary vascular resistance decreases as remodeling of the pulmonary vasculature and capillary bed occurs. This stage is accompanied by a phase of rapid cellular proliferation in both the epithelial and mesenchymal cell populations. Interstitial fibroblasts actively proliferate early in this stage but then slow down as increased synthesis and deposition of collagen, elastin, and fibronectin start to occur. Endothelial growth is brisk throughout this stage, and dividing endothelial cells are located primarily in the developing secondary septal crests. Both type II and type I cells increase in number during this stage, but only type II cells are proliferating actively, suggesting that type I cells are derived from type II cells. Type I cells are thought to be terminally differentiated and to lack the capacity for mitosis. Although type II cells account for two thirds of the total number of alveolar epithelial cells in the adult human lung, the larger squamous type I cells actually occupy 93% of the total alveolar surface. Although type I cells form a tight epithelial barrier that is impervious to extracellular fluid and ions, they are easily injured by oxidants, barotrauma, and infection, readily detaching from the alveolar wall when injured. Injury to the lung during this stage of development can result in abnormal remodeling of the lung with a reduction in the number of alveoli and the development of interstitial fibrosis. Additional factors that may cause disturbances in alveolarization include administration of glucocorticoids, which inhibits cellular proliferation, reducing septation and formation of alveoli. Conversely, glucocorticoid administration enhances thinning of the alveolar septa, increases maturation of type II cells, and enhances the production of surfactant in the premature lung and in fetal lung explants.[130-135]

Disorders associated with disturbances in the alveolar stage of lung development, which present at birth, include persistent fetal circulation and pulmonary hypertension of the newborn, lobar emphysema, meconium aspiration syndrome, pneumonia, RDS caused by asphyxia and/or surfactant deficiency caused by mutations in the *SFTPB, SFTPC,* and *ABCA3* genes,[142-145] and defects in cholesterol synthesis.[146]

Molecular Mechanisms Regulating Alveolar Development

Although many studies describing the effects of exogenous substances and/or mechanical ventilation on alveolar development in the premature lung have been published, little is known about the molecular mechanisms that regulate morphogenesis and cytodifferentiation during the canalicular, saccular, and alveolar stages of normal lung development. Recently, factors that modulate elastin formation in the developing lung have been shown to play an important role in the process of alveologenesis. Alveologenesis is characterized by the development of secondary septae that subdivide the terminal air sacs into definitive alveoli. This process appears to be driven by the synthesis and deposition of elastin by alveolar myofibroblasts located at the tips of the developing septa. PDGF, a potent mitogen and chemoattractant for mesenchymal cells, is expressed in the pulmonary epithelium, and its receptor, PDGFRA, is found on presumptive alveolar smooth muscle cells, or myofibroblasts. In mice with a targeted deletion of the *PdfgA* gene, myofibroblasts fail to multiply and migrate into the primary alveolar septa.[147,148] This results in postnatal development of emphysema, or enlarged alveolar saccules, because of a complete failure of alveologenesis, as well as reduced deposition of elastin in the lung parenchyma. Mice with a targeted deletion of the elastin gene *(Eln−/−)* also developed emphysema in the postnatal period because of the absence of elastin synthesis and deposition, which resulted in the complete failure of alveologenesis.[149] The lungs of mice lacking lysyl oxidase, an enzyme responsible for cross-linking both collagen and elastin in vivo, showed impaired development of the distal and proximal airways with enlarged alveoli and disorganization of elastic and collagen fibers in the surrounding mesenchyme.[150] Mice lacking the microfilament fibulin-4, an ECM molecule important for the stabilization and organization of elastic fibers, exhibited severe lung and vascular defects,[151] and fibulin-5–defective mice exhibited severe emphysema.[152,153] RA has been shown to enhance ongoing alveologenesis by up-regulating the transcription of tropoelastin, the soluble precursor of elastin.[154] Mice bearing compound null deletions in the RA receptors, RARγ−/−, RXRα+/−, demonstrate a decrease in elastin gene expression and elastic tissue with a reduction in alveolar formation in the postnatal lung.[155]

FGF signaling has also been implicated in the process of alveologenesis. The lungs of compound null mutant mice, homozygous for targeted deletion of both the *Fgfr3* and *Fgfr4* genes, are completely blocked in alveologenesis and do not form definitive alveoli.[156] In contrast to the *PdfgA*- and *Eln*-null mutant mice, no abnormalities in the alveolar myofibroblast cell population or in elastin synthesis and deposition during alveologenesis were observed, although increased elastin deposition was detected later in the postnatal period (day 21), suggesting that elastin synthesis is increased. Although the double mutant mice were 50% smaller than normal mice, were sickly, and died within the first few months of life, no differences in cell proliferation, cell death, or surfactant protein production were found in their lungs.

Of interest, several nuclear transcription factors important for early lung development are also important for cytodifferentiation

and maturation of the lung. These include FOXA2, TTF1, and GATA6, which are important transcriptional regulators of a variety of target genes during the later stages of lung development, including those important for surfactant production, fluid and electrolyte transport, and vasculogenesis. Mutation of *Titf1*[33] and type II cell–specific deletion of *Foxa2*[157] in transgenic mice impaired lung maturation in the saccular and/or alveolar stage of lung development, resulting in respiratory failure at birth caused by poor gas diffusion. Cytodifferentiation of alveolar type I and type II cells, surfactant synthesis, fluid and electrolyte transport, and vasculogenesis were all disrupted in these models. Lung-specific expression of a GATA6-Engrailed, dominant-negative, fusion protein in transgenic mice also impaired maturation of the alveolar epithelium.[158,159] Transgenic mice lacked detectable alveolar type I cells, with decreased expression of the type I cell markers, aquaporin-5 and T1α. Although the distal airways were dilated, squamous differentiation of the alveolar epithelium was disrupted. Instead, the distal airways were lined with cuboidal alveolar epithelial cells. The alveolar septae were thickened with a relatively undeveloped capillary network. Expression of SP-B, SP-C, CCSP, and FOXJ1 was also decreased.

Metabolic disturbances in pathways associated with cholesterol and lipid synthesis, as well as the generation and packaging of surfactant phospholipids and proteins, also contribute to disturbances in morphogenesis and function in the alveolar stage of lung development. Neonatal mice lacking functional 7-dehydrocholesterol reductase (DHCR7), a model for the human disease Smith-Lemli-Opitz syndrome (SLOS), are deficient in cholesterol and die within 24 hours of birth of respiratory failure caused by pulmonary hypoplasia with impaired sacculation of the lung, defective alveolar type I cell differentiation, and delayed vascular development of the alveolar capillary network.[146] Of interest, pulmonary hypoplasia, abnormal pulmonary lobation, and anomalies of laryngeal and tracheal development have also been reported in patients with SLOS.[160] C/EBPa, a member of the bZip domain–containing family of transcription factors important for the regulation of genes involved in lipid synthesis, is also expressed in epithelial cells of the developing lung.[161] *Cebpa*-null mutant mice die of respiratory failure at birth, exhibiting findings similar to those found in the *Titf1* mutant and *Foxa2*-deleted mice.[162,163] Structural and biochemical maturation of the lung was delayed; cytodifferentiation of alveolar type I and type II cells was arrested, and both surfactant lipid and protein synthesis was decreased. Although null mutant mice lacking the surfactant protein SP-B[164] or the phospholipid transporter ABCA3,[165-167] important for lamellar body formation, do not exhibit structural abnormalities in their lungs, these mice die at birth of acute respiratory distress caused by surfactant deficiency. Likewise, mutations in the human *SFTPB* and *ABCA3* genes are associated with acute respiratory distress and failure in the neonatal period.[168,169]

ABNORMAL DEVELOPMENT OF THE LUNG AND CONDUCTING AIRWAYS

As can be seen from Table 78-1, the majority of pulmonary malformations arise during the *embryonic* and *pseudoglandular* stages of lung development. These malformations represent a spectrum of closely related abnormalities associated with the early stage of lung bud formation, branching morphogenesis, separation of the trachea from the esophagus, and failure of the pleuroperitoneal cavity to close properly. Abnormalities in other organ systems, such as renal agenesis, dysplastic growth of the kidney, or congenital diaphragmatic hernia, may also affect branching morphogenesis of the lung during these early developmental stages. During the canalicular and saccular stages of lung development, abnormalities related to growth and maturation of the respiratory parenchyma and its vasculature predominate, leading to abnormalities in acinar development, alveolar capillary dysplasia, pulmonary hypoplasia, and respiratory insufficiency. Infants born prematurely, during the saccular and early alveolar stages of development, are subject to clinical complications and syndromes that are related primarily to biochemical immaturity of the lung, or surfactant deficiency. Surfactant deficiency causes respiratory distress in the immediate postnatal period and has been associated with HMD in the past. Acute lung injury in the neonatal period may alter subsequent alveolar growth and differentiation, resulting in BPD or chronic interstitial lung disease. Mutations in the *SFTPB* and *ABCA3* genes have been associated with respiratory distress and failure in term infants,[168,169] and mutations in the *SFTPC* gene, and in a subset of mutations in the *ABCA3* gene, have been associated with the onset of chronic interstitial lung disease in the first year of life.[170-173]

Congenital Malformations of the Tracheobronchial Tree

Tracheoesophageal Fistulas

Most congenital malformations of the tracheobronchial tree arise during formation of the respiratory diverticulum and branching morphogenesis of the lung. One of the most critical events in the formation of the respiratory system is the initial separation of the primitive foregut into the respiratory and alimentary tracts. This process begins during the third week of gestation and is complete by the sixth week. Failure of this process to proceed normally results in the formation of a tracheoesophageal fistula, one of the most commonly encountered abnormalities of the trachea. Tracheoesophageal fistulas are usually found in combination with various forms of esophageal atresia.[10,174,175] The most common combination is esophageal atresia with a lower, or distal, tracheoesophageal fistula: the upper segment of the esophagus ends in a blind pouch, and the lower segment originates from the trachea just above the bifurcation. This combination accounts for 80% to 90% of all cases. Other combinations are (1) the upper esophagus ending in the trachea and the upper portion of the lower esophagus forming a blind pouch; (2) a double fistula, where both upper and lower portions of the esophagus join the trachea at separate points along its length; (3) a common fistula without esophageal atresia; (4) esophageal atresia without a fistula, or connection to the trachea; and (5) atresia, or absence, of the trachea, with normal bronchi and lungs. In the latter case, the trachea ends in a blind sac just below the larynx, and the lungs may be connected directly to the esophagus via the bronchi or bronchoesophageal fistulas. Tracheoesophageal fistula in low-birth-weight infants is often associated with a variety of other malformations, which carries a high risk of a poor outcome. In comparison, survival from isolated tracheoesophageal fistula is almost 100% in term infants. Tracheoesophageal fistula is found in VACTERL syndrome, in association with vertebral anomalies, anal atresia, congenital cardiac disease, renal anomalies, and limb abnormalities.[50] From their mutant analysis of the Gli genes, which encode transcription factors mediating SHH signal transduction, Kim and colleagues[176,177] observed that defective SHH signaling leads to a spectrum of developmental anomalies in mice strikingly similar to those of VACTERL. They proposed that VACTERL could be caused by defective SHH signaling during human embryogenesis.

Tracheal Agenesis, Tracheal Stenosis, and Tracheomalacia

Tracheal agenesis is a rare, but fatal, anomaly thought to be caused by displacement of the tracheoesophageal septum. Classification of anatomic variations in this malformation is based on the length of the agenetic segment and the presence or absence of an esophageal fistula.[175,178] The most common variation is complete absence of the trachea below the larynx with a fistula connecting fused main stem bronchi and the esophagus. Other variations are tracheal agenesis with fistulas connecting each main stem bronchus to the esophagus; agenesis of the proximal trachea with main stem bronchi fused to form the distal trachea,

with or without a fistulous connection to the esophagus; or a short segment of tracheal agenesis between the proximal and distal segments of the trachea, linked by an atretic fibrous band of tissue.

Tracheal stenosis is a rare malformation in which the trachea is narrowed, because of either intrinsic abnormalities in cartilage formation or external compression by abnormal vessel formation, or vascular rings.[178] Narrowing of the trachea by compression results in local obstruction to the passage of air, and cartilage deformities may cause obstruction of the airway on both inspiration and expiration. The major underlying causes of intrinsic tracheal stenosis are abnormalities in cartilaginous ring formation, because of either posterior fusion of the normally C-shaped rings or formation of a complete cartilaginous sleeve. The latter malformation has been reported in children with craniosynostosis syndrome, including *Crouzon, Apert,* and *Pfeiffer* syndromes.[50,51,66-70] These syndromes involve abnormal fusion of skeletal or osseous structures and are associated with mutations in the FGF receptor, *FGFR2*.[50,51,69,70] These malformations represent mesenchymal defects in which the cells do not respond normally to FGF signaling. Extrinsic stenosis of the trachea is caused by external compression of the trachea, usually associated with abnormally situated blood vessels, termed vascular rings. These include a double aortic arch, a right aortic arch with a left ligamentum arteriosum, an aberrant (retroesophageal) right subclavian artery, an anomalous left innominate or carotid artery, a sling (retrotracheal) pulmonary artery, or a right aortic arch with aberrant left subclavian artery.

Tracheomalacia occurs when an absence or "softening" of the cartilaginous rings exists, which causes the trachea to collapse on expiration, creating an airway obstruction.[175,178] In the normal trachea, the cartilage–to–soft tissue ratio is 4.5:1, a ratio that remains constant throughout childhood. In tracheomalacia, a reduction in this ratio occurs, in some instances as low as 2:1.[178] This malformation may be segmental or diffuse. In most cases, tracheomalacia is associated with other congenital malformations, such as tracheoesophageal fistula and vascular rings. Tracheomalacia is rare, and no definitive prevalence rates are available.

Bronchial Atresia, Bronchial Stenosis, and Bronchomalacia

Bronchial atresia is a rare anomaly. The most common affected lobe is the left upper lobe, but atresia of the right upper and lower lobes has also been reported. The segmental bronchus is the more common site of atresia, but subsegmental and lobar bronchi can also be affected.[175,178] The distal lung is hypoplastic, emphysematous, or hyperinflated. Often a deficiency of bronchi and vessels exists in the affected lobe, as well as an absence of segmentation and interlobular septae. Like tracheal stenosis, *bronchial stenosis* may be intrinsic or caused by extrinsic compression.[179] Intrinsic bronchial stenosis is rare and is usually associated with anomalous cartilage segmentation. Extrinsic bronchial stenosis caused by compression is usually associated with congenital heart disease. Compression occurs when the pulmonary arteries enlarge in response to pulmonary hypertension, compressing the left upper lobe bronchus. An enlarged left atrium, a bronchogenic cyst, or a teratoma may also compress the left main bronchus. *Bronchomalacia* is caused by abnormalities in the bronchial cartilage, which leads to collapse, or bronchiectasis, of the affected airway during respiration. Bronchomalacia may be associated with other anomalies, various skeletal dysplasias, or widespread, congenital cartilage deficiency.[178]

Bronchopulmonary Sequestration

This malformation develops as a mass of abnormal pulmonary tissue, which is not connected to the tracheobronchial tree and which receives its blood supply from one or more anomalous systemic arteries arising from the aorta.[178-181] Two forms of bronchopulmonary sequestration exist. Intralobar sequestrations occur within the visceral pleural lining of a pulmonary lobe, and extralobar sequestrations are found outside the pleural lining. Both types of sequestration occur more frequently on the left side, sometimes in association with diaphragmatic defects. Rarely, a sequestration may be connected to the esophagus or to the stomach.

Intralobar sequestrations are found most frequently in the posterior basal segment of the left lower lobe. The blood supply is derived from either the thoracic or abdominal aorta, and the venous drainage is to the pulmonary vein of the affected lobe. Embryologically, the pulmonary artery appears to fail to supply a peripheral portion of the lung. Instead, the arterial supply is derived from a persistent ventral branch of the primitive dorsal aorta. Although many cases of intralobar sequestration occur in children, at least half of affected patients are over 20 years old when the diagnosis is made. Clinically, these patients present with recurrent pulmonary infection, cough, or chest pain. The affected tissue is often cystic, lined with either columnar or cuboidal epithelium, and filled with mucus. Again, a continuous accumulation of mucous secretions exists, which gives rise to acute and/or chronic infections and inflammation.

Extralobar sequestration develops as a complete, separate segment of pulmonary tissue, or accessory lobe, which is enclosed within its own pleural sac. Although the embryologic origin of this malformation is unknown, it may develop from the primitive gut as an extra, more distally placed, lung bud, which is then sealed off. Extralobar sequestration usually occurs on the lower left side of the thorax, often between the left lower lobe and the diaphragm. Other extrapulmonary sites of sequestration include paraesophageal, mediastinal, or paracardiac regions, as well as within the muscle of the diaphragm and below the diaphragm in the retroperitoneum. The arterial supply is from the abdominal aorta or one of its branches, while the venous drainage is into the venous system, creating a left-to-right shunt. This malformation is frequently associated with other congenital anomalies, especially congenital diaphragmatic defects, which occur in more than half of the cases. The majority of extralobar sequestrations are found in children under 1 year of age, but the lesion occurs in older children and adults as well. Clinically, extralobar sequestration is usually asymptomatic and is often discovered during repair of a diaphragmatic defect. If the sequestration is located in the wall of the esophagus, however, it may cause dysphasia and hematemesis. Mediastinal or hilar locations may also cause symptoms because of bronchial obstruction and overinflation of the lobe, or, conversely, because of compression of normal pulmonary parenchyma. If the sequestered lobe becomes infected, it may appear to be a chronic pulmonary abscess accompanied by fever, chest pain, cough, and bloody, purulent sputum. Histologically, the lesion may be composed of normal lung or of immature or dysplastic pulmonary parenchyma, with absent or reduced number of cartilaginous bronchi and an irregular pattern of bronchiole-like structures resembling congenital adenomatoid malformation (see later).

Congenital Bronchogenic Cysts

Bronchogenic cysts are caused by abnormal budding and branching of the tracheobronchial tree during its development.[175,179] Most bronchogenic cysts are found in paratracheal, carinal, hilar, or paraesophageal regions (middle mediastinum), but they may also be found in the lungs as pulmonary cysts, which communicate with the tracheobronchial tree. In neonates, communication between a cyst and the tracheobronchial tree may incorporate a check valve mechanism, which results in rapid expansion of the cysts. Sometimes the cyst becomes so large that it compresses the mediastinum, compromising the heart and resulting in death. Mediastinal cysts, on the other hand, rarely communicate with the tracheobronchial tree. They are often lined with ciliated columnar epithelial cells and rarely contain distal lung

parenchyma. These cysts are filled with a clear, serous fluid unless they become infected. The walls of these cysts generally contain smooth muscle, cartilage, and mucous glands.

Congenital Lobar Emphysema (Pulmonary Overinflation)

Congenital lobar emphysema, or pulmonary overinflation, can be divided into two different types: (1) congenital lobar overinflation and (2) regional, or segmental, pulmonary overinflation.[175,180] In congenital lobar overinflation, either an upper or a middle lobe of the lung is hyperinflated and compresses the remaining ipsilateral lung or lobes. If a marked shift occurs of the mediastinum to the opposite side, a ventilatory crisis ensues with dyspnea, cyanosis, and sometimes circulatory failure. Most cases are caused by partial bronchial obstruction. Extrinsic bronchial obstruction may be caused by dilated pulmonary vessels, as in patent ductus arteriosus, total anomalous venous return, and other cardiac defects that cause increased pulmonary blood flow. Intrathoracic masses, such as bronchogenic cysts, extralobar sequestrations, enlarged lymph nodes, and neoplasm may also cause bronchial compression. Intrinsic bronchial obstruction is most often related to defects in the bronchial cartilage with absent or incomplete rings. These abnormal bronchi collapse during expiration, leading to distal air trapping and overinflation of the affected lobe. In regional, or segmental, pulmonary overinflation, only a small segment of the lung is hyperinflated, usually because of bronchial atresia.

Congenital Malformations of the Distal Lung Parenchyma

Pulmonary Agenesis and Aplasia

Pulmonary agenesis and aplasia represent two different forms of arrested lung development that results in the absence of the distal lung parenchyma.[175,178] Pulmonary agenesis is the complete absence of one or both lungs, including bronchi, bronchioles, vasculature, and respiratory parenchyma. In pulmonary aplasia, only rudimentary bronchi are present, each of which ends in a blind pouch, with no pulmonary vessels or respiratory parenchyma. Bronchial hypoplasia with variable reduction in lung tissue (hypoplasia) has also been reported.[178] The incidence of these anomalies is rare and represents failure of one of the primitive foregut branches to develop during the early, embryonic stage of lung development. Developmental arrest at a later stage may result in lobar agenesis or pulmonary dysplasia; some bronchial elements are present but no alveoli exist.

Bilateral agenesis of the lung is very rare and is caused by developmental arrest in the outgrowth of the respiratory primordium during the embryonic stage of lung development. Several cases of bilateral agenesis of the lung have been reported in the literature.[174] In one case, a trachea with 10 cartilaginous rings remained connected to the esophagus throughout its length. No lung buds or pleural cavities existed. In another case, the trachea was separated from the esophagus but ended blindly with only two cartilaginous rings. In other cases, branching morphogenesis was arrested at the bronchial bud stage.

Unilateral pulmonary agenesis is more common than bilateral pulmonary agenesis and may represent an imbalance in the growth of the lung buds. If balanced growth is not established between the left and right lung buds, then one side will develop normally whereas the other will fail completely (aplasia) or undergo limited development (dysplasia or hypoplasia). These defects arise early in lung development, when the respiratory primordium bifurcates into the right and left primitive lung buds at the end of the fourth week of gestation. These malformations suggest an absence or imbalance in the number of progenitor cells located in the two primitive lung buds that results in differential growth or arrest of lung development. Unilateral pulmonary agenesis may affect either lung, although the right side is more commonly affected. Usually no serious clinical consequences occur because of compensatory growth, or hyperplasia, of the contralateral lung. Pulmonary agenesis is frequently associated, however, with other congenital anomalies, such as tracheal stenosis, esophageal atresia, tracheoesophageal fistula, bronchogenic cysts, patent ductus arteriosus, tetralogy of Fallot, and anomalies of the great vessels.

Pulmonary Hypoplasia

Pulmonary hypoplasia is defined as deficient or incomplete development of the lungs and develops as a result of other abnormalities in the developing fetus, such as renal agenesis, dysplastic growth of the kidney, oligohydramnios, urinary outlet obstruction, loss or reduction of amniotic fluid because of premature rupture of membranes, diaphragmatic hernia, pleural effusion, congenital anomalies of the neuromuscular system, and chromosomal abnormalities, including trisomy 13, 18, and 21.[175,178,182] Many of these abnormalities cause a reduction in the volume of the pleural cavity, which physically restricts the growth, or expansion, of the peripheral lung. Disturbances in the production of fetal lung fluid, fetal breathing, loss of amniotic fluid, or external compression of the thoracic cavity can all cause defects in the growth, or expansion, of the distal respiratory parenchyma, resulting in a reduced number of alveoli.

In congenital diaphragmatic hernia, the pleuroperitoneal cavity fails to close.[178] This allows the developing abdominal viscera to bulge into the pleural cavity and stunts the growth of the lung. Usually the left side of the diaphragm is involved more often than the right, probably because the left pericardioperitoneal canal is larger and closes later than the right. The severity of the resulting pulmonary hypoplasia varies depending on the timing of the onset of compression. With early, severe compression of the lung, marked hypoplasia occurs, resulting in the affected lung being less than half the weight of the contralateral lung. This is accompanied by a decrease in alveolar number and size, decreased gas-exchange surface area, and a proportional decrease in the pulmonary vasculature. Infants with diaphragmatic hernia are seen with cyanosis and dyspnea soon after birth and have difficulty nursing properly. Often evidence exists of severe pulmonary hypertension, most likely because of an increased proportion of muscular arteries in the periphery of the lung, which results in increased pulmonary vascular resistance. Diaphragmatic hernia can be surgically corrected at birth. However, if the hernia has resulted in severe pulmonary hypoplasia, the newborn infant may die of pulmonary insufficiency, even if the hernia is repaired.

Oligohydramnios, or an insufficient amount of amniotic fluid, is thought to cause pulmonary hypoplasia by mechanical restriction of the fetal chest wall, that is, by allowing the uterine wall to compress the fetal thorax.[183] Beginning at approximately 16 weeks gestation, a substantial fraction of amniotic fluid is contributed by the fetal kidney. Therefore renal agenesis, or failure of the kidneys to form, results in oligohydramnios and, secondarily, in pulmonary hypoplasia. Reduced amniotic fluid for an extended period of time in the absence of renal anomalies, such as in prolonged rupture of the amniotic membranes, has also been associated with pulmonary hypoplasia.

Congenital Cysts of the Lung

Unlike bronchogenic cysts, bronchiolar cysts are in communication with the more proximal branches of the bronchial tree, as well as with distal alveolar ducts and alveoli, although the connections may be small and tortuous.[175,178] Bronchiolar cysts are lined with ciliated pseudostratified epithelium and may have mucous glands, smooth muscle, and cartilage in their walls. These cysts are usually multiple and restricted to a single lobe. They may be filled with air, fluid, or both. Alveolar cysts are lined with cuboidal or squamous epithelium. No muscle or cartilage appears in the walls, but connective tissue hyperplasia may exist. Both types of

cysts affect the right lung more frequently than the left and lower lobes more frequently than upper lobes. Because congenital pulmonary cysts may be difficult to distinguish from acquired cysts, the pathogenesis of these structures is still obscure.

Congenital Cystic Adenomatoid Malformations

Congenital cystic adenomatoid malformations (CCAM) are most often found in the lungs of infants and have features of both immaturity and malformation of the small airways and distal lung parenchyma.[175,178-180] Five types of CCAM exist, which are classified on the basis of gross appearance and histologic features. Type 0 lesions are rare and are composed of 0.5-cm, bronchial-like, cystic structures with abundant cartilage in their wall. Type 1 lesions are the most common, accounting for more than 50% of the cases and are composed of one or more large cysts ranging from 3 to 10 cm in diameter. These lesions contain fibrous septa lined by pseudostratified, ciliated columnar or cuboidal cells, with clusters of mucus-filled cells resembling goblet cells. Cartilaginous foci are also present in 5% to 10% of these lesions. Type 2 lesions are the second most common and are characterized by evenly spaced, uniform cysts that are usually less than 2 cm in diameter. These bronchiolar-like structures are lined by cuboidal and/or ciliated columnar cells. Striated muscle may be present in the septa or adjacent to the cysts. Type 3 lesions are composed of a solid mass of tissue with multiple, microscopic cysts of less than 0.2 cm that are lined by cuboidal or low columnar epithelial cells. Type 4 lesions are found in the peripheral lung and are characterized by large (up to 7 cm in diameter), thin-walled cysts that are lined by alveolar epithelial cells. Immunohistochemical analysis of cytodifferentiation markers for specific pulmonary epithelial cells revealed that CCAM types 1, 2, and 3 contained clusters of GRP-positive neuroendocrine cells and CCSP-positive Clara cells, demonstrating a bronchiolar origin for these cysts.[184] The epithelial lining of CCAM type 4 cysts was immunopositive for a type I cell–associated surface antigen and the type II cell, surfactant-associated proteins, SP-A, SP-B, and SP-C.[184] These findings suggest that CCAM types 1, 2, and 3 arise during the embryonic and pseudoglandular stage of branching morphogenesis, whereas CCAM type 1 arises during the canalicular and/or saccular stage of acinar development.

Alveolar Capillary Dysplasia

Alveolar capillary dysplasia, with misalignment of the pulmonary veins, is characterized by inadequate vascularization of the alveolar parenchyma resulting in a reduced number of capillaries in the alveolar wall.[178,180] In addition, the pulmonary lobules are malformed, and the pulmonary veins are displaced, or "misaligned," in that they course with the pulmonary arteries in the peribronchiolar connective tissue instead of in the interlobular septa. This malformation causes persistent pulmonary hypertension in the neonate and is fatal.

Congenital Pulmonary Lymphangiectasis

Congenital pulmonary lymphangiectasis is an extremely rare condition, consisting of markedly distended or dilated pulmonary lymphatics, which are found in the bronchovascular connective tissue, along the interlobular septa, and in the pleura.[180] The dilated lymphatic channels are thin walled, lined by endothelial cells, and form a network of communicating channels. This condition has been associated with Noonan, Ulrich-Turner, and Down syndromes. Males are more frequently affected than females (2:1). Pulmonary lymphangiectasis can be divided into three main categories: (1) primary, (2) secondary, and (3) generalized lymphangiectasis.[180] Primary lymphangiectasis is a fatal developmental defect in which the pulmonary lymphatics fail to communicate with the systemic lymphatics. Affected infants present with RDS and pleural effusions and die shortly after birth. Secondary pulmonary lymphangiectasis is associated with cardiovascular malformations, including anomalous pulmonary venous return, atrioventricular valve defects, ostium secundum, pulmonary stenosis, ventricular septal defect, mitral atresia, hypoplastic left heart, cor triatriatum, and atresia of the common pulmonary veins.[178] Generalized pulmonary lymphangiectasis is characterized by proliferation of the lymphatic spaces and occurs in the lung as part of a systemic abnormality in which multiple lymphangiomas are also found in the bones, viscera, and soft tissues.

79 Regulation of Alveolarization

Jeanne M. Snyder

The alveolus is the primary functional unit of the lung, the site at which oxygen and carbon dioxide are exchanged between inspired air and the blood. Alveolar growth is optimized to provide an enormous surface area throughout which the blood in pulmonary capillaries circulates within a few micrometers of the inspired air. The capillary blood and the inspired air are separated by a barrier that consists of the thin wall of an endothelial cell on the capillary side, a fused basal lamina, and the attenuated cytoplasm of an epithelial cell on the alveolar side (specifically, an alveolar type I epithelial cell).[1] A set of adult human lungs contains approximately 300×10^6 alveoli, most of which are formed by 18 months of age.[2,3] Further growth and development of the distal lung parenchyma involve the thinning of the alveolar wall, an increase in capillary density, and a modest increase in the diameter of the alveoli.[2,3]

The postnatal formation of alveoli is impaired in bronchopulmonary dysplasia (BPD), a disease of prematurity that is thought to be caused by injury resulting from mechanical ventilation, hyperoxia, and inflammation.[4,5] Husain and co-workers[4] have described the "new" BPD as a chronic lung disease, prominent in very low-birth-weight infants who have been treated with surfactant replacement therapy, that is characterized by impaired alveolarization. A similar impairment has been observed in experiments in which premature baboons were subjected to mechanical ventilation with elevated oxygen levels; the lungs of these animals had alveoli that were decreased in number and larger than normal.[6] It is hypothesized that mechanical ventilation or exposure of the lung to high levels of oxygen very early in development leads to impaired alveolarization and eventually chronic lung disease.[5] Although surfactant therapy has lessened the impact of some aspects of the lung injury (fibrosis and inflammation), it has not affected the impairment of alveolarization.[5]

When one lung is removed, new alveoli can form in the remaining lung.[7,8] The number of alveoli in the lung also appears to change in response to physiologic stimuli such as starvation, age, oxygen tension, or hormonal status.[9] In addition, it has been reported that treatment with retinoic acid can increase the number of alveoli in neonatal and adult rats.[10,11] Still not fully understood, however, are the processes that regulate the formation of new alveoli in the developing lung, or how to affect these processes in humans. The ability to program the human lung to form new alveoli is a major and elusive goal in pulmonary biology.

STRUCTURE OF THE ALVEOLAR WALL

The alveolar wall consists of a connective tissue core in which many capillaries are suspended.[1] The capillary bed of the lung alveoli probably is the largest in the body. The cells present within the alveolar wall (i.e., primarily fibroblasts and myofibroblasts) produce an extracellular matrix that is particularly rich in elastin and also contains collagen, proteoglycans, and glycosaminoglycans.[12]

The surface of the alveolar wall is lined by two epithelial cell types, alveolar type I and type II.[13] Type I cells are extremely attenuated squamous cells whose cytoplasm forms part of the

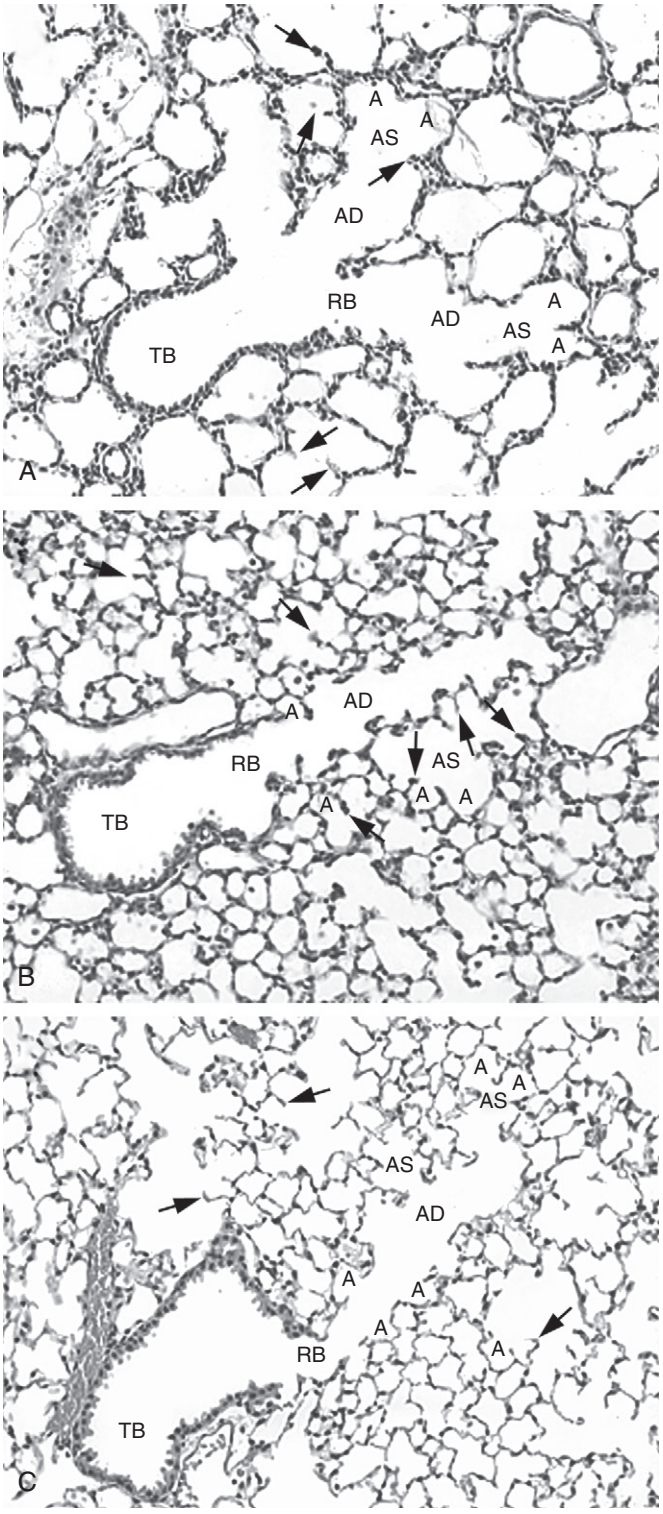

Figure 79-1 Alveolarization in mouse lung tissue. Mouse lung tissue was harvested at postnatal days 0, 12, and 56 (**A, B,** and **C,** respectively) and then inflation-fixed at constant pressure, paraffin-embedded, sectioned, and stained with hematoxylin and eosin. Terminal bronchioles *(TB)* in the lung open into respiratory bronchioles (RB), which in turn open into alveolar ducts *(AD)* ending in alveolar sacs *(AS).* Alveoli *(A)* are found at every level of the respiratory acinus. **A,** At day 0 postnatally, the walls of the alveolar ducts and sacs are the primary septa. Secondary septa *(arrows)* grow into the lumen and begin dividing the primitive alveolar duct and sac air spaces into alveoli. **B,** By 12 days postnatally, the number of secondary septa *(arrows)* has increased dramatically, and many alveoli have been formed, thereby increasing the surface area in the lung available for gas exchange. Note the decrease in the wall thickness of the alveoli from day 0 to day 12. **C,** At 56 days postnatally, the alveolar septa *(arrows)* are much thinner and longer than observed at the earlier postnatal stages of development.

air–blood gas exchange barrier. Approximately 90% of the alveolar surface is lined by alveolar type I cells.[14] Type II cells are cuboidal secretory cells, often located at the corner of an alveolus, that produce pulmonary surfactant, a lipoprotein substance that lowers surface tension in the alveolus and plays an important role in lung host defense mechanisms.[15] Although type II cells account for only a small proportion of the alveolar surface area, approximately equal numbers of alveolar type I and II cells are present in the alveolus.[14]

FORMATION OF ALVEOLI IN THE DEVELOPING LUNG

In the human, some alveoli form prenatally (approximately 20% of the eventual total); however, most alveoli form after birth.[2,3] Studies suggest that most human alveoli are formed within the first 18 months.[16,17] Much of the current understanding of the processes involved in alveolar formation is derived from studies in rodents, primarily the rat and the mouse[9] (Figure 79-1). In these species, alveolarization occurs during the first 2 weeks of postnatal life.[9]

OVERVIEW OF EARLY LUNG DEVELOPMENT

Pseudoglandular Phase

Very early lung development, before the formation of alveoli, is characterized by branching morphogenesis, which occurs during the pseudoglandular phase.[18] The lung buds and trachea originate as diverticula from the endoderm-lined foregut. The lung buds then undergo repeated dichotomous branching to give rise to the conducting airways of the lungs. It has been estimated that approximately 22 orders of branching airways are formed by around 16 weeks of gestation in the human. The branching ducts in the developing lung are lined by tall columnar epithelial cells that begin to differentiate into ciliated and secretory cells proximally but remain undifferentiated at the distal aspects of the branching tree system.[13] Within the epithelium of the conducting airways, at their most distal aspect, are cellular progenitors that will give rise to the alveolar region of the lung.[19]

Canalicular Phase

From 16 to 24 weeks gestation in the human, during the canalicular phase of lung development, the distal aspect of the branching tubes in the developing lung undergoes considerable remodeling.[18] The epithelium that lines the ducts changes from tall columnar to low columnar/cuboidal in shape. The number of blood vessels, primarily capillaries, in the connective tissue between the ducts increases strikingly. Starting at weeks 20 to 22, some of the epithelial cells begin to differentiate into alveolar type II cells, which synthesize and secrete pulmonary surfactant.[13] In addition, the distal lung epithelial cells that are close to the underlying capillaries begin to thin and differentiate into alveolar type I cells.[13]

Saccular Phase

The terminal portion of the branching duct system in the embryonic lung lengthens and will eventually give rise to the alveolar ducts and alveolar sacs, the spaces from which true alveoli will form via septation.[9,18] This phase of lung development, called the saccular phase, extends from approximately 24 weeks to term in the human.[18] Simultaneously with changes in the structure of the epithelium-lined ducts, profound remodeling occurs in the connective tissue surrounding the primitive lung ducts. The relative amount of ductal lumen (the future air space) in the distal lung tissue increases dramatically, while the relative amount of connective tissue (both cells and extracellular matrix components) simultaneously decreases as a component of the distal lung tissue.[18]

FORMATION OF ALVEOLI IN THE DEVELOPING LUNG

The formation of pulmonary alveoli in the human fetus begins prenatally; however, most alveoli are formed after birth (approximately 80%).[16,17] Premature infants who are born when their lungs are quite immature structurally (i.e., in the range of 24 to 28 weeks) are still capable of adequate respiration to maintain viability.[5] In guinea pigs, sheep, pigs, and cows, almost all alveolarization occurs in utero.[9] In rodents such as mice and rats, alveoli are formed during the first few weeks of postnatal life.[20,21] During development, the formation of alveoli increases the pulmonary gas exchange surface area in proportion to the growth of the whole organism.[9] The mechanisms by which the growth of an organism promotes a corresponding increase in the formation of its lung alveoli are not well understood.[9]

Beginning at the end of gestation in the human, and postnatally in rodents such as mice or rats, the terminal sacs in the developing lung begin to undergo septation to form true alveoli.[9,22] The conducting airway system ends at the level of the respiratory bronchiole, which is a structure characterized by occasional alveoli interrupting the airway wall.[1] The epithelium of a respiratory bronchiole is columnar proximally and gradually undergoes a transition to the typical alveolar epithelium that lines the alveolar ducts, alveolar sacs, and alveoli. The entire functional unit (the respiratory acinus) consists, in order, of a respiratory bronchiole (several orders of respiratory bronchioles are possible), alveolar ducts (again, several orders or branches of alveolar ducts can be present), and alveolar sacs.[1] Alveolar ducts can constitute a major portion of the gas exchange tissue in the lung, up to approximately 30% in some species.[23] Alveoli branch from the alveolar ducts, either singly or in clusters from an alveolar sac, which is the terminus of the alveolar duct. Alveoli are present at every level of the respiratory acinus—in the respiratory bronchiole, alveolar duct, and alveolar sac. It is believed that all of these alveoli are equally functional.

In the prenatal human lung and in the postnatal mouse lung, alveoli form by the growth of secondary septa that project from the wall of the terminal saccule.[9] The secondary septa are evenly spaced and extend into the saccule to a similar extent. The growth of secondary septa into the lumen of the terminal saccule is mediated, at least in part, by the proliferation of fibroblasts.[24] A subset of interstitial fibroblasts in the developing lung is characterized by cytoplasmic lipid droplets.[25] The function of these cells is not fully understood, but they probably play an important role in the morphogenesis of the alveolar wall.[25] At the tip of the secondary septum is a myofibroblast, a cell type that produces elastin and other important extracellular matrix components present in the alveolar wall.[26] This particular cell type probably plays a key role in alveolarization, because the absence of myofibroblasts results in a failure to produce alveoli in postnatal life, with an emphysematous lung phenotype.[27,28]

The connective tissue core of the secondary alveolar septa is characterized by abundant elastin, probably laid down by the myofibroblast.[29] The elastin fibers are arranged in an orderly and predictable manner within the alveolar septa.[30-32] Elastin gene expression peaks during the period of postnatal alveolarization.[33,34] The cross-linking of elastin monomers is a critical process in alveolarization, because inhibition of this process leads to a decreased surface area in the lung.[35] Elastin fiber deposition also involves the coordinated expression of fibrillins, emelin, fibulin, and microfibril-associated glycoproteins.[29] In addition, type I, III, and IX collagens are produced by connective tissue cells and are deposited in the alveolar wall during the formation of the secondary septa, where they convey mechanical strength.[36] Glycosaminoglycans, such as hyaluronic acid, chondroitin sulfate, and heparan sulfate, also are present in the alveolar wall and make important contributions to its mechanical properties.[37] Finally, proteoglycans, adhesive glycoproteins such as fibronectin, and components of the basal lamina, including laminins and type IV collagen, also are produced and are laid down during alveolarization in a regulated and integrated manner.[38]

REGULATORS

Vascular Endothelial Growth Factor

The process of alveolarization includes the morphogenesis of an elaborate pulmonary capillary bed in the distal lung, which must form in concert with the differentiation of the alveolar epithelium, and the eruption of secondary septa. The growth and differentiation of pulmonary vasculature begin in the fetal lung coincident with the canalicular and saccular stages of lung development.[39] Initially, the capillaries in the wall of the septa are a double capillary system; that is, one capillary is associated with each surface of the forming alveolar septa.[40] As alveolarization proceeds, however, the alveolar wall thins, and a single capillary system forms in the alveolar wall, with the capillaries coming to lie very close to one of the wall surfaces.[40]

Vascular endothelial growth factor (VEGF) is a growth factor that acts as a mitogen for endothelial cells.[41] VEGF stimulates angiogenesis and vasculogenesis and also regulates endothelial permeability.[41] VEGF binds to at least two receptors: Flk-1 (VEGF receptor 2) and Flt-1 (VEGF receptor 1).[41] VEGF and its receptors are expressed in the developing lung in a coordinated fashion that peaks at the end of gestation and during early neonatal life.[42,43] Several VEGF isoforms of different molecular weights are recognized; however, VEGF 188 predominates in the fetal lung.[43] Transgenic mice that overexpress VEGF in alveolar epithelial cells exhibit disrupted lung development—that is, disrupted branching morphogenesis, hypertrophy of blood vessels, decreased number of terminal saccules, and decreased connective tissue.[44]

VEGF increases cell division in human fetal lung type II cells.[45] In utero administration of anti-VEGF receptor 2 antibodies has been shown to delay fetal mouse lung development.[46] Conversely, lung development in mice, as assessed by the production of surfactant, structural changes, and survival, was accelerated by the prenatal or postnatal administration of VEGF.[46] In a study conducted in adult rats, treatment with a VEGF receptor blocker, SU5416, led to an enlargement of alveoli and a decrease in alveolar surface area—a pattern similar to that observed in emphysema.[47] When the same VEGF inhibitor was administered to newborn rats, alveolar formation was significantly impaired.[48] The inhibitory effects of treatment with SU5416 for 24 hours on the second day after birth persisted until the age of 3 to 4 months.[49] Other inhibitors of angiogenesis, such as thalidomide and fumagillin, administered to neonatal rats during the peak period of alveolarization, also inhibit the formation of alveoli.[49] Taken together, these results suggest that VEGF probably plays a key role in the process of alveolarization.

The growth of pulmonary capillaries and the formation of alveoli during the period of alveolarization are closely linked in the postnatal lung. The functional relationship between these

processes is unknown, but defects in the formation of blood vessels and alveolarization are characteristic of BPD.[4,50] In a primate model of BPD, in the premature baboon, decreased numbers of endothelial cells and a disrupted microvasculature were observed in the distal lung.[6] Bhatt and co-workers[51] observed both decreased numbers and an abnormal distribution of capillaries in the alveolar septa of patients with BPD. The lung tissue of infants with known BPD also was characterized by decreased VEGF and VEGF-2 receptor gene expression.[51] Other animal models in which alveolarization has been impaired also are characterized by decreased numbers of alveolar capillaries (e.g., in neonatal rats exposed to high oxygen and in premature ventilated lambs).[23,52] The role of vascular growth factors in hyperoxia-induced injury in the developing lung has been reviewed by D'Angio and Maniscalco.[53]

Other Regulators of Angiogenesis

In addition to VEGF and its receptors, many other mediators of angiogenesis and vasculogenesis are known whose roles in lung development are still relatively unexplored. For example, angiopoietins, ephrins, and semaphorins, all of which have been shown to play a role in angiogenesis in other systems, are present in the developing lung and may play an important role in alveolarization.[54-56] Angiopoietins 1 to 4 bind to Tie 2 receptors in endothelial cells and act together with VEGF and its receptors to influence angiogenesis.[54] Angiopoietin 1 is expressed in the developing lung but apparently does not change in concentration during development.[57,58] Ephrins are growth factors that bind to tyrosine kinase–linked receptors and are involved in vasculogenesis and angiogenesis.[55] The role of these growth factors and their receptors in lung development is unknown. Semaphorins are a more recently described class of growth factors, initially noted in the central nervous system, that bind to receptors called neuropilins.[56] Neuropilins may act as co-receptors with VEGF receptor 2 and play a role in angiogenesis.[56] Both semaphorins and neuropilins have been detected in the developing lung.[59] Blockade of neuropilins in the newborn rat results in defects in alveolarization.[60]

Platelet-Derived Growth Factors

Platelet-derived growth factors (PDGFs) are dimers of A and B polypeptide chains that bind to two receptor tyrosine kinases, PDGF-Rα and PDGF-Rβ.[61] PDGF is a potent mitogenic factor for connective tissue cells.[61] PDGF-A is expressed by epithelial cells in the developing lung.[62] PDGF-A homozygous gene–deleted mice die early in the postnatal period because of failure of postnatal alveolarization.[27,28] The PDGF-A–knock-out mice lack alveolar myofibroblasts that express PDGF-Rα in their primary septa.[27,28] In addition, these mice do not have a normal elastin deposition pattern in their lungs and do not form secondary septa.[27,28] These data are suggestive that the PDGF-Rα–positive myofibroblasts in the developing postnatal lung play a major role in alveolar septation and that PDGF-A is an important regulator of alveolarization.[63]

Glucocorticoids

Glucocorticoids are steroid hormones produced by the adrenal gland in response to adrenocorticotropic hormone, a peptide produced by the pituitary.[64] Release of adrenocorticotropic hormone from the pituitary is, in turn, regulated by another peptide, corticotropin-releasing hormone (CRH), which is produced in the hypothalamus.[64] Glucocorticoids bind to glucocorticoid receptors (GRs), which are members of the steroid hormone receptor family of transcription factors.[64] Antenatal glucocorticoids, administered to the mother at risk for delivering prematurely, can accelerate lung development and reduce the risk of neonatal respiratory distress syndrome.[65,66] Respiratory distress syndrome is caused by surfactant deficiency; thus glucocorticoids presumably act by increasing the production of surfactant in differentiated alveolar type II cells.[64] However, glucocorticoids have many other effects on the developing lung.[64]

Antenatal glucocorticoids accelerate structural maturation of the lung—in particular, thinning of the alveolar wall.[67,68] In rats, which undergo alveolarization postnatally, glucocorticoids inhibit alveolarization.[67] The formation of secondary alveolar septa is impaired in the lungs of glucocorticoid-treated neonatal rats, resulting in fewer and larger alveoli in the mature lung.[67] Similar findings were obtained when glucocorticoids were administered to the rats antenatally.[69] The glucocorticoid effects on lung structure appear to be permanent, at least in the rat.[69] The effects of glucocorticoids on primate lung development are consistent with observations made in the rat model; that is, glucocorticoids impair alveolarization in the developing lung.[70]

The concept that glucocorticoids play a key role in lung development is supported by the observation that mice that are CRH gene–deleted die of respiratory failure resulting from inadequate lung development.[71] The effect of the CRH gene deletion on lung development probably is structural, because surfactant components are not as strongly affected by the CRH gene deletion.[71] A similar observation was made in GR-deficient mice: The effects of the GR gene deletion include immature structural development of the lung, whereas surfactant components such as the surfactant proteins are not as strongly affected.[72]

BPD is caused by multiple factors; however, mechanical ventilation, oxygen toxicity, and inflammation have key roles in the pathophysiology of this disease.[73] Glucocorticoids are effective in treating BPD, perhaps because of their antiinflammatory effects.[64] The long-term effects of glucocorticoid treatment of premature infants with BPD are still not fully understood and are of great concern. It is known, however, that the lungs of infants with BPD have fewer and larger alveoli, so the use of glucocorticoids, which impair alveolarization, to treat these infants is inherently problematic.[4,74]

Retinoic Acid

Retinoic acid plays a key role in the differentiation and maintenance of differentiation of all respiratory epithelia, from the trachea to the alveolus.[75,76] All-*trans* retinoic acid, which is the best-characterized, most abundant, biologically active retinoid, binds to retinoic acid receptors (RARs) and to retinoid X receptors (RXRs).[77] RARs and RXRs are members of the steroid hormone receptor family of transcription factors.[77] Three RAR genes (RARα, -β, and -γ) and three RXR genes (α, β, and γ), each of which produces several isoforms, have been identified.[77] The RARs form heterodimers with RXRs and bind to *cis*-acting elements in retinoic acid–responsive genes.[77]

All-*trans* retinoic acid has been shown to play a key role in regulating alveolarization in rats and mice.[10,11,78] In the initial report by Massaro and Massaro concerning the effects of retinoic acid, postnatal rats were treated with all-*trans* retinoic acid or dexamethasone.[10] Dexamethasone administration to postnatal rats inhibits alveolarization.[79] Treatment with retinoic acid alone caused an increase in the number of alveoli, but it had no effect on lung gas exchange surface area when compared with alveoli in control animals.[10] In addition, retinoic acid abolished many of the inhibitory effects of glucocorticoids on alveolarization.[10] Specifically, treatment with retinoic acid plus glucocorticoid resulted in greater numbers of alveoli and greater surface area (corrected for body weight) in the lung than in the glucocorticoid-alone condition.[10] In another study by the same investigators, adult rats were treated with intratracheal elastase to create a model of emphysema.[11] When the rats were treated with all-*trans* retinoic acid, the effects of the elastase on the number of alveoli and amount of gas exchange surface area were reversed.[11] It has been

reported that treatment of newborn rats with retinoic acid during exposure to hyperoxia protected their lungs from the deleterious effects of too much oxygen on alveolar formation.[80]

Morphometric studies in transgenic mice revealed that the lungs of RARβ gene-deleted mice have more, but smaller, alveoli.[78] Gas exchange surface area, however, was the same in the RARβ gene–deleted mice and and in wild-type mice.[78] In the same studies, it was shown that treatment of postnatal rats with an RARβ agonist impairs the formation of alveoli.[78] Together, these observations suggest that RARβ may be an endogenous inhibitor of alveolarization.[78] In another transgenic mouse model, McGowan and co-workers[81] showed that RARγ probably mediates some of the effects of retinoic acid on alveolarization. RARγ gene–deleted mice had lungs with fewer and larger alveoli than in lungs of age-matched wild-type mice.[81] The effects of RARγ gene deletion were magnified in mice that were heterozygous for the deletion of RXRα.[81] Taken together, these data support a role for RARγ/RXRα heterodimers in the regulation of alveolarization.[81]

Elastin is an important component of the alveolar wall that is involved in alveolarization and is regulated by all-*trans* retinoic acid.[29,82] Retinyl esters increase in the lung during development and decrease thereafter.[83] The retinyl esters are concentrated in lipid-laden fibroblasts, a prominent cell type in the connective tissue component of the primary septa in the developing lung.[84] McGowan and co-workers[82] showed that endogenous retinoids in the developing lung increase lung elastin gene expression. Retinoids also increase elastin gene expression in vitro in isolated, cultured lipid-laden fibroblasts.[82] In RARγ gene–deleted mice, elastin messenger RNA (mRNA) levels in lipid-laden fibroblasts isolated from postnatal lung were decreased in comparison with those in lung fibroblasts from wild-type, control mice.[81] In addition, the number of elastin fibers was markedly decreased in the alveolar walls of lungs from RARγ gene–deleted mice in comparison with that in the lungs of control animals.[81] Taken together, these data suggest that retinoic acid regulates elastin gene expression and elastin fiber deposition, two important events in alveolarization in the postnatal lung.

The plasma concentration of vitamin A (retinol, the metabolic precursor to all-*trans* retinoic acid) is significantly lower in very low-birth-weight, premature infants.[85] Some of the histopathologic characteristics of lung tissue in vitamin A–deficient models and in BPD are similar.[75,76] Kennedy and co-workers[86] performed metaanalysis of four small clinical trials in which vitamin A supplementation in very low-birth-weight infants decreased mortality and the incidence of BPD. The results of a more recent, large clinical trial suggest that vitamin A supplementation in extremely low-birth-weight infants decreases their risk of subsequent chronic lung disease.[87] These clinical data illustrate the potential usefulness of retinoids in accelerating lung development and in decreasing the incidence of BPD in newborn infants. One of the beneficial effects of the clinical use of retinoids may be in promoting alveolarization; however, this point has yet to be established.

The loss of sufficient numbers of alveoli in the adult lung leads to inadequate gas exchange surface area and the ensuing pathophysiologic changes of emphysema.[88] No clinical treatment that promotes the regeneration of alveoli in the adult lung is available as yet. In light of observations in rats indicating that retinoic acid treatment leads to de novo alveolarization, clinical trials in which all-*trans* retinoic acid is administered to patients with emphysema have been performed.[89] In preliminary findings, retinoid treatment was well tolerated and was associated with relatively few side effects.[89] Unfortunately, no clinical benefits of the retinoid treatment were observed in the feasibility study.[90] The use of a retinoic acid receptor gamma agonist (Palovarotene) is currently being investigated for the treatment of emphysema in clinical trials.[91]

Estrogen and Testosterone

Lung development is influenced by the sex of the fetus: Lung maturation has been shown to be delayed in male fetuses in comparison with that in females.[92] The incidence of respiratory distress syndrome is greater and the infant mortality rate is higher in males than in females.[93] It has been hypothesized that androgens, present primarily in the male, delay lung development in the male fetus.[92] However, the lungs of androgen receptor–negative male mice have been shown to have the same body weight–adjusted surface area as in wild-type male mice.[94]

Some evidence also suggests a sex-specific difference in the formation of alveoli in the neonatal lung.[95] Massaro and co-workers[95] reported that female rats and mice (60 days old) have smaller and more numerous lung alveoli and that their body weight–adjusted lung surface area is significantly greater than in male rats.[95] In another study, these same investigators showed that estrogen mediates the sex-linked effects on lung structure in rats.[94] Treatment of female newborn rats with androgens did not alter their lung structure.[94] Taken together, these data suggest that estrogen regulates alveolarization in the postnatal lung.

During pregnancy, the fetus (male or female) is exposed to very high levels of estrogens, which drop dramatically after birth.[96] Some clinicians have suggested that preterm infants may benefit from estrogen therapy. In fact, a beneficial effect of estrogen therapy in terms of the incidence of chronic lung disease has been reported.[97] It is not known whether this effect reflects differences in alveolus formation.

Nutrition

Caloric restriction reduces the metabolic rate and physiologic requirement for oxygen.[98] Studies performed primarily in rats showed that caloric restriction in adults increases the size of the alveoli and reduces the lung gas exchange surface area available for respiration.[99] Refeeding apparently reverses these changes.[99] These observations were confirmed in a morphometric study in adult mice.[100] Observations in the inhabitants of the Warsaw Ghetto during World War II are consistent with a similar process occurring in humans; that is, an emphysema-like morphology was observed in the lungs of severely malnourished adults.[101]

Massaro and co-workers[9] hypothesized that during periods of low oxygen requirements (e.g., caloric restriction), alveoli are destroyed, whereas during refeeding, which would increase oxygen needs, alveolar regeneration is activated.

Oxygen

The lung alveolar surface area functions as a gas exchange unit, and oxygen has a potent influence on the formation of alveoli in the developing lung.[9] Dimensions of the surface area available for gas exchange are directly related to the oxygen needs of the organism.[102] In general, in newborn rats undergoing alveolarization, hyperoxia tends to decrease the alveolar surface area.[9] Burri and Weibel[103] showed that neonatal rats reared in 40% oxygen had decreased alveolar surface area when compared with air-breathing control animals. Similar observations were made by Randell and co-workers[104] in a study in which neonatal rats were reared in 95% oxygen for the first 7 days after birth. Exposure to high oxygen concentrations for 7 days followed by rearing in room air until the age of 40 days also resulted in impaired alveolarization, that is, a decreased alveolar surface area in the oxygen-exposed animals in comparison with that in control animals reared in room air.[23]

The signaling pathway in the developing lung that senses oxygen levels and regulates alveolar surface area is unclear at present. However, it has been shown that hyperoxia inhibits the expression of VEGF in neonatal rabbit lung.[105] Hyperoxia also increases apoptosis in the distal lung of neonatal mice[106] and is a potent

regulator of alveolar formation.[9,107] Blanco and co-workers[108] and Massaro and associates[109] showed that rearing newborn rats in 13% oxygen results in fewer alveoli and decreased gas exchange surface area.

Inflammation

Alveolarization in premature human newborns is thought to be inhibited by many factors, including mechanical ventilation, oxygen, inadequate nutrition, glucocorticoids, and, possibly, infection. All of these stimuli can result in inflammation. Thus many investigators have hypothesized that inflammatory mediators impair alveolarization.[110-112] Intrauterine infection is a common cause of preterm birth, and it is now apparent that such infection also may influence postnatal lung development.[113] A final common pathway in many inflammatory states is the activation of matrix metalloproteinases, a process that results in the destruction of extracellular matrix components and consequent changes in lung structure and function.[114] An important function of the pulmonary surfactant proteins SP-A and SP-D may be to regulate inflammation in the lung alveolus.[115] In this regard, emphysema develops postnatally in SP-D gene–deleted mice and SP-A/SP-D double gene–deleted mice.[116,117] In addition, inflammation is now closely linked to the destruction of alveoli in adult lung that frequently is observed in chronic obstructive pulmonary disease.[118-120]

Other Mediators of Alveolarization

Treatment of newborn rats with thyroid hormone accelerates the formation of lung alveoli and results in smaller alveoli and an increase in gas exchange surface area.[121] Conversely, a drug that inhibits thyroxine, propylthiouracil, impairs the formation of alveoli and decreases respiratory surface area.[121] Thus thyroid hormone should be added to the list of mediators that influence the formation of lung alveoli in the developing lung.

Fibroblast growth factors (FGF) are a family of peptides that play an important role in many aspects of lung development.[122] These factors bind to one of several tyrosine kinase receptors (i.e., FGFRs).[122] In mice that are deficient in FGFR-3 and FGFR-4, formation of normal alveoli during postnatal life does not occur.[123]

Many other growth factors, growth factor receptors, and transcription factors are known to regulate aspects of lung development.[19,124,125] Many of these mediators affect lung development at multiple sites and at several stages of development. It is therefore difficult to ascribe a specific role to some of these factors in the formation of alveoli. Many of these regulatory factors, however, probably do influence the formation of alveoli in the developing lung.

CONCLUSIONS AND FUTURE DIRECTIONS

Our understanding of the formation of pulmonary alveoli has advanced, but a comprehensive and detailed picture will require additional research. Although careful morphologic and morphometric descriptions of the alveolarization process are available for many species, human data remain incomplete. The processes of formation and destruction of alveoli are known to be responsive to several physiologic stimuli including nutritional status, oxygenation, and removal of one lung or part of a lung (Box 79-1). In addition, strong evidence points to the influence of regulatory factors, including retinoic acid, glucocorticoids, estrogen, and growth factors such as VEGF and PDGF, on the formation of alveoli in the developing lung. Nevertheless, no specific therapies have been clinically proved to increase the formation of alveoli in humans, either in the neonate or in the adult lung.

BOX 79-1
Mediators of Alveolarization

Positive Regulators
- Vascular endothelial growth factor[47]
- Neuropilins[61]
- Platelet-derived growth factor A[28]
- Retinoic acid[11,12]
- Estrogen[92]
- Thyroid hormone[119]
- Fibroblast growth factor[121]
- Nutrition[97]

Negative Regulators
- Glucocorticoids[68]
- Oxygen[102]
- Inflammation[109]

The transgenic mouse model has been extremely fruitful for studying lung development, including the formation of alveoli. However, the study of the formation of alveoli in the lung would greatly benefit from the availability of an in vitro model of alveolarization, as well as from the establishment of biochemical end points that could be used to assess the degree of alveolarization in both in vitro and in vivo model systems. A better understanding of the regulatory link between pulmonary vasculogenesis and alveolarization also is greatly needed. Finally, the hierarchy of genes that influence alveolarization, starting with the transcription factors that may act as master regulators, requires further elucidation. Powerful new tools such as microchip gene array analysis and the availability of mouse genome sequences can be expected to facilitate the search for the regulators of alveolarization.[126,127]

Physiologic Mechanisms of Normal and Altered Lung Growth Before and After Birth

Lung growth both before and after birth is an important determinant of respiratory health in that appropriate and timely development is essential to produce a system of airways that permit effective exchange of respiratory gases, from infancy through to adult life. Lung growth in the fetus has a major impact on the ability of the neonate to make a smooth transition from fetal to postnatal life. Normal lung growth after birth is necessary to enable the lung to meet increasing metabolic demands during infancy and childhood and into adulthood. During its development, the lung must acquire an intricate system of airways allowing low-resistance airflow to and from the respiratory zone; its internal surface area must be large and closely apposed to a dense vascular network with a high level of blood flow. In terms of its mechanical properties, lung tissue must permit easy expansion during inspiration but retain sufficient recoil to drive expiration, and surfactant is required to prevent collapse at end-expiration. It is now apparent that the physiologic processes controlling lung growth before and after birth are quite different, although the molecular mechanisms are likely to be similar. This chapter presents an overview of the physiologic control of lung growth before and after birth, as well as pathophysiologic processes that perturb normal lung growth.

FETAL LUNG GROWTH

During fetal life, the future air spaces of the lungs are filled with a unique liquid that is produced by the lung as a result of net transepithelial chloride and sodium flux.[1] This fetal lung fluid (FLF) plays a critical role in lung development by maintaining the future air spaces in a distended state; it also limits the entry of amniotic fluid into the lungs, which can have damaging effects. The volume of FLF within the future air spaces, and its flux to and from the lower airways, are influenced by fetal muscular activity as well as by fetal posture and other factors that influence fetal transpulmonary pressure.[2] By maintaining this distended state, FLF serves as an internal "splint" around which the distal air spaces of the lungs develop.[1-3] Without this underlying degree of expansion, the fetal lung is unable to grow and structurally mature.[2] Consequently, much attention has focused on elucidation of how the volume of FLF is controlled and of the mechanisms by which it influences the growth and remodeling of fetal lung tissue. It is now apparent that the fetal metabolic and endocrine environments also play important roles in lung development, especially in lung maturation. The physical factors that are critical for normal lung development and underlie many common disorders of fetal lung growth are the major focus of this chapter.

CONTROL OF FETAL LUNG EXPANSION

Data on the control of fetal lung expansion and its fundamental role in lung growth are derived almost entirely from studies of chronically catheterized fetal sheep.[1,2,4] During the latter half of ovine gestation, the volume of FLF within the fetal lungs progressively increases, reaching 35 to 45 mL/kg during the last weeks of gestation[2]; this is considerably greater than the functional residual capacity (FRC) of the air-filled lung after birth (25 to 30 mL/kg)[5] (Figure 80-1). The high level of fetal lung expansion is actively maintained, involving both fetal breathing movements (FBMs)[6,7] and laryngeal adductor muscles[2] (Figure 80-2). It also is influenced by the transpulmonary pressure gradient, which in turn is influenced by the available intrathoracic and intrauterine space (see further on). Thus values obtained for dead, anesthetized, exteriorized, or paralyzed fetuses will necessarily underestimate lung luminal volumes, because FLF is lost under these conditions[2,6] (see Figure 80-2). Similarly, measurements of FLF volume are questionable unless they were made in the absence of fetal hypoxemia or labor, and in the presence of normal amniotic fluid volume.[8,9] Both labor and reduced amniotic fluid volume reduce FLF volume by compressive forces on the fetus, which increase spinal flexion and, consequently, transpulmonary pressure.[8,9]

In the absence of labor, the volume of FLF in healthy fetuses is determined by fetal muscular activity and the transpulmonary pressure gradient; alterations in the secretion rate of fetal lung liquid have little or no effect.[10] The rate of FLF efflux from the fetal lung by way of the trachea is dependent on the pressure gradient between the lung lumen and the amniotic sac (transpulmonary

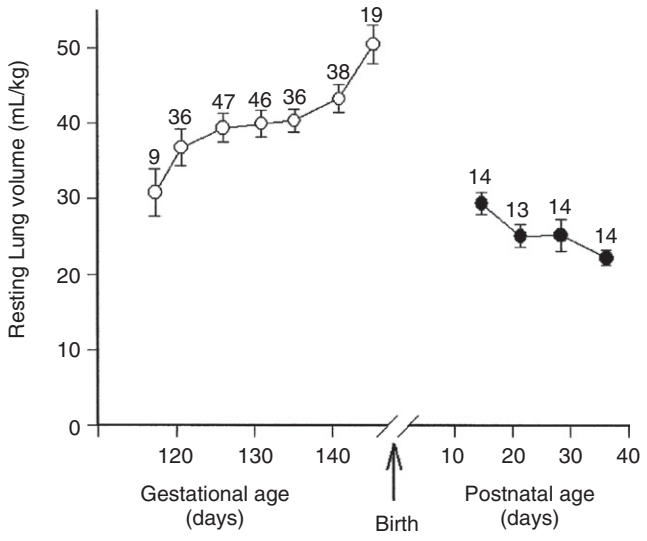

Figure 80-1 Basal lung luminal volumes in fetal and postnatal sheep. The fetal data *(open symbols)* are derived from measurements of the volume of fetal lung fluid within the future airways, made using a dilution technique (numbers of animals are shown above symbols). The postnatal data *(closed symbols)* are derived from measurements of the volume of air remaining within the lungs at end-expiration (functional residual capacity [FRC]), made using a helium dilution technique. *(Data from Harding R, Hooper SB: Regulation of lung expansion and lung growth before birth,* J Appl Physiol *81:209-224,1996.)*

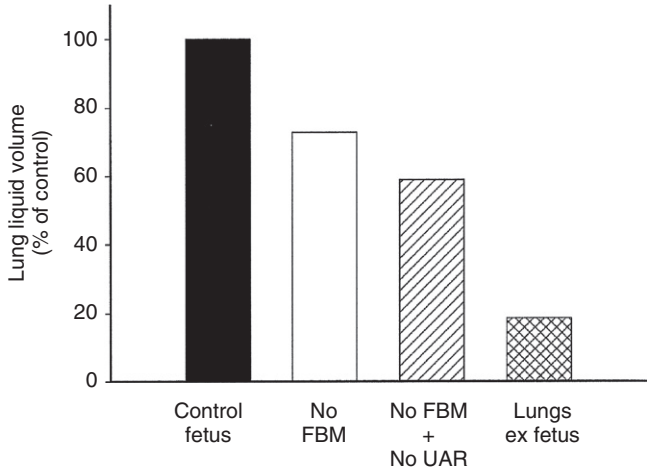

Figure 80-2 The influence of fetal muscular activity on the volume of liquid retained within the future airways. The inhibition of fetal breathing movements (FBMs), by either fetal spinal cord transection[7] or selective blockade of the phrenic nerves,[6] causes an approximately 25% decrease in fetal lung liquid volume from that in control fetuses, demonstrating the importance of FBMs in maintaining the volume of fetal lung liquid. If the fetal upper airway is bypassed, eliminating upper airway resistance *(UAR)* in addition to the abolition of FBMs, the volume of lung liquid is reduced further, demonstrating the independent effect of the fetal upper airway on maintaining fetal lung liquid volumes.The further reduction in lung luminal volume after the removal of the lungs from the fetus demonstrates the contribution of the fetal chest wall to maintaining fetal lung liquid volumes. *(From Harding R, Hooper SB: Regulation of lung expansion and lung growth before birth,* J Appl Physiol *81:209-224, 1996.)*

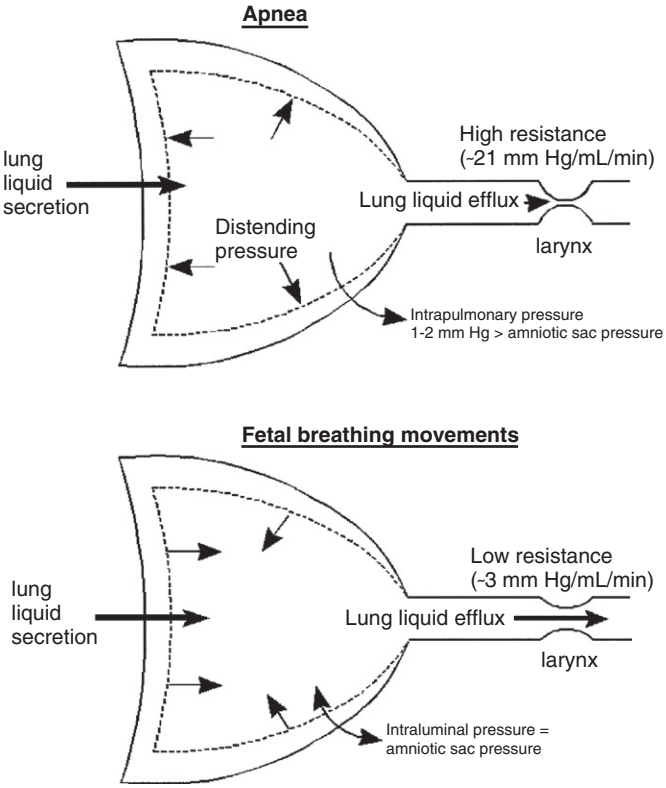

Figure 80-3 Diagram showing the role of the fetal upper airway in regulating the efflux of lung liquid during periods of apnea *(upper panel)* and of fetal breathing movements (FBMs) *(lower panel).* During periods of apnea, the resistance to lung liquid efflux through the upper airway is high (owing to lack of laryngeal abductor activity and presence of tonic adductor activity); as a result, liquid tends to accumulate within the future airways, causing the lungs to expand.This liquid accumulation is responsible for generating a transpulmonary pressure gradient of 1 to 2 mm Hg (intraairway pressure > amniotic sac pressure). During periods of FBM, the resistance to lung liquid efflux through the upper airway decreases (owing to phasic dilator activity of glottic abductor muscles and lack of sustained activity in adductor muscles); therefore liquid leaves the lungs at an increased rate.

pressure) as well as the resistance to efflux in the upper respiratory tract.[11,12] In the absence of FBMs (i.e., with fetal apnea), the pulmonary intraluminal pressure is 1 to 2 mm Hg above amniotic sac pressure,[13] owing to the inherent recoil of lung tissue and the resistance of the upper airway.[12] During apnea, the efflux of FLF throughf the trachea is, on average, lower than its rate of production, and liquid accumulates within the lungs[4] (Figure 80-3). During episodes of FBM, the resistance to efflux is reduced owing to phasic dilation of the glottis,[12] permitting FLF efflux from the lungs.[4]Thus, despite rhythmic contractions of the diaphragm, the average net flow of liquid from the lungs during FBM episodes is two to three times greater than the rate of efflux during intervening apneic periods.[11] Although amniotic fluid can enter the fetal lungs during periods of accentuated FBM, the net flow is out of the lungs.[11] This essentially unidirectional flux helps maintain a constant chemical environment within the future air spaces, limiting the entry of potentially harmful substances in amniotic fluid such as meconium. However, substances dissolved or suspended in amniotic fluid can enter the fetal lungs,[14] which is most likely to occur during episodes of augmented fetal breathing.

The transpulmonary pressure gradient and hence the efflux of FLF also are influenced by factors external to the lungs, such as abdominal pressure.[8] Changes in fetal posture (e.g., trunk flexion) that increase abdominal pressure also increase the transpulmonary pressure gradient, leading to a reduction in FLF volume.[8] Such changes in transpulmonary pressure can be caused by uterine contractions or may develop when intrauterine space is limited as a result of oligohydramnios[8] or presence of multiple fetuses. Lack of amniotic fluid forces the fetus into a more flexed posture.[8,15] Increased flexion increases fetal abdominal pressure and thus transpulmonary pressure, leading to increased FLF efflux and a reduced lung volume.[8] This is the likely cause of lung hypoplasia associated with prolonged oligohydramnios.[8] Because the fetal lungs and chest wall are highly compliant, even small changes in transpulmonary pressure will have marked effects on the degree of lung expansion.

Effects of Reduced Lung Expansion

Sustained reductions in fetal lung expansion are a common cause of hypoplasia and retarded structural development of the lung, including effects on the vascular bed and alveolar epithelial cell (AEC) phenotypes. The hypoplastic effects appear to depend on the degree to which lung expansion is decreased. For example, a 25% reduction in lung expansion causes lung growth to be reduced by approximately 25%,[7] whereas total lung deflation causes lung tissue growth to effectively cease.[3,16,17] Little is known about the underlying mechanisms, although a reduction in the expression of insulin-like growth factor-II (IGF-II) has been observed in two models of reduced lung expansion.[7] It is more likely, however, that the absence of direct mechanical stimuli, which are required to activate or suppress key regulatory gene pathways, is the principal underlying mechanism.[18,19] The

remodeling of lung parenchyma that characterizes normal structural development of the lung also is retarded by reduced lung expansion.[3] In particular, perialveolar tissue volume is increased,[3] leading to thicker septa and a reduced diffusing capacity for respiratory gases. Furthermore, alveolarization is attenuated,[3] which probably is related to impaired elastogenesis.[20] Fetal lung hypoplasia resulting from prolonged underexpansion of the lung also is characterized by reduced growth and maturation of the pulmonary vascular bed, resulting in elevated pulmonary vascular resistance.[21]

The alveolar epithelium of the fetal lung also is affected by prolonged reductions in fetal lung expansion.[3,22] Such reductions promote differentiation of type I into type II cells,[22] whereas prolonged overexpansion reduces the proportion of type II AECs to less than 2% and increases the proportion of type I AECs to greater than 90%.[23] These findings support in vitro evidence that type I cells are not terminally differentiated and can transdifferentiate into type II cells.[24]

Effects of Increased Lung Expansion

Prolonged overexpansion of the fetal lungs, such as that induced by tracheal obstruction, is a potent stimulus for fetal lung growth and tissue remodeling.[3,25] The increase in lung cell proliferation is time-dependent[26] and is restricted to the expanded lung tissue.[16] The growth response to tracheal obstruction differs according to the stage of fetal lung development. During the alveolar stage in fetal sheep, the acceleration in lung growth is completed within 7 days of tracheal obstruction, resulting in an almost doubling of lung DNA content[19,26]; the eventual cessation of accelerated growth probably is due to restraint by the chest wall. By contrast, during the late pseudoglandular–early canalicular stage, the acceleration in lung growth is slower,[27] but eventually results in a greater increase in lung DNA content (an approximately 200% increase)[28]; similar results have been obtained in fetal rabbits.[29] The lower rate of accelerated lung growth in younger fetuses may be due to a lower lung compliance and thus less lung expansion.[27,28] The eventual greater increase in lung DNA content in younger fetuses probably is due to greater compliance of the chest wall, allowing the lungs to expand to a greater degree than in older fetuses.[28]

The mechanisms by which tissue stress affects the rate of lung growth are under active investigation (see further on). It must be recognized, however, that the mechanical stresses imposed on lung tissue by sustained alterations in lung expansion are likely to be very different, depending on the location within the tissue. For example, in response to increased lung expansion, some cells will experience a stretch-like stimulus, whereas other may experience compression.

The characteristics of the lung growth response to increased lung expansion also differ according to the stage of lung development. During the alveolar stage, increased lung expansion causes the proliferation of most major cell types,[25] but during the late pseudoglandular–early canalicular stage, it causes primarily mesenchymal cell proliferation,[28] leading to a large increase in perisaccular tissue volume.[28] By contrast, during the later stages of fetal lung development, prolonged lung expansion accelerates the structural maturation of the lung; that is, the proportion of tissue space is reduced and alveolar number and surface area are increased.[3,25,29,30] The mechanisms by which an increase in fetal lung expansion stimulates septation and alveolarization are unknown but may be linked to the associated increase in tropoelastin expression.[20]

THE ROLE OF FETAL BREATHING MOVEMENTS

FBMs begin early in fetal life and progressively become organized into discrete episodes that are largely associated with a fetal behavioral state resembling rapid eye movement (REM) sleep.[31] During the latter half of gestation, the overall incidence of FBMs is 40% to 50%.[32] The major muscle used in FBMs is the diaphragm; respiratory activity of the intercostal muscles is largely absent, as in postnatal REM sleep. During FBM episodes, the laryngeal abductor (dilator) muscles are active in phase with the diaphragm, whereas during fetal apnea, this dilator activity is absent and the glottis is closed by sustained adductor activity.[12] Typically, individual FBMs lower intrathoracic pressure by up to 5 mm Hg[31] and cause small oscillations of fluid flow within the fetal upper airway.[33,34] Much interest has focused on FBMs because they constitute an important determinant of fetal lung development, although their precise role in vivo has only recently been established.[1,2]

In exploring the functional role of FBMs, numerous techniques have been used to eliminate or blunt their effects, including fetal paralysis,[35] sectioning[36,37] and reversible blockade of the phrenic nerves,[6] sectioning of the fetal spinal cord above the outflow of the phrenic motoneurons,[7,38,39] and replacing sections of the thoracic wall with a compliant membrane.[40] Observations in these studies must be interpreted with caution, owing to confounding factors associated with the experimental procedures. For example, phrenic nerve section causes the diaphragm muscle to atrophy, whereas thoracoplasty may allow lung compression; fetal paralysis abolishes laryngeal adductor activity and may alter fetal posture. To identify the specific role of FBMs in lung development, it is necessary to alter only FBM and then to measure fetal lung luminal volume. With this investigative approach, it is apparent that the reduction in lung growth induced by the abolition of FBM can be explained by the associated decrease in the basal level of fetal lung expansion[6,7]; indeed, the percent decrease in lung expansion is similar to the reduction in lung growth.[7] The decrease in lung expansion after abolition of the thoracic component of FBM can be explained by persistence of laryngeal dilator activity.[7] As a result of this activity, the efflux of FLF is increased during centrally generated "FBM" over that observed in intact fetuses.[6,7] Thus, in intact fetuses, rhythmic activation of the diaphragm in FBM apparently plays a key role in restricting the loss of lung liquid when the resistance to lung liquid efflux is lowered by glottic dilation.[1,2] Collectively, these data show that fetal muscular activity, whether it is active glottic adduction during apnea or activation of the diaphragm during FBM, helps to defend FLF volume and hence the degree of lung expansion (see Figure 80-2). At present, no in vivo evidence has emerged to show that phasic stretch, per se, of the lung during FBMs is an important determinant of fetal lung growth, although in vitro evidence suggests that this is possible.

Numerous in vitro studies have shown that phasic stretch of fetal lung cells in culture, in a manner that attempts to simulate FBMs in vivo, stimulates lung cell proliferation.[41] These experiments have provided important information on the transduction pathways by which phasic mechanical stimuli initiate lung cell proliferation. However, the stimulus used (approximately 5% stretch) probably exceeds that induced by FBMs in vivo. In vivo, individual FBMs are essentially isovolumic, so the percent length change experienced by a lung cell with each FBM will be negligible. This is because the fetal chest wall is very compliant, and fetal lung liquid is very viscous compared with air and, owing to its mass, has a large inertia. Thus, although activation of the diaphragm causes a reduction in intrathoracic pressure, very little liquid is inhaled with each inspiratory effort, because other sections of the chest wall are simultaneously drawn in[42]; free liquid must be present within the pharynx before any liquid can be inhaled.[12] As a result, the tidal volume (V_T) in the fetus is very small; in late-gestation fetal sheep, V_T usually is less than 0.5 mL[31] at FBM rates of up to 3/second. In human fetuses during the last trimester, the mean FBM frequency is approximately 1/second,[33] although respiratory cycle times of up to 1.5 to 2.0 seconds have been reported. Color Doppler ultrasound imaging has been used to measure fluid flow velocity waveforms in the

trachea and nasopharynx of human fetuses, although the contribution of this fluid movement to lung volume changes is currently unclear.[34] Thus, at least in the sheep, fetal V_T is less than 1% of resting lung volume but markedly increases immediately after birth to approximately 20% of resting lung volume.

MECHANOTRANSDUCTION MECHANISMS AFFECTING GROWTH AND DIFFERENTIATION

All cells, tissues, and even whole organs are subjected to physical forces in vivo, including shear stress, stretch, and compression; such forces can result from gravity, osmotic pressures, fluid flow, intracellular tensile forces, body movements, and changes in the internal volume of hollow organs. It has been proposed that cells exist in a state of isometric tension that is generated by the intracellular contractile filaments of the cell.[43] Thus externally applied forces are thought to be imposed on a preexisting equilibrium of forces, causing changes in cell shape and intracellular structural fiber alignment until the force equilibrium is reestablished.[43,44]

Physical forces play an important role in cellular growth and differentiation, are critical regulators of three-dimensional tissue structure,[44] particularly in the lung,[1,45] and constitute an important means by which cells interact with their environment.[43] The transduction pathways by which physical forces are translated into chemical stimuli, leading to changes in cell function, are beginning to be understood. The discovery of cell surface receptors that bind to a variety of extracellular membrane (ECM) proteins has greatly advanced the understanding of mechanotransduction mechanisms. For example, the "integrin" family of transmembrane proteins cluster at focal adhesion sites and bind to a specific sequence, Arg-Gly-Asp (RGD), that is common in many ECM proteins.[46] The intracellular domains of these receptors are mechanically linked to fibrillar-actin bundles via a variety of cytoskeleton-associated proteins (e.g., talin, vinculin, paxillin) and are associated with a number of protein kinases.[46] Because actin bundles are a major component of the intracellular scaffolding, the intra- and extracellular structural components are mechanically coupled, by way of ECM receptors, to form a structural continuum (Figure 80-4). It is through these physical couplings that mechanical forces can be detected and translated into intracellular chemical signals.[44] Although the intracellular signaling pathways are less well defined, they are likely to include stretch-activated ion channels, activation of intracellular second messenger systems, and the direct activation of RNA polymerases and DNA-synthetic enzymes mediated by changes in nuclear shape.

It is possible that increased expansion of the fetal lung stimulates the synthesis and release of specific growth factors that act locally, in a paracrine manner, to stimulate cellular proliferation. The fetal lung produces a number of growth factors including platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), IGF-II, keratinocyte growth factor (KGF), and transforming growth factor-β_1 (TGF-β_1). Although IGF-II expression is increased by sustained lung expansion,[19] IGF-II messenger RNA (mRNA) levels do not parallel the increase in DNA synthesis rates[47]; these are maximal at 2 days of tracheal obstruction and then decline to control values by 10 days.[26] Similarly, PDGF-B expression was reduced in response to tracheal obstruction, when DNA synthesis rates were elevated, indicating that the accelerated lung growth is not mediated by increased expression of these growth factors.[47] Although it also is important to understand how expression of specific growth factor receptors changes in response to an increase in fetal lung expansion, the finding that activation of the mitogen-activated protein (MAP) kinase pathway is not increased by this stimulus[47] indicates that growth factor receptor activation is not a major regulatory pathway. However, VEGF expression was transiently increased by tracheal obstruction, indicating that VEGF may regulate endothelial cell proliferation in growth-accelerated lungs.[47]

To identify gene pathways activated or suppressed in response to an increase in fetal lung expansion, differential gene analysis techniques have been used. In an animal model, overexpanded and control lung tissue samples were collected from the same fetus.[18,48] Increased fetal lung expansion induced differential expression of more than 80 genes, many of which have known roles in cell growth and differentiation and ECM remodeling[18]; these genes are likely to play an important role in stimulating and coordinating the growth and development response of the lung. In particular, a number of immediate early response genes including *EGR1, CTGF,* and *CYR61* have been identified, providing

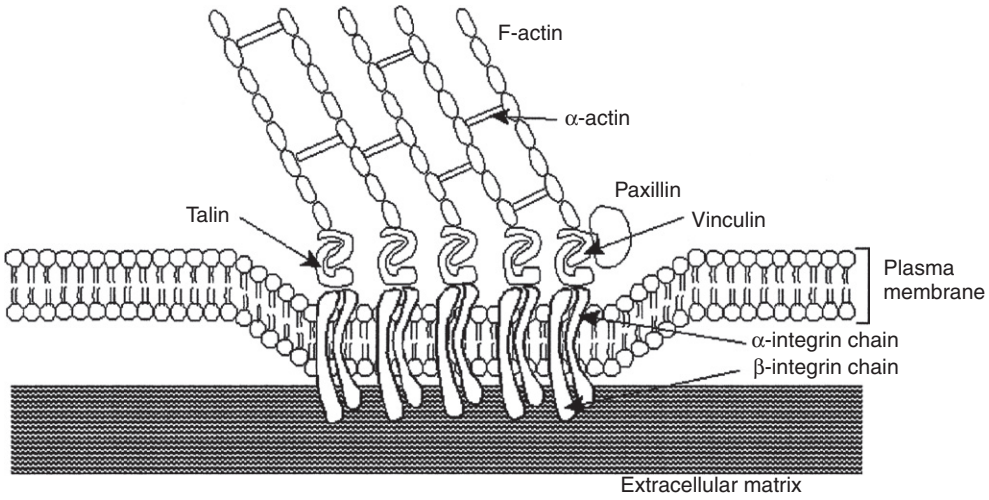

Figure 80-4 Schematic diagram demonstrating how the extracellular matrix (ECM) receptors (integrins) mechanically couple the intracellular microfilaments with the ECM to form a structural continuum. Proteins associated with the intracellular domain are associated with numerous intracellular signaling pathways, which may mediate the response to alterations in fetal lung expansion. *(Data from Ingber D, Karp S, Plopper G, et al: Mechanochemical transduction across extracellular matrix and through the cytoskeleton. In Fransas JA, editor:* Physical Forces and the Mammalian Cell, *San Diego, 1993, Academic Press, p 61; and Rubin K, Gullberg D, Tomasini-Johansson B, et al: Molecular recognition of the extracellular matrix by cell surface receptors. In Comper WD, editor:* Extracellular Matrix, *Amsterdam, 1997, Harwood Academic Publishers, p 262.)*

important clues for identifying factors that initiate the growth response to increased lung expansion.[18]

PHYSICAL CAUSES OF FETAL LUNG HYPOPLASIA

Fetal lung hypoplasia, which can be defined as a reduction in lung tissue weight or cellular content, can result from a diverse group of disorders of pregnancy. Such disorders include oligohydramnios secondary to premature rupture of membranes or fetal anuria; congenital diaphragmatic hernia (CDH); thoracic space-occupying lesions such as pulmonary cysts, tumors, and pleural effusions; and fetal musculoskeletal deformities. The common mechanism for inducing fetal lung hypoplasia in these situations presumably is a prolonged reduction in the degree of fetal lung expansion.[15]

Oligohydramnios

Oligohydramnios occurs in approximately 10% of pregnancies and usually is caused by premature rupture of the fetal membranes. Another cause is inadequate production of fetal urine due to fetal urinary tract disorders, including renal agenesis, renal dysplasia and agenesis or stenosis of the ureters, urethra or urethral valve.[15] The severity of the lung growth deficit depends on the gestational age at onset and the duration and severity of the oligohydramnios.[49] The likely mechanism by which oligohydramnios causes fetal lung hypoplasia involves a prolonged reduction in lung expansion.[8] In the absence of amniotic fluid, the intrauterine space is reduced, so the fetal trunk is increasingly flexed.[8,15] This positioning leads to an increase in abdominal pressure, elevation of the diaphragm, compression of the lungs, and the loss of lung liquid[8]; the efflux of FLF is increased during nonlabor uterine contractions, which further increase the degree of fetal spinal flexion.

Congenital Diaphragmatic Hernia

CDH is less common than oligohydramnios but usually results in more severe, often fatal lung hypoplasia. CDH is a result of failure of the embryonic diaphragm to close (at approximately 12 weeks gestation), allowing abdominal contents to enter the thorax.[50] The hernia can be either unilateral (i.e., left- or right-sided) or bilateral, causing chronic lung collapse on the affected side (s). The perforated thoracic compartment allows unimpeded lung recoil, so the ipsilateral lung is unable to expand, hence lung growth cannot occur. Furthermore, FBMs would not have the effect of opposing lung recoil, as in an intact fetus, because of the diaphragmatic defect; any phasic strain-related effects of FBMs on the lung also would be absent. In addition, the abdominal contents may compress the contralateral lung as a consequence of a shift in the mediastinal ligament. Because the defect occurs early in fetal life, it usually results in severe lung hypoplasia, with major impairments in lung structure and function.

Musculoskeletal Disorders

A variety of fetal musculoskeletal disorders can result in severe lung hypoplasia[15]; although the precise mechanisms depend on the type of disorder, they probably all involve a prolonged reduction in lung expansion. Because the activity of both the diaphragm and glottic adductor muscles plays a crucial role in maintaining fetal lung expansion,[8] interference with such activity would be expected to have an impact on fetal lung growth.

EFFECTS OF CORTICOSTEROIDS ON GROWTH AND MATURATION OF THE FETAL LUNG

During development, the fetal lung is naturally exposed to corticosteroids of maternal and fetal origin, particularly during late gestation and under conditions of fetal distress. Researchers have directed much attention to corticosteroids owing to their therapeutic value in enhancing lung maturity, although their precise effects on lung development in vivo are still unclear. In the fetal lung, elevated circulating corticosteroid levels have important effects on (1) structural development, (2) the surfactant system, and (3) the reabsorption of FLF at birth. Other potential effects of corticosteroids include reduced lung tissue growth and stimulation of type II AEC differentiation. In this section, the focus is on the role of cortisol in fetal lung growth and structural maturation.

It often is assumed that corticosteroids induce fetal lung maturation at the expense of lung growth, but the in vivo data are contradictory, probably reflecting species differences as well as differences in dose, number of doses used, and route of administration. Most studies have used synthetic glucocorticoids (betamethasone or dexamethasone), which have a 30- to 40-fold greater bioactivity than that of cortisol. When administered to the mother, betamethasone[51] causes a decrease in both fetal body and lung growth, effects that become greater with increasing number of doses.[52,53] When administered directly to the fetus, however, betamethasone does not affect fetal body or lung growth.[54] Similarly, physiologic doses of cortisol, infused directly into the fetus to simulate the preparturient increase in fetal plasma cortisol levels, induce structural maturation of the lung without affecting either fetal lung or body growth.[55,56] These data suggest that the effects of maternally administered betamethasone on fetal body and lung growth are dose-dependent, mediated through an effect on the placenta, or related to the duration of exposure (i.e., half-life).

The removal or abolition of the endogenous source of corticosteroids in the fetus also has led to conflicting results in studies examining fetal lung growth. Adrenalectomy[57] and hypophysectomy[58] in fetal sheep significantly reduce lung protein, rather than DNA, content[57]; this observation indicates that endogenous cortisol may contribute to lung protein accumulation. By contrast, knock-out of the corticotropin-releasing hormone (CRH) gene in mice increases fetal lung DNA content and rates of cellular proliferation, particularly in epithelial cells.[59] Similarly, knock-out of the glucocorticoid receptor causes lung hypercellularity (increase in DNA content), indicating that endogenous corticosteroids suppress lung cell proliferation.[60] Other interspecies differences in the pulmonary effects of glucorticoids are evident. For example, homozygous (−/−) CRH knock-out mice from heterozygote (+/−) mothers survive birth, probably as a consequence of the placental transfer of corticosteroids from the +/− mothers.[61] Thus it appears that the survival of newborn mice at birth is not dependent on exposure to the preparturient increase in circulating corticosteroids, as it is in humans and sheep, although some circulating corticosteroids are required.

One of the principal effects of corticosteroids is enhanced structural maturation of the fetal lung, resulting in improved lung mechanics after birth.[62] Both natural and synthetic corticosteroids markedly reduce perialveolar tissue volume, leading to a reduction in cellularity (cell density within the tissue) and a marked increase in potential air space volume; these changes would be expected to increase lung compliance. By contrast, adrenalectomy and hypophysectomy in fetal sheep, hypophysectomy in fetal pigs,[63] and knock-outs of both the GR and CRH genes in mice all have been documented to increase perialveolar tissue volumes, decrease air space volumes, and increase cellularity, resulting in respiratory failure at birth, presumably owing to a reduction in lung compliance. Although their effect on lung structure is arguably the major beneficial effect of corticosteroids on the developing lung, the mechanisms remain largely unknown.[62]

Corticosteroids also can affect alveolarization, although this effect may be dose- or species-dependent. Betamethasone has been shown to arrest alveolarization in postnatal rats,[64] whereas physiologic doses of cortisol administered to fetal sheep increase alveolar number.[65] In addition, the increase in fetal lung

compliance induced by corticosteroids interacts with the relationship between lung expansion and lung growth, causing an enhanced lung growth response subsequent to increased lung expansion.[56]

Antenatal corticosteroids also stimulate the maturation of the pulmonary vascular bed in normal fetal lungs[66] and in hypoplastic fetal lungs.[67] In sheep, antenatal corticosteroids enhance pulmonary vasodilator responsiveness and increase the fall in pulmonary vascular resistance and rise in pulmonary blood flow at the time of birth. These effects may be mediated by acceleration of vascular and parenchymal maturity; it seems unlikely, however, that changes in vascular density or wall structure are involved.[67]

EFFECTS OF METABOLIC FACTORS ON FETAL LUNG GROWTH AND MATURATION

Impaired nutrient and O_2 delivery during fetal life can affect the developing lung. Studies of respiratory function in infants,[68] children,[69] and adults[70] suggest that lung development may be affected by intrauterine conditions that inhibit fetal growth and lead to low birth weight. A common cause of fetal growth restriction (FGR) is chronic placental insufficiency, which reduces the availability of nutrients and oxygen to the fetus. The effects of fetal hypoxemia differ from those of nutrient restriction. Prolonged hypoxemia in the absence of hypoglycemia leads to reduced DNA synthesis rates in ovine fetal lungs.[71] In rats, fetal hypoxia from early in gestation resulted in the lungs being small relative to body weight.[72] Nutrient restriction has been shown to impair alveolus formation. For example, in rats, in which alveolus formation occurs postnatally,[73] intermittent starvation soon after birth was associated with enlarged alveoli with thicker septa and reduced elastin deposition.[74] In sheep, hypoxemia and nutrient restriction during late gestation (coinciding with pulmonary saccular and alveolus formation) also leads to reduced alveolarization.[75] Similar findings have been documented in undernourished postnatal rats[74] and in guinea pigs undernourished during late gestation and in early neonatal life.[76] Impaired alveolarization secondary to FGR could be a result of fetal hypoxemia, hypoglycemia, or elevated corticosteroid levels. Furthermore, glucose transport to the lungs of growth restricted fetal rats is reduced,[77] which could reduce metabolic activity within lung cells.

The alveolar blood-gas barrier also can be affected by restricted fetal growth. In sheep, severe FGR during late gestation increases the blood-air barrier thickness, an effect that persists for at least 2 years after birth.[78] In guinea pigs born after maternal undernutrition during pregnancy, the alveolar surface area was reduced, leading to a reduced diffusing capacity[76]; a smaller surface area was still apparent at 18 weeks, in spite of catch-up growth in body weight and lung volume. Such changes, together with alterations in airway development, may potentially impair lung function later in life.[79,80]

Structural elements of the lung, such as elastic fibers, collagens, proteoglycans, and basement membrane proteins, are laid down during early development and these processes may be affected by nutritional status. Elastin is necessary for airway and alveolar development and affects lung compliance.[81] Tropoelastin is expressed principally by fibroblasts, particularly during alveolus formation.[82,83] Owing to the long half-life of elastin,[84] alterations in elastin deposition during development may exert persistent effects on the mechanical properties of the lung, and it is now apparent that nutritional factors can affect elastin deposition. For example, in growing rats, protein restriction caused a loss of lung desmosine and an increase in alveolar dimensions.[85] In humans, most elastin accumulates in the lungs between 25 weeks gestation and 15 weeks after birth, and this accumulation is not significantly affected by FGR.[86] Similarly, pulmonary tropoelastin expression and elastin content are not altered in fetal sheep subjected to FGR during late gestation.[87]

During fetal life, both hypoxia and fetal undernutrition may be associated with increased levels of corticosteroids[88]; these may affect elastin synthesis as exogenous corticosteroids can both increase[82] and decrease[89] elastin formation in the fetal lungs. Elastin deposition in the lung also may be affected by hypoxia as it down-regulates tropoelastin in pulmonary fibroblasts[90] and in pulmonary artery smooth muscle cells.[91] Paradoxically, hypoxia also increases pulmonary lysyl oxidase activity, the extracellular enzyme responsible for cross-linking elastin and collagen. However, an inhibitory effect of hypoxia on elastin synthesis was not observed in growing rats.[92]

Collagen provides the lung and airways with mechanical strength.[93] In contrast with elastin, collagen is synthesized and degraded throughout life,[93] and it is well established that collagen metabolism is affected by nutritional status.[94] Lung collagen content is reduced in postnatal rats fed a low-protein diet.[85] It is of interest that procollagen gene expression in lung fibroblasts is increased by hypoxia,[95] which is a feature of FGR.

Proteoglycans are a major component of lung ECM, yet no data apparently exist on the influence of impaired nutrition or oxygenation on proteoglycan synthesis in the developing lung. In vascular tissue, hypoxia has been shown to decrease proteoglycan production.[96,97]

Development of pulmonary surfactant is affected by nutritional factors. Undernutrition of pregnant rats results in impaired surface tension–lowering properties of fetal lung extracts[98]; the maturation of type II AECs in these offspring also is delayed, because their glycogen content was increased and lamellar bodies were decreased.[99] Prolonged periods of fetal hypoxemia, induced by placental restriction, also increase expression of surfactant proteins SP-A and SP-B at 0.88 of gestation[100] but not near term.[101] This observation suggests that FGR or nutrient restriction may have beneficial effects on lung maturity in preterm infants but not in those born at term. The effects of undernutrition and hypoxia on type II AECs are likely to differ according to gestational timing and alterations in cortisol levels.

Certain micronutrients are known to be essential for normal lung development. Vitamin A (retinol) and retinoic acid play important roles early in lung development, during embryogenesis and organogenesis. Retinoic acid appears to be the most active of the retinoids[102] and affects many aspects of lung development including early airway branching, alveolus formation, and the synthesis of surfactant and surfactant proteins.[103] For example, vitamin A deficiency during gestation reduces the expression of SP-A, SP-B, and SP-C in fetal rat lungs.[104] Considerable interest has been directed toward understanding the effects of retinoic acid on alveolus formation and surfactant synthesis. These effects must include elastogenesis, because inhibitors of retinoid metabolism decrease tropoelastin expression in fetal rat lung explants,[105] and vitamin A deficiency during pregnancy reduces elastin staining in fetal rat lungs.[106] Some evidence suggests that a reduction in alveolus formation during early development may be reversible, because treatment with retinoic acid is able to increase the number of alveoli, at least in rats and mice.[64,107]

Vitamin D can affect the developing lung, possibly through binding sites on type II AECs.[108] It can advance maturation of type II AECs as indicated by a reduction in glycogen content and increased surfactant synthesis.[109] Selenium also is important, because it is necessary for the activity of glutathione peroxidase, an important antioxidant defense enzyme. Selenium deficiency in rats leads to altered lung development, particularly alveolar septation.[110]

POSTNATAL LUNG GROWTH

In humans, although the formation of significant numbers of alveoli ceases at 1.5 to 3 years after birth,[111] lung growth continues for another 15 to 18 years, until the chest stops growing

in late adolescence. Thus much more lung tissue growth occurs after birth than during fetal life. In the sheep, for example, the weight of the lung tissue increases from approximately 100 g at birth to around 220 g at 6 weeks, and to 600 g in the mature animal. Paradoxically, however, less is known about the physiologic control of lung growth after birth than before birth. Much of what is currently known about the control of postnatal lung growth has been derived from experimental and clinical studies observing lung growth after lung resection (i.e., postpneumonectomy lung growth) and in disorders affecting chest wall development (e.g., kyphoscoliosis).

An understanding of lung growth after birth is of particular interest in the clinical approach to premature infants, infants with hypoplastic lungs (e.g., after preterm premature rupture of membranes [PPROM] or CDH), infants affected by FGR who then experience postnatal catch-up in body growth, and infants and children with feeding problems or nutritional deficiencies. Not only does lung growth increase the surface area for gas exchange, but it is necessary for normal development of the pulmonary vascular bed and, consequently, a normal pulmonary circulation. Children with problems from impaired lung growth before or after birth may benefit from treatments that accelerate lung parenchymal growth and development, some of which are discussed further on.

THE ROLE OF THE PHYSICAL ENVIRONMENT

It generally is assumed that as the thoracic cavity enlarges with skeletal growth, lung growth follows passively to fill the chest; put simply, if the chest wall does not grow, then the lung is unlikely to grow. Thus a full understanding of postnatal lung growth will ultimately require knowledge of how chest wall growth, and its stiffness, are regulated. The lungs exert a chronic traction on the chest wall, so an intimate relation must exist between lung growth and thoracic wall growth, with each affecting the other; it is likely, however, that the lung, which ultimately fills the space available, will stop growing once the chest is no longer enlarging. Immediately after birth, the chest wall is very compliant and can influence lung growth to a significant extent only after the ribs and sternum become ossified; the rate at which this ossification proceeds will therefore have an effect on lung growth. Ossification of the chest wall in preterm infants may be delayed, and this could impair lung growth in these infants, unless they receive CPAP or PEEP.

Lung resection experiments have shown that the postnatal lung will grow to fill the space available, which may be dependent on the presence of a subatmospheric intrapleural pressure. This pressure differential in turn creates a transpulmonary pressure that effectively expands the lung by exerting chronic traction on the lung pleura.[112] The mechanical stress and strain imposed on the lung are presumed to activate intracellular processes that precipitate events that increase cell replication and tissue remodeling. The stimulated lung growth has the effect of reducing stress and strain in the alveolar septa, which limits the stimulus for further growth; it is likely that this process continues until the thoracic cavity reaches its final dimensions.[112]

Available evidence suggests that the basal level of lung expansion is an important determinant of lung growth and structural development after birth, as it is in the fetus, although the mechanical forces exerted on the air-filled lung are considerably more complex. Indeed, in the fetus it is apparent that lung growth may drive chest wall growth, whereas the reverse seems to be true after birth. The relationship between the basal level of lung expansion and lung development is graphically demonstrated by the marked reduction in the rates of lung tissue growth[113] (Figure 80-5) and alveolarization[111,114] (Figure 80-6) that occurs after birth, when the degree of lung expansion is chronically reduced, as shown in Figure 80-1.

An increasing amount of evidence indicates that tissue stretch is a major stimulus to postnatal lung growth. Chronic, localized distention of a region of the lung with perfluorocarbon accelerates lung growth and alveolarization in that region, an effect seen in growing but not adult animals.[115] The use of CPAP and positive end-expiratory pressure (PEEP), both of which would be expected to increase the basal degree of lung expansion by increasing end-expiratory lung volume (i.e., FRC), has been shown to enhance lung growth in growing ferrets[116] and lambs.[117] Similarly, the compensatory lung growth induced by

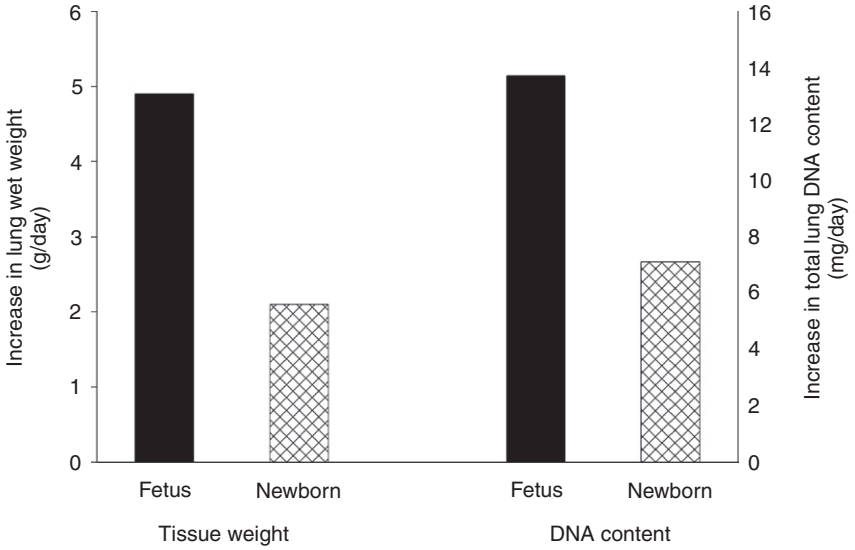

Figure 80-5 Lung growth rates measured in ovine fetuses during late gestation *(closed bars)* and in postnatal lambs *(cross-hatched bars).* Lung growth rates were calculated as the increase in wet tissue weight (g/day) *(left panel)* and total DNA content (mg/day) *(right panel)* using fetuses killed at 114 and 138 days of the 147-day gestation, and postnatal lambs killed at 1 day and 46 days after birth (n = 5 for each age-group). Of note, lung growth rates in postnatal lambs are considerably lower than in the fetus. *(From Hooper SB, Wallace M: Role of the physicochemical environment in lung development,* Clin Exp Pharmacol Physiol *33:273-279, 2006.)*

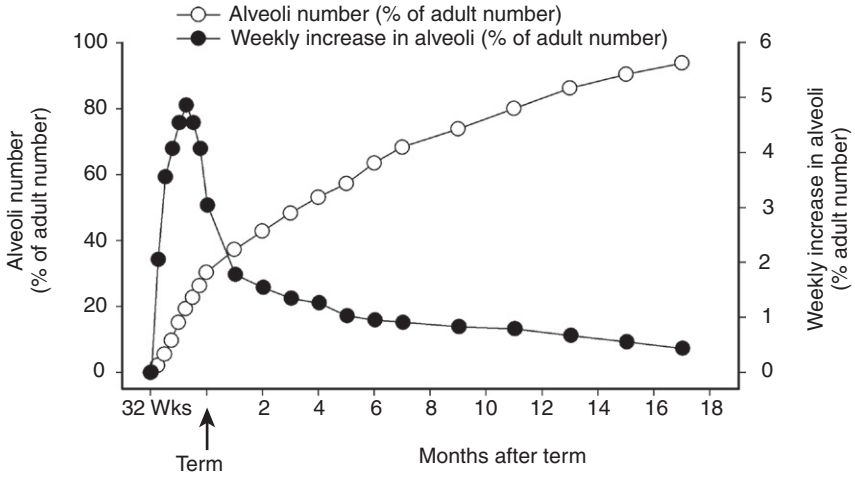

Figure 80-6 Changes with fetal and postnatal age in alveolar number and weekly rate of accumulation of alveoli in humans. The *filled circles* show the weekly rate of alveolus formation expressed as a percentage of the final adult number of alveoli (% alveoli/week); the *open circles* show the percentage of the final adult number of alveoli that have been formed at each time point (% adult number of alveoli). Of note, the rate of alveolus formation is markedly reduced after birth. *(From Jobe A: Lung development and maturation. In Martin RJ, Fanaroff AA, Walsh MC, editors:* Neonatal-Perinatal Medicine, *ed 8, St Louis, 2006, Mosby, pp 1069-1086. Idealized curves data from Langston C, et al: Human lung growth in late gestation and in the neonate,* Am Rev Respir Dis *129:607-613, 1984; and Hislop AA, Wigglesworth JS, Desai R: Alveolar development in the human fetus and infant,* Early Hum Dev *13:1-11, 1986.)*

partial resection of the air-filled lung after birth is thought to be expansion-dependent.[118] It has been suggested that phasic expansion of the lung during breathing acts as a stimulus for lung growth. Of note, however, experimentally increasing the phasic component of postnatal breathing movements does not affect lung growth or lung structure.[119] Combined, these findings indicate that lung growth after birth is regulated primarily by the basal degree of lung expansion, as it is in the fetus.

EFFECTS OF METABOLIC AND ENDOCRINE FACTORS

Although it is now apparent that mechanical tissue strain is the major signaling mechanism underlying postnatal lung growth, nonmechanical factors are likely to play a role in modifying the growth response.[112] These may include metabolic factors such as the availability of nutrients, micronutrients, and oxygen and endocrine factors such as corticosteroids, growth hormone, sex hormones, IGFs, and thyroid hormones.

Nutrition

Numerous studies have shown that as in the fetus, postnatal nutrition can have a profound effect on lung development.[120] In children, severe malnutrition has been shown to adversely affect lung function, but such effects could be related in part to altered musculoskeletal development.[121] Animal studies have shown specific effects of postnatal undernutrition on lung structure, including alveolarization.[74,122] The adverse effects of undernutrition during postnatal development may persist to maturity. For example, a study in sheep has shown that animals that grow slowly after birth have smaller lung volumes, and smaller pulmonary surface areas relative to lung and body size, than those measured in normally growing animals.[122a]

Corticosteroid Exposure

Preterm infants may be administered corticosteroids to accelerate lung maturity and to reduce the time spent on a mechanical ventilator. Although available data on the structural effects of postnatal exposure to exogenous corticosteroids are very limited for human infants, such exposures have been shown in animals to affect lung growth and alveolarization. In postnatal rats, dexamethasone accelerates thinning of interalveolar septa; however, alveolarization is inhibited—an effect that can be permanent or transient, depending on when it is given.[123] Dexamethasone also has been shown to retard rates of both lung cell proliferation and apoptosis[124] and to accelerate microvascular maturation.[125]

POTENTIAL TREATMENTS FOR LUNG GROWTH DISORDERS

Fetal Treatments

It is now clear that lung growth and structural development are a consequence of a complex interaction among mechanical, endocrine and metabolic factors. The challenge is to translate this knowledge into therapeutic treatments that will improve outcomes for preterm infants and infants with hypoplastic lungs. Because increased fetal lung expansion is a potent stimulus for fetal lung growth and structural maturation, it has been tried as an in utero treatment for severe lung hypoplasia. Experimental studies have shown that increases in fetal lung expansion induced by tracheal obstruction can rapidly reverse fetal lung growth deficits in utero[17,126,127] and can reverse postnatal respiratory dysfunction that would otherwise be fatal.[128] However, clinical trials in fetuses with severe pulmonary hypoplasia resulting from CDH have had mixed success, although some improved outcomes have been reported.[129] The major problems relate to preterm labor, failure to adequately stimulate fetal lung growth, and postnatal respiratory insufficiency despite induced lung growth.[129] Thus a significant discrepancy exists between the results of clinical trials and those obtained in animal experiments. These discrepancies may relate to the stage of lung development at which the treatment was applied, the duration of the tracheal obstruction, and the severity of the fetal lung hypoplasia. For example, most tracheal obstruction procedures in humans have been carried out before 28 weeks gestation, when the lungs are at the early to mid-canalicular stage of development.[129,130] When tracheal obstruction is performed at this

stage of lung development in fetal sheep, the induced lung growth is associated with mesenchymal cell proliferation and increased perisaccular tissue volume.[28] Similarly, sustained increases in fetal lung expansion can severely reduce the numbers of type II AECs[23] and limit surfactant protein gene expression.[131-133] Although this reduction in type II AECs[22] and surfactant protein gene expression is not necessarily permanent, the obstruction must be released before birth for normalization to occur.[134] The fetus must then spend sufficient time in utero for the AECs to transdifferentiate and reestablish near-normal proportions. Thus inappropriate growth and reduced type II cell numbers may help explain why infants subjected to prolonged tracheal obstruction in utero can suffer respiratory insufficiency after birth, despite having a normal-sized or larger-than-normal lung.

The failure to stimulate lung growth by tracheal obstruction in human fetuses with CDH also may be explained by the inability of fetal lung liquid secretion to expand the fetal lungs. Because the severely hypoplastic fetal lung is relatively incompliant, it is difficult to expand. Thus, if the internal distending pressure required to expand it is greater than the osmotic pressure driving lung liquid secretion, which is only approximately 4 to 5 mm Hg,[26] the lung will not expand, despite the trachea being occluded. Ongoing lung liquid secretion and increased lung expansion are requirements for accelerated fetal lung growth[26,56]; without continued lung liquid secretion, therefore, the lung growth response will not be activated.[129]

Another complication associated with tracheal obstruction for the correction of CDH-induced lung hypoplasia in human fetuses is the development of fetal hydrops.[129] This phenomenon also has been observed in fetal sheep,[28] but only when the tracheal obstruction procedure is performed during the pseudoglandular-canalicular stages of lung development; it does not occur during the alveolar stage. The hydrops is thought to result from the greater increase in lung expansion and lung growth that occurs in the immature fetus; this is thought to result from an immature chest wall that allows the lungs to expand to a much greater degree.[28] The resultant hydrops probably is due to restricted venous return or to mechanical constraint of the heart by the expanded lungs. Taken together, these data indicate that if tracheal obstruction is to be used successfully to stimulate lung growth in fetal humans, (1) the obstruction procedure is better performed later in gestation, (2) the obstruction needs to be reversible or intermittent, and (3) it may be beneficial to use corticosteroids to improve lung compliance, before the onset of obstruction.

Postnatal Treatments

The stimulation of lung growth in the early postnatal period is of interest in the management of infants born with hypoplastic lungs, such as in CDH. PEEP often is used with preterm neonates to enhance oxygenation and prevent lung collapse and injury. Because PEEP causes a sustained increase in the basal degree of lung expansion (i.e., FRC), it may have the added effect of enhancing postnatal lung growth; this effect has not been demonstrated in human infants but has been observed in normal postnatal ferrets[116] and lambs[117] Although a potential complication of increasing end-expiratory lung volumes in ventilated preterm infants is an alteration in the proportions of AECs, leading to a reduction in type II cells, a study in normal lambs failed to detect an effect of 48 hours of PEEP on AECs.[117]

SUMMARY

Growth and structural maturation of the lung both before and after birth result from a complex interaction among physical, endocrine, and metabolic factors. Sustained expansion of the developing lung appears to be crucial for normal lung development both before and after birth. In the fetus, a high degree of lung expansion is actively maintained and is dependent on diaphragmatic and laryngeal muscle activity. Factors that inhibit these muscular activities or alter the transpulmonary pressure gradient result in a reduction in fetal lung expansion, now recognized as being the common underlying mechanism by which a variety of disorders result in pulmonary hypoplasia. After birth, the major stimulus for lung growth also is likely to be physical lung expansion, which is provided by growth of the rib cage. The mechanisms by which alterations in lung expansion accelerate or retard the growth and development of the lung are largely unknown but represent vital areas of research that may yield substantial clinical benefits.

81 Molecular Mechanisms of Lung Development and Lung Branching Morphogenesis

Martin Rutter, Minke Van Tuyl, and Martin Post

When one examines the development of animals throughout time, the effect of certain influences on the evolution of body plan can be seen. However, one factor in particular emerges as the most influential of all, because its developmental pressure has affected the evolution of nearly every animal. That factor is oxygen, and the ability to extract sufficient amounts of oxygen from the surrounding environment has had an incredible impact on the design of respiratory systems. In particular, land mammals with their high metabolic rates have been forced to evolve a sophisticated organ to meet their oxygen requirements. We explore this process of development and examine a variety of important molecular regulators affecting lung formation.

Lung development can be subdivided into six distinct stages (Table 81-1).[1-3] The early stages of lung formation comprise the embryonic and pseudoglandular periods, after which the prospective conductive airways have been formed and the acinar limits can be recognized. During the pseudoglandular period the primitive airway epithelium starts to differentiate, and neuroendocrine, ciliated, and goblet cells appear while mesenchymal cells have begun to form cartilage and smooth muscle cells. In the subsequent canalicular period, the airway branching pattern is completed, and the prospective gas exchange region starts to develop. During this period respiratory bronchioli appear, interstitial tissue decreases, vascularization of peripheral mesenchyme increases, and distal cuboidal epithelium differentiates into type I and type II cells. In the saccular (terminal sac) period, the growth of the pulmonary parenchyma, the thinning of the connective tissue between the air spaces, and maturation of the surfactant system are the most important steps toward ex utero life. Although already functional, the lung is structurally still in an immature condition at birth. The air spaces present are smooth-walled transitory ducts and saccules with primitive septa that are thick and contain a double capillary network. The final two phases of lung development are alveolarization and microvascular maturation. These two phases occur concurrently and are distinguished by formation of the alveoli through a septation process that greatly increases the gas exchange surface area and by the fusion of the dual-layer capillaries into a single-layer network. One of the important hallmarks occurring throughout lung development is the signaling between the epithelial and mesenchymal tissue layers. The combination, concentration, and spatial-temporal localization of a multitude of molecular signaling factors all working in harmony determine the fate of branching, growth, and cellular differentiation of the developing lung. In this chapter, we summarize studies on lung development from the past two decades and also explore current thoughts on the molecular mechanisms that determine lung pattern formation.

EARLY LUNG DEVELOPMENT

Lung development starts as an endodermal outgrowth of the ventral foregut around the fourth week of human development. This foregut mass rapidly elongates into a single tube dividing into a ventral esophagus and a dorsal trachea, the latter of which bifurcates into the left and right primary lung buds. In a slightly different process, the mouse respiratory system develops from a pair of endodermal buds in the ventral half of the primitive foregut, just anterior to the developing stomach at 9.5 days gestation. The two buds will then elongate in a posterior-ventral direction, while at the same time starting from the primary branch point the single gut tube begins to pinch into two tubes creating the dorsal esophagus and ventral trachea. In humans, the left lung bud will give rise to two main stem bronchi, and the right lung bud gives rise to three main stem bronchi. In the mouse, the right lung bud will form four stem bronchi whereas the left lung consists of one stem bronchus. The secondary bronchi will then branch and rebranch in a dichotomous manner, eventually forming the airway tree in a process termed branching morphogenesis. Endoderm-derived epithelial cells will line the airways, while the surrounding mesenchyme will provide the elastic tissue, smooth muscles, cartilage, vascular system, and other connective tissues. The formation of the bronchial tree is finished at 16 days gestation in the mouse and 16 weeks gestation in humans. At this stage of development, the tracheobronchial tree from the trachea to the terminal bronchioles resembles a system of branching tubules that terminate in exocrine gland–like structures.

MOLECULAR BASIS OF LUNG BUD AND LOBE FORMATION

The outgrowth of the ventral foregut, formation of the trachea, and outgrowth of the main pulmonary bronchi take place during the embryonic period of lung development. The crucial event at this stage is the initiation of lung formation at the right place along the anterior-posterior axis of the foregut. Genetic studies have implicated several transcription factors, morphogens, peptide growth factors, and their cognate receptors in specifying the morphogenetic progenitor field of the lung along the foregut axis (Figure 81-1). One important transcription factor in this process is forkhead box A2 (FOXA2), formerly known as HNF3B.[4,5] FOXA2 is expressed in the ventral foregut endoderm before and immediately at the start of lung bud formation.[6-8] Targeted ablation of FOXA2 in mice led to embryonic death between E6.5 and E9.5, before the onset of lung formation.[9,10] However, chimeras rescued for the embryonic-extraembryonic constriction showed that FOXA2 was essential for foregut and lung formation.[11]

Fibroblast growth factor (FGF) 10 is a member of the large family of FGFs essential to many processes during embryonic development.[12-14] In the murine lung, FGF10 messenger RNA (mRNA) is dynamically expressed in the distal mesenchyme adjacent to the primitive lung buds.[15] The importance of FGF10 for lung development was shown in Fgf10-deficient mice that die at birth because of respiratory failure.[16,17] The Fgf10-deficient mice had complete lung agenesis; that is, lung development had stopped after the formation of the trachea.[16,17] FGFs bind to and signal via FGF tyrosine kinase receptors (FGFR).[12,13,18] The FGF10 receptor (FGFR2IIIB), an FGFR2 splice variant, is expressed in lung bud epithelium.[19] The appositional expression of FGF10 and FGFR2IIIB is in line with lung patterning being dependent on epithelial-mesenchymal interactions.[19] FGFR2b

TABLE 81-1

Stages of Lung Development

	GESTATIONAL AGE			
Stage	**Human (wk)**	**Mouse (days)**	**Main events**	**Epithelial differentiation state**
Embryonic	3.5-7	9.5-14.2	Formation of lung bud, trachea, left and right primary bronchus, and major airways	Undifferentiated columnar epithelium
Pseudoglandular	5-17	14.2-16.6	Establishment of the bronchial tree; all preacinar bronchi are formed	Proximal: columnar epithelium; ciliated, nonciliated, basal, neuroendocrine cells Distal: cuboidal epithelium; precursor type II cells
Canalicular	16-26	16.6-17.4	Formation of the prospective pulmonary acinus, increase of capillary bed	Proximal: columnar epithelium; ciliated, nonciliated, basal, neuroendocrine cells Distal: differentiation of cuboid type II to squamous type I cells
Saccular	24-38	17.4-5 dpn	Formation of saccules, alveolar ducts, and alveolar air sacs	Proximal: ciliated, nonciliated Clara, basal, neuroendocrine cells Distal: type I cells flatten and II cells mature

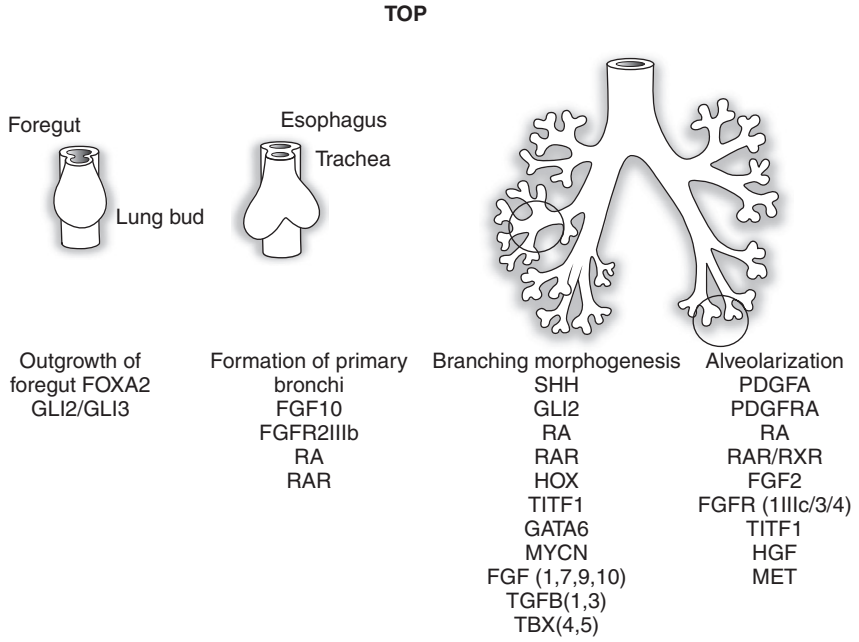

Figure 81-1 Transcription and growth factors regulating lung development (drawings represent a human lung, which in the normal situation consists of two lobes on the left and three lobes on the right side).

is capable of binding FGF1 and FGF7, which have also been implicated in lung development.[13,15,20] Because targeted mutation of FGFR2 resulted in an early lethal phenotype caused by placental insufficiency,[21,22] Fgfr2$^{-/-}$ chimeras were created to overcome this early lethality and allow lung development to be analyzed.[19] As in Fgf10-deficient mice, only the trachea formed without any further pulmonary branching.[19] Similarly, transgenic mice overexpressing a dominant negative FGFR2IIIb splice variant in distal lung epithelium show a severe pulmonary defect, forming only a trachea and two main bronchi, without any lateral branches.[23] Moreover, Cre-mediated excision to generate mice lacking the IIIb form of FGFR2 while retaining expression of the IIIc splice form resulted in mice that had no lungs and that died at birth.[24] Taken together, these data indicate that FGF10 signaling via FGFR2IIIb plays a crucial role in the initiation of lung bud formation (see Figure 81-1). The "no lung" phenotype as a result of inhibited FGF10 signaling shows a striking similarity to a phenotype resulting from the loss of function of either Branchless (BNL) or Breathless (BTL) in *Drosophila*. BNL encodes an FGF homologue that functions as a ligand for BTL, which encodes a *Drosophila* homologue of FGFR. Loss of function of either BNL or BTL prevented tracheal branching in the fly.[25,26]

Sonic hedgehog (SHH) is a secreted signaling molecule and a mammalian homologue of the *Drosophila* Hedgehog (HH) protein, known to be involved in many fundamental processes during *Drosophila* embryonic development.[27] SHH is expressed in the early pulmonary epithelium, with the highest levels of gene expression seen at the tips of developing lung branches.[28] SHH signals via the mesenchymal-located Patched (PTC) receptor, suggesting that the SHH pathway is an important regulator of epithelial-mesenchymal signaling during lung development.[28] The importance of SHH for lung development was shown when the Shh gene was genetically ablated and resulted in a simplistic-looking lung consisting of only one lobe on each side of the trachea (pulmonary left isomerism).[29,30] Thus, in contrast to the Fgf10-null mutant, the initiation of lung formation does occur in SHH-null mutants, but there is an incorrect number of lung lobes and a subsequent failure of branching morphogenesis.[29,30] This was confirmed in work with the creation of a lung-specific Shh-null mouse.[31] In these mice, when SHH expression was removed before E13.5, tracheal, bronchial, and peripheral lung defects were seen similar to those of the Shh-null mouse. The mesenchyme appears to be the primary target of SHH deficiency, showing decreased cell proliferation and increased cell death in the absence of SHH.[29] The effect of SHH on pulmonary mesenchyme was also demonstrated when SHH was overexpressed in distal lung epithelium with use of the surfactant protein C (SFTPC) promoter.[28] Overexpression of SHH resulted in smaller lungs at birth that lacked functional alveoli most likely as the result of hypercellularity of the mesenchyme. Together, these results denote the important function of SHH in epithelial-mesenchymal signaling during early lung formation.

Cubitus interruptus (CI) has been identified as a downstream target in HH signaling in *Drosophila.*[27] Mammalian Gli genes are the putative homologues of *Drosophila* Ci and have also been implicated in mammalian SHH signaling.[27] Three Gli genes have been described in mice: Gli1, Gli2, and Gli3, all of which are expressed in the early pulmonary mesenchyme.[32] Gli3-null mice only show a mild lung defect with a slight reduction in size. However, Gli2-null mice have respiratory failure at birth, presenting with defective airway branching, left pulmonary isomerism, and severe hypoplasia.[33] Concurrent deletion of both Gli2 and Gli3 revealed an even more dramatic phenotype. These $Gli2^{-/-};Gli3^{-/-}$ double-mutant mice have no lung, trachea, or esophagus and die early in gestation. Of interest, other foregut derivatives such as the pancreas, thymus, and stomach do develop in the $Gli2^{-/-};Gli3^{-/-}$-mutant mice, although they are hypoplastic. These data indicate that the combined function of both GLI2 and GLI3 is crucial for the initiation of lung bud formation (see Figure 81-1). The complete absence of trachea and lung formation was ameliorated by the presence of one Gli3 gene, because the $Gli2^{-/-};Gli3^{+/-}$ mutant had a lung consisting of one hypoplastic lobe.[33] The fact that ablation of both Gli2 and Gli3 resulted in a far worse lung phenotype than the deficiency of SHH alone may indicate that SHH is not the only regulator of Gli genes during lung development. The complete absence of a lung in $Gli2^{-/-};Gli3^{-/-}$-mutant mice is similar to the "no lung" phenotype seen in Fgf10-deficient mice. The only difference is that the trachea and esophagus are present in Fgf10-deficient mice but absent in Gli2;Gli3-deficient mice, implicating different signaling pathways. Other single or compound mutants for the three Gli genes show a variable degree of lung hypoplasia with an aberrant number of lung lobes and decreased branching morphogenesis.[33-35] However, another compound mutant recently analyzed revealed an interesting relationship between SHH and Gli3 during lung development. The $Shh^{-/-};Gli3^{-/-}$ mouse shows a phenotype that is less severe than the Shh-null lung alone, with enhanced vasculogenesis and growth potential.[36] Therefore Gli3 must bring about some of the negative effects seen in the Shh-null mouse and clearly denotes the need for SHH to counter the negative function of Gli3 during lung development. For a complete review of SHH-GLI pathway interactions and effect of mutations on lung development, see Rutter and Post.[37]

Retinoic acid (RA) plays a crucial role during gestation and is involved in the developmental processes of almost every organ.[38,39] Both a deficiency and an excess of RA cause congenital defects during human development in a variety of organs.[38,39] RA exerts its effects via the RAR and RXR tyrosine kinase receptors, which function as transcriptional regulators of RA target genes. The RAR family is composed of three genes producing several isoforms: $RARA_{1,2}$, B_{1-4}, and $G_{1,2}$, all activated by both all-trans RA and 9-cis RA, whereas the three isoforms from the RXR family, RXRA, B, and G, are activated only by 9-cis RA.[39] Mice deficient for only one of the isoforms show a less-severe phenotype than expected on the basis of their expression patterns, indicating a high degree of redundancy among the RA receptors.[39] In contrast, compound mutant mice had similar congenital defects as seen with fetal vitamin A deficiency.[38,39] $Rara^{-/-};b2^{-/-}$ double-mutant mice die soon after birth with agenesis of the left lung and hypoplasia of the right lung.[40] Lung hypoplasia was also reported in $Rara1^{-/-};b^{-/-}$ and $Rxra^{-/-};Rara^{-/-}$ double mutants.[41,42] In addition, RA has profound influences on lung development during branching morphogenesis and alveolarization (see later). Furthermore, RA may regulate HOX genes.[43-46] HOX genes form a large family of homeobox-containing transcription factors that are implicated in the specification of cells that form morphologic structures along an anterior-posterior axis. HOX genes are arranged in four chromosomal clusters, and the 3′ to 5′ position of each gene within a cluster corresponds to their expression pattern along the anterior-posterior axis of the developing body.[47] Genes of the 3′ regions of the HOX clusters A and B are expressed in the developing lung, with the HOXB cluster predominantly expressed in the early pulmonary mesenchyme.[43-46,48-53] Within the mesenchyme HOXB genes express in a proximal-distal expression gradient, suggesting a role for HOXB genes in specifying proximal from distal pulmonary mesenchyme.[49] Several mutant models have been created and illustrate the importance of HOX genes during lung development. Single-mutant mice for Hox genes are generally normal, most likely because of redundancy. However, compound $Hoxa1^{-/-};Hoxb1^{-/-}$ mutants have severe lung hypoplasia with a phenotype ranging from five hypoplastic lung lobes to a lung with only two lobes.[54] $Hoxa5^{-/-}$ mice die in the perinatal period and present with laryngotracheal malformations, a reduced tracheal lumen, and lung hypoplasia.[55]

Another homeodomain transcription factor expressed at the onset of lung morphogenesis is thyroid transcription factor 1 (TITF1), previously known as NKX2.1.[56-58] Expression of TITF1 mRNA is localized to epithelial cells of the developing pulmonary tubules and decreases in more proximal conducting airways with advancing gestation.[8,59,60] TITF1 continues to be expressed in adult bronchiolar and alveolar epithelial type II cells, where it plays an important role in the regulation of Clara cell secreted protein (CCSP) and surfactant protein synthesis (see later). Targeted disruption of Titf1 results in severe hypoplasia of the thyroid and lung, with a developmental arrest at the pseudoglandular stage of lung development.[61] In contrast to the different null mutants in the SHH/GLI signaling pathway, Titf1-null mutants lack distal epithelial cell differentiation.[58,61]

SEPARATING ESOPHAGUS AND TRACHEA

The formation of a tracheoesophageal septum will divide the ventral trachea from the dorsal esophagus, and failure to do so will result in a not uncommon congenital defect in humans called tracheoesophageal fistula.[62] Deficiency of all aforementioned growth and transcription factors that are implicated in the etiology of lung agenesis or hypoplasia also results in tracheoesophageal fistula with different gradations of severity

(Table 81-2). Gli2$^{-/-}$;Gli3$^{-/-}$-mutant mice have no trachea, nor do they form an esophagus, and Gli2$^{-/-}$;Gli3$^{+/-}$ mutants have a single tracheoesophageal tube connected to the stomach.[33] In SHH$^{-/-}$-mutant mice, the trachea and esophagus fail to separate, resulting in tracheoesophageal fistula.[29,30] Mice haploinsufficient for the transcription factor forkhead box F1 (FOXF1) also known as HFH8 exhibit foregut abnormalities including narrowing and, sometimes, atresia of the esophagus, as well as frequent fusion of trachea and esophagus.[63] FOXF1 expression was absent in foregut derivates (trachea, esophagus, oral cavity, lungs) of Shh$^{-/-}$ mutants, indicating that SHH signaling is required for activation of FOXF1 in these tissues.[63] Surprisingly, separation of the trachea and esophagus occurs normally in FGF10-deficient mice,[16,17] whereas Titf1-deficient mice have a complete tracheoesophageal defect.[58] Rara$^{-/-}$;B2$^{-/-}$-, Rara1$^{-/-}$;B$^{-/-}$-, and Rxra$^{-/-}$;Rara$^{-/-}$-mutant mice all exhibit a tracheoesophageal septum defect and other tracheal malformations such as disorganized cartilaginous rings and shortening of the trachea.[40-42] The end result of RA signaling in relation to lung development appears to be mediated through FGF10. This became evident in studies using the pan-RAR antagonist BMS493 in foregut explant cultures, which resulted in failure of initial lung bud outgrowth in the prospective lung field because of inhibition of FGF10 expression in the foregut mesenchyme.[64]

LEFT-RIGHT ASYMMETRY

Around 5 weeks gestation, five separate lobes can be identified in the human lung: two on the left and three on the right. In the mouse, the right lung has four major lobes whereas the left lung consists of only one small lobe. Such left-right asymmetries during development are an integral part of the establishment of a body plan, and several highly conserved mechanisms have been found to initiate the vertebrate left-right axis, including the SHH signaling pathway.[65] Molecules such as SHH,[66,67] FGF8,[66,68] N-cadherin,[69] activin B, the activin receptor IIB,[70] and FOXJ1 (HFH4)[71] have all been shown to influence left-right asymmetry during development (Figure 81-2). However, it appears that all these pathways converge to influence the expression patterns of genes in the transforming growth factor B (TGFB) family of cell-cell signaling factors called NODAL, LEFTY1, and LEFTY2.[72-75] SHH and LEFTY1 mutants have left pulmonary isomerisms with only one lobe on each side of the lung.[29,30,67,73] Both SHH and FOXA2 are thought to act upstream of LEFTY1 and are normal in Lefty1$^{-/-}$ mice.[73] Although no data are available on the expression of LEFTY1 in the Shh$^{-/-}$-mutant lung, LEFTY1 is absent in SHH$^{-/-}$ mutant lateral plate mesoderm (LPM).[67] Lefty1$^{-/-}$ mice show bilateral expression of NODAL and LEFTY2 in LPM, which results in ectopic expression of the homeobox transcription regulator paired-like homeodomain transcription factor 2 (PITX2) in the right side of the foregut region.[73] PITX2 is clearly a powerful determinant of left-right asymmetry because ectopic expression of PITX2 in the right LPM alters looping of the heart and gut and reverses body rotation in *Xenopus* embryos.[76] In contrast, the phenotype of Pitx2$^{-/-}$ mice demonstrates right pulmonary isomerism and altered cardiac position.[77-79] Growth differentiation factor 1 (GDF1) encodes another member of the TGFB superfamily, and it is proposed to act upstream of NODAL, LEFTY1 and 2, and PITX2.[80] Mice deficient for this factor, as well as hypomorphic mutants for NODAL, exhibit right pulmonary isomerism.[72,80] It has not been possible to investigate the role of FOXA2 in left-right asymmetry formation of the lung, because Foxa2-null mutant mice die before the onset of lung formation. However, in rescued Foxa2 mutant mice SHH was not detected in the foregut region.[11] Another FOX family member, FOXJ1, has been shown to have a critical role in left-right axis determination because the Foxj1-null mutant shows random left-right asymmetry of the visceral organs (lung included) resulting from defective ciliary development.[71,81]

BRANCHING MORPHOGENESIS

The early branching of the primary bronchi is monopodal; then starting at the level of the secondary bronchus, each bronchus subsequently undergoes dichotomous branching where each branch bifurcates repeatedly into two branches. The enlarging bronchial tree expands through 23 generations of branching (in humans) into the surrounding mesenchyme, which will eventually furrow into the characteristic lobes of the lung: two on the left and three on right in humans and one left and four right in mice. Of the 23 generations of lung branching, the first 16 are genetically hard wired and thus reproducible, but the latter half appear to have a random distribution.[82]

Early studies indicated that branching of the lung buds is controlled by epithelial-mesenchymal tissue interactions,[83,84] where

Transcription and growth factors involved in the separation of esophagus and trachea around gestational week 4 in humans and day 10 in mice. A failure of separation results in a (in)complete trachea-esophagus septum defect, a not uncommon congenital anomaly in humans.

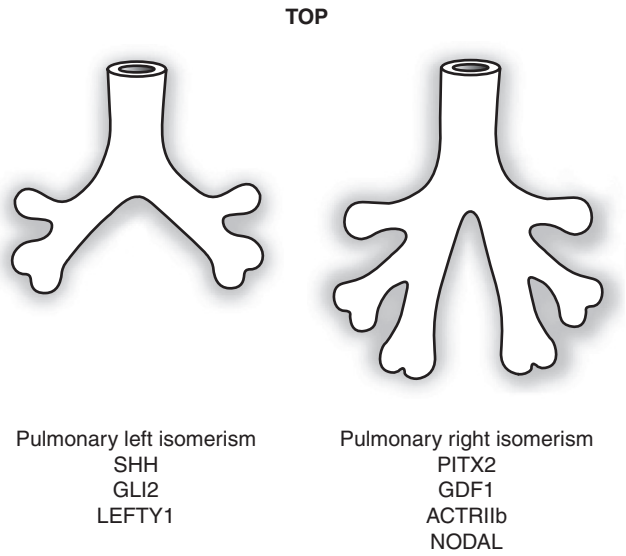

Figure 81-2 Transcription and growth factors involved in left-right determination of the developing mouse lung (drawings represent a human lung, which in the normal situation consists of two lobes on the left and three lobes on the right side).

a soluble factor from the mesenchymal compartment appeared most likely to dictate the branching pattern of the epithelium.[85] The strong inductive capacity of pulmonary mesenchyme was shown when pulmonary mesenchyme was used to induce a lung epithelial phenotype in epithelial ureter buds.[86] Branching appears also to be regulated by positional information along the anterior-posterior axis of the lung because proximal (trachea and main bronchi) and distal (lung bud) mesenchyme differ in their ability to support epithelial branching morphogenesis.[87-89] Some progress has been made in elucidating the complex mixture of transcription factors and morphogens, which guide proper lung branching (see Figure 81-1). Although alterations in cell adhesion and matrix remodeling at the epithelial-mesenchymal interface also contribute to lung branching morphogenesis, they will not be discussed, and the reader is referred to Keijzer and Post.[90]

Although the already mentioned transcription factors belonging to the GLI, HOX, and FOX families are likely involved in this process, other transcription factors that have been implicated in lung branching morphogenesis include GATA binding protein 6 (GATA6) and MYCN. GATA6 belongs to the GATA family of zinc finger–containing transcription factors and is expressed in epithelial and mesenchymal cells of the developing lung bud.[91,92] GATA6 is essential for endoderm formation because targeted deletion of GATA6 resulted in embryonic death before lung formation caused by failure of visceral endoderm formation.[93,94] In the lung, GATA6 appears to be important for branching morphogenesis, because inhibition of GATA6 expression results in decreased branching morphogenesis.[91,94] In addition, expression of a GATA6 engrailed dominant negative fusion protein in the distal lung epithelium resulted in a lack of alveolar type I cells and a perturbation in alveolar type II cells together with a reduction in the number of proximal airway tubules.[95] On the other hand, overexpression of GATA6 using the SFTPC promoter resulted in disrupted branching morphogenesis and a lack of distal epithelial cell differentiation.[96] This suggests that a balanced GATA6 expression level is important for branching morphogenesis during the pseudoglandular period of lung development and also during later stages of lung development when alveolar type I and II cells differentiate and the gas exchange area matures. MYCN is a member of the myc family of proto-oncogenes, which includes MYCN, MYC, and MYCL, and all belong to the basic helix-loop-helix (bHLH) class of transcription factors. In the lung, MYCN is expressed in pulmonary epithelium,[97,98] and mice homozygous for the Mycn-null mutation die at midgestation.[98,99] Leaky null mutants for MYCN survive to the point when lung development starts; however, pulmonary branching morphogenesis is dramatically reduced, resulting in severe lung hypoplasia.[97,100] More recently, mice containing a lung-specific Mycn-null mutation confirmed the critical role of MYCN during lung development, because these mice have abnormal lungs showing a loss of proliferation, increased apoptosis, and a reduction in branching morphogenesis.[101] Additional experiments from this group using transgenic mice expressing MYCN under the SFTPC promoter confirmed the link between MYCN and lung growth because these mice showed increased proliferation, apoptosis, and a reduction in cellular differentiation.

Several growth factors including FGFs and TGFBs have been shown to regulate lung branching morphogenesis.[90,102] FGFs are generally produced by the pulmonary mesenchyme whereas FGFR1 and FGFR2 have been localized to embryonic and fetal lung epithelium.[103,104] Transcripts for FGF7 are detected in lung mesenchyme and are expressed at sites of active branching morphogenesis.[105,106] Exogenous FGF7 inhibits rat lung branching morphogenesis in vitro[107] but stimulates proliferation of adult type II pneumocytes in vitro[108] and in vivo.[109,110] Surprisingly, mice bearing a null mutation of the FGF7 gene had no obvious lung abnormalities,[111] suggesting that the function of FGF7 can be replaced by other factors such as FGF1 and/or FGF10. FGF1 binds to both FGFR2 splice variants, FGFR2IIIb and FGFR2IIIc, and is crucial for branching of embryonic mouse epithelium in mesenchyme-free culture.[112] FGF2, which binds to FGFR2IIIc, but not to FGFR2IIIb, did not affect epithelial branching in these cultures, suggesting that the effects of FGF1 on epithelial branching are mediated via the FGFR2IIIb receptor, which also binds FGF7.[113] As mentioned earlier, FGF10 binds to FGFR2IIIb, and both null mutants for FGFR2IIIb and FGF10 show complete lung agenesis.[16,17,24] Of interest, antisense oligonucleotides directed toward T-box genes 4 (Tbx4) or 5 (Tbx5) to attenuate their transcript levels reduced branching morphogenesis in mouse lung explant cultures.[114] Concurrent knockdown of both TBX4 and TBX5 resulted in complete loss of lung branching in culture. On closer examination it was found that FGF10 transcript levels were completely attenuated in the double knockdown lung cultures and reduced in the case of individual TBX4 or TBX5 targeting. In vitro FGF10 elicits endodermal expansion and bud formation, whereas FGF7 induces expansion of the endoderm but never progresses to bud formation.[115] This suggests that FGF7 and FGF10 signals are transduced in different physiologic responses and may explain why FGF7 cannot compensate for loss of FGF10. Another member of the FGF family, FGF9, is expressed in pulmonary mesothelium and epithelium in early development and later only in the mesothelium.[19,116] However, more recent data indicate that FGF9 is expressed at significant levels in the lung epithelium at E14.5.[117] This expression pattern is different from that of FGF1, FGF7, and FGF10, which are expressed only in the lung mesenchyme. Targeted deletion of FGF9 resulted in severe lung hypoplasia and immediate postnatal death.[116] Analysis of the lungs revealed decreased branching morphogenesis and a lack of alveoli; however, the number of lung lobes and primary bronchi were normal.[116] Recent studies using recombinant FGF9 on lung explant cultures showed potent effects on growth, differentiation, and branching morphogenesis, and furthermore FGF9 exerts its influence on both the epithelium and mesenchyme separately.[117] It also appears that the impact of FGF9 on lung development is effected through changes in expression of FGF10 and FGF7. Additional studies using an inducible system spatially regulated by the SFTPC promoter to express FGF9 during lung development also demonstrate that FGF9 has the ability to induce SHH, PTC, SPRY2, and BMP4 expression, indicating that FGF9 may be a crucial regulator of epithelial-mesenchymal signaling.[118]

TGFB belongs to a superfamily that includes activin, bone morphogenic protein (BMP), and TGFB1, 2, and 3. These peptides can exert a variety of biologic effects including regulation of cell growth, differentiation, and expression of a variety of proteins. In the lung, TGFB1 mRNA and protein are found in the mesenchyme and epithelium, respectively.[119-121] Both addition of exogenous TGFB1 to cultured embryonic mouse lung explants and in vivo overexpression of TGFB1 in distal lung epithelial cells resulted in decreased branching morphogenesis, inhibited distal epithelial cell differentiation, and inhibited formation of the pulmonary vasculature, indicating an inhibitory role for TGFB1 during branching morphogenesis.[122-126] Most, if not all, biologic activities of TGFB are transmitted via transmembrane Ser/Thr kinase receptors, known as type I and type II receptors.[127] Signal transduction requires the formation of a heteromeric complex of type I (TGFBR1) and type II (TGFBR2) receptors. Inhibition of TGFBR2 signaling stimulated lung morphogenesis in whole lung explants in culture, underlining again the negative effects of TGFB signaling on branching morphogenesis.[128] In vivo studies show that Tgfb1-null mutants per se have no gross developmental abnormalities; however, 50% of the null mutants die before E11.5 as a result of defects in yolk sac vascularization.[129,130] Tgfb3-null mutants die after birth with cleft palate and delayed pulmonary development,[131] and Tgfb2-deficient mice die after birth and display a lung phenotype with postnatal collapse of alveoli and terminal airways.[132] SMAD proteins are downstream

effecter proteins in the TGFB signaling pathway.[133] SMAD1-3 proteins are expressed in distal lung epithelium, and SMAD4 is expressed in both distal lung epithelium and mesenchyme.[134,135] Down-regulation of SMAD2/3 and SMAD4 expression increased branching morphogenesis in cultured lung explants. Exogenous TGFB1 did not reverse this inhibitory effect, which is consistent with TGFB1 being upstream of SMAD proteins.[135]

EPITHELIAL DIFFERENTIATION

As branching proceeds, numerous different cell phenotypes are formed along the proximodistal axis of the developing epithelial tubules and associated mesenchymal components, each with different morphologies and patterns of gene expression. This patterning of differentiated lung cells may also be controlled by epithelial-mesenchymal interactions.[85,87] Over the last decade some regulatory molecules involved in epithelial morphogenic patterning in the lung have been identified (Figure 81-3).

Pulmonary neuroendocrine cells (PNECs) are the first cells to differentiate in humans and animals.[136,137] MASH1 is a bHLH transcription factor implicated in neural differentiation.[138] In the lung, MASH1 is expressed in clusters or single-progenitor PNECs.[139] Mice deficient for Mash1 do not develop PNECs, indicating an essential role for this transcription factor in the differentiation of PNECs.[139] HES1 encodes a bHLH protein that is up-regulated in response to NOTCH activation and represses downstream targets such as MASH1, thereby preventing neural differentiation.[140] This finding was supported by recent work using approaches to both knockdown and up-regulate NOTCH1 expression to show effects on HES1 regulation and PNEC differentiation.[141] Indeed, Hes1-deficient embryos have increased MASH1 mRNA expression and PNECs in their lungs.[142] Whether the NOTCH signaling pathway plays a further role in distal epithelial specification remains to be elucidated. Transcription factor 21 (TCF21), formerly POD1, is another bHLH protein that acts as transcriptional regulatory protein that governs cell fate determination and differentiation in a variety of tissues. The Tcf21-null mutant dies at birth with severely hypoplastic lungs that have a reduced number of tertiary branches and a lack of acinar tubules, terminal air sacs, and alveoli.[143] Marker analysis revealed a disturbance in proximal-distal patterning of the lung epithelium with increased CCSP and decreased SFTPC expression.

Epithelial transcription factors such as FOXA2, GATA6, and TITF1 have also been shown to influence lung epithelial specification. In both fetal mouse and human lung, the spatial-temporal distribution of TITF1 follows the pattern of expression of surfactant proteins.[8,59] It has been shown that TITF1 regulates the transcription of SFTPA, B, and C[144-148] and CC10,[144,149] and consequently Titf1-null mutants lack distal epithelial cell differentiation, whereas the proximal epithelial cell marker FOXJ1 was unaffected.[150] Taken together, these data underline the importance of TITF1 for the establishment of the distal epithelial cell phenotype. Also, GATA6 transactivates SFTPA and TITF1,[151,152] and it has recently been shown that GATA6 acts synergistically with TITF1 to influence the activity of the SFTPC promoter.[153] A role for GATA6 in bronchial epithelial specification has been suggested by the observation that Gata6$^{-/-}$ embryonic stem cells fail to contribute to bronchial epithelial cells.[94] In some respiratory epithelial cells, TITF1 is coexpressed with members of the FOX family of transcription factors. Transcripts for FOXA1 and FOXA2 are detected in foregut cells forming the embryonic lung bud and later in the distal epithelium of the developing and mature lung.[8,154] Like TITF1, FOXA1 and FOXA2 appear to modulate the expression of SFTPB and CCSP.[144,154,155] FOXA1 and FOXA2 have been proposed to be upstream regulators of TITF1,[156] and it is possible that both members of the FOX family confer

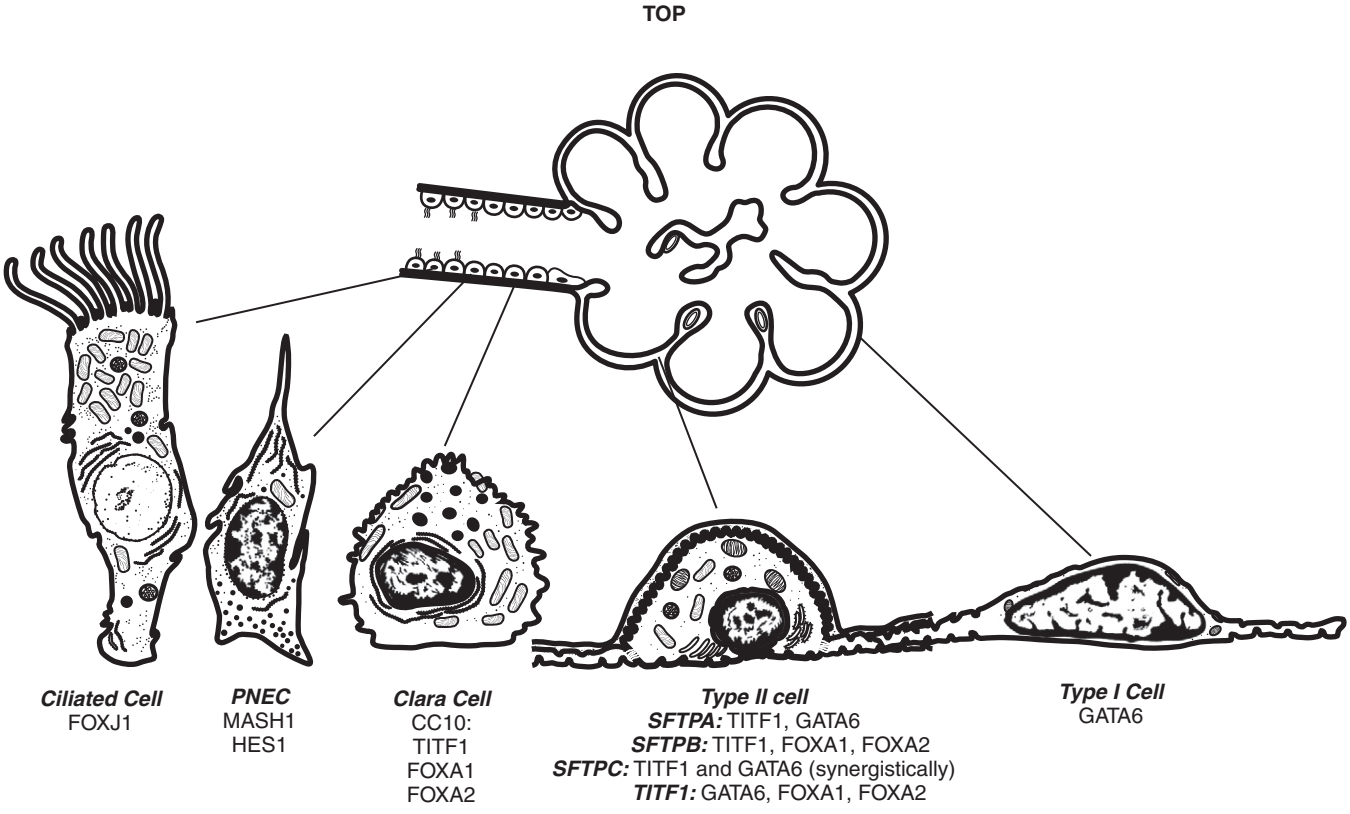

Figure 81-3 Molecular control of epithelial cell differentiation during lung development (drawings represent a human lung, which in the normal situation consist of two lobes on the left and three lobes on the right side).

lung-specific gene expression in the primitive foregut through TITF1 as the intermediate. FOXJ1 is a transcription factor of the winged helix–forkhead family, expressed in various tissues during development. In the developing and adult lung, FOXJ1 expression is restricted to ciliated cells of the bronchial and bronchiolar epithelium.[150,157] The role of FOXJ1 in ciliated cell differentiation was clearly demonstrated when FOXJ1 was overexpressed in distal pulmonary epithelial cells. High levels of FOXJ1 expression inhibited branching morphogenesis and development of distal epithelial cells; however, it enhanced the development of ciliated cells.[158] In contrast, Foxj1-null mutant mice completely lack respiratory ciliated cells.[71,159] These data indicate that FOXJ1 is essential for the development of pulmonary ciliated cells.

The secreted morphogen SHH does not appear to be involved in regulating proximodistal epithelial specification because SFTPC and CCSP are expressed in Shh-deficient mice.[30] In *Drosophila*, HH may regulate the expression of Decapentaplegic (DPP), the *Drosophila* counterpart of bone morphogenetic proteins (BMP).[27] In the murine lung, BMP4 is implicated in lung epithelial specification. BMP4 is expressed in early distal lung tips and at lower levels in the mesenchyme adjacent to the distal lung buds.[160,161] Overexpression of BMP4 in the distal epithelium in vivo resulted in hypoplastic lungs with grossly dilated terminal lung buds separated by abundant mesenchyme.[160] Distal epithelial differentiation was abnormal with decreased SFTPC expression, whereas proximal differentiation (CCSP expression) was normal.[160] In vitro, exogenous BMP4 clearly enhanced peripheral lung epithelial branching morphogenesis and SFTPC expression.[162] The secreted BMP antagonist Xnoggin is expressed in distal mouse lung mesenchyme early on in development.[161] Overexpression of Xnoggin or the dominant negative BMP receptor dnAlk6 in distal pulmonary epithelium resulted in a proximal pulmonary epithelial phenotype.[161] Similar results were obtained when Gremlin, another BMP antagonist, was overexpressed in the distal lung epithelium.[163] These studies clearly indicate a role for BMP4 in proximodistal epithelial differentiation during lung development and as a result probably argue against SHH regulating BMP4 expression.

ALVEOLAR DEVELOPMENT

Alveolarization is the last step of lung development that induces physical changes to the internal surface area of the lung. Alveoli are formed by septation of the pulmonary saccules that form the immature lung. In both humans and mice, alveolarization occurs predominately after birth. One of the key players in the alveolarization process (see Figure 81-1) appears to be one of the three isoforms of the platelet-derived growth factors (PDGF), namely PDGF-A.[164] PDGF-A is normally expressed in early pulmonary epithelium and becomes undetectable at later gestations.[165] Its receptor (PDGFR-α) is expressed in the mesenchyme adjacent to the epithelium that expresses PDGF-A, signifying a paracrine signaling mechanism between the epithelium and the mesenchyme.[165-167] In mice, absence of PDGF-A results in prenatal and postnatal death. Postnatal deaths were characterized by emphysematous lungs with areas of atelectasis, without any formation of septa and/or alveoli, instead, dilated prealveolar saccules were found.[166,167] In normal mice, alveolar septa contain smooth muscle cell alpha actin (α-SMA)–positive myofibroblasts. The postnatal Pdgf-A–null mutant lungs lack alveolar staining for α-SMA, indicating a lack of alveolar myofibroblasts. In addition, they were almost completely devoid of parenchymal elastin fibers, which most likely contributed to the failure of alveolar formation.[166,167] Of interest, myofibroblasts surrounding vessels and bronchioles appeared normal and were tropoelastin positive, suggesting a different developmental lineage.[167] Moreover, PDGFR-α–positive cells were specifically missing from lungs of PDGF-A–null mutants, and it has been proposed that these cells are progenitor cells for alveolar myofibroblasts.[166,167] With these data taken together, PDGF-A is important for the formation of alveolar myofibroblasts that produce elastin, which in turn is important for alveolar formation. Pdgfr-α–deficient mice die in utero with severe skeletal malformations and incomplete cephalic closure. Pdgfr-α–deficient lungs were hypoplastic; however, primary branching and histology were not affected.[168,169] Obviously, postnatal alveolar formation could not be examined in these mice.

Both FGFR3 and FGFR4 are expressed in postnatal pulmonary mesenchyme, whereas their ligands are expressed in pulmonary epithelial cells.[170] Although a null mutation of either FGFR3 or FGFR4 caused no obvious lung defects, concurrent silencing of both receptors resulted in severe overall body growth retardation and a failure of postnatal alveolar formation. Despite the large dilated saccules without any proper alveolar septation, differentiation (including α-SMA–positive myofibroblasts) and proliferation proceeded normally.[170] A recent study examining postnatal alveolar formation in the rat has found a new connection with FGF signaling in postnatal lung development.[171] When signaling of FGF2 (most likely through FGFR1IIIc) was blocked, it inhibited normal postnatal lung development. Histologically these lungs presented with a reduction in secondary septation and a decrease in apoptosis, resulting in increased tissue to air ratio. Besides its role in prenatal lung development, TITF1 also regulates postnatal lung development and homeostasis. After birth, TITF1 expression decreases dramatically; however, expression remains detectable in adult alveolar type II cells. Overexpression of TITF1 in distal lung epithelial cells, using the SFTPC promoter, does not affect prenatal lung development but perturbs postnatal alveolarization, leading to emphysema, severe inflammation, and fibrosis.[172] RA has been shown to increase the number of alveoli in postnatal rats and even abrogates the decreased alveolarization seen after the experimental use of dexamethasone or elastase that decreases alveolar formation. This indicates that RA is a potential controlling factor in "neoalveogenesis" in prematurity or after lung injury.[173-176] Similarly, compound mice homozygous for RARG and heterozygous for RXRA deletion have a reduced number of alveoli and less elastic fiber in their alveolar walls.[177] RARB on the other hand appears to be an endogenous inhibitor of septation, and as a result the Rarb-null mutant shows early onset septation resulting in twice as many alveoli in the null mutant lungs when compared with wild-type lungs.[178] Hepatocyte growth factor (HGF) is a heparin-binding glycoprotein with mitogenic and morphogenic effects on a variety of tissues. Recently it was shown that HGF-neutralizing antibodies injected intraperitoneally into rat pups caused a reduction in the number of alveoli.[179] This was also true when a truncated soluble form of the hepatocyte growth factor receptor (MET) was injected intraperitoneally. These two results combined clearly indicate an important and previously unknown role for HGF signaling in the lung during postnatal alveolarization.

VASCULAR DEVELOPMENT

The lung is composed of a complex network of airways and vessels, and, although a great deal has been discovered regarding the mechanisms controlling lung bud formation and airway branching, the elements guiding vascular formation remain obscure. The lung is unique among most other organs in that it possesses a dual vascular system: the pulmonary system that transports the blood to be oxygenated from and back to the heart and the bronchial system that provides oxygenated blood to the nonrespiratory parts of the lung. Three processes are thought to control pulmonary vascular development: angiogenesis, which is defined as sprouting of new vessels from preexisting ones and gives rise to the central vessels; vasculogenesis, which is de novo synthesis of blood vessels from blood lakes in the periphery of the lung; and the fusion of proximal and peripheral vessels to form the

pulmonary circulation.[180] More recently it was shown that even in the early stages of lung development vascular connections are well established and that pulmonary vascular formation occurs at all developmental stages, with completion of a single capillary network during the period of microvascular maturation.[3,181] A third mechanism of pulmonary vascular formation that relies heavily on vascular remodeling has been proposed and contradicts the other two. This theory uses a distal angiogenesis-driven model in which the vasculature is formed very early on in lung development and surrounds the epithelial bud tips as they grow out into the splanchnic mesenchyme.[182] As the epithelial buds branch and rebranch growing outward, the developing vasculature rapidly expands and remodels with the bud tips. These epithelial-endothelial interactions between the capillary plexus and the epithelial bud tip coordinate growth between the developing airways and vasculature.

Members of the vascular endothelial growth factor (VEGF),[183,184] the angiopoietin,[185,186] and the ephrin families[187] have all been implicated in controlling vascularization of the pulmonary system. VEGF is a potent mitogen for endothelial cells, influencing angiogenesis and vasculogenesis.[188] It is essential for embryonic development, and even haploinsufficiency of VEGF results in embryonic lethality.[189,190] In both the embryonic and adult lung, VEGF mRNA is detected in the lung epithelium[191-193] and signals via two high-affinity receptors: FLT1 and KDR (formerly FLK), which in the embryonic lung are localized to the mesenchyme.[191,192] The complementary expression patterns of VEGF in lung epithelium and the two VEGF receptors in the mesenchyme suggest an epithelial-mesenchymal signaling mechanism and possible influence on lung development and branching morphogenesis.[194] Overexpression of the VEGF 164 isoform in distal airway epithelium results in perinatal death.[195] The lungs appear abnormal, with dilated respiratory tubules and saccules and have a decreased number of terminal buds. KDR expression in the mesenchyme was increased, indicative of a regulatory role of VEGF between pulmonary epithelium and mesenchyme. Mice that lack the VEGF isoforms 164 and 188 and express only the 120 isoform have decreased peripheral vascular development with fewer air-blood barriers and a general delay in lung development.[196] Another factor implicated in pulmonary vascular development is FOXF1. Foxf1-null mutant mice die in utero because of defects in mesodermal differentiation and cell adhesion.[197] In the lung, FOXF1 is expressed in smooth muscle cells surrounding bronchioles and alveolar endothelial cells.[198,199] Heterozygous mutant mice carrying a disruption of the Foxf1 gene, in which FOXF1 levels are reduced by 80%, displayed a 55% postnatal mortality with lung hemorrhaging. Analysis of the lungs revealed abnormalities in alveolar formation and pulmonary vasculature.[198] FOXA2 has also been demonstrated to have effects on vascular development of the lung. Experiments using the SFTPC promoter to express FOXA2 in the distal lung epithelium showed disrupted airway branching, vasculogenesis, and arrested differentiation of epithelial cells.[200] However, this finding was complicated by a more recent study using mice containing a conditional knockout for FOXA2, which showed defects only in alveolarization and differentiation.[201]

From these studies one can reason that a disruption in pulmonary vascular development goes hand in hand with impaired branching morphogenesis and lung hypoplasia. Indeed, some recent evidence suggests that development of the vascular system exerts a strong influence over lung morphogenesis. Blocking VEGF signaling by using a pharmacologic inhibitor has been shown to impair not only vascular growth but alveolarization as well.[202] This was confirmed in other experiments using antisense oligonucleotides targeted toward VEGF that caused a reduction in both airway branching and vascular development.[203] In vivo delivery of VEGF using intratracheal administration of an adenovirus carrying the VEGF expression construct not only results in increased vessel formation but restores alveolar growth in an experimental rat model of BPD.[204] Finally, both loss and gain of function experiments were used in mouse lung cultures to confirm the effect of VEGF on both the lung epithelium and endothelium, in terms of proliferation, differentiation, and branching morphogenesis.[205] However, the question still remains whether the airway branching phenotype is the direct result of physical disruption of blood vessel formation or whether it is the molecular signaling factors of vascular development alone affecting airway branching morphogenesis.

SUMMARY

Molecular studies of lung development have started to unravel the complex series of events that control proper formation of the lung. Observations such as no lung formation are interesting for understanding organogenesis of the lung per se, but the clinical relevance is minimal because having no lung is incompatible with life. However, the finding that factors implicated in foregut specification are also regulating lung morphogenesis is tremendously intriguing for clinical practice (see Figure 81-1). One of the major complications with preterm birth is immaturity of the lung. Despite modern management, many infants exhibit lung dysfunction characterized by arrested lung development and interrupted alveolarization. A better understanding of the molecular basis of pulmonary development may guide clinicians in the design of strategies to mimic normal lung maturation in a premature infant.

82 Regulation of Liquid Secretion and Absorption by the Fetal and Neonatal Lung

David P. Carlton

The fetal lung is filled with liquid secreted by the developing lung epithelia. The rate and volume of liquid secreted into the fetal lung are calibrated to maintain lung volume at approximately functional residual capacity and are major determinants of normal lung growth. At birth, effective transition from placental to pulmonary gas exchange requires removal of liquid from the lung. The process of emptying the lung begins before birth, is augmented by labor, and is mostly complete after 2 hours of independent breathing. Liquid is removed from the lung lumen by a combination of mechanical drainage and liquid absorption across the lung epithelium (Figure 82-1). The liquid absorption mechanism is switched on by the perinatal epinephrine surge associated with labor and delivery. This epinephrine responsiveness is absent in the immature fetal lung and is induced in the last half of gestation by the rise in active thyroid and steroid hormones in the fetal circulation. The increase in oxygen tension (Po_2) associated with the onset of air breathing at birth consolidates the switch to liquid absorption. Because the absorptive mechanism of the fetal lung develops in the latter part of gestation, infants who are born prematurely may have a restricted ability to clear fluid from their lungs.

DYNAMICS OF LUNG LIQUID FLOW BEFORE AND AFTER BIRTH

Lung Liquid Formation and Flow During Fetal Life

Because it is intuitive that the fetal lung lumen must be filled with liquid rather than air, early debate about the fetal lung revolved around the origins of this liquid. The preferred early hypothesis was that liquid was aspirated by fetal breathing movements into the lung from the amniotic cavity.[1] However, the proposed amniotic origin of lung liquid was disproved in the 1940s by Jost and Policard,[2] who observed progressive lung distention in fetal rabbits whose tracheas had been ligated. Further evidence of local production of fetal lung liquid came from the observation in fetal sheep that the ionic composition of fetal lung liquid differed from that of amniotic fluid—sodium (Na^+) and chloride (Cl^-) concentrations are lower in amniotic fluid, and potassium (K^+) is higher.[3,4] In addition, the observation that the Cl^- concentration of fetal lung liquid was higher that that of plasma or interstitial fluid was the strongest early evidence that lung liquid may be actively secreted by the pulmonary epithelium.[4]

Liquid Secretion

The source of lung liquid was subsequently shown to derive from an active secretory process by the epithelium lining the developing lung.[5] The rate of liquid secretion was measured in fetal guinea pig, goat, and sheep by collection of diverted tracheal fluid, by tracheal flowmeter, and by the indicator dilution method.[5-10] There is an apparent increase in the secretion rate in fetal sheep from approximately 1.5 mL/kg/hour at midgestation to approximately 5 mL/kg/hour in late gestation.[11,12] The secreted liquid is then passively expelled into the trachea and into the oropharynx, where it is either swallowed or expelled into the amniotic cavity. The volume of liquid in the fetal lung lumen is regulated by the distending pressure of approximately 2 mm Hg (relative to amniotic fluid) generated by liquid secretion and resistance to liquid efflux through the fetal larynx.[13-15] The volume of liquid in the fetal lung increases with growth of the fetus and with the increasing alveolarization of the lung during gestation. In the latter part of gestation, the developing fetal sheep lung is distended to a volume (approximately 30 mL/kg) that approximates functional residual capacity of a term newborn infant.[16] The volume to which the fetal lung is distended is apparently crucial for normal lung development. Experimental continuous intrauterine drainage of liquid from fetal sheep lungs resulted in lung hypoplasia, whereas overdistention of the fetal lung by tracheal ligation resulted in hyperplasia.[17-19]

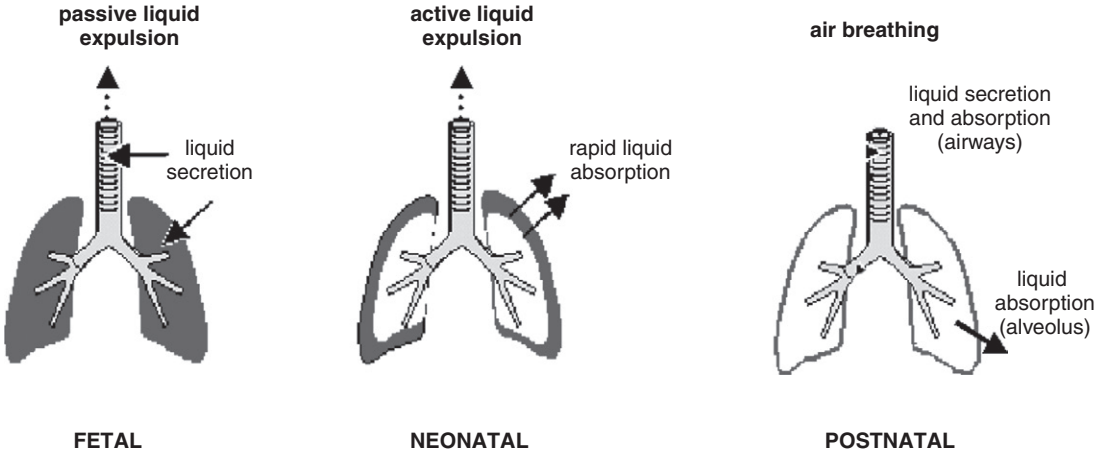

Figure 82-1 Fetal, neonatal, and postnatal phases of liquid flow across lung epithelia.

Fetal Breathing Movements

Fetal breathing movements initiated by diaphragmatic contractions result in small oscillations of liquid flow (~0.5 mL) in the conducting airways.[20-22] Disruption of fetal breathing by phrenic nerve section or cervical cord lesions results in lung hypoplasia through mechanisms that most likely are related to decreased fetal lung volume.[23-25] Although it is likely that these breathing movements are important for normal lung growth, they do not influence the rate of liquid secretion or the net movement of lung liquid out of the lung.

Airway Wall Contractions

Peristaltic contractions of the developing airways cause changes in local lung liquid flow and pressure that may also be important in lung development. Striking contractions of embryonic airways were first observed in chick embryos in the 1920s.[26] Studies on various animal models demonstrate that these contractions cause peristalsis of the airway similar to that seen in the gut.These peristaltic waves propagate distal movement of intraluminal liquid and cause expansion of the endbuds.[27] Smooth muscle contractions were inhibited by the calcium (Ca^{2+}) channel blocker nifedipine.[28] However, it is not clear whether the observed lung hypoplasia after nifedipine administration was the result of inhibition of peristalsis or whether liquid secretion was influenced by this intervention.

Surgical Intervention

Given that ligation of fetal airways promotes lung growth distal to that point, surgical obstruction of the fetal airway has evolved as a technique for prevention or correction of potential lung hypoplasia, particularly with lung anomalies associated with congenital diaphragmatic hernia. However, early enthusiasm for fetal surgery has been tempered by poor results.[29] The traditional hypothesis that lung hypoplasia results from compression by herniating abdominal viscera has been challenged because pulmonary anomalies have been observed before herniation of abdominal contents into the chest.[30,31] The role of ion transport in the pathogenesis lung hypoplasia is not known.

Perinatal Changes in Lung Liquid Flow

At the time of birth, the newborn infant switches from placental to pulmonary gas exchange.This requires an abrupt replacement of the liquid in the lung lumen with air.Within a few hours, approximately 100 mL of fetal lung liquid contained in the human lung lumen must be cleared.This is achieved by the initiation of complex series of mechanical and ion transport events.

Decrease in Lung Liquid Volume Before Labor

Some investigators, working mainly with fetal rabbits and sheep, observed a decrease in both lung liquid volume and secretion rates toward the end of gestation.[6,8,12,32] It is likely that mechanical forces (for example, active fetal exhalation) may participate in some of the expulsion of liquid in the hours leading up to the onset of labor.[33]

Role of Labor

The finding that delivery by cesarean section (CS) slowed lung liquid clearance, particularly when the procedure was undertaken before the onset of labor, indicated that labor was in some way important to the removal of lung liquid.[34,35] Rabbits that were born at term, either vaginally or by CS after the onset of labor, had less water in their lungs than did rabbits that were delivered operatively without prior labor (Figure 82-2). This observation contrasted with the previously held notion that any significant amount of lung liquid is squeezed out of the lungs by thoracic compression during vaginal delivery. These data provided evidence that labor induces other (nonmechanical) mechanisms that must be responsible for lung liquid clearance before birth.

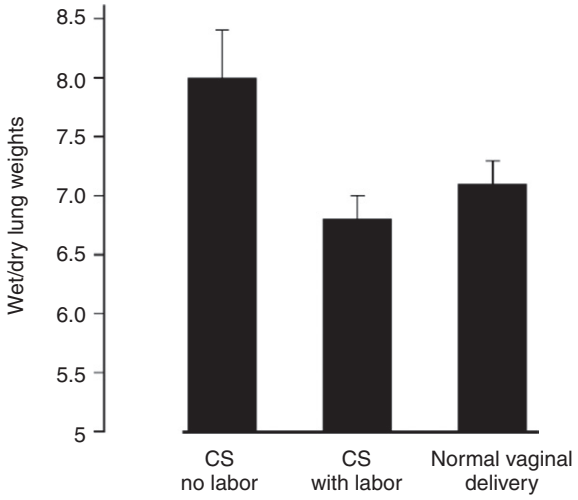

Figure 82-2 Effect of labor on lung water content (wet/dry weight) of newborn rabbit pups born after normal vaginal delivery or by cesarean section *(CS)*. *(From Bland RD, Bressack MA, McMillan DD: Labor decreases the lung water content of newborn rabbits,* Am J Obstet Gynecol *135(3):364–37, 1979.)*

Fate of Lung Liquid During Labor and Delivery

Once labor is initiated, there is rapid removal of liquid from the lung caused by a reversal of the direction of liquid flow across the pulmonary epithelium.[12] The secretory process that dominates fetal life is abruptly switched to allow absorption of liquid from the lung lumen into the fetal circulation.[12] It is now clear that active transcellular Na^+ absorption drives liquid out of the lumen into the interstitial space (see farther on).[36] Most interstitial liquid moves into the fetal-newborn pulmonary circulation and some drains via the lung lymphatics.[37] Starling forces that may assist liquid absorption (for example, osmotic pressure and hydrostatic gradients between the lung interstitium and the lung lumen) do not change during labor, and they are not thought to play a role in removal of fetal lung liquid before birth.

Liquid Movement After Birth

After birth, there is an acceleration of active liquid absorption, and most of the liquid is cleared from the term newborn lung within 2 hours of independent breathing.[12,38] Egan and coworkers[39] noted a transient increase in solute permeability of the alveolar epithelium at the onset of breathing and speculated that this "window" of decreased paracellular resistance may assist with passive liquid absorption at birth.

BASIC MECHANISMS OF TRANSEPITHELIAL ION TRANSPORT

The ion transport mechanisms located in the pulmonary epithelium drive the secretion and absorption of liquid into and out of the lumen of the fetal and newborn lung. Advances in understanding of perinatal lung liquid flow have derived from better characterization of the function, regulation, and molecular identity of these channels and transporters.

Boston, Humphreys, Olver, Strang, and their associates[40,41] launched a series of studies in the 1960s and 1970s that described the flow of liquid from the pulmonary circulation to the lung lumen; characterized the barrier properties of the epithelium and endothelium; and provided the first evidence of secondary active Cl^- transport as the mechanism for lung liquid secretion by the

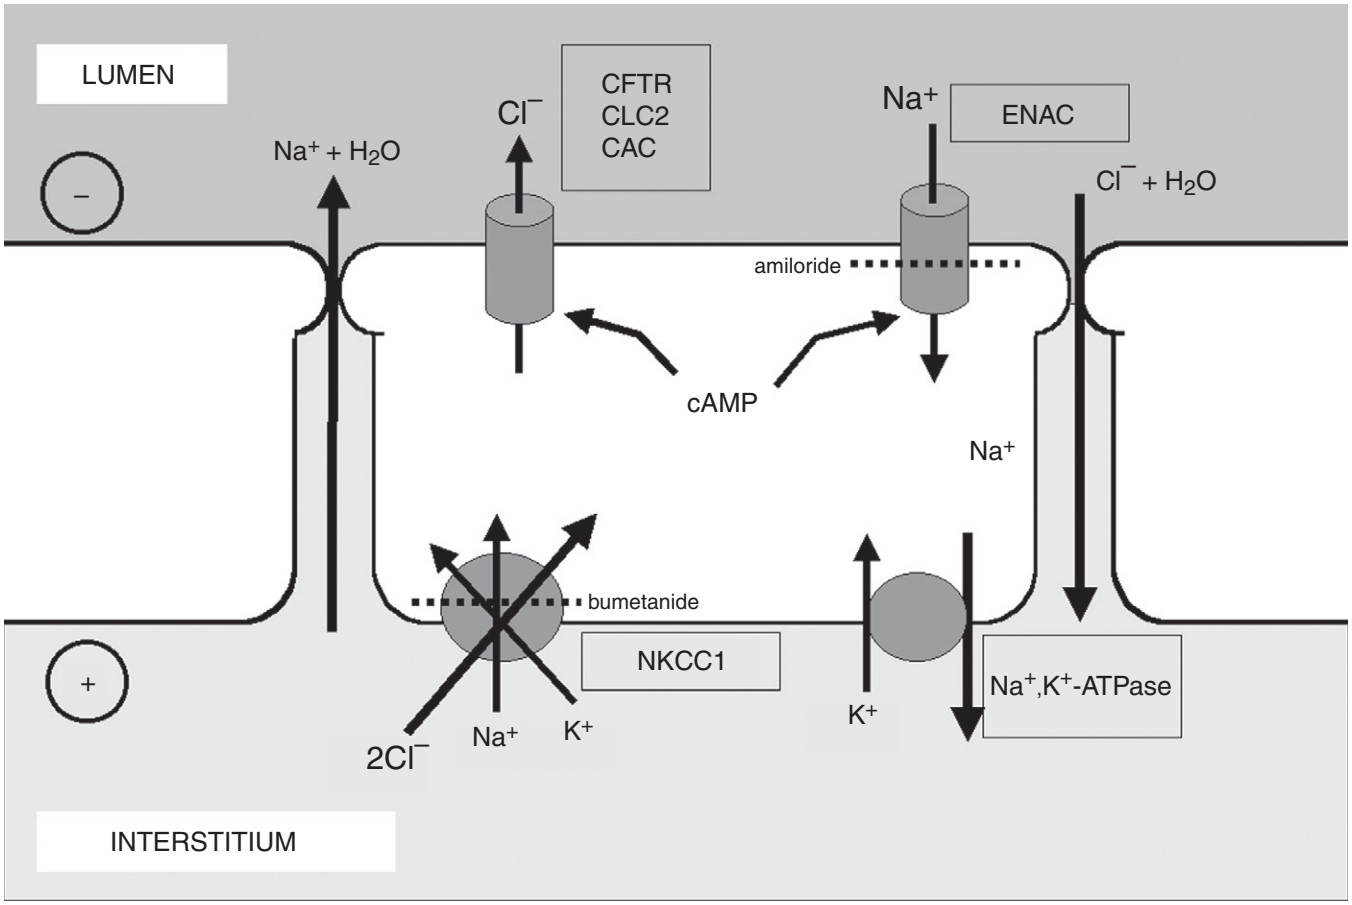

Figure 82-3 Arrangement of ion transporters and pumps in the lung epithelia of fetal lung. Amiloride is a specific inhibitor of the epithelial sodium (Na^+) channel *(ENAC),* and bumetanide blocks Na^+, potassium (K^+), chloride (Cl^-) cotransporter 1 *(NKCC1)*.The "plus" and "minus" signs indicate polarity of the lumen with respect to the interstitium. *CAC*, Calcium-activated channel; *cAMP*, cyclic adenosine monophosphate; *CFTR*, cystic fibrosis transmembrane conductance regulator; *CLC2*, voltage-gated Cl^- channel 2.

fetal lung.[5,11,42]These studies showed that the alveolar epithelium was highly restrictive to macromolecules compared to the endothelium. This barrier property accounts for the virtual absence of protein in the fetal lung lumen, in contrast to the interstitium and circulation. Despite this oncotic gradient across the alveolar epithelium, lung liquid is secreted actively by transcellular Cl^- transport. Researchers from the same laboratory were the first to show that clearance of lung liquid at birth was also driven by an active ion transport process, namely, Na^+ absorption.[36]

The basic configuration of ion transporters and channels follows a pattern that is similar to that found in other mammalian ion-transporting epithelia.The electrochemical gradient for entry and exit of ions to and from the lung epithelial cells is established by Na^+,K^+-adenosine triphosphatase (ATPase) at the basolateral membrane. Activity of this transporter results in the low intracellular [Na^+] that creates a gradient for Na^+ to enter the cell through either the basolateral membrane (entraining Cl^- as part of the secretory process) or through apical membrane (first step in the absorptive process).The main identified transporters and channels that result in liquid secretion and absorption are shown in Figure 82-3.

The molecular identities of the main transporters and pumps located on the interstitial facing membrane (Na^+ pump, Na^+,K^+-ATPase, and Na^+,K^+,2Cl^- cotransporter [NKCC1]) are known (see Figure 82-3). Likewise, the principal Na^+ channel on the luminal membrane (epithelial Na^+ channel [ENaC]) has been cloned.[43] However, the identity of the principal mechanism responsible for fetal Cl^- secretion across the lumen membrane is not known. Candidates for Cl^- channels include the cystic fibrosis transmembrane conductance regulator (CFTR, cloned in 1989) and the voltage-gated Cl^- channels 2 and 3 (CLC2, CLC3, cloned in 1995), all of which are expressed in the fetal lung.[44-47] There is strong functional evidence for a purinoceptor-Ca^{2+}–activated Cl^- channel in fetal lung epithelia, but this channel has yet to be cloned.[48,49]

Chloride Secretion

The "uphill" movement of Cl^- from the interstitium to the lung lumen was shown by Olver and Strang[5] to be the driving force for fetal lung liquid secretion. Since then, the identity of the entry and exit steps for Cl^- transit across the lung epithelium have been sought. From studies of other Cl^--secreting mammalian epithelia, NaK2Cl (NKCC) cotransporter family members were likely candidates for the Cl^- entry mechanism through the basolateral membrane. On the apical membrane, it is assumed that Cl^- channels, exchangers, or cotransporters must be responsible for exit of Cl^- into the lumen.

Sodium, Potassium, Chloride Cotransporter

In fetal sheep and guinea pig lung, addition of the loop diuretic bumetanide or furosemide (specific NKCC inhibitors) to fetal lung liquid caused slowing of lung liquid secretion or liquid absorption.[50,51] Loop diuretics also inhibited liquid secretion in vitro by distal lung explants from fetal rat lung, and they decreased basal short-circuit current by excised fetal canine or rabbit trachea.[52-55] Of the two NKCC isoforms that have been described,

mRNA of NKCC1 but not NKCC2 is abundantly expressed in epithelia from all regions of the late-gestation fetal mouse lung.[56] Postnatally, there is a significant decrease in NKCC1 expression by mouse tracheal epithelia.[57] The likely existence of non-NKCC Cl^- entry mechanisms is suggested by the minimal inhibition by bumetanide of basal and cyclic adenosine monophosphate (cAMP)–induced Cl^- secretion across fetal human and mouse distal lung epithelium and apparently normal survival and lung health in NKCC-knockout ($NKCC^{-/-}$) mice.[48,56-59] Studies of fetal $NKCC1^{-/-}$ did show that maximal (cAMP-mediated) but not basal Cl^- secretion was compromised by NKCC1 deletion. Studies of postnatal $NKCC1^{-/-}$ mice showed that NKCC1-mediated Cl^- secretion by airway epithelium wanes after birth, matching the apparent decrease in NKCC mRNA expression in postnatal airways.[57] The molecular expression of other potential Cl^- entry mechanisms (for example, Cl^--bicarbonate exchanger) in fetal lung epithelia have not been reported.

Cystic Fibrosis Transmembrane Conductance Regulator

Studies of postnatal cystic fibrosis (CF) epithelia indicate that CFTR provides a critical apical membrane conduit for Cl^- secretion and is an important regulator of Na^+ transport in lung epithelia after birth.[60,61] However, non-CFTR mechanisms must exist for liquid secretion by fetal lung epithelia because the lungs of fetuses with CF are normally developed and explants of CF-affected human fetal lung are inflated with secreted liquid.[62,63]

A role for CFTR in fetal lung liquid secretion is suggested by intense expression of CFTR mRNA in all regions of first trimester human fetal lung, with less intense expression in the alveolar and large airway epithelia during the second and third trimesters.[64] In the postnatal lung, CFTR mRNA signal is localized to small airways and submucosal gland epithelium and is not detected in the alveolar epithelium.[65]

Lungs from $CFTR^{-/-}$ mouse fetuses are normally inflated with liquid, and airway explants from these fetuses have basal and cAMP-stimulated anion secretion that is indistinguishable from wild-type littermate controls.[66] There is also evidence of liquid secretion by lung epithelia of human fetuses with CF. However, exposure to cAMP causes no change in liquid volume in CF fetal lung explants, whereas additional liquid secretion was induced by cAMP in normal fetal lung tissue.[63] These studies suggest that CFTR has some role in, but is not required for, basal fetal lung liquid secretion.

Other Fetal Chloride Channels

The identity of non-CFTR anion secretory paths in fetal lung epithelia remains elusive. Purinoceptor-activated Cl^- secretion has been observed in $CFTR^{-/-}$ fetal mouse lung and in wild-type fetal rat and fetal human lung epithelia.[48,49,66] The molecular identity of the purinoceptor-activated Cl^- channel is not known. The developmental expression pattern of CLC2 and CLC3 indicates a possible role for these channels in fetal lung liquid secretion.[47] However, the absence of either functional studies in fetal lung tissues or a knockout model deficient in either CLC2 or CLC3 makes the significance of these channels difficult to determine at present.

Role of Sodium Absorption in Perinatal Lung Liquid Clearance

The observation that spontaneous or epinephrine-induced absorption of fetal lung liquid was associated with a large increase in net Na^+ transport out of the lumen and could be blocked by amiloride, a specific Na^+ channel blocker (Figure 82-4), provided the first conclusive evidence that perinatal liquid absorption is mediated through Na^+ transport.[36] Some Na^+ and cation channels have been identified by electrophysiologic means (patch clamp or Ussing chamber studies) on the apical membrane of fetal distal lung epithelial (FDLE) cells isolated from rodents.[67] However, the observation that all activated and spontaneous liquid absorption could be inhibited by mixing the Na^+ channel blocker amiloride into fetal lung liquid demonstrated a critical role for amiloride-sensitive Na^+ transport in perinatal lung liquid clearance. This finding was strengthened by the observation that amiloride instilled into the trachea of the newborn guinea pig impaired lung water clearance in a dose-dependent manner, and it was later confirmed by ENaC-knockout murine studies (see later).[68,69] The roles of the high-energy Na^+,K^+-ATPase pump on the basolateral membrane and ENaC on the apical membrane have been extensively studied since the molecular identity of these genes became known.[43,70]

Na^+,K^+-Adenosine Triphosphatase

Evidence that labor was also crucial for activation of the lung epithelial Na^+,K^+-ATPase pump came from measurements of the ouabain-sensitive uptake of rubidium-86 ($^{86}Rb^+$, a surrogate for K^+ uptake) in alveolar type II cells freshly isolated from newborn rabbit pups. These studies demonstrated that labor was associated with a threefold to fourfold increase in pump activity in fetal alveolar type II cells.[71,72] In rat and mouse whole lung, expression of $\alpha 1$ and $\beta 1$ subunits increases from low levels in early fetal life to a peak around the time of birth.[73,74] Fetal $\alpha 1$ subunit mRNA is expressed in both epithelium and endothelium, whereas $\beta 1$ subunit expression is localized to epithelium only. By the end of the first week of life, epithelial expression of $\alpha 1$ and $\beta 1$ subunit mRNA is localized to small airways and the basolateral surface of alveolar type II but not type I cells.[74,75]

Epithelial Sodium Channel

ENaC subunit mRNA expression has been studied extensively in developing human and rodent lung epithelia. In both rat and mouse whole lung, an abrupt increase in αENaC mRNA expression in late gestation reaches levels seen in the adult lung shortly after birth.[76,77] In mouse lung, there is a similar increase in expression of γENaC and a more gradual increase in βENaC that peaks in adult lung (Figure 82-5). Expression of γENaC parallels that of αENaC, with intense expression of subunit mRNA in all regions of the fetal lung, whereas βENaC expression in fetal and early postnatal lung is restricted to the airway epithelium.[76] Studies in guinea pig showed that both αENaC mRNA expression and the sensitivity of lung liquid clearance to amiloride and to β-adrenoceptor blockade were highest shortly after birth, and they declined in parallel with endogenous plasma epinephrine concentration, findings providing further support for the key role of β-adrenoceptor activation of Na^+ channels at birth. Immunocytochemical studies of human fetal lung surprisingly showed significant αENaC protein expression in early midtrimester fetal lung, at a time when the fetal lung is not thought to be capable of significant Na^+ transport.[78,79] Whereas the function or location of this protein within the cell is not known, it is possible that there is a discrepancy between developmental ENaC expression in human and rodent lung.

Other Sodium Channels

Other putative amiloride-sensitive Na^+-permeable channels in fetal lung have been described that may contribute to the driving force for lung liquid clearance. These include certain amiloride-sensitive, poorly nonselective cation channels: G-protein–regulated, β-adrenoceptor agonist/Ca^{2+}–activated, and cyclic nucleotide-gated channels.[80-82] According to at least one school of thought, the β-adrenoceptor responsive, nonselective channel may be a multimer of αENaC subunits, and the role of β and γ subunits may be to confer selectivity on the channel.[83] An additional pathway for Na^+ absorption is Na^+–glucose cotransport, which has been reported in fetal sheep lung epithelia.[84]

Knockout Models of Sodium Transport

Certain knockout and other transgenic mouse models were used to explore the role of ion transport in the perinatal regulation of lung liquid flow. Knockout mice for all three ENaC subunits

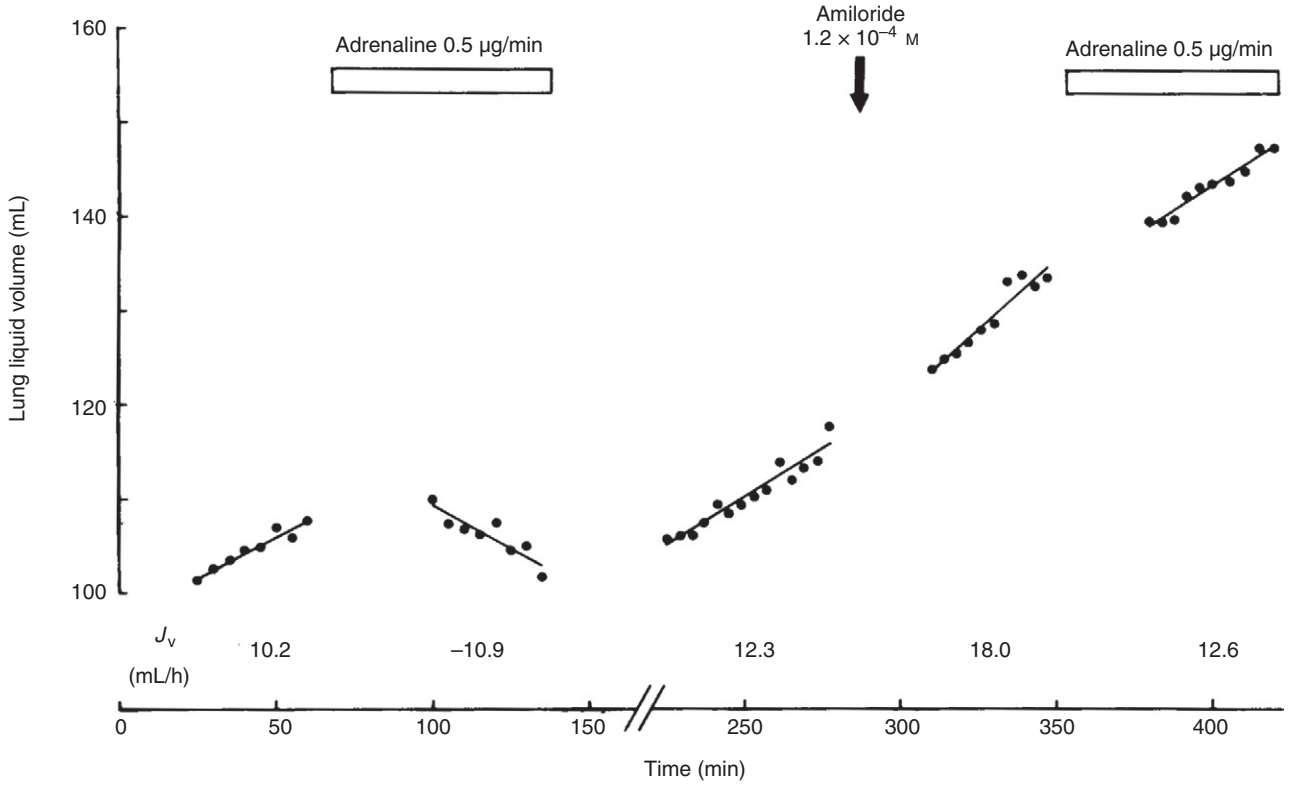

Figure 82-4 Effect of epinephrine (adrenaline) infusion and topical amiloride on cumulative lung volume across the lung epithelium of a near-term fetal sheep. At the start of the study, volume increases because of liquid secretion (J_v 10.2 mL/hour). Epinephrine infusion abruptly causes a decrease in lung volume, reversing the direction of flow (J_v −10.9 mL/hour) from secretion to absorption. Secretion is restored when the epinephrine infusion is discontinued. Addition of the sodium channel blocker amiloride to lung liquid prevents liquid absorption when the epinephrine infusion is restarted. *(From Olver RE, Ramsden CA, Strang LB, Walters DV: The role of amiloride-blockable sodium transport in adrenaline-induced lung liquid reabsorption in the fetal lamb,* J Physiol *376:321–340, 1986.)*

were reported, and additional ENaC mutants were studied.[69,85-88] The most striking finding was that mutant newborns lacking the αENaC gene were unable to clear lung liquid from the alveolar spaces after birth (Figure 82-6). These mice were readily identifiable compared with their unaffected littermates by increased work of breathing, failure to feed, and failure to move around. Mice with γENaC or βENaC null mutations had delayed liquid clearance, but they had near normal lung water content 12 hours after birth. All subunit mutations resulted in severe hyperkalemia, which was the most likely cause of death in the early neonatal period. αENaC null mice that were "rescued" with an αENaC transgene were able to clear lung liquid in the newborn period at near-normal rates with approximately 50% Na^+ channel activity.[88] These studies indicate that ENaC function is a critical requirement for clearance of neonatal lung liquid in the newborn period and suggest that the αENaC subunit is the core, rate-limiting part of the Na^+ channel in lung epithelia. Evidently, neonatal and postnatal lung liquid clearance can be sustained in the murine model with approximately 50% normal Na^+ channel activity.

HORMONAL REGULATION OF ION AND LIQUID TRANSPORT

Cyclic Adenosine Monophosphate–Mediated Liquid Transport

Although cAMP stimulates liquid and Cl^- secretion by both proximal and distal regions of the cultured immature human fetal lung, its net effect in late gestation is the opposite, namely, the induction of liquid absorption.[48,63] Birth is known to be associated with a surge in fetal catecholamine secretion.[89] The link between β-adrenergic stimulation and lung liquid clearance was made in 1978 by Walters and Olver,[90] who discovered that epinephrine and isoproterenol, but not norepinephrine, caused the rapid absorption of lung liquid by late-gestation fetal sheep lungs, and the absorptive response could be inhibited by prior treatment with propranolol. In addition to effects on liquid secretion and lung water, β-adrenoceptor agonists caused release of surfactant, and the two physiologic processes combined to improve early neonatal lung aeration and gas exchange.[91-94]

These observations were subsequently extended to demonstrate that, at any particular stage of gestation, a log-linear relationship exists between fetal plasma epinephrine concentration and the degree of inhibition of secretion or absorption of liquid.[12] The threshold for absorption falls in late gestation to reach an epinephrine level of 0.12 nmol/mL at term. During spontaneous labor, the relationship between endogenous fetal plasma epinephrine and the rate of liquid absorption is similar to that obtained by epinephrine infusion. Classically, β-adrenoreceptor agonists act via the cAMP/PKA (prekallikrein activator) signaling pathway, and, as predicted, the addition of a lipid-soluble analogue of cAMP, dibutyryl cAMP (db-cAMP), can mimic the effect of epinephrine in the mature fetal lamb.[95] The finding that the response to db-cAMP had a similar gestation dependence indicates that the rate-limiting step involved post-cAMP regulation of Na^+ transport rather than changes at the β-receptor.

Because cAMP mediates both liquid secretion and liquid absorption in the fetal lung, the potential exists for an epinephrine surge

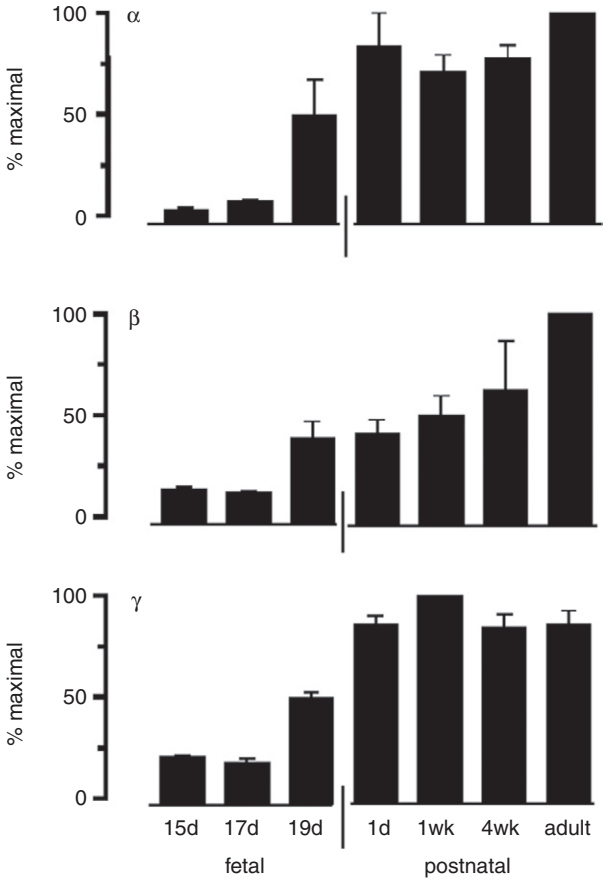

Figure 82-5 α, β, and γ Epithelial sodium channel subunit mRNA expression in fetal (term = 19 days) and postnatal whole mouse lung. *(From Talbot CL, Bosworth DG, Briley EL, et al: Quantitation and localization of ENaC subunit expression in fetal, newborn, and adult mouse lung,* Am J Respir Cell Mol Biol *20:398–406, 1999.)*

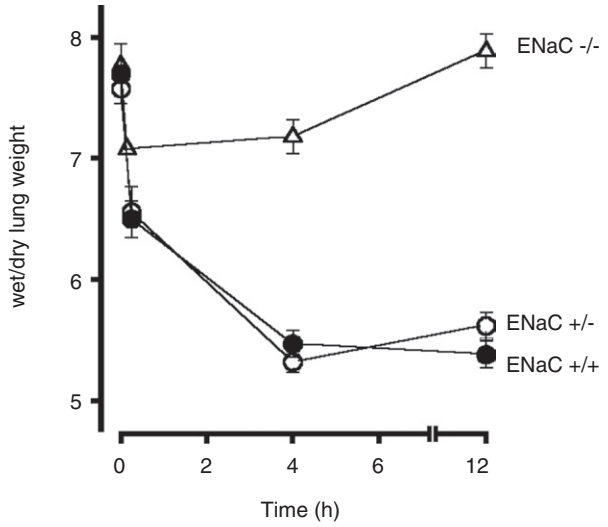

Figure 82-6 Lung water content (wet/dry lung weight) before (0 hour) and after birth (15 minutes, 4 hours, 12 hours) in α-epithelial sodium channel (αENaC) knockout mice (αENaC −/−) and littermate controls (αENaC +/− and +/+). *(From Hummler E, Barker P, Gatzy J, et al: Early death due to defective neonatal lung liquid clearance in alpha-ENaC-deficient mice,* Nat Genet *12:325–328, 1996.)*

to cause inappropriate lung liquid secretion in neonates born very prematurely. In explants of human fetal lung, cAMP caused a striking increase in liquid volume (Figure 82-7, *A*). This effect was attenuated by pretreatment of explants with thyroid and steroid hormones (Figure 82-7, *B*). The maturational effect of these hormones on liquid secretion and absorption is discussed later.

Arginine vasopressin, another hormone that increases cellular cAMP, rises during labor. Although it can be shown to inhibit lung liquid secretion, probably acting via the V_1 receptor and protein kinase C, its effect is weaker than that of epinephrine, and its role is uncertain.[96-98] It has been suggested that arginine vasopressin may provide back-up for the β-adrenoceptor–dependent pathway and may explain why β-adrenoceptor blockade fails to prevent lung liquid absorption during labor.[99]

Thyroid and Steroid Hormones

The role of thyroid and glucocorticoid hormones in the maturation of the absorptive response to epinephrine is evident from a series of experiments by Barker and co-workers.[100,101] Their initial studies showed a profound blunting of the response to epinephrine (and db-cAMP) in thyroidectomized fetal lambs that was reversed by infusion of triiodothyronine (T_3) alone. Neither T_3 nor hydrocortisone was capable of advancing maturation of the epinephrine response in normal fetuses with intact thyroid glands when they were given separately, but a powerful synergistic effect was observed when they were given concurrently (Figure 82-8).[102] In thyroidectomized fetal lambs, the response to epinephrine was detectable within 2 hours of the start of infusion of the hormone combination. This induction of epinephrine-sensitive liquid absorption was lost within 24 hours of cessation of hormone administration.[103] These data—together with the observation that T_3 and betamethasone have an additive effect in up-regulating fetal rat lung surfactant synthesis in vivo—emphasize the high degree of coordination of development of the lung liquid clearance and surfactant systems for efficient lung adaptation at birth.[104]

The observation that the rise in αENaC expression parallels plasma cortisol (but not T_3) in the late-gestation and newborn guinea pig, and can be blocked by metyrapone after delivery by CS, underscores the pivotal role of this hormone in the regulation of ENaC near term.[105] Tchepichev and colleagues[77] demonstrated that prenatal steroids, but not thyroid hormones, could advance timing of the increase in αENaC mRNA in fetal rat lung, but neither hormone had any effect on expression of βENaC or γENaC subunit mRNA expression. Champigny and associates[106] also reported no effect of thyroid hormones on ENaC mRNA expression, but they did report a potentiation by thyroid hormones of the steroid effect on Na^+ currents in rat alveolar epithelial cells. Otulakowski and colleagues[107] subsequently identified putative binding sites for thyroid and glucocorticoid receptors in the promoter region of αENaC, and although T_3 alone had no effect on reporter gene activity, it potentiated gene stimulation by steroid hormones.

A similar pattern of regulation has been reported for the subunits of Na^+,K^+-ATPase. Studies of 18-day rat FDLE cells treated with dexamethasone showed a threefold increase in α1 and β1 mRNA expression.[108] Studies of postnatal alveolar cells showed similar effects of steroid hormones on Na^+,K^+-ATPase activity. In addition, there is a large body of evidence in postnatal alveolar cell studies that activity of Na^+,K^+-ATPase can be up-regulated by intracellular cAMP.[109,110] The similarity of hormonal regulation of ENaC and Na^+,K^+-ATPase implies a coordinated increase in activity of the two principal mechanisms that underlie the perinatal absorptive response.

REGULATION OF ION TRANSPORT BY OXYGEN

O_2 appears to be a particularly important factor in maintaining the liquid absorptive response after birth. The onset of breathing results in a sharp increase in alveolar P_{O_2} from the fetal level of

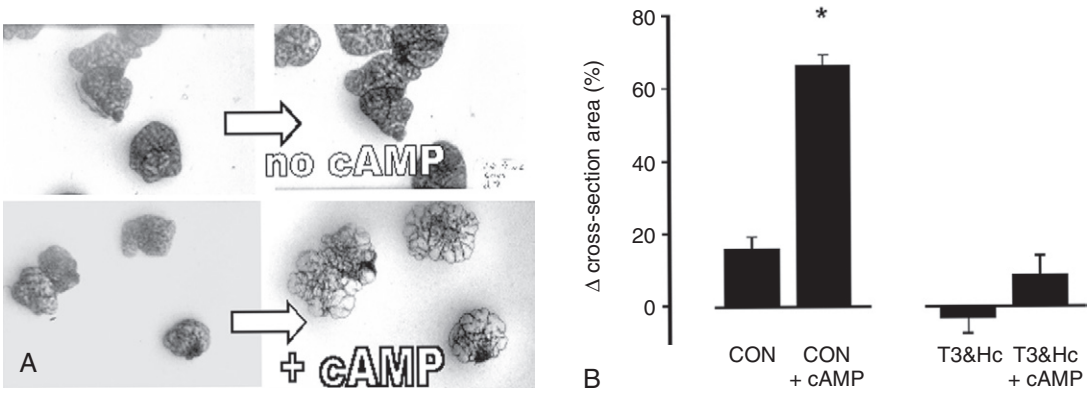

Figure 82-7 **A,** These 20-week human fetal lung explants expanded with liquid when they were exposed for 24 hours to 10^{-4} mol cyclic adenosine monophosphate *(cAMP)*. **B,** This increase in diameter was attenuated in explants preincubated for 48 hours with 10^{-9} mol triiodothyronine (T_3) and 10^{-6} mol hydrocortisone *(Hc)*. *CON,* Control.

Thyroid (triiodothyronine [T_3]) and steroid hormone exposure did not affect basal secretion rates. Only fetuses that had been treated with thyroid *and* steroid hormone for 3 days were able to absorb lung liquid during epinephrine infusion. - -, Effect of IV epinephrine; □, hydrocortisone; ○, T_3; △, T_3 and hydrocortisone. *(From Barker PM, Markiewicz M, Parker KA, et al: Synergistic action of triiodothyronine and hydrocortisone on epinephrine-induced reabsorption of fetal lung liquid,* Pediatr Res *27:588–591, 1990.)*

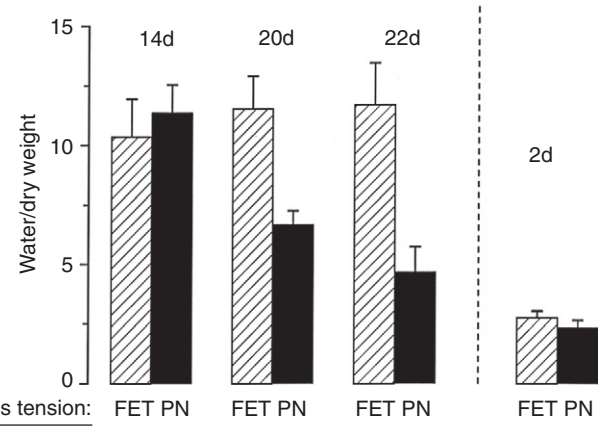

Figure 82-9 Effect of fetal (*FET,* ambient O_2 of 3%) or postnatal (*PN,* ambient O_2 of 21%) conditions on liquid volume of distal lung explants derived from fetal mouse lung. *(From Barker PM, Gatzy JT: Effect of gas composition on liquid secretion by explants of distal lung of fetal rat in submersion culture,* Am J Physiol *265:L512–L517, 1993.)*

23 to 25 mm Hg to about 100 mm Hg postnatally. The potential for this change in ambient O_2 to switch the fetal lung from a secretory to an absorptive state was first shown by Barker and Gatzy[111] in studies of fetal rat distal lung explants. A shift from fetal P_{O_2} (≈25 mm Hg) to room air (≈150 mm Hg) inhibited liquid secretion (reduction in lung water/dry weight ratios and in the number and size of liquid-filled cysts) by fetal lung explants in late-gestation lung explants, whereas there was no inhibition of liquid secretion by high P_{O_2} at very early gestations (Figure 82-9). By contrast, no liquid secretion was induced in postnatal explants with exposure to fetal gas concentrations, a finding suggesting that the switch to liquid absorption may be irreversible 2 days after birth. The effect of O_2 on liquid secretion could be induced in immature explants by coculture in thyroid and steroid hormones. These studies further demonstrated a crucial role of thyroid and steroid hormones in priming the distal lung epithelium to respond to triggers (epinephrine and O_2) that switch transepithelial liquid flow from secretion to absorption at birth.

Subsequently, studies with rat FDLE monolayers showed that the increase in Na^+ transport induced by raising P_{O_2} from 30 to 150 mm Hg was accompanied by an increase in ENaC mRNA expression.[112] This shift in P_{O_2} was accompanied by a temporary fall in epithelial resistance lasting several hours, consistent with the increase in solute permeability noted by Egan and co-workers[39] at the onset of breathing in vivo that may assist passive liquid absorption. Vivona and co-workers[113] showed that hypoxia in adult rats decreased alveolar liquid clearance, an effect that was independent of ENaC and Na^+,K^+-ATPase subunit expression. These studies indicate that the mechanisms of postnatal O_2-induced neonatal alveolar Na^+ and liquid transport include posttranscriptional regulation of ENaC and may be reversible.

Further experiments were undertaken in mature rat FDLE cells to determine how the effects of shifting P_{O_2} from fetal to neonatal levels and the action of hormones are integrated to control lung liquid transport.[114] In these studies, glucocorticoid and thyroid hormones up-regulated Na^+ transport and up-regulated β-agonist–induced apical Na^+ conductance (G_{Na}) independently of ambient P_{O_2}. In contrast, a shift to neonatal P_{O_2} was a prerequisite for hormonal up-regulation of Na^+,K^+-ATPase. These findings contrasted with the reported effects of thyroid hormones

and steroids on immature fetal sheep lung, which were restricted to induction of β-agonist–responsive liquid absorption, with no effect on basal secretion rates.[102] Postnatally, steroids and P_{O_2} also have an additive effect in up-regulating expression of ENaC-like Na^+ channels in type II alveolar cells.[115]

The promoter region of α-rENaC contains a consensus nuclear factor-κB (NF-κB) binding element. Further experiments in rat FDLE cells showed that a rise in P_{O_2} to 150 mm Hg induced this redox-sensitive transcription factor, and blocking NF-κB activation reduced the O_2-evoked rise in G_{Na}.[116,117] These findings could be interpreted as indicating that P_{O_2} activation of NF-κB up-regulated the expression of ENaC, thus increasing Na^+ transport at the onset of breathing. However, subsequent experiments using FDLE monolayers demonstrated that a shift from fetal (23 mm Hg) to postnatal (100 mm Hg) alveolar P_{O_2}, which induces a maximal Na^+ response, resulted in an immediate increase in NF-κB expression and a detectable increase in Na^+ pump capacity within 6 hours, whereas activation of the αENaC promoter was not seen until after 24 hours, reaching a maximum (together with G_{Na}) at 48 hours.[118,119]

It therefore appears that the early increase in fluid absorptive capacity in response to the rise in alveolar P_{O_2} at birth is primarily the result of an increase in Na^+,K^+-ATPase pump capacity, and the increase in G_{Na} may be secondary to this increase in Na^+ transport, not its cause. Both components of the response are enhanced by glucocorticoid and thyroid hormones, which are also required for β-adrenoceptor–mediated control of G_{Na}. This discrepancy between the effects of these hormones in rat versus sheep studies raises the possibility that thyroid and steroid hormones may inhibit basal secretion rates or increase G_{Na} in late, but not early, gestation. The discrepancy in the time course of NF-κB activation and the rise in αENaC expression indicates that activation of the αENaC promoter requires additional transcription factors.

LUNG LIQUID AND ION TRANSPORT IN NEONATAL RESPIRATORY DISEASE

This section reviews the evidence that inefficient lung water clearance can result in neonatal lung disease and examines the contribution of abnormal airway ion transport.

Lung Liquid

Animal studies show a clear correlation between intraluminal liquid volume and respiratory function at birth. Berger and colleagues[120] examined the effect of residual lung liquid volume at birth on gas exchange in lambs delivered by CS near term. Animals that had approximately 45% lung liquid volume removed just before delivery had significantly better respiratory function than those delivered without liquid removal. The first clinical evidence that lung liquid may play a role in neonatal respiratory disease came from an analysis by DeSa[121] of postmortem lung findings after perinatal death. Infants who died of idiopathic respiratory distress syndrome (RDS) had significantly higher lung liquid content (determined as the percentage of wet weight of the lung) compared with infants who died of other, nonrespiratory causes.[122] These findings were supported by other evidence of lung liquid excess on histologic examination after RDS (Figure 82-10).[121]

In an early review, Bland[123] identified certain factors that may predispose the newborn preterm infant to pulmonary edema, as follows:

1. Persistent pulmonary hypertension is more common in this group of infants, particularly if they experience hypoxia or patent ductus arteriosus.
2. A large transpulmonary pressure that drives fluid into the alveolar compartment may develop in areas of the lung with surfactant deficiency. The advent of artificial surfactant therapy has significantly decreased the incidence of RDS, and some of its effect may result from decreased surface tension and improved gas exchange in areas of the preterm lung that are not completely emptied of alveolar liquid at birth.[124]
3. Mechanical ventilation likely disrupts the epithelial barrier and allows entry to the alveolar space of proteins that, in turn, may increase intraalveolar fluid.
4. High inspired O_2 releases toxic metabolites that may interfere with essential cellular functions, including ion transport.

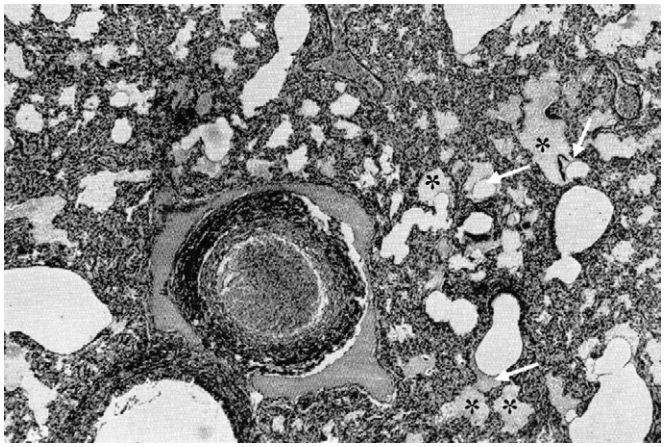

Figure 82-10 Photomicrograph of a lung from a 1300-g infant who died of respiratory distress syndrome at 8 hours without mechanical ventilation. The *arrows* show meniscus of liquid *(asterisk)* contained inside the alveoli. *(From DeSa DJ: Pulmonary fluid content in infants with respiratory distress,* J Pathol *97:469–478, 1969.)*

Against this background of susceptibility to pulmonary edema, ion transport—a major defense against alveolar flooding—is almost certainly incompletely developed in infants born very prematurely.[125]

The correlation between preterm delivery and respiratory distress is clear; however, some clinical studies, both prospective and retrospective, also demonstrate a link between mode of delivery and respiratory condition in the neonate.[126-128] Elective CS without labor is associated with a small but significant increased risk of RDS. This risk is exacerbated by delivery even a couple of weeks before term.[129]

The condition of transient tachypnea of the newborn (TTN) is probably the best-described consequence of inadequate neonatal lung liquid clearance. This self-limiting disease, characterized by an increase in respiratory rate, occurs more frequently in infants delivered by elective CS and is thought to result from delayed activation of liquid clearance in infants not subjected to the stress of labor.[130,131] These clinical data are consistent with animal studies demonstrating the importance of gestation and labor in perinatal lung water clearance and successful adaptation to air breathing.

Airway Ion Transport Studies

Some investigators have used nasal electrical potential difference (PD) to measure ion transport directly across the upper airway in vivo. Nasal PD measures the electrical potential generated by active transport of charged ions (Cl^- and Na^+) across the nasal membrane. The use of nasal PD to infer patterns of ion transport in the lower airways and alveoli has been validated by measurement of similar ion transport patterns in nasal and lower bronchial epithelia for both normal subjects and and those with CF.[132,133] Furthermore, nasal PD can predict who will be susceptible to high-altitude pulmonary edema.[134] Gowen and

colleagues[135] reported that nasal PD could distinguish newborn infants with CF from healthy neonates and those with non-CF respiratory disease. This test also detected ion transport differences that reflected the mode of delivery. Nasal PD was significantly higher in infants born by elective CS compared with those born normally or by CS after labor. Infants with TTN had the highest nasal PD, but they also had decreased amiloride-sensitive Na^+ transport compared with babies who did not have TTN.[136] These preliminary studies support the notion that TTN may result in persistence of a fetal ion transport phenotype after birth.

In a more recent study, these investigators examined the relationship between airway ion transport at birth and development of RDS in infants at or less than 30 weeks gestational age.[137] The RDS group had significantly lower maximal PDs and less inhibition after amiloride perfusion (Figure 82-11), a finding suggesting reduced ENaC-mediated Na^+ absorption. However, this group demonstrated a close correlation between maximal PD and birth weight, and the lower birth weight of the RDS group could represent a significant confounding variable. Although more studies are needed in this area, the available evidence supports an etiologic role for immature ion transport processes in the evolution of acute and possibly chronic lung disease (CLD) in preterm infants.

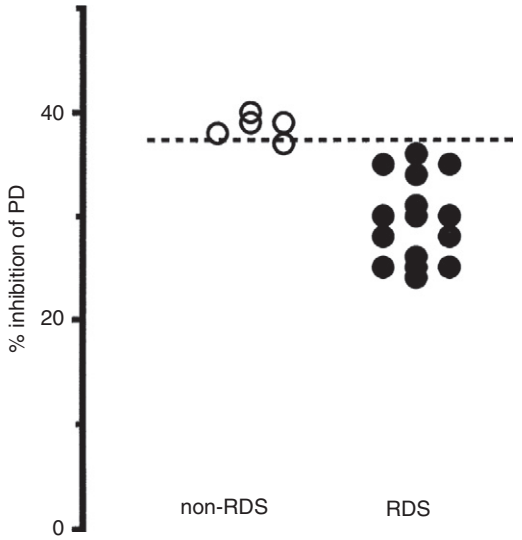

Figure 82-11 The percentage of inhibition of nasal potential difference *(PD)* by the sodium channel blocker amiloride discriminates between infants who subsequently developed respiratory distress syndrome (RDS) *(closed circles)* and those who did not develop RDS *(open circles)*. *(From Barker PM, Markiewicz M, Parker KA, et al: Synergistic action of triiodothyronine and hydrocortisone on epinephrine-induced reabsorption of fetal lung liquid,* Pediatr Res *27:588–591, 1990.)*

Therapeutic Considerations

Our understanding of the role of labor in clearing fetal liquid from the perinatal lung is supported by clinical studies that show a protective effect of labor on subsequent respiratory outcome. Drugs that augment the switch from liquid secretion to liquid absorption at birth are candidates for novel therapies to treat lung disease associated with premature birth. Possible strategies include inhibition of Cl^- secretion and augmenting of Na^+ transport across respiratory epithelia.

Effect of Labor

Respiratory morbidity of both term and preterm infants is related to mode of delivery. In term infants born to mothers undergoing repeat CS, there was a higher incidence of TTN after birth without a trial of labor (6%) compared with those born with a trial of labor (3%). The TTN rate in infants who had a trial of labor was similar to that of those born during routine vaginal births.[138] In both preterm and term infants, the rates of all respiratory problems were significantly higher in infants born by CS without labor compared with those born by either route with labor.[139]

β-Adrenergic Stimulation

In term infants undergoing CS without labor, there was significant improvement in dynamic lung compliance and a decrease in respiratory rate for those whose mothers had received a β-adrenergic agonist during the last 2 hours of labor compared with infants who were not exposed to these drugs.[140] These studies confirm the important role of labor in clearing lung liquid in preparation for air breathing, and the finding supports the hypothesis that β-adrenergic stimulation induced by labor plays a key role in triggering the absorptive process. This beneficial effect of prenatal β-adrenergic stimulation on respiratory morbidity was also observed in preterm infants.[141]

Sodium Transport

Steroid and thyroid hormones exert a major maturational effect on Na^+ transport in the developing fetal lung. Both hormones have been used for prevention and treatment of neonatal lung disease. Meta-analyses of multiple randomized trials suggest that prenatal steroids reduce the risk of RDS by about 50%. But even combined with surfactant therapy, antenatal steroid therapy has not decreased CLD in preterm infants.[142,143] Some clinical trials examining the addition of thyrotropin-releasing hormone to antenatal steroids have been reported. Early trials suggested some reduction in respiratory morbidity in infants of mothers given the hormone; however, subsequent larger studies have not confirmed these findings and have suggested potentially negative outcomes, both short term and long term, after treatment with thyrotropin-releasing hormone.[144-148] Postnatal steroid administration has been used extensively to treat ventilator-dependent lung disease in preterm infants, and studies showed that short courses of dexamethasone given early (in the first 2 weeks of life) may prevent bronchopulmonary dysplasia.[149-152] However, enthusiasm for steroid therapy has been tempered by reports of negative effects of both prenatal and postnatal glucocorticoids on lung development and pathologic findings in multiple organs.[153] These concerns have generated interest in the possibility that lower doses of steroids may be effective and may generate fewer side effects. Pilot studies in very preterm infants suggest that adrenal insufficiency can be reversed and CLD can be prevented with low doses of glucocorticoids.[154-156] The mechanism of low-dose steroid benefit for CLD is not known. We speculate that this treatment may enhance maturity of the ion transport system and may result in more effective lung water clearance in these preterm infants.

Chloride Secretion

Furosemide, a drug that inhibits Cl^- secretion by blocking the basolateral NKCC, has been investigated for the treatment of CLD after preterm delivery. Two systematic reviews for the Cochrane Database examined use of furosemide for CLD after preterm studies. Studies of aerosolized furosemide suggested a short-term benefit in lung mechanics after a single administration; however no data were available on clinical outcome and repeated administration.[157] Similar conclusions were drawn for administration by oral or intravenous routes, although long-term administration by these routes was associated with consistent improvement in lung compliance and oxygenation.[158] Strategies to reduce fetal Cl^- secretion will be assisted by better molecular characterization of fetal Cl^- pathways.

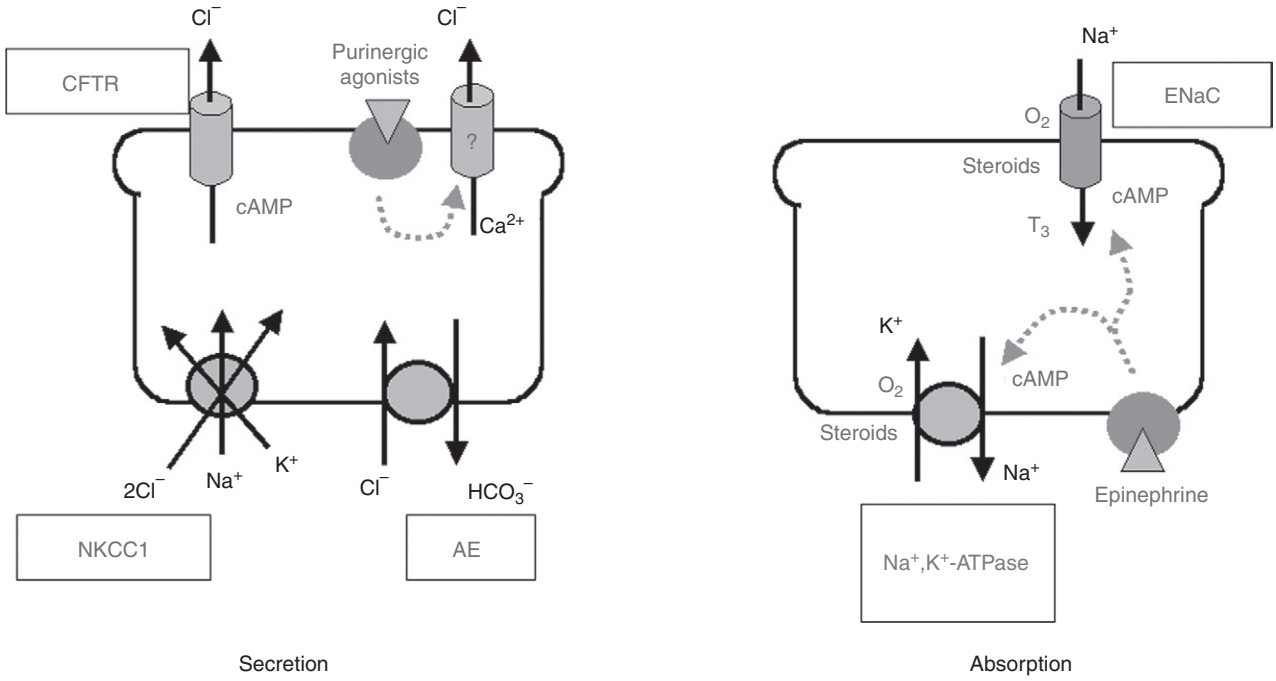

Figure 82-12 Summary of ion transport components and regulations. *AE,* Anion exchanger; *cAMP,* cyclic adenosine monophosphate; *CFTR,* cystic fibrosis transmembrane conductance regulator; *ENaC,* epithelial sodium channel; HCO_3^-, bicarbonate; *NKCC1,* sodium-potassium-chloride co-transporter 1; T_3, triiodothyronine.

SUMMARY

Ion transport has a key role in the switch from liquid-filled to air-filled lungs at birth. Although this physiologic process occurs over hours, the adaptive processes that prepare the fetal lung for birth are initiated at a much earlier stage of pregnancy. There is clear evidence that active Cl^- secretion underpins fetal lung liquid secretion and that this process is critical for normal lung growth in utero. Although there has been progress on elucidating mechanisms for Cl^- entry into the airway cells, the molecular identity of the channel or channels involved in transporting Cl^- into the lung lumen remains elusive. The functional and molecular basis of liquid absorption has been well characterized with detailed animal studies and molecular identification of the key components (ENaC and Na^+,K^+-ATPase) of this process (Figure 82-12). Both Cl^- secretion and Na^+ absorption are activated by a rise in cellular cAMP, and an alternative path for Cl^- secretion is activated by a rise in intracellular Ca^{2+}. The sequence of events that switch liquid secretion to liquid absorption is known. In late gestation, a rise in fetal glucocorticoids and active thyroid hormones readies, but does not activate, the Na^+ absorptive mechanism. In the last few days of gestation, there is some decrease in lung liquid production and intraluminal liquid volume. Labor has an important role in initiating lung liquid clearance in preparation for air breathing. During labor, some liquid is actively exhaled, but the main mechanism for clearing liquid is activation of Na^+ transport by coordinated induction of ENaC and Na^+,K^+-ATPase. A rise in fetal epinephrine levels in response to the stress of contractions and birth appears to trigger the switch from liquid secretion to liquid absorption. After birth, a rise in ambient O_2 augments Na^+ absorption, which completes the transition to the postnatal state. After birth, the lung retains some liquid secretory capability, and a balance of liquid secretion and liquid absorption sustains a thin film of liquid on the airway surface of the air-filled lung. There is strong circumstantial evidence that incomplete maturation of ion transport contributes to respiratory disease in very preterm infants, but future studies will need to confirm this cause-and-effect relationship. Better understanding of the regulation of ion transport across the fetal and newborn lung will open the possibility of novel therapeutic approaches to acute lung disease and CLD associated with preterm birth.

Upper Airway Structure: Function, Regulation, and Development

Although the conducting airways are formed well in advance of fetal viability, they undergo significant maturational changes in late gestation. They are susceptible to damage until they acquire the characteristics of more mature airways. Controversy exists concerning the pathogenesis of bronchopulmonary dysplasia (BPD) in the neonate[1-3]; in any case, prolonged mechanical ventilation and oxygen toxicity appear to be major contributing factors. Serial evaluations of pulmonary function in infants surviving hyaline membrane disease in whom BPD develops subsequently have demonstrated conclusively that the duration and pressure magnitude of mechanical ventilation, rather than increased inspired oxygen tension, damage the airways and lead to interference with their growth.[4,5] Within this context, the greater mechanical ventilation requirements of the very premature infant relative to the older infant precipitate an age-related predisposition to airway damage.

This chapter summarizes the function-structure characteristics and regulation of the developing upper airway and the impact of mechanical ventilation on airway function and reviews the clinical assessment of airway function.

STRUCTURE-FUNCTION CHARACTERISTICS

Airway Embryology

It has been shown that airway development in humans begins during the fourth week of gestation when the respiratory diverticulum, or lung bud, branches from the embryonic foregut.[6] The esophagotracheal septum forms and separates the foregut into the esophagus dorsally and the trachea ventrally. Thus the developing airway is of foregut endodermal origin. Elongation of the respiratory diverticulum forms the trachea, whereas the main bronchi are formed by branching. Growth and elongation continue in the caudal direction under the influence of airway secretions and physical forces.

Maturation of the airway occurs first in the trachea and proceeds distally. Tracheal cartilage formation begins during the seventh week of gestation. Full maturation of the distal airway cartilage is not completed until after birth. Epithelial differentiation begins in the trachea during week 10 of gestation. Together with the phasic contractions of the fetal airway smooth muscle, which are present after gestational week 23, lung fluid secreted from the epithelial cells promotes the growth and development of the respiratory system.[7]

Airway Structure

The airway tree is a branched conducting system whose major functions include the delivery, distribution, and conditioning of gas to the gas exchange units of the lung. The lower airway has three primary components: epithelium, cartilage, and smooth muscle. The epithelium lines the entire length of the airway. From the trachea to the large bronchioles, it is composed of a pseudostratified ciliated columnar epithelium referred to as respiratory epithelium. The designation *pseudostratified* applies because the respiratory epithelium is one cell layer thick and all cells attach to the basement membrane, but not all cells extend out to the airway lumen, giving the histologic appearance of multiple cell layers. Beyond the large bronchioles, the airway epithelium undergoes a gradual transition to a simple ciliated columnar epithelium and, finally, a cuboidal epithelium. The airway epithelium is composed of approximately eight different cell types. The primary cell type in the epithelium is the columnar epithelial cell, which contains a layer of cilia on its apical surface. Other cell types present include mucus-secreting cells, brush cells, small granule cells, and basal cells.

Cartilage is present from the trachea to the bronchioles. In the trachea, cartilage exists as C-shaped rings that are open posteriorly. In the bronchi, the cartilage forms plates that encompass the

entire airway circumference. At more distal airway generations, the cartilage plates become smaller and more discontinuous, gradually disappearing before the bronchioles. As with the airway cartilage, the architectural disposition of airway smooth muscle also varies, with different configurations along progressive airway generations. In the trachea, the airway smooth muscle is confined to the trachealis muscle. The trachealis, along with fibroelastic tissue, bridges the gap between the tips of the C-shaped cartilage rings and forms the posterior wall of the trachea. By contrast, bronchial airway smooth muscle forms a complete circumferential layer that gradually diminishes and becomes discontinuous at lower generations.

A mucosal layer covers the inner surface of the trachea. The mucosa consists of an epithelial layer supported by a basement membrane. This basement membrane is part of a loose connective tissue layer referred to as the lamina propria. The lamina propria is very cellular, containing lymphocytes and lymphatic tissue, plasma and mast cells, eosinophils, and fibroblasts. Also included within the mucosal layer are glands that send ducts to the epithelial surface.

Below the mucosa lies the submucosa. The submucosa is a connective tissue layer containing the distributing blood vessels, lymphatics, and mucus-secreting glands. The submucosa ends when it blends into the perichondrium of the cartilage rings. The outer layer of the trachea consists of adventitia, which binds the trachea to adjacent structures such as the esophagus, neck musculature, and mediastinal structures. The adventitia contains the large blood vessels and nerves supplying the components of the tracheal wall.

The primary innervation of the trachea is cholinergic from the vagus nerve.[8] Vagal stimulation results in contraction of airway smooth muscle. In addition, nonadrenergic, noncholinergic innervation controls both bronchoconstrictive and bronchodilatory actions through mediators such as nitric oxide, vasoactive intestinal peptide, neurokinins, and substance P. Little if any direct sympathetic innervation of the airway is present. Sympathetic control is provided primarily through circulating catecholamines.

More recent studies on structural maturation of airway smooth muscle at the cellular, ultrastructural, and protein expression levels have elucidated structural mechanisms for developmental changes in function.[9-11] Although the individual lengths of isolated tracheal smooth muscle cells increased from prematurity to adulthood, a linear increase in cell length was not demonstrated during the neonatal period, precluding cell length changes as a mechanism for functional development.[9] Similarly, developmental alterations in the electron microscopic ultrastructure of the tracheal smooth muscle could not be identified as potential mechanisms. At the protein expression level, the expression of smooth muscle myosin SM1 and SM2 heavy chain isoforms increased across development. This increase correlates with the developmental increase in tracheal smooth muscle force development, providing a likely mechanism for the functional maturation of this airway smooth muscle.

In developing rabbit trachea, clear patterns of expression or activation of matrix metalloproteinases MMP2 and MMP-9, as well as their (tissue) inhibitors TIMP-1 and TIMP-2, have been demonstrated during the progression of airway development.[12] In the lung, differences in MMP activity have been associated with BPD[13] and other chronic fibrotic lung diseases.[14] Thus it is implied that the progression of lung disease involves the alteration in MMP activity. As noted by Miller and associates, total MMP-2 quantity decreased steadily with increasing age in both the pre- and postgestational periods, whereas the active-to-latent ratio decreased only in the postgestational period. This change in the proteolytic potential in MMP-2 was compounded in the postgestational period by an age-dependent rise in TIMP-2. In that these arbitrary units of protein quantity are relative to a constant total protein load, the rise in TIMP-2 affirms that the significant fall in MMP-2 levels is not likely to be the result of an increase in inert, structural protein diluting the quantity of functional mediators of structural development. Of interest in this study is the lack of MMP-7 activity in developing trachea, in contrast with in the developing lung, where MMP-7 activity is present. These data support the assessment by other researchers that MMP-7 serves as a regulator for passage across the alveolar epithelium[15,16] and thus is not a mediator in development of conducting airways. In this regard, MMP-7 may play a role in the differentiation between airway and lung development.

Mechanics and Regulation of the Developing Airway

It is well accepted that infant airways are more compliant than adult airways. Early studies in necropsied human tracheobronchial segments indicated that airway pressure-volume relationships could be correlated with maturity.[17,18] Accordingly, a reduction in airway compliance with maturity results in decreased collapsibility and increased resistance to deformation during positive-pressure ventilation. Therefore the immature airway is more likely to sustain deformational changes resulting from barotrauma than is the less compliant airway of the older infant or adult.

Animal tracheas have been used extensively as models to study mechanisms that determine maturational changes in airway function. A study of in vitro rabbit tracheal segments,[19] as shown in Figure 83-1, documentedan age-related decrease in compliance in the developing rabbit airway that parallels that seen in neonates.[17] An in vivo study of the innervated and perfused trachea of the lamb demonstrated similar developmental changes in airway compliance and a decrease in the tracheal relaxation time constant.[20] It is noteworthy that in comparison with the results of in vitro studies, the absolute values of specific tracheal compliance in vivo were lower. Contribution of forces of surrounding connective tissue, or neurohumoral influences on airway smooth muscle tone, may affect the elastic properties of the developing airway and account for these observed differences. In addition, the decrease in relaxation time constant with maturation also is suggestive of age-related differences in smooth muscle tone in vivo. Alterations of smooth muscle tone modulate mechanical properties and pressure-flow relationships of the trachea in

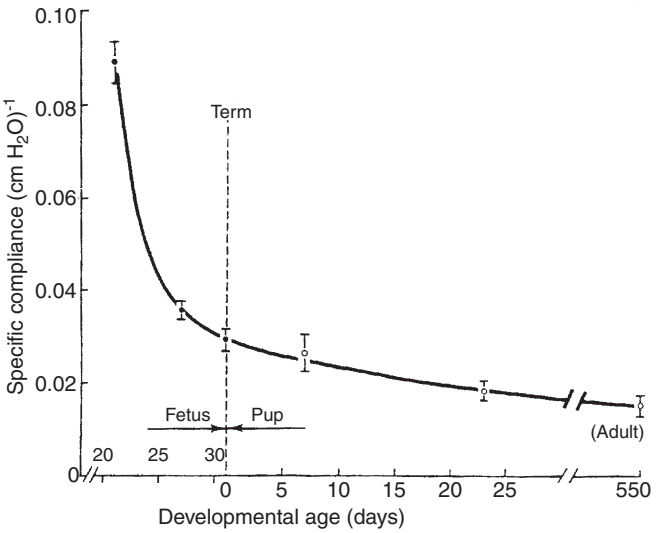

Figure 83-1 Developmental change in specific tracheal compliance in the rabbit. (Term = 31 days.) *(From Bhutani VK, Rubenstein SD, Shaffer TH: Pressure-volume relationships of tracheae in fetal newborn and adult rabbits,* Respir Physiol *43:221-231, 1981.)*

preterm and newborn lambs.[21-23] In general, tracheas stimulated with acetylcholine become stiffer and are less compressible, as reflected by decreased resistance to airflow when they are subjected to compressive forces.[23-25] Specifically, however, comparison of data suggests that the effect of pharmacologic stimulation on airway mechanics is age-dependent, and that the ability of airway smooth muscle to decrease airway compliance and increase flow may be limited in the preterm trachea.

The inability of airway smooth muscle to generate as much force as that produced by its adult counterpart probably contributes to this limitation. The effect of postnatal aging on airway smooth muscle maximal force production and sensitivity to various agonists remains controversial.[26] Some studies show that contractility and sensitivity increase with age,[8,27,28] whereas others suggest that contractility and sensitivity reach their peak early in postnatal life, declining thereafter.[29,30] When the extremes of the developmental spectrum are compared, however, a clear pattern emerges (Figure 83-2). Several investigators have shown that maximal contractility of airway smooth muscle increases between two- and four-fold from preterm or newborn to adult.[8,23,24,27] Furthermore, maximum active stress has been shown to increase significantly during late gestation in both the lamb[27] and pig.[10] This change is not the result of an increase in smooth muscle mass, because normalization for cross-sectional area eliminates that factor.

Developmental changes in force generation of airway and nonairway smooth muscle in various species have been related to an increase in contractile proteins (actin and myosin) per unit area and to age-related differences in amount and type of myosin isoforms.[9,29,31,32] Age-related increases in contractile responses of vessels also have been related to alterations in the orientation of vascular smooth muscle cells, which changes from a circular to oblique relative to the long axis of the vessel wall.[33]

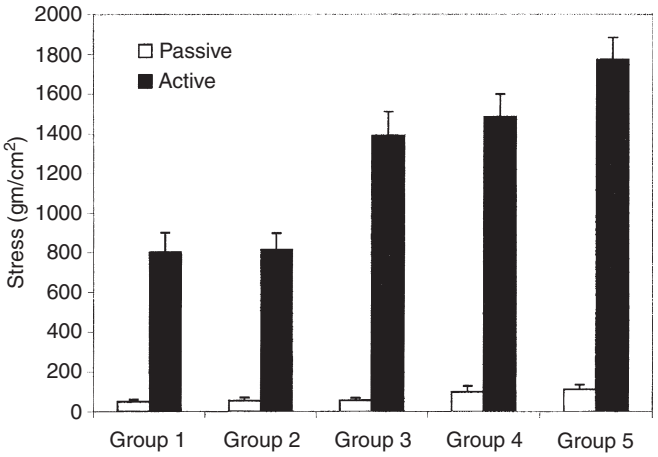

Figure 83-2 Active and passive stress values from muscle bath studies in isolated trachealis muscle strips from preterm, newborn, and adult sheep. Data are normalized for cross-sectional area and for percentage of muscle fibers within the strip. *Group 1:* preterm at 110 days of gestation (n = 8); *group 2:* preterm at 110 to 124 days of gestation (n = 25); *group 3:* preterm at 125 to 140 days of gestation (n = 5); *group 4:* term newborns (n = 10); and *group 5:* adults (n = 16). (Term = 147 ± 3 days of gestation.) A significant increase in both active and passive stress as a function of age was noted ($p < .001$). Post hoc analysis disclosed significant differences in active stress between group 1 and groups 3, 4, and 5, and between group 2 and groups 4 and 5. Similarly, passive stress increased between groups 1 to 3 and group 5. Values are means ± SEM. *(From Panitch HB, et al: Maturational changes in airway smooth muscle structure-function relationships,* Pediatr Res *31:151-156, 1992.)*

Furthermore, age-related shifts in the synthetic activity of vascular smooth muscle cells have been identified in neonatal rats. Initially, synthetic activity is primarily secretory, producing extracellular proteins, collagen, and elastin; after the age of 4 weeks, synthetic activity is primarily contractile, producing the intracellular protein actomyosin.[34] Also along these lines, Driska and co-workers[35] identified age-related differences in morphometry and similar shortening responses in airway smooth muscle cells isolated from preterm and adult sheep. Adult cells were similar in size and appearance to adult arterial smooth muscle cells, but velocity of shortening (0.54 sec^{-1}) was approximately three times faster. Isolated preterm airway smooth muscle cells were approximately half as long and thick as adult cells, but shortening velocities were similar.

Airway epithelium plays an important role in the modulation of smooth muscle function. Studies of adult airways have shown that airway epithelium generates relaxant and contractile factors that modulate the tone of the underlying smooth muscle.[36-40] Furthermore, epithelial damage has been associated with bronchial hyperreactivity.[41] In a similar study of deepithelialized preterm lamb trachea, force generation in response to acetylcholine stimulation was increased over that measured for the intact tracheal smooth muscle strip.[42] These data demonstrate that preterm airway epithelium is able to modulate the responsiveness of smooth muscle. Additionally, the magnitude of the effect was unchanged with maturation (from preterm to adult). Thus, even during late gestation, epithelial integrity may be an important determinant of smooth muscle function, bronchial hyperreactivity, and bronchodilator responsiveness. Not completely understood is whether regional differences in airway epithelium exert differential contractile or relaxant influences on airway smooth muscle in the developing airway.

The fact that the structural arrangement of muscle and cartilage in the adult trachea is different from that in the bronchi suggests that the functional effects of muscle contraction also may be different in these tissues in the adult, and presumably during development as well.[40]

Studies of the adult trachea suggest that the elasticity of the passive trachealis muscle and connective tissue is greater than that of the bronchial wall.[43] Moreover, these studies demonstrated that tracheal smooth muscle is capable of generating larger circumferential tensions than bronchial muscle, presumably because of the circumferential alignment and relatively greater proportion of the smooth muscle cells in the trachealis muscle, compared with helical orientation and fewer smooth muscle cells in the bronchial wall. Regional differences in force generation have been noted in the airway of premature sheep as well.[42] Passive, active, and total stress development decreased significantly as a function of airway generation, from trachea (0 generation 0) to the subsegmental bronchi (generation 4). The receptor-mediated response to acetylcholine was significantly less in generations 0, 1, and 2 than in generations 3 and 4. In addition, the internal radius-to-wall thickness ratio (r/t) decreased from trachea to fourth-generation airway. The law of Laplace predicts that because of this decline in r/t, the trachea would be exposed to the greatest degree of wall stress during positive-pressure ventilation.[42] Taken together, these data help to explain the structural changes as well as physiologic changes in airway reactivity seen in the premature infant after mechanical ventilation.

Although the intact trachea serves as a suitable preparation for studying the mechanical function of the muscle and cartilage, it is important to consider the individual differences in airway smooth muscle function and contribution of cartilage. Along these lines, several investigators have suggested that airway cartilage plays an important role in determining airway compressibility and inflatibility.[44-46] Moreno and co-workers[47] softened rabbit tracheas with papain and demonstrated alterations in unstressed tracheal volume and compliance. In a related study using papain-treated

rabbits, McCormack and associates[42] observed changes in pulmonary function indicative of increased airway collapsibility. The maturational effects of cartilage contribution to airway function was demonstrated by Penn and co-workers,[46] who showed that tracheal cartilage in preterm lambs is extremely compliant relative to that in the adult sheep. In addition, it was suggested that these age-related changes in cartilage paralleled developmental differences in tracheal smooth muscle and tracheal mechanics.[22,27,48] Therefore age-related differences in airway mechanical function may reflect an increase in stiffness that occurs in both airway muscle and cartilage.

Effects of Mechanical Ventilation on Airway Function

Although mechanical ventilation undoubtedly increases the survival of patients in respiratory compromise, it also is associated with increased morbidity.[49] The volumes, pressures, and oxygen concentrations that are incumbent in mechanical ventilation provide a mechanism of injury to a respiratory system that is not suited to such exposure.[50] This dilemma is most obvious in the premature and neonatal patient population.[51,52] Owing to the low compliance of the premature or surfactant-deficient lung, the inspired oxygen concentrations and ventilatory pressure requirements often are extreme.

Even though mechanical ventilation can be associated with systemic morbidity from specific nonpulmonary entities such as intraventricular hemorrhage, the primary pathologic changes consequent to mechanical ventilation involve the respiratory system. Mechanical ventilation is known to result in ventilator-induced lung injury and concomitant respiratory dysfunction. The signs of ventilator-induced lung injury include atelectasis, progressive respiratory failure, and pulmonary edema with hyaline membrane formation. It has been demonstrated in adults and infants that inflammatory cytokines are mediators of respiratory injury and dysfunction.[53,54] Altered production of many cytokines has been implicated, including tumor necrosis factor-α (TNF-α) and the interleukins IL-1β, IL-6, and IL-8. These cytokines not only act on the respiratory system but also exert their effects systemically.

The current thinking regarding minimization of lung injury focuses on limiting ventilatory pressures. Reduction of these pressures, however, comes with a paradox: Although elevated mean airway pressures are implicated in the pathogenesis of lung injury, maintaining adequate positive end-expiratory pressure (PEEP) may attenuate this damage. Including a level of PEEP in the ventilation strategy sufficient to ensure that tidal ventilation occurs at pressures greater than the lower inflection point is thought to minimize lung damage. When end-expiratory pressures fall below the inflection point, some alveoli close. These closed alveoli must then reopen during subsequent inspiratory cycles. This alveolar opening–closing action is thought to be involved in the lung injury and inflammatory process.[55] Additionally, in the absence of PEEP, the closing-reopening of the alveoli has been shown to disrupt the surfactant layer and thereby exacerbate already impaired lung function.

Mechanical ventilation has little effect on adult airways but has been shown to alter the dimensions[55-58] and mechanical properties of preterm and newborn airways.[59,60] The extent of ventilation-induced deformation appears to be directly related to the compliance of the airway and inversely related to age. Our own observations in a preterm lamb model of the effects of mechanical ventilation included an increase in tracheal diameter, thinning of cartilage and muscle, disruption of the muscle-cartilage junction, and focal abrasions of the epithelium.[56] As shown in Figure 83-3, in comparison with unventilated trachea, decreased inflation and increased collapsing compliance of the trachea after ventilation produce a structure analogous to that of a fire hose, which is difficult to expand but easier to collapse.[60]

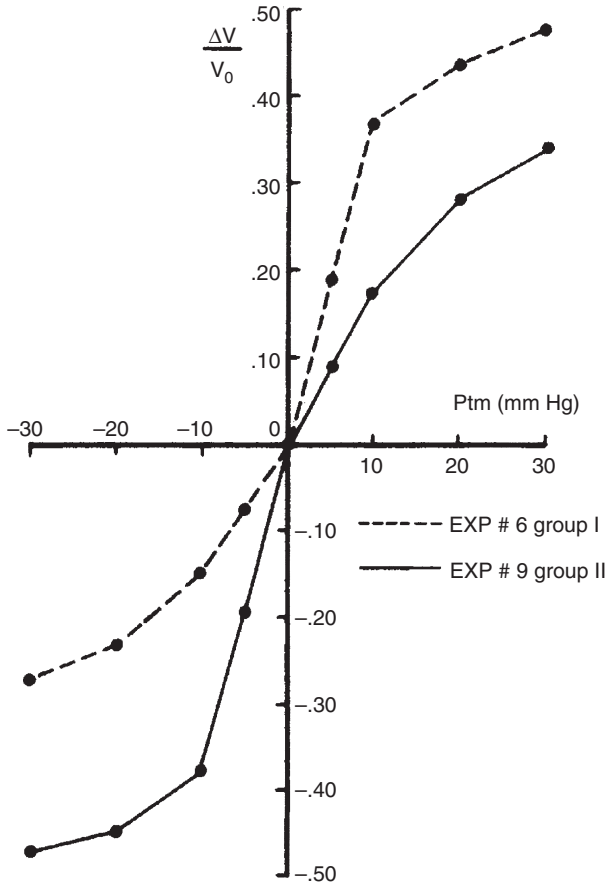

Figure 83-3 Transmural airway pressure *(Ptm)* as a function of normalized volume change ($\Delta V/V_0$) in a typical unventilated *(group I)* and ventilated *(group II)* trachea segment. *(From Penn RB, Wolfson MR, Shaffer TH: Effect of ventilation on mechanical properties and pressure-flow relationships of immature airways,* Pediatr Res *23:519-524, 1988.)*

In addition, ventilated tracheas showed greater resistance to airflow. The clinical implications of these studies include increased dead space, flow limitation, elevated airway resistance and work of breathing, and gas trapping.[61]

The mechanisms that precipitate the alterations in mechanical properties of the ventilated trachea are unclear. Preliminary studies of airway smooth muscle force generation are inconclusive, and further investigation is required. In light of the epithelial disruption demonstrated, it is possible that loss of an epithelial relaxant factor explains the intensive bronchoconstrictor response to inhaled agonists seen in infants with pulmonary dysfunction.[62,63] Focal abrasion and denudation of the airway epithelium after mechanical ventilation have been reported[61] and are illustrated in Figure 83-4. The cells of the airway epithelium play an important role in the modulation of airway smooth muscle. Through the release of both contractile and relaxant paracrine mediators, the epithelium modulates the tone of the underlying smooth muscle. Disruption of this epithelium may have a significant impact on airway function and sensitivity.[64,65]

Disruption of the muscle-cartilage junction may reduce the ability of the airway to resist compressive forces such as excessive supra-atmospheric pressures produced by infants with airflow obstruction. Pressure-induced alterations in the orientation of airway smooth muscle fibers may affect the force-generating capabilities or impair the ability of smooth muscle contraction to stiffen the airway and resist deformation. It also is possible that

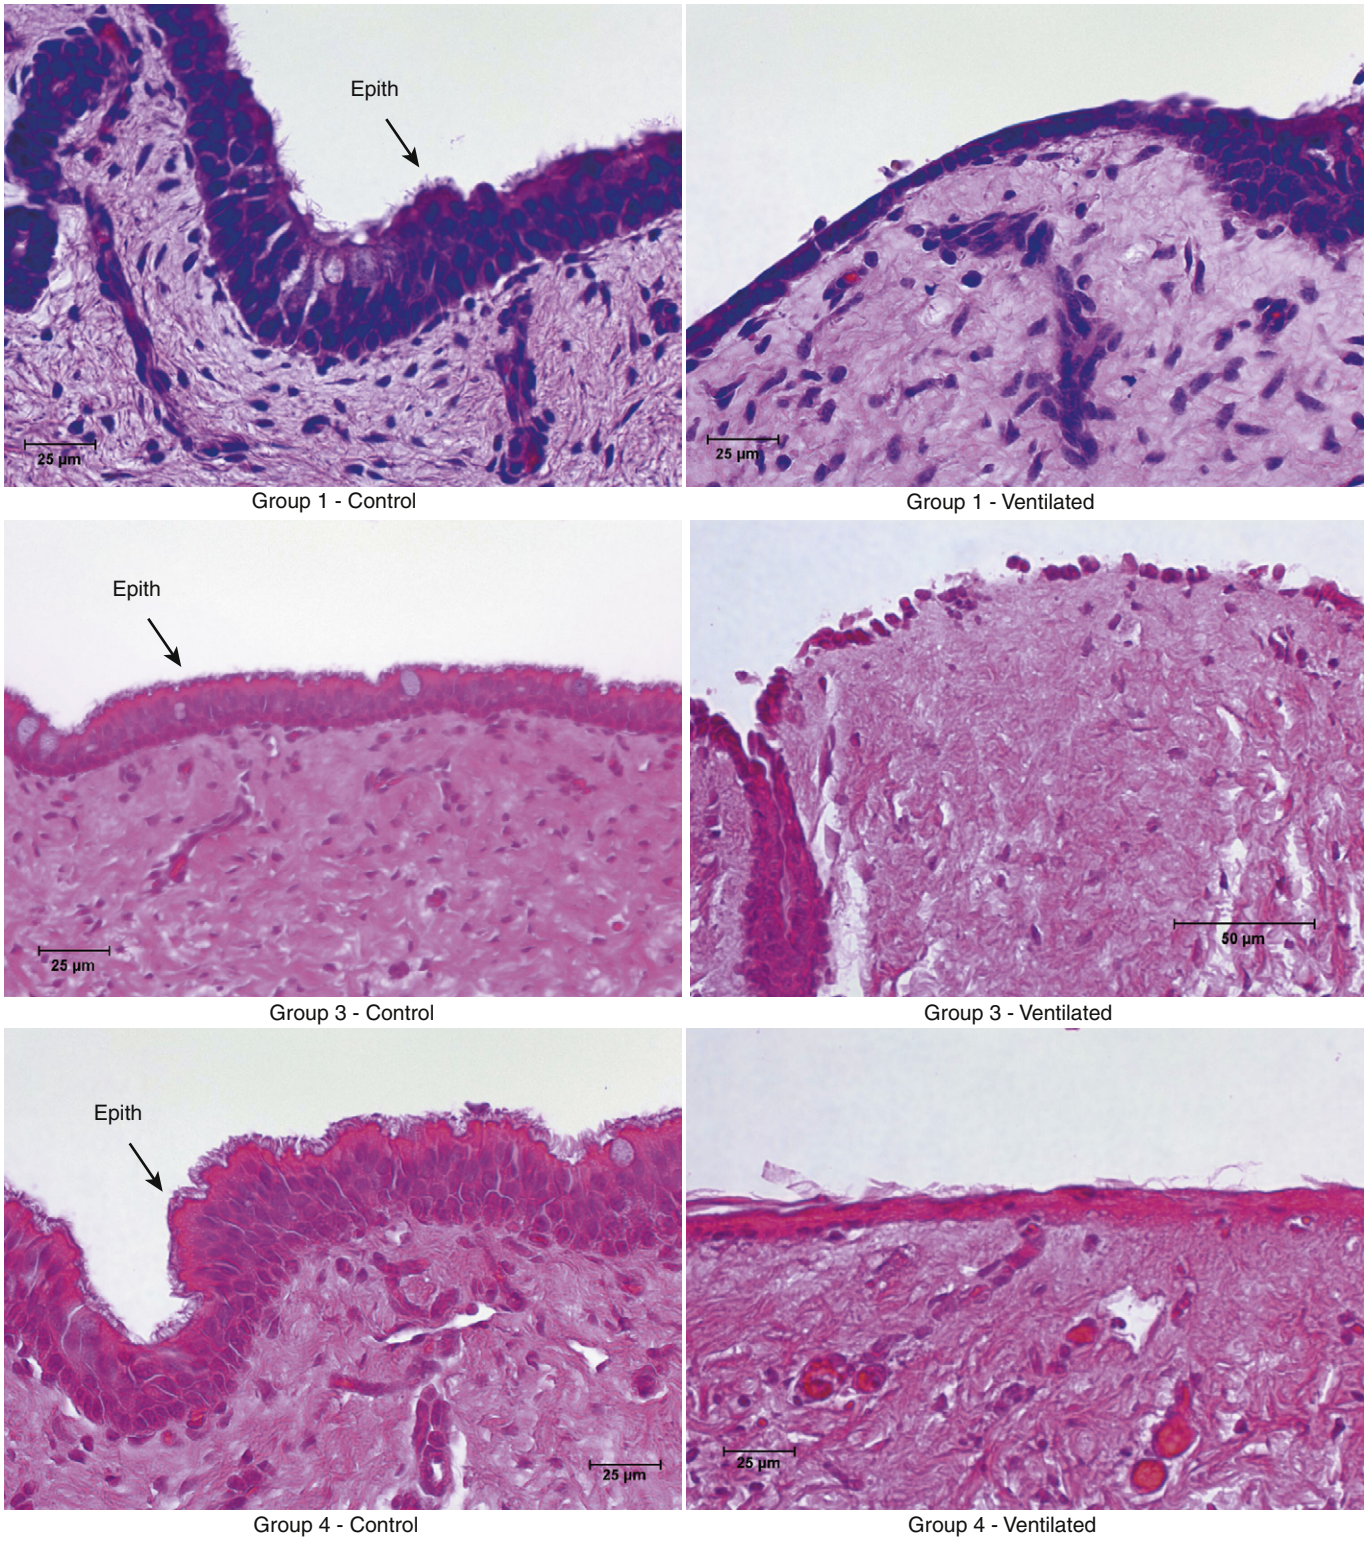

Figure 83-4 Effect of mechanical ventilation on epithelial lining of neonatal lamb trachea in four different age-groups: *group 1:* preterm at 110 to 116 days; *group 3:* preterm at 129 to 132 days; *group 4:* term at 149 to 157 days. (Term = 147 ± 3 days of gestation.) *Left panel:* Nonventilated control animals. *Right panel:* Lambs subjected to mechanical ventilation (mean airway pressure = 15 cm H_2O, duration = 2.8 hours). *(From Cullen AB, et al: The impact of mechanical ventilation on immature airway smooth muscle: functional, structural, histological and molecular correlates,* Biol Neonate *90:17-27, 2006.)*

pressure-induced alterations in the alignment of cartilage components (i.e., proteoglycan-collagen configuration) may attenuate the contribution of cartilage as a structural support for the trachea. In addition to pressure-induced tracheomegaly, histologic studies of ventilated neonatal human and animal lungs describe widening of the peripheral airways.[66,67] Apart from the qualitative assessment of dimensions, the effects of ventilation on the peripheral airways are not known. Presumably age-related and regional differences in the amount of cartilage, orientation, force-generating capabilities, and receptor sensitivity of airway smooth muscle may exacerbate the effect of ventilation on the relatively more compliant distal (as compared with proximal) airways. This effect would be further potentiated by a ventilatory schema wherein an inspiratory hold is produced by long inspiratory times. Long inspiratory times favor equilibration of pressures throughout the tracheobronchial tree, thereby increasing the length of time over which the highly compliant distal airways are subjected to barotrauma. Of note, however, high-frequency jet ventilation (HFJV) evaluated in preterm rabbit airways was associated with significant dimensional and mechanical deformation of tracheal segments, as well as an increased propensity for collapsibility after cessation of the ventilation.[68] Therefore ventilation techniques that attempt to minimize pulmonary barotrauma may potentially still have some deleterious effect on immature proximal airways.

Airway conductance of the adult tracheobronchial tree also may be affected.[69] It previously has been shown that increased muscle tone can increase the rigidity of the trachea in the full-term newborn lamb.[19] This finding suggests a mechanism whereby ventilation-induced alterations of the airway can be ameliorated: If the ability of airway smooth muscle to increase tone in response to pharmacologic stimulation is age- or region-dependent, then prophylactic treatment before ventilation may have differential effects on the proximal versus peripheral airways of the developing animal.

Both mechanical ventilation and chronic lung and airway disease have been associated with the presence of inflammatory mediators in airway aspirates. These mediators attract and activate neutrophils, which in turn generate additional free radicals, cytokines, and proteolytic enzymes such as elastase and collagenase. Previous studies have shown increased levels of TNF-α, endothelin-1 (ET-1), IL-6, IL-8, IL-1β, and IL-1 and decreased fibrinolytic activity in tracheal aspirates from infants in whom BPD and chronic lung disease subsequently develop. Additionally, the infants with BPD exhibit a prolonged neutrophil influx during the first week of life compared with infants with self-limited respiratory distress syndrome (RDS).[54] Thus substantial, chronic airway injury is associated with mechanical ventilation, necessitating elucidation of its pathogenesis to minimize further injury.

In a recent report, it was demonstrated that ultrasound imaging can provide insight into the mechanical properties of the developing airway.[70] Ultrasound imaging of the isolated tracheal segment allows for real-time assessment, with the following specific advantages: (1) airway dimensions can be assessed with the adhesions to surrounding tissue as well as blood supply and innervations intact; (2) static pressure-volume relationship data can be corrected with a more accurate resting volume calculation and without sacrifice of the preparation; and (3) stress-strain relationships can be recorded and analyzed during dynamic pressure pulses, which account for tissue kinetics and the trachea's elastic modulus. More important, an application of this methodology demonstrated that mechanical ventilation has a significant effect on both static and dynamic mechanical properties of the sheep neonatal trachea.[71] Furthermore, mechanical ventilation resulted in breakdown and thinning of the trachealis muscle boundary, as well as increased segment volume and thus anatomic dead space. These data serve as a standard for comparison to evaluate various "protective" alternatives to conventional mechanical ventilation with respect to preservation of airway function. In addition, with an indication of the time dependence of acute alteration in tracheal mechanical properties, future studies can correlate these trends with biomarkers from tracheal tissue samples and segment washings that reflect tissue damage and structural modeling.

CLINICAL ASSESSMENT OF AIRWAY FUNCTION

Modalities for evaluation of airway function in the pediatric population include measurement of lung function during tidal breathing or forced exhalation, radiography, fluoroscopy, and airway endoscopy. In combination, these assessment modalities can be used to identify and quantitate the predicted functional abnormalities found in preterm airways exposed to positive-pressure ventilation, including elevated resistance, decreased forced expiratory flow, airway hyperreactivity, and excessive central airway collapsibility. In addition, these diagnostic procedures have provided important insight into the effects of early injury on future airway growth and function and can be used to test the effectiveness of newer therapies. Evaluation of airway function is especially useful and should be considered in infants whose clinical course is not one of gradual improvement or is marked by frequent severe pulmonary exacerbations, and in infants who demonstrate stridor, chronic wheezing, or focal areas of chronic atelectasis or hyperinflation.

Pulmonary Function Profile

With the simultaneous measurement of respiratory pressures, volumes, and air flow, pulmonary mechanics can be monitored relatively noninvasively.[72] Pulmonary function profiles can be determined to assess initial disease etiology, response to therapy, and disease sequelae during follow-up.[73] For example, the pressure-volume relationship for a premature infant can identify the degree of respiratory function and monitor the response after surfactant administration. In addition, the evaluation of tidal breath pressure-volume relationships serves as a tool to optimize the parameters of mechanical ventilation. Over time, sequential assessments of pulmonary mechanics can be used to monitor progression or improvement in both lung and airway abnormalities.

Measurements of Airway Function During Tidal Breathing

Dynamic pulmonary compliance as measured by the esophageal balloon and pneumotachnometry technique is significantly lower in infants in whom chronic lung disease develops subsequently than in normal infants or those who recover uneventfully from neonatal respiratory distress.[73-75] Although these measurements reflect the elastic properties of the lung to some degree, they also are influenced by maldistribution of ventilation associated with regions having differing time constants (frequency dependence of compliance).[74] Thus dynamic compliance measurements in infants with chronic lung disease probably also reflect some degree of airway obstruction. Quasistatic methods of measuring respiratory system compliance in infants with BPD have verified that alterations in the elastic properties of the lung contribute significantly to the observed decrease in compliance.[76] Studies comparing static and dynamic compliance measurements in this group of infants, however, have not been performed. Thus it is not clear whether the improvement in dynamic compliance seen in infants with moderate to severe BPD studied longitudinally[73,75] represents a change in the characteristics of the lung parenchyma, or if it is reflective of a coexistent decrease in respiratory rate or improvement in airway obstruction. Of interest, both static and dynamic measurements of compliance have been shown to have predictive value regarding the development of BPD in mechanically ventilated preterm infants.[77,78]

Resistance measurements, including airway resistance as determined by plethysmography, pulmonary resistance measured by the esophageal balloon and pneumotachometry technique, and respiratory system resistance determined by the airway occlusion technique, are significantly elevated in infants with BPD.[73,75,79-81] When measurements of resistance or its reciprocal, conductance, have been made serially, values have approached normal over the first 2 to 3 years of life.[73,75] Longitudinal changes in resistance can reflect either resolution of airway obstruction or merely an increase in airway diameter related to growth. To eliminate the influence of growth or changes in lung volume on these measurements, investigators also have reported size-corrected values for resistance or conductance—namely, *specific conductance,* defined as the conductance divided by lung volume at functional residual capacity (FRC). Data reported in this way confirm the presence of airway obstruction in infants with BPD.[73,75] In the relevant study, although pulmonary resistance decreased to only one fourth of the original measurement over the first 3 years of life, specific conductance rose only minimally and remained below normal at the end of the study period. Arad and co-workers[82] found that specific conductance rose from 57% ± 7% of predicted in infancy to 90% ± 8% of predicted by the age of 5 to 7 years, although the children who required mechanical ventilation in infancy demonstrated air trapping and small airway obstruction at the time of the study.

Forced Expiratory Flow Measurements

Measurements of tidal mechanics include significant contributions of the nasopharynx, pharynx, and central airways. In a number of studies, either the rapid thoracic compression technique[79,83,84] or the rapid deflation technique[85,86] has been applied in infants with BPD to obtain information more reflective of small airway status, and to compare data obtained in infancy more easily with spirometric measurements made in routine testing performed later in childhood. Such studies also demonstrate significant airway obstruction in infancy, with evidence of incomplete recovery with growth. When maximum expiratory flow-volume (MEFV) curves were generated by the rapid deflation technique in a group of preterm infants during the acute phase of BPD, severe small airway obstruction as determined by a marked reduction in $Vmax_{25}$ was noted, and the shape of the MEFV curve was concave to the volume axis.[85] When patients with moderate BPD who weaned from mechanical ventilation before 5 months of age were studied longitudinally with the same technique, there was a gradual increase in $Vmax_{25}$ to approximately 40% of predicted by the age of 3 years.[86] By contrast, those patients who required extended periods of mechanical ventilation (>10 months) showed no increase in $Vmax_{25}$ over the same time period.

Similar evidence of airway obstruction has been demonstrated using the rapid compression technique.[79,83] Partial expiratory flow-volume (PEFV) curves were generated over the tidal range of breathing and quantitated by measuring maximal flow at FRC ($Vmax_{FRC}$) in young infants with BPD. Furthermore, the separation between tidal flow and forced flow curves was interpreted as a measure of expiratory flow reserve.[83] The shape of the PEFV curve typically was concave to the volume axis, and expiratory flow reserve was smaller than in infants with normal lungs. Size-corrected forced expiratory flows were only half those of normal controls, and did not increase by the age of 14.5 to 22 months.[83] Furthermore, the slope of the regression equation for $Vmax_{FRC}$ versus age was lower in the BPD group than in normal infants. These data suggest that early exposure to positive-pressure ventilation and high concentrations of oxygen not only caused early airway damage but also interfered with subsequent normal airway growth.

Values of $Vmax_{FRC}$ usually have been considered to be representative of small airway function. More recently, however, studies have shown that central airway collapsibility (i.e., tracheomalacia or bronchomalacia) can cause a marked reduction in values of $Vmax_{FRC}$ and appear graphically similar to small airway obstruction.[84,87] Panitch and co-workers[84] studied five infants with BPD who had bronchoscopic evidence of tracheobronchomalacia using the rapid compression technique. As shown in Figure 83-5, when continuous positive airway pressure (CPAP) was applied to the airway opening, an incremental increase in $Vmax_{FRC}$ was observed. Additionally, in several subjects, the shape of the PEFV curve changed from concave to convex, suggesting that CPAP acted as an intraairway stent to prevent collapse. Furthermore, the ratio of forced-to-tidal flows at midexpiration, a reflection of expiratory flow reserve, increased with application of CPAP. Thus it is possible that reductions in $Vmax_{FRC}$ previously ascribed to small airway damage in infants with BPD may also represent a component of central airway injury.

Assessment of Airway Reactivity

Airway reactivity, as determined by bronchodilator responsiveness, has been well documented in infants with BPD using assessments of both tidal mechanics and forced expiratory flows. Acute decreases in pulmonary, respiratory system, and airway resistance ranging from 23% to 48% have been reported in response to a variety of β-agonist and anticholinergic drugs.[80,81,88-92] The magnitude of this response was even more dramatic when forced flows were tested: Kao and colleagues reported an increase of 86% over baseline values of $Vmax_{FRC}$ in 15 infants with BPD at a mean age of 15.8 weeks after treatment with metaproterenol, and of 45% over baseline after treatment with atropine.[80] Similarly, Motoyama and associates[85] found an increase of 214% over baseline values of $Vmax_{25}$ after isoetharine inhalation in 32 intubated and mechanically ventilated infants. Bronchodilator responsiveness could be demonstrated in infants as young as 26 weeks postconceptual age, and as early as at 12 days postnatal age.

Other investigators have also demonstrated early evidence of bronchodilator responsiveness. Gomez-Del Rio and associates[90] found significant improvement in pulmonary resistance in 30 mechanically ventilated preterm infants younger than 20 days of age after isoetharine inhalation. The youngest was only three days of age, and gestational ages ranged from 27 to 34 weeks. Denjean and co-workers[88] measured significant decreases in respiratory system resistance after salbutamol inhalation in ventilator-dependent preterm infants at 13.3 ± 4.9 days of postnatal age. These observations of early bronchodilator responsiveness suggest that loss of epithelial modulation, as well as airway smooth muscle hypertrophy, probably contribute to airway hyperreactivity seen in chronically ventilated infants.

Radiographic Evaluation of Airway Injury

Acquired tracheomalacia has been evaluated fluoroscopically and by computed tomography (CT). Sotomayor and colleagues[93] used fluoroscopy in anteroposterior, oblique, or lateral views to document central airway collapse in infants with BPD who required mechanical ventilation for periods of 3 weeks to 4 months. These investigators also used fluoroscopy to determine the amount of distending pressure required to maintain airway patency in those infants. McCubbin and co-workers[94] studied central airway collapse in 10 infants (3.3 to 20.5 months of age) with BPD, using cine-CT. A group of seven children of similar age with glottic or supraglottic obstruction but no evidence of lower airway disease was used as a control group. The median percent decrease in airway cross-sectional area during exhalation in the BPD group was 63.5% (range, 23% to 100%), whereas that of the

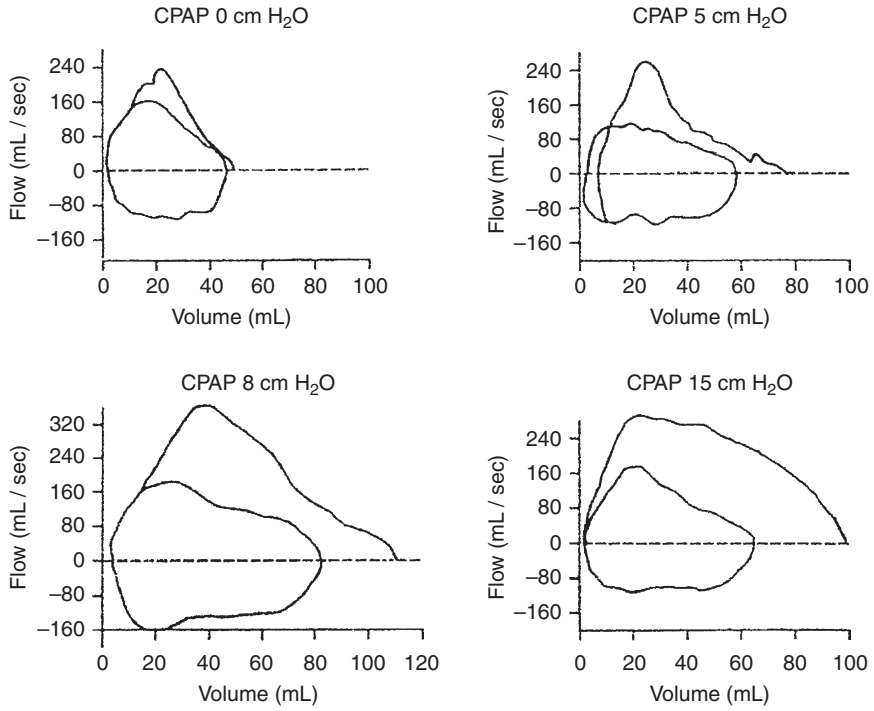

Figure 83-5 Series of partial expiratory flow-volume curves from an infant with bronchopulmonary dysplasia (BPD) and bronchoscopically documented tracheobronchomalacia, showing the effect of increasing levels of continuous positive airway pressure (CPAP). Off CPAP, the curve shape becomes straight, and at higher levels of CPAP, it becomes convex. At each level of CPAP, expiratory flow reserve increases as well. Values for maximal flow at functional residual capacity (V_{maxFRC}) at each level of CPAP are 26 mL/second at 0 cm H_2O; 53 mL/second at 5 cm H_2O; 120 mL/second at 8 cm H_2O; and 204 mL/second at 15 cm H_2O. *(From Panitch HB, et al: Effects of CPAP on lung mechanics in infants with acquired tracheobronchomalacia,* Am J Respir Crit Care Med *150:1341-1346, 1994.)*

control group was only 9% (range, 5% to 13%). This significant difference in collapsibility was present in a short segment of airway in six children and was diffuse in the other four patients. Because narrowing was not always diffuse, these authors speculated that the underlying cause of collapse must include local sites of injury as well as transmural pressure changes.

Bhutani and associates[58] described roentgenographic evidence of acquired tracheomegaly in very preterm neonates (i.e., with birth weight less than 1000 g) who had received mechanical ventilatory support. Increases in tracheal width at the level of the thoracic inlet and carina were present when compared with individually weight-matched nonventilated control infants. These workers speculated that the persistent airway dimensional deformation seen in those infants resulted in increased anatomic dead space and contributed to carbon dioxide retention after extubation.

The ability to evaluate small airway abnormalities with conventional bronchographic agents has been limited by poor resolution of the bronchioles at the secondary lobule level.[87] Because of the high density, low surface tension, and radiopacity of the perfluorochemical liquid perflubron, it has been used as a bronchographic contrast agent for high-resolution computed tomography (HRCT) direct visualization of the airways through the centrilobar bronchioles and their first-order branches, with definition within a millimeter of the lung surface.[96,97]

Radiographic studies of the perflubron-filled lungs of animals and humans with congenital diaphragmatic hernia have proved informative in qualitative delineating the degree of pulmonary hypoplasia and in identifying the distribution and elimination pattern of the perfluorocarbon liquid.[98,99] Regional differences in perfluorocarbon clearing, detected on x-ray studies, were related to localized bronchial obstruction.[98]

Endoscopic Evaluation of Airway Injury

Airway endoscopy provides for both diagnosis and treatment of anatomic lesions of supraglottic, glottic, and subglottic regions, as well as of the trachea and bronchi down to the segmental level.[100-106] Two recent prospective studies of infants who required intubation in the newborn period found that the incidence of moderate to severe subglottic stenosis was 9.8% and 12.8%, respectively,[101,102] but the incidence of other fixed anatomic lesions is unknown. Endoscopy of the airway was selected when infants presented with acquired lobar emphysema, persistent lobar atelectasis, or unexplained medical failure.[104,105,107-110] Typically, with lobar emphysema, the right lower lobe and right middle lobes were more commonly affected.[104,105,107-109,111]

Direct visualization of the airways during spontaneous breathing is the most direct method of identifying central airway collapse. Although both rigid and flexible fiberoptic bronchoscopic techniques are available for the study of pediatric airways, rigid bronchoscopy must be performed while the patient is under general anesthesia. Often the child receives assisted ventilation during the procedure. Consequently, the patient's effort of breathing is decreased, and exhalation may be completely passive. Thus many cases of central airway collapse would be underdiagnosed with use of this approach.

By contrast, flexible bronchoscopy usually is performed using conscious sedation. The patient breathes spontaneously but must breathe around the bronchoscope as well. Variation in expiratory effort can influence the degree of intrathoracic airway collapse. Because of these technical considerations and the lack of universally agreed-on criteria, the frequency of diagnosis of central airway collapse will vary from center to center. In order to circumvent these inconsistencies, some researchers have based the diagnosis on extent of airway narrowing observed during

exhalation.[84,106,112] Mair and Parsons have recommended a grading system based on percent of airway narrowing present at end-expiration during spontaneous respiration, together with an increase in the membrane-to-cartilage ratio.[112] Other workers have defined tracheobronchomalacia as collapse resulting in either less than 50%[84,113] or less than 75%[93] obstruction during spontaneous breathing, with no mention of changes in the proportion of membrane relative to cartilage.Acquired extrathoracic tracheomalacia also has been described in patients with BPD.[102]

To date, most quantitative studies of the inherent characteristics of the developing airway wall have required excision of an airway segment or surgical creation of an isolated segment. A more recent laboratory study demonstrated that airway wall characteristics at various collapsing pressures and attendant changes in stiffness after smooth muscle stimulation could be quantitated bronchoscopically from airway pressure-area relationships.[114] Neonatal lamb tracheal segments were suspended over hollow mounts in a buffer-filled chamber and then subjected to a range (0 to –4.0 kPa) of pressures to determine wall stiffness under collapsing forces before and after stimulation of the trachealis with methacholine. Luminal images were recorded through a 3.6-mm flexible bronchoscope under the same conditions, and the cross-sectional area was calculated from data thus obtained. Both pressure-volume and pressure-area relationships detected significant changes in airway wall stiffness after methacholine administration ($p < .002$), with similar magnitudes of change for both quantities. In a subsequent study, this same method was reported to quantitate airway stiffness in vivo.[115] The speculation is that this technique may be clinically useful to quantitate airway collapsibility and can differentiate whether deformation is secondary to effort or to intrinsic abnormalities of the airway wall.

SUMMARY AND FUTURE DIRECTIONS

Considerable progress has been made in characterizing developmental (preterm, newborn, and adult) differences in airway physiology with respect to pressure-volume and pressure-flow relationships, the effects of mechanical ventilation, and pharmacologic stimulation. In this regard, studies conducted using in vivo, in vitro, and muscle bath preparations have provided valuable insight into how the very premature infant may differ from the later-term and full-term neonate with respect to airway function. Nevertheless, little is known about how positive-pressure ventilation alters the cellular, biochemical, and molecular constituents of the components of the immature airway, and why mechanical ventilation is associated with the development of severe airway dysfunction in some premature infants but not in others. Ultrastructural studies that assess airway damage with greater sensitivity and biochemical and molecular analysis that can detect alterations in collagen muscle and connective tissue composition would improve current understanding of the pathogenesis of pressure- or stretch-related injury. Data from such studies, coupled with clinical results of pulmonary function testing and further characterization of airway anatomy, would be expected to elucidate basic biologic development of the lungs, facilitating continual advancement of neonatal and pediatric clinical respiratory management.

84 Regulation of Lower Airway Function

Richard J. Martin and Musa A. Haxhiu

Significant progress has been made in elucidating development of lower airway structures and regulation of their function. During early development airway smooth muscle differentiates from the mesenchyme of the primordial lung and envelops the emerging bronchial tree.[1] Airway smooth muscle at this early stage provides phasic rhythmic contractility that is thought to propel lung fluid distally and enhance lung development. Neural structures emerge in parallel to airway muscle, and their functional roles are rapidly integrated such that during postnatal life tonic, rather than phasic, contractile and relaxant functions dominate.[2]

Although it is well accepted that the potential effect of the lower airway on prenatal and postnatal lung function is considerable, our understanding on the link between neurotransmitter specific networks involved in the regulation of airway function is incomplete. Furthermore, when compared with healthy and diseased adult airways, little attention has been paid to the diverse neural mechanisms that regulate airway caliber in the perinatal period. This subject has gained considerable interest because of the injurious effects of increased inspired oxygen and positive pressure ventilation on neonatal airway function. It is therefore important to gain greater understanding of the normal maturational changes exhibited by airway smooth muscle contractile and relaxant mechanisms superimposed on the immature structural elements that compose the airways.[3]

THE HIERARCHIC NEURAL REGULATION OF THE LOWER AIRWAYS

Airway-Related Vagal Preganglionic Neurons: Cholinergic Control of Lower Airways

During development most studies on neural control of the airways have focused on the regulation of smooth muscle, even though many of the same principles apply to control of mucus production, and blood flow in the airways.[4] In general, at any given age neural control of airway functions (Figure 84-1, *level 4*) involves integrated networks along the neural axis that funnel information to tracheobronchopulmonary effector units via airway-related vagal preganglionic neurons (AVPNs) in the medulla oblongata.[5,6] The AVPNs are the final common pathway from the brain to the airways and transmit excitatory signals to the intrinsic tracheobronchial ganglia that are part of the network for feedback control *(level 3)*.

The AVPNs innervating airways, from the extra thoracic trachea[5] to the most distal bronchiole,[7,8] arise mainly within the

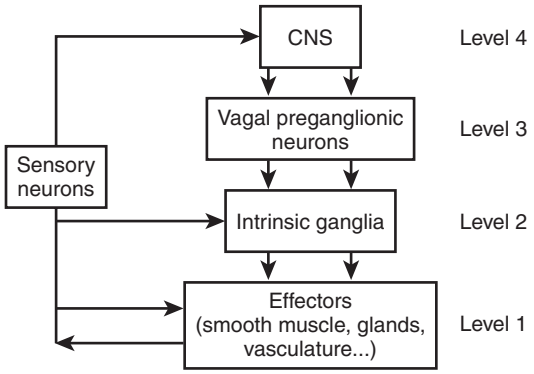

Figure 84-1 General scheme illustrating the organization of autonomic parasympathetic control of airway functions. Central nervous system (CNS) cell groups *(level 4)* regulate the activity of airway-related vagal preganglionic neurons (AVPNs) *(level 3)* that present the final common pathway to the airways. Projections from the AVPNs' synapse on intrinsic ganglionic neurons within the airway walls *(level 2)*. These ganglia give rise to postganglionic fibers that control the function of specific effector targets (i.e., airway smooth muscle, mucus glands, and blood vessels). Sensory feedback for these systems occurs via sensory fibers originating from sensory ganglia (nodose and jugular ganglionic neurons). These fibers innervate sensory receptors and transmit information from the airways to the CNS. They modulate the activity of the AVPNs through the central multisynaptic pathways and may affect function of effector organs via two ill-defined local networks that include axon reflex responses *(level 1)* and sensory innervation of intrinsic airway ganglia *(level 2)*.

brain stem from the rostral nucleus ambiguus (rNA) and to a lesser degree from the rostral portion of the dorsal motor nucleus of the vagus (DMV). These cholinergic cells (see Figure 84-1, *level 3*) that express vasoactive intestinal peptide (VIP)[9] and brain-derived neurotrophic factor,[10] transmit cholinergic signals to intrinsic tracheobronchial ganglia[11] (see Figure 84-1, *level 2*). The individual innervation of postganglionic neurons from the vagus nerve gives rise to postganglionic fibers that regulate functions of specific effector targets (see Figure 84-1, *level 1*). Varicose fibers from these postganglionic neurons are randomly distributed around airway smooth muscle cells, submucosal glands, and arterial blood vessels. In the postnatal period neuronal innervation is already well developed and choline acetyltranferase, a specific marker for cholinergic traits that synthesizes acetylcholine, appears in vagal preganglionic neurons, postganglionic neurons, and postganglionic fibers.

Signals transmitted through preganglionic nerves are relayed, filtered, integrated, and modulated by intrinsic ganglionic neurons before reaching their airway neuroeffector sites through postganglionic axons. This structural organization could explain the strong effects of a relatively small number of vagal efferent fibers on coordinated reflex changes in airway smooth muscle tone, submucosal gland secretion, and blood flow along the tracheobronchial tree. Each ganglion, located in proximity to its effector system, possesses a relatively large number of neurons that can be considered as an expanded parasympathetic, preganglionic efferent motor system. Postnatally, cholinergic innervation is the principal tonic input to airway smooth muscle bundles, and serves to protect the airways from collapsing during expiration-induced compressive narrowing.[12]

The postganglionic cholinergic innervation does not exclude the probability that some of the AVPNs also provide, to a lesser degree, direct innervation of airway smooth muscle bundles,[1] epithelial cells, and the alveolar interstitium of the lung, because ganglia are absent altogether from the bronchial subepithelial space and the most distal gas exchanging units.[7] These observations suggest that AVPNs may be involved in regulating the release of biologically active molecules from epithelial cells, that is, activation of nitric oxide synthase (NOS) and release of nitric oxide (NO), that might oppose excessive cholinergically mediated airway contractile responses at peripheral sites (see later). Furthermore, cholinergic mechanisms are involved in controlling the conductivity of the most distal airways[13] and tissue resistance[14] in early life by influencing smooth muscle tone, lung interstitial pericytes, and alveolar myofibroblasts.[15] However, it is not clear whether individual AVPNs provide parallel simultaneous innervation to airway smooth muscle, submucosal glands, and local blood vessels. Alternatively, it is also possible that groups of functionally selective AVPNs may exert a highly coordinated control over multiple airway functions by central mechanisms that synchronize their output to individual effectors. Presumptive gap junctions between identified AVPNs may serve to synchronize their electrical activity in the rNA of the brain stem. Alterations in central mechanisms that mediate such synchronization could cause regional differences in airway reflex responses, expressed as inhomogeneity in ventilation. For example, in induced bronchoconstriction some branches of the airway may totally close while others remain normal. Future studies should address the question of the central mechanisms and origin of synchronization and asynchrony of bronchoconstrictive reflex responses during development.

Acetylcholine, released from cholinergic nerve endings, may affect lower airway function via signaling through muscarinic and nicotinic acetylcholine receptors (nAChRs) (Figure 84-2).

Muscarinic Receptor Signaling

Muscarinic receptors mediate the responsiveness of airway smooth muscle, submucosal glands, and blood flow to acetylcholine during early development and adult life. Studies in the

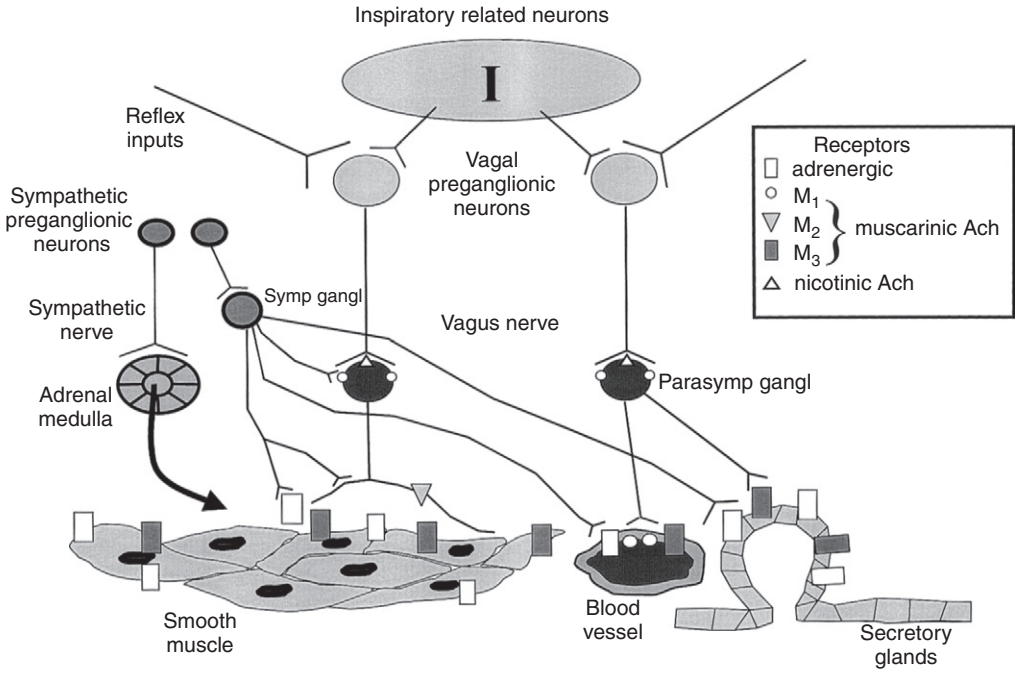

Figure 84-2 Schematic representation of the major parasympathetic, or cholinergic (contractile), and sympathetic, or adrenal adrenergic (relaxant), pathways that innervate (or regulate) airway smooth muscle. Efferent output from vagal preganglionic neurons to airways is influenced by various afferent reflex inputs, and inspiratory-related neurons (I) in the brain stem. Excitation of parasympathetic efferents also increases the output of submucosal secretory glands and results in relaxation of adjacent vascular structures. See text for the functional roles of the various muscarinic (cholinergic) receptor subtypes.

developing airways and porcine lung from birth to adulthood reveal maturational changes in muscarinic receptor subtypes (M_1, M_2, M_3) that may explain pharmacologic changes during development.[16] These muscarinic receptor subtypes, coupled to the family of G proteins, mediate airway contractile responses and their modulation, although there are considerable interspecies differences in their roles.[17] M_1 receptors are largely present on neuronal tissue and ganglia, and the selective M_1 receptor antagonist pirenzepine reduces the contractile response to vagal stimulation in newborn animals.[18,19]

M_2 receptors are located on prejunctional postganglionic cholinergic fibers in airway smooth muscle in some species, and exhibit an autoinhibitory action whereby the quantal release of ACh in response to nerve stimulation is reduced due to feedback inhibition.[20] Sinus node M_2 receptors also mediate the bradycardia seen with vagal stimulation. Selective blockade, or down-regulation, of M_2 receptors may enhance vagally mediated bronchoconstrictor responses and cause a reduction in the bradycardia response. M_2 autoinhibitory actions may be reduced or absent in the newborn because blockade of M_2 receptors does not enhance bronchoconstrictor responses to vagal stimulation.[19] The potential role of lung injury and infection in modulating physiologic responses coupled to M_2 receptors in the newborn remains to be explored.

M_3 receptors are present on smooth muscle and mucus glands and airway epithelial cells, where they initiate the events leading to smooth muscle contraction, airway narrowing, and mucus secretion.[21,22] In the newborn, the density of M_3 receptors has been reported to be similar to that in the adult; however, they do not appear to be tightly coupled to G-protein signal transduction mechanisms that lead to smooth muscle contraction.[18] In vivo studies show that M_3 receptor antagonism decreases bronchoconstrictor responses to vagal stimulation in the newborn that, at low dosages, does not affect the bradycardic response.[19] Among the many unanswered questions in the newborn are the extent of receptor subtype differentiation in human neonates, investigation of G-protein signal transduction, the role of M_2 autoinhibitory receptors in modulating airway tone, and the possible effect of inflammatory lung disease on muscarinic receptor regulation and its pharmacologic manipulation.

Nicotine Receptor Signaling

nAChRs are ligand-gated ion channels formed by five homologous subunits that are involved in processes including signal transduction, proliferation, and apoptosis. The developmental role of these receptors and their role in pathology of lower airways during development, however, is unclear. Nicotine AChRs are composed of 12 subunits that play the important role in mediating ganglionic transmission to their natural ligand acetylcholine, or transmitting effects of nicotine and nicotine-like substances. During ontogeny, nonneuronal and neuronal nAChRs undergo changes in distribution and subunit composition. Nonneuronal expression of nAChR subunits may precede functional innervation and then could undergo changes in distribution on the surface of cells. Airway-related vagal preganglionic neurons express multiple nAChRs subunits.[23] The β4 subunits are also abundantly expressed by ganglionic cells, forming acetylcholine-binding sites with α3 or α4, α5, or α7 subunits as pentameric receptors. In the lungs, nAChRs are found in a variety of nonneuronal locations, such as respiratory epithelial, mesenchymal, and collagen-producing cells. Maternal nicotine exposure up-regulates collagen gene expression that may explain the observed alterations in lung mechanics in the infants of mothers who smoke during pregnancy.[24] In these infants postnatal exposure to environmental smoke may exacerbate pediatric respiratory disease and possibly[24,25] predispose infants to sudden infant death syndrome (SIDS).

Vagal Afferent Sensory Fibers Innervating the Lower Airways

The bronchopulmonary sensory receptors are specialized units for detecting changes in chemical, mechanical, or thermal stimuli. They originate from the bipolar airway vagal afferent neurons that are located in the nodose and jugular ganglia and participate in reflex events. Sensory fibers affect function of lower airway effector units via a local network that includes axon reflex responses. Endogenous substance P released from sensory nerve endings (i.e., C fibers that are mainly nonmyelinated nerve terminals), facilitates synaptic transmission in airway postganglionic neurons,[26] suggesting the presence of control mechanisms within the tracheobronchial system, that also reflexly influence activity of AVPNs. Furthermore, afferent nerve endings (i.e., C fibers) are also believed to be responsible for mediating local axon reflexes and neurogenic inflammation via release of neuropeptides such as substance P,[27] other members of the neurokinin family, and activation of neurokinin receptors (i.e., NK-1, NK-2, NK-3R) or calcitonin gene-related peptide (CGRP).

Vagal Afferent Sensory Fibers Controlling Discharge of AVPNs

The central portion of sensory neural fibers enters the brainstem through the solitary tract and make synapses with the second-order nucleus tractus solitarius (NTS) neurons that project to the AVPNs. Excitatory signals arise from bronchopulmonary rapidly adapting lightly myelinated receptor afferents or nonmyelinated C-fiber terminals via release of glutamate that activates AMPA receptors expressed by these NTS neurons.[28] Processed information is then transmitted to AVPNs via the glutamate-AMPA signaling pathway, and from the AVPNs to the bronchopulmonary effector system through acetylcholine release. The strength of bronchoconstrictive reflex responses can be increased by stimulation of peripheral chemoreceptors, but attenuated by multiple peripheral inputs, such as those from myelinated pulmonary stretch receptors, somatosensory afferents, and baroreceptors. Furthermore, central nervous system (CNS) cell groups that project to the AVPNs, such as GABAergic, serotonergic, and catecholaminergic pathways, inhibit cholinergic outflow to the airway, via hyperpolarization of AVPNs.[28] Catecholaminergic pathways also affect airway smooth muscle tone, mainly via adrenergic receptor subtype expressed by airway effector cells at prejunctinal or postjuctional levels.

Sympathetic Control of Lower Airways

Extrinsic sympathetic innervation of airway smooth muscle is highly species specific, and in airway smooth muscle in humans, direct sympathetic innervation appears to be lacking (Figure 84-3). Nevertheless, circulating catecholamines activate airway adrenoreceptors to exert specific actions that affect smooth muscle contractile function.[29,30] β-Adrenergic responses in airway smooth muscle are composed of two inhibitory actions: first, relaxation of airway smooth muscle mediated by airway β_2-receptors that are coupled to the stimulatory G-protein (Gs) and adenylate cyclase; and second, inhibition of ACh release from postganglionic vagal axons through prejunctional α_2-adrenergic and β_1 receptors in some species.[31] Activation of β-adrenergic receptors is the pharmacologic basis for neonatal bronchodilator therapy. Maturational studies have demonstrated that β-adrenergic receptors in lung tissue increase with advancing gestation and subsequent postnatal development, but this may be more important for their role in surfactant synthesis and release.[32,33] The airway relaxant response to β-adrenoreceptor stimulation actually appears to decrease with advancing maturation, and several mechanisms including greater muscarinic antagonism of

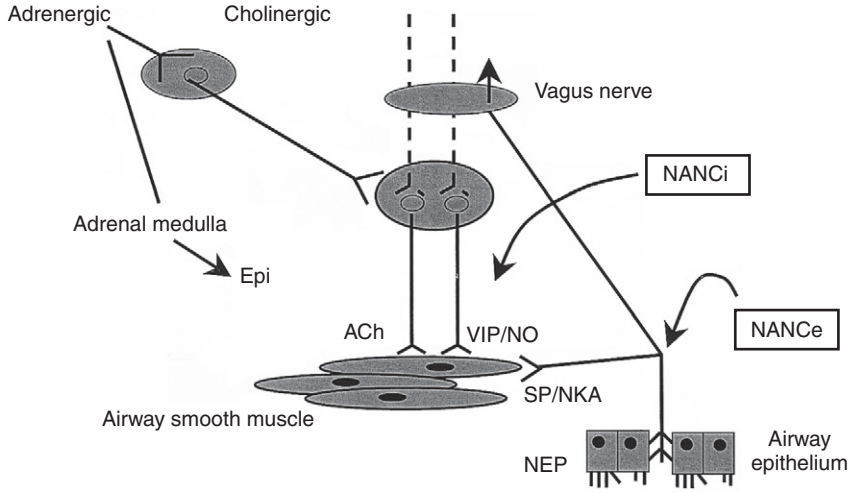

Figure 84-3 Representation of the nonadrenergic noncholinergic (NANC) innervation of airway smooth muscle and related epithelium that complements traditional cholinergic and adrenergic pathways. The inhibitory component of this system (NANCi) appears to be mediated primarily by release of nitric oxide (NO) and vasoactive intestinal peptide (VIP). NANC excitatory mechanisms (NANCe) are initiated by release of neuropeptides such as substance P (SP) and neurokinin A (NKA) from C-fiber afferent nerve endings, and this is modulated by the neuropeptide degrading enzyme, neutral endopeptidase (NEP), in epithelial cells.

β-receptor responses and attenuated expression of M_2 muscarinic receptors have been proposed.[34-36]

The second category of adrenergic responses is attributed to α-adrenoceptors, of which both α_1- and α_2-subtypes play a role. Available data indicate that in adult humans α-adrenergic contractile responses of airway smooth muscle are weak or absent, although this may not hold true for the newborn. A potential role for α-adrenergic receptors in the control of airway smooth muscle in newborn infants with bronchopulmonary dysplasia is supported by observations in preterm infants with chronic lung disease in whom ophthalmic application of the α_1-adrenergic agonist phenylephrine resulted in an increase in total pulmonary resistance and a decrease in compliance.[37] The deterioration in lung mechanics was attributed to α_1-receptor–mediated contraction of airway smooth muscle. Furthermore, adrenergic agonists having mixed α- and β-receptor actions cause airway smooth muscle contraction in newborn puppies,[38,39] and both α_1- and α_2-adrenoreceptors appear to be involved in mediating the response. Neonatal porcine tracheal smooth muscle does not display a contractile response to norepinephrine,[40] a finding similar to that of the adult.[41] Nevertheless, infusion of norepinephrine in newborn pigs increases lung resistance reminiscent of the adult response. In the piglet the contractile effects of norepinephrine are evident in parenchymal tissue, suggesting that circulating catecholamines may exert an action on gas exchange, at least in this species.[40] The implications of the mentioned studies for human infants remain to be seen; however, they may be part of a previously unappreciated component of the pulmonary response to the surge of systemically released catecholamine at parturition.[42] α_2-Adrenergic receptors are present in preganglionic and postganglionic nerve terminals as well as nonmyelinated C-fibers. Their activation inhibits release of ACh and substance P (SP), implicating multiple neurotransmitter systems.[43]

Nonadrenergic Noncholinergic Control of the Lower Airways

Rather than representing a separate pathway for modulation of airway caliber, the nonadrenergic noncholinergic (NANC) system comprises both inhibitory and excitatory mechanisms modulated by several neurotransmitters located in intrinsic ganglia and their fibers (see Figure 84-3). Reference to noncholinergic (i.e., NANC) innervation reflects the neurotransmitters known *not* to mediate its effects. The system is highly species specific, but has been identified in human airways. The NANC inhibitory component of vagal innervation[44] is demonstrated in vivo and in vitro by measuring the response to vagal stimulation or to electrical field stimulation, after muscarinic and β-adrenergic effects on airway smooth muscle are blocked by atropine and propranolol; then airway tone is elevated by an infusion of contractile agonist (e.g., serotonin or histamine).[29] Under these conditions stimulation of vagal preganglionic axons causes bronchodilation. Vasoactive intestinal peptide was initially proposed as the primary neurotransmitter of the NANC system. Mice lacking the VIP gene show airway hyperresponsiveness and airway inflammation, partially reversible by VIP.[45] Subsequently, NO was also shown to act as a NANC neurotransmitter, suggesting involvement of multiple substances and molecules in airway smooth muscle relaxation with considerable interspecies variation[46] (Figure 84-4).

Limited information is available about the ontogeny of this system in the airways. Activation of vagal preganglionic axons results in a NANC-mediated bronchodilation in newborn feline airways, a response that is eliminated by ganglionic blockade with hexamethonium, confirming the efferent nature of the response.[47] Comparison with the mature response is confounded by the necessity of infusing an agonist to measure a response, and the possibility that neonatal and adult airways may possess different sensitivities to the contractile agonist. NANC inhibitory innervation also appears to be functional in young guinea pigs and rat pups.[48] In some species NANC inhibitory responses undergo significant developmental changes; for example, NANC relaxation responses are not present in rabbits until 2 weeks of age.[49] Interestingly, allergen sensitization significantly reduced the NANC response at 2, 4, and 12 weeks of age,[49] suggesting that host or environmental factors may alter the maturation of the inhibitory NANC system and predispose to airway reactivity. The NANC inhibitory system has not been explored in human neonatal airways; data on other airway neurotransmitters suggest that it might be expected to be present.[50]

NO has received considerable attention for its ability to reverse persistent pulmonary hypertension of the newborn, and this has largely overshadowed investigation of its role in control

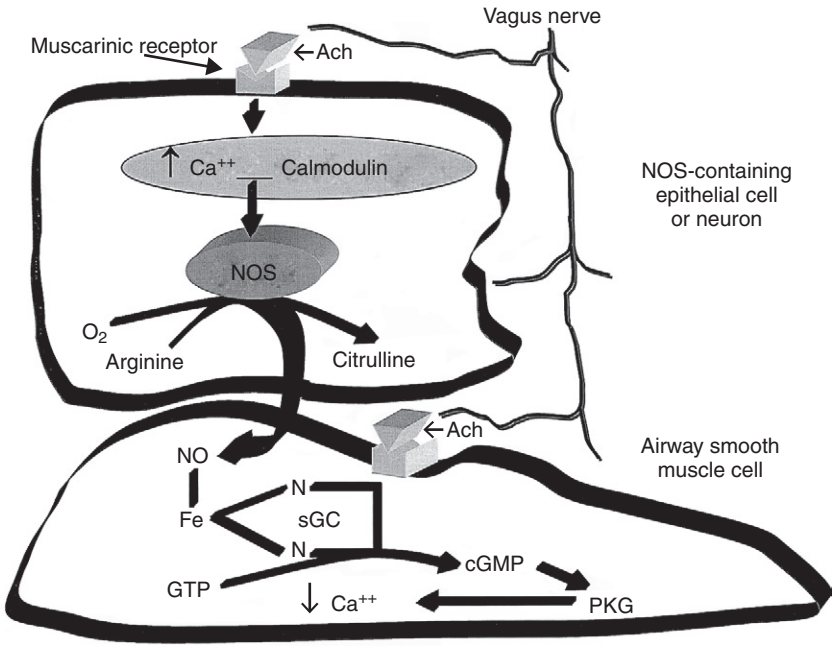

Figure 84-4 Diagrammatic representation of the nitric oxide cyclic guanosine monophosphate (NO-cGMP) pathway that mediates airway smooth muscle relaxation. NO synthase (NOS)–containing epithelial cells or neurons (as well as airway smooth muscle cells) are innervated by cholinergic fibers and express muscarinic receptors. Activation of these NOS-containing cells results in production of NO (from its L-arginine substrate), which diffuses into the smooth muscle layer and interacts with the heme moiety of soluble guanylyl cyclase (sGC), leading to intracellular accumulation of cGMP. This causes activation of protein kinase G (PKG), which in turn causes a decrease in inositol 1,4,5-triphosphate ($InsP_3$)–stimulated elevation of intracellular Ca^{2+} and consequent smooth muscle relaxation.

of airway smooth muscle. Nevertheless, some evidence indicates that expression of neuronal NO synthase is developmentally regulated, declining during late gestation, but subsequently increasing postnatally in the rat.[51] In developing sheep lungs, all three isoforms of NO synthase are expressed in airway epithelium and so might be expected to modulate underlying contractile responses.[52] It has been shown that release of endogenous NO from airway epithelium opposes cholinergically mediated contraction of piglet tracheal smooth muscle.[22] This phenomenon decreases with advancing postnatal age, requires an intact epithelium, and correlates with a relative up-regulation of M_3 muscarinic receptors in airway epithelium of the youngest animals. In the newborn piglet NO inhalation causes a modest decrease in total lung resistance with decreases in both airway and tissue (lung parenchymal) resistance.[53] In the same animal model, inhibition of NO synthase increases tissue more than airway resistance, suggesting a role for endogenous NO in relaxing primarily distal (parenchymal) areas of lung tissue.[54] Thus the NANC inhibitory system and NO may play a significant role in modulating airway and lung function in the neonate, and this may be disturbed in response to inflammatory airway disease.

NANC excitatory mechanisms also play a role in modulating airway smooth muscle. Within this system the tachykinin peptides, such as substance P and neurokinin A, have undergone some study during early postnatal development. As already indicated, these tachykinins are synthesized in sensory neurons and transported to sensory nerve endings from which they are released and have the ability to elicit airway contractile responses by several interrelated mechanisms. Tachykinin release from C-fiber nerve endings may directly or reflexly elicit smooth muscle contraction, modulate cholinergic responses through muscarinic receptors, and induce histamine release from mast cells. In young rabbits, substance P–induced modulation of ACh release increases with advancing postnatal age.[55] In newborn piglets, exogenously administered substance P elicits weak contractile responses of tracheal smooth muscle when compared with older animals.[56] This weak smooth muscle contractile response elicited by the NK_1-receptor agonist substance P in newborn pigs is associated with an adult complement of NK_1 receptors in trachea and lung, but with immature G protein coupling,[57] as observed for muscarinic receptors in the piglet airway.[18]

There is some debate about whether increased expression of substance P or other neuropeptides contributes to lung or airway pathophysiology. In mature animal models, chronic exposure to irritant gas increases substance P content; however, it is controversial whether this serves to aggravate airway hyperreactivity or serves a protective role for airway and lung structures.[58,59] Furthermore, in addition to eliciting airway smooth muscle constriction, substance P may induce relaxation of preconstricted neonatal tracheal tissue by release of NO and relaxant prostaglandins.[60] Newborn and 3-week-old rats exposed to hyperoxia exhibit increased tachykinin precursor expression, increased substance P content in the lung, and increased cholinergic responsiveness, although the relationship of the latter to the increased substance P content is not clear.[61] Ongoing studies focus on the signaling pathways that modulate airway smooth muscle relaxant responses through NO- and prostaglandin-mediated mechanisms in health and disease.

Carbon monoxide (CO), like NO, a gaseous molecule, is formed in neuronal and nonneuronal cells through enzymatic degradation of heme by the constitutive isoform heme oxygenase 2 (HO-2). This molecule mediates its effects by binding to the heme moiety of the soluble guanylate cyclase,[62] inducing formation of the second messenger cyclic guanosine monophosphate (cGMP) and airway smooth muscle relaxation. Further studies are needed to determine the role of interaction between CO and other molecules, such as VIP that may mediate NANC inhibitory influences in the developing lung and during lung injury.[63,64]

MATURATIONAL CHANGES IN AIRWAY PHYSIOLOGIC RESPONSES

Elegant immunohistochemical studies of developing human and porcine fetal airways have been performed from as early as the first trimester.[1] These have revealed the development of an airway smooth layer by the end of the human embryonic period extending from the trachea to terminal lung sacs, as well as an extensive nerve plexus comprising nerve trunks and ganglia investing the airways and innervating smooth muscle. This layer of airway smooth muscle is functional in the first trimester as evidenced by phasic spontaneous narrowing and relaxation of airways with back-and-forth movement of lung fluid.[1,65] Phasic or tonic activity in airway smooth muscle might stimulate lung growth by providing positive intraluminal pressure. These data are consistent with human autopsy findings that airway smooth muscle is present at 23 weeks gestation at all levels of the conducting airways and increased in amount during the earliest signs of developing chronic lung disease, as early as 10 days of birth.[66]

Despite clear evidence of an intact airway smooth muscle layer early in gestation, the effect of postnatal maturation on airway contractile responses is somewhat controversial.[67] Studies using methacholine (cholinergic) challenge have demonstrated greater airway narrowing during bronchoconstriction in immature animals largely attributable to greater airway compliance or distensibility in the walls of distal airways.[68] This was associated with less cartilage and proportionately more muscle in the airway wall of immature versus mature rabbits.[69,70] In contrast, physiologic studies using isolated tracheal smooth muscle strips from several species have demonstrated decreased cholinergic responsiveness in early postnatal life.[18,71,72] These in vitro studies are complicated by the need to carefully normalize the airway contractile response for smooth muscle mass and myosin content.[73] Nonetheless, the weight of evidence appears to point to an anatomically intact, but functionally diminished, airway smooth muscle layer superimposed on highly compliant airway structures in early postnatal life.

AIRWAY FUNCTION IN NEONATAL LUNG INJURY

Positive pressure ventilation and mechanical strain exert structural and functional changes on airway smooth muscle over a wide range of developmental ages. It appears that vagally mediated bronchoconstrictor tone is minimal under baseline conditions in the newborn period.[74] Furthermore, the high deformability or compliance of the trachea in the preterm period appears to be a consequence of decreased airway smooth muscle contractility[75] and diminished cartilaginous support.[69,76] The obvious result is that tracheas, and possibly lower airways, are vulnerable to deformation during positive pressure ventilation. Greater understanding of the detrimental effects of positive pressure ventilation at high inflating pressures has decreased the risk of deformation injury to the immature airway. However, increased airway reactivity and wheezing disorders in infants and children remain a major problem in the preterm survivors of neonatal intensive care.[77,78] The contribution of neonatal assisted ventilation to this problem is unclear. However, recent data in rat pups indicate that enhancement of airway reactivity occurs even after short-term mechanical ventilation.[79] Abnormal mechanical stress and its effect on smooth muscle contractility may serve as a useful model for characterizing one aspect of neonatal lung and airway injury.[80-82] Cultured airway smooth muscle cells exposed to such stress eliminate the confounding effects of deformational strain on surrounding tissues. Such studies have demonstrated strain-induced increases in cell myosin light-chain kinase (MLCK) accompanied by increased phosphorylation of the myosin light chain, all key steps in the smooth muscle contractile response.[83]

Exposure of the immature airway to increased supplemental oxygen is common in neonatal practice and may predispose preterm infants to the development of airway injury, especially in the presence of assisted ventilation. In newborn animal models, most notably the guinea pig and rat pup, hyperoxic exposure has been associated with development of airway hyperreactivity.[61,84,85] Although hyperoxic exposure may increase smooth muscle area, this effect is variable and does not, of itself, explain the development of hyperoxia-induced airway hyperresponsiveness.[86,87]

Epithelial injury with loss of airway relaxant factors may contribute to the hyperoxia-induced increase in airway contractile responses. This is supported by data from tracheal strips in preterm sheep, in which epithelium removal was associated with greater cholinergic responsiveness.[88] A similar phenomenon is observed in rat pups in whom the response of lung resistance induced by vagal stimulation was increased after nonspecific blockade of NOS in normoxic animals. However, after hyperoxic exposure NOS blockade no longer affected the contractile response induced by vagal stimulation.[89] These findings indicate that NO, released by stimulation of vagal preganglionic fibers, modulates bronchopulmonary contractile responses to endogenously released ACh in rat pups. This effect appears to be lost after prolonged hyperoxic exposure and may contribute to airway hyperreactivity under these conditions. Impairment of the prostaglandin/cyclic adenosine monophosphate (cAMP) signaling pathway may also contribute hyperoxia-induced airway hyperreactivity.[90] These findings are somewhat analogous to observations made in young ferrets infected with human respiratory syncytial virus (RSV) in whom nonadrenergic noncholinergic inhibitory responses of tracheal smooth muscle were significantly decreased for a prolonged period.[91] Data suggest that hyperoxic conditioning during early postnatal life impairs relaxation by impairing myosin light-chain (LC20) dephosphorylation.[92]

There is considerable interest in the potential of inhaled NO to decrease neonatal lung injury or bronchopulmonary dysplasia in preterm infants.[93,94] The underlying mechanism for this beneficial effect of prolonged inhaled NO in some clinical trials remains unclear. However, data from animal studies employing lamb and baboon models of neonatal lung injury implicate decreased airway smooth muscle mass and improved lung resistance in NO-treated animals.[95,96] Inhaled NO therapy may therefore reverse airway and lung parenchymal structural changes associated with depletion of endogenous NO in neonatal lung injury. Potential long-term benefit from such therapy on airway function is being explored.[97]

Neurotrophins and Lung Injury

The neurotrophins belong to a protein family essential for vertebrate nervous system development. They are also expressed in nonneuronal tissues that are under neuronal control. The neurotrophin family includes brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), neurotrophin 3, and neurotrophin 4. They share common structural features and act through their corresponding high-affinity tyrosine kinase (Trk) receptor subtypes.[98] The rapid excitatory activity of BDNF is via activation of the TrkB receptor. BDNF appears to stabilize excitatory (e.g., cholinergic) postsynaptic receptors, and/or enhance quantal excitatory neurotransmitter release probably via postsynaptic Ca^{++} signaling.[10,99]

During development, regulation of the lower airway appears to be influenced by neurotrophins. Recent data show the presence of neurotrophins and their corresponding receptor on airway smooth muscle cells in developing rat pups and up-regulation of the BDNF system after hyperoxic exposure.[100,101] This is consistent with observations from adult human tissue in which BDNF immunoreactivity was intense in bronchial epithelium,

although neurotrophin immunostaining was seen in bronchial smooth muscle, and TrkB (BDNF high affinity receptor) immunoreactivity was strongly expressed in bronchial smooth muscle.[102] Furthermore, BDNF, acting via TrkB receptors, facilitates responses of airway smooth muscle to different contractile stimuli, including ACh. The precise role of BDNF in up-regulating contractile responses of immature airways and respiratory structures remains to be determined.[103] Consistent with these findings, neurotrophins are overexpressed in the lower airways of RSV-infected human infants known to be at great risk for increased airway reactivity.[104]

CONCLUSIONS AND FUTURE STUDIES

The degree and nature of the relationship between different pathways regulating lung homeostasis during development are imperfectly known, a fact that should elevate the enthusiasm for future studies. For example, investigation of the molecular network and signaling pathways, that lead ultimately to hyperresponsiveness of AVPNs, will provide a better understanding of the mechanisms through which lung injury sets the stage for airway hyperreactivity. Another example of our limited knowledge relates to the biologic basis of a link between neurotransmitter specific networks involved in state and arousal and the regulation of airway function during early development. Progress made in our understanding of the control of the airways will contribute to the construction of a more complete conceptual framework that will provide deeper insight into the pathophysiology of airway disorders, and allow us to identify effective new treatment of neonates and infants with airway dysfunctions.

85 Functional Development of Respiratory Muscles

Carlos B. Mantilla, Mohamed Abdelmonem Fahim, and Gary C. Sieck

This chapter provides a snapshot of fetal and neonatal development of the diaphragm muscle (DIAm), the major inspiratory muscle in mammals located between the thoracic and abdominal cavities. The DIAm appears rather late in evolution, being present only in mammals, whereas other vertebrates use different means of ventilation. The embryologic origin of the DIAm has been elucidated by recent studies using molecular markers of muscle development, reflecting a common origin to the DIAm in the pleuroperitoneal fold. The traditional view of DIAm development called for multiple sites of origin reflecting a complex derivation, consistent with its multiple anatomical origin and insertion sites. The mechanical actions of the DIAm reflect its major function is in inspiration. The DIAm is also involved in several nonventilatory motor behaviors such as coughing, defecation, emesis, micturition, parturition, sneezing, vocalization and weightlifting.

Neural control of the DIAm is similar to neural control of other skeletal muscles and is based on recruitment and frequency coding of motor units. Motor units in the adult DIAm, each comprising a motoneuron and the muscle fibers it innervates, vary considerably in their mechanical, histochemical, and biochemical properties,[1-3] and this heterogeneity provides the range of control of muscle force generation that occurs during different motor behaviors. It is the cumulative contractile and fatigue properties of the motor unit pool that determine the constraints under which the DIAm responds to the various mechanical demands placed on it during different ventilatory and nonventilatory behaviors. Clearly these motor demands can change during development, and the DIAm must adapt or remodel to accommodate these changing demands.

The DIAm becomes rhythmically active during late fetal development (fetal respiratory movements), and at birth it must be ready to sustain ventilation. Postnatally, the DIAm is one of the most active skeletal muscles, with a duty cycle (time active versus relaxed) of approximately 30% to 40%, compared to limb muscles (duty cycles ranging from 2% to 15%). It is not surprising therefore that fetal and neonatal pathology of the DIAm often lead to ventilatory failure and premature death. Despite the vital importance of the DIAm, previous studies have provided mostly descriptive information about its development and growth. However, there is accumulating information about myogenesis and neural development that derives from in vitro model systems, which may be applicable to the mechanisms regulating DIAm development in vivo. Yet, the applicability of these in vitro results regarding the basis of myogenesis and neural development remains to be established, especially in the context of maturation of other systems, for example, the central nervous system, the lung, the thoracic, and abdominal walls. Unfortunately such integrative information is lacking.

Rodent models are increasingly being used to explore the genetic basis for developmental plasticity in neuromotor control. Accordingly, chapter focuses on recent results obtained in rats and mice. Benchmarks for the development of the mouse DIAm are summarized in Figure 85-1. The fetal and neonatal developmental benchmarks in rats are generally comparable to those in mice (offset by approximately 2 days). In mice, developmental benchmarks for the DIAm begin at approximately embryonic day 11 or 12 (E11, E12), when the phrenic nerve makes initial contact with the primordial DIAm. In both rats and mice, the final pattern of adult motor units and muscle fiber types is not achieved until postnatal day 28 (D28). During this 5- to 6-week span, dramatic changes occur in DIAm innervation, contractile protein expression, and function. The timeline for such developmental benchmarks in humans is far more protracted, but it is likely that similar convergence of neural and myogenic events also occurs. Therefore much can be learned by studying the integrated aspects of myogenesis and neural development of the DIAm in rodent models.

Embryologic Derivation and Innervation of the Diaphragm Muscle

Myogenesis

Skeletal muscle fibers, including those in the DIAm, are formed in two stages. The first stage is commitment (also known as determination), when mesodermal progenitor cells are transformed to myoblasts. The second stage is terminal differentiation, when myoblasts fuse to form myotubes and myofibers (Figure 85-2). Myogenesis may proceed via an intrinsic genetic program, or it may require either the presence of positive extrinsic signals or the removal of inhibitory signals.[4] None of these potential mechanisms can be presently excluded. However, there is converging evidence that myogenesis is induced in a variety of nonmuscle cells by the expression of proteins belonging to the basic helix-loop-helix (bHLH) superfamily.[5,6] Collectively, these are known as muscle regulatory factors (MRFs) and include MyoD,[7] myogenin,[8] Myf-5,[9] and MRF4.[10] In human muscle, MRF4 is also known as Myf-6.[11] In addition to providing a molecular mechanism for the regulation of myogenesis in fetal and neonatal muscle, MRFs are also involved in determining the expression of myosin heavy chain (MHC) isoforms in adult muscle.[12]

Genetic determinants of myoblast commitment have been most extensively studied in *Drosophila*, but this information is likely to be directly applicable to myoblast commitment in the mammalian DIAm as well. In *Drosophila* it has been shown that neural-derived proteins (for example, sonic hedgehog, Wnt 1, 3, and 4) promote commitment to myoblasts within a myotome.[4,13] Expression of sonic hedgehog (or other signals) commits mesodermal cells to form myoblasts possibly by releasing suppression of the expression of specific MRFs.[14] The process of myoblast commitment is marked by the expression of the paired-box protein Pax-3, which appears to positively regulate MRF expression. For example, it has been shown that ectopic expression of Pax-3 induces both MyoD and Myf-5 in embryonic tissue.[15] The consequent increase in MRFs then initiates a cascade of signals that continues through differentiation, thus sustaining myogenesis. Indeed, transplantation of Pax-3–expressing embryonic

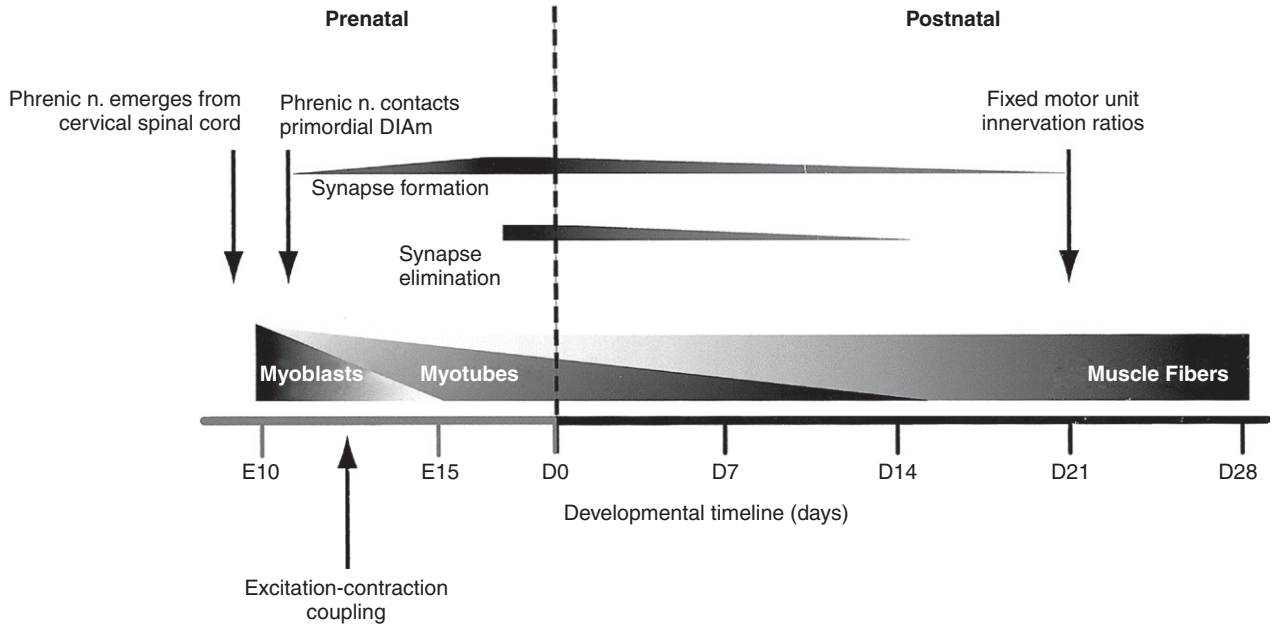

Figure 85-1 Timeline for major events in the development of mouse DIAm. Similar seminal events occur in the embryonic and early postnatal development of the DIAm in other mammals including humans, although temporal characteristics and interrelationships may vary.

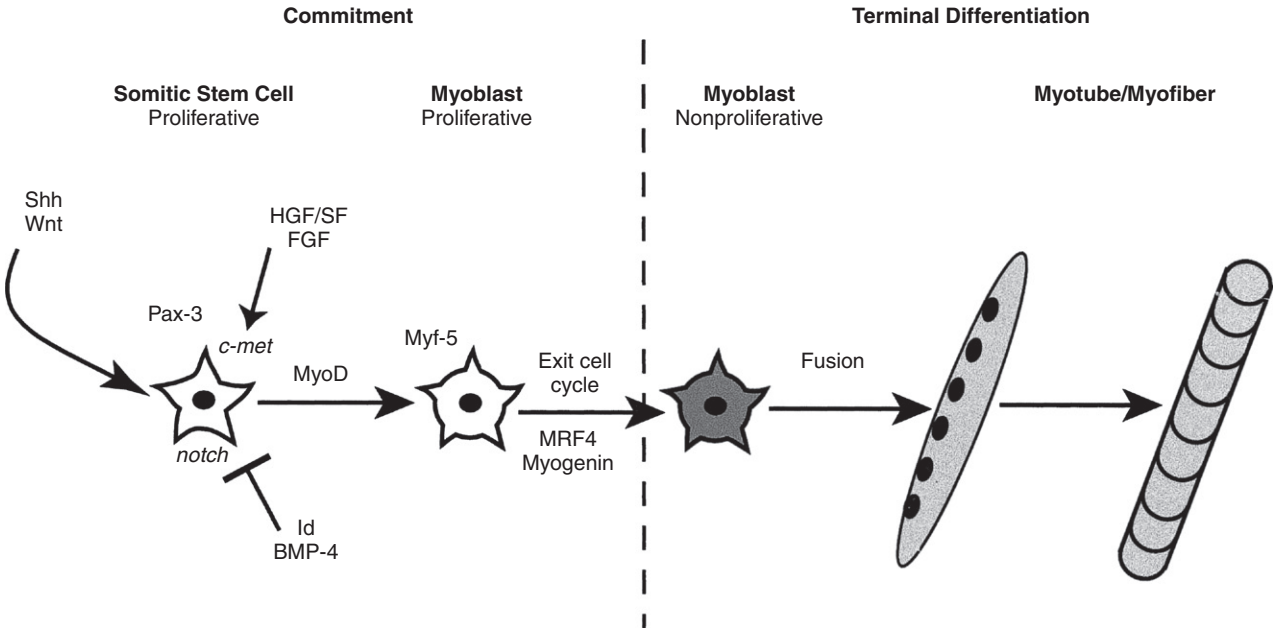

Figure 85-2 The two major stages of myogenesis—commitment and terminal differentiation. During commitment, somitic stem cells proliferate and are committed to myoblasts, a process marked by MyoD and Myf-5 expression. This process ends when proliferating myoblasts exit the cell cycle, influenced by expression of MRF4 and myogenin. The exit of myoblasts from the cell cycle marks the beginning of the differentiation stage. Thereafter, nonproliferative myoblasts fuse to form myotubes, and subsequently, myotubes become myofibers once distinct sarcomeres are present. The differentiation process continues until adult fiber types are established.

stem cells into dystrophic mice resulted in engraftment of stem cell precursors with adult myofibers and enhanced contractile function.[16]

The MRFs function as molecular switches, initiating myogenesis by inducing expression of muscle-specific genes through binding of the bHLH motif to *cis*-acting DNA control elements of muscle-specific genes, known as E-boxes.[17] The E-box is a CANNTG sequence-containing motif present in the promoter regions of many skeletal muscle specific genes.[18] Transcriptional regulation mediated by MRFs may also involve interactions of MRFs with the family of MADS-box proteins, termed myocyte enhancer factor 2 (MEF2A-D), which may determine muscle specificity for genes lacking MRF binding domains. Binding sites for MEF2 factors are located in the promoter regions of many

muscle-specific genes including myogenin. However, MEF2 binding alone is not sufficient to induce myogenesis.

It is also possible that myoblast commitment is determined by release from inhibition by signals that actively suppress MRF expression. For example, a class of HLH proteins termed Id factors (Id1-Id4) inhibit MRF activity by forming heterodimers with E2 products (ubiquitously expressed HLH-containing proteins encoded for by E2 genes). These products prevent dimerization with MRFs and thus block subsequent activation of skeletal muscle specific genes.[19] The Id proteins lack the basic DNA binding domain; therefore heterodimerization of bHLH proteins with Id proteins prevents the strong binding to DNA by either E proteins or MRFs.[20] Twist is another protein that in mice sequesters E-proteins inhibiting MRF activity by preventing the formation of MRF-E protein heterodimers.[21] Yet another inhibitory factor is Mist1, which binds with MyoD to form an inactive heterodimer.[22] The balance between inhibitory and promyogenic signals likely determines the timing and location of muscle precursor development. Recently, calcineurin was shown to activate MyoD indirectly by decreasing the expression of the Id-inhibitory proteins.[23] Myogenic inhibitory signals may also be critical to prevent ectopic formation of skeletal muscle since mesodermal somite cells can follow both myogenic and nonmyogenic programs.

In hypaxial muscles (for example, limb muscles, chest and abdominal wall muscles, and DIAm) MyoD is the first MRF to be expressed. MyoD expression then initiates a cascade resulting in subsequent expression of Myf-5, MRF4, and myogenin.[24] The sequence of MRF expression appears to be critical for the development of normal muscle. MyoD and Myf-5 are highly expressed in proliferating myoblasts, suggesting a primary role for these MRFs during this stage of myogenesis.[7] In mutant mice lacking MyoD or MRF4,[25,26] there is no apparent effect on normal skeletal muscle development, but Myf-5 and myogenin are upregulated, respectively. Therefore it is possible that redundant MRF expression may rescue normal skeletal muscle phenotype in these animals. Similarly, Myf-5–deficient mice appear to have normal skeletal muscle, but they succumb to asphyxiation soon after birth due to rib cage abnormalities.[27] In contrast, myogenin-deficient mice have only myoblasts without the development of myotubes/myofibers,[28,29] suggesting that myogenin is indispensable for differentiation of myotubes/myofibers. In mice lacking both Myf-5 and MyoD, no myoblasts are present suggesting that expression of both of these MRFs is required for myoblast commitment.[30] Mice lacking Myf-5 and MRF4 resemble Myf-5 knockouts, suggesting that MRF4 regulates later aspects of myogenesis.

With terminal differentiation, committed mononucleated myoblasts are nonreversibly transformed into multinucleated myotubes/myofibers with expression of contractile proteins (see Figure 85-2). Thus terminal differentiation represents the irreversible exit of proliferating myoblasts from the cell cycle. Yet, not all myoblasts lose their ability to proliferate because a pool of myoblasts (satellite cells) persists into adulthood, and their proliferative capacity is important in processes of injury and repair as well as other conditions of muscle remodeling. Throughout life, proliferating myoblasts are susceptible to apoptosis (programmed cell death) until they are terminally differentiated and exit the cell cycle. The balance between proliferation and apoptosis may play an important role in controlling the total number of muscle fibers of a given type.[31] Terminal differentiation of myoblasts in hypaxial muscles does not occur in vivo until they have migrated from the myotome to their final location (thoracic or abdominal walls or the limbs). As myoblasts migrate from the lateral dermomyotome, they express Myf-5 and *c-met* (a tyrosine kinase receptor for hepatocyte growth factor/scatter factor), which thus can be used as markers for this process of differentiation. In hypaxial muscle precursors, including those for the DIAm, expression of Myf-5 and *c-met* begins at approximately E10 and continues through E12.[32] Expression of MyoD is also important in the process of terminal differentiation and can be inhibited in vitro by bone morphogenic protein-4 or fibroblast growth factor-5,[14] both of which have been implicated in maintenance of the myoblast proliferative capacity and inhibition of differentiation.

Following terminal differentiation, myoblasts fuse, forming multinucleated myotubes/myofibers. Although the formation of myotubes/myofibers is coincident with the initial appearance of innervation in hypaxial muscles, converging evidence from in vitro and in vivo models indicates that terminal differentiation can be initiated in the absence of neural influence. Myotubes/myofibers can form in vitro in the absence of innervation, but at a much slower pace compared to that observed in vivo. This suggests that neural influence may facilitate the normal process of terminal differentiation and formation of myotubes/myofibers. This potential facilitating influence of innervation needs to be further explored. There is evidence, based on in vitro model systems, that terminal differentiation and myotube/myofiber formation depend on the expression of several nonneural proteins. This includes those present in the extracellular matrix (for example, fibronectins and laminins); basal lamina (for example, muscle cell adhesion molecule [M-CAM], neural cell adhesion molecule [N-CAM], and M-cadherin); cell membrane (for example, β1-integrin); and cytoskeleton (for example, actin and desmin).[33,34] Obviously, terminal differentiation and myotube/myofiber formation involves very complex interactions between differentiating cells and their surrounding environment. Current research is only beginning to unravel these complex interactions. It should be noted that even though the process of myoblast fusion into myotubes/myofibers is called terminal differentiation, there is subsequent differentiation of these nascent muscle fibers into adult muscle fiber types (see later discussion).

Other factors may also influence myogenesis. For example, in vitro passive mechanical strain results in both myotube hyperplasia and hypertrophy.[35,36] Thus both myoblast proliferation and differentiation are affected by passive strain. Passive stretching can also prevent the atrophy of myotubes, which normally occurs in culture media lacking growth factors. The mechanisms responsible for transduction of passive strain into a proliferative and/or trophic influence is unclear but may involve mediators such as $PGF_2\alpha$, IGF_1 or other cytokines.[36] Although these in vitro studies employed passive strain, these results suggest that early mechanical activation of the fetal DIAm (fetal respiratory movements) may be important in promoting further myogenesis.

Myosin Heavy Chain

Myosin is a hexameric protein (MW = 480 kD) comprising two heavy chains and four light chains. At the rod-shaped COOH-terminus end of the myosin molecule, the two heavy chains (MW = 200 kD) dimerize into a 200 nm alpha-helical tail. At the NH3-terminus, the heavy chains separate and form two distinct heads (S-1), which contain both actin and nucleotide-binding domains. The S-1 converts chemical energy into mechanical work through a process that involves stereo-specific docking of S-1 with actin, thereby reversing the intramolecular conformational changes induced by ATP hydrolysis.[37,38] A number of myosin heavy chain (MHC) isoforms exists, all of which are encoded by a highly conserved multigene family located on chromosome 17 (human) or 11 (mouse).[39] The rate of ATP hydrolysis at the S-1 varies among the different MHC isoforms, thereby providing the molecular basis for fiber-type differences in mechanical properties.[40-43] The essential (MLC_{20}) and regulatory (MLC_{17}) myosin light chains provide structural support and possibly modulate mechanical performance of the MHC.[44] Different MLC isoforms may differentially modulate the kinetic properties of MHC.[45] Evidence also exists that both Ca^{2+} binding to MLC_{17} and phosphorylation of MLC_{17} modulate S-1 ATPase activity.[46-48]

Adult skeletal muscle fibers are classified histochemically as types I, IIa, and IIb, based on the pH lability of myofibrillar ATPase staining.[49] Muscle fiber type classification in the adult corresponds with the expression of different MHC isoforms. Fibers classified as type I express MHC_{Slow}. IIa fibers express MHC_{2A}. IIb fibers express MHC_{2B} and/or MHC_{2X}.[39,50-52] Such histochemical classification of muscle fiber types is not possible during fetal and neonatal development. During this period there are dramatic transitions in MHC isoform expression, with a high incidence of co-expression of MHC isoforms that precludes ready distinction of different muscle fiber types.[53-56] In the fetal mouse and rat DIAm, an embryonic MHC isoform (MHC_{Emb}) is predominantly expressed together with MHC_{Slow} and MHC_{2A}. At or close to birth, the predominant isoform expression switches to a neonatal MHC isoform (MHC_{Neo}), together with MHC_{Slow} and MHC_{2A}.Thereafter, MHC_{Neo} expression gradually disappears and is totally absent in the mouse and rat DIAm by D28. Expression of MHC_{2X} and MHC_{2B} isoforms emerges only after D14 in the mouse and rat DIAm, and the proportion of fibers expressing these isoforms increases until about D28, when the adult pattern of MHC isoform expression is fully established.[57] This dramatic postnatal transition in MHC isoform expression in the DIAm represents an important stage of muscle fiber differentiation, especially with respect to the development of mature contractile properties (see section on Association of Contractile Properties with Fiber Type and MHC Isoform Expression, later). Beyond D28, the relative contribution of each MHC isoform changes as a result of the disproportionate growth of DIAm fibers, for example, the growth of fibers expressing MHC_{2X} and MHC_{2B} is approximately twofold to threefold greater than that of fibers expressing MHC_{Slow} and MHC_{2A} isoforms.[58,59] Based on the temporal associations between innervation and the major developmental events in myogenesis (see section on Innervation, later this page), it would seem reasonable that the nervous system can either directly (for example, activity, nerve traffic) or indirectly (for example, secretion of trophic factors) influence DIAm development.[60] However, the precise mechanisms by which activation history and/or trophic factors influence DIAm development remain largely unknown.

The time course for developmental transitions in MHC isoform expression in the DIAm is also influenced by the hormonal milieu (thyroid hormones, growth hormone, insulin-like growth factor, etc.) surrounding the fibers. For example, MHC expression is sensitive to thyroid hormone levels.[61,62] Nutritional status can also affect myogenesis and MHC isoform expression.[58]

The determination of skeletal muscle fiber type has received considerable attention. Expression of class II histone de-acetylases (HDACs) may determine muscle fiber type by inhibiting the transcription factor MEF2.[63] MEF2 factors are required for the transcription of oxidative genes found in slow fibers.[64] HDAC activity is also regulated posttranslationally via ubiquitination and proteasome degradation.[65] Whether these mechanisms play a role in the developmental determination of muscle fiber type is still to be explored. In recent studies we examined MHC mRNA expression during postnatal development of DIAm and found postnatal changes in mRNA and protein expression were not concordant for adult MHC isoforms, suggesting that changes in MHC expression in the developing rat DIAm are not driven solely by changes in mRNA expression.[57] Furthermore, myonuclear domain size (reflecting the volume of myoplasm under transcriptional control by a single myonucleus) increased postnatally as fibers increased in cross-sectional area, indicating that changes in transcriptional activity (although present) do not exclusively determine the postnatal growth of the DIAm.[66]

Embryologic Origin

The DIAm derives from the pleuroperitoneal fold.[67] The pleuroperitoneal fold forms a partition separating the coelomic cavity into thoracic portions (superior, containing the developing heart and pericardium) and abdominal portions (inferior, containing the future peritoneal cavity). Growth of the embryonic axis causes a progressive caudal displacement of the pleuroperitoneal fold, with its anterior edge eventually becoming attached at the midthoracic level while its dorsal edge becomes attached at the lowest thoracic level. Committed myoblasts migrate within the pleuroperitoneal fold and eventually differentiate to form DIAm myotubes/myofibers. Coincident with myoblast migration, the phrenic nerves exit the cervical spinal cord following the septum transversum and migrating myoblasts.[68,69] The exact target of phrenic nerve terminals is not clear, but the site of phrenic nerve contact seems to be consistent (located medially within the pleuroperitoneal fold) with nerve axons being surrounded by migrating myoblasts.[70,71] Phrenic motor axons start branching within the pleuroperitoneal fold as myoblasts radiate into the dorsocostal, sternocostal, and crural regions of the DIAm.[67] The mechanisms by which phrenic nerve axons are guided toward the primordial DIAm remain unclear.

Innervation

All regions of the DIAm are innervated by cervical spinal cord segments.[72] Innervation of the DIAm displays a somatotopic pattern, with the sternal and more ventral aspects of both costal and crural regions being innervated by phrenic motoneurons located in more rostral segments of the cervical spinal cord. It remains unclear whether the somatotopic pattern of DIAm innervation develops before or after initial synapse formation (that is, it could reflect either the pattern of phrenic nerve outgrowth or the location of myotubes/myofibers).

In the mouse, the phrenic nerve arrives at the developing DIAm by E11 (see Figures 85-1 and 85-3) 2 days sooner than in the rat.[71] After arrival at the primordial DIAm, phrenic motor axons branch extensively, in close proximity with Schwann cells (Figures 85-3 and 85-4). Both Schwann cells and nerve terminals at this early stage display coated vesicles suggesting vesicular release (Figure 85-5). A number of regulatory processes may be involved in guiding Schwann cell and phrenic axon terminal outgrowth, both with respect to the initial targeting to the pleuroperitoneal fold and the subsequent contact with myotubes/myofibers. These regulatory processes may involve components of the extracellular matrix, the release of trophic factors or chemotactic substances. Schwann cell migration and branching may be essential to the outgrowth and branching of phrenic nerve terminals. Unfortunately, most of the available literature in this important area is limited by the fact that it is based on measurements of axonal outgrowth and branching using in vitro preparations. Recent studies, however, suggest that perineurial sheaths may serve as a scaffold for Schwann cell growth and alignment, thus targeting motor axons toward muscle fibers.[73,74] Clearly, this is a complex integrated system in which in vitro measurements may not accurately reflect in vivo conditions.

Trophic factors derived from motor axons may be important in determining DIAm development. For instance, nerve-derived agrin is important not only for neuromuscular junction development but also for the development of excitation-contraction coupling mechanisms in cultured human myotubes. Maturation of cultured myotubes including expression of ryanodine receptors and voltage-gated L-type Ca^{2+} channels is promoted by spinal cord explants as well as exogenous administration of neural agrin.[75,76] This suggests that soluble factors (rather than electrical activity) may be responsible for the effects of nerves on muscle development. Neuregulin (a member of the larger epidermal growth factor family)[77-80] is also expressed by motoneurons during embryonic and early postnatal development and may activate receptor tyrosine kinases of the ErbB family present in mature skeletal muscles,[81] including rat DIAm.[82] Neuregulin is known to induce acetylcholine receptor expression at embryonic development via its effects on Schwann cells.[83] Whether neuregulin constitutes a nerve-derived trophic influence for muscle fiber

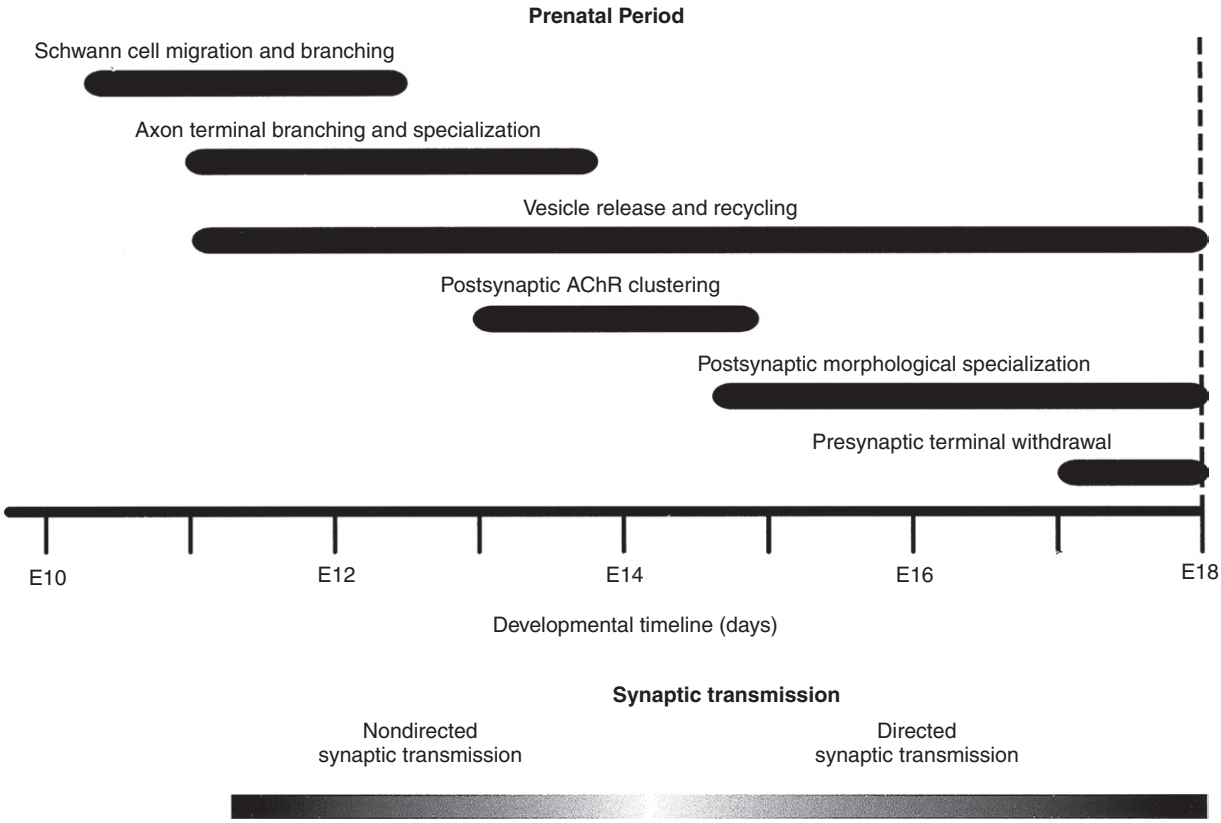

Figure 85-3 The timeline for major events in synapse formation in the mouse DIAm including differentiation of presynaptic and postsynaptic elements of neuromuscular junctions. Experimental evidence suggests that synaptic transmission is initially "nondirected" toward specific postsynaptic targets (that is, cholinergic receptor clusters that define motor end plates). With cholinergic receptor clustering and differentiation of postsynaptic specializations, synaptic transmission becomes "directed" toward these targets.

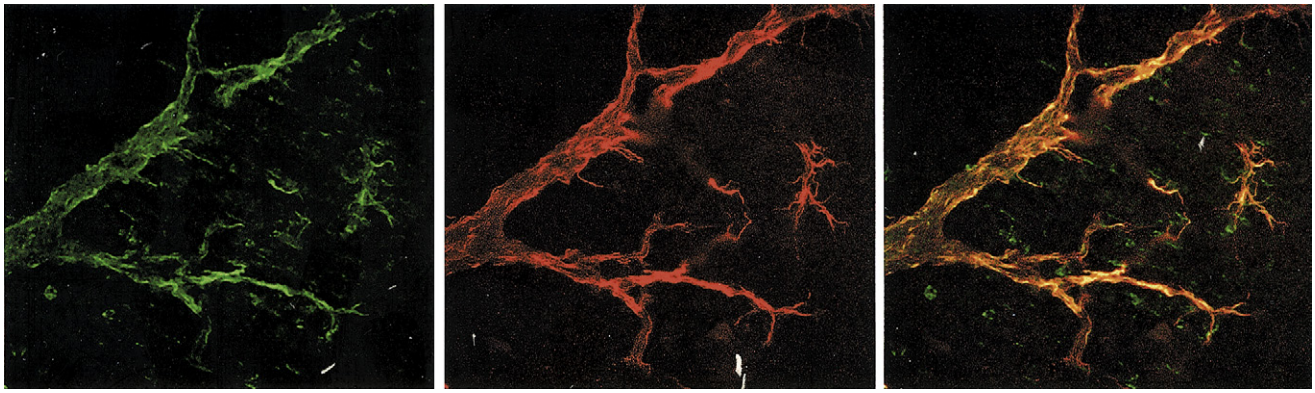

Figure 85-4 Confocal photomicrographs displaying immunoreactivity for neurofilamin (NF, to mark branching nerve fibers) and S-100 (to mark Schwann cells) in the mouse DIAm at E12.5. Note the extensive branching and overlap of both nerve fibers and Schwann cells at this early age.

growth during perinatal development and the relative importance of different trophic factor signaling pathways (for example, agrin versus neuregulin) remain to be determined.

Concurrent with the outgrowth of phrenic motor axons, there is also a progression of events on the postsynaptic side, with the expression and aggregation of cholinergic receptors. In the mouse DIAm, aggregation and clustering of cholinergic receptors is apparent at approximately E13 (see Figures 85-3 and 85-6). The process of aggregation of cholinergic receptors has received considerable attention, and it is known that this process involves agrin secretion by the nerve terminal and incorporation into the basal lamina, with subsequent activation of MuSK receptors at the postsynaptic membrane and finally rapsyn-mediated cholinergic receptor clustering.[84-86] MuSK phosphorylation seems critical to cholinergic receptor clustering, as the clustering is absent in MuSK double mutants and mice treated with inhibitory RNA designed to block MuSK transcription.[87] MuSK receptors show a gradient of expression in muscle fibers, most abundant in their central regions where MuSK can undergo autoactivation,[88] leading to cholinergic receptor clustering in the absence of neural influence. In neighboring sections of the muscle fiber where MuSK is not as richly expressed, agrin released by motor axons

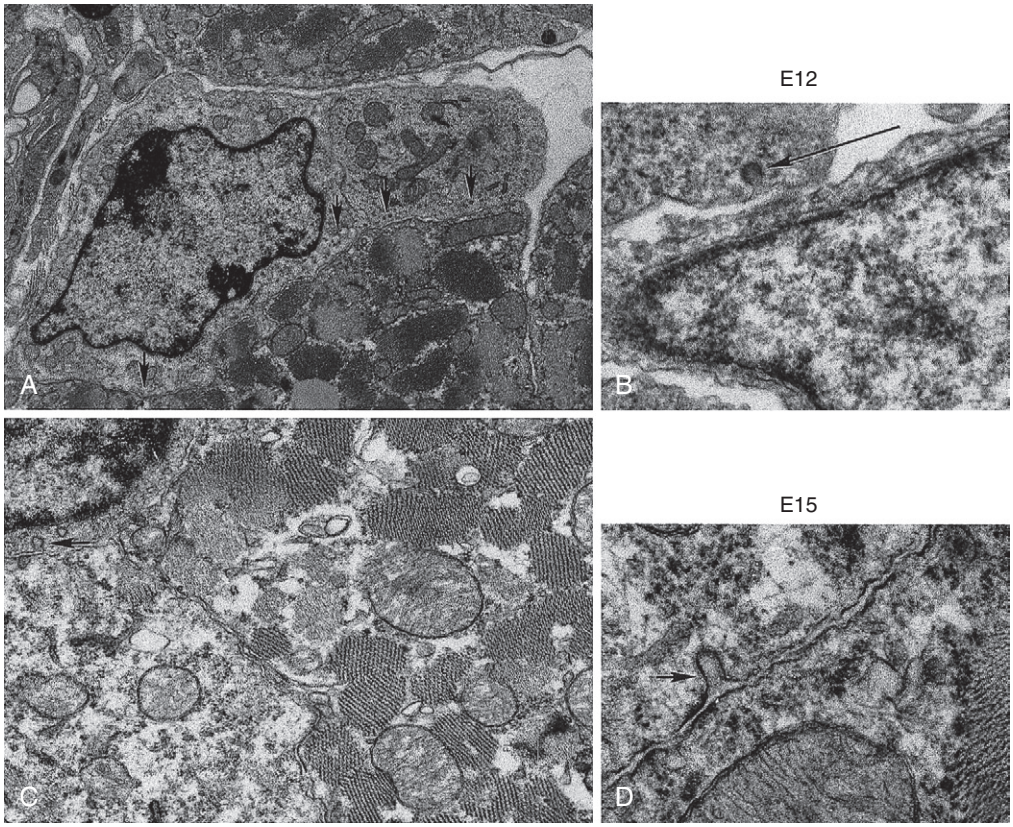

Figure 85-5 Electron photomicrographs showing **A,** the presence of coated vesicles *(arrows)* in both a nerve terminal and Schwann cell (noted by the presence of a distinct nucleus) and **B,** an exocytotic vesicle at a nerve terminal in a mouse DIAm at E12. **C**, Evidence for nondirected vesicular release from both nerve terminals and **D,** Schwann cells continues through E15.

can also lead to cholinergic receptor clustering.[89] This recent model for the formation of postsynaptic components of a neuromuscular junction can account for the apparent "targeting" of motor axons to "preformed" cholinergic clusters,[90,91] as well as the induction of new clusters by nerve-derived influences.[83] Following aggregation of cholinergic receptors, there is further specialization of the postsynaptic membrane with formation of synaptic folds and differentiation of the complex neuromuscular junction structure characteristic of adult DIAm (see Figures 85-3 and 85-7). Previously, it was demonstrated that in the adult rat DIAm, neuromuscular junction morphology varies across different fiber types (Figure 85-8), being far more complex in fibers expressing MHC_{2X} and MHX_{2B} isoforms as compared to fibers expressing MHC_{slow} and MHC_{2A} isoforms.[92,93] Neuromuscular junctions are much smaller and morphologically far less complex in the fetal and neonatal DIAm compared to the adult (Figure 85-9), but there is very little information regarding the mechanisms responsible for development of fiber type-specific differences in neuromuscular junction structure.[94]

Initially, a single myotube/myofiber can be contacted by multiple motoneurons (polyneuronal innervation). Subsequently, polyneuronal innervation disappears through the process of synapse elimination, which in the mouse and rat DIAm is complete by about D14 (see Figures 85-1 and 85-10).[85,95-99] The process of synapse elimination is not fully understood. It has been suggested that there may be competition among motoneurons for target cell innervation depending on activity (Hebbian competition).[98-100] Accordingly, terminal synapses of more active motoneurons would persist at the expense of less active motoneurons. This theory is confounded by the fact that in adult muscle, motor units with the largest innervation ratio (that is, number of muscle fibers innervated by a single motoneuron) are those that are least active (for example, fast-fatigable motor units).[101-103] Thus either the activity patterns of these motoneurons must change dramatically during development (transitioning from most to least active) or these motoneurons must initially innervate a greater number of muscle fibers to account for the subsequent greater loss of synaptic contacts (see Figure 85-10). The pattern of activity (not total activity) and the secretion of so-called synaptotrophins or synaptotoxins may also contribute to maintenance or elimination of synapses.[85] Another possibility is that muscle fibers use intracellular signals called synaptomedins to maintain contact with selected nerve terminals, and this may or may not be dependent on differential activity.[104] None of these possibilities can be excluded at the present time, and it is likely that a combination of mechanisms is responsible for the final pattern of motor unit innervation. However, because differences in innervation ratio exist across motor unit types, it is likely that the mechanisms underlying synapse elimination are linked to muscle fiber lineage or MHC isoform expression. Ultimately, motor unit composition may also be affected by ongoing postnatal myogenesis and formation of new myotubes/myofibers, which occurs until the third postnatal week in rat and mouse DIAm.[58] The final innervation ratio of motor units is not established in the mouse and rat DIAm until about D28.

Fetal respiratory movements indicating intact inspiratory drive and functional synapses have been observed in a number of species, including humans. In the rat, fetal respiratory movements begin at about E17,[105] but the presence and timing of such movements in mice has not been determined. The onset of fetal respiratory movements does not particularly denote the beginning of functional synapses and excitation-contraction coupling in DIAm

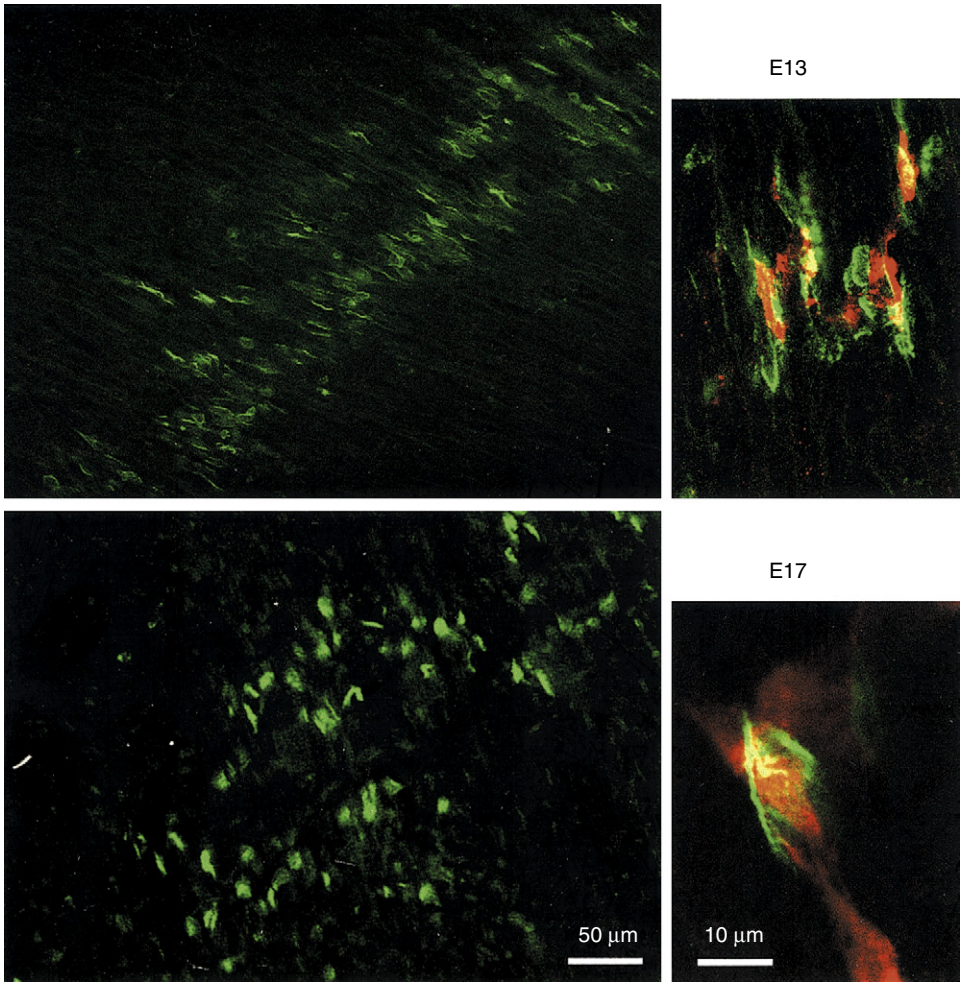

Figure 85-6 Confocal photomicrographs displaying α-bungarotoxin (BTX) labeling of cholinergic receptors and neurofilamin (NF) labeling of phrenic nerve axons and nerve terminals in the mouse DIAm at E13 and E17. Note the more diffuse pattern of BTX staining at E13 compared to E17, indicating a progression toward clustering of cholinergic receptors. Also note the greater overlap between nerve terminals (NF staining) and cholinergic receptors (BTX staining) at E17.

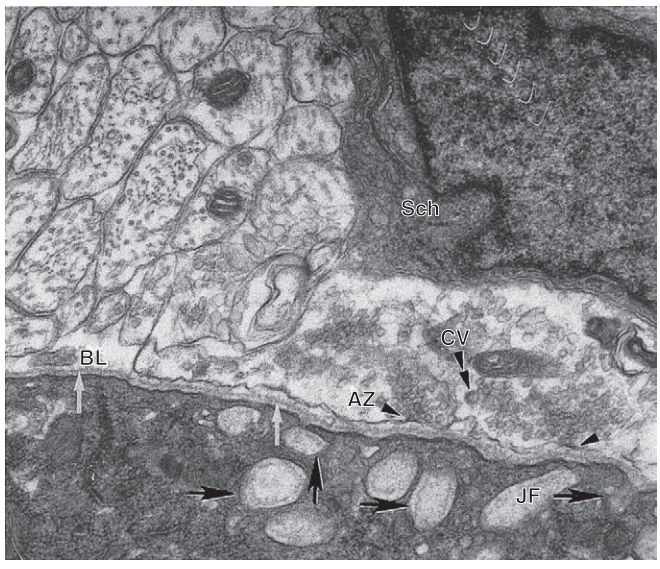

Figure 85-7 Electron photomicrograph illustrating the presence of postsynaptic specializations (for example, basal lamina—*BL, white arrows;* and junctional folds—*JF, black arrows*) at a neuromuscular junction in the mouse DIAm at E16. The electron micrograph also displays nerve terminals containing coated synaptic vesicles *(CV)* aggregating around active zones *(AZ)* and a Schwann cell *(Sch).*

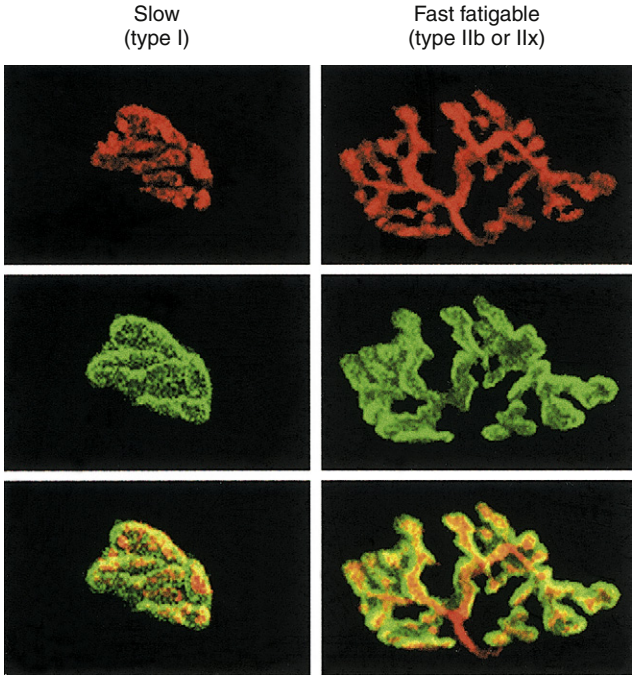

Figure 85-8 Confocal photomicrographs of presynaptic and postsynaptic elements of neuromuscular junctions in the adult rat DIAm. Note differences in complexity and size of neuromuscular junctions that depend on motor unit (muscle fiber) type.

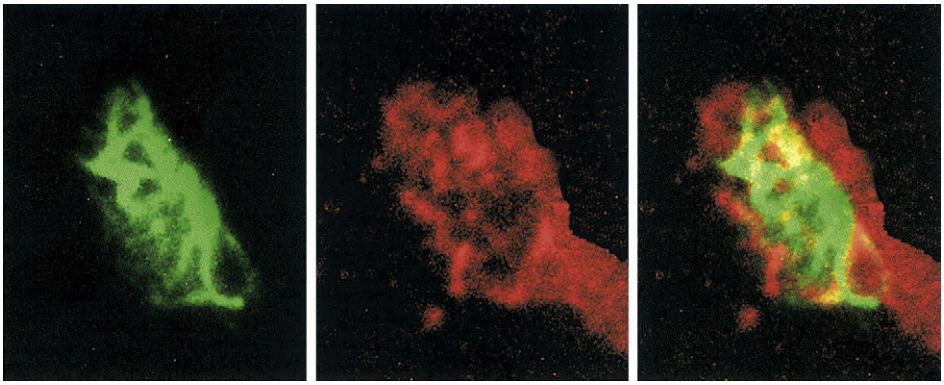

Figure 85-9 Confocal photomicrograph showing the morphology of neuromuscular junctions in the mouse DIAm at E17. Note that in comparison to neuromuscular junctions in the adult DIAm (see Figure 85-8), neuromuscular junctions at this age are substantially smaller and far less complex.

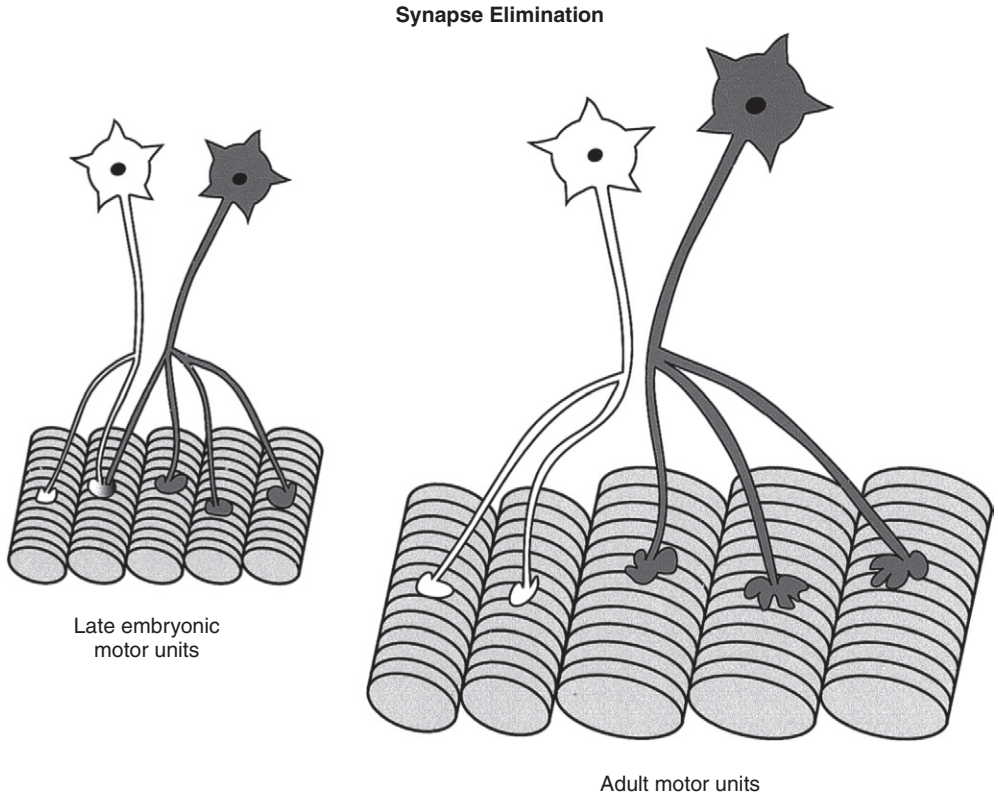

Figure 85-10 Process of synapse elimination. It is thought that differential patterns of motoneuron activity lead to selective withdrawal of motor axon terminals, which may be regulated by the secretion of synaptotrophins or synaptotoxins by the nerve terminal and/or production of synaptomedins within myofibers.

fibers. We found that intracellular Ca^{2+} and contractile responses could be elicited in the mouse DIAm by indirect nerve stimulation as early as E12.5 (Figure 85-11). These intracellular Ca^{2+} and contractile responses were blocked by d-tubocurarine and α-bungarotoxin indicating dependence on acetylcholine release and activation of cholinergic receptors. Yet, at this early age, synapses are only primordial at best, with no postsynaptic specialization and limited clustering of cholinergic receptors. These observations are consistent with the presence of coated vesicles and other indications of vesicular release (see Figure 85-5). Myotubes/myofibers that are forming in the DIAm at this time also display the onset of sarcomeric organization necessary for a mechanical response (Figures 85-12 and 85-13). Thus it appears that the nervous system can induce mechanical responses even before well-defined synapses are present. Such mechanical responses may be important in the subsequent development of myofibers in the DIAm (for example, further sarcomeric organization and alignment of sarcomeres).

Clearly, neuromuscular transmission in the fetal and neonatal DIAm is quite different from that in the adult muscle. In previous studies, it was shown that the neonatal rat DIAm is far more susceptible to neuromuscular transmission failure during repetitive activation than the adult rat DIAm.[106-109] Certainly, the increased susceptibility of the fetal and neonatal DIAm to neuromuscular

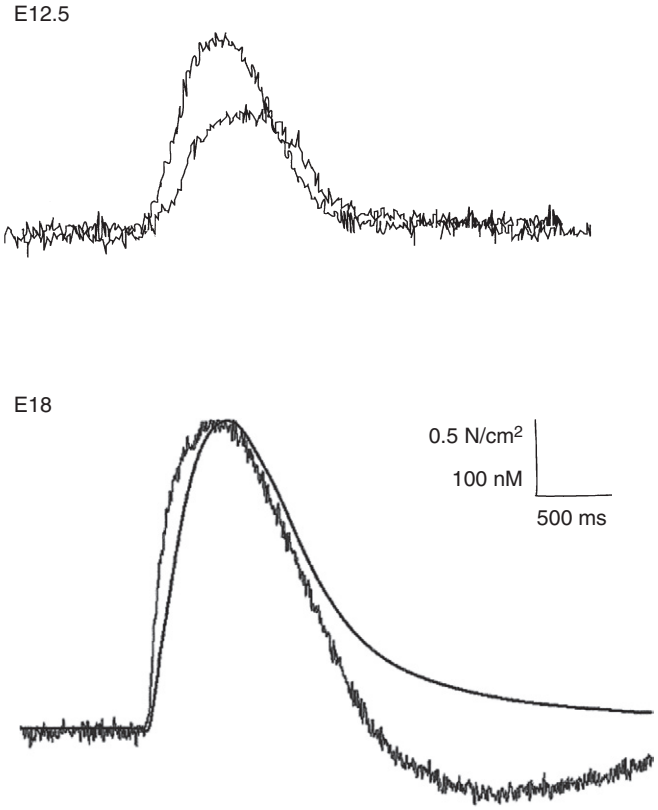

Figure 85-11 Simultaneous measurement of force and intracellular Ca^{2+} responses to phrenic nerve stimulation in the mouse DIAm at E12.5 and E18. Myofibers mounted between force and length transducers in a flow-through chamber were loaded with Fluo-3AM. Phrenic nerve terminals were stimulated using low current short duration (0.1 ms) square wave pulses. Responses were blocked using d-tubocurarine (10 μM).

transmission failure can be attributed, at least in part, to the more extensive branching of phrenic axons (as a result of polyneuronal innervation); thus the greater likelihood of failure of action potential propagation at axonal branch points.[107,109-111] It is also likely that differences in the number of synaptic vesicles, presynaptic neurotransmitter release, or consequent activation of cholinergic receptors all could account for the developmental differences in neuromuscular transmission failure. In the early postnatal DIAm, reduced spontaneous miniature end plate potential frequency and amplitude, as well as evoked end plate potential amplitude, compared to the adult are consistent with reduced neurotransmitter release and/or disproportionately smaller end plate regions (that is, fewer cholinergic receptors).[106-108]

Muscle Fiber Contractile Properties

Excitation-Contraction Coupling

As previously stated, fetal respiratory movements are present in the rat at about E17, but this does not necessarily reflect the onset of excitation-contraction coupling. In fact, intracellular Ca^{2+} and contractile responses are elicited in the mouse DIAm by indirect nerve stimulation as early as E12.5 (see Figure 85-11), indicating excitation-contraction coupling. These early mechanical responses are coincident with the earliest formation of myotubes/myofibers, expression of contractile proteins, and presence of rudimentary sarcomeres (see Figures 85-12 and 85-13). However, the coordination of these events with the emergence of other structures important in excitation-contraction coupling (for example, functional synapses, T-tubules, triads, and sarcoplasmic reticulum) is largely unknown. A number of studies have focused on the embryologic development of the sarcoplasmic reticulum, T-tubules, and triads and their association with myofibrillar organization.[112-122] In recent ultrastructural studies, we observed the presence of T-tubules, triads, and sarcoplasmic reticulum in the mouse DIAm at E14 (Figure 85-14). Takekura and colleagues[123] also presented ultrastructural and confocal evidence for the presence of T-tubules, triads, and sarcoplasmic reticulum in the embryologic mouse DIAm but only as early as E17. These investigators reported the consistent presence of ryanodine receptor clustering at E15 in the mouse DIAm, suggesting the presence of sarcoplasmic reticulum at this early developmental time point. Interestingly, knockout studies indicate that the apposition of sarcoplasmic reticulum to either plasmalemma or T-tubules occurs despite the absence of ryanodine receptors, L-type Ca^{2+} channels (dihydropyridine receptors), or both, despite the lack of functional activation in these mutants.[121,124,125] However, functional Ca^{2+} release is necessary for normal muscle development. Clearly, further studies are needed to elucidate the maturation of the excitation-contraction apparatus and its function during perinatal development.

Association of Contractile Properties with Fiber Type and MHC Isoform Expression

It is well established that mechanical properties of skeletal muscle fibers correlate with fiber type and MHC isoform composition.[39,42,126-133] In rat and mouse DIAm, fibers that express MHC_{2X} and/or MHC_{2B} display faster maximum unloaded shortening velocities (V_o), as seen in Figure 85-15, and greater specific forces (that is, force generated per muscle cross-sectional area), as seen in Figure 85-16, than fibers expressing MHC_{Slow} and MHC_{2A}. In the adult rat DIAm, the greater maximum specific force of fibers expressing MHC_{2X} and/or MHC_{2B} is at least partially explained by differences in MHC protein content per half sarcomere (that is, greater number of cross-bridges in parallel) as well as the force per cross-bridge (see Figure 85-16).[131,132,134,135] Similarly, the faster V_o of adult rat DIAm fibers expressing MHC_{2X} and/or MHC_{2B} is at least partially explained by faster cross-bridge cycling kinetics and a correspondingly higher rate of ATP consumption.[42,129]

During fetal and early postnatal development, DIAm fiber contractile properties change dramatically, corresponding with the transitions in MHC isoform composition that occur. For example, from E15 to approximately D28, specific force generated by rat DIAm increases almost twentyfold (Figure 85-17),[56,58-60,62,136-138] together with an increase in relative expression of fast MHC isoforms and MHC content per half sarcomere.[56,59,132,136] The lower specific force of fetal and neonatal DIAm is due to both a lower MHC content per half sarcomere and reduced force per cross-bridge.[132] During the same developmental period, V_o of the DIAm increases by more than sixfold (Figure 85-18),[59,60,62,138] again corresponding with the increase in relative expression of fast MHC isoforms.[59] The slower V_o of fetal and neonatal DIAm reflects the slower rate of ATP consumption of these fibers, which predominantly express MHC_{Emb} and MHC_{Neo} isoforms (Figure 85-19).[56] With an increase in both force and velocity, there is an accompanying increase in maximum power output and work performance of rat DIAm from birth to D28.[138] However, as power output and work performance of the DIAm increase postnatally, fatigue resistance to repeated activation declines.[137,138]

While it is clear that during early development the contractile properties of DIAm undergo profound shifts, which correspond to the transitions in MHC isoform expression, the signals driving these changes are not yet known. Changes in contractile properties induced by pathophysiologic conditions may not always be reflected by changes in MHC isoform composition alone. For example, with perinatal hypothyroidism there is a dramatic reduction in maximum specific force and a slowing of V_o in the rat DIAm that cannot be fully attributed to the moderate changes in MHC

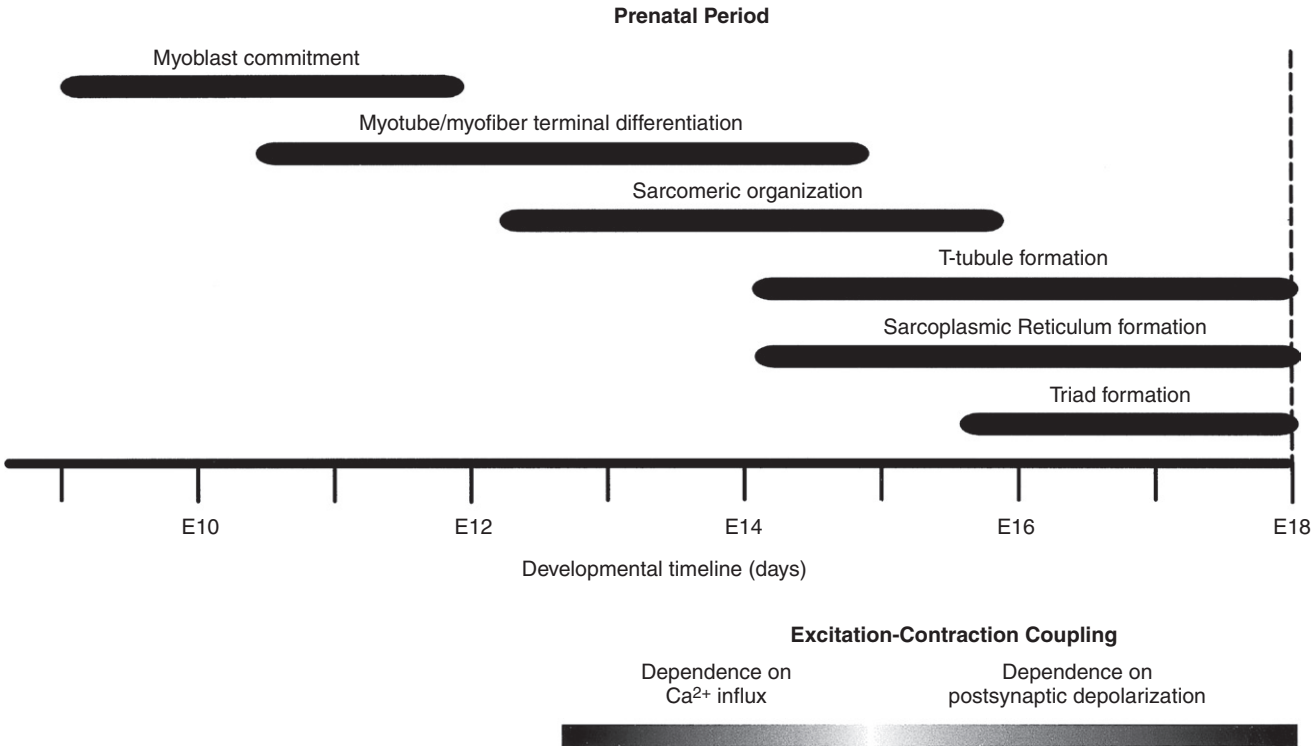

Figure 85-12 Timeline for major embryological events in the formation of myotubes/myofibers in mouse DIAm. It is likely that before the differentiation of distinct T-tubules, triads, and sarcoplasmic reticulum, excitation-contraction coupling is mediated primarily via Ca^{2+} influx, whereas in later embryonic stages mechanisms underlying excitation-contraction coupling resemble those in the adult.

isoform composition.[62] Similarly, following unilateral denervation of the DIAm at D7, there is a marked reduction in maximum specific force and a slowing of V_o that are not predicted from the slight changes in MHC isoform composition. As mentioned above, the changes in specific force may reflect the total MHC content per half sarcomere (that is, number of cross-bridges in parallel) of DIAm fibers rather than MHC isoform expression per se.[131] The slowing of V_o is more difficult to explain. Clearly, these results indicate that cross-bridge cycling kinetics can be slowed independent of the MHC isoform expressed. It is possible that these pathophysiologic conditions affect actomyosin ATPase activity of the myosin S-1 fragment or that there is an increased internal resistance to shortening. In support, we observed that following unilateral denervation of the adult rat DIAm maximum isometric ATP consumption rate was reduced independent of MHC isoform expression.[139]

MHC Isoform Expression and Cross-Bridge Cycling Kinetics in Single Muscle Fibers

In the original model of muscle contraction proposed by Huxley,[140,141] cross-bridges cycle between two functional states: a force-generating state, in which cross-bridges are strongly attached to actin; and a non–force-generating state, in which cross-bridges are detached from actin. The transitions between the two primary functional states of cross-bridges are described by two apparent rate constants: one for cross-bridge attachment (f_{app}) and the second for cross-bridge detachment (g_{app}). An increase in isometric force with increasing myoplasmic Ca^{2+} is explained by the recruitment of cross-bridges into the force-generating state (described by f_{app}). The transition of cross-bridges from force-generating to nonforce-generating states (described by g_{app}) requires the hydrolysis of ATP (actomyosin ATPase). Thus, in the Huxley model, the transduction of chemical to mechanical energy is implicit. Brenner proposed an analytical framework based on Huxley's two-state model of cross-bridge cycling in which this transduction of chemical to mechanical energy is more explicitly described.[142-144] In the Brenner analytical framework, the steady-state fraction of strongly bound cross-bridges in the force-generating state (α_{fs}) is given by:

$$\alpha_{fs} = f_{app} / (f_{app} + g_{app})$$

Isometric force generated by a muscle fiber is then described by following relationship:

$$\text{Isometric Force} = n \cdot F \cdot \alpha_{fs}$$

where n is the number of cross-bridges in parallel per half sarcomere, and F is the mean force per cross-bridge in the force-generating state. Assuming the hydrolysis of one ATP molecule during each cross-bridge cycle, isometric ATP consumption rate (actomyosin ATPase activity) is described by the following relationship:

$$\text{ATPase} = n \cdot b \cdot g_{app} \cdot \alpha_{fs}$$

where b is the number of half sarcomeres within the fiber. At maximal Ca^{2+} activation, where α_{fs} remains constant, actomyosin ATPase activity is directly proportional to g_{app}.

Previously, we employed a quantitative histochemical procedure to determine the maximum velocity of the actomyosin ATPase reaction (V_{max} ATPase) in DIAm fibers expressing different MHC isoforms.[42,129,145] Fibers expressing MHC_{2X} and MHC_{2B} have higher V_{max} ATPase compared to fibers expressing MHC_{Slow} and MHC_{2A}. To determine the ATP consumption rate of single permeabilized rat DIAm fibers during maximum isometric activation (ATP_{iso}), we used an NADH-linked fluorometric procedure.[42,129,146] ATP_{iso} was 30% to 45% lower than V_{max} ATPase, but the dependence on MHC isoform expression was still present, being highest in fibers expressing MHC_{2X} and MHC_{2B} and lowest in fibers expressing MHC_{Slow} and MHC_{2A}. This reflects a reserve capacity for ATP consumption in DIAm fibers, which is consistent with the well-known fact that ATP

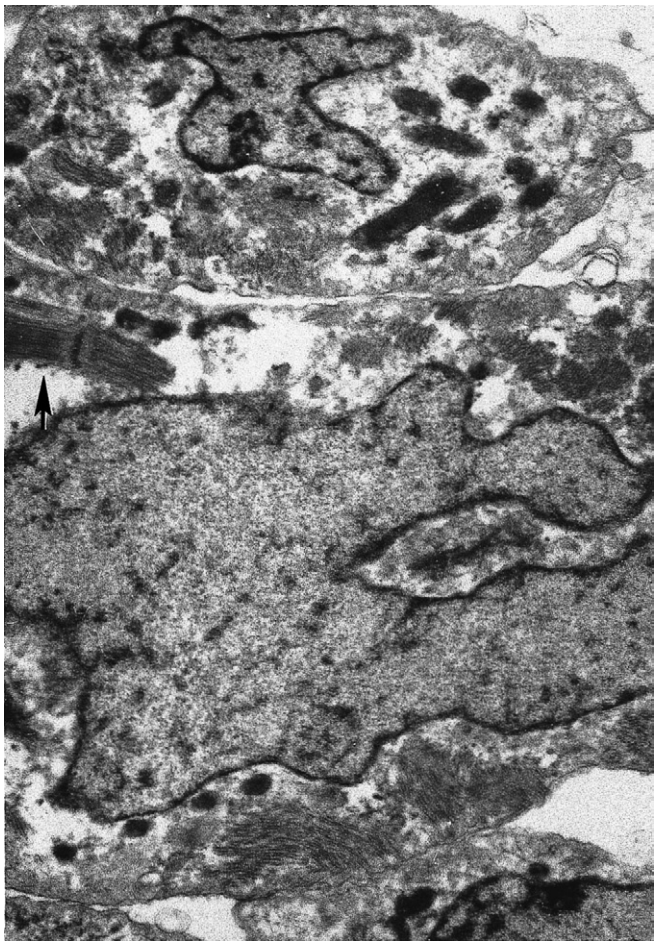

Figure 85-13 Electron photomicrograph displaying rudimentary sarcomeric organization *(arrow)* in the mouse DIAm at E12.5.

consumption rate increases in proportion to work.[147,148] Differences in reserve capacity for ATP consumption may account, at least in part, for differences in fatigability among DIAm fibers.[42,129] In a recent study, we found that the postnatal transition from MHC_{Neo} to adult fast MHC isoform expression in rat DIAm fibers is accompanied by an increase in V_{max} ATPase and ATP_{iso} (Figure 85-19).

MHC Isoform Expression and Ca^{2+} Sensitivity of Muscle Fibers

In skeletal muscle fibers, force generation depends on myoplasmic $[Ca^{2+}]$. The dependency of force generation of myoplasmic $[Ca^{2+}]$ is usually expressed as the force/pCa (-log $[Ca^{2+}]$) relationship. The force/pCa relationship of rat DIAm fibers expressing MHC_{Slow} is shifted leftward compared to fibers expressing adult fast MHC isoforms,[130] consistent with greater Ca^{2+} sensitivity of MHC_{Slow}-expressing DIAm fibers.[149-152]

It is widely recognized that in skeletal muscle, Ca^{2+} binding to the regulatory protein troponin C (TnC) underlies the dependency of force on myoplasmic $[Ca^{2+}]$. Ca^{2+} binding to TnC may simply act to increase the availability of myosin binding sites on actin and thus increase the probability of cross-bridge formation. Different isoforms of TnC from fast (TnC-f) and slow (TnC-s) muscle fibers have different numbers of regulatory binding sites for Ca^{2+} (2 for TnC-f versus 1 for TnC-s) and different binding affinities for Ca^{2+}. These differences in TnC isoforms may underlie the fiber type differences in force/pCa relationships. In support, the force/pCa relationship of rabbit psoas fibers changes when

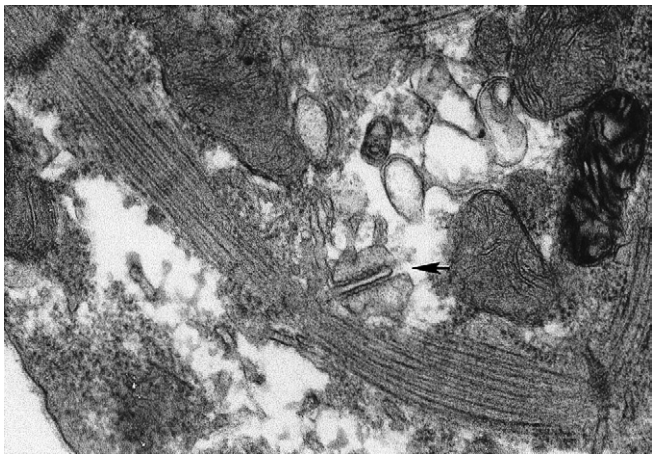

Figure 85-14 Electron photomicrograph showing the presence of a triad *(arrow)* in the mouse DIAm at E14.

the TnC-f present in these fibers is substituted with TnC-s.[153,154] The role of other troponin subunits (TnI or TnT) in regulating muscle contractility is not as well understood, although both slow and fast isoforms exist, and in agreement with TnC findings, fibers containing slow TnI and TnT have higher Ca^{2+} sensitivity than fast Tn-containing fibers.[155]

Functional Implications of Developmental Changes in Mechanical Performance of the DIAm

The DIAm plays a vital role in sustaining ventilation from the time of birth onward, yet its mechanical performance is affected by the concurrent maturation of other structures. For example, with maturation of limb muscles and locomotor function, ventilatory demands placed on the DIAm increase dramatically, and the DIAm must be capable of meeting the increased range of functional demands that coincide with postnatal development.[94] In addition, compliance of the lung and chest wall changes markedly during early development. The neonatal lung is stiffer as a result of greater alveolar recoil, which is offset by expression of surfactant, whereas the chest and abdominal walls are more compliant. As a result, the DIAm must generate greater relative intrathoracic pressures to produce a given level of inspiratory airflow and tidal volume. Yet, the neonatal DIAm generates much lower maximum tetanic force (see Figure 85-17) and has a much slower maximum unloaded shortening velocity (see Figure 85-18) compared to the adult. Thus the functional reserve capacity of the neonatal DIAm is greatly reduced, and a far greater fraction of maximum power output must be recruited to accomplish ventilation. Polyneuronal innervation of DIAm fibers may be particularly important as a neural strategy to accomplish greater fractional recruitment of DIAm motor units. As synapse elimination proceeds, more selective recruitment of DIAm motor units becomes possible, coinciding with the increased range of functions required of the DIAm. In addition, during early postnatal development, expression of MHC_{2X} and MHC_{2B} isoforms in DIAm fibers increases overall functional range, but at the expense of lower energy-efficiency and greater susceptibility to fatigue.[1,3] It is likely that DIAm fibers expressing MHC_{2X} and MHC_{2B} isoforms are recruited only during motor behaviors that require high force output and are of short duration, for example, expulsive behaviors.[1,3] Such motor behaviors of the DIAm may be less necessary in the neonate. Yet, the absence of such functional reserve may cause the neonate be more susceptible to aspiration and asphyxiation. Clearly, greater attention should be focused on the integrative aspects of DIAm development, and it will be important to place the genetic regulation of myogenesis and changing innervation patterns of the DIAm in this more global context.

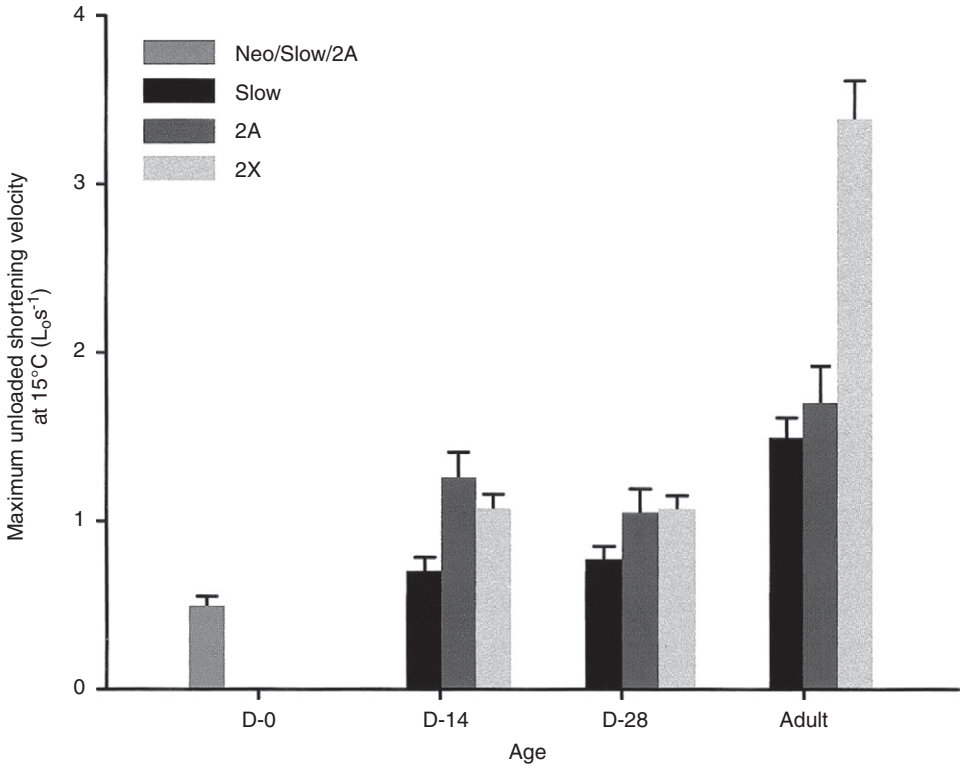

Figure 85-15 Maximum unloaded shortening velocity of single triton-X permeabilized rat DIAm fibers expressing different myosin heavy chain (MHC) isoforms. Maximum unloaded shortening velocity was not solely dependent on MHC isoform expression, but increased with age for fibers expressing the same MHC isoform.

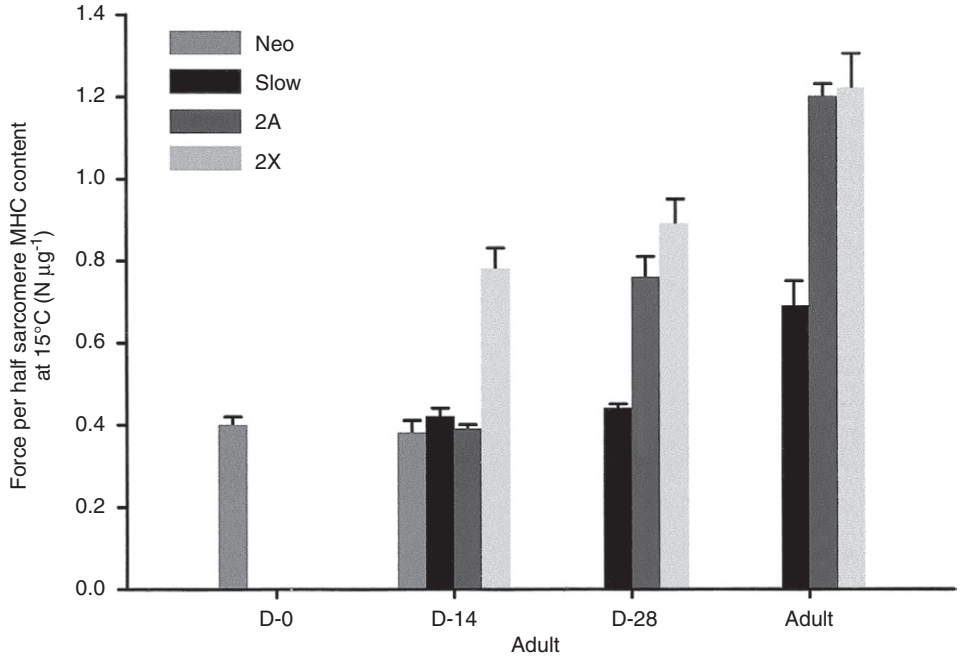

Figure 85-16 Maximum force of single triton-X permeabilized rat DIAm fibers expressing different myosin heavy chain (MHC) isoforms was normalized for MHC content per half sarcomere. Maximum force per half sarcomere MHC content (equivalent to force per cross-bridge) varied with MHC isoform as well as across age-groups for a given isoform.

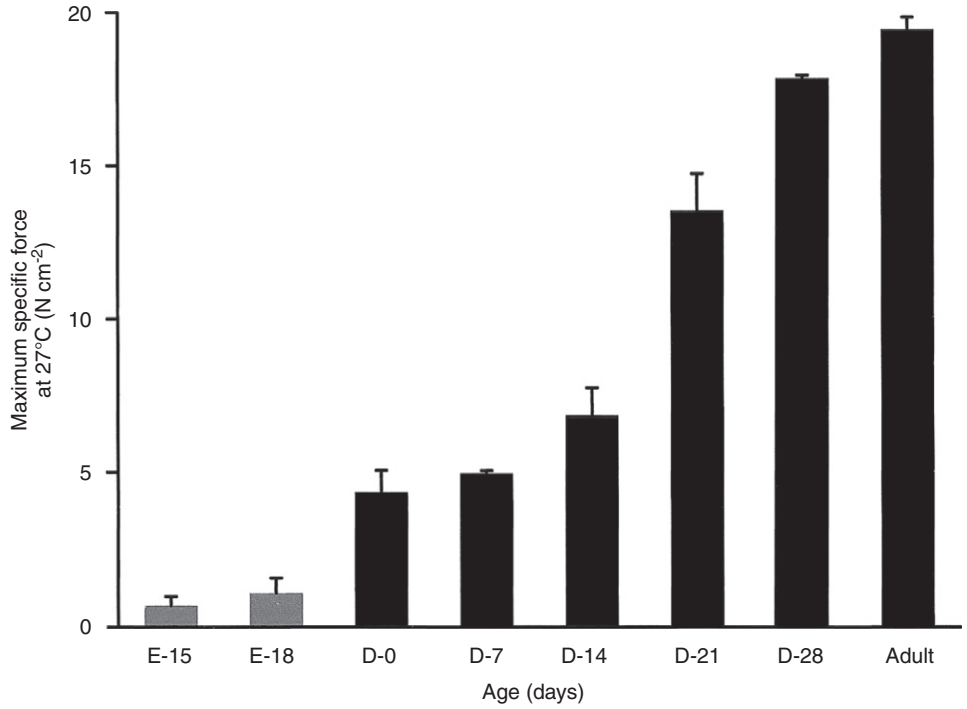

Figure 85-17 Developmental changes in maximum specific force (force per cross-sectional area) of rat DIAm. Maximum specific force increases almost twentyfold from E15 to adulthood.

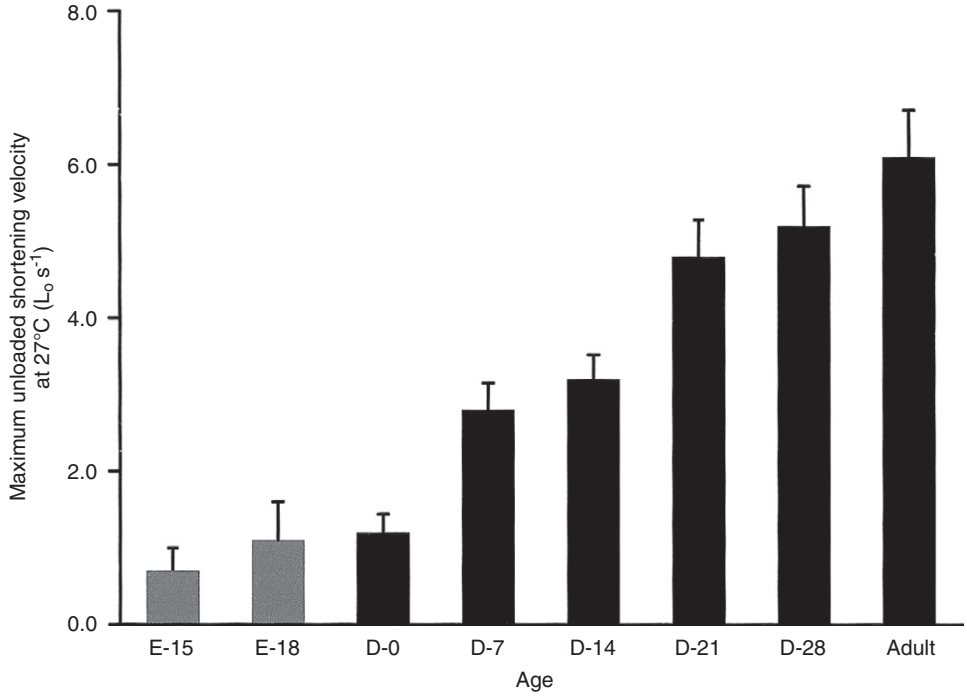

Figure 85-18 Developmental changes in maximum unloaded shortening velocity (expressed as $L_o\ s^{-1}$) of the rat DIAm. Maximum unloaded shortening velocity increases more than sixfold from E15 to adulthood.

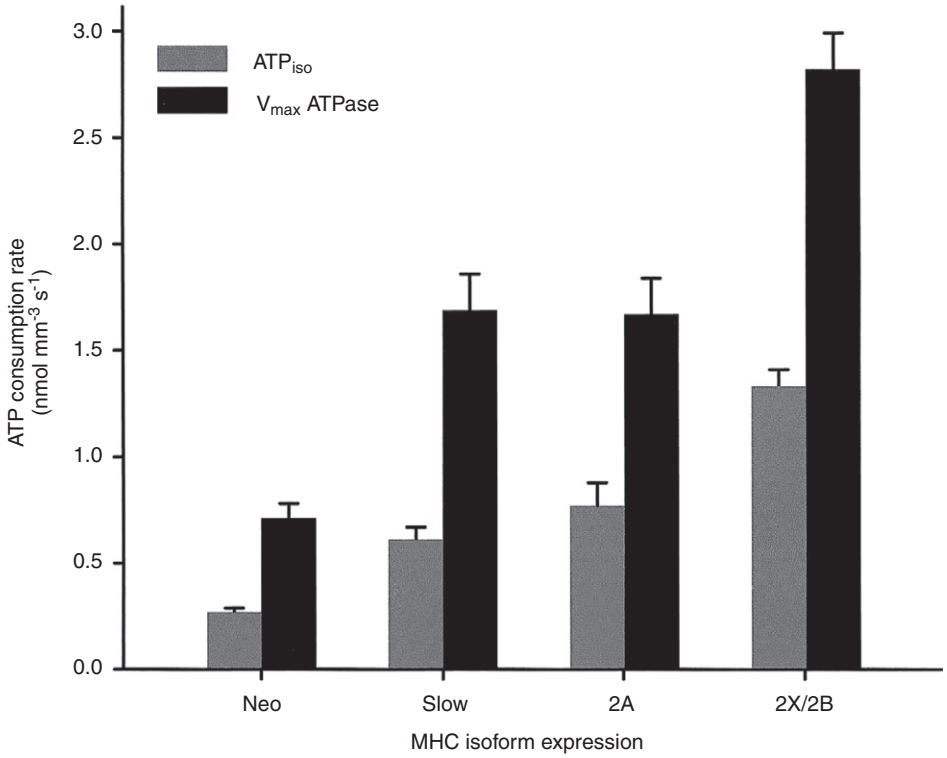

Figure 85-19 Maximum velocity of the actomyosin ATPase reaction (V_{max} ATPase) and maximum isometric ATP consumption rate (ATP_{iso}) of rat DIAm fibers expressing different MHC isoforms. For each fiber type, V_{max} ATPase was greater than ATP_{iso}, indicating substantial reserve capacity for ATP consumption. Although, V_{max} ATPase and ATP_{iso} varied across MHC isoforms and with age, the reserve capacity for ATP consumption remained relatively constant.

86 Mechanics of Breathing

Jacopo P. Mortola

In the chain of events that contribute to the translation of the output of the respiratory rhythm generator into pulmonary ventilation, the mechanical properties of the respiratory system represent a critical step. After activation of the inspiratory muscles, the magnitude of force generated depends on the physical properties of the muscles (i.e., their force-length and force-velocity characteristics). The physical translation of force into inspiratory pressure depends on the configuration of the muscle and the mechanical characteristics of the structure to which the force is applied. Finally, of the total muscle pressure generated, part is required to overcome the elastic properties of the respiratory system to change lung volume *(V),* and part is dissipated to overcome the resistive characteristics of the respiratory system to move air, that is, to generate flow $(\dot{V})$. The additional pressure component required for the acceleration of the gas, and dependent on the inertia of the respiratory system, is usually very small and can be neglected. Hence, the total pressure P generated is equal to the sum of elastic *(Pel)* and resistive *(Pres)* components, the former proportional to V and $1/C$, the latter proportional to $\dot{V}$ and R,

$$P = Pel + Pres = (V \cdot 1/C) + (\dot{V} \cdot R) \quad (1)$$

where C and R are proportionality factors determined by, respectively, the elastic and resistive characteristics of the system.

During *spontaneous breathing*, the total P for inflation is generated by the respiratory muscles, hence P = muscle pressure *(Pmus),* and inflow occurs whenever *(Pmus − Pel)* is greater than 0. Normally, during resting breathing, because tidal volume is entirely above the resting volume of the respiratory system *(Vr),* the inspiratory muscles generate *Pmus,* and expiration is passive. However, in some conditions, for example, certain cases of hyperventilation or during breathing against a positive airways pressure, the expiratory muscles may become active, and breathing occurs across *Vr.* In these cases, inspiration is the combined result of the recoil of the respiratory system after expiratory muscle relaxation plus the active contraction of the inspiratory muscles.

During *artificial ventilation*, $Pmus = 0$, and the driving pressure is generated by the ventilator, which opposes *Pel* and *Pres.* Whenever $Pmus = 0$, we say that the system is in a *passive* mode; this is the case during lung expansion by an external ventilator. It also occurs during the last portion of expiration during resting breathing. In fact, during this phase, the elastic pressure stored during inspiration *(Pel)* is the sole driving pressure generating expiratory flow, that is, $Pel = Pres = \dot{V} \cdot Rrs$.

Whenever *Pmus* differs from 0, we say that the system is in an *active* mode; this is of course the case during spontaneous inspiration, but it can also occur when $\dot{V} = 0$, such as during voluntary breath holding (in which case $Pmus = Pel$).

Whenever $\dot{V} = 0$, Equation 1 simplifies to

$$P = Pel = V \cdot 1/C \quad (2)$$

This condition is defined as *static*, irrespective of whether *Pel* is offset by muscle activity (e.g., during breath holding) or by external means with $Pmus = 0$ (e.g., relaxation against an artificial occlusion of the airways). On the contrary, whenever $\dot{V}$ differs from 0, the system is in a *dynamic* condition, again, irrespective of whether the respiratory muscles are active (e.g., inflation during spontaneous inspiration) or not (e.g., inflation by a ventilator). In conclusion, therefore, the operating modes of the respiratory system can be summarized into four combinations, *static* or *dynamic*, depending on the absence or presence of $\dot{V}$, each either *active* or *passive*, depending on the presence or absence of muscle activity (Box 86-1).

A dynamic condition with no changes in V (or changes in V so small that the component $V \cdot 1/C$ of Equation 1 is negligible) can be approached when $\dot{V}$ is very high and V is very small. This can happen during panting or during high-frequency ventilation. During an inspiratory effort against closed airways, because the change in lung volume equals 0 (and therefore also $\dot{V} = 0$), no external work is performed, and the total pressure is entirely dissipated as heat.

PASSIVE MECHANICAL PROPERTIES OF THE RESPIRATORY SYSTEM

As stated earlier, the respiratory system is in a passive mode when $Pmus = 0$. This is the case during paralysis, with the lungs ventilated by external means (e.g., positive pressure ventilation). Similarly, a passive condition occurs after a period of hyperventilation, when the arterial partial pressure of carbon dioxide ($Paco_2$) is lowered below the threshold for muscle activation, which is just a few mm Hg below the resting $Paco_2$ value.[1] In a spontaneously breathing subject, the passive mode can also be achieved by passively maintaining the lung volume above the resting position of the respiratory system, as for example with an external occlusion of the airways at end-inspiration. In fact, maintaining lung inflation activates the airway slowly adapting stretch receptors and triggers the vagally mediated Hering-Breuer inflation reflex, causing relaxation of the inspiratory muscles. This brief period of artificially provoked muscle relaxation is important in the context of pulmonary function testing in human neonates and is sufficient to evaluate the passive mechanical properties of the respiratory system in a spontaneously breathing infant.

Passive Respiratory Mechanics During Artificial Ventilation

To some extent, measurements of passive mechanics of the respiratory system are easier to perform during artificial ventilation than during spontaneous breathing. In fact, because $Pmus = 0$, the passive conditions are guaranteed. In addition, because it is customary to ventilate the lungs through an endotracheal tube, the infant's upper airways are bypassed, eliminating an important source of nonlinear mechanical behavior. Therefore the respiratory system is more likely to perform as a first-order mechanical system, which substantially simplifies the conceptual approach and the analysis of the measurements.

In an infant with intubation and artificial ventilation, $\dot{V}$ can be easily measured by a pneumotachograph placed in series between the endotracheal tube and the ventilator. The signal is amplified and electronically integrated to obtain the changes in lung volume *(V).* During artificial ventilation, the total P needed to inflate the whole respiratory system (P of Equation 1) is

BOX 86-1

Glossary of Terms, Units, and Common Terminology

BTPS	Body temperature, pressure, saturated with water vapor
C (C_L, *Crs, Cw*)	Compliance (of lungs, respiratory system, chest wall), mL/cm H_2O
FRC	Functional residual capacity (end-expiratory volume), mL
P	Pressure, cm H_2O
Pao	Pressure at the airway opening, cm H_2O
Pel	Elastic pressure (proportional to lung volume), cm H_2O
Pes	Esophageal pressure (proportional to pleural pressure), cm H_2O
Pmus	Pressure generated by the respiratory muscles, cm H_2O
Pres	Resistive pressure (proportional to airflow), cm H_2O
R (R_L, *Rrs, Rw*)	Resistance (of the lungs, respiratory system, chest wall), cm $H_2O \cdot mL^{-1} \cdot s$
τrs	Passive time constant of respiratory system, s
$\tau rs(exp)$	Expiratory time constant of respiratory system, s
V	Volume, mL (BTPS)
V_T	Tidal volume, mL (BTPS)
$\dot{V}$	Flow, mL (BTPS)/s
Vr	Static relaxation volume of respiratory system, mL
Active mode:	*Pmus* >0, respiratory muscles are active.
Passive mode:	*Pmus* = 0, respiratory muscles are relaxed.
Static condition:	$\dot{V} = 0$. (1) *Active:* breath holding by muscle contraction above or below *Vr;* (2) *passive:* relaxation against closed airways above *Vr* (*Pao* >0), below *Vr* (*Pao* <0), or at *Vr* (*Pao* = 0).
Dynamic condition:	$\dot{V} > 0$. (1) *Active:* activation of the respiratory muscles, as during spontaneous breathing; (2) *passive*: respiration driven by external means, with respiratory muscles relaxed, as during mechanical ventilation or in the late portion of expiration during resting breathing.

conveniently measured at the airway opening *(Pao),* such as the mouth or the inlet of the endotracheal tube. From these measurements, the values of *C* and *R* of the respiratory system (*Crs* and *Rrs,* respectively) are either separately computed or derived from the equation of motion of the respiratory system (Equation 1). In fact, because three ($\dot{V}$, *V, Pao)* of the five variables are measured, it is possible to mathematically derive the two unknown constants, *Crs* and *Rrs.* With a conceptually similar approach it is possible to compute *C* and *R* of lungs and chest wall.

The possibility of air leaks around the endotracheal tube and the need for accurate estimation of the tube resistance[2] are common problems. Tube resistance can be estimated in vitro, being aware that the fluid dynamics of small tubes can introduce substantial errors in the traditional computation of resistance from delta pressure and flow.[3] Air leaks can introduce enormous errors in the computation of volume of air delivered to the lungs and parameters related to it. Measuring the changes in inflation pressure at the distal end of the tube gives a more accurate estimate of changes in lung volume than the common way of measuring pressure more proximally. Nevertheless, the pressure value includes a component caused by airflow that increases as the leak increases; therefore it cannot be used with confidence to estimate the changes in lung volume. Methods for measuring changes in lung volume in infants on artificial ventilation—other than using a cuffed endotracheal tube—are the head-out body plethysmography and the respiratory inductance plethysmography; however, the former technique is cumbersome and the latter has some approximation.[4]

Compliance

At end-inflation, the compliance of the respiratory system, *Crs,* equals $\Delta V/\Delta Pao$, where ΔV and ΔPao represent the difference in *V* and *Pao* between the onset of inflation and the zero-flow point at end-inflation. It is important to realize that, at the onset of the inflation, *Pao* is not necessarily zero. In fact, *Pao* is above zero whenever the infant's lungs are ventilated with some positive end-expiratory pressure, which is the most frequent condition. Therefore, if one had to compute *Crs* simply as the ratio of *V* and *Pao*, instead of $\Delta V/\Delta Pao$, the resulting value of *Crs* would be incorrectly low.

Lung compliance *(C_L)* is measured as the ratio between the change in *V* (ΔV) and the change in transpulmonary pressure (ΔP), defined as the difference between *Pao* and pleural pressure; from *Crs* and C_L, chest wall compliance *(Cw)* is computed as $Cw = 1/(1/Crs - 1/C_L)$. As in adults, newborn pleural pressure is usually measured as esophageal pressure *(Pes),* with an esophageal balloon or an esophageal liquid-filled catheter. However, especially in premature infants, to what extent the *Pes* is a faithful representation of the mean change in pleural pressure is debatable.[5-10] Problems originate not only from the technical aspects of the measurements (including the frequency response of the esophageal catheter) but also because of the distortion of the chest, a phenomenon much more pronounced in infants than in adults. In spontaneously breathing infants, a test performed to evaluate the accuracy of the *Pes* recording is accomplished by comparing the change in *Pes* with that of *Pao* during an inspiratory effort with occluded airways.[6,10,11] Because during an inspiratory effort with an occluded airway neither lung volume nor transpulmonary pressure changes, the *Pao-Peso* difference should remain nil. However, in infants, particularly in premature infants, the distortion of the chest is often great and not necessarily the same between the occluded inspiratory effort used to test the reliability of the *Pes* measurement and the normal open-airway inspiration. Therefore one is left with the possibility that what may seem a reliable measurement during effort is not equally valid during normal spontaneous breathing.

Compliance measured as described earlier is often labeled *dynamic* compliance, a term that may be confusing because it seems to contradict the requirement for *static* conditions. In effect, the word *dynamic* is used to stress the fact that the measurement is performed during the dynamic state of continuous ventilation, by taking advantage of the very brief end-inflation condition, when, in fact, $\dot{V} = 0$. Truly static conditions can be achieved by stopping the ventilator, and recording *P,* while the lungs are inflated at a constant level. When this is done in healthy adults, the values of *dynamic* compliance are found to be quite close to the *static* measurements. In infants, however, values of *dynamic* compliance are consistently lower than *static* values,[12-14] mainly because of the lung stress relaxation. Stress relaxation is a phenomenon originating from the viscous properties of biologic tissue and substantially more marked in newborns than in adults.[15,16] The asynchronous behavior of peripheral lung units characteristic of newborns contributes to the *dynamic-static*

difference of compliance,[17] and even more so in conditions of marked chest distortion.[18]

Resistance

At any given time during lung *inflation* the total resistance of the respiratory system *(Rrs)* can be calculated as *Pres/$\dot{V}$*, where *Pres* is the difference between the total *P* of the respiratory system and its elastic components (Equation 1).[19] The measurement is more accurate at the time of peak flow, which is usually in the middle third of inflation. Alternative analytic approaches are based on the computation of *Pres* by planimetry or on various solutions of Equation 1.[20] The total pulmonary resistance *(R_L)* is computed in a very similar way; in this case, *Pres* is the difference between the total inflating transpulmonary pressure and its elastic component. Finally, chest wall resistance *(Rw)* is the difference *Rrs* − *R_L*.

During lung *deflation*, to the extent that the respiratory apparatus behaves mechanically as a first-order system, the decrease in volume and flow follows exponential trajectories. Therefore, during deflation, the logarithmic representation of either signal yields a linear relation, and the reciprocal of the slope represents the time constant (*τrs*).[21] Because the time constant of a first-order mechanical system is the product of the system *C* and *R*, *Rrs* is computed as *τrs/Crs*.

Passive Respiratory Mechanics in the Spontaneously Breathing Infant

For these measurements, the infant is breathing through a face mask connected to a $\dot{V}$- recording device, the pneumotachograph. The $\dot{V}$ signal is electronically integrated to obtain the changes in lung volume *(V),* while also measuring the pressure at the airways opening *(Pao).* Although the face mask modifies the breathing pattern, because of the stimulation of the trigeminal area[22] and because of the added dead space, neither of these has an important effect on respiratory mechanics. In its simplest approach, the investigator holds the mask on the infant's face, covering both mouth and nostrils, then intermittently performs manual brief occlusions of the pneumotachograph outlet, with the effect of maintaining the infant's lung volume constant. Alternatively, the use of a solenoid valve with computerized control[23] may be desirable for the accurate timing of the occlusion. This brief airway occlusion is the maneuver at the core of the measurements of *Crs* and *Rrs* to be described.

Compliance

During the occlusion of the airways at end-inspiration or in expiration (Figure 86-1), *Pao* rises to the recoil pressure of the respiratory system at that volume. The time required for *Pao* to reach its new equilibrium depends on the time needed by the inspiratory muscles to reach full relaxation. This relaxation is triggered by the activation of the airway slowly adapting stretch receptors, which respond to transpulmonary pressure. Therefore the larger the lung volume at which the occlusion is performed, the greater the likelihood of complete muscle relaxation. The passive condition required for the measurement lasts not more than a couple of seconds; after this time, the same vagal reflex inhibiting the inspiratory muscles eventually activates the expiratory muscles. However, this short time is sufficient for the measurements. Because *Crs* is the slope of the Δ*Pao*-Δ*V* relationship (x- and y-axis, respectively), the accuracy of the *Crs* computation improves by collecting many δ*Pao*-δ*V* data points over a wide range of *V*.[12,24-27]

Several other approaches have been proposed to compute *Crs,* with small variations from the method just described.[28-30] One of these methods computes the functional residual capacity (FRC)-*Vr* difference by extrapolation of the expiratory $\dot{V}$-*V* loop (see later); then the FRC-*Vr* is added to the Δ*V* for the correct computation of *Crs,* as (*V* + FRC-*Vr*)/*Pao*). With this approach, during one single brief airway occlusion and its immediate release, it is theoretically possible to compute not only *Crs* and FRC-*Vr* but also the time constant and the resistance of the respiratory system (respectively, *τrs* and *Rrs;* see later).[28] Another approach consists of two brief occlusions of the airways.[29] The first occlusion is performed to establish a reference *V* and the corresponding static *Pao,* and the second occlusion is done at a different *V,* either later in expiration or during the following breath. Then *Crs* is computed from the *V* difference between the two occlusions (Δ*V*) and the corresponding difference in *Pao* (Δ*Pao*), as *Crs* = Δ*V*/Δ*Pao*. This method circumvents the potential problems introduced by the breath-by-breath oscillations in FRC. In all these cases, if also *Pes* was monitored, as schematically indicated in Figure 86-1, it would be possible to partition *Crs* into its lung and chest wall components (respectively, *C_L* and *Cw*).

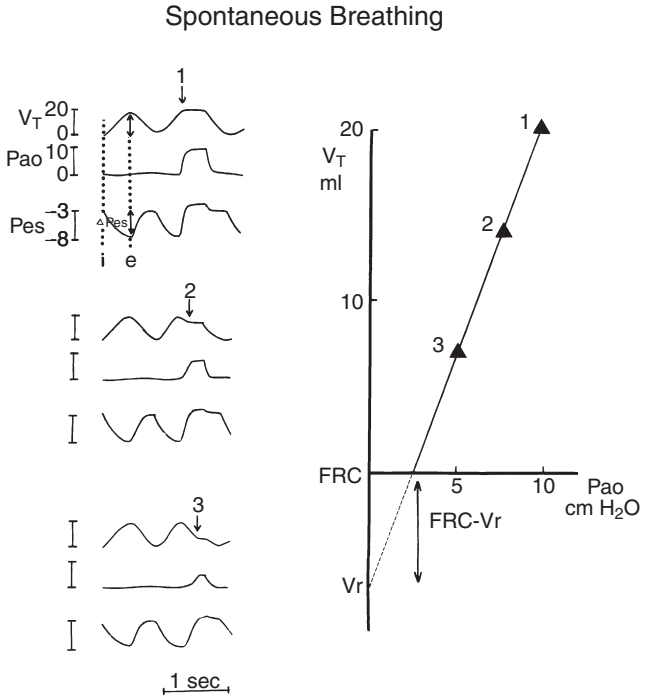

Figure 86-1 Schematic representation of the changes in lung volume (tidal volume, *V_T*), pressure measured at the mouth *(Pao),* and esophageal pressure *(Pes)* in a spontaneously breathing infant. In each of the three examples indicated, from *top* to *bottom,* the recordings start with a breathing cycle followed by an artificial occlusion of the airways. At *1,* the occlusion is at end-inspiration; at *2,* in the first third of expiration; at *3,* in the second half of expiration. The corresponding *Pao-V* points are plotted in the diagram at *right;* the slope of the linear regression represents the compliance of the respiratory system *(Crs),* and the intercept on the y-axis represents the difference between the end-expiratory level and the resting volume (FRC-*Vr* difference). Although only three data points are represented, many more data points through the whole *V_T* range are desirable to improve the accuracy of the linear regression. From *V_T* and *Pes* dynamic lung compliance can be computed as *V_T*/Δ*Pes*, between the two zero-flow points at beginning and end-inspiration *(left panels: i, e)*.

Time Constant and Resistance

Both *C* and *R* vary with large changes in lung volume.[31] Within the *V_T* range, though, their values remain approximately constant. Therefore, during a passive expiration (such as after reopening the airways following a brief airway occlusion at end-inspiration), both *V* and $\dot{V}$ decrease exponentially. The semilog representations

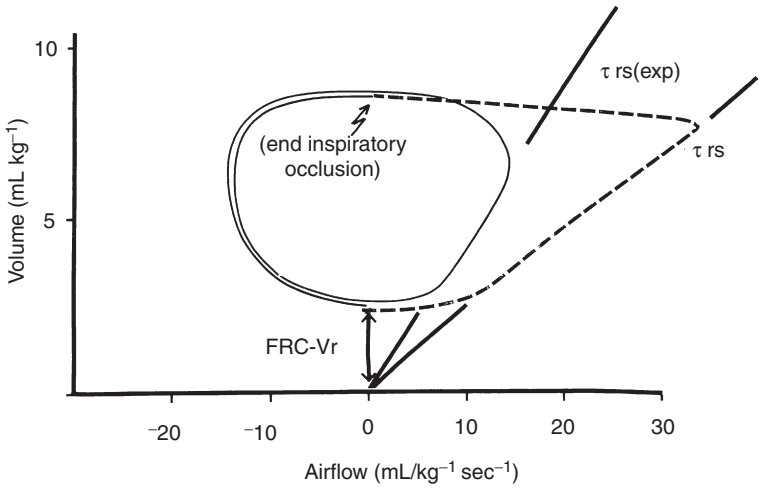

Figure 86-2 Infant, spontaneously breathing. Respiratory airflow and volume are continuously recorded and schematically plotted on the x- and y-axes *(continuous line).* Inspiration is at *left* (negative flows) and expiration is at *right* (positive flows). At end-inspiration of the second breathing cycle, the airways are briefly occluded by the investigator (end-inspiratory occlusion); after release of the occlusion, the slope of the deflation flow-volume curve *(dashed line)* represents the passive time constant of the respiratory system (τrs). Usually, during resting breathing, the expiratory flow-volume curve is at the left of the passive curve, indicating that the expiratory time constant, $\tau rs(exp)$, exceeds τrs. The extrapolation to zero flow of the linear portion of the expiratory flow-volume relationship permits computation of the volume difference between the end-expiratory volume *(FRC)* and the resting volume of the respiratory system *(Vr).*

of such trajectories are linear, and the reciprocal of the slope is the passive time constant of the respiratory system (τrs).[32] More simply, because the ratio of two exponential decays is a constant,[21] the plot of $\dot{V}$ (x-axis) − V (y-axis) during the passive expiration is a linear relationship, the slope of which is τrs[24,28,33] (Figure 86-2). Then Rrs is calculated as $\tau rs/Crs$. Such a simple and very practical approach is not readily applicable whenever the expiratory $\dot{V}$ and V do not follow exponential trajectories. Deviations from the exponential pattern could be due to several reasons, including respiratory muscle activation or nonlinear mechanical behavior of the upper airways. In these cases, the values of τrs and Rrs depend on the $\dot{V}$ at which they are measured.

In infants, during resting breathing, the extrapolation of the linear segment of the $\dot{V} - V$ expiratory curve to zero $\dot{V}$ hits the V-axis below FRC; this difference represents the dynamic elevation of the end-expiratory level (or FRC-Vr difference).[24,25] In fact, in infants, expiration is short with respect to τrs, and inspiration begins at a lung volume higher than Vr.[20] The FRC-Vr difference, sometime referred to as the *dynamic elevation of FRC*, can also be computed from the *Pao-V* curve, as described above (see Figure 86-1); in infants a few days old it averages 7 to 15 mL,[24,25,34,35] or approximately 20% to 30% of tidal volume.

As for other pulmonary function tests, the techniques described previously for measurements of C and R have been the object of numerous discussions, and their technical details can be found in review articles.[27,36-38] Because the transition from the research setting to the bedside is recent, one goal of the discussions is to make the techniques uniform and standardized to facilitate comparison among studies and identification of pathologic situations.

ACTIVE MECHANICAL BEHAVIOR OF THE RESPIRATORY SYSTEM

An important question is whether or not during spontaneous breathing the mechanical properties of the respiratory system are the same as measured during passive conditions. The answer is that the system does not behave as expected on the basis of passive measurements either in inspiration or in expiration. One reason is the difference between *dynamic* and *static* compliance, mentioned earlier. Furthermore, the uneven distribution of forces applied to the chest wall during muscle contraction leads to distortion of the chest; these functional implications are discussed in the next section. During expiration, residual activities of the inspiratory muscles and laryngeal muscles control the expiratory flow and mean lung volume, increasing R and prolonging τrs.[20]

Mechanics of Chest Wall Distortion

During passive inflation of the respiratory system (as during external ventilation provided by a ventilator) both the abdominal and pleural pressures increase. In fact, in the absence of diaphragmatic tension, the changes in pleural and abdominal pressures are the same, and any region of the chest wall (specifically, its two main compartments, rib cage and abdomen) will be driven by the same pressure applied uniformly to all regions.

In active conditions ($Pmus$ >0), when the diaphragm is contracting, the abdominal pressure increases as it does with passive inflation, expanding the abdomen. In contrast, the motion of the rib cage depends on the interplay of several factors.[20] During spontaneous inspiration the pleural pressure is subatmospheric, a situation that tends to collapse both the upper and lower regions of the rib cage, as in quadriplegic patients who have lost the use of the extradiaphragmatic muscles.[39] With respect to the lower rib cage regions, the tendency to collapse is partly offset by the expanding action of the abdominal pressure and also by the direct outward-pulling of the diaphragmatic fibers. In normal infants the inspiratory collapse of the upper rib cage is a common event because their characteristically high Cw is responsible for the poor mechanical coupling between upper and lower rib cage regions. It follows that during spontaneous inspiration, an expansion of the rib cage (to a degree comparable to that observed during passive inflation) can occur only with the intervention of the intercostals or the other extradiaphragmatic muscles, which, indeed, are recruited to compensate the inevitable distortion of the chest wall.[40] The two situations (*absence* of distortion and *compensated* distortion) are quite different when examined in light of the energetics of breathing.

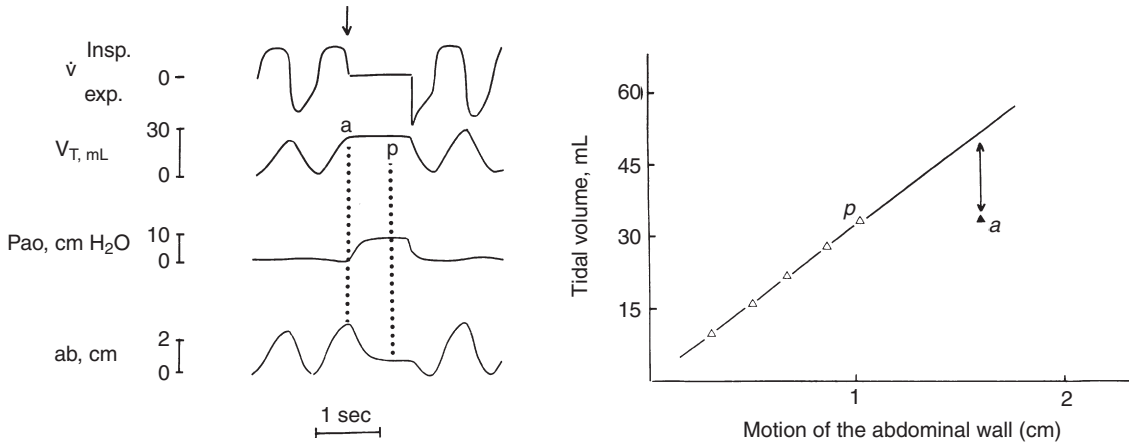

Figure 86-3 Schematic representation (from *top* to *bottom*) of the changes in respiratory airflow *($\dot{V}$),* tidal volume *(V_T),* pressure at the airway opening *(Pao),* and motion of the abdominal wall *(ab)* in a spontaneously breathing infant. At *arrow*, the investigator briefly occludes the airways, and muscle relaxation occurs at the plateau of *Pao.* The active *(a, solid triangle)* and passive *(p) V-ab* points are plotted at *right.* The passive relationship *(open triangles)* is obtained by multiple occlusions at different lung volumes during expiration. The vertical distance between *a* and the passive curve *(double arrow)* indicates the volume loss because of distortion.

A functional evaluation of the net effect of chest distortion can be done by comparing lung volumes between active and passive conditions at the same abdominal pressure (or at the same degree of abdominal expansion, because, in the absence of abdominal muscle activity, changes in abdominal pressure and abdominal displacement are closely related).[40] A schematic example is presented in Figure 86-3, which refers to a newborn infant during sleep. $\dot{V}$, *V,* and *Pao* are recorded, together with the motion of the abdominal wall. At end-inspiration the experimenter briefly occludes the infant's airways, and the plateau in *Pao* during the short time of the occlusion suggests relaxation of the respiratory muscles. Hence, at the same lung volume (end-inspiration), two situations can be recognized; one is *active*, at the end of the spontaneous inspiration, and the other one is *passive*, during the occlusion. By performing many such maneuvers at different lung volumes during expiration, it is possible to construct the passive relationship between abdomen motion and *V,* similar to what was described earlier for the measurement of *Crs* during spontaneous breathing. The difference on the y-axis between the active points (at end-inspiration) and the passive relationship represents the *V* difference between active and passive conditions. Normally (infants during resting breathing, at any given abdominal pressure) V_T is less than the passive *V,* by as much as 50%. This means that breathing in infants involves a substantial *volume loss*.[40] The volume loss is likely to increase in rapid eye movement sleep, when the intercostal muscles are less active and the inspiratory distortion of the rib cage is maximal. In addition, the volume loss probably increases in the supine posture, compared with the prone position,[41] because abdominal compliance is higher in the former case. A very large volume loss could occur in conditions of high *Cw/CL* ratio, as in premature infants, in diseases lowering *CL,* such as bronchopulmonary dysplasia, or in conditions of increased airway resistance. Conversely, a very small volume loss, or a V_T exceeding the passive *V,* could occur in hypoxia or in other situations of elevated motor output to the extradiaphragmatic muscles.

Expiratory Time Constant

Because, in resting conditions, expiration is a passive process, one may expect the expiratory $\dot{V}$ and *V* to follow exponential profiles; hence, the time constant measurable during tidal expiration, $\tau rs(exp)$, should coincide with the passive time constant of the respiratory system (τrs; see Figure 86-2). However, this is often not the case,[24,25,35] and $\tau rs(exp)$ exceeds τrs mainly for two reasons. First, the inspiratory activity does not cease abruptly at end-inspiration but proceeds during part of the expiratory phase, effectively reducing the elastic recoil pressure of the respiratory system. Second, the adduction of the vocal folds during expiration increases airway resistance, prolonging τrs. Graphically, the effects of the activity of the inspiratory and laryngeal muscles in expiration can be appreciated by comparing the tidal expiratory flow-volume loop with the curve obtained after release of an end-inspiratory airway occlusion (see Figure 86-2).[24,25] The finding that the expiratory curve is positioned at the left of the passive curve indicates that $\tau rs(exp)$ is longer than τrs at all volumes during expiration.

The prolongation of $\tau rs(exp)$ causes mean lung volume to remain higher throughout the expiratory phase of the breathing cycle. Also the next inspiration begins at a volume (FRC) higher than *Vr.* Indeed, more than 30 years ago Olinsky and co-workers[42] showed that, during a short period of apnea, FRC decreased in infants, recognizing that during resting breathing, FRC must be maintained actively above *Vr.* Later, it was possible to compute the FRC-*Vr* difference, from the static pressure-volume curve (see Figure 86-1) or from the expiratory flow-volume curve (see Figure 86-2).[24,25,34,35,43] The elevation of FRC above *Vr* results from the combined effects of the breathing rate (which in infants is higher than in adults) and the expiratory action of inspiratory and laryngeal muscles[44] and represents an important mechanism to counteract the infant's predisposition to a low *Vr* caused by the high *Cw-CL* ratio.[20] These mechanisms to control FRC are lost in infants whose lungs are artificially ventilated through an endotracheal tube, because the breathing frequency is controlled by the ventilator, and the laryngeal region is bypassed. In these cases, an end-expiratory *P* of a few centimeters of water[45,46] is added to the expiratory line of the ventilator to avoid the complete deflation of the lungs to *Vr.*

ASPECTS OF THE ENERGETICS OF BREATHING

From the equation of motion of the respiratory system (Equation 1), it is apparent that once *Crs* and *Rrs* are known, it is possible to compute the total pressure required to inflate the lung to a given

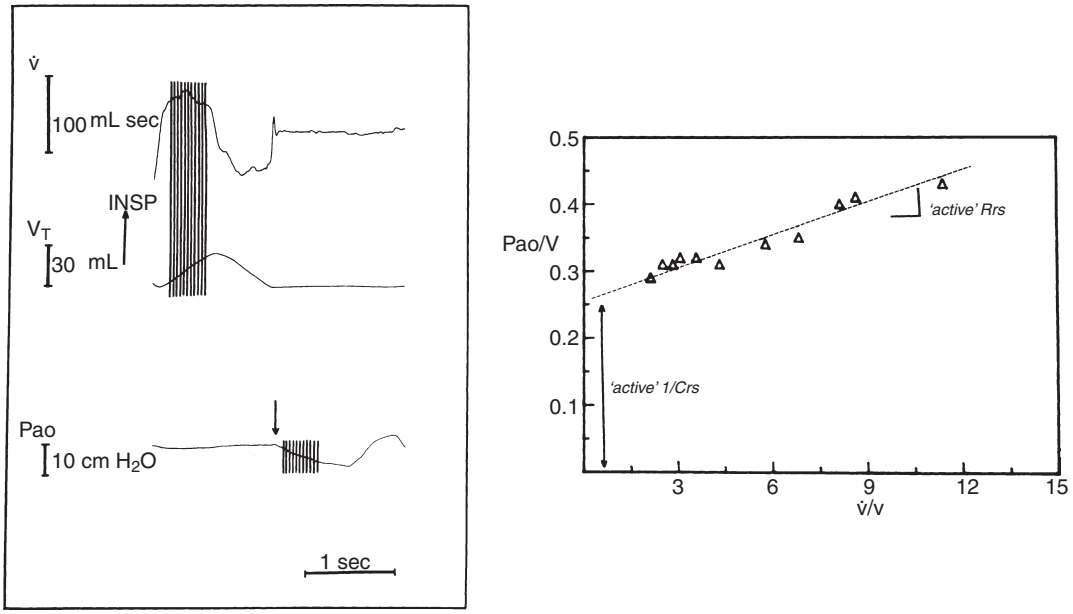

Figure 86-4 *Left*, Newborn infant, spontaneously breathing. From *top* to *bottom*, records of respiratory airflow ($\dot{V}$), tidal volume *(V_T),* and mouth pressure *(Pao).* At the time indicated by the *arrow*, the investigator occludes the infant's airways; then the infant makes an inspiratory effort, as shown by the drop in *Pao* with no changes in V_T. The *vertical parallel lines* indicate isotime measurements of *Pao* (from the onset of the effort), $\dot{V}$, and V_T (from the onset of the preceding breath). *Right*, The isotime *Pao/V-V̇/V* points are plotted; from the linear regression through the data points, the slope and the reciprocal of the intercept represent, respectively, the active resistance and active compliance of the respiratory system. *(Modified from Mortola JP, Saetta M: Measurements of respiratory mechanics in the newborn: a simple approach,* Pediatr Pulmonol *3:123, 1987. With permission from Wiley-Liss, a division of John Wiley & Sons, Inc.)*

volume in a given time. The total work can be calculated on the assumption of a sinusoidal flow pattern, based on the formula originally proposed by Otis and co-workers.[47] These computations have indicated that in newborns, as in adults, resting breathing frequency is controlled to fall within the optimal range of minimal external work although the mechanisms that lead to this optimal performance are still unknown.[24] The respiratory work calculated in this way represents the *passive* work of breathing, because it is based on values of *Crs* and *Rrs* obtained in passive conditions. During spontaneous breathing, though, the *active* work of breathing is likely to exceed the passive value. The main reason for this difference is that the respiratory muscles cannot apply a force to the chest wall as uniformly as it occurs in passive conditions. For example, the main inspiratory muscle, the diaphragm, acts more like a piston expanding the abdomen and simultaneously collapsing the upper rib cage than a uniform chest wall expander. The result of this uneven distribution is that some muscle force is lost in the distortion of the chest wall, instead of being translated into pressure driving the respiratory system. Furthermore, during contraction, a muscle loses force according to its length and velocity of shortening. Therefore, from the point of view of the dynamics and energetics of breathing, one could state that, during active breathing, the respiratory system behaves as if its impedance were higher than in passive conditions, because of a lower *Crs,* higher *Rrs,* or both.

Estimates of the active pressure required to expand the respiratory system have been obtained by measuring the pressure in the airways *(Pao)* generated during an inspiratory effort against an occlusion. In fact, in this condition, the change in lung volume is negligible, and, supposedly, the inspiratory muscles are contracting isometrically. The main assumption underlying this approach is that the *Pao* generated by the muscles is the same pressure required to generate V and $\dot{V}$ during normal breathing. Measurements of *Pao* are made at known time intervals from the onset of the occluded effort and those of flow and volume at the corresponding times from the onset of the preceding open airway breath (Figure 86-4, *left*).[48] From these data, it is possible to construct the *Pao/V* (y-axis) – $\dot{V}/V$ (x-axis) relationship; the slope and intercept represent, respectively, the *active Rrs* and 1/*Crs* (see Figure 86-4, *right*). From several studies that have applied this or similar approaches, it can be concluded that the newborn infant's *Crs* during spontaneous breathing is approximately 65% of the passive value, whereas *Rrs* is approximately the same as in passive conditions. This would mean that the elastic work (and cost) of breathing in a spontaneously breathing infant is approximately 50% (1/0.65) higher than expected from values of respiratory mechanics obtained in passive conditions. Notwithstanding the technical and analytic difficulties, estimates of the active work are useful because they provide a more realistic evaluation of the work imposed on the respiratory muscles than passive measurements would. In addition, the knowledge of the active values of *Crs* and *Rrs* yields more accurate predictions of the ability to maintain ventilation in the face of external elastic or resistive loads.[49]

Several other techniques, in addition to those described, are available to gain insights into the mechanical conditions of the infant's respiratory pump. Among these are methods oriented to measure thoracic gas volume, the mechanical properties of the airways, and their interaction with those of the lung. Lung volumes are usually measured by body plethysmography and the mechanical properties of the airways by forced expiratory maneuvers. These measurements, commonly performed in adults, have some practical difficulties when applied to the infant, mainly because the infant cannot cooperate.[50-52] Forced expiratory maneuvers, for example, require forced suction of air from the airways[53] or forced squeezing on the thorax;[54,55] either approach yields results that depend greatly on how the pressure is applied and how the maneuver is performed.[56,57] Thus these methods are usually confined to specific situations or to the research setting.[58,59] Differently, the measurements of *Crs* and *Rrs*

described in the previous sections are simple techniques readily applicable to a wide range of healthy and sick infants. Because in infants *Cw* is very high by comparison with *CL, Crs* can reflect pathologic changes in *CL* more readily than is the case in adults. Hence, measurements of *Crs* have been found useful in predicting the course and outcome of neonatal respiratory problems, as well as in classifying the severity of some respiratory diseases.

87 Pulmonary Gas Exchange in the Developing Lung

William E. Truog

Integral to the system of pulmonary gas exchange are mechanisms to maintain matching of pulmonary perfusion and alveolar ventilation. The goal is that atmospheric oxygen and pulmonary capillary blood have intimate contact. Requisite features of the gas-exchange apparatus include sustained effective ventilation to replenish the oxygen stores in alveolar gas and free diffusion of both oxygen and carbon dioxide across the alveolar-capillary barrier. Evolution has produced a situation in which gas exchange must and almost always does switch sites from placenta to lung in a very few minutes. Strictly in terms of O_2 exchange, this switch represents an improvement from the circulatory counter-current pattern of the human placenta. Placental gas exchange is associated with a gradient from maternal uterine artery PO_2 of approximately 85 mm Hg at ambient air at sea level to a fetal umbilical venous PO_2 of approximately 35 mm Hg, a gradient approaching 50 mm Hg. Most neonatal lungs demonstrate improved efficiency (see below).

Mechanisms for maintaining the matching of alveolar ventilation ($\dot{V}A$) and pulmonary perfusion ($\dot{Q}p$) and the factors that influence changes in intrapulmonary distribution of $\dot{V}A$ and $\dot{Q}p$ in neonates are the topics of this chapter. The effects of insufficient respiratory drive, insufficient oxygen-carrying capacity, and diminished cardiac output on pulmonary and tissue gas exchange are discussed elsewhere.

Pathophysiologic mechanisms predisposing to pulmonary gas exchange abnormalities can be divided between extrapulmonary and intrapulmonary (Table 87-1). Hypoventilation can be exacerbated by severe hypoxemia, a factor in neonates that illustrates the importance of lung-brain interaction.

A particular feature of postnatal gas exchange to which the lung must accommodate is the different frequency at which $\dot{V}A$ and $\dot{Q}p$ occur. The pulmonary circulation maintains exclusively unidirectional flow, although at varying velocity, through the pulmonary microvasculature. By contrast, the inhalation of gases is periodic, occurring normally at a rate in neonates that is 20% to 50% of the cardiac rate during health and closer to 75% with pulmonary disorders. These different rates of ventilation and perfusion must be accommodated in achieving or maintaining optimal pulmonary gas exchange, a process which is continuous.

To help sustain sufficient oxygen and carbon dioxide flux between gas and blood, an adequate alveolar gas volume or functional residual capacity (FRC) must be established shortly after birth and sustained thereafter. Development of the FRC occurs in the process of transition from fetal to neonatal life as the fluid-filled lung empties itself of liquid and refills itself with resident gas[1] (Figure 87-1). Once established, this gas volume serves as an intrapulmonary reservoir for oxygen.

TABLE 87-1

Abnormalities in Pulmonary Gas Exchange

Extrapulmonary	Intrapulmonary
Hypoventilation	Ventilation/perfusion mismatching
Alveolar hypoxia	Intrapulmonary or extrapulmonary shunt
Cardiac shunt	Diffusion impairment

The newborn infant is particularly vulnerable to the development of arterial hypoxemia for several reasons. First, because the PaO_2 of normal newborns is low compared with that of adults,[2,3] intravascular oxygen reserve is less during periods of no oxygen movement into the lungs (i.e., during apnea). Second, the neonatal lung has a FRC that is close to airway closing volume. Atelectasis, or airway closure, may develop, especially considering the relative paucity of channels of collateral ventilation in the newborn. Third, the metabolic demand for oxygen in infants is greater on a per kilogram basis than in adults. Therefore the infant more quickly depletes oxygen stores in the blood and in resident alveolar gas in attempting to maintain aerobic metabolism. These factors are accentuated in premature babies, who manifest additional problems of susceptibility to apnea because of immaturity of the respiratory centers and to lung segment collapse at end-expiration because of extremely compliant chest walls.

ASSESSMENT OF VENTILATION-PERFUSION RELATIONSHIPS

Oxygen Gradient

The measurement of the partial pressure of oxygen in arterial blood (PaO_2) provides an excellent approximation about the efficiency of the lung as a gas-exchanging organ. The idealized alveolar to arterial oxygen gradient can be calculated by solving the alveolar air equation:

$$PACO_2 = PIO_2 - PACO_2 / R + PACO_2 \times (1 - R) / R$$

where R = respiratory exchange ratio. $PACO_2$ is assumed to be approximately equal to $PaCO_2$ and PIO_2 is calculated from measured barometric pressure and body temperature and assumes that inspired gas is 100% saturated with water vapor on reaching the acinar space.

The alveolar-arterial oxygen partial pressure calculated difference ($AaPO_2$) in normal adults breathing ambient air at sea level is 10 to 20 mm Hg. This value is increased with increasing FIO_2. Neonates have large $AaPO_2$ values during ambient air breathing (as high as 40 to 50 mm Hg shortly after birth), even allowing for R values close to 1.0 (presumably based on relatively high utilization of carbohydrate). The $AaPO_2$ may remain in the 20 to 40 mm Hg range for days after birth in term nondistressed infants[4,5] even with SpO_2 values of >90%.

The $AaPO_2$ quantifies the degree of venous admixture plus alveolar capillary membrane diffusion disequilibrium. However, neither the $AaPO_2$ nor the calculated ratio of arterial to alveolar oxygen tension (the PaO_2/PAO_2) discriminates between these components and both are very insensitive to situations with intrapulmonary shunt and pulmonary parenchymal diseases coexist. Venous admixture includes both intrapulmonary shunt (perfusion of pulmonary capillary blood past nonventilated lung regions before joining the stream of pulmonary venous blood) and perfusion of low $\dot{V}A/\dot{Q}$ areas in which alveolar ventilation is insufficient to restore PAO_2 to the value predicted from the "idealized" PAO_2 calculated earlier. Pulmonary end-capillary to alveolar space equilibrium can be predicted to occur for oxygen and carbon dioxide in low $\dot{V}A/\dot{Q}$ areas because alveolar PO_2 is low and only a small rise in pulmonary arterial PO_2 occurs as blood traverses

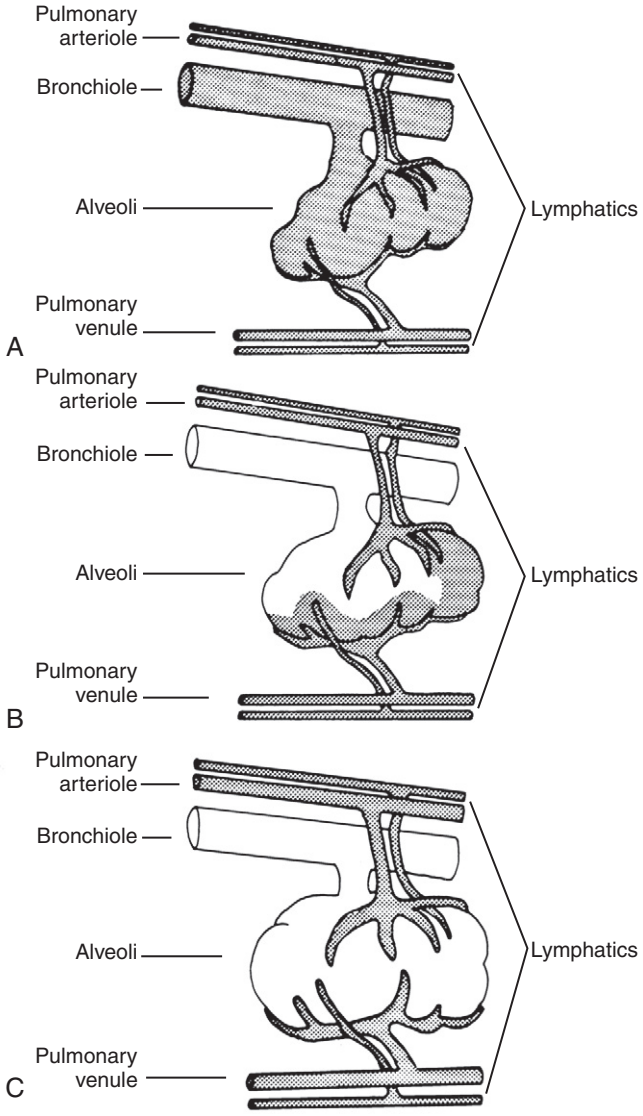

Figure 87-1 Airway fluid is removed from the lungs in several steps during birth. A, Fluid secretion from the lung stops during labor, although the air sacs and airways remain fluid filled. **B** and **C,** Fluid remaining in the airways is squeezed out the mouth and nose and is rapidly reabsorbed into the now expanded pulmonary capillary bed as well as into the lymphatic drainage system of the lung. *(From Carlo WA, Chatburn BL [eds]:* Neonatal Respiratory Care, *ed 2, Chicago, Year Book Medical Publishers, 1988.)*

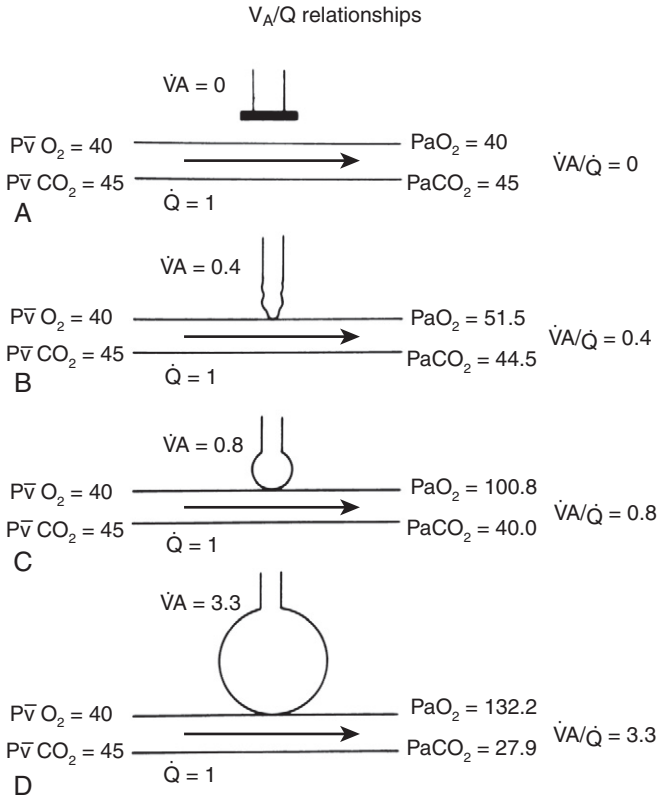

Figure 87-2 Effects of $\dot{V}A/\dot{Q}$ ratios on blood gas tensions, expressed in mm Hg. A, Intrapulmonary shunt leaves mixed venous blood gas tensions unaltered. **B,** Alveolus with low $\dot{V}A/\dot{Q}$ ratio: Only partial oxygenation occurs. **C,** Relatively normal $\dot{V}A/\dot{Q}$ ratio with satisfactory oxygenation of pulmonary capillary blood. **D,** Underperfused alveolus with high $\dot{V}A/\dot{Q}$ ratio. *(From Thibeault DW, Gregory GA [eds]:* Neonatal Pulmonary Care, *ed 2, Norwalk, CT, Appleton & Lange, 1986.)*

the pulmonary microcirculation[6] (Figure 87-2). Depressed pulmonary end-capillary PO_2 is associated with disproportionately depressed oxygen content because of the shape of the oxygen-hemoglobin curve, leading to an exaggerated depression of the mixed arterial PO_2 as measured in the left atrium or systemic arteries (assuming no extrapulmonary right to left shunts). Therefore overall pulmonary gas exchange is the flow-weighted and alveolar ventilation–weighted sum of gas exchange occurring in lung regions or groups of acinar units with a common $\dot{V}A/\dot{Q}$. Note that the rise in PaO_2 in the high $\dot{V}/\dot{Q}$ region depicted (see Figure 87-2, *D*) and the decrease in $PaCO_2$ do not equal levels of alveolar gas partial pressures that would be found if no regional perfusion existed. Lung units with both low $\dot{V}A/\dot{Q}$ and with normal $\dot{V}A/\dot{Q}$ relationships are depicted in Figure 87-3. Also shown is a pulmonary arterial to pulmonary venous connection bypassing any aerated area, which in the neonate could represent shunt through the ductus arteriosus, through the foramen ovale, through connections between pulmonary and bronchial arteries, or through the thebesian circulation.

The $AaPO_2$ measured in ambient air provides an overall summary of pulmonary oxygen exchange efficiency, but tells little about pulmonary reserves or about the cause of an increased difference between alveolar and arterial oxygen partial pressure. The simplified calculation, the oxygen index, combines arterial oxygen tension, FIO_2 and lung distending pressure. This commonly used index in neonatology also does not discriminate among intrapulmonary or extrapulmonary causes of hypoxemia (see Table 87-1).

The presence of a moderate to severe degree of $\dot{V}A/\dot{Q}$ mismatching has an especially depressing effect on PaO_2 when the inspired oxygen fraction is between 0.3 and 0.7 (Figure 87-4).[7] The effect of low $\dot{V}A/\dot{Q}$ areas on the calculation of $AaPO_2$ can be eliminated by breathing 100% oxygen to remove nitrogen from any open but underventilated lung regions. However, absorption atelectasis may then develop, increasing the size of the shunt, which was the subject of the measurement. There is evidence that increased shunt with oxygen breathing occurs in premature infants[8] and neonatal lambs but not in adult dogs.[9] These differences have been attributed to different degrees of development of pathways of collateral ventilation. Hence neither PaO_2 nor the ratio of arterial to alveolar PO_2 provides detailed knowledge of the state of ventilation-perfusion relationships in the lung. The

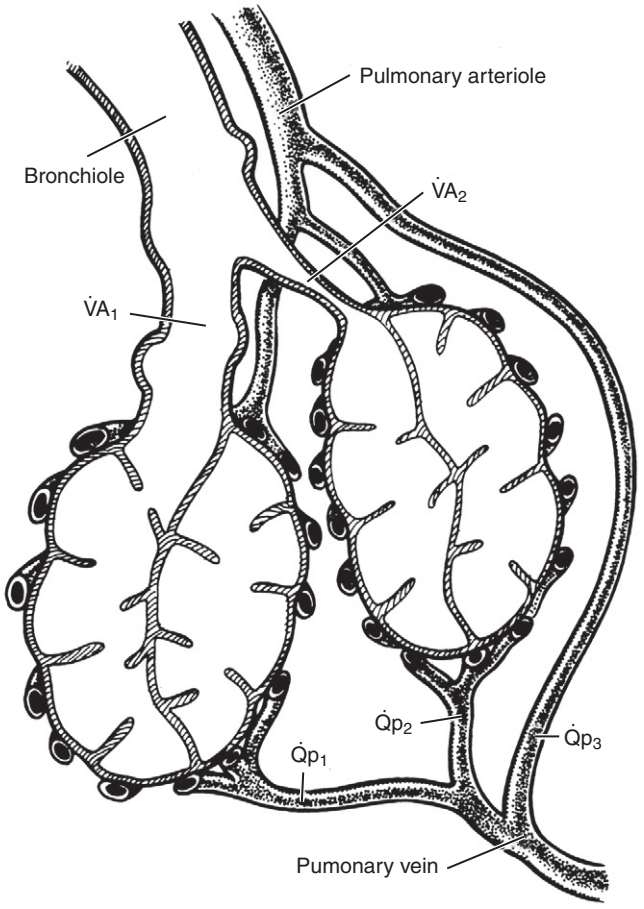

Figure 87-3 Schematic illustration of airway and vascular relationships. The acinar unit, containing many alveolar sacs, is shown with multiple pulmonary capillaries enveloping the saccules, providing maximal gas-exchanging surface area. $\dot{V}A_1/\dot{Q}p_1$ corresponds to an acinar region (containing multiple alveoli) with normal $\dot{V}A/\dot{Q}$; $\dot{V}A_2/\dot{Q}p_2$ represents an acinar region with a low $\dot{V}A/\dot{Q}$ and poor gas exchange. The pulmonary arteriole to pulmonary venous connection, $\dot{Q}p_3$, which bypasses any air-containing spaces, could represent intrapulmonary as well as extrapulmonary shunts.

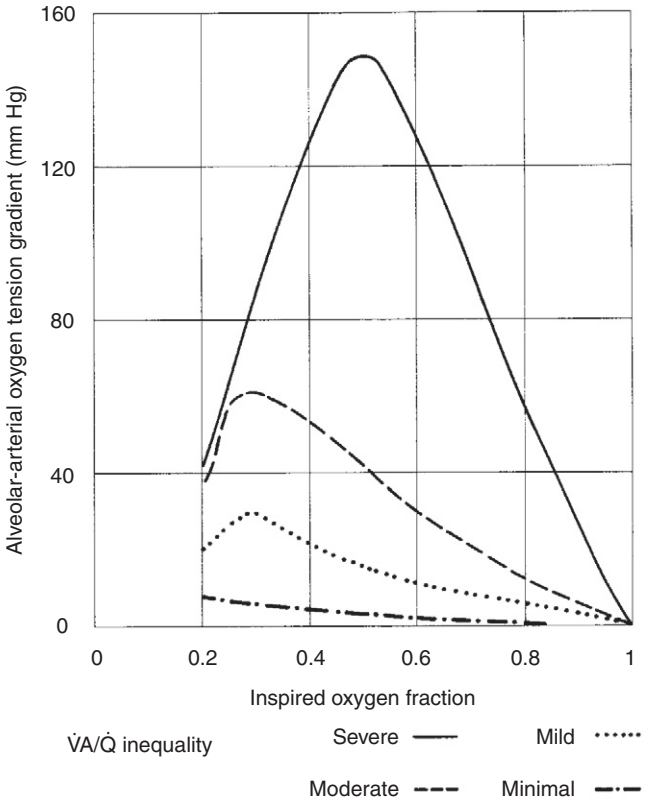

Figure 87-4 The effects of changes in inspired oxygen fraction, shown on the abscissa, on the calculated alveolar-arterial oxygen gradient are plotted for varying degrees of $\dot{V}A/\dot{Q}$ inequality without any coexisting shunt. *(From Dantzker DR: Physiology and pathophysiology of pulmonary gas exchange,* Hosp Pract (Off Ed) *15:135, 1986.)*

unique shape of the oxygen and carbon dioxide hemoglobin dissociation curves make precise quantification of exact patterns of $\dot{V}/\dot{Q}$ heterogeneity difficult to determine. Even the use of multiple inert gases measured together (see later discussion) has not eliminated completely uncertainty in $\dot{V}A/\dot{Q}$ distribution.

Nitrogen Gradient

When PAO_2 is low because of diminished alveolar ventilation (i.e., insufficient replacement of alveolar oxygen from inspiratory gas relative to the rate of removal by pulmonary capillary blood), the alveolar partial pressure of nitrogen (PAN_2) rises because during "no flow" states (end-expiration and end-inspiration) the sum of gas partial pressures in the alveolar spaces must equal atmospheric pressure. PH_2O and $PACO_2$ are relatively constant; therefore when PAO_2 is diminished, the PAN_2 must be increased. If the elevated PAN_2 is sustained, there will be increased absorption of nitrogen into pulmonary capillary blood and development of an arterial to alveolar nitrogen gradient ($aADN_2$), which has been used to estimate the presence of low $\dot{V}A/\dot{Q}$ lung regions. Perfusion of nonventilated lung units produces no increase in PAN_2, because the end-capillary and mixed venous partial pressures are the same for oxygen, carbon dioxide, and nitrogen, as well as any other inert gas solution. An $aADN_2$ gradient can develop because of the presence of either a small area of very low $\dot{V}A/\dot{Q}$ or a larger region of less imbalanced $\dot{V}A/\dot{Q}$, as long as $\dot{V}A/\dot{Q}$ is less than 1.0. Using the $aADN_2$ to indirectly estimate shunt ($\dot{V}A/\dot{Q}=0$) may result in an overestimation of shunt because of the sigmoidal shape of the oxygen-hemoglobin dissociation curve (i.e., small reductions in PAO_2 can disproportionately depress the arterial oxygen content when on the steep part of the curve).

Based on measurements of $AaPO_2$ and $aADN_2$ in healthy newborn infants, Krauss and colleagues[10,11] inferred that a relatively small low $\dot{V}A/\dot{Q}$ region occurred after 1 to 2 days of postnatal life. Furthermore the calculated $aADN_2$ in infants with respiratory distress syndrome showed little contribution from low $\dot{V}A/\dot{Q}$ areas.[12] This observation suggests that the large venous admixture occurring with respiratory distress syndrome results from intrapulmonary or extrapulmonary shunt.

Carbon Dioxide Gradient

Arterial to alveolar differences for carbon dioxide ($aADCO_2$) reflect areas of the lungs that are poorly perfused but have a large dead space because they receive a substantial fraction of minute ventilation ($\dot{V}E$). Mismatching of $\dot{V}A/\dot{Q}$ as a cause of carbon dioxide retention has been emphasized to explain the development of respiratory acidosis when minute ventilation is elevated above normal.[13] A small $aADCO_2$ exists in some newborn infants,[5] but when a normal FRC has been established, the small magnitude of

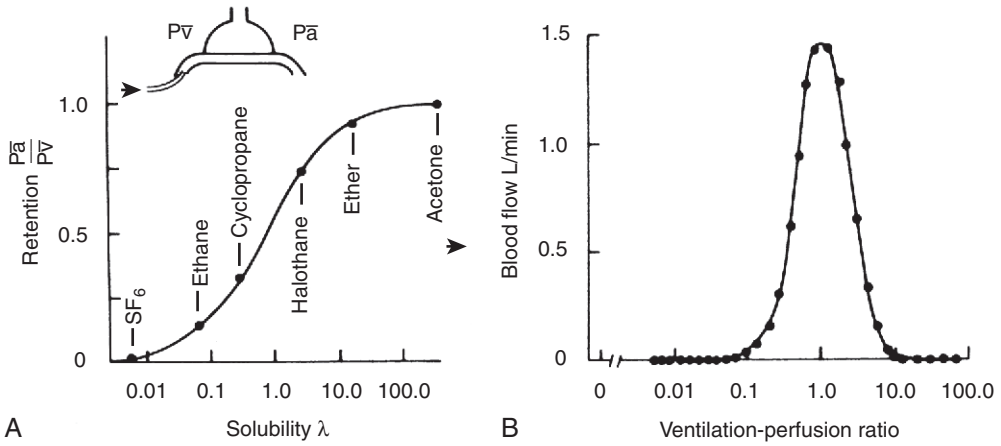

Figure 87-5 A, Retention solubility curve created by the experimental techniques referred to in text. Each of the six gases is plotted against its measured solubility. *Pa,* Partial pressure of each inert gas in arterial blood; *Pv,* partial pressure in mixed venous blood. **B,** The retention solubility curve can be used to derive a distribution of fractional perfusion to each of 50 theoretical lung compartments. *(From West JB: State of the art: ventilation-perfusion relationships,* Am Rev Respir Dis *116:919, 1977.)*

the gradient implies only a modest presence of high $\dot{V}A/\dot{Q}$ areas, except in premature infants.[5] Deficiencies in carbon dioxide exchange during respiratory disorders probably result from excess dead space ventilation with normal or increased tota 1 $\dot{V}E$.[14]

Trace Inert Gases Gradient

Trace quantities of inert gases can be used to quantitate the continuous distribution of ventilation/perfusion ratios from shunt to dead space ($\dot{V}A/\dot{Q}$ of 0 to $\dot{V}A/\dot{Q}$ to infinity).[15] Wagner and colleagues[16,17] described a technique that employs six inert gases (which encompass a wide range of solubility in blood) and in which retention of each gas in blood perfusing the lung can be expressed by the simple relationship:

$$Pa/Pv = Palv/Pv = \lambda/(\lambda + \dot{V}A/\dot{Q})$$

where λ = Ostwald blood-gas solubility coefficient (unique for each gas) and Pa, Pv, and Palv are the partial pressures of the gas measured in arterial blood, mixed venous blood, and alveolar gas (in reality measured in mixed expired gas and corrected for dead space ventilation). The equation assumes that each gas demonstrates a linear dissociation between blood or plasma and air, behavior unlike that demonstrated by the respiratory gases, oxygen ,and carbon dioxide.

Under conditions of presumed steady-state gas exchange, which is always an approximation of in vivo situations, the multiple inert gas elimination technique (MIGET) allows quantification of shunt, dead space, and low and high $\dot{V}A/\dot{Q}$ lung regions during both normal and experimental conditions. A major advantage of the technique is the quantification of shunt, separate from low $\dot{V}A/\dot{Q}$ areas, without the need to resort to 100% oxygen breathing. The experimental data consist of the measured ratios of the mixed arterial to mixed venous and mixed expired to mixed venous partial pressure for each of the gases employed (usually sulfur hexafluoride, ethane, cyclopropane, halothane, diethyl ether, and acetone) and the measured solubility of each gas (Figure 87-5).

Calculation of the standard deviation of pulmonary blood flow (SD $\dot{Q}p$) provides a quantitative index of dispersion of $\dot{Q}p$ about the mean $\dot{V}A/\dot{Q}$ value, separate from shunt and dead space.[18] Under experimental conditions, each of these assessments appears to be consistent with the others in providing semiquantitative estimates of the $\dot{V}A/\dot{Q}$ heterogeneity of the lung (Figure 87-6). Limitations of the inert gas technique include the lack of on-line analysis capacity for assessment of $\dot{V}A/\dot{Q}$ relations and the necessity of the assumption of steady-state gas exchange.[18]

Pulse Doppler Oximetry

The substitution of pulse Doppler oximetry saturation (SpO_2) for arterial PO_2 is seductive but can be misleading. The SpO_2 is precise, reproducible, harmless and painless to obtain. However, change in SpO_2 may not reflect concomitant change in PaO_2 but, rather, may reflect shifting position of the oxyhemoglobin dissociation curve. Acute increases in pH and decreases in PCO_2 can produce leftward shift of the curve, raising SpO_2 without changing PaO_2. Transfusion of adult hemoglobin into term and especially preterm infants will alter the P50, producing a rightward shift and a lower SpO_2 with no change in PaO_2. Lack of awareness of this potential discrepancy may result in inappropriate undertreatment or over-treatment in an effort to maintain SpO_2 in a narrow window. This limitation of SpO_2 predicting PaO_2 also limits the interpretation of the "physiological" diagnosis of bronchopulmonary dysplasia.[19]

Assumptions About Assessment of Ventilation and Perfusion

One important assumption is uniformity of the inspired gas composition. Inspired gas that is altered in composition by rebreathing of expired gas from more slowly emptying adjacent lung areas in the nonhomogeneously ventilated lung will produce series inequality of ventilation, which is difficult to differentiate from the more familiar parallel inequality.[20]

Although the composition of pulmonary arterial blood is relatively uniform, intraregional differences in hematocrit can affect gas exchange.[21] Gas exchange is inhibited when lung units with low $\dot{V}A/\dot{Q}$ are perfused by blood with high hematocrit. If high neonatal hematocrits predispose to greater pulmonary interregional variability, this effect could theoretically contribute to depressed oxygen exchange but the effect is likely minor in infants.

Alveolar end-pulmonary capillary partial pressure disequilibrium, as may occur during a shortened transit time across the pulmonary capillary bed, may limit transport of oxygen (see later discussion). Possibility of alveolar end-capillary disequilibrium for inert gases, with their rapid equilibrium time, is less than with respiratory gases.[22]

All the techniques used for gas exchange analysis have limits because of invasiveness, inaccuracy, reproducibility. They depend on assumptions about steady-state conditions, which in periods of rapid transient change in $\dot{Q}p$ or $\dot{V}A$, or in the presence of pulmonary disease, may not be true. During rapidly evolving disease states, the techniques may not reflect rapidly changing contributions to overall gas exchange inefficiency.[23]

PERINATAL TRANSITION AND GAS EXCHANGE

The decline of Ppa and PVR following birth occurs in conjunction with elimination of some of the intraparenchymal pulmonary fluid. Factors modulating the decline in Ppa include the endogenously produced arachidonate metabolite and vasodilator, prostacyclin,[24] and endogenously produced nitric oxide.[25] Mean Ppa does not approach adult values until days after birth. Wagner[26] has suggested that moderate elevation in Ppa may help maintain $\dot{V}A/\dot{Q}$ matching, given the relatively unstable lung volume of the neonate. However, elevations in PVR also favor passage of vascular fluid into the extravascular alveolar lung spaces, especially if the anatomic site of increased pressure is venular. Such fluid extravasation can have secondary effects on $\dot{V}A/\dot{Q}$ matching by altering bronchiolar dimensions (see Figure 87-3).

The investment of pulmonary arteries with their smooth muscle sheath during the third trimester creates the possibility of an inappropriately vigorous pulmonary vascular response to vasoconstrictive stimuli applied postnatally. Persistent pulmonary hypertension of the newborn (PPHN) may in some instances be a clinical consequence of this phenomenon. In support of this hypothesis, PPHN has been associated with the accumulation of leukotrienes in tracheal lavage fluid; leukotrienes, among many other substances, are potent vasoconstrictors.[27]

Two studies provided data on rate of change in pulse Doppler oxygen saturation in the minutes after delivery of healthy full-term infants.[28,29] Combining a large number of observations in term infants, Kamlin and colleagues[28] demonstrated a rise in SpO_2 from 60% at 1 minute after clamping of the cord (range: 38% to 82%) to a median of 84% by 5 minutes of age (Figure 87-7).[28] The authors note that saturation of greater than 90% was achieved at less than 4 minutes (median time of 2.5 minutes) and a saturation of greater than 90% was achieved in less than 7 minutes in term infants born either vaginally or by cesarean delivery. The previously noted limitations with the use of pulse Doppler oximetry and its correlation with arterial oxygen tension in these infants breathing ambient air also apply to these studies.

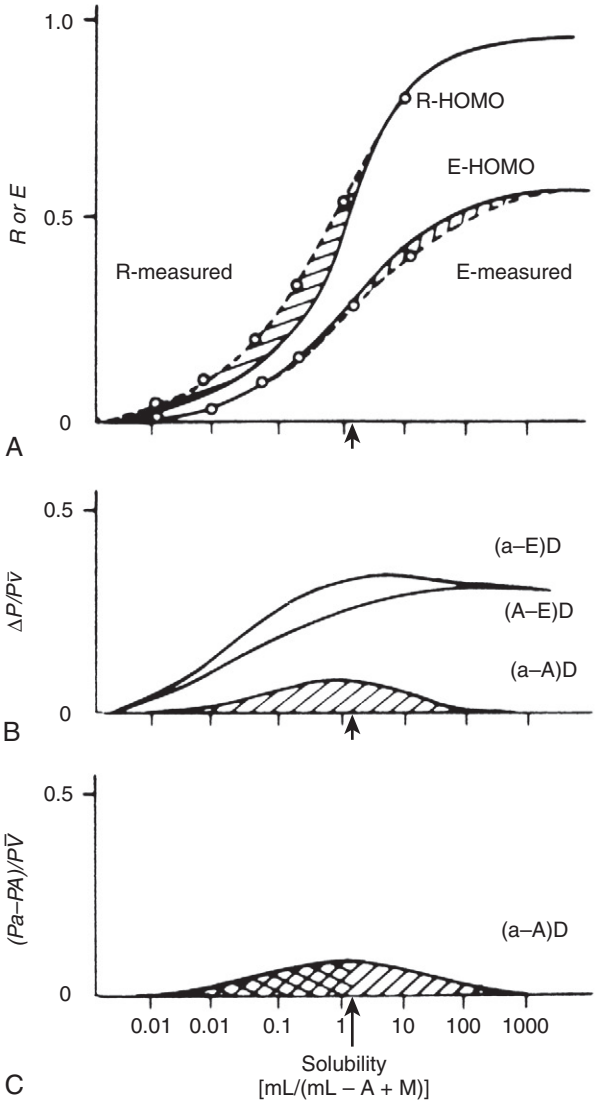

Figure 87-6 **A,** Measured and homogeneous retention *(R)* and excretion *(E)* curves are plotted against solubility, with R and E values shown as open circles. The homogeneous curves would occur if there were no $\dot{V}A/\dot{Q}$ heterogeneity in the lung (i.e., an idealized lung). Hatched areas between measured and homogeneous R and E curves occur because of $\dot{V}A/\dot{Q}$ heterogeneity. **B,** The sum of the areas under the aAD curve is shown. The area under the (a-A) D curve is calculated by subtracting the (A-E) (D) curve from the (a-E) D curve. *Arrow* on the abscissa indicates solubility that is numerically equal to mean $\dot{V}A/\dot{Q}$ in the lung. **C,** The area under the curve to the left of the mean $\dot{V}A/\dot{Q}$ represented by the double-crossed hatch area is an index of low $\dot{V}A/\dot{Q}$ lung areas. *(From Truog WE, Hlastala MP, Standaert TA, et al: Oxygen-induced alteration of ventilation-perfusion relationships in rats,* J Appl Physiol *47:1112, 1979.)*

FACTORS REGULATING VENTILATION-PERFUSION MATCHING IN THE DEVELOPING LUNG

Effects of Increased Pulmonary Arterial Pressure

Pulmonary arterial pressure (Ppa), which equals or exceeds systemic arterial pressure (Psa) during fetal life, declines normally in the hours surrounding birth to a level approximately 50% of Psa.

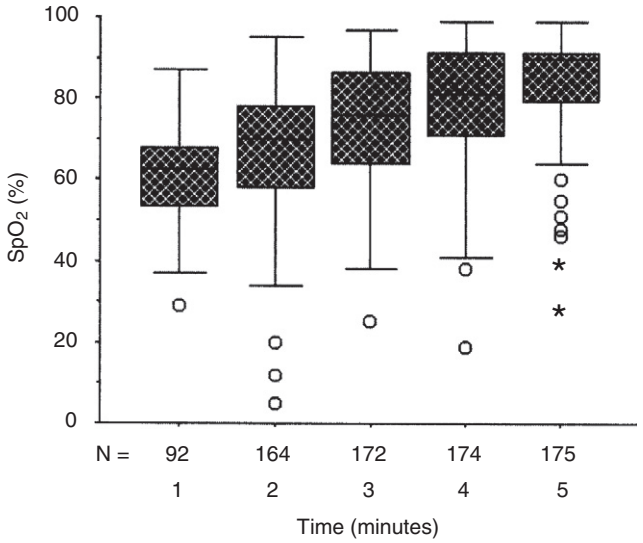

Figure 87-7 Box plots showing the median, quartiles, range (1.5 times the quartile on that side), outliers, and extreme values for SpO_2 at each minute after birth for the first 5 minutes (*N,* Number of patients in whom SpO_2 was obtained). A number less than 175 indicates that SpO_2 was not obtained in all cases. *(From Kamlin CO, O'Donnell CP, Davis PG, Morley CJ: Oxygen saturation in healthy infants immediately after birth,* J Pediatr *148:585, 2006).*

The further decline to adult levels occurs more slowly. Marked (suprasystemic) levels of Ppa can cause hypoxemia due to extrapulmonary shunt, as in PPHN. It is unknown, however, to what extent increased Ppa or persistent elevation of Ppa undermines or contributes to the stability of ventilation-perfusion matching in the neonatal lung during the normal transition to extrauterine life or during pulmonary diseases. Neonatal pulmonary diseases are commonly characterized by elevated Ppa, pulmonary vascular resistance (PVR, and marked vasoreactivity). The diseased neonatal lung may also demonstrate collapsed segments or lobes, which can interfere with $\dot{V}A/\dot{Q}$ matching.

An elevation in Ppa may change the intrapulmonary distribution of $\dot{Q}p$. Elevations in Ppa can occur either because of constriction of smooth muscle (or possibly nonmuscularized endothelial cells) lining the vessels that comprise the pulmonary microvasculature or because of an increase in left atrial pressure. Different vasoactive substances may mediate vasoconstriction at different sites within the microvasculature.[30] If a particular stimulus induces vasoconstriction only in previously dilated small muscular arteries and arterioles (which are conveying blood to well-ventilated areas), and not in already constricted vessels, the ratio in regional resistance of constricted vessels in nonventilated lung areas to resistance in previously dilated vessels in well-ventilated areas would be decreased. One result of this change in the ratio of local vascular resistance could be increased intrapulmonary right to left shunt (perfusion of nonventilated intrapulmonary regions) because of a redistribution of $\dot{Q}p$ favoring flow to nonventilated (hypoxic) regions.

Changes in Ppa are relevant to gas exchange in both the adult and newborn. However, in establishing and maintaining $\dot{V}A/\dot{Q}$ matching, neonates appear to respond differently from adults to certain stimuli affecting Ppa, PVR, and at least theoretically, bronchial and bronchiolar smooth muscle constriction. For instance, lambs have a more vigorous hypoxic pulmonary vasoconstrictive response than do adult sheep, and the onset of the response can be detected at a higher PAO_2.[31] If this phenomenon is also true in humans, it has implications in neonates regarding the effects of even brief apneic episodes on $\dot{V}A/\dot{Q}$ matching. Inferences about effects of the changes in Ppa in neonates with both regional and generalized lung injury cannot be easily extrapolated from results in adults.

Hypoxic Pulmonary Vasoconstriction and $\dot{V}A/\dot{Q}$ Matching

Hypoxic pulmonary vasoconstriction prevents localized mismatching of ventilation and perfusion by diminishing blood flow locally to those areas of the lungs that are underventilated or not ventilated at all. As regional alveolar and acinar PO_2 decline, due to reduced localized ventilation, blood flow through the local pulmonary microvasculature is inhibited by an increase in resistance in muscular small arteries. Blood flow and presumably alveolar ventilation are then redirected into well-ventilated lung regions. The mechanisms by which a decrease in local PO_2 induces constriction of vascular smooth muscle remain incompletely understood. Many modulators, including vasoconstrictive leukotrienes, have been described.[32] However, mediation of this response, as opposed to modulation, may depend on changes in calcium and potassium selective membrane channels in the pulmonary vascular smooth muscle cell membrane.[33]

When regional alveolar hypoxia is created by lobar or segmental atelectasis induced by endobronchial balloon obstruction, a relationship exists between the increase in resistance and increase in overall intrapulmonary shunt (Figure 87-8). Marshall[34] showed that with progressively larger areas of pulmonary parenchymal collapse, up to unilateral atelectasis, the diversion of $\dot{Q}p$ away from atelectatic lung areas and the capacity to maintain satisfactory $\dot{V}A/\dot{Q}$ matching becomes less effective (see Figure 87-8). These studies are particularly relevant to the neonatal condition, in which both lobar and multiregional atelectasis can develop.

In addition to the size of the collapsed and nonventilated segment as a modifier of hypoxic pulmonary vasoconstriction and $\dot{V}A/\dot{Q}$ matching, the presence of inflammatory cells and their products in the affected region has been addressed. Secretions containing bacteria and inflammatory cell products can become trapped in the atelectatic region, possibly inhibiting local hypoxic pulmonary vasoconstriction, resulting in persistent regional blood flow and hypoxemia.

Global or total lung exposure to alveolar hypoxia produces a different challenge for control of pulmonary gas exchange. With these circumstances is the potential for an increase in regional $\dot{Q}p$ to preexisting shunt or low $\dot{V}A/\dot{Q}$ regions. Superimposition of global alveolar hypoxia produces increased resistance to $\dot{Q}p$ in the regions in which resistance beds will become more balanced, with redirection of $\dot{Q}p$ back into low $\dot{V}A/\dot{Q}$ areas. However, in lambs exposed to acute alveolar hypoxia ($FIO_2 = 0.12$), no evidence shows an alteration in $\dot{V}A/\dot{Q}$ matching in spite of a doubling (beyond room air baseline values) of Ppa and PVR.[35] Hansen and colleagues[36] demonstrated redistribution of $\dot{Q}p$ in neonatal lambs during acute alveolar hypoxia, providing indirect evidence of heterogeneity of local vascular resistance during elevated PVR.[36]

One effect of increasing Ppa is the recruitment of pulmonary capillaries, particularly in upper lobes. This process increases gas exchange surface area and represents a "reserve" mechanism to help sustain pulmonary gas exchange during adverse conditions. However, evidence shows that neonatal lambs have an already fully recruited microvasculature, at least as assessed by direct vital microscopy during hypoxia.[37] Indirect evidence for full capillary recruitment present under baseline conditions has also been inferred from work in piglets.[38] If these findings can be generalized to newborn humans, it represents another instance of the decreased reserves available to sustain gas exchange and points to a relative lack of vascular compliance in the neonatal lung.

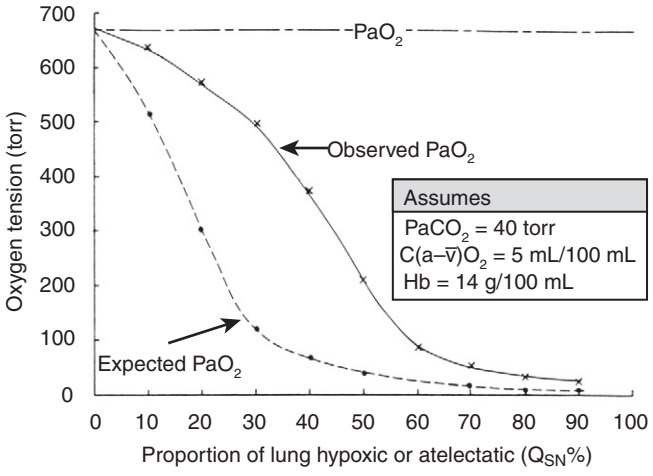

Figure 87-8 The effect of progressively increasing size of atelectatic lung region on arterial oxygen tension is demonstrated by the dashed line, which would occur if no redistribution of blood flow away from atelectatic area occurred. The solid line indicates effects of presumed hypoxic pulmonary vasoconstriction. Note the conversion of the two lines when more than 40% of the lung develops atelectasis. The assumptions regarding O_2 content (CaO_2) are shown in the inset. *(From Marshall BE: Importance of hypoxic pulmonary vasoconstriction with atelectasis,* Adv Shock Res *8:1, 1982.)*

The role of acute hypoxic vasoconstriction in the maintenance of ventilation-perfusion matching has been tested in neonatal animals subjected to 3 days of breathing more than 90% inspired oxygen.[39] This was done to determine if hyperoxia-induced blunting of the vascular response to acute alveolar hypoxia ($FI_O2 = 0.12$) would be associated with worsened $\dot{V}A/\dot{Q}$ matching. Preexposure of animals to hyperoxia did result in diminished hemodynamic response and in deterioration in $\dot{V}A/\dot{Q}$ matching during exposure to acute vasoconstrictive stimuli, such as alveolar hypoxia.

Possible genetic contributions to postnatal regulation of gas exchange in a relatively hypoxic environment due to high altitude have been examined in Tibetan infants.[40] Comparisons of SpO_2 were made in healthy infants born at 3300 meters (~11,800 feet) and normalized for activity state. The infants of the Tibetan (multigenerational) dwellers at altitude demonstrated consistently higher SpO_2 than infants of the Han (recent dwellers) during all relevant activity states (Figure 87-9). As shown, Han infants consistently demonstrated lower O_2 saturation than Tibetan children, suggesting a role for genetics in contributing to hypoxia. Comparisons of SpO_2 were from values obtained during active sleep, the behavioral state associated with irregular breathing effort and reduced FRC because of changes in intercostal muscle tone. Multiple factors contribute to maintenance of SpO_2; the relevant ones that contributed to these findings could not be evaluated. However, the findings suggest that susceptibility to pulmonary hypertension may be genetically determined, even in very young infants.

Vasoactive Mediators Influencing Pulmonary Vascular Resistance and $\dot{V}A/\dot{Q}$ Matching

Stimuli that produce an acute elevation in Ppa may impair $\dot{V}A/\dot{Q}$ matching in neonates. Vasoactive peptides and phospholipid substances are two classes of such agents. These substances are synthesized and released into the circulation in response to bacterial infusion or endotoxin infusion. Their effect on PVR and gas exchange varies with species and with postnatal age. Intravenous infusion of *Escherichia coli* endotoxin into adult goats produced a 200% to 250% rise in Ppa and PVR, yet was associated with a small decrease (of 8 to 9 mm Hg) in PaO_2.[41] Infant or neonatal animals demonstrate a response different from that of adults. In piglets, despite a similar rise in Ppa, as seen in adult animals, infusion of either group B streptococcus or other bacteria resulted in a 30 to 40 mm Hg decline in PO_2.[42,43] This decline was associated with a generalized mismatching of $\dot{V}A/\dot{Q}$, with the development of low $\dot{V}A/\dot{Q}$ areas, but not with an increase in intrapulmonary shunt.[44] The elevation in Ppa induced by bacterial products correlated with increased plasma levels of the vasoconstrictor arachidonic acid metabolite, thromboxane A_2, implying that arachidonate products can alter distribution of perfusion and ventilation.

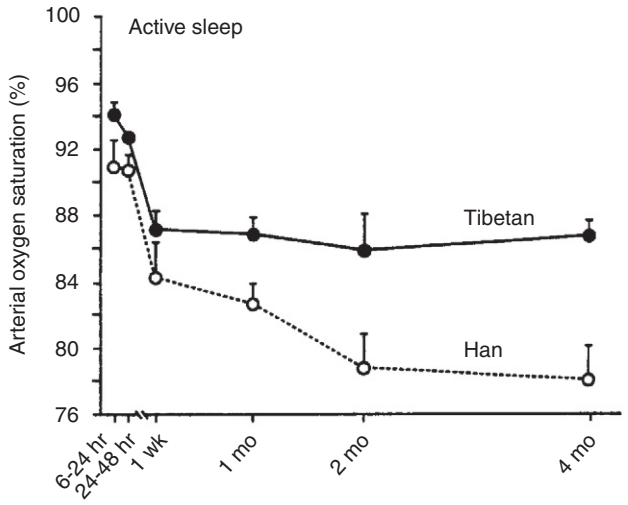

Figure 87-9 Oximetry recorded in multigenerational dwellers' infants at high altitude (Tibetan) versus single generation dwellers' infants (Han). Data were obtained during active sleep in apparently healthy term infants. *(From Figure 1 of Niermeyer S, Yang P, Shanmina, et al:* N Engl J Med *333:1248, 1995.)*

The young piglet has served as a useful model for examining the effects on pulmonary gas exchange of potential antiinflammatory or antiinfective therapies, including antivasoactive agents. After pretreatment with a thromboxane synthase inhibitor, no immediate increase in Ppa, decrease in PaO_2, nor development of $\dot{V}A/\dot{Q}$ mismatching[45] during an infusion of group B streptococcus in piglets was observed. When administered after 2 hours of bacterial infusion, inhibitors of thromboxane synthase decreased Ppa and PVR but did not improve inert or respiratory gas exchange.[46] These findings imply that regulation of hemodynamics and the regulation of $\dot{V}A/\dot{Q}$ matching become increasingly independent phenomena under conditions of ongoing bacterial product stimulation. Gibson and colleagues[47] demonstrated in experimental animals during controlled bacteremia that multiple vasoactive agents participate in the persistence of elevated PVR.

Catecholamines form another class of substances that can alter $\dot{V}A/\dot{Q}$ matching in the neonate by increasing Ppa. Truog and Standaert[35] demonstrated that when dopamine (25 μg/kg/min) is administered to neonatal lambs in which Ppa and PVR are increased due to hypoxic gas ($FIO_2 = 0.12$), a further rise is observed in Ppa, coupled with a deterioration in gas exchange associated with an increase in both intrapulmonary shunt and $\dot{V}A/\dot{Q}$ mismatching, separate from shunt.

Products of the endothelium, endothelin and nitric oxide, participate in regulation of $\dot{Q}p$ by changing local vasoconstriction and hence local vascular resistance.[48] The vasoconstricting effects of endothelin-1 are augmented and the vasodilating effects are attenuated with increasing age in sheep.[49] Vasodilating effects are mediated in part by nitric oxide. Administration of inhaled nitric oxide can result in a simultaneous reduction in PVR and an improvement in PaO_2 in patients with diffuse parenchymal lung diseases, such as ARDS.[50,51] Effects on each (decrease in PRV, V/Q) are dose-related, suggesting different physiologic mechanisms. Other investigators have failed to show significant change in respiratory or inert gas exchange during treatment with inhaled nitric oxide in animals with pulmonary hypertension caused by bacterial infusion.[52]

The effect of elevated Ppa on gas exchange can be difficult to predict in the clinical setting of a neonate with one of many possible causes of respiratory distress. In addition to the disorders discussed earlier, elevation of Ppa may result from a diminished cross-sectional microvascular area secondary to either a primary developmental failure or delayed growth (or inappropriate regression of) the microvasculature. The diminished cross-sectional area increases vascular resistance and results in an extrapulmonary shunt or failure to redistribute $\dot{Q}$ or to recruit lung vessels. Further, presumably a spectrum of local resistances exists across the pulmonary microvasculature shortly after the time of birth, as long as lung fluid is being removed from potential gas-exchange areas. Sudden vasoactive stimulation may result in a redistribution of $\dot{Q}p$, $\dot{V}A/\dot{Q}$ mismatching, and arterial hypoxemia, producing a vicious cycle with diminished pulmonary PVO_2 and further decline in PaO_2. Low mixed venous PO_2 is a secondary stimulus inducing pulmonary arterial hypertension.[53] In situations characterized by low cardiac output and $\dot{V}A/\dot{Q}$ mismatching, the low PVO_2 increases Ppa and PVR. Intrapulmonary shunt or extrapulmonary shunt through the foramen ovale or ductus arteriosus

may result. Measurement of simultaneously obtained pulmonary venous and preductal and postductal arterial PO_2 would be necessary to differentiate among the anatomic sites for the shunt.

Distribution of Ventilation and $\dot{V}A/\dot{Q}$ Matching

Although many studies have examined postnatal changes in lung mechanics, less information is available describing the distribution of ventilation.[54] Analysis of $\dot{V}A$ distribution by nitrogen or xenon washout during 100% oxygen breathing is difficult to perform in sick (or well) neonates because of the need for multiple breath analysis and exposure to radioactivity. However, analysis of $\dot{V}A$ distribution does demonstrate at least two types of acinar spaces, which empty at different rates.[54] The pulmonary function measurement, pulmonary clearance delay, quantitates the presence of these two acinar compartments. It is difficult to draw conclusions about $\dot{V}A/\dot{Q}$ matching from this index because it relates only to ventilation irrespective of relative distribution of $\dot{Q}p$. Engel[55] has reviewed the theoretical and experimental evidence for incomplete alveolar gas mixing with inspiration that develops because of the interaction between diffusion and convection at airway branch points subtending branches of unequal length. It is unknown if this problem is diminished or magnified in the much smaller neonatal lung or to what extent the resulting inhomogeneous alveolar gas mixtures contribute to overall $\dot{V}A/\dot{Q}$ heterogeneity in the neonate. Much would depend on the matching of intraacinar Q distribution and intraacinar V distribution.

The immature lung, with its delayed and variable distal airway and acinar development has not been well studied with regard to the contribution of "regional" $\dot{V}A/\dot{Q}$ inequality to overall gas exchange abnormalities. Similarly, $\dot{V}A/\dot{Q}$ scans that rely on insoluble radioactive tracers injected intravenously may inaccurately portray $\dot{V}A$ or $\dot{Q}p$ distribution because of both shunt and spatial restrictions imposed by the small chest of the neonate or young infant. Factors that influence bronchial and bronchiolar constriction can alter the distribution of each inhaled breath. Some factors relevant in young infants are listed Box 87-1.

Cardiac Function and PVR

An additional factor influencing PVR is the diminished cardiac reserve of neonates, especially premature neonates, who depend largely on chronotropy for raising cardiac output. Older children or adults, by contrast, have effective inotropic mechanisms for increasing cardiac output. The newborn has difficulty doubling the resting cardiac output either by pharmacologic stimulation or by increased sympathetic nervous system activity. Thus efforts to increase PaO_2 (assuming constant tissue oxygen extraction and an unchanging degree of $\dot{V}A/\dot{Q}$ mismatching) by increasing cardiac output (and PVO_2) are not usually successful in the newborn.

NITRIC OXIDE AND VENTILATION PERFUSION MATCHING

Recent investigations have produced a markedly increased appreciation for the complexity of endogenously produced nitric oxide (NO) and its role in regulation of many pulmonary functions, including that of pulmonary gas exchange, specifically ventilation perfusion matching and regulation of pulmonary vascular reactivity.[56,57] Evidence is now available that NO regulates pulmonary function by cGMP-independent mechanisms. Endogenous NO was originally thought to have its primary mode of action by activation of guanylyl cyclase, altering vascular smooth muscle intracellular concentration of cGMP and, by doing so, regulating local calcium concentration and actin-myosin contractility. Evidence is growing that an equally important pathway for NO signaling in the respiratory system is through the S-nitrosothiol (SNO) system. NO synthase activity leads directly to SNO formation and, with the creation of SNO radicals, results in signaling that helps regulate ventilation perfusion matching, pulmonary arterial pressure, and respiratory muscle function. A schematic summary of some of the pathways pertinent to pulmonary gas exchange is shown in Figure 87-10.[56] The contribution of SNOs in bronchial or epithelial lining fluid and in the pulmonary arterioles and erythrocytes in the pulmonary microcirculation provides a exquisitely sensitive level of regulation for small changes in airway muscular tone and lumen size, thus promoting local ventilation perfusion matching. Alterations in SNO metabolism resulting in deficient SNO, especially in the airways, can be associated with bronchoconstriction and overall change in the airway smooth muscle tone and/or change in pulmonary and systemic vascular resistance. Future studies of the therapeutic efficacy to toxicity ratio of NO or NO donor administration must account for SNO and other NO metabolites and changes in endogenous NO production and availability.[57] Few studies in human neonates to date have provided insight into how endogenous NO biology may be altered in important clinical disorders, such as PPHN or bronchopulmonary dysplasia (BPD).

DIFFUSION AND PULMONARY GAS EXCHANGE

Respiratory gas exchange depends on prompt diffusion of respiratory gases between the tissue and plasma, erythrocyte and plasma, plasma and resident alveolar gas, and alveolar gas and gas in the conducting airways. Of these, alveolar-capillary membrane diffusion has been considered the most likely barrier to gas exchange, but it has never been well documented as abnormal in any neonatal condition, including extreme prematurity, when corrected for the size of the gas-exchange surface area available.

Gas movement between alveolar space and pulmonary capillary blood is a passive process, summarized by Fick's law, which asserts that the amount of gas transferred is governed by the partial pressure of that gas in the two compartments, the inverse of the square root of the molecular weight of the gas, and the specific characteristics of the diffusion barrier (thickness and surface area). Thus the transport of gas is expressed by $\dot{V}$ <pi>pt $Dm(PA - P_b)$ where Dm = alveolar-capillary membrane diffusion conductance and $(PA - P_b)$ represents the partial pressure difference across the membrane. To simplify the analysis, it is useful to study a single gas that binds firmly to hemoglobin. Because carbon monoxide combines avidly with hemoglobin, the PCO in pulmonary capillary plasma is virtually zero when small quantities of carbon monoxide are inspired, simplifying the analysis of

Box 87-1

Some Factors Capable of Producing Bronchoconstriction or Bronchiolar Narrowing in the Newborn

Airway inflammation
Mucosal edema
Excess mucous secretion
Sloughing of damaged epithelial cells
Hyperreactive bronchial smooth musculature
Inspiration of cold, dry gas
Increase in parasympathetic nervous system stimulation
Congenital airway stenosis or deficient cartilage development
Bronchiolar narrowing secondary to vascular engorgement
Presence of any foreign body, including partially occluded endotracheal tubes
Trauma from suction catheters
Aspiration of stomach contents into upper airway
Hypoosmolar or hyperosmolar solution in the airway

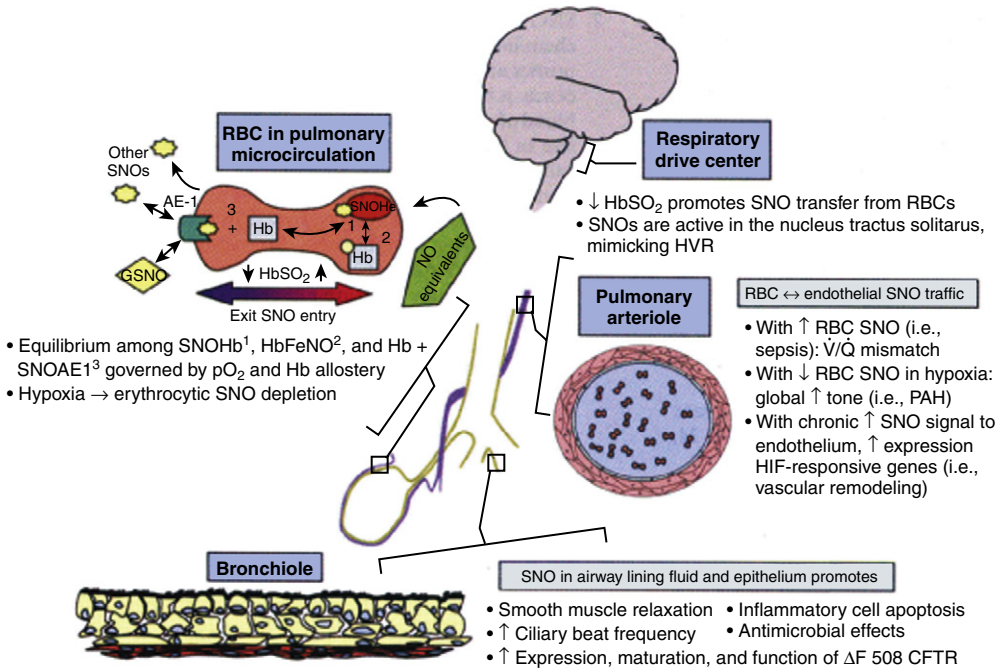

Figure 87-10 Overview of S-nitro-sothiol (SNO) signaling in the respiratory system. SNO signaling affects respiratory control, airway function, and pulmonary vascular tone. *AE1,* Anion exchange protein 1 on the erythrocyte membrane; *CFTR,* cystic fibrosis transmembrane regulatory protein; *GSNO,* S-nitrosoglutathione; *Hb,* hemoglobin; *HbFeNO,* hemoglobin iron nitrosyl; *$HbSO_2$,* oxyhemoglobin saturation; *HIF,* hypoxia inducible factor; *HVR,* hypoxic ventilatory response; *PAH,* pulmonary arterial hypertension; *RBC,* red blood cell. *(From Gaston B, Singel D, Doctor A, Stamler JS: S-nitrosothiol signaling in respiratory biology,* Am J Respir Crit Care Med *173:1186, 2006).*

diffusing capacity. In clinical practice, the diffusing capacity of the lung is expressed by the following:

$$DmCO = \dot{V}CO / PA_{CO}$$

The diffusing capacity of the lung for carbon monoxide is expressed as the volume of carbon monoxide transferred in milliliters of carbon monoxide per minute per millimeter of mercury of alveolar partial pressure of carbon monoxide. Diffusing capacity is usually abbreviated as D_{LCO}. Both a single-breath technique (which is difficult to perform in a neonate) and a steady-state technique can be used for assessing PA_{CO}.

Use of carbon monoxide as the marker gas does not eliminate other variables in interpretation. Ventilation-perfusion heterogeneity, reduced pulmonary capillary transit time, lung volume, and pulmonary capillary blood volume all can affect interpretation of diffusing capacity, as well as intrinsic properties of the alveolar capillary membrane itself—the actual subject of the measurement. Detailed analysis of the effects of these factors on diffusion measurement is available elsewhere.[58] Comparing serial measurements of D_{LCO} assumes that effective $\dot{Q}p$ ($\dot{Q}p_{total} - \dot{Q}p_{shunt}$) is unchanged. This may represent an insupportable assumption in many neonatal pulmonary diseases. Rapid postnatal lung growth and alveolarization, with change in lung volumes, complicates interpretation of serial measurement of diffusion capacity in the neonatal lung. However, Escourrou and colleagues[59] inferred from cross-sectional studies using MIGET in neonatal and infant piglets that diffusion limitation may contribute to early postnatal hypoxemia in animals breathing room air. Either a reduction in surface area or an increase in thickness of the alveolar capillary membrane can reduce D_{LCO}. Although these conditions may occur in neonatal pulmonary diseases, they probably have little practical significance for transport of oxygen because virtually every pulmonary disease is treated with increased PAO_2. Hence, the driving pressure (partial pressure gradient) across the membrane becomes very large for oxygen. Even in these circumstances, there may be lung regions in which diffusion disequilibrium may occur because neonatal pulmonary conditions rarely affect the lung uniformly.

Diffusing capacity for carbon monoxide has been measured acutely in premature infants with and without respiratory distress syndrome and no significant differences have been found.[60] However, D_{LCO} was notably lower than D_{LCO} values measured in earlier studies conducted in full-term healthy infants.[61] The different results may relate to the smaller quantity of both intrapulmonary gas and blood found in the premature newborn. The differences highlight the problems in interpretation of cross-sectional studies of D_{LCO} in the newborn.

Perhaps the most important diffusing capacity measurements are made after recovery and growth. Hakulinen and colleagues[62] made the observation that children born very prematurely and studied at age 7 to 11 years demonstrated modest but significant reduction in D_{LCO} (single breath). This was true for premature infants with or without the diagnosis of BPD. Some "normal" values for D_{LCO} may have overestimated D_{LCO} in some of these children because airflow obstruction, which was common in the preterm infants, may have produced an overestimation of the true D_{LCO}.

IMPAIRED GAS EXCHANGE IN BRONCHOPULMONARY DYSPLASIA

Principles of pulmonary gas exchange discussed in the above sections are supplemented with a brief review of gas exchange abnormalities arising from an important clinical disorder, BPD or

TABLE 87-2

Bronchopulmonary Dysplasia and Impaired Gas Exchange

Abnormality	Effect
Distal airway simplification	Increase in high $\dot{V}/\dot{Q}$ areas and increase in dead space
Bronchial lining thickening	Maldistribution of $\dot{V}$ E
Decrease in capillary network	Increase in high $\dot{V}/\dot{Q}$ areas
Mesenchymal location of pulmonary capillary bed	Decrease in diffusing capacity
Pulmonary to bronchial venous connections	Increased intrapulmonary shunt
Anemia, decreased systemic venous O_2 saturation, decreased Pv O_2	Increased risk of end capillary-alveolar disequilibrium
Altered metabolic function in the lung	Increased Ppa and PVR

chronic lung disease of prematurity. BPD is characterized by multifocal radiographic evidence of lung injury, by postmortem findings of airway and alveolar/acinar simplification with disordered development of the pulmonary microvasculature. A physiological definition of BPD relies on assessment at 36 weeks postmenstrual age. The FIO_2 necessary to maintain SpO_2 of ≥90% is assessed at that age. Although the focus is on impairment in oxygen exchange, alveolar ventilation is also impairment as assessed indirectly by serum bicarbonate measured at the same postmenstrual age. Minute ventilation is normal or increased,[63] so the finding of elevated PCO_2 or serum bicarbonate indicates alveolar hypoventilation and increased high $\dot{V}/\dot{Q}$ areas. Reasons for impairment both in O_2 and CO_2 exchange include the development of intrapulmonary shunt, of both and high low $\dot{V}/\dot{Q}$ areas, possibly diffusion disequilibrium, depending on other circumstances as listed (Table 87-2). Even when infants reach near-term equivalent postmenstrual age, impairment in CO_2 elimination remains. In preterm infants with moderate BPD (FIO_2 ≥0.3) compared with age-matched infants with no BPD and using serum bicarbonate as a proxy for PCO_2, impairment in CO_2 elimination remains.

Infants requiring FIO_2 ≥0.3 at near-term equivalent age are at increased risk for recurrent hospitalization for pneumonia and for reactive airway disease, and the long-term consequences of their pulmonary insufficiency as measured at 36 weeks remain yet to be well-defined. The very profound changes in small airway function, documented in children years after "recovering" from BPD provide a warning to work to reduce the gas exchange inefficiencies accompanying profoundly preterm births.[64]

Oxygen Transport and Delivery

OXYGEN TRANSPORT SYSTEM

The oxygen transport system in humans depends on many interrelated factors, including the fraction of oxygen in inspired air, partial pressure of oxygen in inspired air, alveolar ventilation, relation of ventilation to perfusion of the lungs, arterial blood pH and temperature, cardiac output, blood volume, hemoglobin concentration, and affinity of hemoglobin for oxygen. In normal persons, this complex system, which adjusts to tissue requirements to maintain an adequate end-capillary oxygen tension, has a reasonable reserve capacity and the ability to respond rapidly to changes in oxygen need. Gestation and the immediate postnatal period tax the oxygen transport system more than does any other time period in the human life cycle. In addition to the factors just listed, fetal oxygenation also varies with transplacental oxygen transport—which in turn depends on placental perfusion and Pvo_2 in the uterine vein, thus indirectly reflecting the state of the maternal cardiorespiratory system. Oxygenation of the infant at birth requires a successful transition from fetal to newborn circulatory patterns and establishment of adequate alveolar respiration.

Aerobic metabolism is critically dependent on a constant and adequate supply of oxygen. Although molecular oxygen participates in numerous types of oxidative reactions necessary for cellular metabolism (e.g., production of prostaglandins mediated by cyclooxygenase), its primary role is as the final electron acceptor in the mitochondrial respiratory chain—the process by which energy produced by glycolysis and the citric acid cycle is stored in high-energy phosphate bonds in the form of adenosine triphosphate (ATP). Although ATP is produced during anaerobic glycolysis, the delivery of oxygen to allow aerobic metabolism results in a more than 15-fold increase in the quantity of ATP produced from glucose metabolism. The diffusion of oxygen from midcapillary to the cell is the last step in oxygen transport and depends on several factors, including the oxygen pressure gradient between capillary and cell, the distance between the closest perfusing capillary and the cell, and the impedance to diffusion of the tissue, as reflected by the *diffusion coefficient.* Mitochondrial oxygen supply in vivo ultimately depends on a number of factors, including the distance between the closest perfusing capillary and the cell, the tissue impedance to oxygen diffusion, and the oxygen pressure gradient between capillary and mitochondrion. The pressure gradient, which directly affects mitochondrial oxygen uptake, varies with regional oxygen delivery, tissue oxygen consumption, and the hemoglobin-oxygen affinity. In vitro, mitochondrial function remains at maximal levels at oxygen pressure (Po_2) as low as 0.5 mm Hg; however, a "critical" Po_2 in vivo, below which mitochondrial respiration is compromised, is likely.[1]

Under basal conditions, the lungs load approximately 4 mL of oxygen/minute/kg of body mass onto hemoglobin but can increase this rate 15-fold through input from the carotid and aortic bodies (which sense arterial oxygen content) and brain stem chemoreceptors. Arterial blood transports oxygen from the pulmonary capillaries to the tissues. The oxygen content of the arterial blood usually is high enough to meet cellular oxygen demand. When the oxygen content is decreased, however, local perfusion or hemoglobin oxygen affinity may change to compensate for the lower oxygen content.

The cardiovascular system regulates oxygen supply through variation in cardiac output and distribution of blood flow. Alterations in the metabolic rate of peripheral tissues activate local regulatory mechanisms that modulate arterial blood flow and venous return and, consequently, cardiac output. The distribution of blood flow to specific tissues and organs also is set by local metabolic activity. Accordingly, different controls exist for different tissues.[2] Coronary blood flow, for example, reflects the metabolic activity of heart muscle; because the oxygen extraction of cardiac muscle normally is high, changes in cardiac work

must be matched closely by concomitant changes in coronary blood flow. When oxygen supply is limited, flow is reduced to tissues with low oxygen extraction (such as kidney and gut) in favor of tissues with high extraction (such as heart and brain). The high flow–low extraction areas of the circulation constitute an oxygen reserve system that may be deployed in times of oxygen deprivation.

By contrast, cardiac output does not appear to be directly responsive to moderate changes in either Pa_{O_2} or blood oxygen content[3] (presumably because other mechanisms provide an adequate adjustment) and is virtually unaffected by an increase in Pa_{CO_2} to 50 mm Hg. Blood viscosity and volume are additional determinants of cardiac output. If volume is kept constant and viscosity is altered (e.g., by a change in hematocrit), a reciprocal change in cardiac output occurs. Conversely, cardiac output varies directly with blood volume, presumably through the effect of volume on venous return. The induced alterations in cardiac output that follow changes in viscosity and blood volume are corrected toward normal by subsequent compensatory changes in peripheral vascular resistance. A number of neurohumoral factors also affect cardiac output by direct action on the heart, as reflected in the strength and especially the rate of cardiac contraction.

Hemoglobin concentration is regulated by a renal sensing mechanism that operates to maintain a balance between oxygen supply and oxygen requirement of renal tissues. A decrease in concentration or arterial oxygen saturation of hemoglobin or any increase in hemoglobin affinity for oxygen causes increased erythropoietin production through increased expression of hypoxia-inducible factor (HIF).[4,5] The effect of erythropoietin on bone marrow usually is limited by available iron, so that red blood cell production is stimulated to approximately twice its basal value of 1% of the total red blood cell mass per day. Consequently, red blood cell mass increases slowly in response to hypoxia.[6] Because it increases blood viscosity, a higher hemoglobin concentration at the same total blood volume reduces blood flow and hence oxygen delivery. Normal cardiac output is reestablished by increasing plasma volume proportionately (i.e., by increasing total blood volume).[7]

The affinity of hemoglobin for oxygen, in association with flow distribution, translates oxygen flow into oxygen availability. This characteristic of hemoglobin is classically depicted in the oxygen dissociation curve (oxygen equilibrium curve). Because of its remarkable ability to combine reversibly with large quantities of oxygen, hemoglobin increases the oxygen transport capacity of blood approximately 70-fold over that of oxygen transported dissolved in plasma. For example, if the entire oxygen requirement of the maternal organism had to be met by physically dissolved oxygen, the required cardiac output would be 100 L/minute.

STRUCTURE OF THE HEMOGLOBIN MOLECULE

The hemoglobin molecule contains four heme groups bound to the protein globin. The heme groups, located in crevices near the exterior of the molecule, consist of an organic moiety, protoporphyrin, and an iron atom. The iron in heme binds to the four nitrogens in the center of the protoporphyrin ring (Figure 88-1). The four oxygen-binding sites of hemoglobin are relatively far apart, the distance between the two closest sites being 2.5 nm.

The primary structure of the hemoglobin molecule is genetically determined by the amino acid sequence of the globin chains. The three basic chain structures most important in humans are the α-chain (with 141 amino acids), β-chain (with 146 amino acids), and γ-chain (with 146 amino acids), which together form hemoglobin A (Hb A), with a makeup of $\alpha_2\beta_2$, and hemoglobin F (Hb F), which is $\alpha_2\gamma_2$. The β- and γ-chains differ from each other by only a few amino acid residues. Nine amino acid positions in the sequence are recognized to be the same in all or nearly all species studied thus far. These conserved positions are involved either in the oxygen-binding site directly or in forming hydrogen bonds between helices. The positions of the nonpolar residues in the interior of hemoglobin vary considerably, but substitutions always involve one nonpolar residue for another, thereby conserving the striking nonpolar character of the molecule's interior. Eight α-helices, by convention designated A to H, constitute the secondary structure of the hemoglobin molecule. Helices E and F form a hydrophobic cleft at the insertion of the heme moiety. The position in space of the α-helices with respect to one another provides tertiary structure, whereas the spatial relationship of the subunit globin chains provides the quaternary structure of the hemoglobin molecule.

The quaternary structure of deoxyhemoglobin is termed the *T* or *tense form,* whereas that of oxyhemoglobin is the *R* or *relaxed form.* X-ray crystallographic studies have confirmed that oxygenated and deoxygenated hemoglobin differ in their conformation, with the oxygenated form being more compact.[8] In addition, these conformational changes were found to be crucial for the interactions of hemoglobin with organic phosphates[9] (see later discussion).

In the T form (deoxyhemoglobin), the iron atom is pushed out approximately 0.6 nm from the heme plane because of steric repulsion between the proximal histidine and nitrogen atoms of the porphyrin. On oxygenation, the iron atom moves into the plane of the protoporphyrin ring, forming a strong bond with oxygen. Oxygenation of the first heme group then favors a switch in the quaternary structure from T to R through the proximal histidine group. The heme group and proximal histidine residue make intimate contact with 15 side chains; oxygenation causes

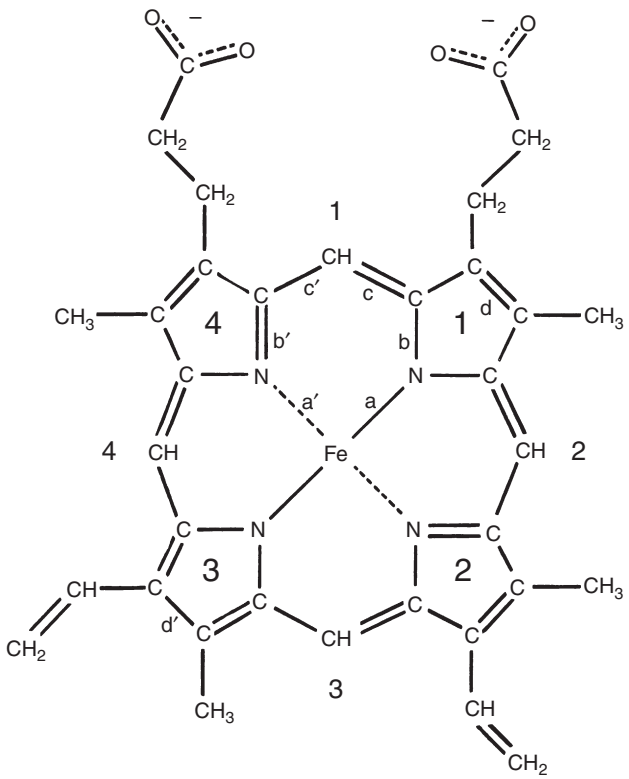

Figure 88-1 The heme group is an essential component of hemoglobins, cytochromes, and enzymes such as catalase and peroxidase. The central porphyrin ring has various side chains: methyl, —CH_3; vinyl, —CH—CH_2; and propionic acid, —CH—CH_2—COOH.

structural changes in the F helix, the EF corner, and the FG corner. These changes are then transmitted to the subunit interfaces (Figures 88-2 and 88-3). The expulsion of a tyrosine residue from the pocket between the F and H helices leads to the rupture of interchain salt links. Consequently, on oxygenation of the first heme group, the equilibrium is shifted in favor of the R form. Each subsequent molecule of oxygen is bound more strongly because fewer salt links remain to be broken. Because each hemoglobin molecule (tetramer) contains four iron atoms, it can combine with four oxygen molecules. Each mole of hemoglobin thus can combine with four moles of oxygen, for a normal blood oxygen capacity of 7.76 mM/L (i.e., 1.94 mM of hemoglobin/L × 4 = 7.76). Expressed alternatively, 1 g of hemoglobin can combine with 1.368 mL of oxygen for an oxygen-carrying capacity of approximately 20 mL/dL when the hemoglobin concentration is 15 g/dL[10] (as detailed in the following section).

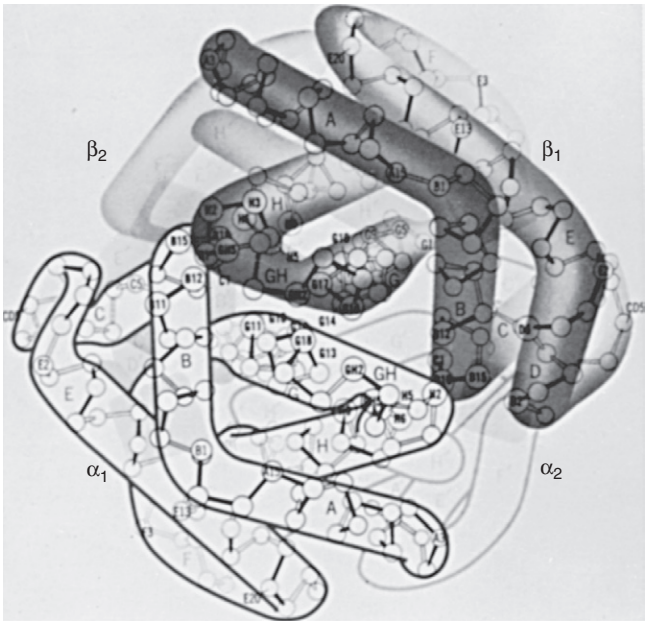

Figure 88-2 Hemoglobin tetramer, $\alpha_1\beta_1$ contacts ($\alpha_2\beta_2$ contacts are identical). The eight α-helices, which constitute the secondary structure, are labeled *A* to *H*. The packing of chains in the hemoglobin molecule is such that close interlocking contact of side chains exists between unlike subunits, but with little contact between α and α or β and β. The $\alpha_1\beta_1$ or $\alpha_2\beta_2$ contacts involving *BGH* helices and the *GH* corner are called *packing contacts* because they represent subunit packing that is unchanged when the hemoglobin molecule goes from its deoxy- to its oxy- configuration.

HEMOGLOBIN-OXYGEN INTERACTIONS

Hemoglobin oxygen affinity is the continuous relationship between hemoglobin oxygen saturation and oxygen tension. It customarily is plotted as the sigmoid-shaped oxygen equilibrium curve, and it can be summarily expressed as the P_{50}—that is, the oxygen tension at which 50% of hemoglobin is saturated with oxygen at standard temperature and pH (Figure 88-4). The sigmoidal shape of the oxygen-hemoglobin equilibrium curve can be explained only if two assumptions are made: (1) that the heme groups react with oxygen in a fixed sequence, and (2) that the oxygenation and deoxygenation of one heme group profoundly affect the oxygenation and deoxygenation of the others. This latter phenomenon has been termed *heme-heme interaction.* As each heme group accepts oxygen, it becomes progressively easier for the next heme group of the molecule to pick up oxygen. This concept is implicit in the Hill equation for percent saturation[11]:

$$y / 100 = k \times Po_2^n / 1 + (k \times Po_2^n)$$

where y is percent saturation with oxygen, k is an equilibrium constant, Po_2 is oxygen partial pressure, and the exponent n is the average number of iron atoms per hemoglobin molecule. The value of n for normal hemoglobin is approximately 2.9.

As blood circulates through the normal lung, Po_2 increases from approximately 40 mm Hg to 110 mm Hg, a pressure sufficient to ensure at least 95% saturation of hemoglobin with oxygen. The oxygen-hemoglobin equilibrium relationship is such that any further increase of oxygen tension in the lung results in only a small increase in saturation. In the normal adult, when oxygen tension has fallen to approximately 27 mm Hg, at a pH of 7.40 and a temperature of 37° C, 50% of hemoglobin is saturated with oxygen (i.e., the P_{50} for whole blood is 27 mm Hg).

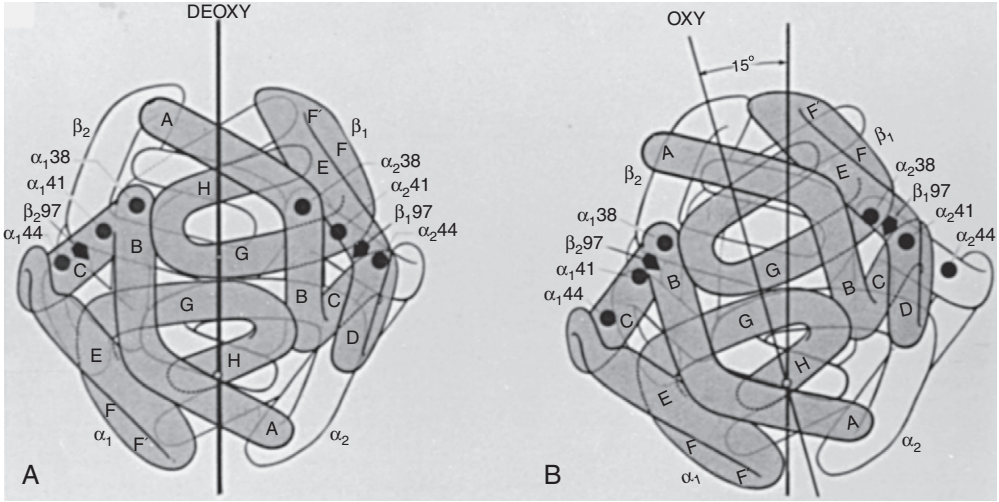

Figure 88-3 Subunit motion in hemoglobin: Combination into deoxyhemoglobin and oxyhemoglobin. Two dimers are superimposed in **A** and **B. A,** The complete tetramer is shown in its deoxyhemoglobin conformation. Note the position of β97 relative to α41 and α44. **B,** In oxyhemoglobin, the $\alpha_1\beta_1$ is rotated 15 degrees relative to $\alpha_2\beta_2$. Note the new positions of β97 between α41 and α38.

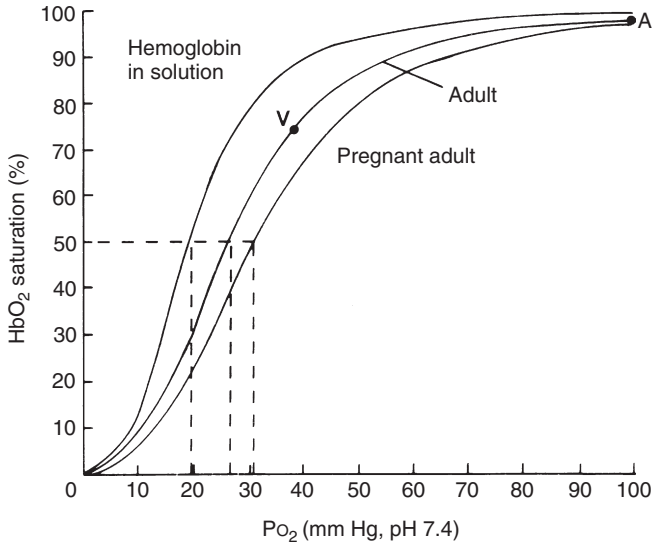

Figure 88-4 Oxyhemoglobin saturation curve under standard conditions for normal blood of pregnant and nonpregnant women. Also shown is the dissociation curve for hemoglobin in solution.

The steep and flat parts of the curve reflect definitive processes in oxygen unloading. As oxygen diffuses from capillary to tissue, at first a rapid fall in Po_2 (represented by the flat part of the curve) occurs until the steep part is reached, after which capillary Po_2 decreases little even though large amounts of oxygen are released. Because oxygen tension at the mitochondrial surface, the point of oxygen utilization, is always approximately 0.5 to 1.0 mm Hg,[1,12] the driving pressure for, and consequently the rate of, oxygen delivery is determined solely by the mean Po_2 in capillary blood. This is in turn set by the position of the dissociation curve on the Po_2 axis and by its steepness, such that relatively little change in driving pressure occurs as the red blood cell moves through the capillary. As the partial pressure of oxygen decreases, tissue oxygenation may become impaired. The term *critical* Po_2 was introduced to indicate the oxygen tension of blood below which diffusion is impaired and organ function is disturbed.[13] A critical Po_2 cannot be a well-defined value that applies to all tissues under all conditions. The oxygen requirements of tissues vary, and in some tissues, such as striated muscle, oxygen requirements are determined by the level of activity. For the brain, an organ in which an adequate oxygen supply is essential for maintaining energy metabolism, the critical Po_2 appears to be approximately 20 mm Hg.

When hemoglobin oxygen affinity is increased (i.e., with lower P_{50}), the curve is shifted to the left, and oxygen (which is bound more tightly to hemoglobin) is released only at lower partial pressures. For example, whereas a Po_2 of 40 mm Hg results in an oxygen saturation of 75% at 37° C and pH 7.40, a leftward shift of the curve results in a higher saturation at the same Po_2. The resulting change in oxygen unloading ultimately could result in impaired diffusion. When affinity is decreased (i.e., with higher P_{50}), the curve is shifted to the right. Consequently, oxygen is bound less tightly to hemoglobin and is released at higher partial pressures, thereby enhancing oxygen unloading at the tissue level. Therefore the release of oxygen from the blood at the tissue level depends on the position of the oxygen equilibrium curve, which in turn is modified by intraerythrocytic pH, Pco_2, temperature, and other factors, including electrolyte concentration, organic phosphate levels, and hemoglobin type.

FACTORS ALTERING BLOOD OXYGEN AFFINITY OF HEMOGLOBIN

The effect of temperature on the oxygen equilibrium curve was first noted by Barcroft and King in 1909.[14] Increased temperature shifts the curve toward the right, thereby facilitating the release of oxygen. In addition, changes in temperature alter both the Bohr factor and the 2,3-diphosphoglycerate (DPG) effect[15] (discussed in the following section).

The *Bohr effect* is the shift to the right of the oxygen equilibrium curve of both adult and fetal blood in response to an increase in Po_2 or a decrease in pH, or both. Oxygen unloading is determined by the Po_2 gradient between blood and tissues. The shift of the oxyhemoglobin dissociation curve to the right as carbon dioxide enters the blood from the tissues tends to raise the oxygen tension, increasing the gradient for any given oxyhemoglobin saturation and facilitating transfer of oxygen to the tissues. The change in log P_{50} per unit change in pH (i.e., $-\Delta \log P_{50}/-\Delta$ pH) is known as the *Bohr factor.* Its value for adult human blood is –0.48, and for the newborn infant it is –0.44. The effective pH is the intracellular pH of the red blood cell, which usually is 0.2 unit less than plasma pH at physiologic levels, although the pH gradient across the red blood cell may vary in disease states. Thus an acute change in pH of 0.1 unit changes P_{50} by approximately 3 mm Hg. The effect of pH changes lasting longer than 2 to 3 hours depends largely on the compensatory change in organic phosphate synthesis (see later discussion). The Bohr effect is more pronounced, at least experimentally, as oxygen saturation decreases and is diminished in 2,3-DPG–depleted blood.[16]

The Bohr effect produced by varying Pco_2 at constant fixed acid is larger (–0.48) than that induced by alterations in metabolic acids at constant Pco_2 (–0.40).[16] The molecular basis of the carbon dioxide effect is two-fold: It follows both carbon dioxide–induced changes in pH and the action of carbon dioxide as a ligand, binding reversibly to uncharged amino groups in the hemoglobin molecule to form carbamates.[17-19] Bound carbamates form salt bridges, stabilizing the T (deoxy-) conformation of hemoglobin and decreasing hemoglobin oxygen affinity. In addition, the affinity of other sites on the hemoglobin molecule for the hydrogen ion (H^+) is enhanced by transition from oxyhemoglobin to deoxyhemoglobin, allowing deoxyhemoglobin to take up much of the H^+ generated from spontaneous decomposition of carbonic acid.

By modifying hemoglobin oxygen affinity, carbon dioxide also facilitates respiratory gas exchange in the lungs. At the lungs, carbon dioxide is given up by red blood cells into the alveoli. Carbon dioxide concentration falls, thereby shifting the oxygen equilibrium curve to the left; the increase in hemoglobin oxygen affinity enhances uptake of oxygen from the alveoli.[20] The combined effects of pH, Pco_2, and temperature on the oxygen equilibrium curve can be viewed, in theory, as advantageous for species survival. An increase in tissue metabolism causes increases in local temperature, H^+ concentration, and Pco_2, all of which raise P_{50}. The result is a higher gradient of oxygen tension between capillary and mitochondrion at the site (tissue) where oxygen consumption is highest. For example, the in vivo oxygen equilibrium curve has been shown to shift markedly rightward during acute exercise as a result of combined Bohr and temperature effects.[21]

EFFECT OF ERYTHROCYTE 2, 3-DIPHOSPHOGLYCERATE ON BLOOD OXYGEN AFFINITY OF HEMOGLOBIN

It has long been recognized that the oxygen affinity of Hb A in free solution is considerably greater than that of the intact fresh erythrocyte. This difference suggested to many investigators that the red blood cell contained a substance or substances capable of interacting with hemoglobin and reducing its affinity for oxygen.

In 1967, it was demonstrated that interaction with a number of organic phosphates decreased the affinity of a hemoglobin solution for oxygen, with 2,3-DPG being the most effective.[22,23] Of the organic phosphates normally found in the human erythrocyte, 2,3-DPG is present in the largest concentrations and thus is both qualitatively and quantitatively the most important phosphate with respect to modulation of hemoglobin oxygen affinity. The content of 2,3-DPG in the human red blood cell averages 4.5 μmol/mL of red blood cells (range, 3.4 to 5.2 μmol/mL), whereas the ATP concentration averages 1.0 μmol/mL of red blood cells (range, 0.8 to 1.4 μmol/mL). The remainder of the organic phosphates generally totals less than 0.4 μmol/mL of red blood cells. Hemoglobin oxygen affinity as indicated by P_{50} is linear with respect to 2,3-DPG concentration over a wide range; a change of 0.43 mmol of 2,3-DPG/mL of red blood cells results in a 1-mm Hg change in P_{50}.[24]

The highly negatively charged anion 2,3-DPG binds preferentially to deoxyhemoglobin in a 1:1 molar ratio under physiologic conditions of solute concentration and pH. On a molecular basis, 2,3-DPG decreases oxygen affinity by stabilizing the quaternary structure of deoxyhemoglobin through cross-linking of β-chains. 2,3-DPG is stereochemically complementary to a constellation of six positively charged groups located on the β-chains and facing the central cavity of the hemoglobin molecule.[25] A single molecule of 2,3-DPG is anchored by six salt bridges to cations at the entrance of the central cavity. On oxygenation, 2,3-DPG is extruded because the central cavity becomes too small. A second mechanism by which 2,3-DPG reduces oxygen affinity is by altering the intraerythrocytic pH relative to plasma pH. The reduction in pH consequently decreases oxygen affinity by the Bohr effect. It has been shown that both mechanisms apply in the intact erythrocyte, and that at concentrations of 2,3-DPG above normal, the latter mechanism predominates.[26] The concentration of 2,3-DPG in human red blood cells varies with gestational and postnatal age and can be influenced by hemoglobin level, pH, oxygenation, and activity of red blood cell enzymes such as hexokinase and pyruvate kinase.[27]

FETAL OXYGEN TRANSPORT

Compared with adult blood, fetal blood has a higher affinity for oxygen and lower P_{50}—an observation first made in 1930.[28] Figure 88-5 shows this relationship for the human fetus near term, when P_{50} is approximately 20 mm Hg under standard conditions. Barcroft working with Elsden[29] and other associates[30] and Hall[31] reported a gradual decrease in the blood oxygen affinity (increase in P_{50}) during the course of gestation, such that the fetal curve progressively approximates the maternal curve. In the placenta, because of the low P_{O_2} at which transfer of oxygen is achieved, the high affinity of fetal hemoglobin favors oxygen uptake in the fetus. The highest P_{O_2} in the fetus is in umbilical venous blood, in which P_{O_2} usually does not go much above 30 mm Hg. At that oxygen tension, the saturation of human fetal blood is 6% to 8% higher than the saturation of maternal blood.[32]

These findings raised questions about the mechanism or mechanisms responsible for the increased oxygen affinity of fetal blood. Hall[31] suggested that this difference might be associated with specific hemoglobin characteristics. Korber,[33] in 1866, had first noted that blood from human newborn umbilical vessels denatured less readily in alkaline or acid solutions than did blood from adults, the difference being most pronounced in alkali. In 1930, Haurowitz[34] demonstrated that the difference in alkaline denaturation resides in the globin chains of hemoglobin and proposed the presence of two hemoglobins in newborn blood: an alkali-susceptible adult fraction and a more resistant fetal fraction. In 1963, the human fetal α-chain was shown to have the same amino acid sequence as for the α-chain of human adult hemoglobin.[35] In addition to the two α-chains, fetal hemoglobin were found to contain two non–α-chains (labeled γ-chains), which resemble the β-chain and contain the same number of amino acids (146) but differ in sequence by a total of 39 amino acids. Each γ-chain contains four isoleucine residues not found in either the α- or the β-chain. In addition, three proline residues present in the β-chain have been substituted by other amino acids.

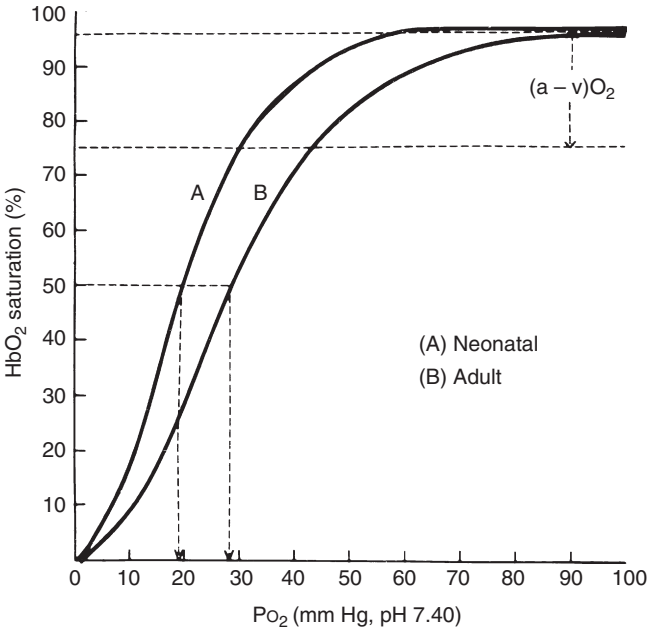

Figure 88-5 Oxyhemoglobin equilibrium curves for blood from term infants at birth and from adults.

A linear correlation between the proportional composition of fetal hemoglobin and the P_{50} at the time of delivery has been noted in humans. At term, Hb A accounts for approximately 25% of total hemoglobin, and the fetal P_{50} is approximately 19 mm Hg.[26,36] Birth, intrauterine hypoxia,[37] and hemolytic disease of the newborn do not cause a change in the proportions of Hb A and Hb F at any given gestational age. During the period of accelerated erythropoiesis near term, however, Hb A synthesis predominates. The subcellular events—transcription and translation—responsible for the gradual, orderly change in synthesis from γ- to β-chains are not completely understood.[38,39] More recent studies, however, suggest that the interaction of multiple transcription factors with the locus control region (LCR) of the globin gene sequence on chromosome 11 regulates the forms of the globin gene (ε, γ, δ, or β) expressed at each stage of development.[40] The erythroid Kruppel-like factor (EKLF) and the stage selector protein (SSP) seem to be particularly important. Although the specific developmental signals that regulate developmental changes in transcription factor expression have not been identified, changes in expression of hypoxia-inducible factor 1 (HIF-1) in response to changes in fetal blood oxygen tension may play a role in this process.[41]

Fetal Blood Oxygen Delivery

Despite an oxygen tension in fetal blood that is only one-fifth to one-fourth that of the adult, fetal arterial blood oxygen content and oxyhemoglobin saturation at term are not much lower than those in the adult (Figure 88-6). This similarity, of course, results from a combination of the high oxygen-carrying capacity and increased oxygen affinity of fetal blood. The greater oxygen affinity of fetal blood generally is considered an advantage in that it allows incorporation of oxygen to nearly saturate fetal hemoglobin at relatively low oxygen tensions. The possible disadvantage

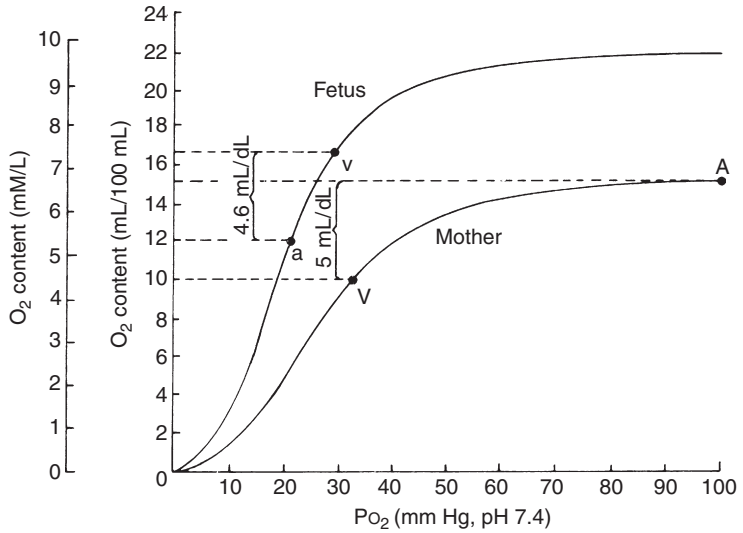

Figure 88-6 Blood oxygen content as a function of oxygen tension in human maternal and near-term fetal blood.

in oxygen delivery to fetal tissues is offset by the fact that the fetal oxyhemoglobin saturation curve is rather steep, so that a small decrease in oxygen tension results in a major decrement in oxyhemoglobin saturation and unloading of oxygen to the tissues.

The actual oxyhemoglobin saturation curve in vivo as blood flows through the placental exchange capillaries is an additional important consideration. Compared with standard conditions, maternal arterial blood is slightly hypocarbic (P_{CO_2} of 32 mm Hg) and alkalotic (pH 7.42), whereas fetal blood is slightly hypercarbic (P_{CO_2} of 45 mm Hg) and acidotic (pH of 7.34). As fetal blood courses through the exchange vessels, it gives up H^+ and carbon dioxide, leading to a rise in pH and a fall in P_{CO_2}. The opposite changes occur in the maternal exchange vessels. Thus, in vivo, the maternal and fetal oxyhemoglobin saturation curves may be almost superimposed (see Figure 88-6). Although the double Bohr effect in the placenta has been credited with significantly augmenting oxygen exchange, theoretical studies suggest that this accounts for only 2% of the total oxygen transferred.[42] As noted earlier, the Bohr effect is expressed by the factor $-\Delta\log P_{50}/-\Delta pH$, which has a value of approximately −0.48 for both fetal and maternal blood at pH values between 7.2 and 7.8. Below a pH of 7.2, however, the Bohr effect is greater for fetal than for maternal blood. An additional factor tending to shift the in vivo fetal dissociation curve to the right is the temperature of the fetus, which exceeds that of the mother by 0.5° to 1.0° C. In human neonates, the dissociation curve also shifts toward that of the mother as the concentration of Hb F decreases.[32,43]

Effect of 2,3-Diphosphoglycerate on Fetal Hemoglobin Oxygen Affinity

In 1971, investigation of the deoxygenation kinetics of isolated fetal and adult hemoglobin revealed significant functional differences.[44] Although 2,3-DPG bound to fetal hemoglobin, the binding constant was lower than for adult hemoglobin.[36] Other experiments performed on whole blood demonstrated a significant fall in P_{50} when erythrocytes were depleted of 2,3-DPG, even in samples of blood with a high percentage of fetal hemoglobin.[45] With the use of pure solutions of fetal and adult hemoglobin, it subsequently has been shown that the effect of 2,3-DPG on the P_{50} of fetal hemoglobin is approximately 40% of its effect on the P_{50} of adult hemoglobin.[46]

On the basis of these findings, the P_{50} of whole blood can be expected to be related to both the 2,3-DPG level and the relative concentrations of adult and fetal hemoglobin. Because the concentrations of adult hemoglobin and 2,3-DPG and, correspondingly, the functioning fraction of DPG (total red blood cell DPG content in nmol/mL of red blood cells times the percentage of adult hemoglobin) increase during gestation, it is not surprising that the P_{50} of whole blood correlates with gestational age (Figure 88-7). (The term *functioning fraction* is not intended to imply that a compartmentalized portion of the red blood cell's 2,3-DPG is in combination with the hemoglobin but instead is used to underscore the fact that both 2,3-DPG and adult hemoglobin act in concert to determine the oxygen affinity of intracellular hemoglobin.) The correlation of P_{50} with gestational age is even closer than with the functioning fraction of DPG, suggesting that other factors contribute to the rise of P_{50} during gestation.

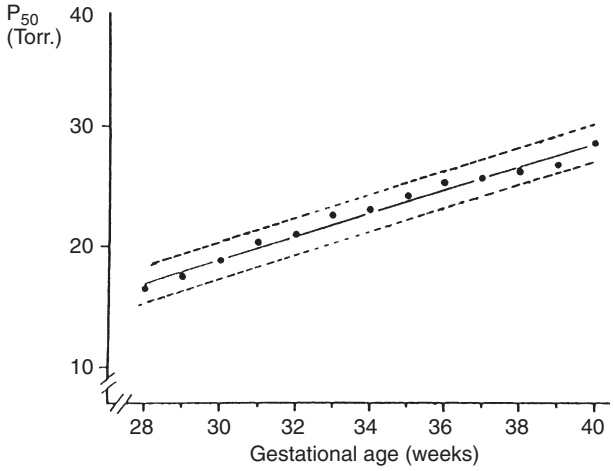

Figure 88-7 Relationship between gestational age and hemoglobin P_{50}. Each *plotted point* represents the mean value for age; *dashed lines* indicate ± 2 SD.

No satisfactory explanation has emerged for the rise in 2,3-DPG levels during gestation. It has been speculated, however, that the increase is the result of increased synthesis of adult hemoglobin, because in vitro studies have shown that the reduced hemoglobin of adults is more effective than the reduced hemoglobin of fetuses in stimulating 2,3-DPG synthesis.[47] This hypothesis also is supported by the significant correlation

TABLE 88-1

Oxygen Transport in Term Infants: Selected Clinical Series

between the percentage of adult hemoglobin and 2,3-DPG content in the neonatal period (Table 88-1).

Postnatal Changes in Oxygen Transport

The high oxygen affinity of fetal blood, which is well adapted to oxygen uptake in the placenta, has disadvantages in postnatal life. With adequate postnatal lung function, the pulmonary circulation is exposed to an oxygen tension of 80 mm Hg or more, so that high affinity at low oxygen tensions has no advantage for oxygen uptake during the newborn period. At the tissue level, the low P_{50} decreases the driving potential for oxygen diffusion, limiting the rate at which oxygen can be unloaded. The newborn infant needs more oxygen than the fetus, for even in a neutral thermal environment and at minimal activity, the oxygen consumption of most species increases by 100% to 150% in the first few days of life.[48] Colder environments and muscle activity further increase the metabolic demand for oxygen. Hence a P_{50} adequate for tissue supply in the fetus does not provide a sufficient rate of net oxygen diffusion in the neonate.

To meet the increased oxygen demands after birth, oxygen-carrying parameters of blood change drastically. In most species, postnatal changes take place in both oxygen affinity and oxygen-carrying capacity, but at different rates and by different amounts. Beginning at birth, the infant's blood oxygen affinity decreases rapidly.[26] On the first day of life, the P_{50} in normal infants is 19.4 ± 1.8 mm Hg, in contrast with a value of 27.0 ± 1.1 mm Hg for the normal adult (all values are mean ± SD). In the term infant, P_{50} increases gradually and reaches normal adult values by 4 to 6 months of life (Figure 88-8), corresponding to the time course of the replacement of fetal hemoglobin by adult hemoglobin. The red blood cell 2,3-DPG concentration on day 1 averages 5.43 ± 1.04 μmol/mL of red blood cells and thus does not differ significantly from the adult value of 5.11 ± 0.42 μmol/mL. By the fifth day, 2,3-DPG increases to 6.58 ± 1.00 μmol/mL of red blood cells.[35] Although this increment has only a modest direct effect on fetal hemoglobin oxygen affinity, it lowers intracellular pH, thereby decreasing blood oxygen affinity.

For most of the first year of life, Hb F decreases from around 75% to approximately 2% of the total, whereas 2,3-DPG concentrations in general remain fairly constant at 5 to 6 μmol/mL of red blood cells. At 8 to 11 months of age, the concentration of 2,3-DPG rises to pproximately 7 μmol/mL. The P_{50} at this age averages 30.3 mm Hg, which exceeds the value for the normal adult, whereas the fetal hemoglobin concentration is decreased to normal adult levels. Average values for the percentage of fetal

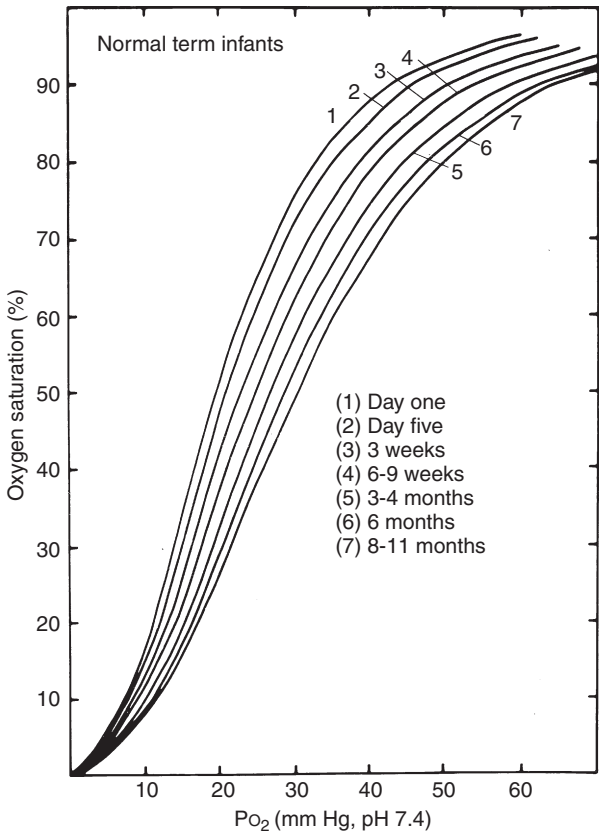

Figure 88-8 Oxygen equilibrium curve for blood from term infants at different postnatal ages.

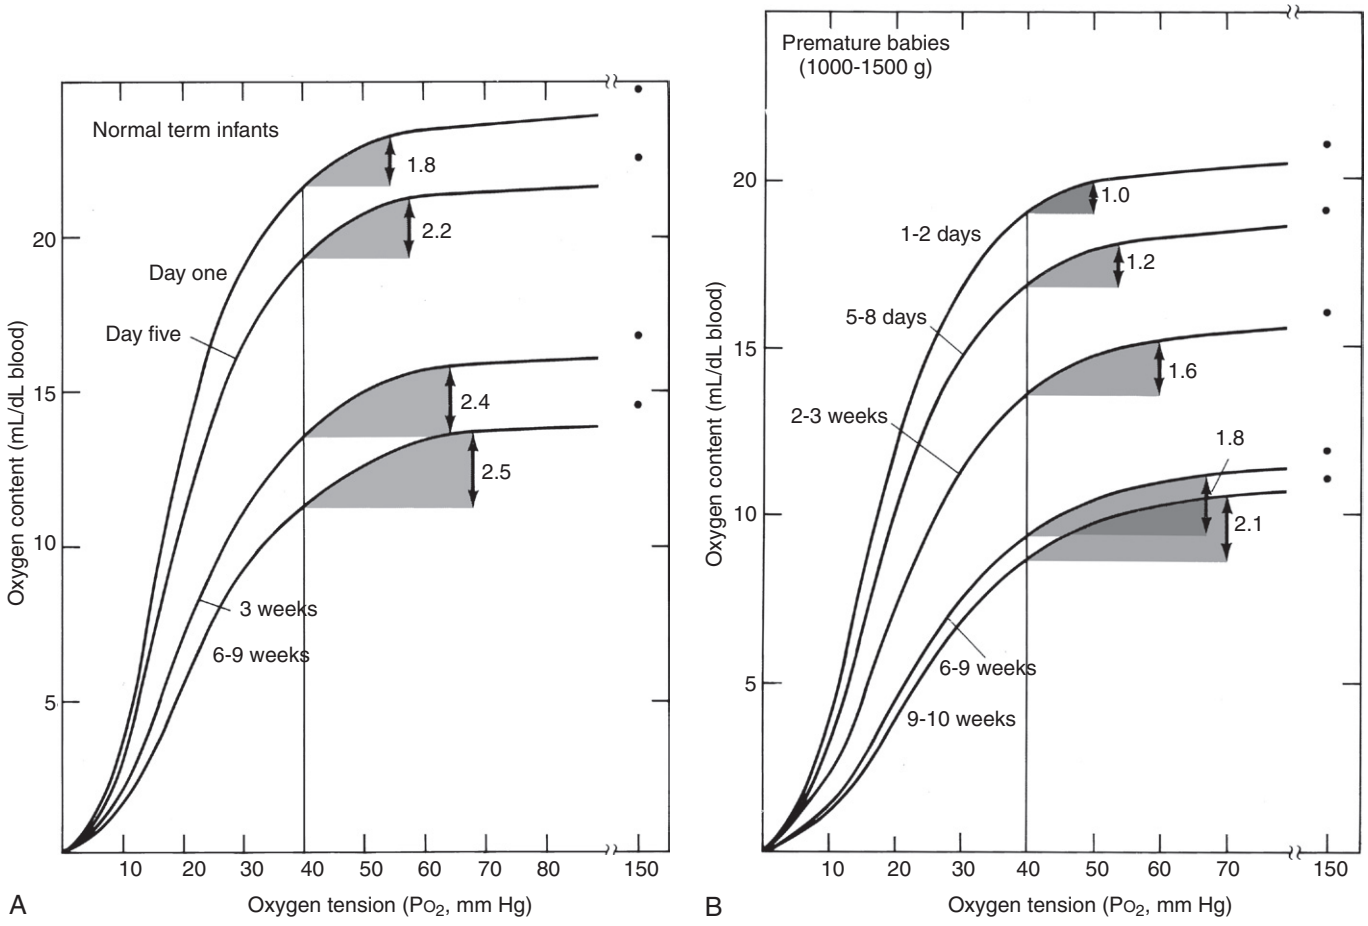

Figure 88-9 Oxygen equilibrium curves for blood from term infants (**A**) and from preterm infants of birth weight 1000 to 1500 g (**B**) at different postnatal ages. *Double arrows* represent the oxygen-unloading capacity between given "arterial" and "venous" Po_2 values. *Points* corresponding to 150 mm Hg on the abscissa are the O_2 capacities; each *curve* represents the mean value for the infants studied in each age group.

hemoglobin, P_{50}, and 2,3-DPG levels for term infants of various postnatal ages are shown in Table 88-1. Thus the postnatal change in P_{50} correlates neither with the change in red blood cell DPG content alone nor with the decline in fetal hemoglobin alone. Instead, the progressive decrease in oxygen affinity during the first 6 months of life correlates significantly with the functioning DPG fraction. The changes in oxygen affinity during postnatal life should be taken into account when the oxygen saturation or content of arterial blood in the neonate is derived from measurements of Pa_{O_2} and pH. In the absence of other measurements, gestational age can be used for a reasonably accurate estimation of the oxygen affinity.

In general, compared with their larger term counterparts, preterm, low-birth-weight infants have a lower erythrocyte 2,3-DPG content, lower P_{50}, and higher fetal hemoglobin concentration. During the first several weeks of life, these small infants have functioning fractions of DPG that are significantly lower than those in term infants. Premature infants have a smaller oxygen-unloading capacity initially than that measured in term infants and do not catch up during the first 3 months of life[3] (Figure 88-9).

Effect of Altered Physiologic States on Oxygen Delivery to Tissues

Various alterations in physiology may have a significant effect on oxygen delivery to the tissues. Under such conditions, variations in oxygen-carrying capacity, blood flow, or hemoglobin oxygen affinity have the potential to improve or impair tissue oxygenation.

Hypoxemia

The response to hypoxemia changes significantly during maturation. Oxidation of the cytochromes of the electron transport chain during hypoxemia is decreased in the newborn infant compared with the adult at any given degree of hemoglobin saturation, presumably because of the presence of fetal hemoglobin in the circulation.[49] The lower level of oxidation preserves mitochondrial metabolism and helps maintain high-energy phosphate production during hypoxemia. The left-shifted hemoglobin-oxygen curve associated with fetal hemoglobin might be expected to be a disadvantage during hypoxemia because release of oxygen to tissues is decreased. On the contrary, tissue oxygen extraction in the fetus and neonate appears to be increased during acute hypoxemia, thereby maintaining normal levels of oxygen consumption.[50] By contrast, animal studies suggest that fetal oxygen extraction is not increased during chronic fetal hypoxemia; instead, fetal oxygen consumption is decreased, presumably reflecting a decrease in metabolic rate in response to reduced oxygen delivery.[51]

The fetal response to hypoxemia also appears to be organ-specific. For example, studies in animal models have shown that cerebral blood flow increases proportionately more during acute hypoxemia when fetal hemoglobin concentration is high. This differential response preserves or even increases oxygen delivery to brain, although the effect is blunted during chronic

hypoxemia.[51,52] Changes in blood flow in response to fetal hypoxemia have not been well-characterized in other organs.

Sepsis

Bacterial sepsis also may affect tissue oxygen transport. Sepsis caused by group B streptococci, for example, is associated with a higher critical venous oxygen saturation (the levels below which tissue acidosis develops) than that typical for hypoxemia.[53] This higher critical point seems to be a specific effect of sepsis, rather than a result of the alterations in circulatory status (e.g., increased catecholamine levels) that occur in response to infection. Oxygen consumption is increased during sepsis, while at the same time oxygen delivery may be decreased as a result of impairment of myocardial function by endotoxin.[54] Additional evidence suggests that sepsis may decrease oxygen extraction at the tissue level, further reducing tissue oxygen delivery.

Anemia

Anemia is a common clinical problem in the premature infant. In otherwise normal infants with no evidence of cardiac disease, pulmonary disease, or increased metabolic needs, a decrease in the oxygen-carrying capacity is a source of concern only if oxygen delivery to the tissues approaches the limit of oxygen stores. As seen in Figure 88-10, infants who at birth exhibit significant differences in total oxygen-carrying capacity but similar oxygen affinities will exhibit the same arteriovenous oxygen content differences. It is worth noting that when oxygen-carrying capacity decreases significantly as a result of anemia, sufficient oxygen unloading occurs without lowering the venous oxygen tension below 30 mm Hg.

A reduction in oxygen-carrying capacity may be more critical under conditions of impaired oxygen uptake, such as in the presence of lung disease. With reduced oxygen uptake, tissue oxygen delivery can be improved by optimizing preload, afterload, Sao_2, and oxygen-carrying capacity (i.e., hemoglobin concentration). The effect of a decrease in Sao_2 on oxygen delivery is significantly less than the effect of anemia.[55,56] For example, Sao_2 would have to decrease from 95% to approximately 80% to have an effect on oxygen content comparable to a 2-g decrease in hemoglobin concentration. Thus, in situations of marginal oxygen delivery, maintenance of hemoglobin concentrations high enough to optimize oxygen-carrying capacity is essential.

Exchange Transfusions

An acute rightward shift of the oxyhemoglobin curve of the newborn infant can be produced by exchange transfusion with adult blood, with its lower oxygen affinity[57,58] (Figure 88-11). The consequences of exchange transfusions with fresh versus stored blood were first demonstrated in 1954 and further delineated in later studies. Infants who underwent exchange transfusion with blood that had been stored for 7 days or longer had a decreased P_{50} compared with that in infants receiving fresh blood (i.e., obtained up to 24 hours previously).[59] The increase in oxygen affinity occurring with blood storage correlated with a simultaneous fall in 2,3-DPG levels.[60] The calculated oxygen-unloading capacity was decreased in infants receiving transfusions of 5-day-old blood, but in those receiving fresh blood it was increased.[36] These studies demonstrated that during the immediate posttransfusion period, the infant's blood reflects the storage characteristics of the blood received.

Further investigations revealed that these findings are specific for blood stored in acid-citrate-dextrose; use of this storage medium results in a prompt fall in 2,3-DPG levels and

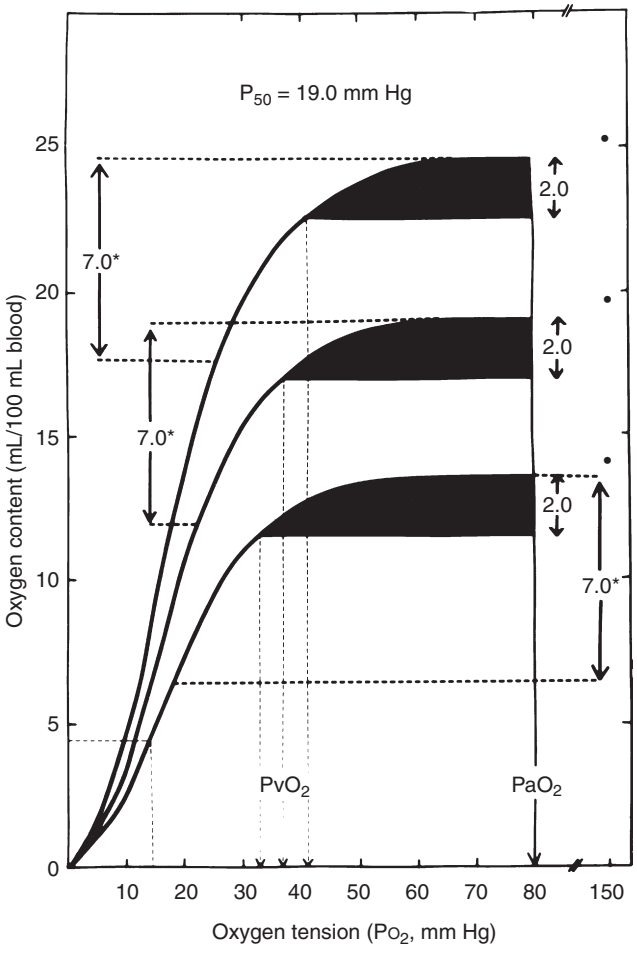

Figure 88-10 The effect of altered hematocrit at a constant P_{50} of 19.0 mm Hg on tissue oxygen unloading in newborn infants. The *asterisk* represents the calculated myocardial extraction of oxygen. In this study, P_{50} = 19.0 mm Hg at pH 7.40 and 37° C.

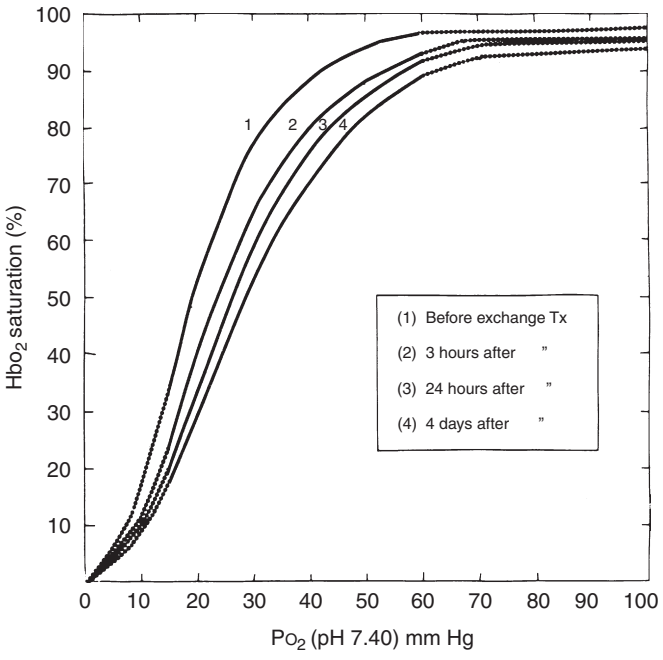

Figure 88-11 The effect of exchange transfusion with fresh adult blood of low oxygen affinity on the oxyhemoglobin dissociation curve for the newborn infant. An acute shift of the curve to the *right* is seen after such a transfusion.

a concomitant rapid increase in oxygen affinity. By contrast, the use of citrate-phosphate-dextrose preserves the oxygen affinity and 2,3-DPG content of the stored blood essentially unchanged throughout normal storage periods.[36] These differences have important physiologic consequences. If blood with a lower P_{50} than that of normal adult hemoglobin is used for exchange transfusion, the amount of oxygen unloaded is decreased. To compensate for this effect, the infant must increase either cardiac output or the arteriovenous oxygen difference.[61] The latter response results in decreased venous oxygen tension, potentially impairing oxygen diffusion from the capillaries to the tissues. Thus knowledge of the storage conditions of the blood products to be used for exchange transfusion may be of critical importance in determining the physiologic impact of the procedure, particularly in the infant with compromised cardiorespiratory function.

89 Control of Breathing in Fetal Life and Onset and Control of Breathing in the Neonate

Ruben E. Alvaro and Henrique Rigatto

In the study of control of breathing during the fetal and neonatal periods, three considerations are of special importance: First, the fetus sleeps all of the time and the neonate most of the time.[1-4] Accordingly, their control of breathing must be studied during sleep, and the findings need to be compared with data for adult subjects obtained during sleep and not during wakefulness.[5-8] In this respect, accurate comparison has not been the norm in the past, leading to some notable misconceptions. Second, the fetus and the neonate are not cooperative subjects. Study of their respiratory control must therefore proceed without benefit of conscious participation as in the adult; consequently, determining whether the measurements obtained reflect corresponding physiologic processes in adult subjects under similar conditions is difficult. Third, measurements in the neonate usually are made, by necessity, in the decubitus position, whereas those in the adult usually are made with the subject sitting or standing.[6,9] The implications of the effect of different positions on the control of breathing also have not been dealt with in previous investigations. Unless some consistency in methodology can be maintained, defining what is actually distinct or unique about the control of breathing in the neonate will prove challenging.

This chapter reviews some of the concepts and progress made in the area of control of breathing in the fetus and newborn. Major developments are summarized, and a critical analysis of the scientific foundations of current knowledge in this area also is presented.

CONCEPTUAL AND HISTORICAL PERSPECTIVES

Although the major advances in current understanding of the control of breathing generally apply to the fetus and newborn, two important aspects that underscore the unique nature of breathing during this period merit special attention: (1) the presence and purpose of fetal breathing and (2) the physiologic mechanism responsible for the establishment of continuous breathing at birth.

In 1970, Dawes and co-workers[10] presented evidence that the fetal sheep makes regular breathing movements during rapid eye movement (REM) sleep. In their work, tracheal pressure changes were measured as an index of fetal breathing. Simultaneously, Merlet and colleagues,[11] using changes in intraesophageal pressure as the index of fetal breathing, demonstrated respiratory activity in fetal sheep. Subsequent work confirmed and expanded these findings by recording the electrical activity of the diaphragm and clearly showing the central origin of the respiratory output in utero.[2,12-16] It is now universally accepted that the fetus performs breathing "exercises" in utero beginning in early pregnancy.[14,15,17-23] Because no gas exchange is associated with this activity, its purpose is unknown. Dawes previously suggested, in a teleologic vein, that the breathing in utero is important to exercise the respiratory muscles for their vital function after birth.[24]

The discovery of fetal breathing brought a new dimension to the events occurring at birth. What had traditionally been called "the initiation of breathing at birth" must now be called "the establishment of continuous breathing at birth." Breathing begins long before birth. The question now is not what determines the appearance of breathing at birth but what makes it continuous. Alternatively, from another perspective, the issue is what makes fetal breathing episodic, present only during low-voltage electrocortical activity. The answers to these questions remain essentially unknown.

The Fetus

Breathing Pattern at Rest

Fetal breathing occurs primarily during periods of low-voltage electrocortical activity, which accounts for 40% of fetal life during the last trimester of gestation in sheep.[2,10,24-26] In the human fetus, the percentage is similar.[17,21,22] During high-voltage electrocortical activity, no established breathing is present, but occasional breaths may surface after episodic, generalized, tonic muscular discharges associated with body movements[2] (Figure 89-1). During low-voltage electrocortical activity, breathing is irregular, with abrupt onset and ending of activity seen on diaphragmatic electromyography (EMG) tracing. Less frequently observed is a progressive increase in envelope amplitude, comparable to the inspiratory slope observed in the anesthetized newborn lamb (Figure 89-2). A gradual decrease in diaphragmatic electromyographic signal at the end of a breath, reflecting postinspiratory activity (as observed in the newborn infant), is rarely seen in the fetus.[2,19,23,27,28] This irregular diaphragmatic activity generates a negative tracheal pressure of approximately 2 to 5 mm Hg. The corresponding changes in tracheal flow are less than those seen postnatally, probably owing to the higher viscosity of lung fluid in the system. The irregular breathing activity observed during this period probably reflects the influence of the reticular formation on breathing characteristic of REM sleep. The average breath has an inspiratory time of 0.45 second, expiratory time of 0.74 second, and a total duration of 1.12 seconds.[27,29] The physiologic mechanism responsible for the occurrence of fetal breathing only during low-voltage electrocortical activity is unknown.

Fetal State

The occurrence of fetal breathing during low-voltage electrocortical activity has led some investigators to believe that the fetus might be awake during part of this period.[30-32] In fact, on the basis of electrophysiologic criteria, it was postulated that during the last part of gestation in sheep the fetus was awake about 5% of the time.[12,13,32,33]

It was further postulated that a number of chemical and pharmacologic agents could alter fetal breathing by "arousing" the fetus.[12,32,33] In the late 1970s, Rigatto and colleagues[16] became interested in determining whether the fetus was at times awake in utero, and whether arousal could be induced by chemical or pharmacologic agents. As measured in this study using electrocorticography (ECoG) during both low-voltage and high-voltage activity (i.e., LVECoG and HVECoG, respectively), the polysynaptic reflexes for the hindlimbs in the chronic fetal sheep preparation were found to be unusually intense during

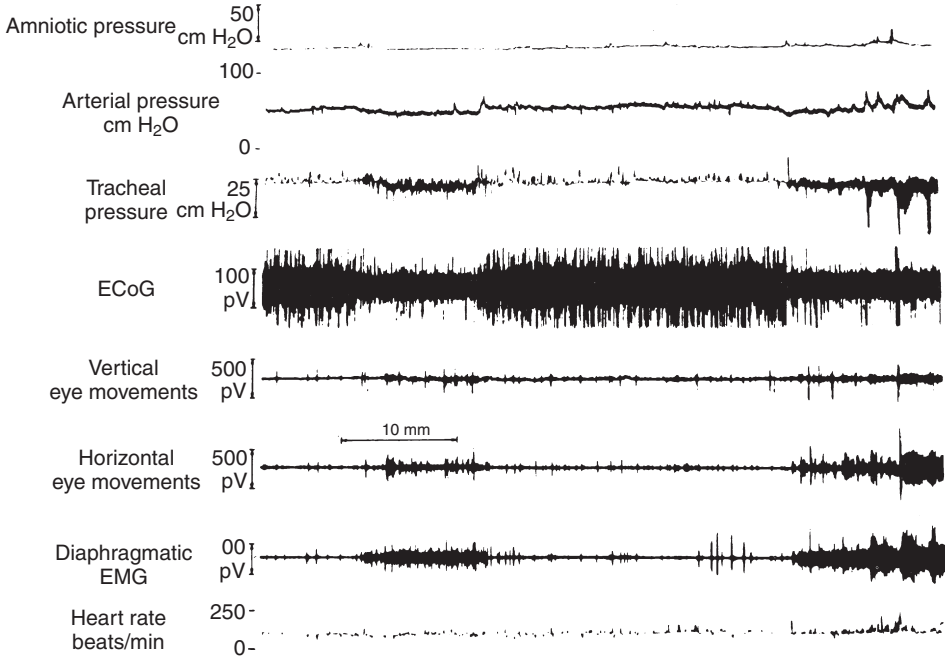

Figure 89-1 Fetal breathing in a fetal lamb at 134 days gestation. Note that the deflections in tracheal pressure and diaphragmatic activity occur during periods of rapid eye movement *(REM)* sleep in low-voltage electrocortical activity *(ECoG)* only. In high-voltage electrocortical activity (quiet sleep), breathing is absent.

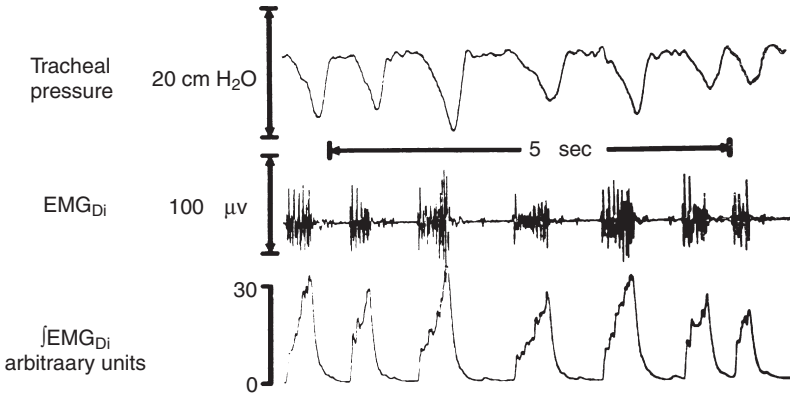

Figure 89-2 Tracheal pressure and diaphragmatic electromyographic activity *(EMG_{Di})* in a fetal lamb at 129 days gestation. The abrupt beginning and ending of diaphragmatic activity in some of the breaths contrast with the progressive increase in activity in others. A gradual decrease in diaphragmatic activity, reflecting postinspiratory activity, as seen in the newborn infant, is rarely seen in the fetus.

transition from low-voltage to high-voltage electrocortical activity.[16] This heightened intensity was speculated to represent fetal wakefulness.

In subsequent studies, a window was implanted on the left flank of the ewe to permit direct observation of the fetus in utero[2,34] (Figure 89-3). The technique proved to be highly successful and has generated substantial new information. Wakefulness, defined by open eyes and purposeful movement of the head, was never observed in the fetus under resting conditions. Analysis of videotapes amounting to more than 5000 hours of observation over 8 years has shown clearly that the fetus alternates between two basic behavioral states: REM (mostly LVECoG) and quiet (mostly HVECoG) sleep.[2,3] Activities such as movement, swallowing, licking, and breathing occur during REM sleep (Figure 89-4). During quiet sleep, the fetus is still and occasionally shows generalized movements associated with tonic discharges. The enhancement of the polysynaptic reflexes observed previously was associated with generalized tonic discharges and rotation of the body and head during the transition from low- to high-voltage ECoG activity. It was not associated with wakefulness.[2,34] This generalized discharge is typical of the transition from low- to high-voltage ECoG. Explication of the neurophysiologic basis for this intense discharge may provide the explanation of how the change from low to high voltage occurs.

Besides the normal irregularity of the respiratory pattern seen in REM sleep, licking and swallowing clearly disturb breathing activity[2,19,28]; breathing becomes slower and irregular, and diaphragmatic activity becomes interspersed with clusters of esophageal electromyographic activity. This digestive tract activity occurs primarily during REM sleep and is translated behaviorally and electrophysiologically as a general increase in electromyographic activity, blood pressure, and heart rate.

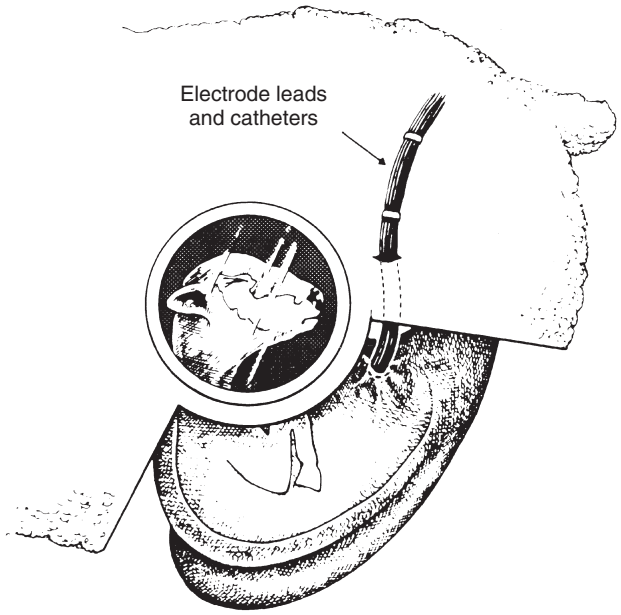

Figure 89-3 View of the head of the lamb fetus through newly created surgical window in the flank of the ewe. The bundle with catheters and electrical leads crosses the abdominal and uterine walls at some distance from the window.

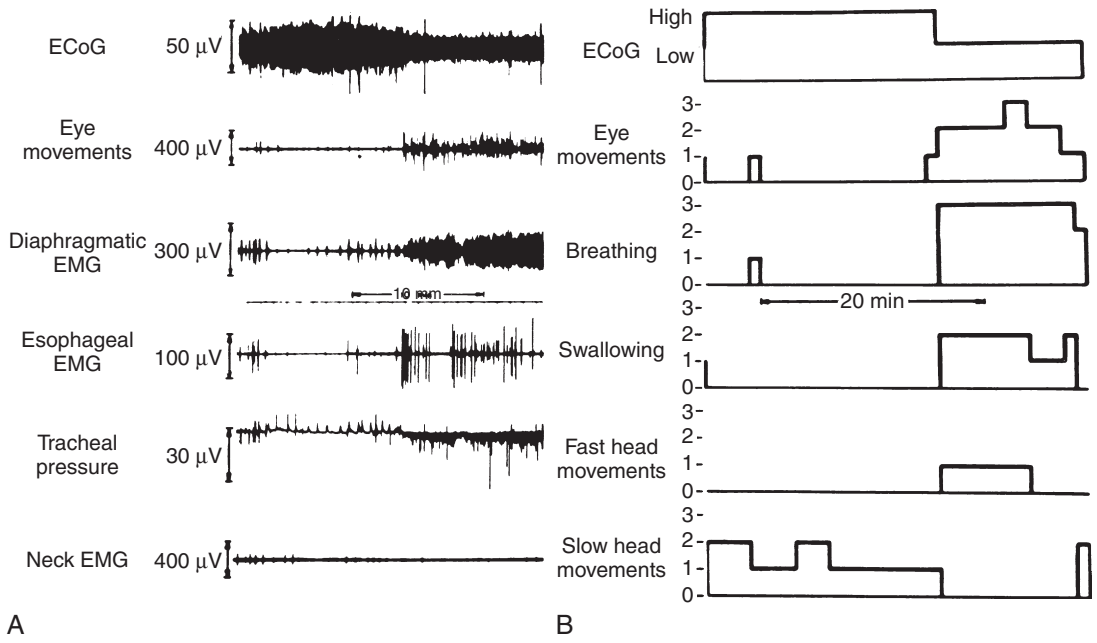

Figure 89-4 A comparative representation of observations made on a polygraph **(A)** and through a double-wall Plexiglas window **(B).** Fetal breathing, eye movements, and swallowing are present predominantly with low-voltage electrocortical activity *(ECoG)* (0 = absent; 1 = low activity; 2 = medium; 3 = high).

Modulation of Fetal Breathing by Carbon Dioxide, Oxygen, Pulmonary Reflexes, and Pharmacologic Agents

Fetal breathing initially was thought by some investigators to depend on behavioral influences, because it was observed only during REM sleep and seemed somewhat refractory to chemical stimuli.[35] Subsequent studies, however, clearly showed that the fetal breathing apparatus is capable of responding well to chemical stimuli and other agents known to modify breathing postnatally. Thus it became clear that the fetus responds to an increase in $Paco_2$ with an increase in breathing.* This increase is associated with increases in tracheal pressure, integrated diaphragmatic activity, and respiratory frequency (Figure 89-5). Both inspiratory and expiratory times decrease, as would be expected from postnatal studies.[29] The increased breathing activity is prolonged into the transitional HVECoG activity but does not continue into the established HVECoG.[29] A specific target of investigation was

*See references 17, 18, 27, 29, 33, 34, 36.

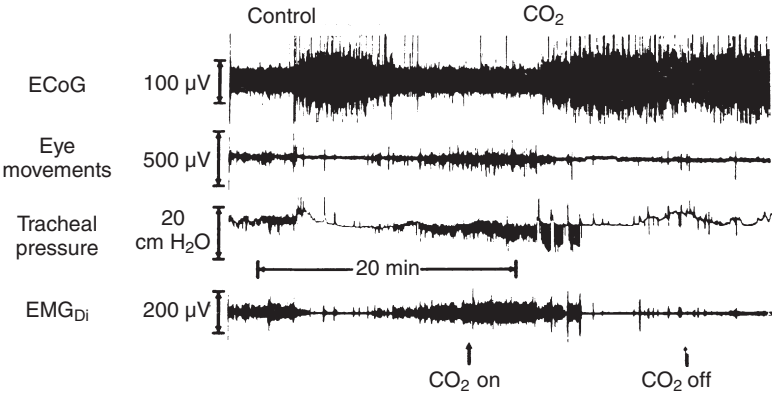

Figure 89-5 Fetal breathing under control conditions and during CO_2 rebreathing. Both tracheal pressure and diaphragmatic activity increase during CO_2 rebreathing. Fetal breathing was prolonged into the transitional low-voltage to high-voltage electrocortical activity *(ECoG)* but stopped in established high-voltage activity.

whether $Paco_2$ could be increased during rebreathing or during direct administration of carbon dioxide to the fetus through an endotracheal tube.[29] Breathing activity was always abolished in established HVECoG, and only when $Paco_2$ was unphysiologically high (greater than 100 mm Hg) and pH was low (less than 7.0 mm Hg) could breathing be initiated in HVECoG. At this level of acidosis, low pH could have been the primary stimulus to initiate breathing, because acidosis has been shown to induce continuous breathing.[37] This increased breathing activity was not associated with wakefulness.[29] Conversely, reducing $Paco_2$ below the "apneic threshold level" abolishes breathing activity,[38] as has been shown in postnatal life.[39-45]

Administration of low oxygen to the fetus by having the ewe breathe hypoxic mixtures abolished fetal breathing. This effect was associated with a decrease in body movements and in the amplitude of the ECoG signal.[18,46] This respiratory inhibition results mainly from direct effects of low O_2 tensions on the fetal brain through activation of adenosine A_{2A} receptors.[47-49] Koos and co-workers[50] found that neuronal lesions of the diencephalon that included the posteromedial group of thalamic nuclei abolished the depressant effects of hypoxia. More recently these investigators observed that neurons within, or proximate or connected to, the thalamic parafascicular nucli were crucially involved in the hypoxic arrest of fetal breathing.[51] Conversely, an increase in arterial Po_2 to levels above 200 mm Hg after the administration of 100% oxygen through an endotracheal tube induced continuous fetal breathing in some experiments in sheep.[52] These findings suggest that the low partial pressure of oxygen in the fetus at rest may be a normal mechanism contributing to inhibition of breathing in utero.

Of the pulmonary reflexes, the inflation reflex of Hering-Breuer is present in fetal life. Lung distention with saline infusion produced decreased frequency of breathing.[14,15] However, fetoplacental gas exchange, the incidence of fetal breathing, and sleep states were not affected by bilateral vagotomy performed during fetal life.[23,30] Although bilateral vagotomy did not prevent the establishment of continuous breathing at birth, vagal innervation was necessary to establish adequate alveolar ventilation in newborn lambs.[53]

A comprehensive review of the effects of various neurochemical agents on fetal breathing has been published.[54] In general, fetal breathing is inhibited by the γ-aminobutyric acid (GABA) agonist muscinol,[55] pentobarbitone,[56] and diazepam[57] acting at the $GABA_A$ receptor complex.[58] Other endogenous inhibitors include adenosine, the prostaglandin PGE_2 (see further on), and endorphins, which may be present at high levels in the fetal circulation. Agents that stimulate fetal breathing movements include prostaglandin inhibitors such as indomethacin, meclofanate, morphine, caffeine, pilocarpine, and 5-hydroxytryptamine (5-HTP). Fetal breathing is inhibited by maternal hypoglycemia, whereas it is stimulated after maternal meals and by hyperglycemia.

Plentiful evidence suggests that the actions of carbon dioxide and those of the pharmacologic agents are central. The effect of hypoxia is poorly understood, but it too seems to act centrally. The peripheral chemoreceptors originally were thought to be inactive in utero; however, the idea that they are completely silent probably was derived from incorrect experimental evidence.[59] Blanco and co-workers[60] have clearly documented activity of the peripheral chemoreceptors in the fetal lamb showing that they are reset at the time of delivery. Johnston and associates[61] found that the response to hypoxia in the fetal lamb with a pontine lesion is mediated through peripheral chemoreceptors. Resection of the carotid bodies does not alter fetal breathing or fetal state substantially and apparently does not alter the establishment of breathing at birth.[62,63] The exact relevance of peripheral chemoreceptors to intrauterine breathing remains undetermined.

Establishment of Continuous Breathing at Birth

The traditional view of the onset of continuous breathing at birth is that labor and delivery produce a transient fetal asphyxia that stimulates the peripheral chemoreceptors to induce the first extrauterine breath. Breathing is then maintained through the input of other stimuli such as cold, touch, and other sensory stimuli.[10,64-67] This overall view was generated through experiments done some years ago in the acute exteriorized fetal preparation at a time when the general consensus was that the fetus did not breathe in utero.

More recent observations have made this general view open to question. First of all, denervation of the carotid and aortic chemoreceptors does not alter fetal breathing or the initiation of continuous breathing at birth[62,63] (Figures 89-6 and 89-7). Moreover, continuous breathing can be initiated in utero, with manifestations of arousal, by raising arterial PO_2 with administration of 100% oxygen to the fetus through an endotracheal tube[52] (Figure 89-8). Continuous breathing does not occur if the arterial Po_2 does not rise. In fetuses in which Pao_2 does not rise, however, continuous breathing will subsequently initiate on cord occlusion.[52] This continuous breathing in response to high arterial Po_2 or cord occlusion is independent of an increase in arterial Pco_2, because the response remains when Pco_2 is kept constant by ventilating the fetus with high-frequency oscillation. These observations during administration of 100% oxygen and cord occlusion suggest that the fetus can resemble a newborn in utero. Breathing can occur in the fetus in the absence

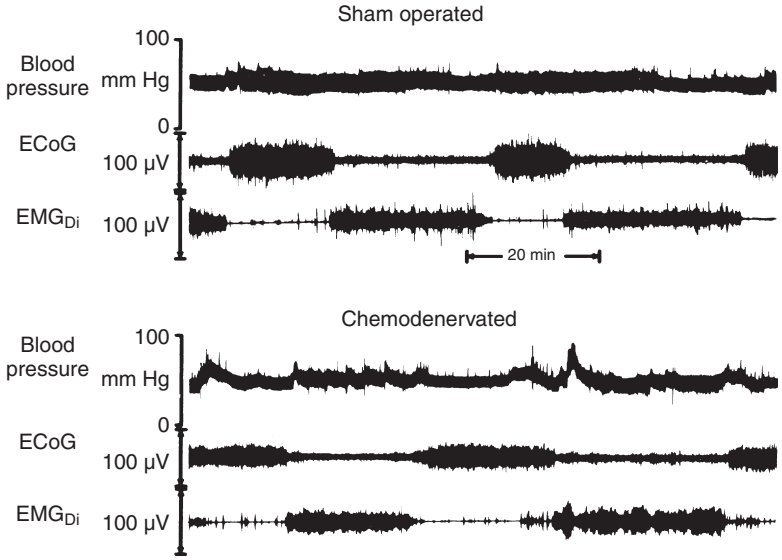

Figure 89-6 Breathing activity in a sham-operated fetal sheep (at 132 days gestation) and in a chemodenervated fetal sheep (at 130 days gestation). Breathing activity remains intact in the chemodenervated fetus. Blood gases were comparable in the two fetuses.

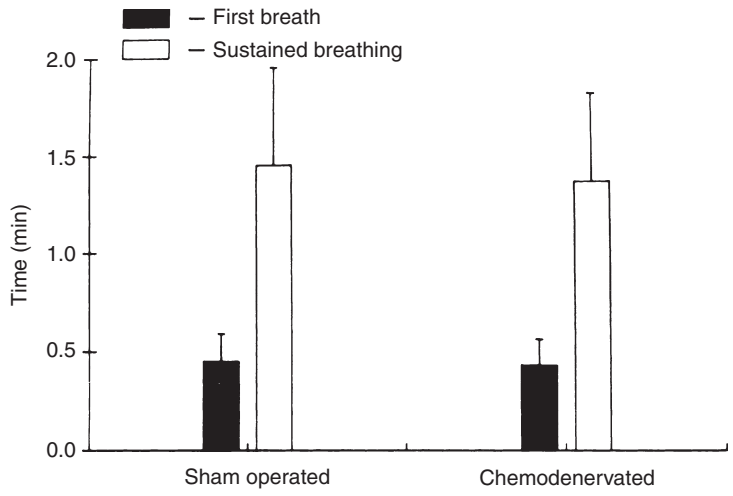

Figure 89-7 Delay in minutes from opening of the window to the appearance of the first breath and to sustained breathing. No significant differences between the two groups are seen.

of transient hypoxemia to stimulate the peripheral chemoreceptors and without any of the sensory stimuli, such as cold, once thought to be important for the establishment of continuous breathing at birth.

Thus the physiologic mechanisms responsible for the inhibition of fetal breathing and the establishment of continuous breathing at birth remain unknown. It has been debated whether the key factors in inducing these changes are intrinsic to the fetal brain or are localized to the placenta. Because placental separation at birth is associated with the onset of continuous breathing, various investigators, ourselves included, have hypothesized that placental factors may be responsible for the inhibition of fetal breathing.[68-72] This line of thinking is based on the assumption that the release of a factor by the placenta into the fetal circulation prevents fetal breathing from being continuous, with inhibition observed during HVECoG, and present only during periods of reticular activation, as observed during LVECoG. In the absence of this factor from the placenta at birth, after cord clamping, the sleep state–related inhibition observed during HVECoG is insufficient to disrupt continuous breathing. An teleologically interesting possibility is that nature may have delegated to the placenta the important role of providing the fetus with gas exchange and nutrients—and it also may have endowed the placenta with some form of chemoreceptor activity regulating fetal breathing and behavior by the secretion of chemical substances into the fetal circulation.

More direct evidence for a placental role has existed since Dawes[65] and Harned and Ferreiro[67] showed that only after the umbilical cord is clamped does the newborn lamb start breathing and behaving like a neonate. Subsequently, Adamson and colleagues[70] induced breathing in the fetus with umbilical cord occlusion and supply of O_2 delivered through an endotracheal catheter. On release of the cord, breathing ceased immediately, before any change in blood gases or pH, suggesting that a factor from the placenta might be involved. Workers in our laboratory were able to induce continuous breathing and wakefulness in fetal sheep by occluding the umbilical cord, so long as a gas exchange area was provided for the fetus in the form of an

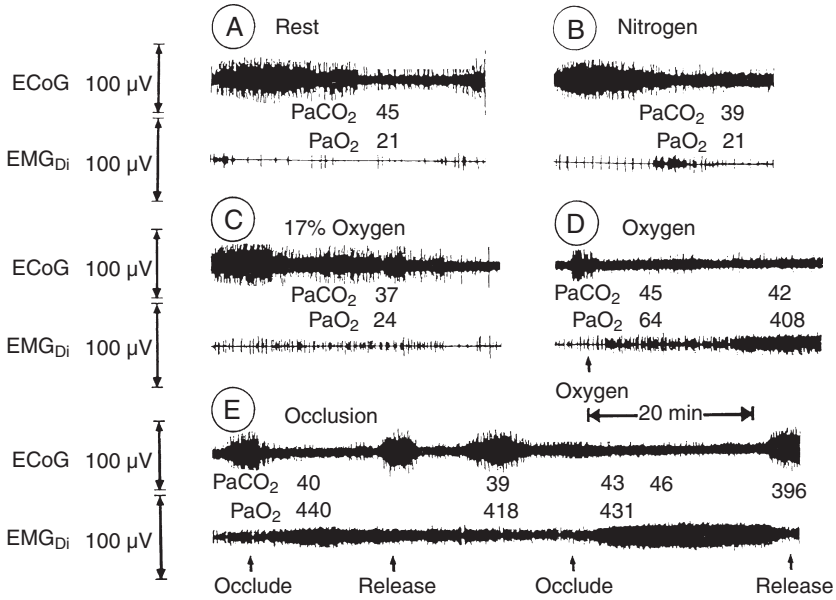

Figure 89-8 Representative tracings showing the effect of various concentrations of O_2 on fetal breathing and electrocortical activity. **A,** Control cycle showing little breathing in fetus in early labor at 143 days gestation. **B,** Lung distention (mean airway pressure 30 cm H_2O) and inspired N_2 do not affect baseline tracing. **C,** 17% O_2 also does not alter breathing. **D,** 100% O_2 induces continuous breathing. **E,** Occlusion on two occasions induces more forceful breathing than that observed with O_2 alone. Of note, continuous breathing was elicited despite preventing the rise of Pa_{CO_2} by subjecting the fetus to high-frequency ventilation (at 15 Hz, with stroke set at 7 cm H_2O).

endotracheal tube.[69,73-75] These experiments suggest the origin in the placenta of a compound that inhibits fetal breathing and fetal activity.

In trying to prove the hypothesis that a factor is released by the placenta, investigators in our laboratory injected the fetal sheep with a placental extract (obtained from cotyledons acutely dissected, sliced, and immersed in Krebs solution) after continuous breathing was induced by cord occlusion.[69] In all experiments, the placental extract decreased or abolished breathing. The infusion of the placental extract into the fetal circulation also inhibited spontaneous fetal breathing present during low-voltage electrocortical activity without inducing significant changes in blood gas tensions, pH, heart rate and blood pressure.[76] This factor appeared specific to the placenta, since the breathing response was absent with extracts from other tissues such as liver, muscle, or blood. Other recent work from our laboratory demonstrated that this factor in the placental extract probably is a prostaglandin, because treatment of the extract with indomethacin–acetylsalicylic acid (ASA) (which significantly reduced the concentration of prostaglandins) eliminated the activity of the extract[77] (Figure 89-9).

Indirect evidence that placental prostaglandins, especially PGE_2, are the mediators responsible for the inhibition of breathing in fetal life has been demonstrated by Kitterman[78] and Wallen[79] and their co-workers, who have shown that infusion of PGE_2 into the circulation of the fetal sheep induced a prompt and complete cessation of breathing movements. In addition, the incidence of fetal breathing movements was inversely correlated with both the PGE_2 dose and the mean PGE_2 concentration. Conversely, intravenous infusion of prostaglandin synthetase inhibitors, such as indomethacin or meclofenamate, induces continuous breathing for many hours in the fetus.[78,80,81] Thus the rate of placental prostaglandin production plays a significant role in setting the level of fetal breathing activity by producing a sleep-related inhibition in the fetal brain stem.

It is unlikely, however, that prostaglandins are involved in the inhibition of fetal breathing observed during hypoxia, because this inhibition persists after the administration of prostaglandin inhibitors. As mentioned previously, several studies have shown that adenosine is the likely mediator of the respiratory depression observed during hypoxia, because intravascular administration of adenosine inhibits fetal breathing and eye movements and the infusion of adenosine receptor antagonists blunts this inhibition.[82,83] In addition, brain disruptions that eliminate hypoxic inhibition of breathing abolish the depressant effects of adenosine.[84]

The Neonate

Breathing Pattern at Rest

The neonate, and particularly the premature infant, breathes irregularly. Great breath-to-breath variability and long stretches of periodic breathing in which breathing and apnea alternate are characteristic.[9,85-89] Haldane's statement that "the surprising fact is not that we breathe regularly, but that we do not breathe periodically most of the time" applies more at this age than at any other.[90] The resting breathing pattern of the neonate is not sleep state–dependent, although sleep greatly modulates it.[3,91]

Sleep traditionally has been divided into quiet, REM, transitional, and indeterminate states. Approximately 29% of sleep time in neonates is spent in quiet sleep, 33% in REM, 7% in transitional sleep, and 31% in indeterminate sleep. The proportion of quiet sleep increases with age, whereas the amount of REM decreases with age. The proportion of wakefulness decreases with decreasing gestational age, and in very immature infants, it becomes difficult to define wakefulness or arousal.[92-94] Studies have shown that periodic breathing, a common breathing pattern in premature infants in which they alternate between breathing intervals and apneic episodes lasting 5 to 10 seconds, occurs in the three states of wakefulness, REM, and quiet, but its prevalence is increased in REM sleep.[3] It frequently is stated in textbooks that in quiet sleep, in analogy with criteria used for adult subjects, breathing is regular. Studies from our laboratory and others, however, have clearly shown that periodic breathing is common

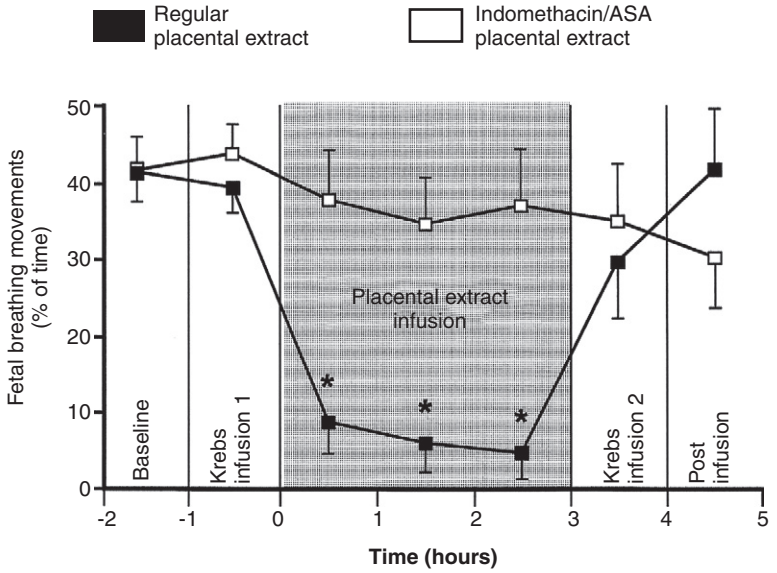

Figure 89-9 The effects of eliminating the prostaglandins from the placental extract on fetal breathing. Of note, fetal breathing remains essentially unchanged with the infusion of a regular placental extract (not treated with indomethacin-ASA), whereas it decreased significantly with the infusion of an indomethacin-ASA–treated extract. *ASA,* Acetylsalicylic acid.

in quiet sleep.[9,95,96] The difference is that periodic breathing is regular in quiet sleep—that is, the breathing and apneic intervals are of similar duration—and very irregular in REM sleep. The most well-defined periodic breathing observable in small babies is in quiet sleep during discontinuous activity in the classic tracé alternant pattern on the electroencephalogram (EEG) (Figure 89-10). Therefore two major differences are recognized between neonates and adults regarding staging of sleep state. One difference relates to the patterns of breathing observed in quiet and REM sleep states and the other to the presence of the tracé alternant EEG pattern during quiet sleep in the neonate. Because this pattern subsides after 44 weeks postconceptual age, it is not used in adults to characterize quiet sleep. Finally, the overall minute ventilation is increased in REM sleep as compared with quiet sleep; this difference is due to a primary increase in respiratory frequency with little change in tidal volume.[3,6,9]

Periodic Breathing and Apnea

Periodic breathing, defined as pauses in respiratory movements that last for up to 20 seconds alternating with breathing, is common in preterm infants. When the respiratory pause is longer than 20 seconds, it is called *apnea.*[97] Although the duration used to distinguish periodic breathing and apnea is arbitrary, it has proved useful and has been widely adopted. Periodic breathing is not as harmful as apnea, because the respiratory pause is short and the decrease in heart rate is minor. By contrast, apnea is a more serious condition, the respiratory pause being longer and frequently associated with decreases in heart rate below 80 beats/minute.[86,97] In very small preterm infants, significant bradycardia can occur with very short apneic pauses. In this instance, therefore, the length of the respiratory pause is not a very useful indicator of severity of the disruption in breathing. For this reason, many centers, including ours, have decided to rely on heart rate as the primary indicator of severity.

Apneic episodes in the neonate are classified according to the absence or presence of breathing efforts during the period of no airflow.[98] Central apneas are those with no flow and no observable breathing efforts. Obstructive apneas are those with no flow despite breathing efforts. Mixed apneas begin as central and end as obstructive apnea. Breath-holding apneas are those in which flow stops at mid-expiration and the remaining expiration occurs just before breathing starts again. A newer method of classifying apneas, devised in our own clinical laboratory, is based on a magnified cardiac stroke–induced pulse observed on the respiratory flow tracing. This method permits detection of presence and timing of airway obstructions with great precision. With use of this method, it has become obvious that some apneas previously classified as central on the basis of absence of respiratory efforts are in fact obstructive.[99] We have been using this method extensively

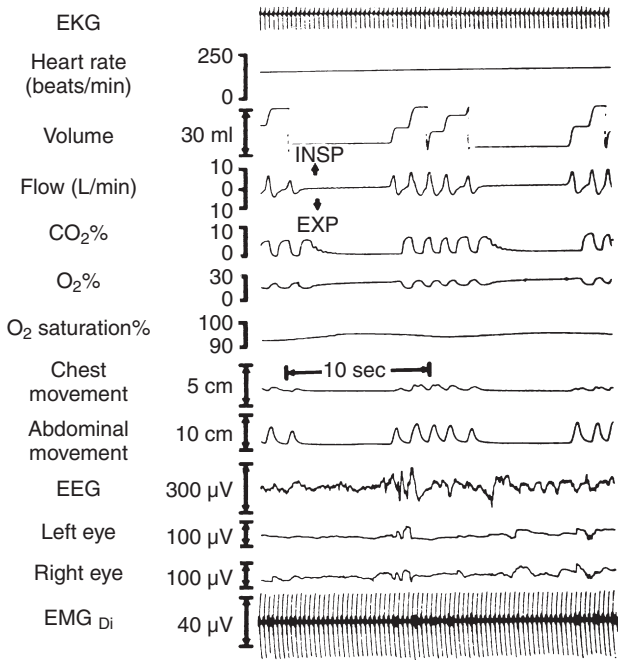

Figure 89-10 Periodic breathing during quiet sleep in an 8-day-old preterm infant born at 32 weeks. The regular periodicity of breathing, with both apneic and breathing intervals of constant length, is characteristic. The classic tracé alternant pattern is evident on the electroencephalogram (EEG).

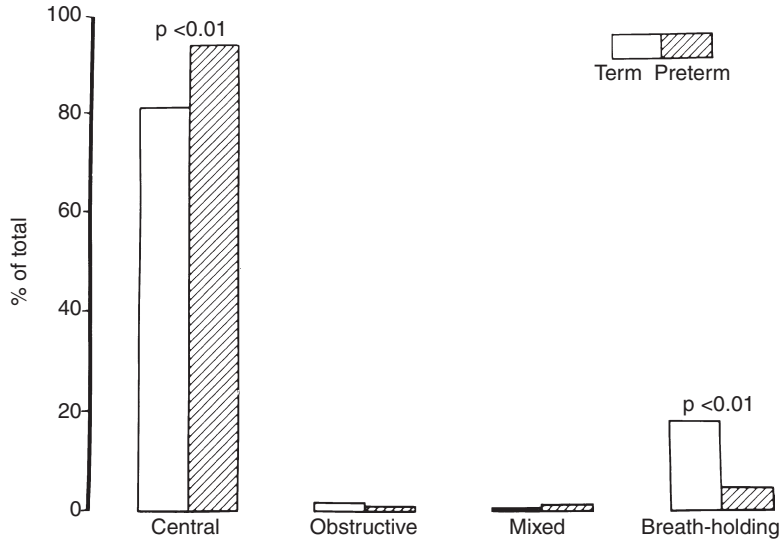

Figure 89-11 Frequency distribution of the various types of apneas in healthy preterm and term infants. Central apneas are predominant. The frequency of breath-holding apneas is greater in term than in preterm infants. Obstructive and mixed types of apneas are rare.

in our experimental studies, but its use in routine clinical care is not yet established.

As determined in preterm infants without underlying disease studied over a period of 3 months, central apneas predominate, and purely obstructive apneas are rare[98] (Figure 89-11). Obstructive apneas more commonly are noted as part of a mixed apneic event. In preterm infants recovering from respiratory support, with some degree of residual lung disease (bronchopulmonary dysplasia), the prevalence of obstructive apneas appears to be increased, accounting for up to 48% of the apneic episodes in some studies. No clear explanation for the obstruction has emerged, but it seems to be at the level of the larynx.[100] Our initial observations suggest that borderline hypoxemia of these infants may be a predisposing factor. One report has described obstruction in 80% of the pauses in preterm infants with periodic breathing.[101] In data from unpublished work in our laboratory, this high prevalence has not been corroborated, but our findings indicate that small preterm infants can exhibit short-duration mixed apneas associated with a significant decrease in heart rate.

Periodic breathing and apnea clearly are a consequence of a disturbance of the respiratory control system, but the precise mechanisms are unclear. Investigators tend to believe that the negative feedback loop controlling respiration is affected by multiple factors related primarily to anatomic and physiologic immaturity. For example, arborization of dendrites at 30 weeks gestation is meager, and neuroconduction and synaptic relay are impaired.[102] Delays in trafficking of neuromessages may then make the system oscillate. Unfortunately, how much immaturity is needed for a given impairment in neurophysiologic traffic has not yet been established. Oscillation in arterial gas tensions, changes in circulation time, incoordination of the respiratory pump secondary to a compliant chest wall, and changes in sleep state all may contribute to this instability of the respiratory control system.[97]

A relevant controversy in the literature has centered on whether periodic breathing and apnea are mechanistically different or whether long apneas constitute just a step further in the basic respiratory disturbance that induces the short apneas of periodic breathing. A study carried out in our laboratory showed that (1) a prolonged apnea almost never occurred in the absence of preceding short apneas, and (2) the risk for occurrence of a prolonged apnea increased significantly when the preceding period contained an increased number of apneic episodes, increased duration of the longest apneic interval, or increased duration of the apneic time.[103] More recent studies have shown that the periodic breathing cycles in REM but not in quiet sleep were associated with progressive decreases in minute ventilation and oxygenation, probably related to the mechanical and chemoreceptor limitations known to be present in this sleep state.[104] In all likelihood, periodic breathing, especially during REM sleep, is a marker for apnea, because apneas almost never arise abruptly in infants breathing regularly but occur only in infants whose respiratory pattern is characterized by significant periodicity.

Compared with infants who are breathing continuously, neonates exhibiting periodic breathing have lower P_{O_2} values, and their peripheral chemoreceptors are more hyperactive, as reflected by the longer apneic period and more pronounced immediate decrease in ventilation in response to inhalation of high-concentration oxygen mixtures.[86,87,105] Thus the major reason for background instability appears to be the significant contribution of the peripheral chemoreceptor drive to normal breathing at this age. Indeed, the arterial P_{O_2} tension in these infants sits on the steep portion of the minute ventilation–arterial P_{O_2} regression curve for human adults. This means that small changes in baseline arterial P_{O_2} produce large changes in baseline ventilation. Hypoxia may be a contributing factor, because inhalation of a low-concentration oxygen mixture easily induces periodic breathing and apnea in these infants.

As reported in a study from our laboratory, the average CO_2 apneic threshold in preterm infants is only 1.5 mm Hg lower than the eupneic P_{CO_2}, whereas in adults it is approximately 5 mm Hg lower.[43] The closeness of eupneic and threshold P_{ACO_2} likely confers a great vulnerability to respiratory stability in these infants. It is not surprising, therefore, that brief startles, movements, or changes in sleep state could allow eupneic P_{CO_2} to dive below the P_{CO_2} apneic threshold, inducing periodic breathing and apnea in these infants (Figure 89-12). We think that the key element responsible for this narrow difference is the well-known hypoxemic status of these infants. Xie and colleagues recently showed that in adults, the time course of the occurrence of apnea after transient hyperpnea was consistent with a peripheral chemoreceptor mechanism. In this study, hypoxia shortened the apnea latency and narrowed the eupneic-apneic alveolar P_{CO_2} (P_{ACO_2}) threshold, whereas hyperoxia delayed the onset of apnea and widened the eupneic-apneic P_{ACO_2} threshold.[45] The same

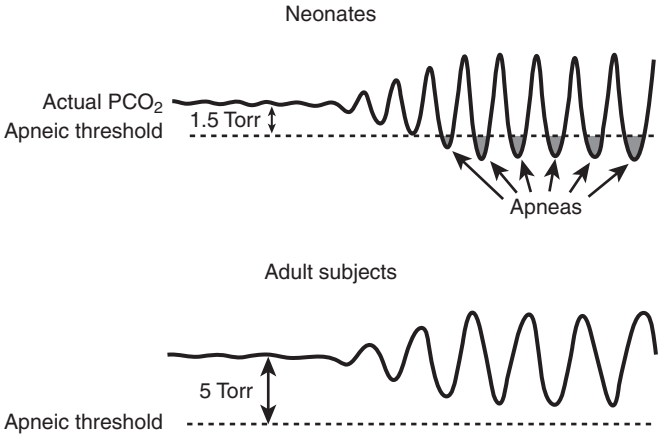

Figure 89-12 Diagrammatic representation of the relationship between the CO_2 apneic threshold and the baseline or actual P_{CO_2} levels in neonates and adults. Because of the proximity of these two levels in the neonate, P_{CO_2} is much more likely to dive below the apneic threshold than in the adult.

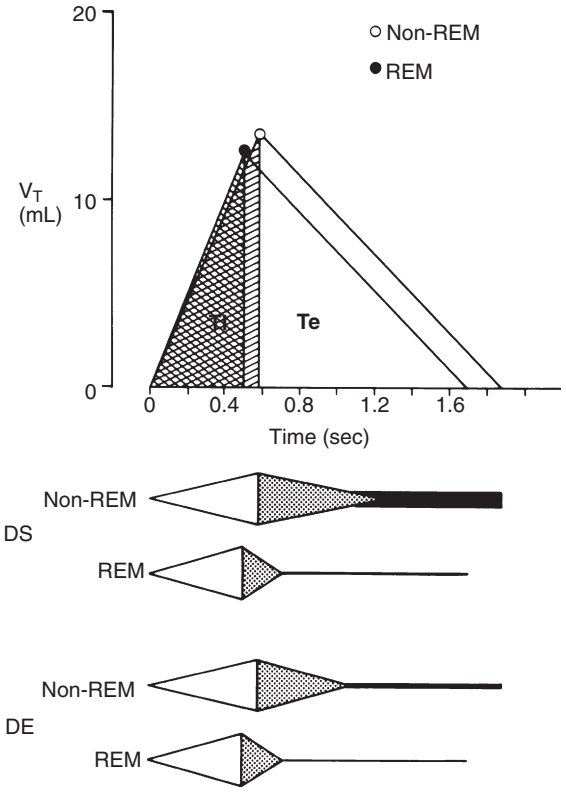

Figure 89-13 Schematic diagram showing changes in tidal volume, timing, and diaphragmatic electromyography (EMG) signal in non–rapid eye movement (non-REM) (quiet) and REM (active) sleep. Of note, total phasic activity diminishes from non-REM to REM sleep. Also, in both sleep states, it is shorter in esophageal *(DE)* than in surface *(DS)* EMG tracings. Expiratory phase activity as a proportion of total phasic activity decreases significantly from non-REM to REM sleep.

investigators previously had shown that the smaller difference between eupneic and apneic P_{ACO_2} during hypoxia was due to a disproportionate reduction in the eupneic P_{ACO_2} rather than a higher apneic threshold.[106] The low arterial P_{O_2} in newborn infants may keep the eupneic P_{CO_2} relatively low, not by hyperventilation as in adult subjects but by a decrease in metabolism that parallels the decrease in arterial P_{O_2}.

The sleep state appears also to be a contributing factor, because periodic breathing and apnea are more frequent in REM sleep than in quiet sleep. The neonate sleeps almost uninterruptedly, continuously alternating between REM sleep and quiet sleep. This pattern increases instability in the respiratory control system. Indeed, minor alterations during sleep, such as a startle or a sigh, produce apnea in these infants. The almost continuous change in baseline ventilation during sleep is what Haldane called "the hunting of the respiratory centre."[90]

Although sleep modulates breathing, it does not cause apnea; apnea also occurs during wakefulness. The high prevalence of apnea during REM sleep may be related to muscle activity in this stage. During REM sleep, the tone of the intercostal muscles is abolished in conjunction with a decrease in diaphragmatic activity and in the tone of the adductor muscles of the upper airway—a combination of factors likely to induce chest distortion, impairment of the braking mechanism during expiration, pulmonary collapse, and apnea[97] (Figure 89-13). When chest distortion occurs, diaphragmatic work increases by approximately 40%, adding to the mechanical impairment. This observation is compatible with the finding that the application of continuous negative pressure around the chest tends to abolish apnea.[107]

Chemical Regulation

Inhalation of carbon dioxide increases ventilation during REM and quiet sleep in newborn infants. The response to steady-state inhalation of carbon dioxide is the same in these two sleep states, but the response during rebreathing of carbon dioxide is less pronounced in REM than in quiet sleep[3,6,8,95] (Figure 89-14). Workers in our laboratory postulated that the differences in response with these two techniques relate to the fact that using rebreathing, it is possible to measure the response in "phasic" REM only, whereas using the steady-state technique the response always covers both "phasic" and "tonic" REM sleep.[95] Because the carbon dioxide response in "tonic" REM is the same as that during quiet sleep, the results with use of the steady-state method tend to resemble those in quiet sleep.[7,108]

The pattern of breathing observed with inhalation of carbon dioxide differs according to the percentage of carbon dioxide inhaled. If the percentage of inhaled carbon dioxide is low (less than 2%) during steady-state inhalation, the response consists primarily of an increase in tidal volume.[9] If the percentage of inhaled carbon dioxide is high (greater than 2%), the response in both sleep states consists of an increase in respiratory frequency and in tidal volume.[87,95] Periodic breathing is abolished with a small increase in inhaled carbon dioxide of approximately 1% to 2%.[9,87] This response has been attributed to the increased central drive and increased stores of carbon dioxide, with better buffering capacity for the oscillations in P_{ACO_2}.

Inhalation of oxygen at low concentrations produces an immediate increase in ventilation (at 1 minute) followed by a later decrease (at 5 minutes).[85,88,109,110] Responses are similar in wakefulness, REM, and quiet sleep, although hyperventilation seems slightly more sustained during late hypoxia in quiet sleep.[3] The more sustained hyperventilation in these infants during quiet sleep reflects the more autonomic control during this sleep state, the system being more responsive to chemical stimuli.[7,108] The immediate increase in ventilation reflects peripheral chemoreceptor stimulation and is associated with an increase in frequency and in tidal volume. The late response is manifested primarily by a decrease in frequency.[86,88]

The mechanism responsible for this response is still unclear and may vary according to species. In humans it is likely to be related to central release of inhibitory neuromodulators.[111] Experiments in kittens and in newborn monkeys, however, suggest that the late

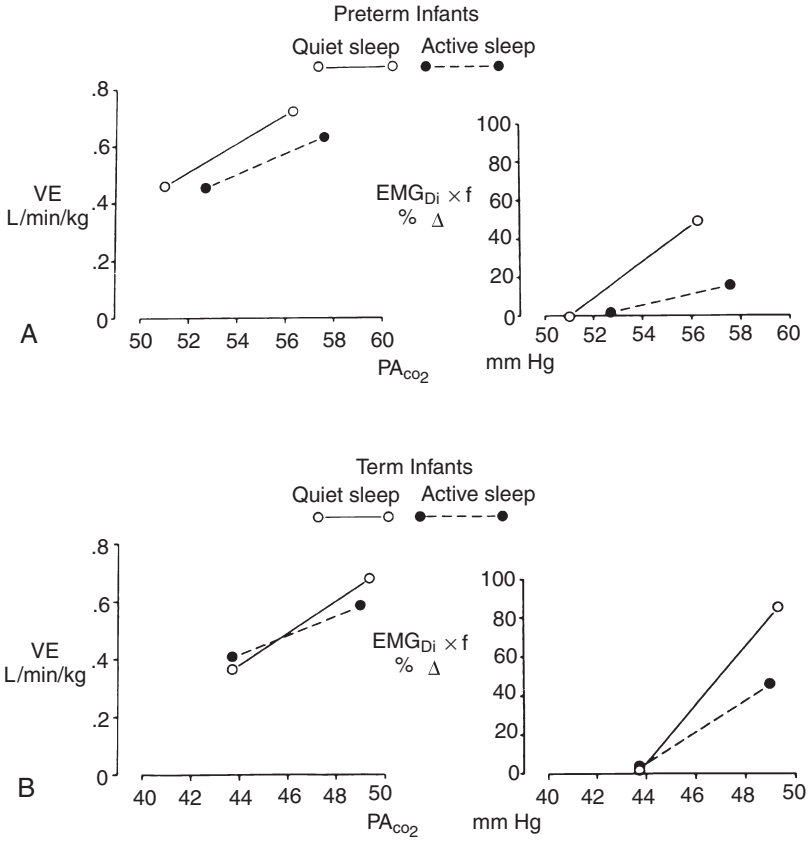

Figure 89-14 The ventilatory response to CO_2 rebreathing in neonates. Both preterm **(A)** and term **(B)** infants showed a decreased response to CO_2 in phasic rapid eye movement sleep as compared with quiet sleep.

decrease in ventilation may be a mechanical effect, rather than a depression of the central respiratory neurons.[112,113] In these experiments, diaphragmatic activity and respiratory frequency remained elevated during hypoxia, but tidal volume decreased below control values during late hypoxia. These experiments were carried out during quiet sleep. The peculiar response of the neonate to low concentrations of inhaled oxygen is of great clinical significance. Infants who are borderline hypoxic tend to breathe periodically or to experience apneic spells. Hypoxia can induce periodic breathing in these infants, as shown previously.[67] Relief of these apneic spells, which frequently are associated with bradycardias, can be obtained by increasing the inspired oxygen concentration.[86,87]

Administration of high concentrations of oxygen, on the other hand, produces an immediate decrease in ventilation followed by hyperventilation—a response that occurs during wakefulness, REM, and quiet sleep alike. These findings suggest a lack of major differences in the activity of the peripheral chemoreceptors during these sleep states.[97,114] The immediate decrease in ventilation after the administration of 100% oxygen is related to a decrease in respiratory frequency (apnea being common in preterm infants) and a decrease in tidal volume. The late increase in ventilation with oxygen probably is related to cerebral vasoconstriction with increased hydrogen ion (H^+) concentration at the chemoreceptor site.[115]

Pulmonary Reflexes

The inflation reflex of Hering-Breuer is much more active in the newborn period than in adult life.[116,117] Small increases in lung volume cause apnea. This response is so powerful in the newborn that many investigators have used this inflation to produce apnea and then study the mechanical properties of the respiratory system during the passive expiratory phase that follows apnea. The action of the stretch receptors is much influenced by sleep, being abolished during REM sleep. The irritant receptors also are poorly developed in preterm infants, and the mediated reflexes are abolished during REM sleep as well.[118] Therefore airway mechanisms responsible for clearing, such as cough, are impaired during REM sleep.

The paradoxical reflex of Head commonly is observed in the neonate in the form of a sigh.[119] Many investigators attribute the high prevalence of sighs to the greater need for lung recruitment at this age.[120] Sighs are more frequent in REM than in quiet sleep and also during periodic breathing than during regular breathing. During periodic breathing, a sigh usually appears during the first or second breath after the apneic episode. When it occurs during regular breathing, it tends to be followed by short apneas.[121] Efforts to discover the mechanisms triggering sighs have been fruitless. Thach and Tauesch[120] showed that asphyxia does not seem to be a stimulus. Alvarez and colleagues,[122] however, have observed that airway occlusion in the presence of hypoxia predisposes to sighs.

Studies of the morphology of sighs in infants and adult subjects found that the sighs in infants were found to be relatively larger than those in adults, and that whereas post-sigh ventilation usually is increased in adults, it is decreased in infants.[123] Because the drive to breathe early in life is dependent on increased peripheral chemoreceptor activity, it is conceivable that the sudden increase in arterial P_{O_2} with sighing could produce a rapid decline in carotid body afferent discharge leading to hypoventilation and apnea. The other almost instantaneous change that occurs with sighing includes a decrease in P_{CO_2}. Because the CO_2 apneic threshold is much closer to the baseline CO_2 in neonates than in adults, the decline in CO_2 below the threshold during a sigh

could trigger an apnea or initiate an epoch of periodic breathing in infants with immature respiratory feedback loop.[43,124] These findings suggest that although the ability to sigh may be an important mechanism to restore lung volume, sighing has the potential to destabilize breathing, leading to hypoventilation and apnea in infants at risk for inadequate control of breathing.[123]

Respiratory Muscles

The activity of the respiratory muscles is much altered by sleep state. Tonic activity of most respiratory muscles is abolished during REM sleep.[19,27,125,126] The disappearance of tone in the intercostal muscles has been suggested as a major factor responsible for the increased chest distortion seen during REM sleep in infants with this condition. Lack of tone leads to chest wall collapse during inspiration, and caudal displacement of the diaphragm has to be twice that normally required to produce the same lung volume displacement.[125,127] Because of chest wall collapse, functional residual capacity is decreased in these infants during REM sleep.[125] Investigators in our laboratory have found that distorted and nondistorted breaths produce the same instantaneous ventilation so long as they are of the same duration, although the work of the diaphragm is 40% greater when distortion is present.[127]

Postinspiratory activity of the diaphragm also is affected by sleep. This activity controls, in part, the duration of expiratory time.[128,129] In neonates, this activity is more pronounced in the lateral than in the crural part of the diaphragm, longer in quiet than in REM sleep, and more prolonged in preterm than in term infants.[130] The duration and variability of this activity in preterm infants suggest that because of their highly compliant chest wall, the postinspiratory diaphragmatic activity can be used as a braking mechanism to maintain lung volume. In addition, controlling expiratory time probably is much more important in preterm infants than in older children and adult subjects. Similarly, sleep state profoundly affects the muscular control of upper airway resistance. Studies in fetal and neonatal lambs suggest that the abductor muscles of the larynx—the posterior cricoarytenoid and cricothyroid—have inspiratory activity in parallel with that of the diaphragm, during both quiet and REM sleep. On the other hand, the adductor muscles of the larynx—the thyroarytenoid, lateral cricoarytenoid, and intraarytenoid—have a phasic expiratory activity during quiet sleep. This activity is lost during REM sleep in the fetus and in the newborn lamb.[19,27] A reduction in adductor activity of the larynx, in conjunction with decreased intercostal and decreased postinspiratory diaphragmatic activity during REM sleep, may cause the decrease in lung volume observed during this sleep state.

CONCLUSION

In summary, although the basic mechanisms involved in the control of breathing during fetal and neonatal life are similar to those investigated more extensively in adult subjects, some relatively recent findings point to the unique nature of control of breathing at this age. First, sleep seems to have a very profound effect during this period of life, particularly in the fetus, in which breathing is allowed to surface only during REM sleep. Second, breathing activity is present in utero since early gestation and without apparent reason, because it is not responsible for gas exchange. The placenta is responsible for gas exchange, being the "lung" of the fetus. It is therefore imperative to discover the purpose of fetal breathing. Third, the discovery of fetal breathing probably is the most exciting contribution made in this area during the past 50-some years. To explain why this episodic breathing in utero becomes continuous after birth is the major challenge of the moment. Elucidation of specific aspects of this change may result in the discovery of key mediators that are at the heart of the mechanism controlling breathing in general.

Basic Mechanisms of Oxygen Sensing and Response to Hypoxia

A large body of experimental work has been performed on oxygen sensing and on the cellular events that result from oxygen deprivation. This work has been performed in a variety of cell types, tissues, and organs, and these comparative studies have contributed to our understanding of O_2 sensing. As a result of these investigations, a number of new concepts regarding O_2 sensing have emerged. Neurons, renal and respiratory epithelial cells, hepatocytes, myocardial cells, vascular smooth muscle, or endothelial cells—virtually every cell type studied has been shown to sense O_2 one way or another. This type of investigation has also been done at various ages, and age has been very important in determining both sensing and responsiveness to lack of O_2. Because we have generally focused in the past on the study of nerve and glial cells during O_2 deprivation, this chapter focuses on excitable tissues. However, an extensive body of new knowledge has demonstrated that much of what is known about the heart's sensing mechanisms can be applied to the central nervous system, for example, and much of what we know about the renal epithelium can be applied to the respiratory cells. It should be recognized, however, that, although there are similarities among tissues, there are often major differences. These differences reflect either differing environments or the function of that particular cell type of tissue. In certain instances, when the duration and severity of the stimulus are not too overwhelming, nerve cells may adapt and possibly survive hypoxia. Often, however, when the stress is too severe, the response of the cells, from sensing to death, is considerably shortened, and it is often difficult to tease apart the processes that control the various stages of response.

The aim of this chapter is to highlight observations that will demonstrate that a number of potential O_2 sensors exist in nerve cells. We detail results and data regarding ionic flux and controlling ionic flux mechanisms. We also detail some newer observations regarding expressional regulation of genes during O_2 deprivation that occurs over much longer periods of time.

OXYGEN SENSING VIA MEMBRANE PROTEINS: IONIC ALTERATIONS

Potassium Ionic Flux and Its Regulation: Short Versus Long Exposures

Potassium ion (K^+) channel modulation has been shown to be an integral and important cellular response to O_2 deprivation in nerve and cardiac cells. It is not clear, however, what signals precede the modulation of K^+ channels. This modulation could be direct or indirect.[1,2] Part of this modulation occurs as a result of changes in the concentrations of cytosolic factors (e.g., adenosine triphosphate and calcium ion [Ca^{2+}]) that are altered during O_2 deprivation. For example, a number of cytosolic factors change during hypoxia: Ca^{2+}, pH, sodium ion (Na^+), adenosine triphosphate–adenosine diphosphate–adenosine monophosphate ratios, and redox.[3-8] These, in turn, modulate a number of ion channels, including K^+ channels.

If K^+ channels can be modulated by cytosolic changes during hypoxia, one should question whether there are mechanisms originating from changes other than in the cytosol. For example, does the partial pressure of O_2 itself affect plasma membrane channels? To test the hypothesis that membrane-delimited mechanisms participate in the O_2-sensing process and are involved in the modulation of K^+ channel activity in central neurons, experiments were performed with use of patch-clamp techniques and dissociated cells from the rat neocortex and substantia nigra.[1,2] Oxygen deprivation produced a biphasic response in current amplitude: an initial transient increase was followed by a pronounced decrease in outward K^+ currents. The reduction in outward currents was a reversible process because perfusion with a normoxic medium with a Po_2 greater than 100 mm Hg (1 mm Hg = 133 Pa) resulted in complete recovery. In cell-free excised membrane patches, we have demonstrated that a specific K^+ current (large conductance, inhibited by micromolar concentrations of adenosine triphosphate and activated by Ca^{2+}) was reversibly inhibited by lack of O_2. This was characterized by a marked decrease in channel open-state probability and a slight reduction in unitary conductance. The magnitude of channel inhibition by O_2 deprivation was closely dependent on O_2 tension. These studies demonstrated the selective nature of the hypoxia-induced inhibition of some K^+ channels[1,2,8] (Figures 90-1 and 90-2) and also provided the first evidence for the regulation of K^+ channel activity by O_2 deprivation in cell-free excised patches of central neurons.[9,10]

It is not well understood how this inhibition occurs. With the use of specific agents that chelate metal, including heme and nonheme iron and copper, our laboratory has demonstrated that iron-center blockers inhibited the channel in excised patches in a fashion similar to that of low Po_2. These results suggested that K^+ channel activity is modulated during hypoxia by iron-containing proteins, thus providing evidence for an O_2-sensing mechanism in neuronal membranes.

Although most ionic fluxes that have been studied during hypoxia are plasma-membrane related, a number of reports on ion channels in mitochondrial membranes have been published.[11,12] However, it is unclear how these are involved in O_2 sensing or in hypoxic injury. We have obtained evidence that the maxi-K channels can be found in mitochondrial membranes and that they play a role in apoptotic cell death induced by serum deprivation. Furthermore, data demonstrate that mitochondrial channels (adenosine triphosphate–dependent K^+ channels) are present in myocardial cells and may be important for hypoxic injury.[13]

The observation of the relative "insensitivity" or the lack of response of the immature cells or tissues to low O_2 tensions compared with the more mature response of differentiated cells is of particular interest. On the basis of a large number of studies investigating ion fluxes and activities, release of neurotransmitters, or changes in membrane electrophysiologic properties, it is clear that the newborn exhibits a blunted response to hypoxia.[3,4,14-17] Although there is a paucity of cellular and molecular work on this subject in the fetus, it is clear from whole-body studies in the fetus exposed to hypoxia that its response is very blunted, if not totally eliminated. In other types of studies, however, investigating the response of the neonatal lung to hypoxia (compared with that of the adult), the response in terms of septation and alveolar formation was more severe in the neonate than in the adult.[18] For example, hypoxia in the first couple of weeks of life will inhibit septation, whereas in the adult there is very little effect on alveolar size.[18] Therefore, depending on the measured variable, the newborn infant may or may not be as responsive as the adult. Because most systems exhibit plasticity at an early stage in life, strong stimuli may affect function and structure much more in the neonate, especially when these stimuli occur over prolonged periods of time. Acute short stresses, however, especially those in the central nervous system, may not be so significant for the newborn infant.

Sodium Ionic Flux and Its Regulation: Short Versus Long Exposures

The concentrations of Na^+ and chloride ion (Cl^-) change markedly during hypoxia. Anoxia induces a drop in extracellular Na^+ in brain slice, and removal of extracellular Na^+ prevents the anoxia-induced morphologic changes in dissociated hippocampal neurons.[6,19,20] For an understanding of the mechanisms that sense O_2 and lead to acute neuronal swelling during anoxia, the ionic movements of Cl^- and Na^+ during O_2 deprivation in the hypoglossal (XII) neurons of rat brain slices have been studied. Baseline extracellular Cl^- and Na^+ activities ($[Cl^-]_o$ and $[Na^+]_o$) were measured in both adult and neonatal brain slices.[6,19,20] During a period of anoxia (4 minutes), $[Na^+]_o$ decreased markedly in adult slices whereas $[Na^+]_o$ did not show any significant change in the neonatal slice. Anoxia induced a significant decrease of $[Cl^-]_o$ in both the adult and neonate; however, $[Cl^-]_o$ dropped seven times more in the adult than in the neonate. Intracellular Cl^- activity ($[Cl^-]_i$) has been studied in adult hypoglossal cells. It is not surprising that an increase in $[Cl^-]_i$ with O_2 deprivation was seen. To also study intracellular Na^+ ($[Na^+]_i$) in isolated neurons, we used the fluorophore Sodium Green in freshly dissociated rat neurons, and sodium-binding benzofuran isophthalate (SBFI), a fluorescent indicator for sodium, in cultured cortical neurons. Ten minutes of anoxia caused an increase in Na^+_i with a latency of approximately 2 minutes. In these neurons, fluorescence increased by an average of approximately 20%. We conclude that during anoxia (1) intracellular $[Cl^-]$ and $[Na^+]$ increase in the adult, most likely because of entry of extracellular ions into the cytosol, and (2) a major maturational difference exists in mechanisms regulating Cl^- and Na^+ homeostasis between neonate and adult brain tissue.

Although it is well known that Na^+_i increases during hypoxia, the sensors for this ionic alteration are not well documented. It is possible that exchangers or transporters and channels are somehow located within the cascade of events that lead to this increase. The regulation of the voltage-sensitive Na^+ channels during hypoxia has been investigated with use of isolated hippocampal neurons.[5,20] Given the prior data demonstrating an

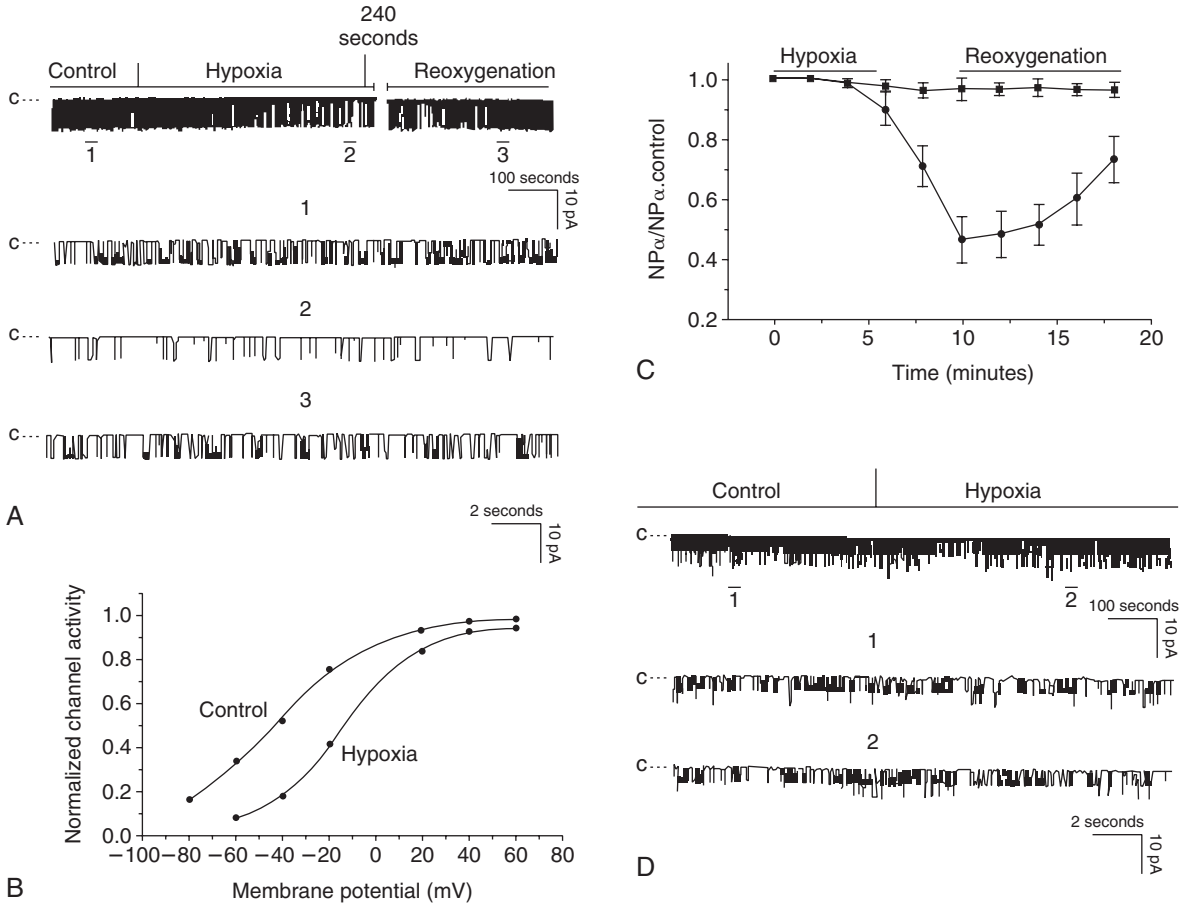

Figure 90-1 Effect of hypoxia on single-channel BK_{Ca} current. A, Effect of hypoxia on single BK_{Ca} channel in a cell-attached patch from a neocortical neuron. Current was recorded with high-KCl (140 mmol/L) solution in the pipette and physiologic solution in the bath at a V_m of −30 mV. The channel closed level is indicated by *C.* Three parts of the compressed trace are shown, as indicated by numbers *1* through *3* (fast-time resolution). **B,** Effect of hypoxia on the voltage activation of BK_{Ca} channel under the ionic condition just described. The line is fitted to a Boltzmann distribution. $V_{0.5}$ shifted from −42.4 ± 4.8 mV to −18.6 ± 3.5 mV after exposure of hypoxia for 10 minutes. **C,** Time course of the hypoxia-induced effect on NP_o. In cell-attached recordings *(filled squares),* channel inhibition started about 5 minutes after the onset of hypoxia, and a maximum inhibition was reached in approximately 10 minutes. After that time, NP_o was markedly reduced to approximately 43% of control level. Reoxygenation led to partial recovery. In inside-out recordings *(filled circles),* NP_o was not significantly affected during hypoxia. **D,** Continuous recording of a single BK_{Ca} channel current from an inside-out patch of a neocortical neuron during hypoxia, with use of a symmetric 140-mmol/L KCl on both sides of the membrane, with a V_m of −30 mV. The channel closed level is indicated by *C.* Two parts of the compressed trace (indicated by the numbers *1* and *2*) are shown at fast-time resolution. *BKCa,* Large-conductance calcium channel; *NPo,* product of number of channels open multiplied by the open probability. *(From Liu H, Moczydlowski E, Haddad GG: O_2 deprivation inhibits Ca^{2+}-activated K^+ channels via cytosolic factors in mice neocortical neurons,* J Clin Invest *104:577, 1999.)*

increase in intracellular Na^+, it is somewhat surprising that hippocampal neurons respond to acute oxygen deprivation with an inhibition of whole-cell Na^+ current (I_{Na}).[10,21] Because kinases can modulate I_{Na} and are activated during hypoxia, we hypothesized that kinase activation may play a role in the hypoxia-induced inhibition of I_{Na}. I_{Na} was recorded at baseline, during exposure to kinase activators (with and without kinase inhibitors), and during acute hypoxia (with and without kinase inhibitors). Hypoxia reduced I_{Na} to approximately 40% of initial values and shifted the steady-state inactivation in the negative direction.[22] Hypoxia produced no effect on activation or fast inactivation. Protein kinase A (PKA) activation with 3′,5′-cyclic adenosine monophosphate, N^6,O_2-dibutyryl, sodium salt (db-cAMP) resulted in a reduction of I_{Na} to 63% without an effect on activation or steady-state inactivation. I_{Na} was also reduced by activation of protein kinase C (PKC) with phorbol 12-myristate 13-acetate (PMA) to 40% or with 1-oleoyl-2-acetyl-*sn*-glycerol (OAG) to 46%. In addition, steady-state inactivation was shifted in the negative direction by PKC activation.

Neither the activation curve nor the kinetics of fast inactivation was altered by PKC activation. The response to PKA activation was blocked by the PKA inhibitor (H-89) and by PKA inhibitory peptide PKA_{5-24} (PKA_i). PKC activation was blocked by the kinase inhibitor (H-7), by the PKC inhibitor calphostin C, and by the inhibitory peptide PKC_{19-31} (PKC_i). The hypoxia-induced inhibition of I_{Na} and shift in steady-state inactivation were greatly attenuated by H-7, calphostin C, or PKC_i but not by H-89 or PKA_i. We conclude that hypoxia activates PKC in rat CA1 neurons and that PKC activation leads to the hypoxia-induced inhibition of I_{Na}. These data indicate that kinases can inhibit whole cell Na^+

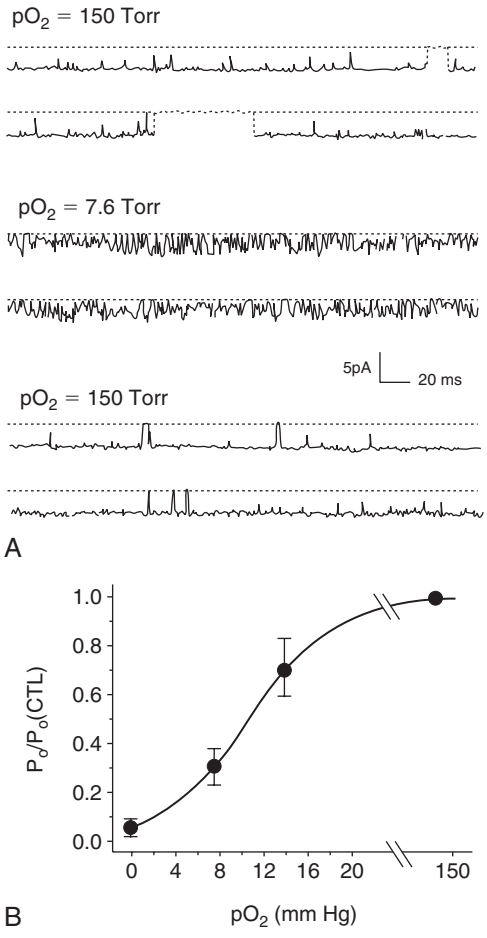

Figure 90-2 A large conductance K^+ current is inhibited during O_2 deprivation. A, Continuous recordings of a single K^+ current from an inside-out patch with the same solution (150 mmol/L K^+) in both internal and external sides, when the membrane potential was held at 20 mV. During baseline *(top two traces),* this channel had a P_{open} of 0.92 and a unitary conductance of 188 picosiemens. *Straight lines* indicate the channel closed level. Hypoxia ($Po_2 \approx 8$ mm Hg) induced a decrease in P_{open} to 0.24 *(middle two traces).* Recovery of P_{open} (0.96) is seen after reperfusion *(lower two traces).* **B,** Dose-dependent inhibition of P_{open} by graded hypoxia. Note that the P_{open} was normalized to its control level. Data presented as means ± SEM (n = 3) are fitted with an equation of $y = 1/\{1 + \exp[(K_d - x)/h]\}$, where $y = P_{open}/P_{open}$ (control), $x = Po_2$, $K_d = 11$, a Po_2 level for 50% inhibition of y, and $h = 4$. $P_{open,}$ Probability of having a channel in the open state. *(From Jiang C, Haddad GG:A direct mechanism for sensing low oxygen levels by central neurons,* Proc Natl Acad Sci U S A *91:7198, 1994.).*

current very much like that observed during hypoxia. However, it is unclear how kinases are activated during hypoxia and what events occur upstream.

From this analysis, we should highlight a few issues pertaining to O_2 sensing: (1) In the studies, sensing is very rapid; whatever the sensor is, the reactions that lead to the electrophysiologic responses observed by using our techniques and approaches must be very quick, on the order of seconds. (2) Most of the alterations are not genetically mediated, and no gene expression is presumably altered in this short period of time.

Chronic hypoxia has also been studied in our laboratory, as well as in others.[23-25] With respect to Na^+ flux, it seems that Na^+ influx increases when neurons are subjected to hypoxia for days.[23,26] It is very important to note that Na^+ influx through voltage-sensitive Na^+ channels can lead to cell death, and this form of cell death is most likely a result of the activation of cell death genes.[25]

OXYGEN SENSING VIA GENE REGULATION: LONGER PERIODS

Neurons vary widely in their capacity to adapt to a limited oxygen supply to the brain, reflecting the diversity of neuronal function and their adaptive mechanisms to oxygen deprivation. The hypoxia-tolerant neurons can be found in every order of vertebrates, such as crucian carp,[27] tadpoles,[28] turtle,[29] and the naked Kenyan mole rat. Neurons from oxygen-sensitive species such as *Rattus norvegicus* are hypoxia tolerant during the embryonic and neonatal periods.[30,31] The discovery of the hypoxia-tolerant property of an invertebrate species, *Drosophila melanogaster*, provided researchers with a new model system to study the mechanism of hypoxia tolerance in neuronal systems.[32,33] Those studies have prompted a number of questions. How do neurons "sense" the lack of microenvironmental O_2? How do they respond? How does sensing O_2 deprivation affect the cascade that follows the initial steps?

Multiple O_2 sensing systems most likely exist, and, although much remains to be learned about how cells sense and adapt to conditions of oxygen scarcity, it is clear that O_2 sensing (and the cascade of events that follow O_2 deprivation) largely depends on the regulation of gene transcription. Such mechanisms are fairly quick, and targets can be multiple. Several transcription factors, such as activator protein 1 (AP-1), early growth response protein-1 (EGR-1),[34] nuclear factor κB (NF-κB),[35] CCAAT enhancer-binding protein beta (C/EBPβ/NF-IL-6),[36] and the hypoxia-inducible factor (HIF), were found to be involved in the modulation of gene expression by oxygen. Among these O_2-sensitive transcriptional systems, perhaps the best described O_2-sensing pathway is the oxygen-sensitive transcription factor HIF, which activates the gene transcription machinery in an oxygen deprivation–dependent manner.[37]

HIFs are heterodimeric transcription factors containing an α- and a β-subunit that belong to the basic-helix-loop-helix (bHLH)-PAS protein superfamily. HIF-1α was first cloned from the human Hep3B cell line[38] and is a member of the PAS superfamily 1 (MOP1). The mouse and rat isoforms also have been cloned.[39,40] In addition, two other α-subunits were cloned, from humans and rats and mice (HIF-2α and HIF-3α). HIF-2α is known as endothelial PAS domain protein 1 (EPAS1), HIF-1α–like factor (HLF), or HIF-related factor (HRF) and is a member of the PAS superfamily 2 (MOP2).[41] HIF-3α is also referred to as MOP7.[41] The β-subunits of HIF, HIF-1β, HIF-2β, and HIF-3β, are members of the arylhydrocarbon receptor nuclear translocator, ARNT family, also named as ARNT1, ARNT2, or ARNT3.[42] HIF-1α and β homologues also exist in *Drosophila* tissues, and studies in this species have provided new data on the cellular adaptive responses to chronic hypoxic stress.[15,43] HIF-1 has been the most extensively studied (Figure 90-3).

Previous investigations have shown that HIF-1 messenger RNA (mRNA) was expressed in the mouse, rat, and human brain.[44] Because the brain is extremely sensitive to hypoxia and ischemia, the regulation of HIF-1 expression is highly relevant. Two of its target gene products in the brain are erythropoietin (EPO) and vascular endothelial growth factor (VEGF).[45,46] In the adult rat brain, HIF-1 mRNA was found in neuronal cells.[47] In hypoxia-treated rats or mice, an increase of HIF-1 mRNA was found in the brain, kidney, and lung. The HIF-1–regulated gene VEGF increased accordingly with a similar expression pattern as HIF-1.

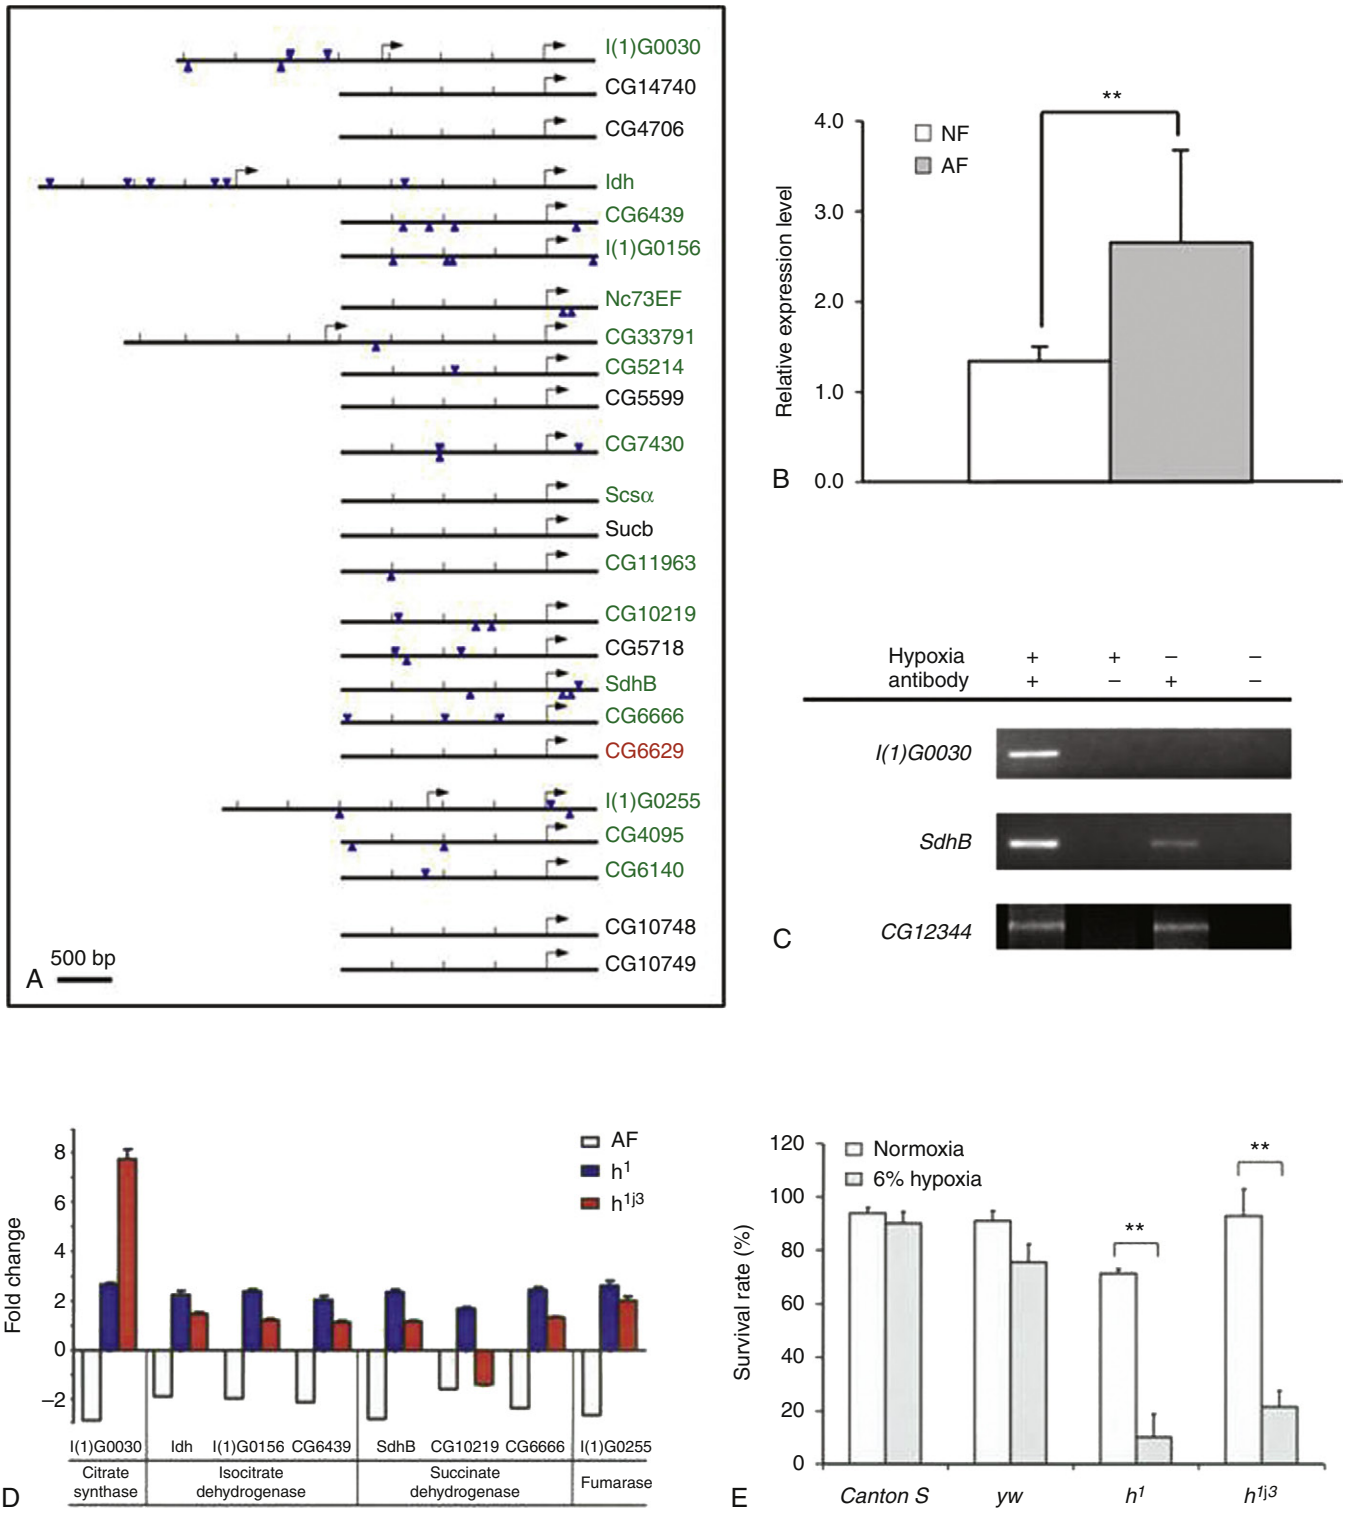

Figure 90-3 Transcriptional suppressor hairy regulates TCA cycle gene expression and hypoxia tolerance. A, Genomic localization of hairy binding elements in the *cis*-regulatory region of genes encoding TCA cycle enzymes. *Arrowheads* indicate consensus hairy binding sites, and *arrows* indicate transcriptional start sites. **B,** Significant up-regulation of hairy expression in hypoxia-selected AF populations ($p < .01$). **C,** Chromatin immunoprecipitation assay of gene l(1)G0030, SdhB, and CG12344 under normoxia or hypoxia. **D,** Abolished suppression of genes encoding TCA cycle enzymes in hairy loss-of-function mutants. **E,** Significant reduction in hypoxia survival in hairy loss-of-function mutants. Embryos from loss-of-function hairy mutants (h^1 and h^{1j3}) and controls (Canton-S and yw) were cultured at normoxic or 6% O_2 hypoxic condition. The ratio of adult flies to pupae was determined as survival rate of each stock. The loss-of-function hairy mutants exhibited a significantly reduced rate of hypoxia survival. Data are presented as means ± SD. $^{**}p < .01$. *AF,* Hypoxia-adapted flies; *TCA,* tricarboxylic acid. *(Modified from Zhou D, Xue J, Lai JC, Schork NJ, et al: Mechanisms underlying hypoxia tolerance in* Drosophila melanogaster: *hairy as a metabolic switch,* PLoS Genet *4(10):e1000221, 2008.)*

This provides evidence for a neuroprotective role of HIF-1 in the central nervous system. HIF-1 has been shown to mediate adaptive responses to reduced O_2 availability, including angiogenesis, glycolysis, and ischemia tolerance in the brain.

Control of angiogenesis through HIF-1 and HIF-2 is regulated by growth factors, including VEGF.[48] Numerous studies have demonstrated that chronic hypoxia induces angiogenesis in the adult brain with an increase in VEGF. A time course study, however, has shown that, after exposure to 10% O_2, HIF-1 rapidly accumulated, remained at high levels for only 14 days, and then decreased by 21 days, despite continuous low arterial oxygen tension. This would indicate either that HIF has a long-lasting effect on target genes or that other HIF targets or long-lasting hypoxia can maintain the induction of genes such as VEGF, because angiogenesis does not regress at a time when HIF has gone back to normal levels.[49] When 21-day adapted rats were exposed to a more severe hypoxic challenge (8% oxygen), HIF-1 increased again indicating that the HIF gene can still be up-regulated with more severe stresses.[49] Thus HIF-1 and its regulated genes appear to have a role in vascular remodeling and metabolic changes that contribute to adaptation of the chronic hypoxia condition.

It has been found that a noninjurious hypoxic stimulation can protect cells from an otherwise lethal hypoxic-ischemic attack several hours or days later. This noninjurious hypoxic stimulation has been termed *preconditioning*. Several studies have suggested that HIF-1 could be an important mediator of hypoxia-induced tolerance to ischemia by preconditioning.[50-52] Indeed, hypoxic preconditioning-induced expression of HIF-1 and its target genes has been found in the neonatal and adult brain. With use of DNA microarray methods combined with real-time reverse transcriptase polymerase chain reaction technologies, a set of HIF-1– but not HIF-2–mediated gene expression has been identified in the neonatal rat brain.[53] In this study, 12 genes were reported to be induced; they are *VEGF*, *EPO*, *GLUT-1*, *adrenomedullin*, *propyl 4-hydroxylase*, *MT-1*, *MKP-1*, *CELF*, *12-lipoxygenase*, *t-PA*, *CAR-1*, and an expressed sequence tag. Some of these genes, such as *GLUT-1*, *MT-1*, *CELF*, *MKP-1*, and *t-PA*, did not show a hypoxic regulation in either neurons or astrocytes, suggesting that other cells are responsible for the up-regulation of these genes in the hypoxic brain. These results also demonstrate that, besides HIF-1 pathway, a number of other endogenous molecular mechanisms might also be involved in the hypoxic preconditioning-induced tolerance.

If the responses to hypoxia over a longer term, such as hours and days, involve HIF-1 and HIF-2 and their target downstream genes, how about hypoxia over even longer periods of time, such as over generations? These types of studies have been relatively scarce. Recently, we have generated a hypoxia-tolerant *Drosophila* strain to study the genetic and molecular basis of adaptation to long-term (i.e., over generations) hypoxic environments.[54] Microarray and genetic analyses have shown that the survival of both larvae and adult flies was accompanied by alterations in a number of major signaling pathways, including EGF, Insulin, Notch, and Toll/Imd pathways. Furthermore, previous studies have demonstrated an enhancement of glycolytic activity as a major metabolic response in cells and tissues after short-term (in minutes or hours) hypoxia. In contrast, our present data showed that many genes encoding glycolytic enzymes were down-regulated in the hypoxia-tolerant flies.[55] Moreover, no significant lactate accumulation was found in the hypoxia-adapted flies (AF).[56] For more than three decades, physiologists have debated the importance of down-regulation of metabolism in hypoxia tolerance.[57,58] Although this idea, based on metabolic data, is intuitively appealing, no information has been obtained about how various metabolic enzymes could be coordinated to survive severe long-lasting hypoxia. Our current work provides the first evidence showing that such coordination can be achieved at a transcriptional level by a seemingly metabolic switch (i.e., *hairy*, a transcriptional suppressor). This notion is supported by a number of observations: (1) expression of *hairy* was up-regulated in hypoxia-tolerant flies; (2) the *hairy*-binding region was present in the *cis*-regulatory regions of the down-regulated genes but not others; (3) functional chromatin immunoprecipitation analysis demonstrated that the down-regulation of these metabolic genes is based on the changes of *hairy*; it is noteworthy that its binding was not increased for other, nonmetabolic target genes, for example, CG12344; and (4) *hairy* loss-of-function mutations abolished the suppression on the expression of tricarboxylic acid (TCA) cycle genes and significantly reduced hypoxia survival in *Drosophila*[55] (see Figure 90-3). The adaptive mechanisms identified in this hypoxia-tolerant *Drosophila* model may also play a crucial role in protecting mammals from hypoxia injury.

Although a great deal of work has been done to understand the biologic role of hypoxia-induced gene expression in the brain, many important questions remain largely unanswered. For example, which genes are expressed and which are inactivated during hypoxia in different brain regions and cell types are still unknown. Further research is needed to describe the diversity of oxygen sensors and the mechanisms by which these sensors regulate the gene transcription machinery.

Pathophysiology of Apnea of Prematurity

EPIDEMIOLOGY AND DEFINITION OF APNEA

Definition

Apnea is a common disorder of respiratory control in premature infants. Such infants may experience respiratory pauses of varying duration, at rest or in conjunction with startles, movement, defecation, or swallowing during feeding. These short respiratory pauses may be self-limiting and are not associated with clinically significant bradycardia (less than 100 beats/minute). *Apnea* has been defined by the American Academy of Pediatrics Task Force as a respiratory pause lasting at least 20 seconds, or a pause accompanied by bradycardia, cyanosis, or pallor.[1] Shorter apnea (e.g., 15 seconds in duration) may, on occasion, require clinical intervention.

Apnea should be distinguished from *periodic breathing,* in which the infant exhibits regular cycles of respiration approximately 10 to 18 seconds in length, interrupted by pauses at least 3 seconds in duration, with this pattern recurring for at least 2 minutes.[2] Periodic breathing has been considered to represent a benign respiratory pattern in the premature or young term

infant. The respiratory pause of apnea, unlike that of periodic breathing, may not be self-limiting and may produce significant physiologic changes. Such changes are considered in detail in the following discussion.

Classification

Apneic events are distinguished not only by their duration but also by the presence or absence of airway obstruction during the episode of apnea. Thach and Stark[3] initially described an increase in the frequency of apnea when the premature infant's neck was flexed. Subsequently, upper airway obstruction was found to accompany apnea in preterm babies, even though neck flexion was not present.[4] The location within the upper airway at which obstruction occurs usually is within the pharynx but may vary. Mathew and co-workers[5] noted that obstruction occurred within the pharynx in 93% of cases of apnea, at the level of the larynx in 1%, and at both the larynx and pharynx in 6% of cases.

The presence or absence of upper airway obstruction forms the basis of the classification of apnea into three types (Figure 91-1). *Mixed apnea* is the most commonly observed clinically significant event in small premature infants and consists of obstructed inspiratory efforts as well as a central pause 2 seconds or longer in duration (see Figure 91-1, *A*). In *obstructive apnea*, obstructed breaths characterized by chest wall motion without nasal airflow continue throughout the entire apnea (see Figure 91-1, *B*). In *central apnea*, inspiratory efforts cease entirely, and obstructed breaths are not observed (see Figure 91-1, *C*). Mixed apnea accounts for approximately 50% to 75% of all instances of apnea in premature infants; obstructive apnea, 10% to 20%; and central apnea, 10% to 25%[6] The proportion of mixed apnea–type events progressively increases (and that of purely central apneic events decreases) the longer the apneic episode lasts.

Apnea duration and classification also may correlate with the neurologic status of the infant. Butcher-Puech and co-workers[7] found that infants who experienced spells of obstructive apnea longer than 20 seconds in duration had a higher incidence of intraventricular hemorrhage, hydrocephalus, prolonged mechanical ventilation, and abnormal neurologic development after the first year of life. It is possible that apnea in a subset of infants is a sign of a diffuse neurologic insult in prenatal or postnatal life that leads to disordered control of breathing. In most infants, however, an underlying neuropathologic process is unlikely, because apnea frequency decreases as the infant matures. Hypothetically, apnea may resolve when central and peripheral chemoreceptors develop to the point at which appropriate responses to change in blood gas status can occur. A further important developmental contribution to resolution of apnea may be the increasing ability of medullary respiratory control centers to activate upper airway–dilating musculature in synchrony with increasing ventilatory drive.

Hypoxemic events resembling apneic spells also have been detected in intubated, mechanically ventilated preterm infants. Bolivar and co-workers[8] described episodes of hypoxemia preceded by an increase in total pulmonary resistance and a decrease in compliance, analogous to changes described by Miller and associates[9] occurring before apnea in unintubated infants. Furthermore, Dimaguila and colleagues[10] reported that such episodes may be preceded by subtle spontaneous movement and are characterized by both central respiratory depression and obstruction to airflow (the latter features being analogous to mixed apnea). These hypoxemic episodes in intubated infants are a consequence of hypoventilation, frequently associated with arousal,[11] and they further illustrate the vulnerability of premature infants to imbalance of central respiratory control and altered pulmonary function.

Physiologic Effects

Cessation of respiration during apnea has significant ventilatory and reflex cardiovascular consequences for the preterm infant. Both hypoxemia and hypercarbia accompany prolonged apnea. The decrease in oxygenation in term infants with apnea has been observed to be directly related to the duration of the apnea and and baseline respiratory status.[12] In most premature infants, apnea, if appropriately treated, is not thought to produce significant long-term complications. In a retrospective analysis, however, Kitchen and associates[13] noted a significant correlation between apnea of infancy requiring treatment with theophylline and later development of manifestations of cerebral palsy. Furthermore, Janvier and co-workers[14] found that neurodevelopmental impairment was significantly associated with the number of days of apnea after extubation. This correlation could reflect early (apnea) and late (cerebral palsy) manifestations of diffuse cerebral hypoxic-ischemic injury in a small subset of premature infants, as discussed later. Whether apnea itself can exacerbate underlying brain injury is as yet unknown.

The reflex effects of apnea include characteristic changes in heart rate, blood pressure, and pulse pressure. Bradycardia may begin within 5 seconds after the onset of the apneic episode[15]

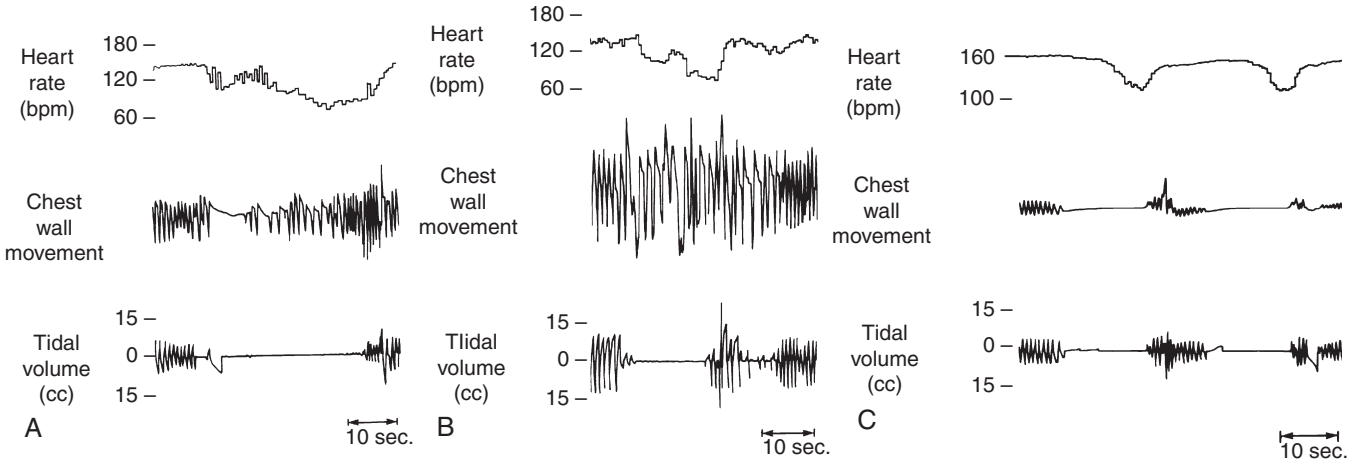

Figure 91-1 **A,** Mixed apnea. Obstructed breaths precede and follow a central respiratory pause. **B,** Obstructive apnea. Breathing efforts continue, although no nasal airflow occurs. **C,** Central apnea. Both nasal airflow and breathing efforts cease simultaneously. *(From Miller MJ: In Edelman N, Santiago T, editors:* Breathing disorders of sleep, *New York, 1986, Churchill Livingstone.)*

During this mixed apnea, the heart rate *(HR)* begins to decrease approximately 5 seconds after the apnea begins. **B,** Relationship between apnea and gastroesophageal reflux. Reflux occurs after the onset of apnea, as indicated by the decrease in lower esophageal pH *(arrow). AB,* Abdomen motion; *ECG,* electrocardiogram; *RC,* rib cage motion; Sa_{O_2}, arterial oxygen saturation; *Vt,* tidal volume (estimated).

(Figure 91-2). The bradyarrhythmia most often is sinus in character, with an occasional infant showing a nodal escape. Dorostkar and associates[16] have observed that 1.8% of preterm infants may even have asystolic events during apnea, defined as absence of QRS complex for more than 3 seconds during apnea. This subgroup of infants appears to have a benign clinical outcome. Henderson-Smart and co-workers[17] noted a significant correlation between the decrease in oxygen saturation and heart rate and postulated that bradycardia during apnea could result from hypoxic stimulation of the carotid body chemoreceptors.

The complex relationship between reflex control of heart rate and breathing was studied by Daly and Scott,[18] who determined the effect of hypoxic perfusion of the isolated carotid body on heart rate in the dog. When ventilation was allowed to increase in response to hypoxia, tachycardia occurred. When this reflex increase in ventilation was prevented, however, bradycardia resulted. In the spontaneously breathing subject, the decrease in heart rate secondary to hypoxic stimulation of the carotid body may be masked by a cardiac accelerator response that may derive from stretch receptors in the lung as well as cycling of the respiratory control center in the medulla.[19] At the onset of apnea, at which time cessation of

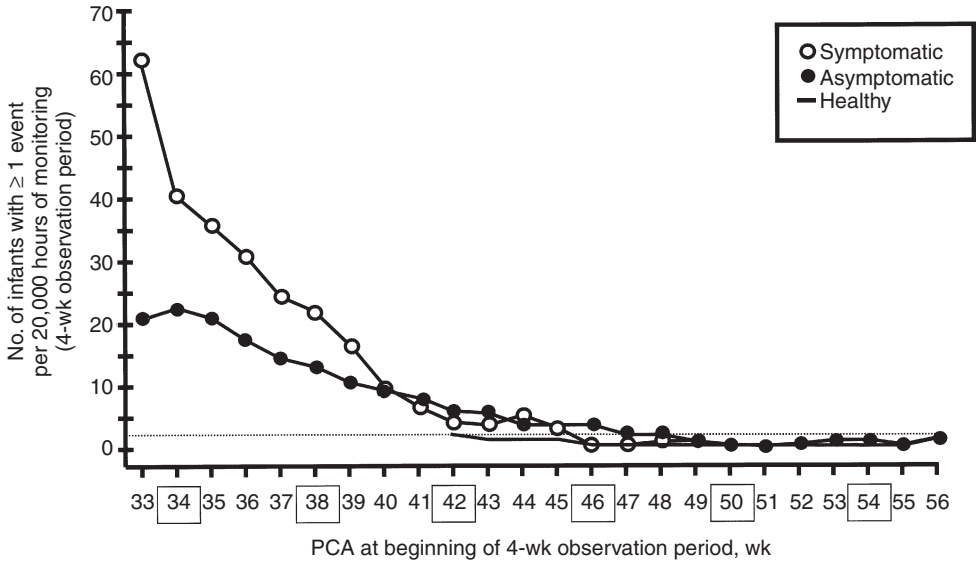

Figure 91-3 The number of infants who experienced at least one apneic episode lasting 30 seconds accompanied by bradycardia decreased with advancing postconceptional age *(PCA).* Data are presented for symptomatic and asymptomatic preterm infants, depending on the persistence of cardiorespiratory events before discharge, and for healthy term infants. *(From Ramanathan R, et al: Cardiorespiratory events recorded on home monitors: comparison of healthy infants with those at increased risk for SIDS,* JAMA *285:2199, 2001.)*

ventilation and onset of hypoxemia occur almost simultaneously, hypoxemia would be expected to produce bradycardia.

Other reflex input may accentuate the bradycardia during hypoxemia. For example, the reflex effects of apnea in infants also have been likened to the diving response of the seal.[20] During reflex apnea in these animals, upper airway afferent input from superior laryngeal and trigeminal nerve stimulation may produce greatly enhanced bradycardia. The contribution of upper airway reflexes to the bradycardia that occurs during apnea has not been studied in human infants. In summary, the rapid onset of bradycardia during apnea may be a complex reflex deriving from multiple sources, including trigeminal receptors and carotid chemoreceptors.

A change in blood pressure also accompanies apnea in newborn infants. Girling[21] noted that the decrease in heart rate during apnea was accompanied by a concomitant rise in pulse pressure, usually owing to an increase in systolic pressure, occasionally accompanied by a fall in diastolic pressure. During bradycardia, filling volume of the heart may increase, leading to a rise in stroke volume and pulse pressure in accordance with Starling's law. With more severe apnea and bradycardia (less than 80 beats/minute), a decrease in systemic blood pressure may occur, accompanied by a fall in cerebral diastolic and systolic blood flow velocity.[22] In premature infants with poor cerebrovascular autoregulation, cerebral blood flow may mirror systemic blood flow, and cerebral perfusion may decrease to very low levels during prolonged apnea. Resolution of apnea then may be accompanied by cerebral hyperperfusion.[23] Thus very prolonged apnea could be analogous to a hypoperfusion-hyperperfusion type of brain insult and theoretically could lead to a form of hypoxic-ischemic brain injury in susceptible premature infants.

Epidemiology

In defining the epidemiology and developmental correlates of apnea, part of the difficulty lies in the numerous definitions of apnea that have been used by various investigators. However, some trends do emerge. Apnea is more frequent in more immature infants, and almost all who weigh less than 1000 g may experience apnea during the neonatal period.[24] Carlo and associates[25] showed that the onset of apnea may be as early as day 1 of life in infants without respiratory distress syndrome. By contrast, spontaneously breathing infants with respiratory distress syndrome may show a delay in the peak frequency of apnea until day 7 of life. Thereafter, both the frequency and duration of apnea decrease with advancing postnatal age,[26] as discussed further on (Figure 91-3). These observations serve to emphasize the developmental immaturity of respiratory control that underlies infantile apnea, as well as the resolution of this disorder over time.

Idiopathic apnea is thought to be related to prematurity. In rare infants, however, underlying specific familial neuropathology may be identified. Adickes and co-workers[27] described a family in which three of six siblings presented between 18 and 26 months of age with sleep apnea and subsequently died of this disorder. Neuropathologic evaluation revealed that the affected children suffered from Leigh disease (subacute necrotizing encephalomyelopathy). In this disease, spongiform degeneration may be present in the areas of the brain stem that regulate ventilation, including the nucleus reticularis and nucleus gigantocellularis. Other disorders affecting the brain stem that may manifest with apnea include olivopontocerebellar atrophy, myotonic dystrophy, and syringobulbia, as well as brain stem infarction resulting from asphyxia.[28]

Apnea can recur in premature infants after the neonatal period in response to specific clinical situations in which respiratory drive is altered. Respiratory syncytial viral infection is well known to elicit apnea, which may be of the typical mixed or obstructive type or may occur in a pattern more reminiscent of periodic breathing.[29] These spells may be severe, necessitating endotracheal intubation. The cause of respiratory depression in respiratory syncytial viral infection is unknown. However, the apnea resolves with recovery from this infection.

Former premature infants also may experience apnea during recovery from general anesthesia.[30] This form of apnea most commonly occurs in the first few months of life, particularly when either ketamine sedation or general anesthesia is used during surgery. For this reason, in former preterm infants, cardiorespiratory monitoring during the acute postoperative period is an important part of their care.

Routine care of the premature infant before discharge includes several practices that may cause temporary recurrence of apnea.

For example, eye examination for retinopathy of prematurity may be associated with cyanosis, apnea, and gastrointestinal side effects.[31] Immunization with diphtheria-tetanus-pertussis vaccine, inactivated poliovaccine, and *Haemophilus influenzae* type b vaccine (DTP-IPV-HIB vaccines) also has been found to be associated with apnea, bradycardia and desaturation. With such practices, therefore, infants require continued monitoring until they are stable, but evidence of a subsequent detrimental effect is lacking.[32]

PHYSIOLOGIC FACTORS

Alteration in Central Drive

Immaturity or depression of central inspiratory drive of the muscles of respiration traditionally has been accepted as a key factor in the pathogenesis of apnea of prematurity. Vulnerability of the bulbopontine respiratory centers in the brain stem to inhibitory mechanisms could explain why apneic episodes are precipitated in preterm infants by such a wide diversity of specific clinicopathologic events, as outlined in Figure 91-4.[33] In other words, apnea may represent the final common response of incompletely organized and interconnected respiratory neurons to a multitude of afferent stimuli. It has been proposed that immature circuits within neuronal networks may be highly susceptible to inhibitory neurotransmitters and neuroregulators such as adenosine and γ-aminobutyric acid (GABA). Unfortunately, the maturation of central respiratory integrative mechanisms and of their biochemical neurotransmitters is inaccessible to study in human infants, and no ideal animal model of spontaneous apnea has been identified for study in the nonanesthetized state.

Using noninvasive techniques, Henderson-Smart and coworkers[34] documented that brain stem conduction times of auditory evoked responses are longer in infants with apnea than in matched premature infants without apnea. This observation provides indirect evidence that infants with apnea exhibit greater-than-expected immaturity of brain stem function on the basis of postconceptual age and supports the concept that stability of central respiratory drive improves as dendritic and other synaptic interconnections multiply in the maturing brain.

The absence of respiratory muscle activity during central apnea unequivocally points to the depression of respiratory center output. In support of this concept, Gauda[35] documented a decrease in diaphragmatic activity on electromyography (EMG) during spontaneously obstructed inspiratory efforts that characterize mixed apnea, as discussed later. Thus both central and mixed apneic episodes share an element of decreased respiratory center output to the respiratory muscles. The role played by the balance of neurotransmitter substances in modulating this inhibition is not yet known. GABA is considered a ubiquitous major inhibitory neurotransmitter within the brain. Physiologic studies in neonatal animal models have implicated GABA in inhibition of respiratory frequency and decreased ventilatory responses during hypercapnia, hypoxia, and superior laryngeal nerve stimulation.[36-38] GABA thus has the potential to play a key role in the vulnerability of preterm infants to apnea.

Other transmitters and neuroeffectors are also involved in control of breathing at the peripheral and central levels. Dopaminergic receptors have been implicated as playing an inhibitory role in both peripheral chemoreceptor responses and central neural mechanisms elicited by hypoxia.[39] Evidence from neonatal animal studies suggests that endogenous endorphins may depress central respiratory drive.[40] Endogenous opiates may modulate the ventilatory response to hypoxia in newborn primate animals[41]; however, a competitive opiate receptor antagonist, naloxone, is of no benefit in resuscitation of the asphyxiated human neonate,[42] nor does naloxone appear to play a therapeutic role in apnea of prematurity.

Infants with sepsis are prone to respiratory compromise, including apnea. The proinflammatory cytokine IL-1β may be released in response to infection, and animal studies have shown

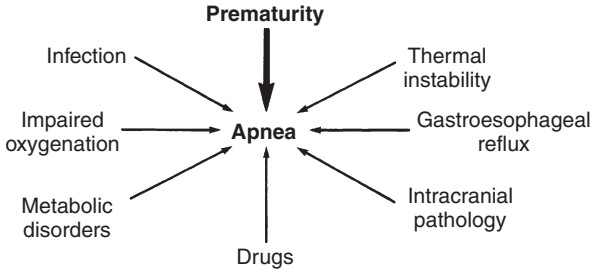

Figure 91-4 Some diverse factors known to precipitate development of apneic episodes in predisposed preterm infants. *(From Martin RJ, Miller MJ, Carlo WA: Pathogenesis of apnea in preterm infants,* J Pediatr *109:733, 1986.)*

that IL-1β can depress respiration by way of a prostaglandin E_2–related mechanism. Thus activation of this pathway may trigger apnea in the infant with infection.[43] The final output of the respiratory control nuclei in the medulla may be a complex function of many inhibitory and stimulatory inputs, both humoral and neural. The exact manner in which these pathways are altered during apnea of prematurity remains to be elucidated.

Role of Sleep State

It became apparent in the mid-1970s that respiratory control is influenced by sleep state in infants. Apnea was observed to occur more commonly during active (or rapid eye movement) and indeterminate (or transitional) sleep, when respiratory patterns are irregular in both timing and amplitude.[44] Apnea is less commonly observed during quiet sleep, when respiration is characteristically regular with little breath-by-breath change in tidal volume or respiratory frequency, although periodic breathing may actually occur predominantly in quiet sleep. In term neonates, respiratory variability alone can be used to stage sleep with a high degree of accuracy.[45] However, sleep state is not easily definable by any criteria before 32 weeks gestation, when apnea occurs most frequently.

The higher incidence of apnea during active sleep probably is the result of the variability of respiratory rhythmicity characterizing that state. Other factors may enhance the infant's vulnerability to apnea during active sleep. Chest wall movements are predominantly asynchronous (or paradoxical) during active sleep, in contrast with quiet sleep.[46] Specifically, abdominal expansion during inspiration is almost always accompanied by inward movement of the rib cage during active sleep, whereas during quiet sleep, rib cage and abdomen expand together. These paradoxical chest wall movements during active sleep appear to be the result of decreased intercostal muscle activity, secondary to spinal motoneuron inhibition.[47] In very preterm infants, however, the paucity of quiet sleep, together with an extremely compliant rib cage, makes paradoxical chest wall movements almost a constant feature. Asynchronous chest wall movements may predispose the infant to apnea by decreasing functional residual capacity and impairing oxygenation.[48] The compensatory increase in diaphragm activity that results may increase diaphragmatic work, potentially leading to diaphragmatic fatigue[49] and collapse of the pharyngeal airway.[50] Thus the enhanced vulnerability to apnea during active sleep may involve simultaneous mechanisms operating at several levels of respiratory function.

Influence of Chemoreceptor and Mechanoreceptor Responses

The ventilatory and respiratory muscle responses to increases in inspired carbon dioxide reflect predominantly central chemoreceptor activity and are less well developed in the immature infant before 33 weeks of postconceptional age.[51]

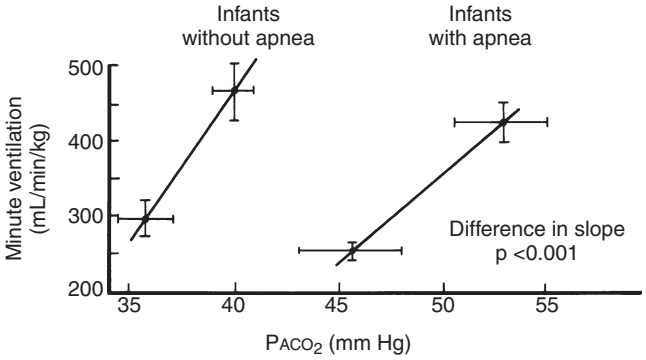

Figure 91-5 Comparison of carbon dioxide sensitivity obtained from ventilatory responses to changing alveolar partial pressure of carbon dioxide (P_{ACO_2}) in preterm infants with and without apnea. Note the less steep ventilatory response in the apneic group. *(From Gerhardt T, Bancalari E: Apnea of prematurity. I. Lung function and regulation of breathing,* Pediatrics *74:58, 1984. Reproduced by permission of* Pediatrics.*)*

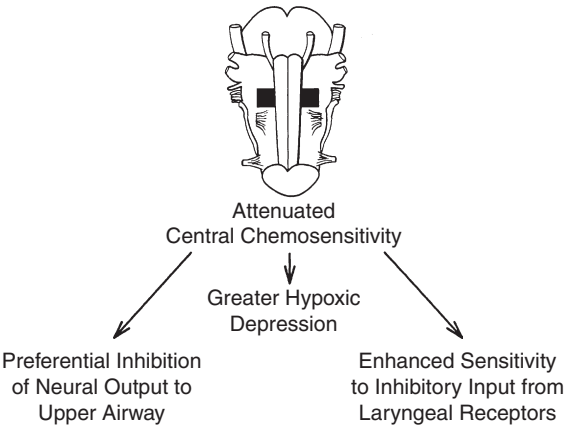

Figure 91-6 Hypothetical framework for mechanisms whereby attenuated central (carbon dioxide) chemosensitivity enhances vulnerability to neonatal apnea. The *black squares* indicate the intermediate area of the ventral medullary surface of the brain stem.

The reduced ventilatory response to carbon dioxide in small preterm infants is primarily the result of decreased central chemosensitivity; however, mechanical factors preventing an appropriate increase in ventilation may contribute. Unlike adults, preterm infants do not increase frequency of ventilation during hypercapnia. In these infants, hypercapnia may be accompanied by prolongation of expiratory duration.[52] It has been shown that the carbon dioxide response curve has a decreased slope (indicating a less steep ventilatory response to increasing carbon dioxide concentrations) in preterm infants who exhibit apnea[53] (Figure 91-5) However, a cause-and-effect relationship between decreased carbon dioxide responsiveness and apnea of prematurity has not been clearly established. Both entities may simply reflect decreased respiratory drive. Administration of carbon dioxide at low inspiratory concentrations would be expected to relieve apnea, as it does periodic breathing; this approach has been investigated but may not be therapeutically feasible in human infants.

A newborn piglet model has been used to identify the physiologic consequences of decreased central (carbon dioxide) chemosensitivity by cooling a discrete area (the intermediate area) of the ventral medullary surface.[54,55] Cooling at this site (or microinjection of inhibitory neurotransmitters) inhibits central chemosensitivity, possibly by directly affecting chemosensitive cells but also by inhibiting neural transmission between central chemosensitive cells and respiratory rhythm generators situated in the brain stem. Obvious limitations arise in extrapolating data from anesthetized newborn piglets to apneic human infants. Nonetheless, as seen in Figure 91-6, attenuated central chemosensitivity may underlie some of the physiologic characteristics of neonatal respiratory control, including preferential inhibition of neural output to the upper airway muscles as compared with the diaphragm, enhanced sensitivity to inhibitory afferents from upper airway (e.g., laryngeal) receptors, and greater hypoxic depression of breathing (as discussed later on).

It has been known for many years that preterm infants respond to a fall in inspired oxygen concentration with a transient increase in ventilation over approximately 1 minute, followed by a return to baseline or even depression of ventilation.[56] The characteristic response to low oxygen in infants appears to result from initial peripheral chemoreceptor stimulation, followed by overriding depression of the respiratory center as a result of hypoxemia. Consistent with these findings is the observation that a progressive decrease in inspired oxygen concentration causes a significant flattening of carbon dioxide responsiveness in preterm infants.[57] This unstable response to low inspired oxygen concentration may play an important role in the origin of neonatal apnea. It offers a physiologic rationale for the decrease in incidence of apnea observed when a slightly increased concentration of inspired oxygen is administered to apneic infants. The biphasic ventilatory response to low inspired oxygen, however, is not unique to apneic infants and probably serves to increase their vulnerability to apnea, rather than causing the problem. Consistent with the prolonged vulnerability of respiratory control in preterm infants is the observation that the characteristic biphasic ventilatory response to hypoxia persists into the second month of postnatal life.[58]

Afferent neural input from pulmonary stretch receptors is capable of substantially modulating respiratory timing in human neonates. This vagally mediated response, called the *Hering-Breuer reflex,* acts to inhibit inspiration, prolong expiration, or both, with increasing lung volume, thereby limiting lung overinflation.[59] Active shortening of expiratory duration with decrease in lung volume may similarly provide a neonatal breathing strategy to preserve functional residual capacity in the presence of a highly compliant chest wall. Another manifestation of this reflex response to lung inflation is that inspiratory duration typically is prolonged after end-expiratory airway obstruction when lung inflation is prevented. This ability of neonates to increase the duration of an obstructed inspiratory effort appears to be an appropriate compensatory mechanism during airway occlusion. More important, upper airway obstruction contributes substantially to the initiation of apneic episodes in preterm infants, and upper airway muscles show preferential reflex activation in response to airway obstruction in infants.[60] Gerhardt and Bancalari[61] compared preterm infants with and those without apnea in their ability to respond to end-expiratory airway occlusion. Prolongation of the occluded inspiratory effort was significantly greater in the nonapneic group, suggesting a more mature respiratory reflex response with stronger compensatory activity to relieve airway obstruction.

Apnea in premature infants is accompanied by complex changes in pulmonary mechanics and ventilatory timing.[9] Before apnea occurs, an increase in total pulmonary resistance has been observed in association with a decrease in tidal volume and a prolongation in expiratory time. Such changes were documented before onset of mixed, obstructive, and central apneic episodes. These observations suggest that a diminution in respiratory drive

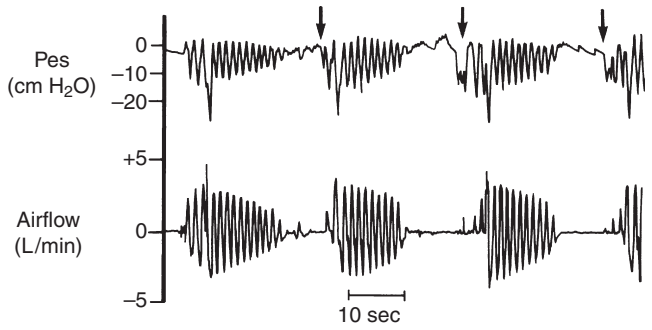

Figure 91-7 During this epoch of periodic breathing, obstructed breaths occur at the onset of each ventilatory cycle, as indicated by esophageal pressure *(Pes)* swings in the absence of nasal airflow. *(From Miller MJ, et al: Airway obstruction during periodic breathing in premature infants,* J Appl Physiol *64:2496, 1988.)*

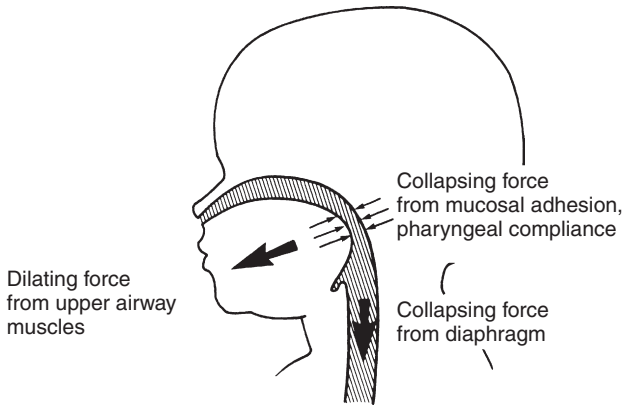

Figure 91-8 Sagittal section of the upper airway, demonstrating various forces operating either to collapse the pharynx or to maintain its patency during normal respiration. *(Modified from Thach BT: The role of pharyngeal airway obstruction in prolonging infantile apneic spells. In Tilden JT, et al, editors:* Sudden infant death syndrome, *New York, 1983, Academic Press.)*

precedes apnea, reminiscent of the cyclic alterations in drive observed by Waggener and co-workers.[62] After the apnea resolves and respiration is resumed, the respiratory drive in premature infants initially is increased (reflected in a higher ratio of tidal volume to inspiratory time), which may represent a response to cumulative hypoxia and hypercapnia. During recovery from apnea, total pulmonary resistance is increased and supraglottic resistance also is elevated, possibly in response to a fall in lung volume and collapse of the upper airway when respiratory drive declines after onset of apnea. Remarkably, within two to three breaths after apnea, the premature infant can restore pulmonary resistance and respiratory drive to normal preapnea values. Thus the neural systems that restore respiratory homeostasis are intact, even in premature infants with apnea.

Relation of Apnea to Periodic Breathing

Periodic breathing, defined earlier as recurrent sequences of pauses in respiration, is so common as to be considered normal in preterm infants.[63] It can be eliminated by increasing environmental oxygen,[63] but because periodic breathing is considered harmless, this intervention is not recommended. Apnea and periodic breathing share many characteristics, but some specific differences have been noted. Both forms of respiratory instability decline in frequency over a 5- to 10-week period after birth. The respiratory pause in both apnea and periodic breathing is preceded by a decline in tidal volume and by a prolongation of respiratory time reminiscent of the cyclic changes in ventilation described by Waggener and co-workers.[62] Both apnea and periodic breathing may be accompanied by obstructed breaths before the onset of respiratory cycles[9,64] (Figure 91-7).

Apnea and periodic breathing do differ in the following respects: The respiratory pauses of apnea are not limited in duration, and they are accompanied by frequent swallows, which are not observed during periodic breathing. Thus the physiologic correlates of these forms of respiratory instability differ in several ways. The specific central neuronal pathways that lead to each have yet to be determined.

Differential Responses of Upper Airway and Chest Wall Muscles

Because premature infants exhibit pharyngeal or laryngeal obstruction during spontaneous apnea, much interest has focused on the interactions among the various respiratory muscle groups in maintaining airway patency. A model was proposed for the pathogenesis of neonatal apnea by Thach,[50] a modification of which is shown in Figure 91-8. According to this model, negative luminal pressures generated in the upper airway during inspiration predispose a compliant pharynx to collapse. Patency can be maintained by activation of upper airway muscles, which may increase tone within the extrathoracic airway through tonic or phasic contraction in synchrony with the chest wall muscles. The relative roles played by active upper airway muscle contraction and passive rigidity of the anatomic framework of the upper airway in maintaining pharyngeal patency in preterm infants are unclear.

Whereas many upper airway muscles, including the alae nasi and laryngeal abductor and adductor muscles, modulate patency of the extrathoracic airway, failure of genioglossus activation has been most widely implicated in mixed and obstructive apnea in both adults and infants. Carlo and co-workers[65] compared activity of the genioglossus muscle with that of the diaphragm in response to hypercapnic stimulation. Consistent with data obtained in animal models,[66] genioglossus activation in preterm infants was delayed for approximately 1 minute after initiation of carbon dioxide rebreathing and occurred only after a P_{CO_2} threshold of approximately 45 mm Hg had been reached.[65] By contrast, diaphragm EMG activity increased linearly with progressive hypercapnia. Thus it is possible that an absent, small, or delayed upper airway muscle response to hypercapnia may result in upper airway instability when accompanied by a linear increase in chest wall activity. This instability may predispose affected infants to obstruction of inspiratory efforts after a period of central apnea. Consistent with this hypothesis is the observation that short apneic episodes are more likely to be central, and longer episodes (lasting longer than 15 seconds) are more likely to be accompanied by obstructed breaths. Furthermore, airway obstruction often occurs toward the end of the longer episodes of mixed apnea, when diaphragmatic activity may be enhanced before that of the upper airway muscles.

Neonates typically exhibit a modest prolongation of inspiratory time when lung inflation is prevented by end-expiratory airway occlusion; as indicated earlier, this response is a manifestation of the Hering-Breuer reflex. Studies in animals demonstrated that this vagally mediated inhibition of normal lung inflation has a greater influence on the upper airway muscles than on the diaphragm.[67] This vagal inhibition is released when the airway is occluded. Consequently, airway occlusion results in a greater increase of upper airway muscle activity, as compared with the diaphragm, for an obstructed inspiratory effort versus the corresponding preocclusion breath. A similar preferential increase in amplitude of the submental (genioglossus) versus diaphragm

EMG tracing has been noted in healthy preterm infants during end-expiratory airway occlusion.[60] It is theoretically possible that exaggerated vagal inhibition of the dilator muscles of the upper airway may contribute to the origin of obstructive apnea.

Gauda and co-workers[68] used sublingual surface electrodes (placed over the insertion of the genioglossus within the mandible) to compare the genioglossus responses with end-expiratory airway occlusion in preterm infants with mixed and obstructive apnea and in nonapneic control infants. In both groups of infants, genioglossus EMG activity typically was absent during unobstructed breathing. Occlusion resulted in immediate release of this inhibition, with resultant augmentation of the genioglossus in the nonapneic infants. In infants with apnea, however, activation of the genioglossus in response to occlusion was significantly delayed. The cause of this delay in genioglossus activation after airway obstruction is not currently understood. This observation suggests that vagal inhibition of the dilator muscles of the upper airway does not contribute to the initiation of apnea.

Subsequently, Gauda and co-workers[35] evaluated the activity of the genioglossus and diaphragm during spontaneously occurring mixed and obstructive apneic episodes. During mixed apnea, the amplitude of the diaphragm EMG activity decreased on the initial obstructed inspiratory effort and did not exceed that for the breath preceding apnea until flow was reestablished (Figure 91-9). Genioglossus activity accompanied approximately 20% of breaths immediately preceding spontaneous apnea; this frequency did not increase significantly until resolution of the apnea, with genioglossus activity present during 40% of breaths associated with reestablishment of airflow. Thus decreased diaphragmatic activity is a major component of spontaneous apnea associated with airway obstruction, and neither diaphragm nor genioglossus activity is increased until resolution of apnea. These findings suggest that central, mixed, and obstructive apneas are caused by a common mechanism—a reduction in central drive affecting the diaphragm and dilating muscles of the upper airway. However, the finding that only 40% of spontaneous apneic episodes were terminated with genioglossus activation indicates that this is not the sole mechanism by which upper airway obstruction is relieved in premature infants.

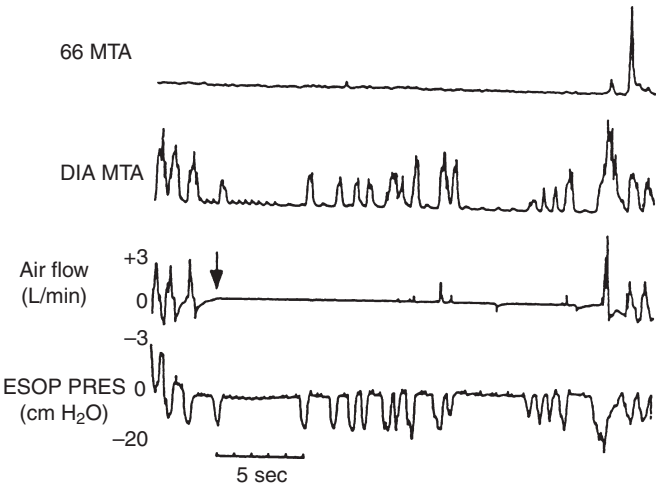

Figure 91-9 A representative tracing of the genioglossus muscle *(GG)* and diaphragm *(DIA)* electromyographic activity during spontaneous apnea. The *arrow* denotes the onset of mixed apnea. The diaphragmatic amplitude of the initial obstructed inspiratory effort is less than the diaphragmatic amplitude of the breath preceding apnea, whereas the diaphragmatic amplitude of the breath at resolution of the apnea exceeds that of the preapneic breath. Electromyographic activity of the genioglossus muscle appears only at resolution of the apnea. The moving time averaged *(MTA)* signals are depicted for both the genioglossus and diaphragm. *ESOP PRES,* Esophageal pressure. *(From Gauda EB, et al: Genioglossus and diaphragm activity during obstructive apnea and airway occlusion in infants,* Pediatr Res *26:583, 1989.)*

Upper Airway Reflexes

Reflexes originating from the upper airway may directly alter the pattern of respiration in infants and may play a crucial role in both the initiation and termination of apnea. The walls of the nasal cavity, nasopharynx and oropharynx, and larynx contain many sensory nerve endings that may respond to a variety of chemical and mechanical stimuli. Sensory input from these upper airway receptors travels to the central nervous system through cranial nerves V, VI, IX, X, XI, and XII and may have powerful effects on respiratory rate and rhythm, heart rate, and vascular resistance.[69] In human infants, interest has focused on two aspects of control of respiration by sensory input from the upper airway—that is, the response elicited from the nasopharynx to changes in luminal pressure and apnea produced by liquid stimulation of chemoreceptors in and around the larynx and hypopharynx.

Abu-Osba and co-workers[70] observed that sensory deprivation of the entire upper airway, including the larynx in rabbits, resulted in pharyngeal collapse. Similarly, topical anesthesia of the upper airway mucous membranes eliminated airway reflex response to pressure and was associated with pharyngeal obstruction, as well as death of the animal. These observations suggest that afferent sensory input from the upper airway is necessary for airway patency. By contrast, in kittens and puppies, steady airflow through the entire upper airway actually has been found to depress respiration.[71] Thus, depending on the species and experimental conditions, inhibitory or excitatory stimuli may originate from the upper airway.

In human infants who have undergone tracheostomy, Thach and colleagues[72] showed that negative pressure within the isolated upper airway depressed ventilation. In adult rabbits, Mathew and Farber[73] examined the effect of upper airway negative pressure on respiratory timing. Application of negative pressure to the isolated upper airway resulted in prolonged diaphragmatic inhibition; however, phasic upper airway muscle activity continued. The ability of the upper airway muscles to respond to increasing negative pressure may be augmented by chemoreceptor drive and inhibited by input from pulmonary stretch receptors.[74] The net balance of these reflex inputs may ultimately determine the patency of the upper airway at any given time. These observations may be relevant to the processes that initiate and resolve obstructive apnea. For example, during apnea, upper airway occlusion would result in increased negative airway pressure below the site of the obstruction. Reflex inhibition of diaphragmatic contraction resulting from increasing negative pressure in the airway lumen could produce the central pause characteristic of mixed apnea (see Figure 91-1), which in turn could result in a decrease in luminal pressure, allowing the airway to reopen.

A second important area of sensory reception in the upper airway lies in and around the larynx. Menon and co-workers[75] described apnea associated with overt regurgitation of gastric contents into the upper airway of human infants. Presumably, acidic stomach contents that enter the larynx excite chemoreceptors that cause both apnea and swallowing. These receptors have been studied in the lamb. Chemoreceptors in the region of the larynx send afferent neural output to the medulla; when these receptors are stimulated by water or ammonium chloride, apnea can be elicited.[76] Menon and co-workers[77] and, more recently, Miller and DiFiore[78] reported an observation that may link idiopathic apnea of prematurity with inhibitory reflexes arising within the upper airway: Swallows were found to be much more common during apnea than during comparable periods of uninterrupted sleep (Figure 91-10). Furthermore, swallowing during the respiratory

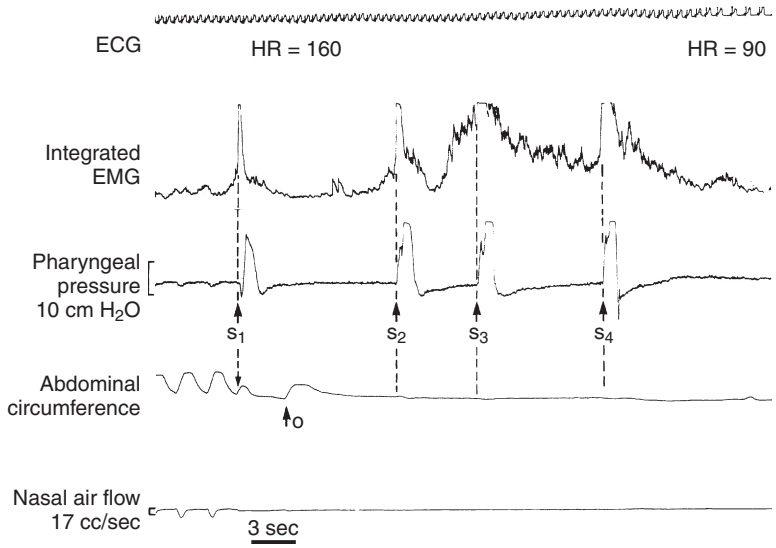

Figure 91-10 A typical prolonged apneic spell with swallowing *(S1)* occurs at apnea onset as well as during the apneic episode *(S2, S3, S4)*. An obstructed breath *(o)* also is seen at apnea onset. *ECG,* Electrocardiogram; *EMG,* electromyogram; *HR,* heart rate. *(From Menon AP, Schefft GL, Thach BT: Frequency and significance of swallowing during prolonged apnea in infants,* Am Rev Respir Dis *130:969, 1984.)*

pause is unique to apnea and does not occur during periodic breathing.[79] The etiology of these swallows is as yet unknown. Apneic episodes of variable duration have been elicited, resembling central or obstructive apnea, by introducing saline boluses into the oropharynx during sleep.[79] Hypothetically, accumulation of saliva in the pharynx could prolong apnea through a chemoreflex mechanism and also elicit swallowing movements.

Gastroesophageal Reflux

Although *gastroesophageal reflux* often is incriminated in causing neonatal apnea, caution should be exercised before the apnea is attributed specifically to reflux. Despite the frequent coexistence of apnea and gastroesophageal reflux in preterm infants, investigations into the timing of reflux in relation to apneic events indicate that they are not commonly temporally related.[80] Monitoring studies demonstrate that when a relationship between reflux and apnea is observed, apnea may precede rather than follow reflux, as seen in Figure 91-2.[81,82] This finding suggests that loss of respiratory neural output during apnea may be accompanied by a decrease in lower esophageal tone and gastroesophageal reflux. Such a phenomenon is supported by data from a newborn piglet model, in which apnea was accompanied by a fall in lower esophageal sphincter pressure.[83] Although physiologic experiments in animals reveal that reflux of gastric contents to the larynx induces reflex apnea, no clear evidence is available showing that treatment of reflux will affect frequency of apnea in most preterm infants.[84] Therefore pharmacologic management of reflux with agents that decrease gastric acidity or enhance gastrointestinal motility generally should be reserved for those preterm infants who exhibit signs of emesis or regurgitation of feedings, regardless of whether apnea is present. Greater understanding of the clinical consequences of gastroesophageal reflux may emerge from studies using transducers embedded in esophageal catheters that also measure impedance to characterize nonacid reflux.

PHYSIOLOGIC RATIONALE FOR THERAPEUTIC INTERVENTIONS

Continuous Positive Airway Pressure

Continuous positive airway pressure (CPAP) delivered by nasal prongs, nasal mask, or face mask at 2 to 5 cm H_2O pressure has proved effective in the treatment of apnea in preterm infants. Initial studies suggested that the beneficial effects of CPAP were mediated by means of an alteration of the Hering-Breuer reflex, stabilization of the chest wall with consequent reduction of the

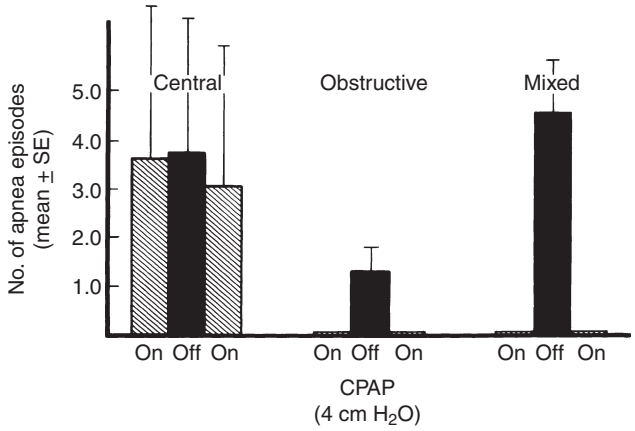

Figure 91-11 Effect of continuous positive airway pressure (CPAP) on the number of apneic episodes lasting 10 seconds or longer in infants of various ages (n = 10). Episodes of mixed and obstructive apnea decreased significantly during both periods of CPAP; however, no effect on central apnea was noted. *(From Miller MJ, Carlo WA, Martin RJ: Continuous positive airway pressure selectively reduces obstructive apnea in preterm infants,* J Pediatr *106:91, 1985.)*

intercostal-phrenic inhibitory reflex, or increase in oxygenation.[85] Although such mechanisms may play a role, nasal CPAP reduces the frequency of only mixed and obstructive apneas, with little or no effect on central apnea in infants[6] (Figure 91-11). It appears, therefore, that CPAP exerts its beneficial effect in infants by splinting the upper airway with positive pressure throughout the respiratory cycle, and nasal cannula flow at 1 to 2.5 L/minute may serve the same purpose.[86] Animal studies have demonstrated that genioglossus activity decreases with CPAP administration[87]; therefore reflex activation of upper airway dilating muscles is unlikely to be involved in the relief of apnea by CPAP.

Pharmacologic Agents

The methylxanthines—theophylline and caffeine—have proved effective in treatment of apnea in the newborn infant.[88,89] Several mechanisms, summarized in Box 91-1, have been proposed whereby methylxanthines decrease the incidence of apnea. Available evidence points to central respiratory stimulation, rather

- Greater efficiency of diaphragmatic contraction
- Improved pulmonary mechanics
- Decreased hypoxic ventilatory depression

Biochemical
- Adenosine receptor antagonism

than bronchodilation, as the major mode of action. Gerhardt and associates[90] observed an increase in respiratory center output in premature infants receiving aminophylline, as measured by an increase in esophageal pressure change per breath, as well as a lowering of the threshold of the respiratory center to carbon dioxide. At the dose of aminophylline used in this study, no increase in carbon dioxide sensitivity or improvement in pulmonary mechanics was observed. A concurrent increase (approximately 20%) in metabolic rate was noted, however, and was subsequently confirmed with similar experiments using caffeine.[91] This metabolic step-up constitutes an adverse effect in preterm infants, who frequently are nutritionally compromised. These findings are in agreement with the central stimulatory effect of theophylline, which has been reported in animals and human adults. Animal data suggest that systemically administered theophylline acts directly on brain stem neurons, because respiratory stimulation occurs in the absence of peripheral (carotid body or vagus) reflex mechanisms, medullary chemoreceptor responses, or suprapontine brain structures.[92] Additional stimulatory effects of aminophylline on peripheral chemoreceptor activity were demonstrated by Cattarossi and associates[93] in the newborn human. Thus, in the infant, aminophylline may exert its effects at both the peripheral and central chemoreceptors.

The xanthines inhibit phosphodiesterase, which normally breaks down cyclic adenosine monophosphate (cAMP), although the relationship of cAMP accumulation with relief of apnea in infants is unproved. Adenosine and its analogues cause respiratory depression, and adenosine antagonism also has been proposed as the predominant mechanism to explain the therapeutic effect of theophylline.[37] In support of this concept, Darnall[94] documented that aminophylline partially reduces the ventilatory depression induced by hypoxia in newborn piglets. Adenosine is formed from nucleotides such as ATP and binds to multiple adenosine receptor subtypes. Whereas activation of adenosine A_1 receptors is primarily inhibitory of neuronal activity, adenosine A_{2A} receptor activation is predominantly excitatory. The latter has been shown to excite GABA-containing neurons, resulting in release of GABA—probably the major inhibitory neurotransmitter.[95] Xanthine therapy thus may excite breathing by blocking either adenosine or GABA effects on respiratory neural output. Xanthines may, however, have additional effects on the respiratory system. In adult patients with emphysema, theophylline appears to enhance diaphragmatic strength, as measured by transdiaphragmatic pressure generated against an occluded airway, while reducing EMG evidence of diaphragmatic fatigue.[96] Enhancement of calcium transport across the sarcolemma is a proposed mechanism by which theophylline increases diaphragm contractility, although the relevance of this action in human infants with apnea is not known.[97] A multicenter clinical trial has demonstrated that caffeine (versus placebo) therapy is associated with decreased duration of necessary ventilatory support in preterm infants.[98] This benefit was accompanied by a temporary reduction in weight gain. Longer-term effects on neurodevelopmental and respiratory outcomes are encouraging.

Doxapram, known to be a potent respiratory stimulant with predominantly peripheral chemoreceptor effects, has been used in neonates with idiopathic apnea of prematurity.[99] This drug may have a limited therapeutic role in infants with apnea refractory to xanthine derivatives, although potential side effects appear to limit its usefulness.[100]

Relation of Apnea to Sudden Infant Death Syndrome

One of the controversial aspects of apnea has been its proposed relation to the *sudden infant death syndrome* (SIDS). Many observations on the epidemiology and physiology of SIDS point to an abnormality of control of ventilation as one underlying cause of this multifactorial disorder. Early reports on the neuropathologic features of SIDS suggested the presence of tissue changes consistent with chronic hypoxia within the areas of the brain stem that regulate breathing and within the carotid body.[101,102] Short and prolonged apnea has been reported in infants with *near-miss SIDS* (now referred to as an *apparent life-threatening event*), a proportion of whom subsequently died of SIDS.[103] Short apneic episodes, periodic breathing, mixed and obstructive apnea, and abnormal ventilatory responses all have been variably identified in infants thought to be at risk for SIDS.[104,105] All of these observations suggested that an abnormality of ventilatory control could contribute to death from SIDS. Such considerations prompted the development of polygraphic monitoring in which variables such as heart rate, nasal airflow, chest and abdominal movement, and transcutaneous oxygen tension or oxygen saturation were measured in an attempt to predict the risk of SIDS in vulnerable infants. However, studies evaluating large cohorts of infants have failed to demonstrate that monitoring of cardiorespiratory variables can prospectively identify SIDS victims.[106] Although evidence implicates an abnormality of ventilatory control in SIDS, the nature of this abnormality is unknown. Indeed, more than one underlying cause of cardiorespiratory instability eventually may be implicated in this disorder. For example, it has been proposed that approximately 2% of infants who die of SIDS may have a sodium channel mutation with resultant predisposition to the long QT syndrome and potentially fatal arrhythmia.[107,108]

More recent research is providing new insights into the genetics of respiratory control development. Congenital central hypoventilation syndrome has been associated with weak or absent hypercapnic ventilatory responses and developmental abnormality of *PHOX2B* gene expression, which is crucial for autonomic nervous system development. Application of knowledge acquired from study of this extremely rare syndrome may solve some of the mysteries of respiratory control development.[109] Similarly, a possible relationship between delayed maturation of serotoninergic chemosensitive medullary neurons and predisposition to SIDS has generated interest in a role for the serotonin transporter gene in disordered respiratory control.[109]

Body Position and Exposure to Smoking

A reduction in postneonatal mortality and in the rate of sudden infant death has been associated with sleeping in the supine position. This finding has been substantiated in many countries and has generated public education campaigns designed to promote supine and avoid prone sleeping.[110] The physiologic mechanisms that underlie this relationship between SIDS and prone positioning are under investigation. Relevant factors include softness and porosity of bedding, which may encourage carbon dioxide rebreathing,[111] and thermal stress, which may destabilize respiratory control by as-yet undetermined mechanisms.[112]

Several studies have documented physiologic benefits for prone versus supine positioning in preterm infants, especially

those with residual lung disease. Such benefits include modest improvement in transcutaneously measured partial pressure of oxygen,[113] more time in quiet sleep,[114] decreased energy expenditure,[115] and greater ventilatory responses to inspired carbon dioxide[116] in the prone as compared with the supine position. The effect of sleep position on apnea is controversial. Heimler and co-workers[117] observed that infants had less apnea in the prone position. However, Bhat and associates noted more central apnea during prone sleeping.[118] Nonetheless, supine positioning also should be recommended for such infants in the home and should be initiated before hospital discharge. Furthermore, it has been proposed that greater sleep efficiency with fewer arousals associated with the prone position may actually enhance SIDS vulnerability. Prenatal and postnatal exposure to smoking also predisposes infants to SIDS. Nicotine affects a multitude of autonomic and sensory functions; however, no clear consensus has emerged regarding how nicotine targets developmental cardiorespiratory control, arousal, and ability to overcome apnea, bradycardia, and hypoxia.[119]

Apnea on a Continuum From Infancy to Childhood and Adulthood and Neurodevelopmental Outcome

Apnea of prematurity generally resolves by approximately 36 to 40 weeks of postconceptional age. In the most premature infants (born at 24 to 28 weeks of gestation), however, apnea frequently persists beyond 36 weeks of postconceptional age, and in occasional infants it may persist beyond 40 weeks. Cardiorespiratory events in such infants return to the baseline "normal" level at approximately 43 to 44 weeks of postconceptional age. In other words, beyond 43 to 44 weeks of postconceptional age, the incidence of cardiorespiratory events in preterm infants does not significantly exceed that in term babies (see Figure 91-3).[26]

Apnea and bradycardia in many preterm infants so affected have resolved by the time they are ready for hospital discharge as determined by maturation of temperature control and feeding pattern. An apnea-free observation period, usually ranging from 3 to 7 days, is used as a criterion for determining discharge date. For a subset of infants, however, the persistence of cardiorespiratory events may delay discharge from the hospital. In these infants, apnea lasting longer than 20 seconds is rare; rather, they exhibit frequent episodes of desaturation to less than 80% or bradycardia at less than 70 to 80 beats/minute with short respiratory pauses. The reason why some infants exhibit marked desaturation and bradycardia with short pauses is unclear.[120-122] For such infants, home cardiorespiratory monitoring until they attain 43 to 44 weeks of postconceptional age may offer an alternative to a prolonged hospital stay.

Because idiopathic apnea most often is seen in high-risk preterm infants, separating the consequences of premature birth from the effects of apnea of prematurity has proved to be difficult. Infants born prematurely often have multiple problems, and many of these conditions, particularly periventricular leukomalacia and intraventricular hemorrhage, may contribute to poor neurodevelopmental outcome. In one study that tracked the progress of preterm infants up to early school age, factors that predicted poor neurodevelopmental outcomes included apnea of prematurity.[123] In another series of very-low-birth-weight infants followed up to 24 months of age, predischarge apnea and desaturation during apnea correlated with lower mental and motor neurodevelopmental scores. The presence of excessive cardiorespiratory events on home monitoring after discharge has been associated with a lower mental developmental index on follow-up.[124] It is possible that recurrent hypoxia is the detrimental feature of the breathing abnormalities exhibited by preterm infants.[125]

A respiratory disorder similar to apnea of infancy, termed *sleep apnea syndrome,* also occurs in adults. Both obese and nonobese adults may present with mixed, obstructive, or central sleep apnea.[126,127] Just as in infantile apnea, adults with sleep apnea syndrome experience upper airway obstruction within the pharynx. Sleep apnea syndrome may be accompanied by daytime somnolence, hypoxemia, cardiac arrhythmias, polycythemia, hypertension, morning headaches, and intellectual deterioration. CPAP has been used effectively to relieve mixed, obstructive, and central apnea in adults.[128] Thus it would seem that the pathophysiology of sleep apnea in adults and infants may share some common elements, including failure of maintenance of patency of the upper airway. Adults and infants do differ in two respects in their respective disorders: In adults, obstructive apnea fails to respond to theophylline therapy.[129] This lack of response may reflect an underlying dissimilarity in the balance of inhibitory and excitatory neurotransmitters that regulate respiration in humans at different ages. Alternatively, the degree of narrowing of the upper airway may be more critical for development of obstructive apnea in adults than in infants. In addition, apnea in adults is not accompanied by an increase in spontaneous swallows. In childhood, sleep-disordered breathing is receiving greater attention, and its potential relation to apnea of prematurity is under study.

The long-term outcome for infants with persistent sleep apnea is not well understood. Guilleminault and co-workers[130] published the first report of data for a series of children 6 months to 17 years of age who had obstructive sleep apnea syndrome. Subsequent studies confirmed an association with pharyngeal narrowing and behavioral problems with poor school performance.[131,132] Thus apnea as a manifestation of instability of respiratory control of the diaphragm and upper airway during sleep has been described in infants, young children, and adults. The underlying complex of factors that produce apnea, including cyclic fluctuation in respiratory center output, imbalance of drive to the upper airway musculature, and anatomic narrowing of the upper airway, may differ in each age-group, but final outcomes, in terms of apnea, are remarkably similar. Sleep apnea thus emerges as a not-so-silent disorder that accompanies humanity from the cradle to the grave.

FUTURE DIRECTIONS

Initiation of Apnea

Two questions may be fundamental both to the cause of apnea and to the nature of the respiratory dysfunction in SIDS:

1. How is apnea initiated?
2. By what mechanisms is apnea terminated?

Cyclic instability of ventilation has been observed in both infants and adults with sleep apnea. Cherniack and Longobardo[133] proposed that apnea may derive from instability in the automatic feedback control of breathing. In this model, cyclic variation in ventilation, such as that observed in periodic breathing, could derive from increased circulation time, increased chemoreceptor sensitivity, or the inherently low stores of oxygen in the circulation. For example, apnea could occur when the respiratory control center in the medulla overcompensates in response to a brief increase in ventilation, resulting in a *central* respiratory pause (central apnea). In addition, obstructive apnea could result from an imbalance of central drive to the upper airway–dilating muscles and diaphragm.

Initiation of apnea also could involve a global alteration in the central regulation of ventilation and muscular function. During all stages of sleep (particularly active sleep), a generalized decrease in skeletal muscle tone is characteristic. A more profound depression of muscle tone may occur during apnea. Schulte and associates[134] reported that monosynaptic reflex excitability decreases during prolonged apnea and speculated that these changes may result from a decrease in output from the reticular activating system to the brain stem as well as higher brain structures. Thus unstable feedback control of ventilation, an imbalance in activity of upper airway muscles and the diaphragm, and a decrease in

output from the reticular activating system all have been proposed as mechanisms that may initiate apnea, but which factor is most crucial has yet to be demonstrated. Sophisticated new anatomic tracer techniques, together with localization of neurotransmitters at key locations in the developing brain stem, should provide an important link to available physiologic data.

Termination of Apnea

Increasing hypoxia and hypercarbia during apnea would be expected to lead to increased ventilatory drive to the diaphragm and upper airway, resulting in eventual resolution of apnea. Why then do some infants apparently fail to respond appropriately to these stimuli? As previously discussed, auditory brain stem conduction times are prolonged in infants with apnea, possibly reflecting decreased synaptic efficiency and myelination.[34] The delayed response of the apneic infant to hypercapnia and hypoxia may simply be the result of immaturity in processing afferent chemosensory information at the brain stem level. The decreased carbon dioxide response observed in apneic infants is consistent with this hypothesis.

Arousal from sleep also may play a role in the ability of the infant to terminate apnea quickly. The nature of the infant's sleep state may determine whether arousal occurs in response to apnea; this issue was investigated by Baker and Fewell[135] in the lamb. In active sleep, arousal was dependent on the rate of change in arterial oxygen concentration. A synergy appeared to exist between arterial carbon dioxide and oxygen levels, with the most rapid arousal occurring when both were changing.[136] Repeated exposure to hypoxemia during sleep resulted in evidence of adaptation, that is, increased time to arousal and decreased saturation at arousal. Such habituation to repeated hypoxic exposure has not been studied in human infants. Depression of reflex response to hypoxia, however, is a potential mechanism by which multiple sequential apneas could occur. Quantification of the frequency and magnitude of episodic hypoxemic episodes associated with apnea is now possible with the latest pulse oximetry technology. Thus several important variables, including peripheral and central chemoreceptor responses, sleep state, and previous exposure to hypoxia, could affect the infant's ability to terminate apnea. Exactly which of these influences is most crucial in resolution of apnea in the human infant remains an important question for future research.

Evaluation of Pulmonary Function in the Neonate

The ability to measure lung function is essential for understanding its physiologic function, diagnosis of pathologic conditions, and evaluating the effect of therapeutic interventions. Early efforts at evaluating lung function were made possible in the 19th century with the invention of a simple spirometer to measure vital capacity.[1,2] Modern pulmonary function testing in adults and children has been used effectively as a research and clinical tool since the 1950s.[3,4] Although testing of infant pulmonary function was introduced around the same time, its practical use has lagged behind, owing to technical limitations, lack of patient cooperation, difficulty with the long duration of testing in this age-group, and time-consuming manual analysis methods.[5-8] In the 1980s, improvements in technology, including sensor miniaturization and computerization, led to mobile equipment systems enabling the clinician to perform routine pulmonary function testing at the bedside. More recently, a new generation of infant ventilators incorporating continuous display of pulmonary function data, as well as on-line graphic display of respiratory waveforms, have become available. Infant pulmonary function testing has thus moved from the research laboratory to the patient bedside, while efforts to reduce invasiveness and improve accuracy continue.

PHYSIOLOGIC BACKGROUND

Each respiratory cycle is governed by a driving pressure that moves a volume of air into and out of the respiratory tract, resulting in measurable airflow and volume changes. During unaided breathing, the driving force required for initiation of inspiratory airflow is generated by contraction of the respiratory muscles and outward movement of the thorax, resulting in a transient decrease in alveolar pressure from atmospheric pressure at end-expiration to a subatmospheric level and peak airflow at mid-inspiration (Figure 92-1). The expiratory driving force is generated by relaxation of the respiratory muscles and inward recoil of the lung. These actions result in an increase in alveolar pressure, causing an expiratory airflow that reaches a peak at mid-expiration and returns to zero at the end of expiration. At this point, alveolar pressure also returns to zero, and another respiratory cycle commences. Thus alveolar pressure cycles from a negative to a positive value relative to atmospheric pressure, and the magnitude of this change is determined chiefly by airway resistance. Pleural pressure, however, remains subatmospheric throughout the breathing cycle owing to a balance of the opposing forces of lung elastic recoil and chest wall outward recoil.

During tidal spontaneous inspiration and expiration in normal healthy lungs, pleural pressure decreases and increases, respectively. The magnitude of these changes is determined by airflow and tissue resistances and by elastic forces in the lungs and chest wall, reaching a maximum at inspiratory and expiratory midpoints, as do the inspiratory and expiratory airflows. Because no airflow occurs at the end-inspiratory and end-expiratory points of the breathing cycle, no flow-resistive losses result at these points, and the pleural pressure is dependent only on elastic forces. This fact aids in the determination of elastic and resistive pulmonary function components as follows.

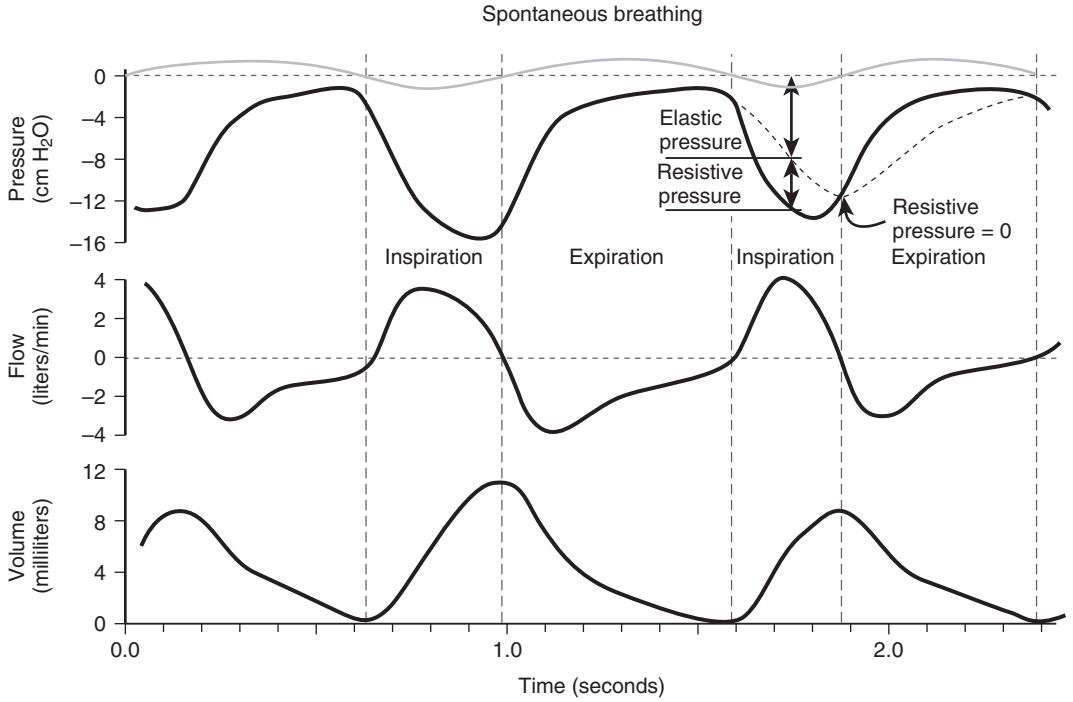

Figure 92-1 Pressure, flow, and volume signals for a respiratory cycle during spontaneous breathing.

Basic evaluation of pulmonary function is based on measurements of the interaction of driving pressure (P), volume (V), and airflow (V').[9,10] The equation of motion relating the motion of gas, chest wall, and lungs is expressed as a force balance equating the total driving force for breathing to a sum of elastic, resistive, and inertial forces:

$$P = EV + RV' + IV''$$

where

E = elastance of the respiratory tract (equivalent to the reciprocal of compliance, or $1/C$)

R = frictional resistance of respiratory tract comprising both airflow and tissue resistances

I = inertance of the respiratory tract, due to gas and tissue acceleration (V'')

This one-compartment linear model relating driving pressure to volume and flow has been considered an ideal elemental equation and constitutes a basic principle of respiratory physiology.[11] However, it is well appreciated that the respiratory system is not a linear system, resistance and compliance are not constants, both being dependent on volume, volume history, flow, and frequency. In addition, the respiratory system is a complex system consisting of multiple components with differing mechanical properties. This consideration is particularly pertinent in the preterm neonate. Despite its inexactness, however, and because of the complexities of dealing with nonlinear modeling, this simple linear model provides a useful framework for examining the dynamic behavior of the normal respiratory system.

INSTRUMENTATION

Instrumentation to measure the pressures, gas flows, and volumes in neonatal pulmonary function testing must meet basic physical capabilities for accuracy, precision, range, frequency response, and calibration integrity.[12,13] Computerized data collection systems also need to conform to signal processing standards such as adequate sampling rates to minimize aliasing in digitized signals, and to permit the use of appropriate automated breath detection algorithms.[14,15] In addition, devices to be used inline with infant breathing circuitry also must meet minimum standards for safety, hygiene, dead space, and resistive load. Equipment specifications and methodologies have been studied extensively in an effort to achieve uniformity among research laboratories and also among the various commercially available infant pulmonary function assessment systems. To this end, comprehensive testing and measurement standards have been established and published.[16,17]

Airflow Measurement

Decades of pulmonary function research have advanced several flow measurement technologies for use in both term and preterm neonates. A consistent objective has been to produce a smaller and lighter flow sensor having minimal dead space and airflow resistance. Some of the most commonly used devices are described next.

Pneumotachometers

Pneumotachometers are flow-resistive–type devices in which gas flows through a tube containing a fixed laminar flow element. Gas flow across the resistive element creates a pressure differential which is easily measured with a sensitive differential pressure transducer connected to each end of the tube. The resistive element can be either a fine-mesh screen or a bundle of small capillaries (Fleish type),[18,19] both of which produce a pressure drop that is linearly proportional to airflow so long as the flow is within a specified laminar flow range.[20,21] Higher flows give rise to turbulence, resulting in a nonlinear output. Accordingly, pneumotachometers should be selected that have linear flow ranges appropriate to the maximum expected normal flow for a given subject. Condensation of water vapor on the resistive element can easily alter its resistive properties, so most pneumotachometers incorporate a heating element to prevent accumulation of moisture. The flow characteristics also may be altered by accumulation of secretions, varying gas viscosity, gas composition, and temperature.[22-25] The pneumotachometer should be calibrated using the

same connectors, adapters, and gas composition as those to be used for actual measurements.[26,27] The differential pressure transducer used in conjunction with the pneumotachometer also must have a linear response over the pressure range being measured and have sufficient frequency response and phase characteristics.[28,29]

Hot Wire Anemometers

Hot wire anemometers are flow sensors that operate on the principle of measuring the amount of electrical current needed to maintain a constant temperature in a fine heated wire suspended across an air stream; the added current increases as the airflow increases and more heat is dissipated.[30-32] The response of the anemometer is inherently nonlinear, requiring linearization either in the signal conditioning circuitry or through computer signal processing algorithms. Another disadvantage is directional insensitivity, usually circumvented by the use of multiple sensors. Advantages are small size, good frequency response, and wide dynamic range, in addition to being a stand-alone device not requiring a pressure transducer. Furthermore, because the operating principle does not involve pressure measurement, the output signal is not subject to artifacts from sudden pressure gradients, or from pressure spikes in the breathing circuit, as are pressure-dependent devices.

Other Flow-Resistive Type Sensors

Other flow-resistive–type sensors include the pitot tube,[33,34] fixed orifice, and variable orifice sensors.[35] These types of flow sensors also require a pressure measurement. Unlike with the laminar flow pneumotachometer, the flow-pressure relationship for these devices is nonlinear, and they require hardware or software linearization. Like the anemometer, these sensors typically are smaller and lighter and thus have a smaller dead space than the pneumotachometer. These devices are therefore more appropriate for long-term monitoring, especially as integral components of mechanical ventilators for flow monitoring and for breath detection and triggering.

Ultrasonic Beam Flow Sensors

The theory behind operation of the ultrasonic beam flow sensor is the fact that sound waves traveling through a medium in flux are either accelerated or slowed down in accordance with the velocity of the medium. By measuring the transit time of a sound wave pulsed through a gas stream in a rigid conduit, the flow rate of the gas can be calculated. The main advantage of the ultrasonic flow meter is a much lower sensitivity to changes in gas properties than that typical for a traditional pneumotachometer.[36,37]

Volume Measurement

When airflow is measured directly at the airway opening using a flow sensor, respiratory volume change may be obtained simply by integration of the flow signal over time—achieved by measuring the area under the flow curve. With the advent of computerized signal processing, electronic integration of the flow signal has been replaced by digital integration. Because inspiratory gas differs from expiratory gas in O_2 and CO_2 composition, amount of water vapor, temperature, and viscosity, the inspiratory and expiratory portions of the resultant tidal volume trace will necessarily be slightly different. Additionally, flow sensors do not always have perfectly symmetric inspiratory and expiratory response characteristics. For these reasons, most volume signal conditioning routines correct for any baseline drift by incorporating an automatic return to zero at end-expiration. Differences in inspiratory and expiratory tidal volumes larger than 10%, however, may be indicative of airflow leakage around the endotracheal tube or face mask. Large drifts also may potentially indicate faulty flow sensor readings, which may be due to factors such as water vapor condensation or buildup of secretions.

Indirect methods for measuring volume change, without connection to the airway opening, may also be implemented when flow measurement is not essential. Inductive plethysmography[38-40] and impedance pneumography[41,42] are two indirect techniques that make use of measurements derived from thoracic and abdominal excursions. Although not as accurate as direct airway measurements, these alternative methods have the advantage of allowing noninvasive continuous monitoring without the alterations in breathing pattern that have been shown to occur with use of facemasks or inline flow sensors[43,44] These modalities are thus especially useful for undisturbed measurements in spontaneously breathing, sleeping infants.[45]

Whole-body plethysmography, when used in a manner in which the subject's airway opening connects to the atmosphere, as a "face-out" device, can be used to assess tidal volume by relating pressure changes in the box with thoracic expansion and contraction to volume changes.[46-48]

LUNG VOLUMES

Static Lung Volumes

Definitions

The components of static lung volumes are illustrated in Figure 92-2. The classical definitions of relevance for lung function testing in neonates are as follows:

Residual volume: Volume of air remaining in the respiratory system at the end of maximum possible expiration.

Functional residual capacity: Volume of air in the respiratory system at the resting level at the end of a normal tidal volume expiration and which is in continuity with the airways. Lung volume at functional residual capacity (FRC) is maintained by the opposing forces of lung elastic recoil and chest wall elastic recoil.

Thoracic gas volume: The total amount of gas in the lung at end expiration; irrespective of whether or not the gas is in communication with the airways. In healthy infants without air trapping, FRC is equivalent to thoracic gas volume.

Expiratory reserve volume: Volume of air that is the difference between FRC and residual volume.

Total lung capacity: Volume of air that is in the respiratory system at the end of a maximum possible inspiration.

Functional Residual Capacity Measurement by Plethysmography

Whole-body plethysmography, first described by DuBois and colleagues in 1956, has been a standard modality for measurement of thoracic lung volume for many years.[49] From Boyle's law it is known that under isothermal conditions, the gas pressure in a closed rigid chamber is inversely proportional to the gas volume by a constant such that for initial and final conditions 1 and 2, respectively,

$$P_1V_1 = P_2V_2$$

For an infant placed in a rigid body plethysmograph and breathing against a momentarily occluded airway,

$$P_1V_1 = (P_1 + \Delta P)(V_1 + \Delta V)$$

where P_1 is initial mouth pressure, V_1 is the initial lung volume, and ΔP and ΔV are the resultant changes in pressure and volume from the respiratory efforts. For this measurement, the infant breathes through a facemask incorporating a remotely controlled shutter, a pneumotachometer to record flow, and a port for recording mouth pressure. When the occlusion is triggered at the end of a resting expiration, lung volume is at FRC, and because no airflow is present, mouth pressure equals

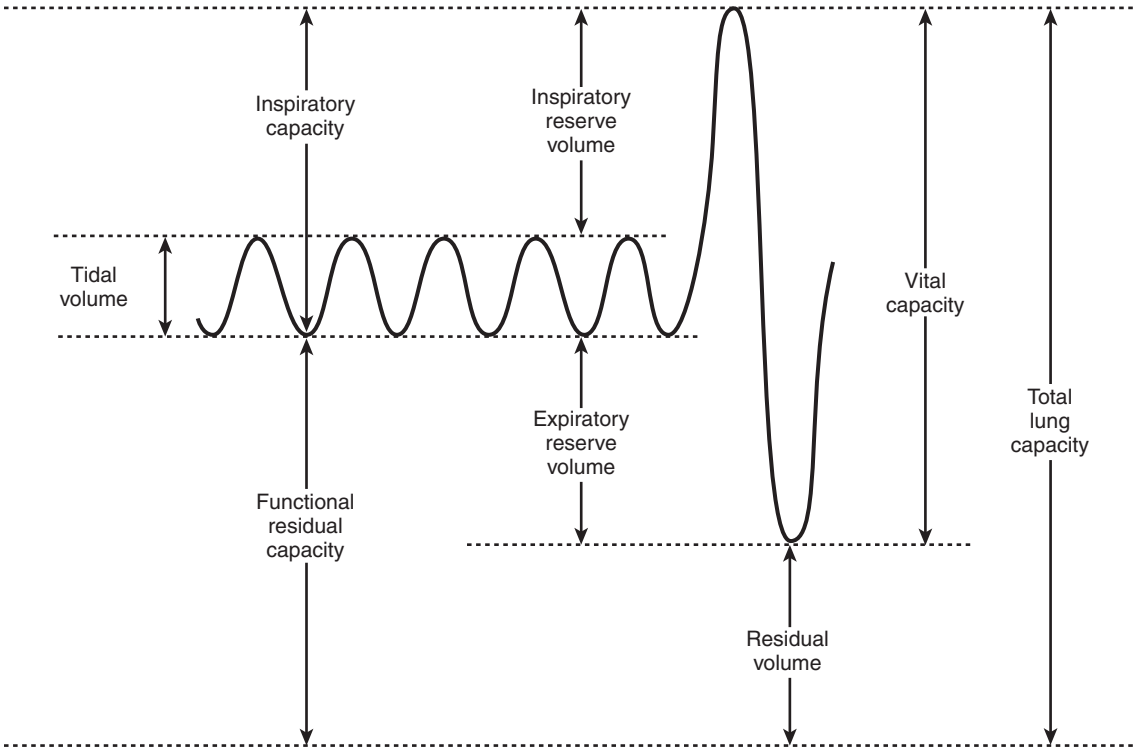

Figure 92-2 Static lung volumes.

alveolar pressure. As the infant breathes against the closed shutter, alveolar pressure changes owing to alternating gas compression and decompression are recorded, as are the concomitant changes in plethysmograph pressure, which are directly proportional to changes in alveolar volume. With appropriate corrections for temperature drift and apparatus dead space, as well as water vapor and body temperature and pressure saturated (BPTS) corrections, Boyle's law can be applied to solve for FRC. Of note, in contrast with tracer gas techniques, which measure only those volumes in communication with airways undergoing tidal ventilation, plethysmography measures total thoracic gas volume (TGV), including trapped air spaces in occluded airways.

Although several commercial infant body-box systems are now available,[50,51] whole-body plethysmography is not a practical technique for routine measurements in newborn infants in the intensive care nursery, and in particular infants receiving assisted ventilation. However, despite the complexities involved, the plethysmographic method has the advantage of allowing rapid repeat measurements within a period of only a few minutes. In addition, with proper BPTS conditioning of the respired gas, simultaneous measurement of airway resistance also is possible with whole-body plethysmography.[52]

Functional Residual Capacity Measurement by Helium Dilution

For measurement of FRC by helium dilution, the infant's airway is connected to a closed breathing circuit containing a known helium concentration (Figure 92-3). The connection to the closed breathing circuit is made at the end of a normal, restful expiration, and the infant then breathes from the circuit for 30 to 60 seconds, during which time the helium concentration is diluted to a lower value and measured.[53] If no helium is lost from the closed system, the amount of helium present before connection is equal to the amount after connection. The mass balance equation for helium is therefore

$$V_iC_i = (V_f + \text{FRC})\, C_f$$
$$\text{FRC} = V_iC_i / C_f - V_f$$

where

V_i = initial volume of the closed breathing circuit before patient connection
C_i = initial helium concentration in V_i
V_f = final volume of the closed breathing circuit after equilibration with the patient's FRC
C_f = final helium concentration in V_f + FRC

The volume V_f includes volume changes resulting from the patient's carbon dioxide production, oxygen consumption, and dead space in the patient connection. Carbon dioxide can be continuously removed from the system by passing the gas stream through carbon dioxide absorbent. To compensate for the patient's oxygen consumption, oxygen is gradually added to the breathing circuit to maintain a constant volume during the connection phase. In variations of the technique, the final system volume of the breathing circuit is measured directly.[54] Modifications of the rebreathing circuit have been used to measure FRC in mechanically ventilated infants.[55-57]

Technical Limitations

Sick infants with airway disease and poor distribution of ventilation have prolonged equilibration time and require long periods of rebreathing, which may lead to hypoxia and hypercapnia. Leaks around the endotracheal tube or face mask also are a frequent source of error, and methods have been developed that attempt to correct for this error.[58] To achieve maximum helium measurement accuracy, and to maximize the dilution effect, the total volume of the breathing circuit should be close to the approximate infant FRC[59,60]; this setting may be impractical, however, owing to the characteristically small lung volumes in premature and small infants. In addition, helium analyzers are not insensitive to other ventilatory gases, thereby potentially also affecting measurement accuracy.

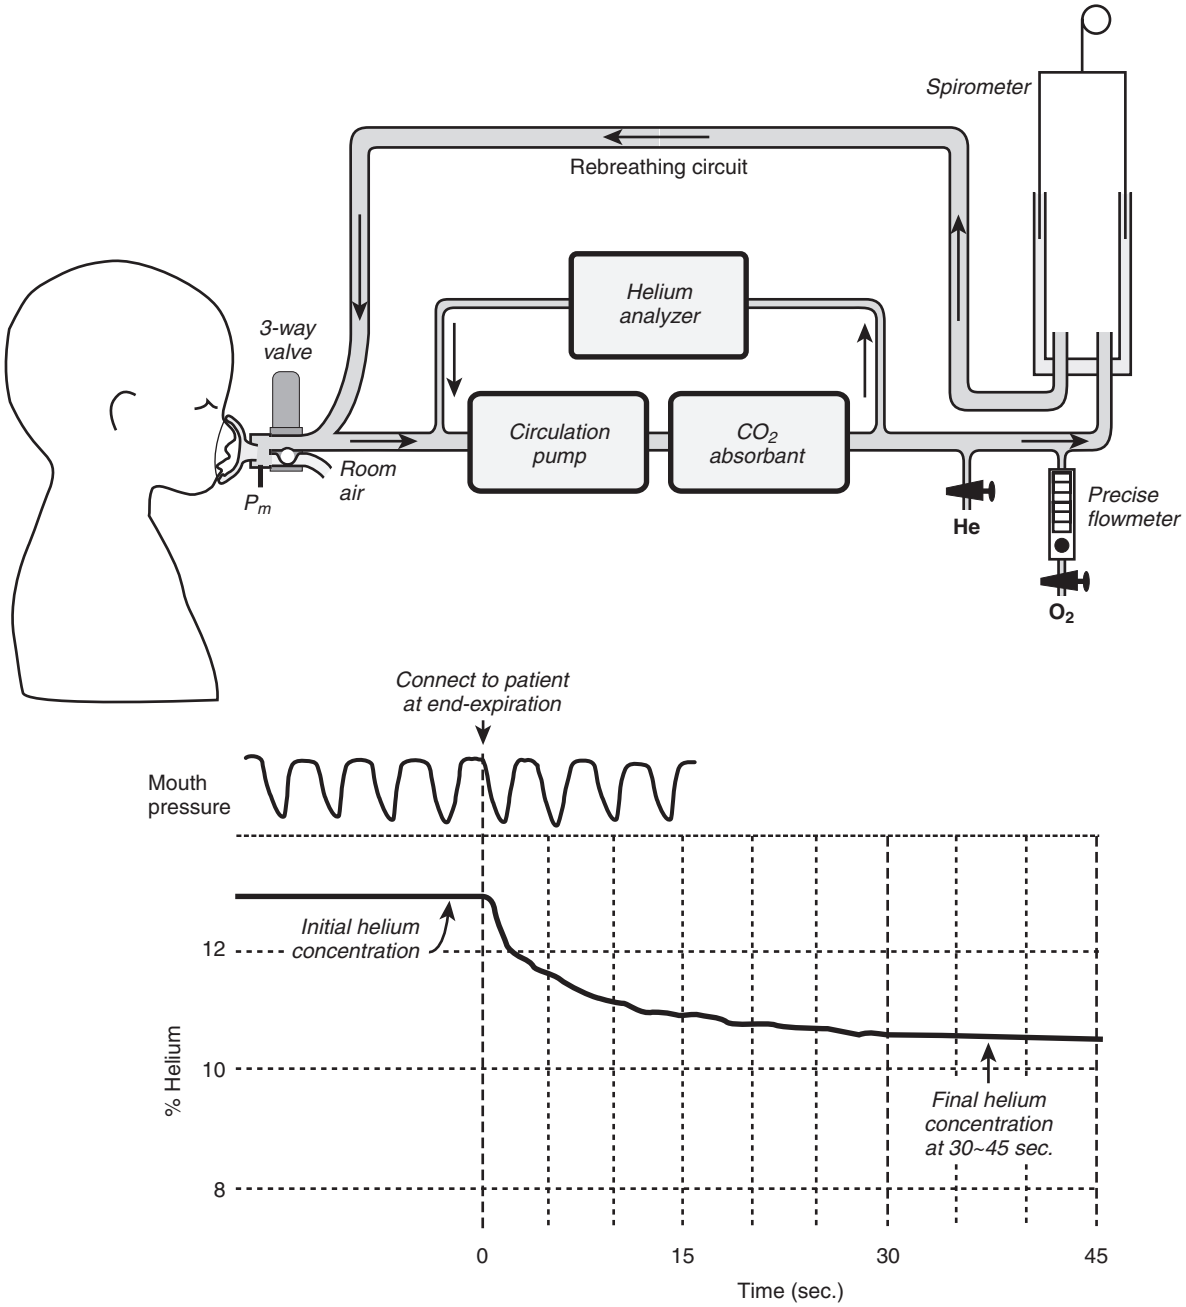

Figure 92-3 Determination of functional residual capacity (FRC) using helium dilution technique. Typical time course for helium concentration during FRC measurement.The mouth pressure signal is used to automatically switch a solenoid valve at end-expiration.

Functional Residual Capacity Measurement by Nitrogen Washout

FRC also can be determined by measurement of the total expired nitrogen "washed out" of the lungs while the infant breathes either 100% oxygen or an oxygen-helium mixture.The basic principle is described by the mass balance equation

$$\text{FRC} = V_{N2} / (C_{iN2} - C_{fN2})$$

where

V_{N2} = volume of nitrogen washed out

$C_{i\,N2}$ = initial, prewashout alveolar nitrogen fractional concentration (assumed to be 0.79)

$C_{f\,N2}$ = final, postwashout alveolar nitrogen fractional concentration (assumed to be 0.0)

The value V_{N2} can be obtained by measuring the nitrogen concentration of the entire expired volume, making this method impractical.Theoretically, V_{N2} could be calculated from the integration of the product of instantaneous flow (V') and the instantaneous nitrogen concentration (C_{N2}) signals over time:

$$V_{N2} = \int V'(t)\, C_{N2}(t)\, dt$$

For this method, known as the *multiple-breath nitrogen washout technique,* flow may be measured using a pneumotachometer. However, care must be taken to correct the flow for varying viscosity, temperature, and gas composition; most important, any phase lag between the flow and nitrogen concentration signals must be carefully synchronized.[61] Alternatively, to circumvent

these complexities, V_{N2} may instead be measured using a much-simplified method in which the infant breathes from a constant bias flow of 100% oxygen.[62] The expired gas is added to the bias flow, which is passed through a mixing chamber to produce an averaged nitrogen washout curve wherein the increase in flow during expiration is assumed to be equal to the decrease in flow during inspiration.[63] Thus the integrated nitrogen concentration signal is simply multiplied by the averaged bias flow (V'), which is treated as a constant in the following equation:

$$V_{N2} = V' \int C_{N2}(t)\, dt$$

The nitrogen washout technique has been widely implemented. When compared with the helium dilution technique, it was found to produce comparable estimates of FRC in infants and very young children.[64,65]

When compared with FRC determined by whole-body plethysmography in paired measurements, nitrogen washout FRC was consistently lower, the difference being larger for infants with BPD than for healthy infants.[66-69] This difference, previously attributed mainly to trapped gases in obstructed airways, recently has been reevaluated as possibly also attributable to methodologic factors.[70] The nitrogen washout technique also has been adapted for application in mechanically ventilated infants through use of a secondary washout ventilator.[71-73]

Technical Limitations

Breathing high oxygen concentration may result in hyperoxia or absorption atelectasis in areas of lung with low ventilation. To circumvent this problem, a helium-oxygen mixture has been used in place of 100% oxygen with favorable results.[74,75] In addition, accurate measurement of expired nitrogen in infants receiving inhaled oxygen greater than 70% is difficult owing to the very low levels of nitrogen present. And, as with the helium dilution method, the nitrogen washout technique is also prone to gas leakage errors.[76]

Functional Residual Capacity Measurement by Sulfur Hexafluoride Washout

An alternative washout technique that uses sulfur hexafluoride (SF_6) as the tracer gas can be used with either spontaneously breathing or ventilated infants on high oxygen concentrations.[77,78] For this technique, an SF_6 dispenser is connected to the inspiratory portion of the breathing circuit, and a low level of the inert gas SF_6 is washed into the lungs until a fixed alveolar level (usually less than 5%) is reached. The SF_6 dispenser is then switched off to initiate a washout period. A rapid-response SF_6 sensor in series with a flow sensor enables near-simultaneous calculation of the cumulative expired volume of SF_6. In a manner similar to the multiple-breath nitrogen washout method, FRC is determined from the breath-by-breath integration of the product of flow and C_{SF6}. In contrast with the nitrogen washout method, however, ventilator and Fio_2 settings need not be altered, and flow sensor accuracy is not compromised with significant changes in gas composition during the testing procedure. Moreover, unlike with the bias-flow nitrogen washout method, no additional ventilator or mixing chamber is needed. In contrast with the more conventional tracer gas techniques, infants on very high Fio_2 levels may be studied since oxygen levels up to 100%, as well as other ventilatory gases, have been shown to have negligible effect on the SF_6 analyzer accuracy.[79,80] More recently the SF_6 dispenser–flow sensor combination has been replaced by an ultrasonic flow meter capable of providing simultaneous measurements of airflow and SF_6 concentration in a single unit.[81-83]

The SF_6 washout method, as well the nitrogen multiple-breath washout method, also may be used for determination of ventilation distribution[84-86] and for estimation of trapped gas.[87] An alternative inert gas that is less expensive than SF_6 and is more widely accepted for clinical use is heptafluoropropane, whichalso has been tested and found to give reproducible results in FRC determinations in newborns.[86,88]

Dynamic Lung Volumes

Definitions

Tidal volume: Tidal volume (V_T) is defined as the volume of gas entering and leaving the respiratory tract with each breath. The volume varies with the activity of the baby.

Minute ventilation: Minute ventilation is defined as the total volume of gas expired over a period of one minute. Accurate measurement of tidal volume (no leak around endotracheal tube or face mask) and respiratory frequency (f_R) allows estimation of minute ventilation as: $V_T f_R$.

Measurement of dynamic lung volumes can be accomplished either directly by spirometry, pneumotachometry, or other flow sensing technology at the airway opening; or indirectly by one of the methods described earlier, such as induction plethysmography.

RESPIRATORY MECHANICS

Definitions

Compliance

Lungs, airways, and thorax are elastic; these tissues stretch due to changes in pressure during inspiration; when the pressure change ceases, the tissues return or recoil to their resting positions. The compliance of a closed elastic structure is defined as the change in volume resulting from a unit change in pressure (i.e., compliance = $\Delta V/\Delta P$).[89]

Static compliance: Static compliance is an accurate determinant of lung elastic properties only. It measures the change in volume for a given pressure during static, non-flow, conditions. A sufficient equilibration period is required to ensure that the actual static pressure change is recorded. Measurement of the systematic change in both pressure and volume during inflation and deflation allows a static pressure-volume curve of the lungs to be plotted. The curves that the lungs follow during inflation and deflation are different and are also influenced by surface tension and viscoelastic tissue resistances. This physical property of the lungs is known as hysteresis.

Dynamic compliance: Dynamic compliance is the determination of the change in volume and pressure during the respiratory cycle, either spontaneous breathing or mechanical ventilation, and is predominantly influenced by breathing frequency.[90,91] During rapid breathing, there may not be sufficient equilibration time to determine the actual change in pressure accurately.

Pulmonary compliance: Compliance of the lung only and as determined from measurement of transpulmonary pressure, that is, the difference between pleural and alveolar pressures. Under static conditions alveolar pressure is equivalent to airway pressure. Pleural pressure may be estimated from measurement of esophageal pressure.

Respiratory system compliance: Volume change of the entire respiratory system as related to the total driving pressure across the lungs and chest wall. During mechanical ventilation, the driving pressure is measured at the airway opening.

Chest wall compliance: Volume change related to the pressure across the chest wall, or trans-thoracic pressure. Transthoracic pressure may be measured as the difference between airway opening and pleural pressure. Alternatively, if the total compliance and lung compliance are known, the following

relationship may be used to calculate chest wall compliance (C_{cw}): total respiratory system elastance = elastance of the lungs + elastance of the chest wall, or terms of compliance:

$$1 / C_{rs} = 1 / C_L + 1 / C_{cw}$$

Specific compliance: Compliance normalized to the lung volume at which it is measured, usually at FRC, or compliance/FRC.

Resistance

Resistance is a frictional phenomenon that is due to the motion of both respiratory gases and tissues. Thus resistance is absent during static respiratory conditions. Tissue resistance is due to the viscoelastic properties of biologic tissues during respiratory movements. Airflow resistance is defined as the change in pressure associated with a unit change in flow of a gas through a conduit (i.e., resistance = $\Delta P/\Delta V'$) and is dependent on the length and diameter of the conduit, and the density and viscosity of the gas. The magnitude of airflow resistance also is dependent on the fluid dynamics of the air stream—for example, turbulent airflow will produce a greater resistance than laminar airflow. Respiratory airflow requires a driving pressure generated by changes in alveolar pressure. When alveolar pressure is less than or greater than atmospheric pressure, air flows into or out of the lungs accordingly, and the magnitude of this airflow is influenced by resistance.

Total resistance: The combined airway, lung tissue, and chest wall resistance of the respiratory system.

Pulmonary resistance: The pressure difference across the lung only—that is, transpulmonary pressure divided by the resultant airflow.

Airway resistance: Resistance of the airway alone, equal to the pressure gradient between alveolar and atmospheric pressure divided by the resulting airflow value. Airway resistance may be responsible for as much as 80% of the total pulmonary resistance in a normal lung and is influenced by the velocity and pattern of airflow, geometry of the airways, and the density or viscosity of the gas itself.

Tissue frictional resistance normally accounts for approximately 20% of the pulmonary resistance and is influenced by the configuration of the chest wall and the lung, as well as by the fluid content of the pulmonary tissue. Inertial resistance, which is less than 1% of pulmonary resistance, usually is more dependent on the breathing frequency and the density of the gas and typically is ignored within the normal range of breathing frequencies.[92,93]

Measurement of Respiratory Mechanics

Dynamic Pulmonary Mechanics

Pulmonary mechanics are calculated from measurements of transpulmonary pressure (the difference between the airway opening and pleural pressures) and flow and volume changes throughout the respiratory cycle. These are dynamic measurements obtained during either spontaneous breathing or mechanical ventilation. Airflow and volume are measured by pneumotachometry or other flow sensor technology as described previously. Pleural pressure can be estimated from esophageal pressure[94-96] measured by a pressure transducer connected to either an air-filled balloon[97,98] or a fluid-filled catheter,[99,100] or by a microtransducer–tipped catheter.[101] The accuracy of the esophageal pressure measurement can be evaluated by an occlusion test.[102-104]

The calculations of compliance and resistance are based on the assumption of a linear model.[3] Thus the driving pressure is always equal to the sum of the elastic and resistive pressures (see Figure 92-1). The calculations may be performed by the Mead-Whittenberger analysis, as shown in Figure 92-4, or by any of several computerized techniques such as least mean squares (LMS) analysis.[105-108]

Technical Limitations

Reliable esophageal pressure measurement by esophageal balloon catheter depends on proper size, positioning, and inflation of the balloon. Water-filled catheters need to be free of gas bubbles and have no accumulation of secretions at the tip. Placement of catheters may generate peristalsis, resulting in an initial pressure drift. Because measured esophageal pressure reflects pleural pressure only at a specific location, its accuracy depends on assuming that the pressure change at the site represents mean pleural pressure changes.[109] Altered patterns of inspiratory muscle contraction or esophageal muscle tone and distortion of the chest wall may potentially result in uneven pleural pressure distribution.[103,110,111]

Accuracy of measurements also is dependent on body position. Measurements should be done with the patient in supine neutral head position, and only during quiet sleep. Flexion or extension of the neck in small infants can affect the airflow resistance.[112] Feeding volume also may affect the measurements and should be standardized in repeated studies.[113,114] In mechanically ventilated infants, the ventilatory support should be kept the same during sequential studies to prevent shifting of the tidal volume to a different portion of the volume-pressure curve.

Commercially available equipment may exhibit variable frequency response, phase shift errors between signals, and drifting calibration values. Testing of such equipment with a calibrated lung simulator before clinical use will ensure accuracy at the expected infant tidal volumes and frequencies.[16]

Passive Respiratory Mechanics: Occlusion Techniques

Passive occlusion techniques constitute a relatively noninvasive method for determining total respiratory system compliance (C_{rs}), resistance (R_{rs}), and time constant (τ_{rs}) and therefore do not require measurement of esophageal pressure. These passive techniques rely on the Hering-Breuer inflation reflex[115-117] to relax both the inspiratory and expiratory respiratory muscles during an expiratory occlusion. Under the resultant condition of complete expiratory relaxation, driving pressure is zero, and the airway opening pressure comes into equilibrium with alveolar pressure.[118,119]

Multiple Occlusion Technique

A series of brief expiratory airway occlusions are performed on multiple spontaneous breaths. During each occlusion the elastic recoil pressure measured at the airway opening (P_{ao}) reaches a plateau as it equilibrates with alveolar pressure. An occlusion is repeated at each of several different volume points on separate breaths and over the first two thirds of expiration. A volume-versus-pressure plot is constructed from the resultant measurement pairs, and the slope of the linear regression fit through these points gives the C_{rs}.

Single-Breath Occlusion Technique

A single end-inspiratory occlusion is performed to invoke the Hering-Breuer inflation reflex to induce relaxation of the respiratory muscles during both the occlusion and the post-occlusion passive expiration. Elastic recoil pressure is measured during the occlusion and a passive flow-volume loop is recorded during the post-occlusion relaxed expiration (Figure 92-5). The reciprocal of the slope of the linear portion of the expiratory flow-volume relationship gives the passive expiratory time constant ($\tau_{rs} = \Delta V/\Delta V' = C_{rs}\, R_{rs}$). Extrapolation of this line to the zero flow point, that is, the elastic equilibrium volume (V_{EEV}), and the volume at start of occlusion (V_0), allows estimation of the occluded volume above the V_{EEV}. Knowing the relaxed plateau pressure, P_{ao}, during zero flow allows estimation of compliance as $C_{rs} = (V_0 - V_{EEV})/P_{ao}$ and resistance as $R_{rs} = \tau_{rs}/C_{rs}$.

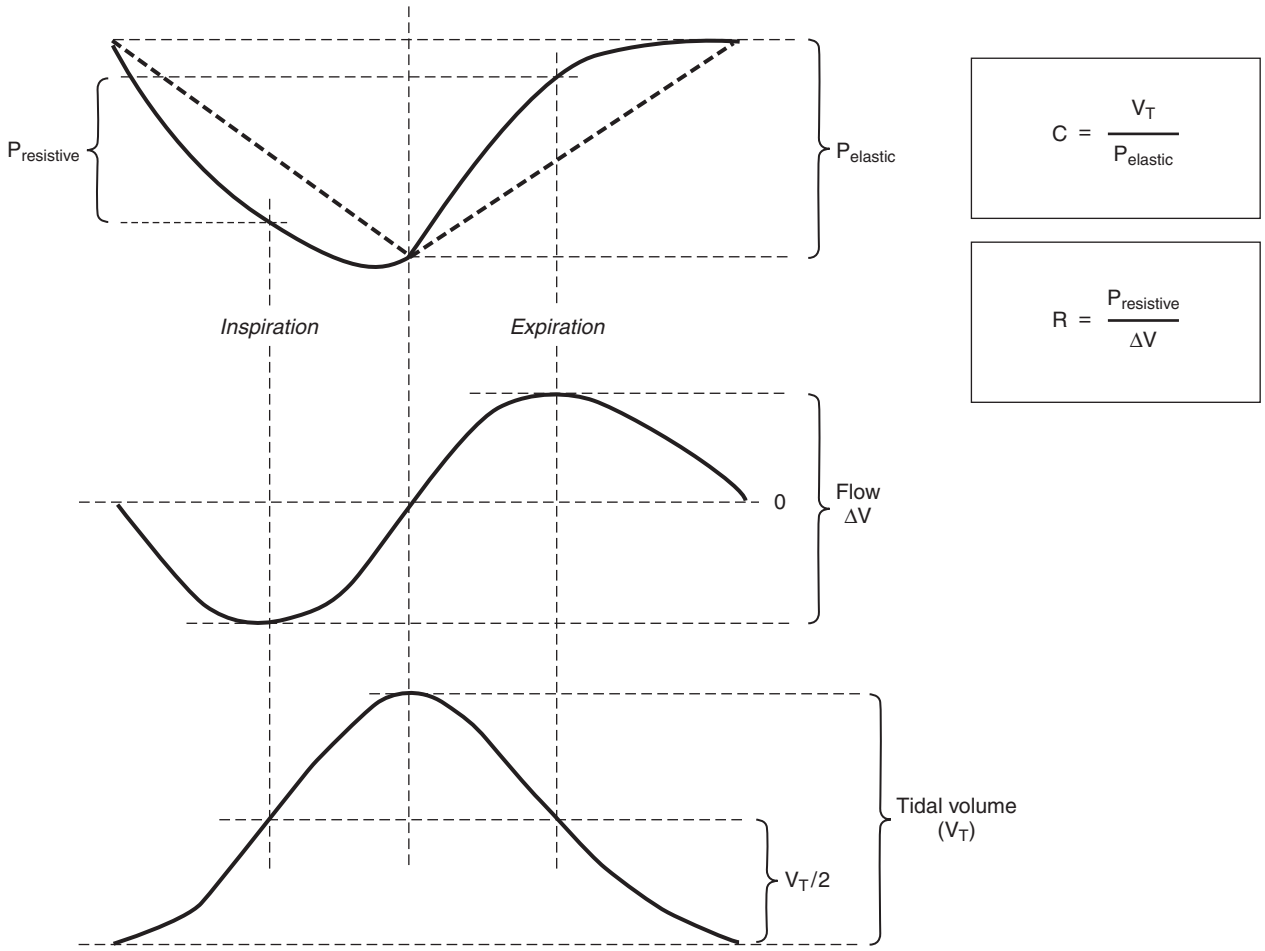

Figure 92-4 Determination of pulmonary mechanics by analysis of pressure, airflow, and volume signals using the Mead-Whittenberger method.

AIRWAY MECHANICS

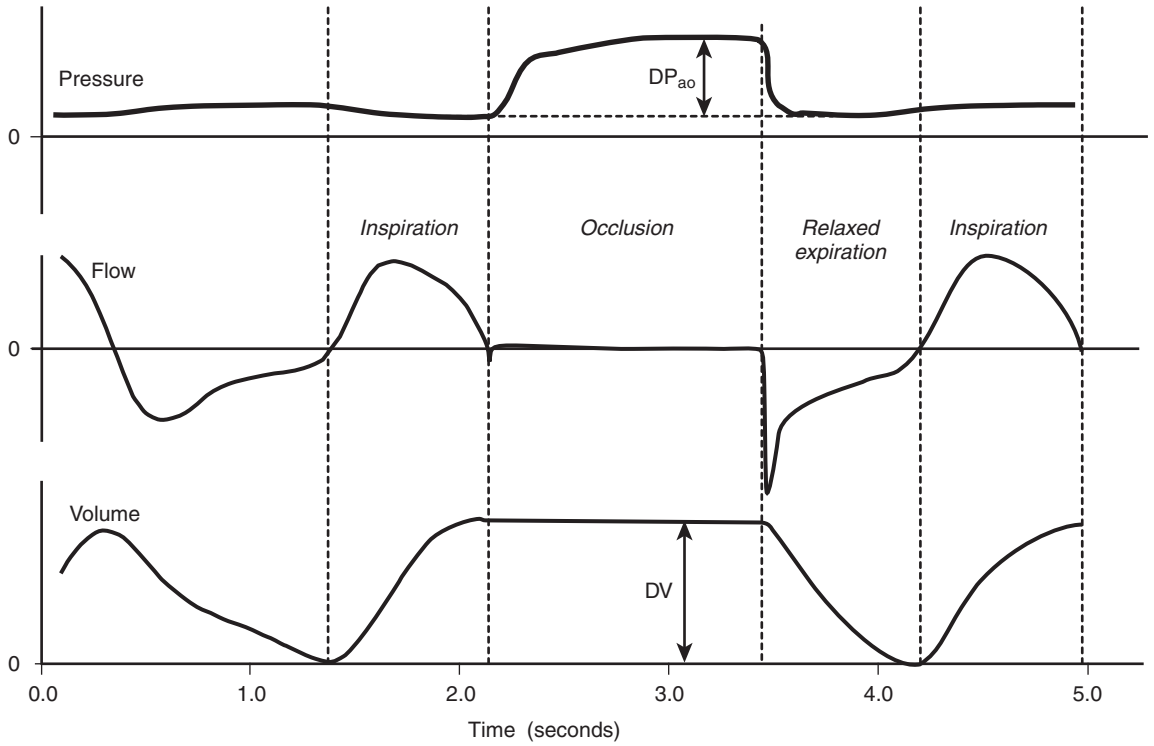
The tone of tracheobronchial smooth muscle provides a mechanism to stabilize the airways and prevent airway collapse.[120] Plugging of the airways, edema, and weakening of the airway walls and the resulting tracheobronchomalacia alter airflow.[121-123] In addition, the increased driving pressure secondary to the high elastic and resistive loads during tidal breathing in infants with bronchopulmonary dysplasia often leads to self-induced expiratory flow limitation.

Measurement

Resistance to airflow is measured by calculation of pulmonary mechanics, as described. It also can be evaluated by the tidal flow-volume relationship obtained using a forced expiratory flow generated by rapid thoracic compression.

Forced Expiratory Flow

Forced expiration commonly is used to detect obstructive lung disease by determining the lung volume at which small airways begin to close. During expiration, flow is limited by airway compression, which in turn is determined by the elastic recoil of the lung, the resistance of the airway, and airway wall mechanics. In infants, forced expiratory flow is generated by rapid thoracic compression, or negative-pressure forced deflation. Rapid thoracic compression is preferred as a noninvasive technique that does not require intubation, paralysis, or deep sedation to generate a partial expiratory flow-volume (PEFV) loop. Parameters that are used to characterize PEFV include peak expiratory flow, forced expiratory flow at functional residual capacity (V'_{max} FRC), and the shape of the expiratory flow curve[124-127] (Figure 92-6).



Technical Limitations

This technique generates only a partial rather than a complete flow-volume loop, which limits the evaluation of true flow limitation in response to the appropriate compression pressure for a particular infant. The main limitation is the variability of FRC in young infants, because inspiration may start before the completion of a full expiration.

NORMAL VALUES

Normal values for pulmonary function parameters are essential for meaningful clinical interpretation. In adults, these values have been predicted on the basis of age, gender, and relationship to height and weight, as well as race and ethnic background. Similar data for neonates have not yet been established. Values for normal term babies, obtained by different techniques, are presented in Table 92-1. Preterm neonates who are considered normal and who have not received mechanical ventilatory support[128-130] are infrequently encountered in clinical practice; the data for such infants also are summarized in Table 92-1.

Any comparison of values needs to take into account the study population and the conditions that affect the measurements such as body and neck posture, feeding, and sleep state.

REAL-TIME PULMONARY GRAPHICS MONITORING

The addition of pneumotachometers and waveform graphics to the latest generation of infant ventilators provides clinicians with respiratory function information that previously was available only with specialized instrumentation requiring specifically trained operators and frequent calibration. These dedicated bedside instruments at best sampled only a few minutes' worth of data, as opposed to continuous monitoring; serial repeat measurements were therefore needed to observe the effect on pulmonary function resulting from changes in ventilator settings or other therapies. The newer graphics-based ventilators make use of improved sensor and microprocessing technology to provide continuous real-time display of the fundamental measurable parameters of respiration—namely, the pressure, flow, and volume signals. These signals may be displayed as waveforms along a time axis or as plots of *x-y* relationships such as volume-versus-pressure and flow-versus-volume loops. In addition to graphic display, measurements from the three signals are used to calculate a limited set of respiratory function data.

Volume-Pressure Loops

A volume-pressure loop is an *x-y* plot of tidal volume as a function of airway pressure. Figure 92-7, *A,* illustrates a volume-pressure loop from a mechanically ventilated neonate. The loop represents

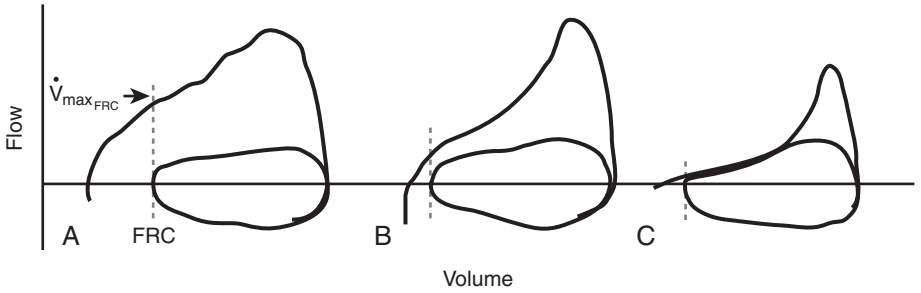

Figure 92-6 Schematics of partial forced expiratory flow relationship: Infants with normal expiratory flow, moderate flow restriction (partial limitation), and severe chronic lung disease (CLD).

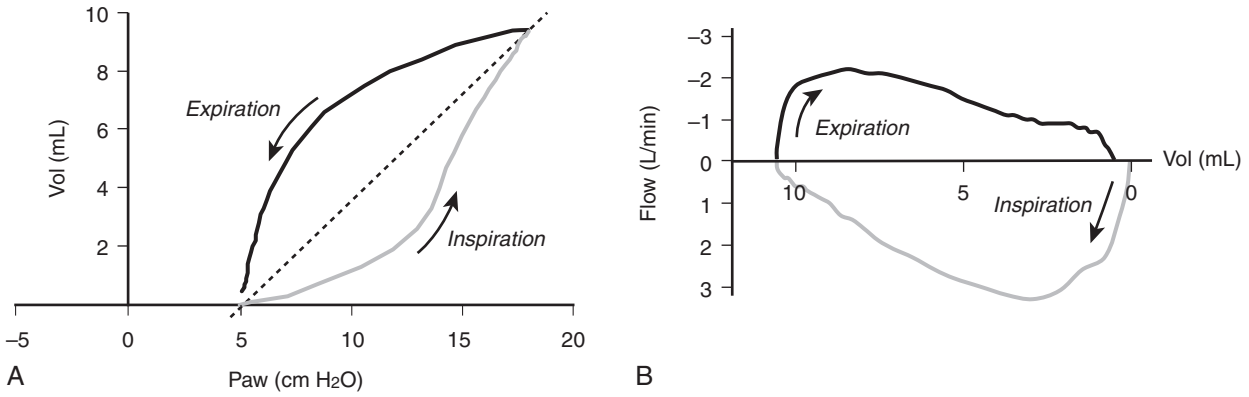

Figure 92-7 Schematic of a typical infant ventilator graphics display for a single breath. **A,** Volume-pressure loop. **B,** Flow-volume loop.

a single breath and is plotted in a counterclockwise direction as the breath progresses from inspiration to expiration. The slope of the dotted line, connecting the zero flow points at end-expiration and end-inspiration, is a good estimate of the overall elasticity or dynamic respiratory system compliance, defined as the ratio of tidal volume to driving pressure, or V_T(PIP − PEEP). Tilting of the loop toward the horizontal or toward the vertical is indicative of either decreased or increased compliance, respectively (Figure 92-8, *A*). Of note, the volume-pressure relationship follows a different course during expiration from that during inspiration. The resulting hysteresis, depicted as the area within the loop, is due to resistive pressures. Increased inspiratory or expiratory resistive work expands the hysteresis to the right or left, respectively (see Figure 92-8, *B*).

Volume-pressure loops are useful in clinical practice for detection of ventilatory overdistention, evidenced by the "beaking" effect as illustrated in Figure 92-8, *C.* In this breath, the compliance of the flattened area within the final 20% of the inspiratory limb (C_{20}) is less than the dynamic compliance of the entire breath (C_{dyn}). It has been suggested that a C_{20}-C_{dyn} ratio less than 0.8 may be an indicator of lung overdistention.[142] Any further pressure increase in the flattened portion of the volume-pressure loop produces negligible volume change, and a small decrease in PIP may be used to reduce overdistention while maintaining the same tidal volume (see Figure 92-8, *D*).

Another abnormality easily detected from observation of the volume-pressure loop is lung atelectasis (see Figure 92-8, *E*), evidenced by a prolonged period of negligible volume recruitment at the start of inspiration. Figure 92-8, *F*, illustrates how an increase in PEEP may be used to shift the FRC upward along the lung's sigmoidal volume-pressure characteristic to a point above the critical opening pressure, thereby preventing alveolar collapse at end-expiration.[143-145] The volume-pressure loop also is useful for detecting other ventilatory abnormalities such as endotracheal tube leaks and air trapping, both of which result in incomplete closure of the graphical volume-pressure loop during end of expiration.

Flow-Volume Loops

A flow-volume loop is a plot of airflow versus tidal volume, as illustrated in Figure 92-7, *B*, which also shows the corresponding volume-pressure loop from the same mechanically ventilated breath. Each loop represents one breath as it progresses downward with inspiration to an upward expiration in a clockwise direction (of note, the direction and orientation may vary among ventilators and monitors from different manufacturers). The tidal flow-volume loop is useful for evaluating changes in inspiratory and expiratory airflow-to-volume response during tidal breathing. In addition to determination of the peak flow values, the patterns of airflow and tidal volumes indicative of turbulence or obstructive flow limitation also may be evaluated.[146-150] A typical flow-volume loop for a healthy newborn infant is shown in Figure 92-9, *A.* Preterm neonates with high chest wall compliance and greater expiratory airway collapsibility, as well as babies with CLD, typically will show an early peak expiratory flow followed by a concave profile (see Figure 92-9, *B*).[151-154] Other loop shapes that are characteristic of intrathoracic and extrathoracic flow limitation are shown in Figure 92-9, *C* to *F*.

CLINICAL APPLICATIONS

The clinical usefulness of neonatal pulmonary function testing is that the functional parameters define the magnitude and pattern of respiratory compromise. Individual disease processes are not differentiated by pulmonary function data. Infants with hyaline membrane disease, pulmonary edema, or pneumonia have low lung compliance, whereas infants with increased airway resistance may have an obstructive disease process such as meconium aspiration syndrome or bronchopulmonary dysplasia. However, pulmonary function data can be used to determine the severity of the pathologic condition, its resolution, and the effect of treatment.

The continuous real-time dynamic time flow-volume and volume-pressure loops and scalar tracings data, along with measurement of lung mechanics, can be used to assist in management of ventilatory support. Potentially useful measures and strategies include adjustment of tidal volume to prevent overdistention,[155,156] determination of optimal inspiratory time,[157] estimation of optimal end-distending pressure, assessment of the appropriateness of manual ventilation,[158] testing for airways reactivity,[159,160] and evaluation of the effect of therapeutic interventions.[161-168]

The serial evaluation of pulmonary outcome in the immediate postnatal period[169,170] and during infancy[171-174] provides the information necessary for detection of the late-onset complications or for resolution of the acute lung injury and adjustment of the treatment.

93 Pathophysiology of Hyaline Membrane Disease (Excluding Surfactant)

Robert B. Cotton

Hyaline membrane disease is a disorder of newborn premature infants that is characterized by respiratory failure beginning at birth. Unless modified by surfactant treatment, the disease progresses to maximal severity by 24 to 48 hours after birth. Almost all of the 5% to 10% mortality associated with hyaline membrane disease is limited to extremely immature infants weighing less than 1000 g at birth. Of those who survive the initial course of acute respiratory failure, 15% to 30% experience a prolonged course of ventilatory failure known as *bronchopulmonary dysplasia* or *chronic lung disease of prematurity,* which may last months or longer and occasionally ends in death. Figure 93-1 illustrates the strong influence of birth weight on the outcome of hyaline membrane disease.

The clinical course of hyaline membrane disease has changed remarkably since the introduction of surfactant replacement therapy on a routine basis in the early 1990s. With surfactant therapy, oxygen and airway pressure requirements during the classic 3- to 5-day course of respiratory failure have been markedly attenuated. In extremely-low-birth-weight infants, the transition in clinical findings from one of respiratory insufficiency due to inadequate surfactant to one of respiratory insufficiency due to continuing lung injury of the immature lung resulting from oxygen therapy, mechanical ventilation, and inflammatory processes may not be obvious.

Hyaline membrane disease, respiratory distress syndrome, and idiopathic respiratory distress syndrome are interchangeable labels for the same disease. By calling attention to an important histopathologic feature of the disorder, the term *hyaline membrane disease* is a useful reminder that its pathogenesis includes destruction of terminal airway epithelium. This finding is not seen in the various syndromes of transient respiratory distress, which largely have run their course by 24 to 48 hours after birth. *Respiratory distress syndrome* is the most commonly encountered label for this disease.

The stage was set for our current understanding of the pathophysiology of hyaline membrane disease by investigations in the 1950s and 1960s that described the disease based on classic models of pulmonary function. It was also during this era that the role of persistent fetal circulatory pathways in hyaline membrane disease was discovered. Further understanding of the mechanisms underlying impaired gas exchange during hyaline membrane disease came in the 1970s, as investigators sought to explain the spectacular success of constant distending airway pressure on oxygenation and survival. In the 1980s, conclusive demonstrations of the efficacy of surfactant replacement validated the idea put forth by Avery and Meade[1] in 1959 that "lack of a normal lining material in the lungs of infants would contribute to the atelectasis seen in hyaline membrane disease."

This chapter describes the mechanisms involved that underlie the clinical manifestations of hyaline membrane disease. In regard to surfactant, this chapter limits the discussion to the major pathophysiologic consequences of deficiency of this material. The biochemistry of surfactant, mechanisms governing its production, release, and action, and issues surrounding its use in prevention and treatment of hyaline membrane disease are discussed elsewhere in this volume.

PATHOLOGY

Total lung volume is not decreased in hyaline membrane disease. Postmortem examination of human infants dying during the acute phase of this disorder reveals lungs that are described as full[2] or even voluminous.[3] They are often compared with liver to emphasize their appearance as a solid, airless organ that is congested and dark purplish red. Microscopic examination reveals marked capillary and venous congestion. Interstitial edema is widespread and is especially prominent in the adventitia surrounding small arterioles, which are markedly constricted early in the disease. Dilated lymphatic spaces are frequently seen adjacent to respiratory bronchioles and arterioles. Hyaline membrane formation, which represents a coagulum of sloughed cell debris in a protein matrix, occurs characteristically at the junction of respiratory bronchioles and alveolar ducts. Hyaline membranes are visible evidence that this disease involves a massive exudation of plasma proteins occurring in association with a destructive injury of the epithelial lining of the terminal conducting airways. The fully formed membrane often has the appearance of an eschar plastered against the denuded epithelial basement membrane. The respiratory bronchioles and alveolar ducts are frequently dilated and may be filled with protein-rich edema fluid in association with membrane formation early in the course of the disease.

The pathologic appearance of the lung of infants dying early in the course of hyaline membrane disease presents a picture of lung injury characterized by vascular engorgement and

interstitial edema in association with terminal airways filled with protein-containing fluid. These features are consistent with physiologic findings that include delayed clearance of fetal lung liquid,[4-7] increased permeability of both epithelial[4,8,9] and endothelial barriers,[6] delayed lung lymph protein clearance,[5,6] and a grossly increased pulmonary blood volume.[10] These physiologic observations confirm that the pathologic appearance of the lung in hyaline membrane disease results from disruption of the normal segregation of gas and liquid compartments.

LUNG INJURY AND PERMEABILITY PROBLEMS

In the presence of hyaline membrane disease, total lung water, which includes water in the airways and vascular spaces as well as interstitial and intracellular water, is increased almost 50% in premature lambs. When compared with control animals, lambs with hyaline membrane disease have more than twice as much extravascular water and 50% more intravascular blood volume (Figure 93-2).[10] The increased extravascular water represents both delayed clearance of fetal lung liquid and an accumulation of water resulting from increased transvascular filtration of fluid across the pulmonary capillary bed. The marked increase in lung lymph protein clearance, the appearance of proteinaceous edema fluid within the terminal conducting airways, and the subsequent widespread development of hyaline membranes signify the escape of protein as well as water from the microvascular circulation in a process involving increased vascular permeability.[6]

Permeability of the epithelial lining of terminal airways is also increased in hyaline membrane disease.[4,8,9] A large bidirectional protein flux can be demonstrated between the airways and circulation of prematurely delivered lambs,[9] a finding consistent with the microscopic findings of widespread destruction of terminal airway epithelium at the respiratory bronchioles and alveolar ducts that leaves only the basement membrane as a barrier between air space and interstitium. Surfactant deficiency and ischemia are two mechanisms that contribute to this injury.

Surfactant Deficiency

Evidence indicates that *surfactant deficiency* per se is responsible for the epithelial lesion of hyaline membrane disease. Endotracheal surfactant treatment of premature newborn rabbits before positive pressure ventilation prevents the widespread necrosis and desquamation of bronchiolar epithelium seen in untreated littermates.[11] In the presence of inadequate surfactant at gas-liquid interfaces, the high pressure required to overcome surface tension forces in terminal conducting airways leads to epithelial injury and necrosis. The respiratory bronchioles and alveolar ducts are poorly supported structures in the immature lung and, under these conditions, are particularly susceptible to disruption as a result of overdistention. Based on comparisons between surfactant-deficient rabbits ventilated with conventional mechanical ventilation and those receiving high-frequency ventilation, the degree of epithelial damage appears to be related to the magnitude of pressure swings, rather than mean pressure within the airways.[12] In addition, surfactant deficiency and accompanying high surface tensions at gas-liquid interfaces in terminal conducting airways may cause hydrostatic pressure gradients that interfere with the expedient disposal of fetal lung liquid or promote interstitial accumulation of edema fluid filtered from the microvascular circulation.

Injury to the terminal airway units induced by mechanical ventilation of the surfactant deficient lung can involve several mechanisms. High airway pressure, distention of terminal airways, repeated lung collapse and re-expansion, and the inflammatory process that is evoked by the injury itself all contribute to lung damage.[13-15] The extent of this injury that occurs with hyaline membrane disease in the early neonatal period is a significant predictor of the severity of chronic lung disease (bronchopulmonary dysplasia) that occurs as a long-term complication of this disorder.

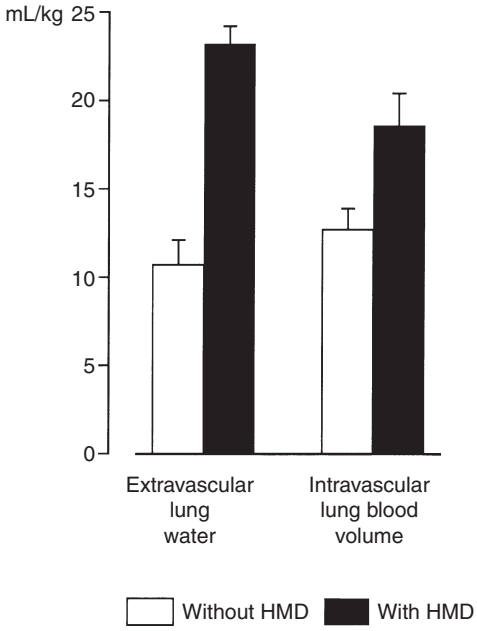

Figure 93-2 Extravascular lung water and intravascular lung blood volume measured in premature lambs with hyaline membrane disease using a multiple indicator dilution method. *(Data from Sundell HW, Harris TR, Cannon JR, et al: Lung water and vascular permeability-surface area in premature newborn lambs with hyaline membrane disease,* Circ Res *60:923-932, 1987.)*

Ischemic Damage

Under some circumstances the pathologic lesion of hyaline membrane disease may represent *ischemic necrosis* of the epithelial lining of terminal airways at the junctions of respiratory bronchioles and alveolar ducts. Both experimental and epidemiologic findings link acute asphyxia to the incidence and severity of this disease. Occasionally hyaline membrane disease occurs in the near-term infant with a mature amniotic fluid lecithin-sphingomyelin ratio. Similarly, premature infants with immature lecithin-sphingomyelin ratios do not always have hyaline membrane disease. Infants with a prolapsed umbilical cord, bleeding placenta previa, or placental abruption have an increased incidence of hyaline membrane disease. Incidence and severity of the disease are increased in the second-born twin. These factors point to the possible role of acute perinatal stress in the pathogenesis of hyaline membrane disease. Moreover, the tightly constricted arteriole characteristically adjacent to a respiratory bronchiole that is undergoing epithelial slough provides histopathologic evidence that ischemia may be involved in a process in which surfactant deficiency may be a secondary consequence of injury and necrosis of the epithelial lining.[16]

PERSISTENT FETAL VASCULAR PATHWAYS

During the 1950s many investigators considered hyaline membrane disease to be the result of left ventricular failure and pulmonary congestion caused by left-to-right shunting through the ductus arteriosus.[17-19] The presence of this shunt during the course of hyaline membrane disease, suspected on the basis of physical and radiographic findings, was confirmed by indicator dilution studies.[20,21] In 1960, Dr. Clement Smith[22] stated, "Although the primary cause [of hyaline membrane disease]

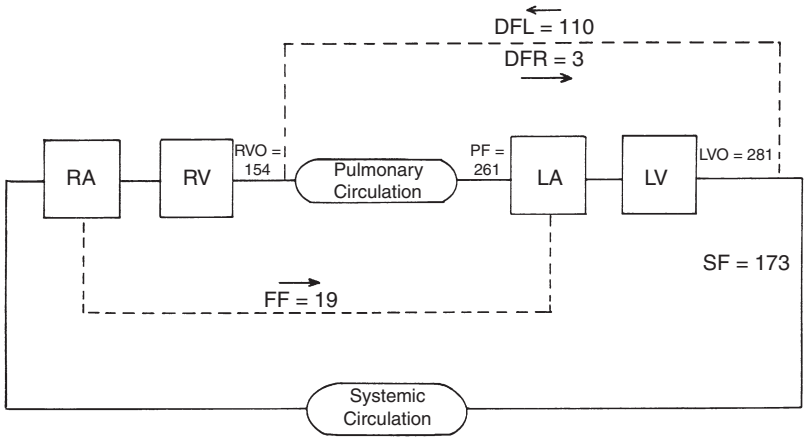

Figure 93-3 Mean values for components of cardiac output in 10 premature lambs with hyaline membrane disease. Flows are expressed as mL/kg/min. *DFL* and *DFR,* Left-to-right and right-to-left flow through the ductus arteriosus; *FF,* right-to-left flow across the foramen ovale; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle; *SF,* systemic flow. *(From Cotton RB, Lindstom DP, Kanarek KS, Sundell H, Stahlman MT. Quantitation of cardiac output components in the presence of bidirectional shunts,* J Appl Physiol *43:352-356, 1977.)*

may be elsewhere, we continue to think that circulatory factors lie somewhere near the center of this puzzling and important problem."

During the acute phase of hyaline membrane disease, traditional clinical signs of a patent ductus arteriosus such as prominent murmur and precordial hyperactivity are usually absent. Nevertheless, left-to-right ductus shunting can be demonstrated in this setting by indicator dilution studies[21] or by Doppler ultrasound examinations[23,24] in most, if not all, newborn infants with hyaline membrane disease. A quantitative description of flows at different sites in the central circulation during hyaline membrane disease is shown in Figure 93-3.[25] In this composite example, which is based on studies of newborn premature lambs with the disease, 39% of left ventricular output is diverted back across the ductus and is recirculated through the pulmonary vascular bed. Figure 93-3 also illustrates the possibility of simultaneous right-to-left shunting across the foramen ovale. In fact, bidirectional shunting (right-to-left at the foramen ovale and left-to-right at the ductus arteriosus) is probably not uncommon in infants making strong respiratory efforts. Right-to-left flow across the foramen ovale is thought to occur during the inspiratory phase of spontaneous ventilation. When the infant with hyaline membrane disease makes vigorous inspiratory efforts against poorly compliant lungs, intrathoracic negative pressure deflections are created that promote blood flow from the inferior vena cava across the foramen ovale into the left atrium.[26]

The lungs of infants with hyaline membrane disease are characteristically fluid laden for reasons described earlier in this section. As discussed later, hypoxemia occurs in large part because of venous admixture resulting from right-to-left shunts through terminal airway units that are fluid filled or collapsed. The problem of fluid and protein accumulation by the lungs is further exacerbated by left-to-right ductus shunting.[9] In the past some investigators considered that the clinical expression of hyaline membrane disease in extremely immature infants was dominated by the consequences of left-to-right ductus shunting, rather than by surfactant deficiency.[27]

MECHANISMS OF HYPOXEMIA IN HYALINE MEMBRANE DISEASE

The principal mechanism of *hypoxemia* in hyaline membrane disease is venous admixture resulting from both intrapulmonary shunting and right-to-left shunting across the foramen ovale. When hyaline membrane disease is complicated by pulmonary vasoconstriction, right-to-left shunting may also occur across an open ductus arteriosus. Venous admixture is quantified by assuming that the oxygen content of arterial blood is the result of adding venous blood to blood equilibrated with alveolar gas. Venous admixture, an expression of the percentage of this mixture made up of venous blood, can be derived from the standard shunt equation:

$$VA(\%) = (CcO_2 - CaO_2)/(Cc'O_2 - CvO_2) \times 100$$

where VA = venous admixture, $Cc'o_2$ = the end-pulmonary capillary blood oxygen content, Cao_2 = the arterial blood oxygen content, and Cvo_2 = the mixed venous blood oxygen content.[28] Figure 93-4 shows how arterial partial pressure of oxygen (Pao_2) responds to changes in the fraction of inspired oxygen (Fio_2) at selected amounts of venous admixture.[29] When venous admixture is less than 40%, increasing the Fio_2 will usually result in an adequate Pao_2. When venous admixture is 50% or more, increasing Fio_2 from room air to 1.0 increases Pao_2 by only a few millimeters of mercury, and adequate oxygenation is not achieved.

Intrapulmonary Shunting

In hyaline membrane disease, intrapulmonary venous admixture occurs largely as a result of the perfusion of terminal airways that are partially collapsed, collapsed, or fluid filled. For the most part these terminal airways are either extremely underventilated or not ventilated at all as a result of epithelial slough, exudation, and hyaline membrane formation at the junction of the respiratory bronchioles and alveolar ducts. Based on studies of alveolar-arterial gradients of nitrogen and carbon dioxide, the lung in hyaline membrane disease can be modeled as comprising three compartments.[30,31] One compartment is made up of terminal gas exchange units that are intact and are adequately ventilated and perfused. The second compartment is characterized by terminal airways that are open but markedly underventilated; these units may be perfused, but only if local alveolar hypoxia can be relieved by breathing 100% oxygen. The third compartment is totally unventilated but may be perfused. It includes those units with terminal conducting airways that are severely affected by epithelial damage, exudate, and slough. In addition, this compartment also represents any present anatomic right-to-left shunt.[32]

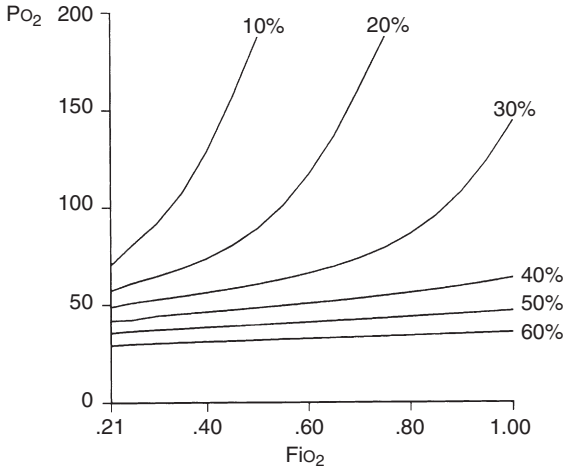

Figure 93-4 Arterial oxygen pressure (P_{O_2}) response to changes in the fraction of inspired oxygen (F_{IO_2}) at selected amounts of venous admixture between 10% and 60%. *(Data obtained using computer software provided by Daniel P. Lindstrom and Torsten Olsson.)*

Extrapulmonary Shunting

A complex but predictable pattern of shunting through persistent fetal circulatory pathways evolves during the natural course of hyaline membrane disease.[21] During the first 12 hours after birth, the predominant shunt is from right to left, from the inferior vena cava across the foramen ovale into the left atrium. Even though the ductus is widely patent, there is little flow through it in either direction until after 12 to 24 hours of age, when a left-to-right shunt of increasing magnitude occurs as a result of falling pulmonary vascular resistance. In some cases pulmonary vascular resistance remains high beyond the immediate period after birth and may lead to severe hypoxemia, especially in the presence of hypercarbia, acidosis, or severe systemic hypotension. Low-dose inhaled nitric oxide has been shown to improve oxygenation in such infants by either decreasing pulmonary vascular resistance and extrapulmonary shunting or by improving ventilation-perfusion matching. However, overall survival is not improved in these infants.[33]

PULMONARY FUNCTION IN HYALINE MEMBRANE DISEASE

Functional Residual Capacity

Functional residual capacity (FRC) is decreased in hyaline membrane disease.[34-38] In newborn infants without lung disease, FRC is approximately 30 mL/kg,[35,38] a volume coinciding with the volume of fetal lung liquid present in the airways before birth.[39] Loss of FRC occurs in hyaline membrane disease as a result of surfactant deficiency and displacement of gas volume by pulmonary vascular congestion, interstitial edema, and airway flooding with proteinaceous fluid.

During the course of hyaline membrane disease FRC is influenced by numerous factors including the patient's spontaneous ventilatory effort, the stability of the chest wall, and the patient's ability to muster an effective grunt. Defense of FRC against encroachment by a rising tide of lung water is the principal strategy of management for this disorder. When the patient's own defenses are overcome, FRC can be recovered and protected mechanically by the addition of distending airway pressure in the form of continuous positive pressure or intermittent mandatory ventilation.

Changes in FRC mirror the improvement in oxygenation that occurs with the addition of distending airway pressure or with spontaneous recovery beginning on the second or third day after birth.[36,40-42] During recovery there is a striking correlation between improving arterial oxygenation and increasing FRC and diuresis as excess lung water recedes into the circulation and is cleared by the kidneys.[40,43]

Mechanical Properties of the Lung

The abnormal mechanical properties of the lung in hyaline membrane disease are the consequence of interacting pathophysiologic events.[44] The marked decrease in *lung compliance,* one of the hallmarks of hyaline membrane disease, is the consequence of two factors: (1) a decrease in the number of ventilated terminal air spaces (i.e., *de-recruitment*); and (2) an increase in the recoil pressure of ventilated terminal air spaces. In addition, dynamic, but not static, compliance is further reduced in hyaline membrane disease owing to changes in the viscoelastic properties of lung tissue and the presence of ventilation inhomogeneity.[45]

De-recruitment and the consequent loss of FRC occur as a result of the collapse of unstable terminal air spaces or as a result of alveolar flooding and tissue injury. The effects of air space instability on compliance and lung volume are discussed later. The elastic recoil pressure of ventilated air spaces in hyaline membrane disease may be increased for a variety of reasons. Surface elastic forces are increased in hyaline membrane disease as a result of surfactant deficiency, inhibited surfactant function, or both (see Section XIII of this text). Alveolar flooding[46,47] may also increase surface elastic forces. Tissue elastic forces may be increased with engorgement of the pulmonary vascular bed[48] but it is unclear that this is the mechanism of decreased compliance observed in patients with hyaline membrane disease complicated by symptomatic patent ductus arteriosus.[49] Increased elastic recoil resulting from both surface forces and tissue elastic forces occurs when the infant with hyaline membrane disease is ventilated high on the volume axis of the lung's pressure-volume curve, either inadvertently or out of necessity. In the presence of extensive de-recruitment, the small compartment of ventilated air spaces that remains must provide more than its normal share of ventilation to achieve adequate gas transport. The smaller the ventilated compartment is, the more distended will its terminal air spaces become at end inspiration for a given tidal volume. At high volume, surface forces are minimally reduced by surfactant, and tissue elastance increases as the elastin network, which dominates at low- and middle-volume ranges, gives way to the structural influence of poorly compliant collagen.[50]

Like FRC, compliance also mirrors the course of pulmonary insufficiency in hyaline membrane disease.[40] Intercostal and sternal retractions in the infant capable of a spontaneous ventilatory effort provide a visual assessment of compliance at the bedside. As compliance improves, with manipulations of mechanical ventilation, surfactant replacement therapy, or evolution of the natural course of disease, chest wall retractions diminish, a finding indicating that less transpulmonary pressure is required to expand the lung.

Lung resistance measured in hyaline membrane disease during spontaneous breathing without mechanical ventilation is not substantially different from that in newborn infants without lung disease.[44] However, lung resistance is higher in infants with hyaline membrane disease requiring mechanical ventilation with an endotracheal tube in place.[44] Some of the increased resistance in these infants may include the resistance of the endotracheal tube, but this increment does not appear sufficient to account for all of the increased resistance measured in patients with hyaline membrane disease.[51] It has also been suggested that some of the increase in resistance results from damage to conducting airways or from peribronchial edema.[52] In addition, conductance of the

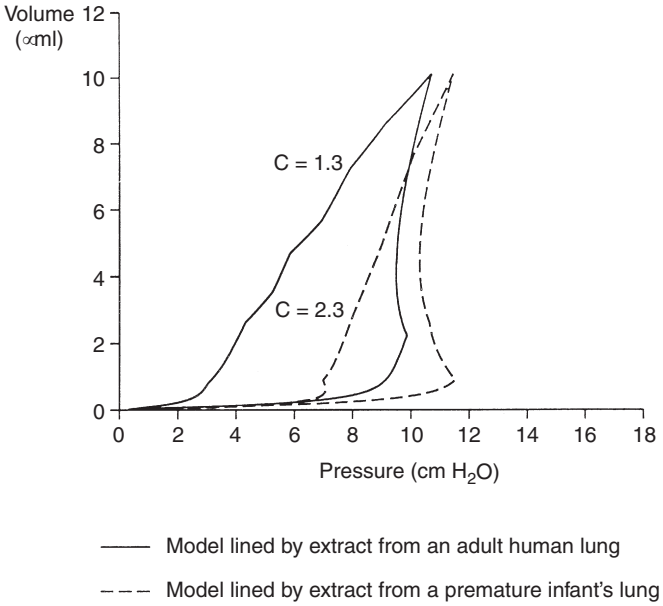

Figure 93-5 Pressure volume characteristics of a model alveolus when lined by extract from a premature infant's lung *(broken line)* or when lined by extract from an adult human lung *(solid line). (The data and model used to construct these pressure volume curves were taken from Clements JA, Hustead RH, Johnson RP, Gribetz I: Pulmonary surface tension and alveolar stability,* J Appl Physiol *16:444-450, 1961 and Cotton R: A model of the effect of surfactant treatment on gas exchange in hyaline membrane disease,* Semin Perinatol *18:19-22, 1994.)*

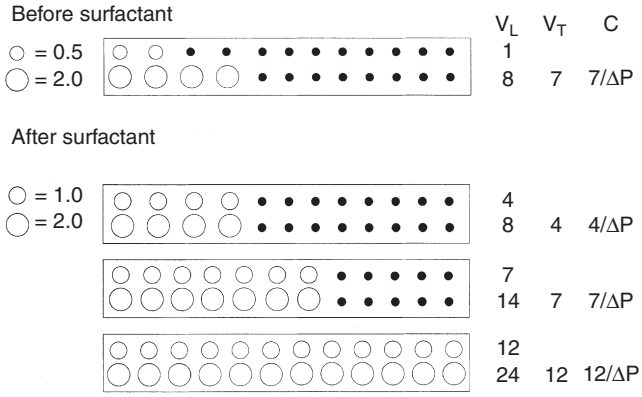

Figure 93-6 Alveolar stabilization and recruitment. Model of a 12-alveolus lung in which the top row of each panel represents the volume of each alveolus at end expiration and the bottom row represents the volume of each alveolus at end inspiration. The solid circles indicate alveolar collapse. The open circles indicate alveoli that are not collapsed. The end-expiratory volume and end-inspiratory volume of an individual alveolus are shown to the left of panels 1 and 2. Before surfactant treatment, two ventilated alveoli are stable, two ventilated alveoli are unstable, and eight collapsed alveoli constitute an unventilated compartment. In panel 2, after surfactant, the two ventilated alveoli that were unstable before surfactant have become stabilized. The unventilated compartment of eight collapsed alveoli remains the same as before surfactant. In panel 3, three alveoli from the unventilated compartment have been recruited and stabilized. In panel 4, the unventilated compartment has been fully recruited, and all alveoli are ventilated and stable. The stepwise effect of this process of stabilization and recruitment on lung volume (V_L), tidal volume (V_T), and compliance (C) is shown to the right of the panels. *(From Cotton R: A model of the effect of surfactant treatment on gas exchange in hyaline membrane disease,* Semin Perinatol *18:19-22, 1994.)*

respiratory system is highly correlated with lung volume in hyaline membrane disease (calculated from previously reported results),[53] implying that a major cause of increased resistance of the respiratory system in infants with hyaline membrane disease is related to a decrease in the cross-sectional area of distal conducting airways.

Effects of Alveolar Instability on Lung Volume and Compliance

Alveolar instability refers to the tendency for an alveolus to switch abruptly between the inflated state and the collapsed state.[54] When pressure across the alveolus exceeds the critical opening pressure, an unstable alveolus inflates suddenly. During deflation an unstable alveolus collapses abruptly when transalveolar pressure falls to less than the critical closing pressure. Figure 93-5 illustrates the stabilizing effect of surfactant treatment on an unstable alveolus with a critical opening pressure of slightly more than 11 cm H_2O and a critical closing pressure of just less than 7 cm H_2O.

Because the dimensions of the terminal air spaces are not uniform throughout the lung, all alveoli do not behave uniformly in surfactant deficiency. Under these conditions there is a range of critical opening and closing pressures. As a result there are several populations or compartments of terminal air spaces. One compartment remains collapsed throughout inspiration and expiration, another is ventilated during inspiration but collapses during each expiration, and a third is ventilated and stable to the extent that gas volume is retained at end expiration. The distribution of these compartments is affected by a variety of factors, especially treatment with surfactant replacement or with distending airway pressure. How changes in the relative size of these compartments affect lung volumes and compliance during fixed conditions of pressure-limited mechanical ventilation is illustrated in Figure 93-6. In this model, stabilization alone results in increased FRC and decreased compliance. Tidal volume and compliance do not improve until recruitment of new terminal air spaces from the previously unventilated compartment.

Ventilation

Infants with hyaline membrane disease who can be managed without intermittent positive pressure ventilation have spontaneous tidal volumes of 4 to 6 mL/kg, the same or only slightly less than the tidal volume of newborn infants with normal lung function. In contrast to infants with normal lungs, dead space makes up a much larger portion of tidal volume, 60% to 80% versus 30% to 40%.[55-57] After subtracting dead space from tidal volume, infants with hyaline membrane disease are left with a decreased alveolar portion of tidal volume for which they compensate by breathing faster. As a result of increasing respiratory rate, a nearly normal alveolar ventilation and arterial carbon dioxide tension can be attained. A decreased alveolar portion of tidal volume is the expected pathophysiologic consequence of encroachment on terminal air spaces by lung water and is consistent with the well-documented loss of FRC in this disease.

Physiologic dead space is derived from systemic arterial carbon dioxide tension; *anatomic dead space* is derived from an estimate of alveolar carbon dioxide tension obtained from end-tidal gas analysis. The difference between the two dead spaces is referred to as *alveolar dead space.* (Physiologic dead space = anatomic dead space + alveolar dead space.[57]) In newborn infants with normal lungs, there is no detectable difference between physiologic and anatomic dead space because their arterial-alveolar carbon dioxide gradient is close to zero. Infants

with hyaline membrane disease have a significant gradient of 12 to 16 mm Hg in carbon dioxide tension between arterial blood and alveolar gas, which results in an increase in measured physiologic dead space. This gradient has been explained as the result of a relative underperfusion of ventilated alveoli.[30,57] When terminal airway units are totally obstructed by epithelial slough and exudate, dilated respiratory bronchioles proximal to the obstruction behave as unperfused but ventilated "alveoli."

TREATMENT: PATHOPHYSIOLOGIC CONSIDERATIONS

Surfactant replacement therapy has become a standard part of the treatment of hyaline membrane disease and has proven to be enormously successful in bringing about highly significant reductions in mortality and pulmonary complications, especially air-leak syndromes (Chapters 104 and 106 are devoted to the subject of surfactant replacement therapy). The following discussion of treatment of hyaline membrane disease is limited to the role of oxygen therapy and the effects of mechanical ventilation and distending airway pressure on the pathophysiology of this disorder.

The primary challenge in managing the pulmonary insufficiency of hyaline membrane disease is achieving an adequate Pao_2. If oxygenation can be achieved, carbon dioxide removal is only a matter of increasing minute ventilation sufficiently to make up for an inadequate alveolar portion of tidal volume. Management of the hypoxemia of hyaline membrane disease should be approached by recognizing the impact of venous admixture on Pao_2 as a function of Fio_2 (see Figure 93-4). Oxygenation can be achieved under conditions of modest venous admixture up to 30% or 40% by increasing Fio_2. With severe disease characterized by venous admixture greater than 40%, something must be done to reduce right-to-left shunt before adjustments in Fio_2 have any significant effect on Pao_2.

Oxygen Administration

Some reduction in venous admixture can be realized by increasing the Fio_2 to 100%.[30,31] In part, this reduction in venous admixture reflects events in a lung compartment made up of gas exchange units that are extremely poorly ventilated. When the patient breathes 100% oxygen, local alveolar hypoxia is relieved, and perfusion is restored to those units that are open. In addition to reducing right-to-left intrapulmonary shunting, it is also possible to manipulate the magnitude of right-to-left shunt across fetal pathways by changing Fio_2.[21]

Even though simple oxygen administration without adding positive airway pressure can lead to a reduction in venous admixture, oxygen therapy by itself is often of limited efficacy. Before use of mechanical ventilation, survival from hyaline membrane disease was predicated more on effective grunting and increased respiratory effort than on oxygen therapy. Unless a patient could sustain adequate spontaneous ventilation and an effective grunt, the hypoxemia of hyaline membrane disease could not be overcome, even by hyperbaric oxygen therapy (Figure 93-7).[58]

Distending Airway Pressure

Application of distending airway pressure to the airway of patients with hyaline membrane disease brings about a prompt reduction in venous admixture. The reduction in venous admixture results from a decrease in intrapulmonary right-to-left shunting as well as a decrease in right-to-left shunting across the foramen ovale.

Distending airway pressure may be applied in a variety of ways. In the original report[59] of its successful use in hyaline membrane disease, constant distending pressure was applied to an indwelling endotracheal tube by means of a continuous flow through an anesthesia bag that had an adjustable leak in its tail. Continuous positive airway pressure can also be applied by face mask, nasal prongs, or head chamber. All these methods deliver a continuous distending pressure during which ventilation depends on spontaneous breathing by the patient.

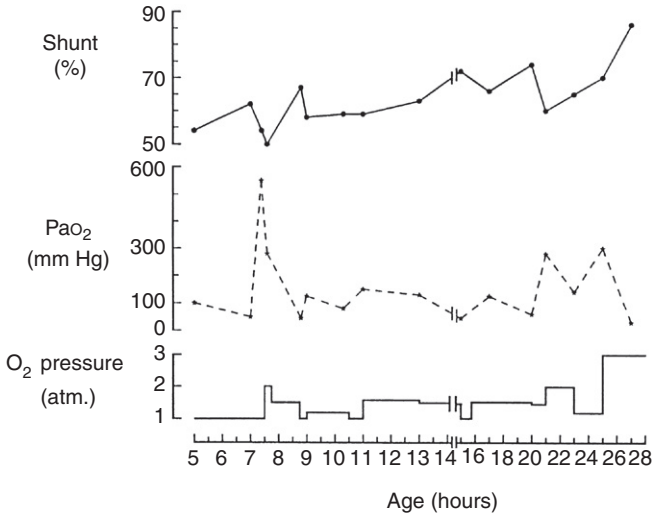

Figure 93-7 Serial arterial oxygen tensions in an infant with hyaline membrane disease treated with hyperbaric oxygen. The increase in arterial partial pressure of oxygen (Pao_2) after each increment in inspired oxygen pressure is transient. The overall course is one of progressive venous admixture (shunt %) despite the administration of 100% oxygen at pressures up to 3 atmospheres. *(From Cochran WD, Levison H, Muirhead DM, et al: A clinical trial of high-oxygen pressure for the respiratory-distress syndrome,* N Engl J Med *272:347-351, 1965. Reprinted by permission of the New England Journal of Medicine.)*

With increasing distending airway pressure, FRC increases[36] and venous admixture decreases as a result of stabilization and recruitment of effective ventilatory units. There is a significant decrease in the gradients of carbon dioxide[30] and nitrogen[60] between alveolar gas and arterial blood, indicating an improved perfusion of ventilated units and an improved ventilation of perfused units, respectively. In patients able to sustain spontaneous ventilation, application of distending airway pressure is followed by a reduction in minute ventilation. For the most part, this reduction can be accounted for by a decrease in tidal volume[41,59]; to a lesser extent, a decrease in the rate of breathing plays a role.[41] When distending airway pressure is applied, there is little or no change in arterial partial pressure of carbon dioxide,[41,59] signifying that alveolar ventilation is maintained in spite of the reduction in minute ventilation. This suggests that the dead space–tidal volume ratio is also decreased by distending airway pressure. The decrease in dead space–tidal volume ratio results from an increase in the alveolar portion of tidal volume caused by stabilization and recruitment of terminal air spaces.

Although application of distending airway pressure causes a prompt increase in arterial oxygen tension as a result of decreasing right-to-left shunt, there is no corresponding increase in dynamic lung compliance.[59] In fact, dynamic compliance may decrease after the application of distending airway pressure.[41] This response in dynamic compliance, which is similar to that reported after surfactant replacement therapy,[53,61,62] can be explained by the stabilizing effect of distending airway pressure on terminal air spaces. Figure 93-6 illustrates the effects of stabilization and recruitment on lung volumes and compliance. The results are similar, regardless of whether those effects are mediated by surfactant replacement or by increased end-expiratory pressure.

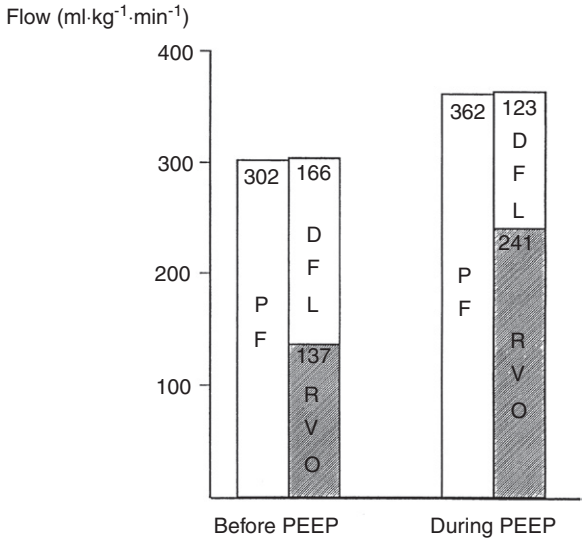

Figure 93-8 Effect or positive end-expiratory pressure *(PEEP)* on the components of pulmonary blood flow *(PF)* in premature lambs with hyaline membrane disease. *DFL,* Left-to-right blood flow across the ductus arteriosus; *RVO,* right ventricular output. *(From Cotton RB: In Stern L [ed]:* Hyaline Membrane Disease: Pathogenesis and Pathophysiology. *Orlando, FL, Grune & Stratton, 1984, p 184.)*

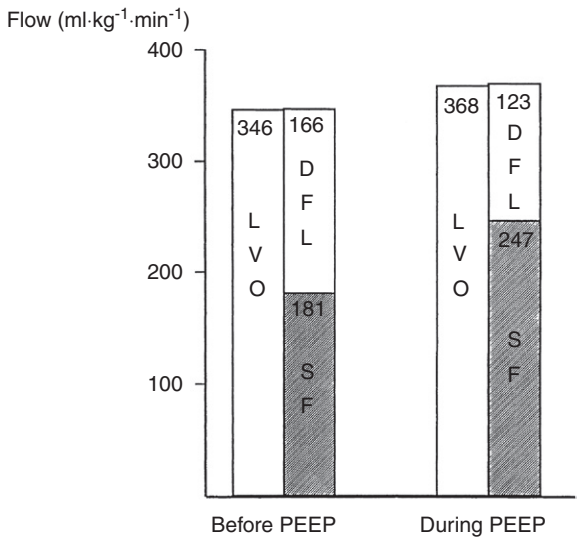

Figure 93-9 Effect or positive end-expiratory pressure *(PEEP)* on the components of left ventricular output *(LVO)* in premature lambs with hyaline membrane disease. *DFL,* Left-to-right blood flow across the ductus arteriosus; SF, systemic blood flow. *(From Cotton RB: In Stern L [ed]:* Hyaline Membrane Disease: Pathogenesis and Pathophysiology. *Orlando, FL, Grune & Stratton, 1984, p 184.)*

It has been recommended that the optimal level of distending airway pressure should be that level at which compliance increases.[63,64] Above this optimal level of distending airway pressure, compliance decreases, signifying that the dominant effect has become an over-distention of open gas exchange units rather than recruitment of new units. Even though compliance does not necessarily increase when distending airway pressure is applied to the airway of infants with hyaline membrane disease,[41,59] the pattern of breathing may still become more regular and the chest wall may appear more stable as a result of a decrease in tidal volume and respiratory rate.

Outside the lung, distending airway pressure has a beneficial effect on the distribution of cardiac output and on right-to-left shunting through the foramen ovale. In hyaline membrane disease, left ventricular output exceeds right ventricular output as a result of the bidirectional shunting discussed earlier. One increment in the extra volume load of the left ventricle can be accounted for by the portion of left ventricular output that is diverted back through the pulmonary circulation by way of the ductus arteriosus. A second increment results when a portion of systemic venous return is shunted from the inferior vena cava across the foramen ovale into the left atrium during vigorous inspiratory efforts. When distending airway pressure in the form of positive end-expiratory pressure (PEEP) is added to the positive pressure ventilation of newborn premature lambs with hyaline membrane disease, a series of effects on the circulatory pattern can be demonstrated (Figures 93-8 and 93-9).[26] The triggering event is thought to be a reduction in right-to-left shunting across the foramen ovale. The rerouted right-to-left foramen shunt appears as additional right ventricular output, which displaces a major part of the left-to-right ductus shunt from the pulmonary circulation forward into the systemic circulation. Pulmonary vascular resistance, pulmonary blood flow, and left ventricular output do not change appreciably. Right ventricular output and systemic blood flow increase. The net result of these changes is an increase in systemic arterial Po_2 caused by reduced venous admixture at the foramen ovale, as well as decreased lung congestion and protein leak subsequent to the reduction in left-to-right ductus shunting.

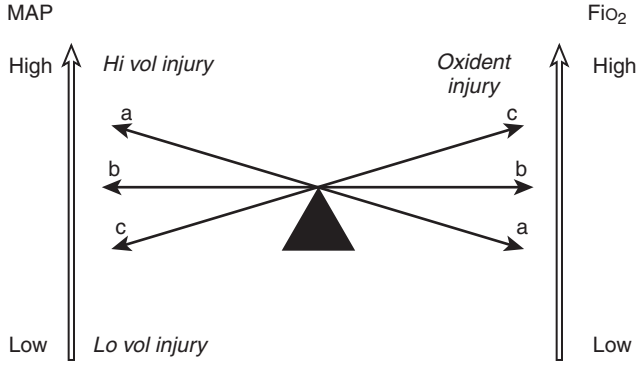

Figure 93-10 There is an inverse relationship between the intensity of positive pressure ventilation measured by mean airway pressure *(MAP)* and the fraction of inspired oxygen *(Fio_2)* required to achieve acceptable oxyhemoglobin saturation. Although a high MAP allows oxygenation at a low Fio_2, this combination increases the risk of high-volume lung injury *(line a).* On the other hand, using a low MAP in combination with a high Fio_2 may increase the risk of low volume lung injury as well as oxidant injury *(line c).* Theoretically, MAP and Fio_2 both should be set as low as possible to minimize both high volume lung injury and oxidant injury *(line b).*

Mechanical Ventilation

An understanding of the pathophysiology underlying impaired gas exchange in hyaline membrane disease provides a rational basis for the use of mechanical ventilation in the management of this disorder. The positive intermittent pressure (PIP) provided by conventional mechanical ventilation can be regarded as the "recruiting tool," and the PEEP can be regarded as the "stabilizing tool." The area under the pressure wave form applied to the airway, that is, mean airway pressure (MAP), can be regarded as an index of the overall intensity of positive pressure ventilation being applied. As recruitment progresses, lung compliance and

alveolar ventilation improve, allowing PIP to be lowered. When newly recruited terminal airways are stabilized by PEEP, they become more easily inflated than if they are allowed to collapse during expiration.

There is an inverse relationship between the intensity of positive pressure ventilation measured by MAP and the Fio_2 required to achieve acceptable oxyhemoglobin saturation (Figure 93-10). An attempt to minimize the required Fio_2 by using high MAP increases the risk of high volume lung injury. However, using a low MAP combined with high Fio_2 may increase the risk of low volume lung injury, which occurs due to the repetitive reinflations of unstable terminal airways that collapse during expiration.[13] In order to minimize lung injury during mechanical ventilation, it would seem reasonable that ventilator settings be based on the magnitude of applied MAP required to achieve acceptable oxygenation, so that high MAP is reserved for cases that have the greatest intrapulmonary shunting and that low MAP be used when oxygenation can be achieved with low inspired oxygen concentrations.

94 Mechanisms of Neonatal Lung Injury

Richard L. Auten, Jr.

At birth the term newborn lung is at the alveolar phase of lung development, with a smaller number of alveoli normalized to body weight than an adult has. The lung must make the rapid transition from a fluid-filled structure with low stretch frequency and low strain to an air-filled structure subjected to high strain at variable frequency in order to support gas exchange. Spontaneous breathing efforts just after delivery at 40 weeks' gestation can generate high transpleural or transpulmonic pressures during the first few breaths. Failure to reabsorb amniotic fluid can lead to uneven gas distribution during spontaneous breathing or positive pressure ventilation, generating stress points that contribute to strain, injury, alveolar rupture, and pneumothorax (Figure 94-1). The prevalence of spontaneous pneumothorax is undoubtedly higher than recognized because many are clinically insignificant. In case-control studies, pneumothorax is associated with meconium-stained amniotic fluid[1,2] and elective repeat cesarean deliveries.[3]

In babies born very prematurely, at less than 26 weeks, the fetal lung is completing the transition from the cannalicular stage to the saccular stage of development. Air sacs are relatively thick walled, and pulmonary capillaries are incompletely branched and do not extend to the ends of the alveolar septa. Surfactant synthesis and secretion are decreased. Enzymatic antioxidants, superoxide dismutase, catalase, and glutathione peroxidase are relatively low, and less inducible than at term. Nutritional antioxidants such as vitamin E and retinoids are also relatively low.[4] In order to support ventilation, the extremely premature newborn lung with these liabilities is often subjected to supplemental oxygen, endotracheal intubation, and positive pressure ventilation, all of which can injure developing lung, leading to impaired alveolar development and chronic lung disease of prematurity, or bronchopulmonary dysplasia (BPD) (Figure 94-2).

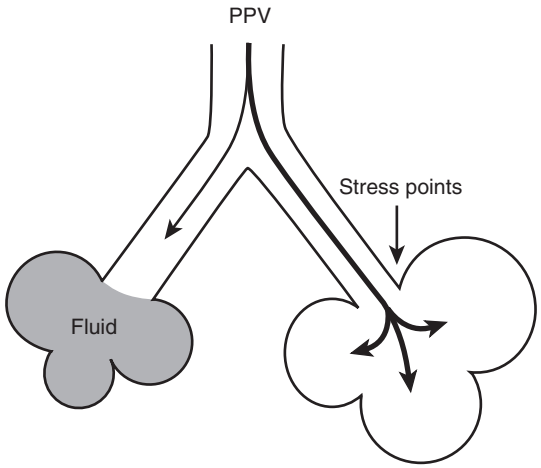

Figure 94-1 During inspiration, fluid filled atelectatic alveoli *(gray)* allow gas to be shunted to more compliant alveoli, leading to overdistention and alveolar wall stress.

MECHANICAL MECHANISMS OF LUNG INJURY

Mechanical Lung Injury at Birth

Vulnerability to mechanical lung injury is significant immediately after birth.[5] Animal studies have shown that structural damage and inflammatory response can be generated after only a few overdistending breaths.[6,7] Significant lung injury can take place after brief periods of mechanical ventilation of the incompletely recruited lung. Forced "recruitment" maneuvers may be harmful. In preterm, surfactant-treated lambs, initial recruitment maneuvers with tidal volumes varying from 8 to 30 mL/kg had no benefit, and caused "dose-dependent" histologic damage with increasing tidal volumes.[8,9] Lung volumes at less than optimal functional residual capacity (FRC) require higher than optimal peak pressures in later breaths to fully re-recruit alveoli. Maneuvers designed to avoid de-recruitment, such as use of continuous positive airway pressure (CPAP),[10] have decreased injury markers in experimental models of prematurity and respiratory distress syndrome (RDS). Choosing and delivering the appropriate tidal volume during delivery room resuscitation remain important, but as yet unrealized goals in the quest to minimize lung injury, particularly in the extremely premature newborn at high risk for developing BPD.

De-recruitment

Trauma to delicate airways can easily result if the lung is de-recruited to volumes at less than FRC (Figure 94-3), resulting in alveolar collapse (atelectasis). Higher airway pressures are then

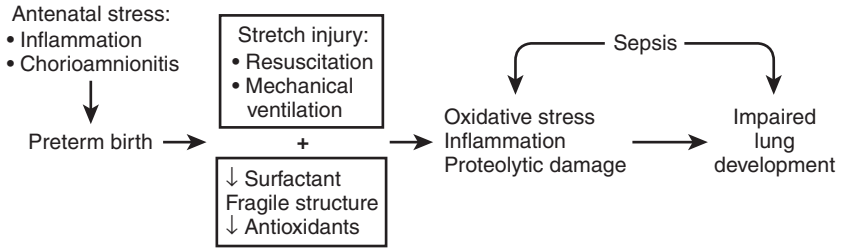

Figure 94-2 Developmental lung vulnerabilities superimposed with mechanical injury and maladaptive inflammation, leading to disrupted lung development.

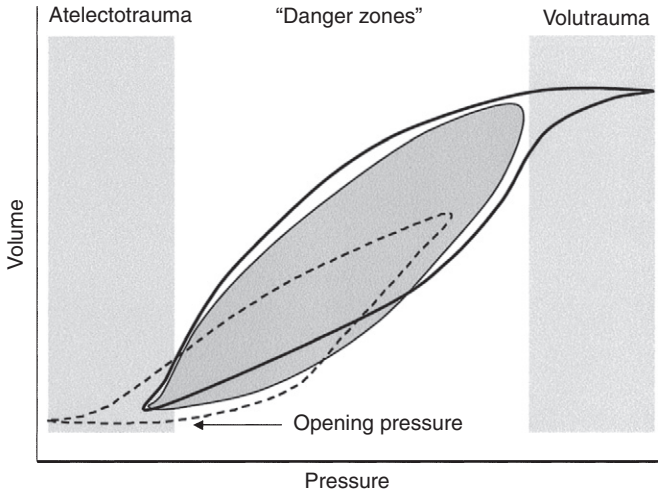

Figure 94-3 Static P-V loop after recruitment *(solid line, gray fill)* of lung volume above functional residual capacity (FRC). After derecruitment the P-V loop demonstrates decreased hysteresis *(dashed line),* decreased slope, and loss of lung volume at end-deflation, predisposing to "atelectotrauma." Overinflation *(dark solid line)* of the lung leads to increased luminal pressure without increased accumulation of lung volume, increasing shear stress to airways, and predisposing to "volutrauma."

required during subsequent mechanical breaths in order to re-recruit alveoli, leading to stretch injuries in terminal airways.[11] The spontaneously breathing patient must generate greater negative pressures to achieve the same goal, also leading to the same stretch injury, higher work of breathing, and fatigued muscles of respiration. Considerations for mechanical ventilation strategies designed to avoid lung injury due to de-recruitment and atelectasis are discussed in Chapters 97 and 98.

Overexpansion

As the mechanical breath volume increases to approach the total lung capacity, increased airway pressure and mechanical shear force are applied to the airways and alveoli without a proportional increase in lung volume at the upper inflection point (see Figure 94-3). The widespread use of in-line flow or pressure sensors capable of displaying the pressure-volume relationship can detect overinflation, demonstrating the flattened inspiration and expiration limbs and decreased pressure-volume loop hysteresis at the end of inspiration. Overinflation is more likely to occur when patients are receiving time-cycled, pressure-limited ventilation at a time when compliance rapidly improves, for example, immediately after surfactant therapy, or on achieving full alveolar recruitment.

Balancing the risks of lung injury due to de-recruitment or atelectotrauma against the risks of overinflation can be complex, particularly when the pathophysiology that affects the lung microenvironment is nonuniform, and produces underinflated and overinflated regions. Experimental studies have blended the so-called low lung volume approach with intermittent recruiting breaths, or "sighs," and have demonstrated in adult mice that an optimal sigh frequency can minimize evidence of cellular injury.[12]

Use of Continuous Positive Airway Pressure to Avoid Lung Injury

Because the accurate determination of a "safe" tidal volume for use in mechanically ventilated newborns is problematic, less invasive approaches to assist respiration have gained wider use in an effort to avoid injury. Early use of CPAP, within a minute or two of delivery (in the spontaneously breathing infant), may avert lung injury by allowing gradual recruitment and avoiding the need for mechanical ventilation. Although lower rates of surfactant use and mechanical ventilation have been reported in some centers, it is unclear whether the use of CPAP as the initial ventilatory approach avoids lung injury and BPD. Preclinical investigations have shown improved lung development in preterm lambs[10] and baboons[13] treated with CPAP. Pilot studies suggest that initial use of CPAP does not increase the need for later mechanical ventilation.[14,15] However, a large, multicenter, randomized, controlled clinical trial comparing the use of CPAP with intubation and prophylactic surfactant demonstrated that CPAP was equal to or slightly better than intubation and surfactant for prevention of BPD.[16]

Surfactant to Prevent Injury

Nonuniform compliance and resistance can promote mechanical strain, so it follows that achieving more uniform compliance by correcting surfactant deficiency common in those prematurely born should prevent mechanical injury. For short-term lung injury outcomes such as pneumothorax, and duration of mechanical ventilation, and for survival in some subgroups, surfactant treatment has been shown to be beneficial in multicenter randomized trials (see reference 17 for review). Early use of selective, empiric surfactant therapy of very premature newborns, typically less than 26 weeks estimated gestational age, has been shown to reduce the risk of pneumothorax and BPD.[18] However, uneven or asymmetric surfactant distribution may contribute to the heterogeneous clinical response, and may further contribute to lung injury by directing positive airway pressure preferentially to the compliant parts of the lung. This often injures the compliant lung and spares (for a while) the noncompliant, non–surfactant-treated lung. In an effort to avoid mechanical ventilation, some have used immediate surfactant treatment followed by CPAP, but there is no clear evidence that this prevents BPD as typically defined,[19] with its multifactorial etiology (see Chapter 97).

Lung Water, Patent Ductus Contribute to Mechanical Lung Injury

Patent ductus arteriosus (PDA) in the setting of low pulmonary vascular resistance contributes to pulmonary edema by allowing pulmonary overcirculation, which results in elevated left atrial

pressures. PDA has been associated in numerous clinical studies with the development of chronic lung disease of prematurity, and is discussed in detail in Chapters 73 and 97. Persistence or recurrence of a PDA is highly correlated with the development of BPD, probably because of uneven effects on lung compliance. Alternatively, recurrence of the PDA is often associated with sepsis, which itself may contribute to inflammatory lung injury.[20] Chorioamnionitis and fetal inflammation may also contribute to the production of prostaglandins that promote ductal patency by the same mechanisms, and may contribute to lung injury via inflammation, making it difficult to separate the physiologic contribution of the PDA to lung injury in the premature newborn.

Intravenous fluid management using rates exceeding 200 mL/kg/day in the first days of life for extremely premature newborns has been linked to later development of BPD,[21] but the precise role in lung injury remains unclear because pulmonary lymphatic drainage appears to compensate for increased pulmonary blood flow in experimental animals given similarly high rates of intravenous fluids.[22] High fluid rates have been linked to arterial ductus patency in clinical trials and observational studies and may contribute to lung injury through this mechanism.

HUMORAL LUNG INJURY: INFECTION AND INFLAMMATION

Congenital, Perinatal, and Postnatal Sepsis

Premature newborns are likely to have been exposed to infection in utero because infection often precipitates preterm labor.[23] Epidemiologic evidence correlates fetal exposure to chorioamnionitis with development of BPD.[24] Infection and inflammation damage lung cells as a result of the maladaptive inflammatory response that amplifies the cycle of mechanical or oxidative injury, which leads to inflammation and additional injury. Fetal exposure to inflammatory or immunologic challenge can directly injure lung cells without the additional burdens of oxygen therapy and mechanical ventilation.[25]

Postnatal sepsis may provoke a systemic inflammatory response, accompanied by significant pulmonary neutrophil influx, alveolar-capillary leak, and in some cases, necrotizing tracheobronchitis. Premature newborns are more likely to develop BPD if they develop postnatal sepsis.[26,27] Death or dysregulation of lung progenitor cells,[28] ordinarily destined to complete repair and development, may interrupt normal alveolar and capillary development. Exposure to proinflammatory cytokines or endotoxin components without actual infection can disrupt alveolar development (see Chapter 96).

Ureaplasma infection has been implicated in the pathogenesis of BPD and may impair lung development through its provocation of inflammation. Autopsy studies of premature newborns with pneumonia have linked the presence of *U. urealyticum* in the lung to fibrotic histologic changes often found in advanced BPD. These studies linked *Ureaplasma* infection with a "pro-fibrotic" phenotype in alveolar macrophages that strongly expressed transforming growth factor β, a cytokine linked to fibroblast proliferation.[29] Experimental infection with *Ureaplasma* in premature baboons caused lung injury and abnormal alveolar development.[29] Whether it does so in humans remains to be determined. The role of *U. urealyticum* in apparent exacerbations of respiratory failure in very-low-birth-weight prematures may be underestimated.

Late-onset sepsis in prematures has been strongly predictive of later development of BPD.[20] In the premature newborn lung subjected to oxidative and mechanical stress, infection may represent another instance of the "second hit" that further amplifies inflammation and contributes to dysregulated lung development and repair.

ASPIRATION INJURY

Meconium Aspiration

Passage of meconium is associated with compromised uteroplacental blood flow at or near full-term gestation, and under certain circumstances may be aspirated in utero or at delivery. Animal models using human meconium routinely demonstrate lung injury, but lack the in utero pulmonary vascular remodeling that may accompany clinical meconium aspiration syndrome. Mechanical obstruction of small airways with particulate meconium can lead to air trapping and pneumothorax. Meconium present at birth is associated with pneumothorax as noted previously.

Meconium components are toxic to the lung. Meconium contains fatty acids, and oleic acid in particular can be directly toxic to epithelial membranes. In vitro, neutrophils exposed to meconium release interleukin (IL)-8,[30,31] and in vivo aspiration models also demonstrate elevated IL-8 levels in tracheal aspirates.[32] In addition, oleic acid, hemoglobin, and other components in meconium may inactivate lung surfactant, leading to alveolar instability that contributes to shear stress and cellular injury.[17] Experimental and clinical treatment with exogenous surfactant restores minimum surface tension, improves oxygenation,[33] and reduces the need for extracorporeal membrane oxygen (ECMO) in patients with meconium aspiration syndrome.[34]

Amniotic Fluid Aspiration

At first glance it may seem paradoxical that amniotic fluid, which is produced in part by the fetal lung, would be toxic to pulmonary epithelium. However, the aspiration of cellular debris and the components of dead cells are likely to provoke an inflammatory response by the same mechanisms attributed to meconium aspiration: direct cellular toxicity, release of humoral mediators, and surfactant inactivation. Although the net flux of pulmonary fluid in fetal life is toward the mouth and away from the lung, mixing occurs during labor, particularly if the fetus gasps in response to hypoxia. Infected amniotic contents have been reported frequently in postmortem examinations. In addition, experiments in fetal lambs have demonstrated the exposure of the fetal lung to proinflammatory cytokines[10] derived from inflamed fetal membranes.

LEUKOCYTE-MEDIATED INJURY

Neonatal Pulmonary Inflammatory Responses

Inflammation—regardless of its initiating cause—exacerbates newborn lung injury. Different injuries or exposures can alter the timing and sequence of inflammatory cell influx. In neonatal surfactant deficiency and in experimental oxygen toxicity in newborn rats, resident alveolar macrophages[35] both precede and succeed the influx of neutrophils[36] that are isolated from bronchoalveolar lavage fluid of newborns with respiratory distress syndrome. Cellular inflammatory responses to mechanical or oxidative injury in the lung are prompted by release of prostanoids, or by the binding of pathogens to signal molecules that activate proinflammatory cytokines, such as IL-1β or tumor necrosis factor-alpha (TNFα). These stimulate expression of monocyte chemokines, such as monocyte chemoattractant protein-1, known to be expressed in alveolar epithelium, which in turn recruits macrophages into the lung.[37] The recruitment of leukocytes, particularly neutrophils, into the lung hinges on the complex interplay of cytokines, chemokines, and cellular adhesion molecules summarized in Figure 94-4.

Large animal models designed to mimic clinical BPD (use of appropriate oxygen therapy, moderate ventilation, and surfactant treatment after premature delivery) have shown a similar sequence of the development of injury and inflammation even

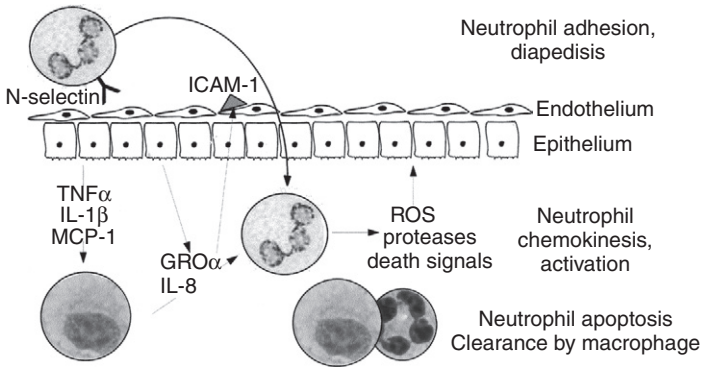

Figure 94-4 Damaged cells release proinflammatory cytokines that up-regulate adhesion molecules on circulating leukocytes and endothelium. Both epithelium and macrophages produce neutrophil chemokines, for example, GROα and interluekin 8 (IL-8), that further up-regulate adhesion of neutrophils and regulate chemotaxis, chemokinesis, and the reactive oxygen-producing respiratory burst. On activation, the neutrophil requires continuous chemokine signal transduction without which the neutrophil undergoes apoptosis and is cleared by alveolar macrophages. Activated neutrophils release reactive oxygen species, proteases, and other toxic materials that can damage adjacent cells.

though they lack antecedent labor.[38] Premature newborns that later develop BPD are likely to have elevations of proinflammatory cytokines and chemokines in tracheal aspirate samples.[39] These elevations may be present at birth, suggesting that the inflammatory response was begun antenatally, or shortly after delivery, perhaps during the initial resuscitation (Figure 94-5).

Inflammatory Processes Interrupt Lung Development

Damage to the developing lung may be sustained during a critical period, leading to death of particular progenitor cells necessary to orderly transition from the cannalicular to the alveolar stage of lung development. Indirect effects of reactive oxygen species produced by leukocytes following oxidative stress in newborns[40] may damage lung cell deoxyribonucleic acid (DNA) in certain proliferating cell types,[41] necessitating DNA repair and thereby delaying orderly mitosis and tissue development.[42] This may occur by disrupting the normal order of cell proliferation or by accelerating pathologic lung cell apoptosis.[43] Therapies aimed at selective modification or prevention of maladaptive inflammatory responses may attenuate lung injury and permit orderly postnatal lung development.[44]

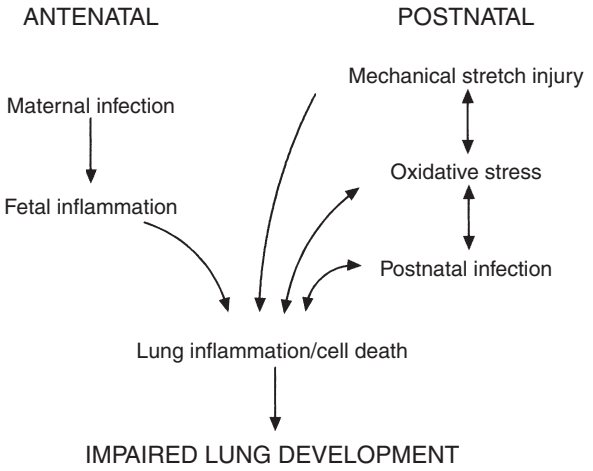

Figure 94-5 Combined antenatal and postnatal cellular injuries at critical phases of development contribute to bronchopulmonary dysplasia (BPD).

OXIDATIVE STRESS, ACUTE NEONATAL LUNG INJURY, AND BRONCHOPULMONARY DYSPLASIA

Deficiency of Antioxidant Defenses in Prematurity

Numerous oxygen radicals including superoxide, hydrogen peroxide, peroxyl radical, singlet oxygen, and hydroxyl radical can develop in particular compartments (in vitro) within the lung and inside lung cells. These compounds can damage lipid, protein, carbohydrate, and nucleic acid cell components. What is unknown at present, is whether they *do* occur in sufficient measure to cause enough lung cell injury to lead to BPD. The strength of the evidence implicating each reactive species in the pathology of newborn lung injury is variable and has been reviewed elsewhere.[45] Effects of reactive oxygen and nitrogen species on cell viability, function, and their ultimate effects on lung injury and development depend on the microenvironment in which they are formed and metabolized.

Premature newborns have relatively low chemical and enzymatic or inducible antioxidant systems compared with term and adult animals and are subjected to relatively high oxidative stress. The transition from the fetal milieu, wherein the oxygen delivery at relatively low arterial Po_2 is adequate to meet the metabolic demands, to the extrauterine existence with its significantly higher metabolic demands of thermogenesis and work of breathing, is typically accompanied by supplemental oxygen treatment. Studies in premature animals have shown that gene expression and the enzymatic activities of superoxide dismutases, catalase, and glutathione peroxidase are decreased.[4] This suggests the circumstance of antioxidant deficiency in the face of relatively increased oxidative stress, leading to impaired cellular metabolism, direct biomolecular damage, and structural cellular damage. However, the nature of the contribution of oxidative stress depends on the relevant biologic compartments and relationships among potential molecular substrates.[46] Serum glutathione stores are diminished (relative to adults) in premature newborns at risk to develop BPD. Oxidation of proteins isolated from tracheal aspirates of newborns destined to develop BPD provides indirect evidence of inadequate antioxidant defense.[47] Treatment with exogenous antioxidants such as vitamin A[48] or superoxide dimutase[49] has been shown to reduce bronchopulmonary dysplasia or its sequelae.

Metals and Oxidant-Mediated Lung Injury

Likely oxidant-stress mechanisms involved in the initiation and propagation of lung injury include oxidation and or nitrosylation of proteins, lipids, and nucleic acids. In addition, free metals such as iron or complexed iron can take part in a wide variety of reactions that are likely to produce reactive oxygen species or to damage critical catalytic components of enzymes or cofactors, for example:

I. $Fe^{3+} + O_2^{\bullet -} \rightarrow Fe^{2+} + O_2$ formation of ferrous iron
II. $Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + HO^{\bullet}$ formation of hydroxyl radical
III. $Fe^{2+} + LOOH \rightarrow Fe^{3+} + LO^{\bullet} + OH^-$ catalysis of lipid peroxidation "chain reaction"

Normally iron is handled very carefully by cells as a result of its powerful redox capacity for catalyzing these potentially damaging reactions. Direct and indirect evidence points to this pathway as a contributor to lung injury. Free iron contributes to lipid peroxidation in ischemia-reperfusion injury.[50] Newborns that developed chronic lung disease were found to have higher serum ceruloplasmin and ferritin levels, and had twice as many blood transfusions as age-matched nonchronic lung disease control patients.[51] Low plasma antioxidant activity and frequent red blood cell transfusions were associated with bronchopulmonary dysplasia.[52] Erythropoietin treatment in hyperoxia-exposed rabbits increased the resistance of blood and tracheal aspirates to lipid peroxidation.[53] This coupled with the relatively decreased inducibility of heme oxygenase-1 in newborns, a principal chelator of free iron, suggests that iron may contribute to oxidant-mediated lung damage in newborns.[54]

SUMMARY

Lung injury with lifelong consequences for pulmonary function and cognitive development may occur during fetal life. Mechanical injury and resulting inflammation that may lead to nonuniform lung mechanics invite repetitive stretch injury in mechanically ventilated patients, and may begin at birth during initial resuscitation. Individual differences in host antioxidant defenses, and in inflammatory responses and their regulation, very likely contribute substantially to variability of resistance to initial injury, and to the variability of successful repair in the vulnerable newborn lung (see Chapters 96 and 97). Direct cytotoxic injuries—oxygen, aspiration, sepsis—provoke inflammation, which is often maladaptive and contributes to further injury.

95 Impaired Lung Growth After Injury in Premature Lung

Kurt H. Albertine and Theodore J. Pysher

Premature birth is any delivery, regardless of birth weight, that occurs before 37 completed weeks from the first day of the last menstrual cycle (term is 40 weeks in humans).[1] In this regard, *gestational age* is dated from the first day of the last menstrual cycle. Pregnancies that end before 20 completed weeks gestation are termed *abortions.* A reasonable definition of premature birth, therefore, is any delivery that occurs between 20 and 37 weeks gestation. In the United States and Canada, the overall rate of prematurity is approximately 10%,[2,3] despite the extensive use of tocolytic agents to arrest premature labor.[4-6]

Today, infants who are born as early as 22 weeks gestational age may survive if supported by intensive medical care, important components of which are antenatal steroids and postnatal surfactant replacement, and ventilatory support with supplemental oxygen. These and other supportive measures are required because the gas exchange regions of the lungs of the prematurely born infant are not sufficiently developed, either structurally or functionally, for extrauterine life. This chapter describes the impact of premature birth on lung growth, with emphasis on alveolar formation.

STRUCTURE OF DISTAL LUNG IN CONTEXT OF PRINCIPAL LUNG FUNCTION

Exchange of oxygen and carbon dioxide in the mature lung occurs in relatively large units that are referred to as *terminal respiratory units.* Each such unit—approximately 5 mm in diameter with a volume of around 0.02 mL at functional residual capacity—consists of all of the alveolar ducts, together with their accompanying alveoli, that stem from a single respiratory bronchiole.[7] In the adult human lung, one terminal respiratory unit contains approximately 100 alveolar ducts and 2000 anatomic alveoli. Together, the two lungs of the adult human contain approximately 150,000 of these specialized units.[8]

The function of the terminal respiratory unit is such that diffusion of oxygen and carbon dioxide in the gas phase is so rapid that the partial pressures of each gas are uniform throughout the unit. From each inspired breath, oxygen that reaches the alveolar duct gas diffuses into all of the associated alveoli, because the incoming air has a higher oxygen concentration than that of the alveolar gas. Oxygen subsequently diffuses through the air-blood barrier into red blood cells, where oxygen combines with hemoglobin as the red blood cells flow along the capillaries. Carbon dioxide diffuses in the opposite direction.

In the normal adult human lung, the air-blood barrier is exceedingly thin, which facilitates gas diffusion through the barrier. The average width of the air-blood barrier is approximately 1.5 μm.[8,9] For oxygen, the air-blood barrier's structural components are, in the order in which they are encountered by incoming air, alveolar epithelium and its subjacent basal lamina, alveolar wall interstitium, basal lamina of the capillary endothelium and the capillary endothelium, plasma, the membrane of red blood cells, and finally, hemoglobin molecules. For carbon dioxide, the obstacles to diffusion are encountered in the opposite sequence.

STRUCTURE OF THE PREMATURE LUNG

In the prematurely born infant, the terminal respiratory units are incompletely developed, and the air-blood barrier is too thick to allow efficient exchange of oxygen and carbon dioxide. This structural problem is greater with earlier preterm birth, because development of the terminal respiratory units occurs during the second half of gestation and the thickness of the air-blood barrier is inversely related to gestational age. A brief review of the stages of lung development in humans is presented next to illustrate these points[10] (Figure 95-1).

Branching of the bronchial tree and major pulmonary vessels is complete by 16 weeks gestation in humans. Before 17 weeks, the future bronchi and bronchioles extend into a core of relatively undifferentiated mesenchyme that contains few blood vessels (see Figure 95-1, *A*). This period of lung development is called the *pseudoglandular* stage. From weeks 16 to 26 gestation, the human fetal lung is at the *canalicular* stage. Lung architecture at this stage is characterized by more elongated profiles of the

Figure 95-1 Comparison of normal lung histology during development in humans to lung histopathology associated with acute lung injury or neonatal chronic lung disease. All of the lungs were fixed at low lung volume when fixed at autopsy. **A,** Infant stillborn at 12 to 14 weeks gestation. Although considerable autolysis (postmortem degeneration) is evident, larger airways *(AW)* are lined by columnar epithelium that is largely desquamated. There is no development in the intervening mesenchyme *(M)*, which is devoid of blood vessels in this tissue section. **B,** Infant stillborn at 20 weeks gestation. Canaliculi *(C)* lined by low cuboidal epithelium are visible beyond the larger airway *(AW)*. Capillaries *(arrows)* are visible deep within the developing mesenchyme. **C,** Infant stillborn at 29 weeks gestation. Saccules *(S)* and capillaries *(arrows)* are present in the thick primary septa. A larger airway *(AW)* is visible near the edge of the panel. **D,** Infant stillborn at 40 weeks gestation (term). Alveolar development has progressed to where the primary septa are thinner and secondary septa (crests; *arrowhead*) protrude into the developing alveoli *(A)*. The alveolar walls have numerous capillaries *(arrow)*. **E** and **F,** Examples of hyaline membrane disease *(HMD)*. **E,** Birth at 25 weeks gestation followed by 6 hours of mechanical ventilation. In the first few hours of life, the premature, mechanically ventilated lung shows uneven expansion of the distal air spaces *(DAS)*, vascular congestion, and interstitial edema. Hyaline membranes *(arrow)* are focally present. Some patchy hemorrhage also may be present. **F,** Birth at 29 weeks gestation followed by 2 days of mechanical ventilation. The distribution of ventilation is uneven, with centriacinar expansion and peripheral collapse, and hyaline membranes *(arrowhead)* are more extensive. **G** and **H,** Bronchopulmonary dysplasia *(BPD)*. **G,** Birth at 22 weeks gestation followed by 44 days of mechanical ventilation (28 to 29 weeks postconceptual age). The distal air spaces *(DAS)* have cellular debris *(*)*. Thick, cellular mesenchyme *(M)* separates the adjacent distal air spaces. **H,** Birth at 24 weeks gestation followed by 151 days of mechanical ventilation (45 weeks postconceptual age). Simplification and overdistension of the distal air spaces *(DAS)* is clearly evident. Primary septa are thick and cellular. Secondary septa (crests; *arrowhead*) are infrequently visible; those that are visible are short, thick, and devoid of capillaries near their tips. **A** to **H** are the same magnification (the scale bar is 100 μm in length). **A** to **F** and **H** were stained with hematoxylin and eosin; **G** with Masson's trichrome stain.

distalmost airways and proliferation of capillaries. Although capillary proliferation is robust, the developing capillaries are distant from the distal canals (see Figure 95-1, *B*). During this period, the cells lining the distal canals become cuboidal and show ultrastructural evidence of differentiation toward alveolar type II epithelial cells, in the form of osmiophilic lamellar bodies.[11] Arising from cuboidal epithelial cells are alveolar type I (squamous) epithelial cells. These terminally differentiated cells, although fewer in number than their cuboidal counterpart, eventually cover approximately 90% to 95% of the alveolar surface area of the peripheral lung in the adult.[12] Both structural attributes of alveolar type I epithelial cells provide a large, thin cellular barrier specialized for gas exchange.

From approximately weeks 24 to 38 gestation, lung development is at the *saccular* stage. During this stage, the initially cylindrical distal canals become divided by primary septa into which capillaries extend, resulting in greater surface area. Continual growth results in thinning of the mesenchyme. The result of these structural changes is a marked increase in the potential gas exchange surface of the lung. From around 36 weeks gestation and continuing through the first 18 to 24 months of postnatal life, alveoli are formed by progressive expansion and subdivision of the terminal air sacs (see Figure 95-1, *C*). Subdivision occurs during the process of secondary septation (also called secondary crest formation). During the alveolar stage, the air-blood barrier attains its adult thinness by further reduction of the connective tissue compartment in the developing alveolar walls and juxtaposition of the alveolar walls and alveolar capillaries.

Alveolar type II epithelial cells, and the surfactant phospholipids and apoproteins that they synthesize, secrete, and recycle are essential for normal lung function. In the human lung, type II cells containing lamellar bodies are histologically recognizable at the transition from the canalicular to the saccular stages of lung development. Surfactant synthesis normally begins later, during the saccular stage (around 30 weeks gestation),[13] but can be induced earlier, as discussed further on. From the saccular stage to the end of term gestation, the concentrations of dipalmitoyl phosphatidylcholine and other surfactant phospholipids increase in lung tissue, lung lavage liquid, and amniotic fluid. Surfactant apoproteins SP-A, SP-B, and SP-C, expressed only in lung tissue, also are developmentally regulated but not concordantly. Human SP-A messenger RNA (mRNA) and protein in lung tissue are not detectable until the saccular stage of lung development (around 30 weeks gestation).[13-16] Human SP-B and SP-C mRNAs are detectable in lung tissue at very low levels earlier than SP-A, during the transition from the canalicular stage to the saccular stage (around 24 weeks gestation).[17] Detection of SP-B and SP-C proteins, however, is later in development, during the saccular stage (about 30 weeks gestation).[16] Human SP-D protein has been detected only in amniotic fluid during the transition from the canalicular stage to the saccular stage of lung development (around 24 weeks gestation).[18,19] Thus the cellular and biochemical machinery to reduce surface tension at air-liquid interfaces in the future air spaces develops during the third trimester in humans. Many premature infants are born before the third trimester and are therefore at risk for respiratory failure because their lungs are deficient in surfactant. An approach to assessment of lung development before birth is to measure these secretory products in amniotic fluid.[20]

Another impediment to gas diffusion in the lungs of premature infants is the presence of liquid in the interstitium and potential air spaces. Fluid is an impediment because diffusion is much faster in the gas phase than in water. For example, the solubility of oxygen in water is low (0.03 mL/L × mm Hg Pa_{O_2}) compared with carbon dioxide, the solubility of which is approximately 20 times more than oxygen (0.7 mL/L × mm Hg Pa_{CO_2}). The advantage for carbon dioxide persists even though the driving pressure for carbon dioxide diffusion is only one-tenth that for oxygen entering the blood. Therefore oxygen diffusion is much slower in the relatively hydrated environment of the premature lung.

Normal intrauterine lung growth requires appropriate distension by lung luminal liquid.[21] The fetal lungs are filled with liquid that flows from the pulmonary vascular compartment, through the mesenchyme, to the potential air spaces. Liquid flows to the fetal potential air spaces because chloride is secreted across the fetal respiratory epithelium into the potential air spaces,[22] causing an osmotic concentration gradient that promotes flow of water into the potential air spaces. Lung luminal liquid is propelled centrally along the conducting airways to the oropharynx, where the liquid is either swallowed or expelled into the amniotic sac. Balance between production and drainage of lung luminal liquid is required for normal intrauterine lung growth.[21] When drainage exceeds production, the fetal lung is not exposed to continuous liquid-distending pressure; consequently, lung growth is inhibited.[23] Near or at the time of term birth, the

secretory activity of the respiratory epithelium switches from a predominantly chloride-secreting membrane to a predominantly sodium-absorbing membrane.[24-26] This molecular switch reverses water movement, thereby drying the potential air spaces for gaseous diffusion.

Structural and functional characteristics of the airways also may be affected by premature birth. During the canalicular and saccular stages of lung development, the airways have little smooth muscle in their wall, the epithelium is immature, and cell-cell adhesion is weak. Physiologic studies of human tracheobronchial segments ex vivo indicate that pressure-volume relations are affected by maturity,[27,28] such that airway compliance is inversely related to maturity. Less compliance of the airways of premature infants may explain the need for higher airway pressures than those adequate in term infants.[29] Furthermore, increased volume may be needed to inflate the collapsed gas exchange regions of premature infants compared to term infants.[29] The dearth of smooth muscle and weak adhesion between cells of the immature airway serve to increase the premature infant's airway susceptibility to injury by the increased pressures and volumes that are required to effect ventilation.

Acute Lung Injury of Prematurity (Respiratory Distress Syndrome)

When an infant is born prematurely, the structurally immature lungs are deficient in surfactant. Therefore, surface tension forces are high and the alveoli are unstable.[30] Alveolar instability leads to alveolar collapse (atelectasis). This atelectasis results in ventilation-perfusion mismatch. Such mismatch results in turn in intrapulmonary shunting, thereby contributing to poor oxygenation.[31] Opening the collapsed air spaces requires transmission of high ventilatory pressures to the immature distal airways and gas exchange regions of the lung. In effect, the extreme effort required to expand the lungs with the first breath must be repeated with each breath, because surfactant is not present to prevent collapse of the distal air spaces. Prematurely born infants who have these characteristics tire quickly, leading to the development of respiratory distress syndrome (RDS).

RDS affects approximately 30,000 infants annually in the United States. The incidence is around 50% to 60% in infants who are born before 30 weeks of gestation.[32] The incidence increases with decreasing gestational age.[33-35] RDS is more prevalent and severe in male than in female premature infants, for reasons that remain unclear.

Because RDS is a predictable consequence of lung immaturity, strategies have been developed to accelerate lung development before premature delivery. One such strategy is administration of hormones, such as glucocorticoids.[36-39] Seminal studies by Liggins[40] and, subsequently, Liggins and Howie[41] demonstrated that glucocorticoids accelerate lung maturation of fetal sheep and decrease the incidence of RDS in human infants after antenatal corticosteroid therapy.[40,41] The maturational effect of corticosteroid treatment on lung structure was first described by Kikkawa and colleagues.[42] Corticosteroids (betamethasone or dexamethasone) accelerate maturation of alveolar type II epithelial cells, which are the source of pulmonary surfactant. For these reasons, mothers who are in premature labor and are at risk of giving birth to a premature infant between 24 and 35 weeks gestation are treated antenatally with glucocorticoids.[43]

A treatment strategy to reduce lung stiffness (increase lung compliance) after premature birth is to instill surfactant into the airways.[44] Surfactant replacement therapy is beneficial because once it becomes widely and thinly distributed in the lung, the exogenous surfactant reduces surface tension at air-liquid interfaces, thereby stabilizing alveoli when they are deflated. After surfactant replacement, oxygenation improves swiftly, followed for several hours by progressive improvement in gas exchange and lung mechanics.[45-47] Other improvements, at least in premature lambs, are reduced vascular injury and edema.[48] Thus surfactant replacement therapy reduces the incidence and severity of RDS after premature birth. Instilled surfactant is not recycled as efficiently as native surfactant, but by reducing the lung injury associated with management of RDS, this therapy improves the opportunity for the premature lung to repair and grow.

The pathologic findings in RDS are similar to those in adults with acute respiratory distress syndrome (ARDS),[49] superimposed on the immature lung.[50] Lesions in the lungs reflect both the disease and its treatment with mechanical ventilation and supplemental oxygen. Within the first 3 to 4 hours, the lungs may only show uneven ventilation of distal air spaces resulting from surfactant deficiency, interstitial edema resulting from incomplete removal of fetal lung liquid or acute injury to microvascular endothelial cells, and congestion of capillaries (see Figure 95-1, *E*). By 12 to 24 hours, necrosis of alveolar and bronchiolar epithelial cells develops, and the denuded walls become coated by characteristic *hyaline membranes,* which are eosinophilic transudates of plasma proteins admixed with necrotic epithelial cells and fibrin (see Figure 95-1, *E* and *F*).[51] These histopathologic features are similar to those in the exudative phase of ARDS in adults, but the alveolar type II epithelial cell hyperplasia that constitutes the proliferative phase of ARDS in adults is not as prominent in hyaline membrane disease seen in autopsy slides from premature infants.

Mechanical ventilation of premature infants can result in ventilator-induced lung injury,[52] even after repeated doses of exogenous surfactant. The injurious effects of mechanical ventilation depend on a number of factors, among which are the magnitude of airway pressure (barotrauma) and lung volume (volutrauma)[53,54] and the concentration of inspired oxygen (oxygen toxicity). Several experimental animal studies have compared indices of ventilator-induced lung injury between conditions that raised airway pressure and increased lung volume.[55-57] Those studies suggest that large lung volumes, rather than high peak airway pressures per se, are the cause of ventilator-induced lung injury. For this reason, the term *volutrauma* is used to describe the injury that is associated with mechanical ventilation.

How does volutrauma induce lung injury, especially after premature birth? Evidence suggests that some of the circumstances described above are exacerbated. For example, regional overinflation increases microvascular permeability, either directly or indirectly (through release of inflammatory mediators from sequestered leukocytes in the lung), which leads to alveolar flooding. Alveolar flooding is in turn associated with inactivation of surfactant, leading to atelectasis and decreased lung compliance. If these cycles are not broken, lung injury recurs, necessitating higher airway pressure, larger tidal volume, and more supplemental oxygen. As the extent and duration of mechanical ventilation with supplemental oxygen increase, and lung volutrauma persists or increases, acute lung injury may progress to chronic lung disease (CLD).

CHRONIC LUNG DISEASE OF PREMATURITY

Survival of prematurely born infants with RDS has significantly improved since the introduction of antenatal steroid and postnatal surfactant replacement therapies and use of gentler ventilation strategies.[34,58-60] As described earlier, 84% of premature infants weighing 500 to 1500 g at birth now survive. Unfortunately, in approximately 8,000 to 10,000 premature infants in whom RDS develops in the United States annually, and who receive antenatal glucocorticoids and postnatal surfactant replacement, the disease progresses to CLD of prematurity (i.e., bronchopulmonary dysplasia [BPD]). The reported incidence of CLD in premature infants ranges between 15% and 60%.[61-63] As expected, compared with larger premature infants, smaller infants are at greater risk

for this disorder. After adjustment for a number of risk factors, development of CLD most frequently is associated with need for high inspired oxygen concentration 96 hours after birth, high peak inspiratory pressure, and high fluid intake.

The original description of BPD was by Northway and colleagues.[64] The principal clinical criterion was the requirement for supplemental oxygen for at least 28 days after birth (a duration selected because the first preterm neonates were managed during the month of February (Northway WH Jr, personal communication, 2009). The major radiologic criteria were cyst formation and hyperexpansion mixed with atelectasis. The characteristic histopathologic findings at autopsy depended on the duration of disease before death: Classic hyaline membrane disease is seen in the first 2 to 3 days. A regenerative phase is seen over the next week that consists of necrosis and regeneration of bronchiolar and alveolar epithelium, in addition to hyaline membranes. Over the next 10 days, hyperplasia of bronchiolar and arteriolar smooth muscle, fibrosis, and dilation or collapse of distal air sacs ensue. In the final stage, these alternating areas of overdistention and atelectasis become fixed. The term *bronchopulmonary* was chosen to identify airway and blood vessel involvement; *dysplasia* was chosen to describe the failure of the distal air sacs to develop into normal anatomic alveoli (Northway WH Jr, personal communication, 2009). Today, CLD usually is defined clinically as either oxygen dependency at 28 days of life with appropriate radiologic findings or oxygen dependency at 36 weeks postconceptual age.[65,66]

BPD as originally described by Northway and colleagues[64] was diagnosed in premature infants who did not recover from RDS. However, treatment of respiratory failure from other causes, including meconium aspiration pneumonia,[67] neonatal pneumonia,[68] congestive heart failure,[69] or congenital diaphragmatic hernia,[70] may be associated with CLD.

Prematurely born infants diagnosed with CLD today are much younger (23 to 26 weeks gestation) and smaller (less than 1000 g) than those with BPD as described in early reports (31 to 34 weeks gestation and approximately 2000 g at birth), and the radiologic and pathologic features of their lung disease are less severe. Today, the radiologic abnormalities include lung hyperinflation, emphysema, and interstitial densities. The principal histopathologic finding at autopsy is dilated and simplified distal air sacs[71,72] (see Figure 95-1, *G* and *H*). Usually missing are the classic histopathologic changes in the central airways. Recognition of these distinctions between contemporary CLD and BPD, as originally described, has prompted some clinicians and investigators to call today's CLD "new BPD." Debate continues about whether the disease that is seen today is in fact new or represents a less severe variant of BPD.

Impaired Alveolar Formation After Injury in Premature Lung

Simplification of distal air sacs is characteristic of the histopathologic pattern in premature lungs. Simplification is related to failure of alveolar secondary septa (crests) to sprout into the distal air sacs. The mechanisms that participate in normal or abnormal secondary septation of alveoli are not known and are a topic of intense investigation today.[65]

Alveolar formation is initiated near the end of the fetal period and continues postnatally after term gestation.[10,73-77] At term gestation, alveolar formation is less complete in humans, baboons, and mice.[10,73-77] than in sheep and other ruminants.[78-80]

Alveolar formation is structurally manifested by evagination of partitions along the smoothly curved saccular walls during late gestation and early postnatal life.[10] Regardless of the speed with which alveolar formation occurs among species, low ridges elongate into secondary septa. Capillary loops accompany these septal evaginations, resulting in a thin air-blood interface on either side of the septa, and attenuation of the mesenchymal core through apoptosis.[81] These processes increase surface area and thinness of air-blood barriers, resulting in minimal impediment to the diffusion of oxygen and carbon dioxide.[82]

Because of the late initiation of and prolonged period for alveolar formation, success with use of knockout or transgenic mice as models to identify regulatory molecules during alveolar formation has been limited. With such approaches, the earliest stages often are affected profoundly, sometimes resulting in embryonic or fetal death before alveolar formation is initiated. An important exception is the platelet-derived growth factor-A (PDGF-A)–null mouse.[83] Some of the PDGF-A$^{-/-}$ mice survive through the postnatal period, but these mice lack both alveolar myofibroblasts and alveolar elastin. Their lungs have simplified distal air spaces. Another exception is the elastin-null mouse.[84] The elastin$^{-/-}$ mice survive through the first several days of postnatal life, but they are cyanotic. Their lungs have reduced airway and vascular generations, with arrest of distal air spaces at the saccular stage.

Because CLD occurs almost exclusively after premature birth and weeks of mechanical ventilation with supplemental oxygen, reproducing the human disease in animal models requires intensive, large-animal protocols. Coalson and co-workers developed the baboon (primate) model that has the pathologic features of CLD, including alveolar simplification.[85-88] These investigators showed that early application of high-frequency ventilation may reduce the severity of the histopathologic changes.[89-91] and speculated that hyperoxia and tidal ventilation of the premature lung leads to lung overstretch and release of inflammatory mediators that cause loss of alveoli and alveolar capillary surface area.[86,92] Bland and colleagues also developed a model of CLD using preterm lambs.[93-96] Mechanical ventilation of preterm lambs for 3 to 4 weeks, using large tidal volumes (15 mL/kg of body weight), resulted in inhibition of alveolar formation and alveolar capillary growth, disruption of gas exchange, diminished numbers of microvessels, persistent muscularization of resistance arterioles, increased pulmonary vascular resistance, and decreased expression of endothelial nitric oxide synthase protein.[93-96] Management of premature lambs with high-frequency jet ventilation, on the other hand, was associated with improved structural formation of alveoli and alveolar capillary growth.[97]

A consequence of failed septation is reduced surface area for gas exchange, including the capillary surface area.[92,94] However, the latter observation in experimental animals with evolving CLD has not been confirmed in autopsy tissue from infants who died with established CLD.[98] One explanation for this discordance is the time frame of CLD studies. Experimental animal studies are relatively short (up to 4 weeks, with evolving CLD), whereas premature infants with CLD may be managed with mechanical ventilation and supplemental oxygen for much longer periods (months, with established CLD), suggesting that capillary proliferation may be an adaptive response to impaired septation in CLD.

Studies using premature lambs with evolving CLD also indicated that the elastin gene is excessively and continuously upregulated.[96] Up-regulation occurs on the third day of continuous mechanical ventilation[99] and persists for 3 to 4 weeks. Although the results from the premature lambs with evolving CLD and elastin-knockout mice[84] (described earlier) seem contradictory, they actually suggest that tropoelastin gene expression has to be tightly regulated for normal septation. Too little or too much tropoelastin gene expression is detrimental to normal septation.

Appropriate stretch of the developing lung appears to be of key importance for formation of normal alveoli. Overstretch leads to distortion of cells and extracellular matrix in the developing lung. The distortion may lead to the local synthesis and release of regulatory molecules that affect cellular division, phenotype, and metabolic activity. High lung inflation (overstretch), for example, increases mRNA levels for transforming growth factor (TGF)-β_1

four-fold and basic fibroblast growth factor (bFGF) (i.e., FGF2) by 60% compared with values obtained for low lung inflation in adult rabbits.[100] In this regard, PDGF is involved in stretch-mediated signaling, and elastin also is a stretch-responsive gene. These data emphasize the importance of mechanical stretch in alveolar formation.

Among the mediators proposed to link overstretch and arrested alveolar formation are growth factors, cytokines, and matrix-degrading proteinases released by epithelial and mesenchymal cells, as well as resident and infiltrating inflammatory cells. For example, the developing lung has the ability to synthesize and release vascular endothelial growth factor (VEGF),[101] FGFs,[102] PDGFs,[103,104] TGFs,[105,106] insulin-like growth factors,[107,108] and epidermal growth factor (EGF),[109,110] as well as their receptors. Of these growth factors, VEGF[111-115] and related vascular growth–signaling molecules,[116,117] FGF signaling,[118,119] and PDGF-A[83,103] are implicated in alveolar formation.

VEGF expression is regulated by other growth factors, such as TGF-β[120] and PDGF,[121] and dexamethasone.[101] The biologic function of VEGF in disease states may rely on altered amounts of VEGF protein, as well as altered VEGF receptor (VEGF-R) protein and affinity. For example, hypoxia induces pulmonary production of VEGF and its receptor, VEGF-R2 (also named FLK-1 [fetal liver kinase-1] or KDR [kinase insert domain–containing receptor]).[101,122] The latter paracrine ligand/receptor pair is responsible for differentiation of angioblasts into capillary endothelial cells in the lung.[123] The converse is true for hyperoxia,[124] which is a risk factor for failed alveolar formation.[124,125] In this regard, disruption of pulmonary blood vessel formation in rats, by blocking binding of VEGF to its receptor, results in lung histopathologic changes that look like CLD.[113,114] Recovery of neonatal and adult rabbits from hyperoxia is associated with VEGF message expression by alveolar epithelial cells.[124,126] These findings suggest a role for VEGF in regulating alveolar capillary proliferation normally and after oxidant injury; the latter plays a central role in the pathogenesis of CLD.

Deficiency of retinol or retinol-binding protein after premature birth may contribute to the development of CLD in neonates.[127-130] Clinical trials of retinol treatment of neonates at risk for CLD, however, have yielded conflicting results. In a randomized, double-blind controlled trial,[131] infants who received vitamin A had a significantly lower incidence of CLD and reduced need for supplemental O_2, mechanical ventilation, and intensive care. In a subsequent study, retinol supplementation had no effect on the incidence of CLD in preterm infants.[132] More recently, however, large multicenter studies of retinol versus placebo treatment of tiny preterm infants have shown a significant reduction in the incidence of CLD among the retinol-treated infants.[133,134]

Experimental animal studies have provided promising results in this regard. One study showed that retinoid signaling is required for alveolar formation.[135] Another study used pregnant rats treated with dexamethasone repeatedly to inhibit lung development in utero.[136] The newborn pups, treated with all-*trans*-retinoic acid postnatally, demonstrated greater alveolar formation than that in the untreated control rat pups. A third study showed that retinoids reversed steroid-induced suppression of lung growth and epithelial cell proliferation in cultured fetal rat lung.[137] A fourth study showed that retinoic acid treatment of adult rats with elastase-induced pulmonary emphysema was associated with reversal of emphysematous lesions.[138] Initial studies from our own clinical laboratory using premature lambs with evolving CLD of prematurity have shown that daily treatment with vitamin A (Aquasol) is associated with enhanced formation of alveoli and alveolar capillaries and increased expression of VEGF and VEGF-R2.[112] The molecular mechanisms by which vitamin A up-regulates expression of VEGF and VEGF-R2 are being investigated. More recent studies suggest involvement of retinoic acid receptors.[139]

Ongoing research is providing exciting evidence that nasal continuous positive airway pressure (nasal CPAP) permits alveolar formation. From a clinical standpoint, the incidence of CLD of prematurity is lower in preterm neonates managed by nasal CPAP than in those receiving mechanical ventilation.[140,141] Why the incidence is less is starting to become evident, through studies using chronically ventilated preterm lambs or baboons. For example, Jobe and colleagues compared the inflammatory milieux in two groups of preterm lambs that were managed for 2 hours by mechanical ventilation or nasal CPAP. Preterm lambs managed by conventional mechanical ventilation had almost seven times more neutrophils and hydrogen peroxide in alveolar washings than in those from preterm lambs managed by nasal CPAP.[142] A subsequent study by Thomson and colleagues examined indices of alveolar formation in preterm baboons that received nasal CPAP for 28 days.[143] Alveolar complexity was greater in the preterm baboons than in historical control baboons managed by mechanical ventilation. The lungs of the nasal CPAP–managed preterm baboons had enlarged, thin-walled air spaces, with greater immunolocalization of capillary endothelial cells (on platelet endothelial cell adhesion molecule [PECAM] immunostaining), scattered secondary septa, and minimal fibroproliferation. Internal surface area and surface-to-volume ratio dimensions were similar to those in 156-day gestational control lungs, the intrauterine developmental control.

In preliminary studies from our laboratory using chronically ventilated preterm lambs, comparable results have been obtained.[144] For instance, management of preterm lambs by nasal CPAP for 21 days resulted in three- to four-fold enhancement of alveolar septation and capillary development, as well as up-regulation of VEGF and FLK-1 gene expression, compared with mechanical ventilation for 21 days. In addition, the fractional inspired O_2 to achieve a target Pa_{O_2} of 60 to 70 mm Hg was significantly less in the nasal CPAP group than in the mechanically ventilated group at 1, 2, and 3 weeks of life. For the target Pa_{CO_2} (50 to 60 mm Hg), peak inspiratory pressure, positive end-expiratory pressure, and mean airway pressure also were significantly less in the nasal CPAP group than in the mechanically ventilated group at weeks 1, 2, and 3 of life.

Our more recent studies suggest that preterm lambs managed by nasal CPAP have thinner distal air space wall thickness, less cell proliferation of mesenchymal cells, and more apoptosis of mesenchymal cells.[3,145] Thus results such as these from the only two large-animal models of CLD of prematurity are providing new mechanistic insights into how and why outcomes appear to be better for preterm neonates managed by nasal CPAP than for those managed by mechanical ventilation. The common theme appears to be that nasal CPAP permits alveolar formation, whereas mechanical ventilation arrests alveolar formation.

SUMMARY

The structural and functional immaturity of the premature infant's lung necessitates use of antenatal steroids, perinatal surfactant replacement therapy, postnatal mechanical ventilation and oxygen supplementation, and other supportive measures. Acute lung injury often occurs as a result of lung immaturity and the therapy that it necessitates. If recovery does not ensue, the affected premature infants progress to CLD. Although CLD continues to be one of the most serious of today's pediatric public health issues, important progress has been made. For example, CLD of prematurity now occurs infrequently in larger (2 kg or greater) and more mature (32 weeks and beyond) premature infants, the population that Northway and colleagues described in their original report on BPD.[64] Moreover, the severity of CLD is less today than at the time of that report. These encouraging changes reflect better understanding of lung developmental biology and improvements in clinical management of prematurely born infants, such as use

of nasal CPAP. Nonetheless, challenges remain, because the incidence of premature birth is increasing, the size of the premature infant who can be supported is decreasing, and the incidence of CLD among the smallest premature infants remains very high.

Antenatal Factors That Influence Postnatal Lung Development and Injury

SPECTRUM OF LUNG DISEASE IN PRETERM INFANTS

The fetal lung at 26 weeks gestation is in an early saccular stage of development and surfactant deficient. Surfactant treatment and the use of more gentle modes of assisted ventilation have resulted in populations of very preterm infants with a wide range of lung diseases not easily classifiable into the traditional categories of respiratory distress syndrome (RDS), lung immaturity, transient tachypnea, and normal. In one large series, the mortality rate for infants weighing 501 to 1500 g at birth was only 14%, but *bronchopulmonary dysplasia* (BPD), defined as the need for supplemental oxygen at 36 weeks, occurred in 23% of these infants.[1] For the population of very preterm infants in the 750- to 1000-g birth-weight range, 37% of the infants did not have RDS, but 42% ultimately had BPD. In some instances, then, BPD may develop without preceding RDS.

In a series of 177 surviving infants with birth weights less than 1250 g, 115 infants had RDS, which progressed to BPD in 61 infants.[2] Of 88 infants with BPD, the disease developed in 27 infants, either after resolution of the RDS or in the absence of preexisting lung disease. Thus, in 30% of the infants with BPD, the clinical course was not characteristic of the usual progression from RDS to BPD associated with assisted ventilation in the neonate.

A complex interplay of antenatal and postnatal factors is now recognized to affect postnatal lung development after premature birth and, ultimately, the incidence of BPD (Figure 96-1). This chapter explores some of the antenatal factors that may modulate lung development and thereby alter the postnatal clinical course of lung disease in preterm infants.

CHORIOAMNIONITIS

The fetal lungs are protected from the traditional mechanisms of lung injury, but infection and inflammation can reach the fetal lung. Infective organisms from the lower genital flora can ascend through the cervix, with subsequent spread of infection between the chorioamnion and the uterine wall; this mode of transmission is commonly associated with early preterm labor.[3] Inflammation of the chorioamnion, termed *chorioamnionitis,* can be confirmed only by histopathologic examination, for a diagnosis of "histologic chorioamnionitis." In clinical practice, chorioamnionitis is diagnosed using a combination of indicators such as elevated maternal temperature, uterine tenderness, malodorous vaginal discharge, maternal leukocytosis, and fetal tachycardia.[4] Spread of the inflammatory process to the amniotic fluid can be evaluated by amniocentesis to obtain amniotic fluid for culture

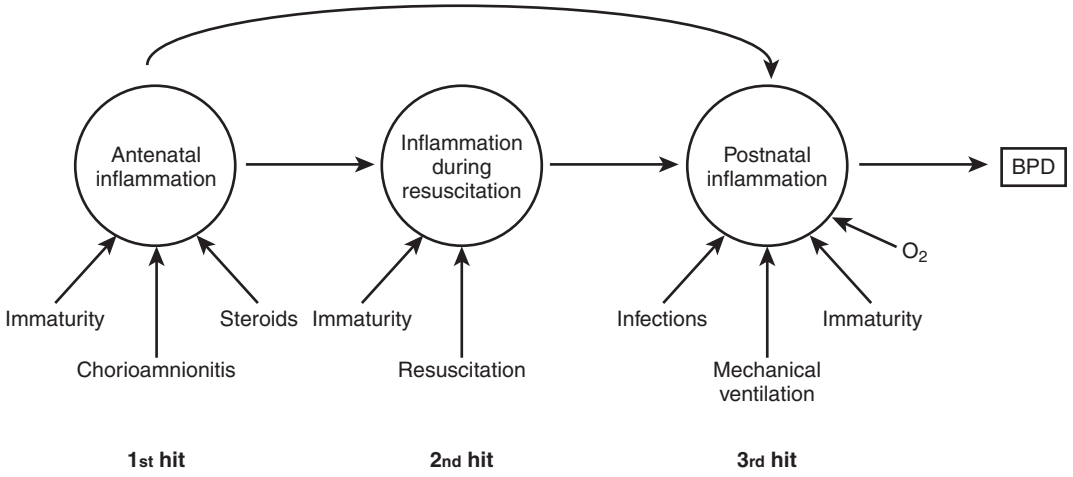

Figure 96-1 A model for the interplay of fetal exposures on early postnatal events that may contribute to altered lung development and injury.

or cell counts, or by measurement of proinflammatory mediators. Further spread of the infection or inflammation to the fetus can occur by either of two routes[5]: Normal fetal swallowing may lead to aspiration of the inflammatory products in the amniotic fluid, with subsequent development of a pneumonia-sepsis syndrome, or the fetus may mount an inflammatory response to signals from the inflamed fetal placenta and chorioamnion. The fetal inflammatory response in chorioamnionitis has been defined as an elevation of interleukin (IL)-6 in fetal cord blood obtained by cordocentesis or in cord blood after delivery.[6] Funisitis, or inflammation of the cord, correlates with elevated cord blood IL-6 levels and signs of generalized fetal inflammation.

The rapidly progressive chorioamnionitis or bloodstream infection caused by organisms such as *Escherichia coli, Listeria monocytogenes,* or group B streptococci is relatively infrequent in the preterm population. By contrast, clinically asymptomatic histologic chorioamnionitis caused by low-virulence or commensal organisms increases in frequency as gestational age at delivery decreases. In one series, approximately 70% of infants (born before 30 weeks gestation) delivered by cesarean section with intact membranes had histologic chorioamnionitis.[3] This clinically inapparent chorioamnionitis is associated with recurrent preterm deliveries, and indicators of inflammation may be present before midgestation.

The diagnosis of chorioamnionitis can be problematic. In general, various markers of chorioamnionitis—amniotic fluid cytokines, neutrophils in amnion or chorion, and positive microbiologic findings—correlate with one other. However, in a study involving preterm infants born at 23 to 32 weeks gestation, evidence of histologic chorioamnionitis was lacking in 25% of cases with positive amniotic fluid culture, whereas in 20% of the cases with histologic chorioamnionitis, amniotic fluid culture result was negative.[7] Similarly, in 35% of the cases with evidence of histologic chorioamnionitis, no elevation of amniotic fluid IL-6 level was noted. The correlation of clinical chorioamnionitis with histologic chorioamnionitis is even more tenuous, with absence of clinical manifestations in more than 75% of cases with positive histopathologic findings.[7] Even in cases with negative amniotic fluid culture, evidence of bacterial RNA was present in the placenta of most preterm infants adding another dimension of complexity in the definition of chorioamnionitis.[8]

Growing evidence suggests that endometrium is not normally sterile. In a clinical study using careful techniques to prevent contamination, at least one organism was isolated from endometrial cultures in 85% of nonpregnant women.[9] Amniotic fluid sampled before 20 weeks gestation for genetic diagnostic indications can contain elevated proinflammatory mediators and be culture-positive for low-virulence pathogenic organisms.[10] Often the infants born to mothers with such amniotic fluid markers have no overt signs of infection at delivery. Thus a majority of fetuses may be exposed to bacterial products for a long time in utero without clinically apparent complications. Nevertheless, the most common cause of fetal death or death soon after birth for very low-birthweight infants was sepsis or pneumonia in an autopsy series.[11] Evidently, then, the effects of chorioamnionitis on the preterm fetus may range from severe infection or death to normal fetal development, with histologic chorioamnionitis as an incidental finding. Attempts to secure a definitive diagnosis of chorioamnionitis typically are limited by a lack of information about its duration, intensity, or extent or the organisms responsible for the clinical or histopathologic findings. In the face of exposure to commonly encountered infectious agents, down-regulation of inflammatory responses in utero may be a key coping mechanism of the fetus.

CHORIOAMNIONITIS AND FETAL LUNG INJURY

The traditional concept is that fetal infection or inflammation associated with chorioamnionitis can result in an aspiration pneumonia syndrome and sepsis. Gomez and colleagues[6] proposed that the fetal inflammatory response was equivalent to acute RDS in adults, with systemic inflammatory mediators targeting the lungs. In other fetuses exposed to inflammation in the amniotic fluid, however, elevation of plasma IL-6 levels is not seen. Elevated IL-1β, IL-6, and IL-8 levels in amniotic fluid measured within 5 days of preterm delivery predicted the subsequent development of BPD.[12] Histologic chorioamnionitis was not useful retrospectively in the reported series because it was present in 92% of infants with subsequent BPD and in 62% of those without BPD. RDS also was not a good predictor of BPD. In another report, severe histologic chorioamnionitis and elevated tumor necrosis factor-α (TNF-α) concentration in amniotic fluid were associated with an increased incidence of RDS and subsequent BPD.[13] In a comparison of the predictive values for the development of BPD, elevated cord plasma IL-6 was a better predictor than elevated IL-6 in the amniotic fluid.[14] Fetal exposure to inflammation was associated with a lung injury process that results in an increase in the incidence of BPD. A graded increasing risk of BPD was observed, ranging from histologic chorioamnionitis, to elevation of inflammatory mediators in amniotic fluid, to a fetal inflammatory response with elevated IL-6 in fetal blood. This association, however, was not apparent in a more recent series of 466 consecutive singleton births before 32 weeks gestation[7] (Table 96-1).

TABLE 96-1

Associations Between Histologic Chorioamnionitis and Outcomes for 446 Consecutive Singleton Deliveries Before 32 Weeks Gestation

	MEMBRANES		CORD		
Clinical Outcome	**Yes (%)**	**No (%)**	**Yes (%)**	**No (%)**	**Statistically Significant**
Ureaplasma + *Mycoplasma*	81	32	49	21	•

BPD, Bronchopulmonary dysplasia; *IVH,* intravascular hemorrhage; *NEC,* necrotizing enterocolitis; *RDS,* respiratory distress syndrome; *SIRS,* systemic inflammatory response syndrome.

The lack of consistent association probably reflects the poor precision of the diagnosis of chorioamnionitis and the multiple contrasting effects of fetal exposures that can both injure the lungs and induce their maturation.

CLINICAL LUNG MATURATION

Although chorioamnionitis generally is considered to have adverse effects on the fetus, some reports indicate a clinical benefit. Watterberg and colleagues[15] reported that histologic chorioamnionitis and high IL-1β in airway samples determined on the first postnatal day predicted a decreased incidence of RDS but an increased incidence of BPD. Infants in whom blood cultures were positive for *Ureaplasma urealyticum* also exhibited a lower incidence of RDS but a higher incidence of BPD than in infants with negative blood cultures.[16] Higher cord plasma levels of IL-6 predicted a lower incidence of RDS in another report.[17] Although these small clinical series may reflect a reporting bias, the presence of chorioamnionitis was associated with improved survival for 881 infants born at less than 26 weeks in the United Kingdom and Ireland in 1995.[18] Histologic chorioamnionitis also was associated with less RDS in 446 consecutive singleton births before 32 weeks gestation (see Table 96-1).

The associations of chorioamnionitis with outcomes such as RDS and BPD are likely to be quite complex. In a large epidemiologic report, histologic chorioamnionitis predicted a decreased incidence of BPD unless the infant received mechanical ventilation or developed postnatal sepsis, which in combination with histologic chorioamnionitis increased the risk of BPD.[19] This study suggests that fetal exposure to inflammation can induce clinically apparent maturation of the lung, but that subsequent injury (as from ventilation or sepsis) may increase the injury response, thereby resulting in BPD.

ANIMAL MODELS OF CHORIOAMNIONITIS

Bry and colleagues[20] reported that intraamniotic injections of recombinant IL-1α induced messenger RNA (mRNA) for surfactant proteins SP-A and SP-B and improved the pressure-volume curves in preterm rabbits. IL-1α also increased mRNA for SP-A, -B, and -C in early-gestation explants of rabbit lung.[21] To further explore the relationships between inflammation and maturation, *E. coli* endotoxin was given by intraamniotic injection in sheep.[22] The fetal sheep lung responded to intraamniotic endotoxin with a large increase in compliance and lung gas volume within 5 to 7 days. These improvements in lung function after preterm birth were accompanied by persistent increases in the mRNA for SP-A, -B, -C, and -D, and by hundred-fold increases in the surfactant proteins in the air spaces.[23] The processing of SP-B was induced, the amount of surfactant lipid increased, and the antioxidant enzymes increased.[24]

In the preterm lamb model, "clinical maturation" was a late response of the lung to inflammation (Figure 96-2). Within hours of the intraamniotic injection of endotoxin, white cells producing the mRNA for the proinflammatory cytokines IL-1β, IL-6, and IL-8 infiltrated the chorioamnion and subsequently appeared in the amniotic fluid.[25] The cells in amniotic fluid expressed the mRNA for IL-1β and IL-8 for at least 1 week after the endotoxin exposure. Within 5 hours of intraamniotic endotoxin administration, the fetal lung contained activated granulocytes, and the airways expressed heat shock protein 70 (HSP70).[26] The amount of H_2O_2 in cells lavaged from the lungs was maximal at 24 hours, and both the lung tissue and lavage cells expressed proinflammatory cytokines.[27] Apoptosis increased at 24 hours and cell replication increased by 72 hours. The fetal lung exhibited an acute but modest generalized inflammatory response that resolved to "clinical maturation" in that lung function was strikingly improved after preterm delivery and ventilation.

The lung maturational response in the preterm lamb model did not occur in the absence of chorioamnionitis and lung inflammation. A low dose of endotoxin that induced very mild inflammation did not result in lung maturation.[25] When inflammatory cell recruitment to the lung was blocked with an anti-CD18 antibody, the lung maturational changes did not occur.[28] The inflammation in the chorioamnion and lung did not result in increased plasma cortisol or a significant systemic inflammatory response.[22] Therefore the inflammation-mediated mechanisms for inducing lung maturation were independent of the adrenal axis. The fetal sheep responded to intraamniotic administration of recombinant ovine IL-1α or IL-1β with chorioamnionitis and lung maturation.[29] Similarly, endotoxin from periodontal organisms and chronic fetal colonization with live *Ureaplasma* organisms caused lung inflammation with improved lung function.[30,31] When chorioamnionitis was induced by intraamniotic endotoxin, it had no effect on the fetal lung when it was surgically isolated from the amniotic fluid.[32] By contrast, endotoxin infused over 24 hours into the fetal lung fluid resulted in striking lung maturation. These findings show that endotoxin, other inflammatory mediators, or the products of inflammation can induce lung maturation by direct contact with the fetal lung, indicating that lung maturation seems to be a consistent response of the fetal lung to inflammation.

CYTOKINES AND ALTERED LUNG DEVELOPMENT

Preterm infants in whom proinflammatory cytokines are increased in bronchoalveolar lavage fluid are at increased risk for the development of BPD.[33] A number of animal experiments show

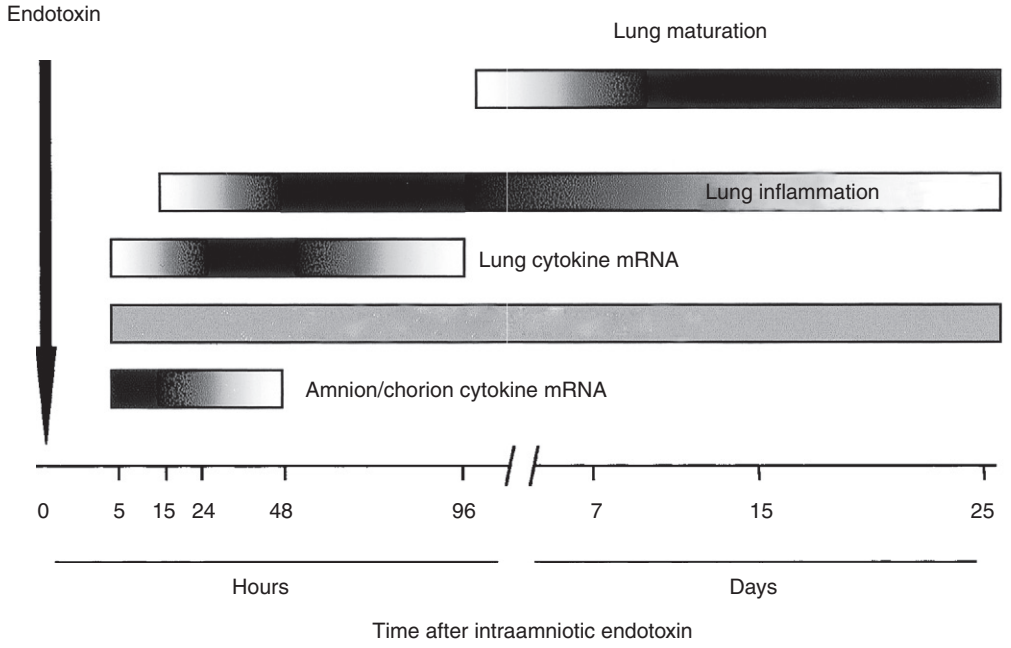

Figure 96-2 The time course of lung inflammation and maturation after intraamniotic endotoxin in preterm lambs.The *shading* within each box is proportional to the intensity and magnitude of the responses. *(Data from Kramer BW, et al: Dose and time response after intra-amniotic endotoxin in preterm lambs,* Am J Respir Crit Care Med *164:982, 2001; Kramer BW, et al: Injury, inflammation and remodeling in fetal sheep lung after intra-amniotic endotoxin,* Am J Physiol Lung Cell Mol Physiol *283:L452, 2002; and Kallapur SG, et al: Intra-amniotic endotoxin: Chorioamnionitis precedes lung maturation in preterm lambs,* Am J Physiol *280:L527, 2001.)*

that exposure of the developing lung to cytokines alters both the lung architecture and expression of components of the surfactant system.Transgenic mice that overexpress TNF-α,[34] transforming growth factor-α (TGF-α),[35] IL-6,[36] IL-13, and interferon-γ[37] have fewer and larger alveoli.Although overexpression of each of these cytokines resulted in different associated lung abnormalities, the common theme was interference with alveolar development. Proinflammatory cytokines also are uniformly elevated in the BPD caused by chronic ventilation of preterm sheep and baboons.[38] Oxidant exposures that disrupt alveolar septation cause increases in proinflammatory cytokines,[39] also identifying proinflammatory cytokines as a consistent association with BPD-like changes in animal models. Cytokines also regulate surfactant homeostasis. Mice that lack granulocyte-macrophage colony-stimulating factor (GM-CSF) or the GM-CSF receptor have alveolar proteinosis as a consequence of decreased catabolism of saturated phosphatidylcholine and SP-A.[40]

Preterm fetal rabbits or lambs exposed to intraamniotic IL-1α or endotoxin exhibit increased surfactant pool sizes and improved lung compliance.[20] IL-1 and endotoxin injected in amniotic fluid induce comparable maturational changes in fetal lamb lung.[29] The mechanism of lung maturation in this model is not known, but both IL-1 and the Toll-like receptors involved in endotoxin signal transduction share common components.[41] Although the endotoxin-induced lung maturation is striking in the preterm lamb, these changes also are accompanied by structural changes of fewer and larger alveoli—a pathologic hallmark of BPD.[32,42]

The fetal lung response to a proinflammatory stimulus also is dependent on the gestational age at exposure and the developmental milieu of the fetus. Exposure of explants of preterm fetal rabbit lung to IL-1 caused increased surfactant protein mRNA, whereas IL-1 inhibited surfactant protein mRNA in explants from term lungs.[21] Similarly, postnatal exposure to endotoxin decreased SP-B mRNA synthesis in mouse lung, whereas intrauterine exposure to endotoxin increased SP-B synthesis in lamb lungs.[23] Thus the preterm infant probably responds to proinflammatory stimuli in a complex fashion with changes in the developmental program of the saccular lung. Some of these changes are beneficial to ex-utero survival of the preterm, whereas others may predispose the fetus to development of BPD.

ANTENATAL INFECTION AND VASCULAR INJURY

Infants with BPD have a decreased and disorganized lung microvasculature with decreased expression of angiogenic growth factors such as vascular endothelial growth factor (VEGF) and its receptors[43,44] (Figure 96-3). This decreased microvascular development also was observed in preterm lamb and baboon models of BPD induced by mechanical ventilation.[38,45] In recombination experiments using rat embryo tissue, epithelial cells were required to maintain expression of fetal liver kinase-1 (Flk-1), a marker of endothelial cells, in the distal lung mesenchymal cells.[46] Alveolar development was disrupted in transgenic mice that overexpressed VEGF or in mice lacking the higher-molecular-weight heparin-binding VEGF isoforms.[47,48]

Abnormalities of pulmonary circulation were associated with lung hypoplasia in animal models.[49,50] In neonatal rat pups in which VEGF signaling was disrupted with pharmacologic inhibitors of the Flk-1/KDR receptor, impaired alveolarization was observed.[51] These experiments demonstrate the phenomenon of cross-talk between the mediators of vascular and alveolar development in the lung. Intraamniotic endotoxin caused impaired alveolarization in lambs[42,52] (Figure 96-4). The chemokines IP-10 (*i*nterferon-γ–inducible *p*rotein-10) and MIG (*m*onokine *i*nduced by interferon-*g*amma), known to inhibit vascular development in other animal models, are robustly induced in the lungs of preterm lambs exposed to intraamniotic endotoxin.[53] The lung inflammatory response in these preterm lambs is

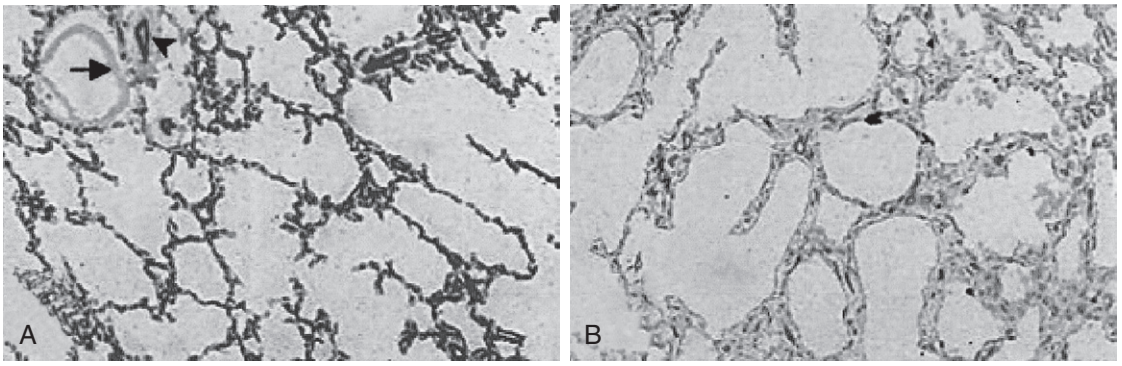

Figure 96-3 Lung sections from infants who died from nonlung causes **(A)** or bronchopulmonary dysplasia (BPD) **(B).** The sections were immunostained for PECAM-1 (CD31) antigen, which is specific for vascular endothelium. Staining for platelet–endothelial cell adhesion molecule (PECAM) was decreased in lungs from infants with BPD, indicating impaired vascular growth. *Arrowhead* shows PECAM staining in the alveolar wall. *(From Bhatt AJ, et al: Disrupted pulmonary vasculature and decreased vascular endothelial growth factor, Flt-1 and Tie-2 in human infants dying with bronchopulmonary dysplasia,* Am J Respir Crit Care Med *164:1971, 2001.)*

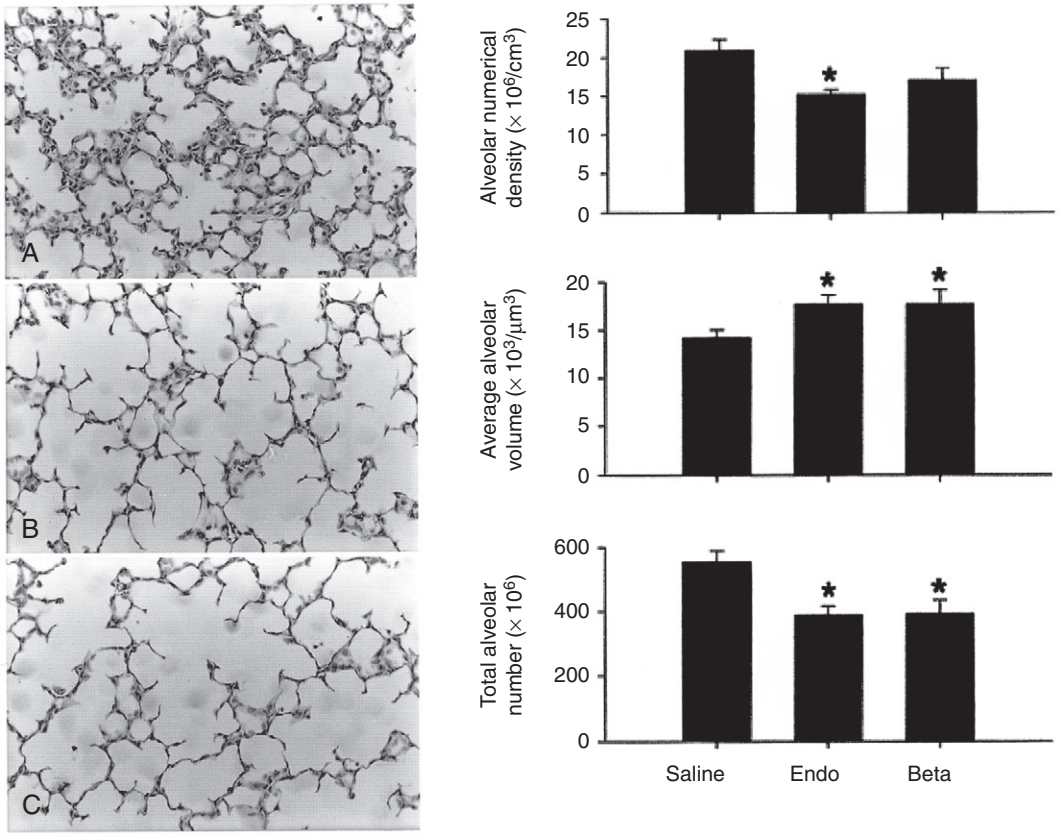

Figure 96-4 Preterm lamb lungs at 125 days gestation, 7 days after administration of control intraamniotic saline **(A),** intraamniotic endotoxin *(Endo)* **(B),** or maternal betamethasone *(Beta)* **(C).** *Bar graphs* give indices of alveolar development in treated versus control groups of preterm lambs. Note that both endotoxin and maternal betamethasone impaired alveolar development. *$p < .05$ versus control data. *(From Willet KE, et al: Antenatal endotoxin and glucocorticoid effects on lung morphometry in preterm lambs,* Pediatr Res *48:782, 2000.)*

accompanied by decreased expression of endothelial proteins in the lung important for blood vessel formation (e.g., VEGF receptor-2 [VEGFR-2], endothelial nitric oxide synthase [eNOS]).[54] The preterm fetal lambs exposed to intraamniotic endotoxin developed smooth muscle hypertrophy in resistance lung arterioles and adventitial fibrosis in large blood vessels. These vascular remodeling changes are similar to those described in human infants with BPD.[55]

IMMUNOLOGIC RESPONSES AFTER FETAL LUNG INFLAMMATION

The inflammatory responses of the fetal lung differ from adult responses in that multiple components that make up a mature inflammatory response to injury are deficient in the former. The preterm fetal lung does not respond to bioactive TNF-α in the amniotic fluid or to TNF-α given intravenously.[56] The preterm

fetal lung contains almost no macrophages or granulocytes, and normal host defense proteins such as SP-A and SP-D are present in very low amounts.[57] Although multiple components of innate immune response are deficient, preterm fetal sheep at 50% gestation can recruit inflammatory cells in the airway and mount an inflammatory response to intraamniotic endotoxin.[52]

Endotoxin tolerance is a state in which the cells have a diminished ability to respond to repeated challenges with endotoxin. Whereas endotoxin tolerance is well described in adult monocytes, little information about endotoxin tolerance in fetuses is available. Exposure of fetal sheep to intraamniotic endotoxin induces an endotoxin tolerance response in systemic blood monocytes early after exposure, followed by an amplification of endotoxin responsiveness by 7 days.[58] Consistent with the endotoxin tolerance response, repeated doses or continuous intraamniotic infusions of endotoxin did not result in severe or progressive lung inflammation and induced endotoxin tolerance in blood monocytes.[52,58,59] As a result, and in contrast with effects of exposure to a single-dose endotoxin, chronic or multiple doses of intraamniotic endotoxin did not increase inhibition of alveolar development or cause any sustained structural abnormalities in the fetal lung.[59] The complex effects of chronic exposure of the fetal lung to antenatal inflammation probably will alter postnatal lung and systemic inflammatory responses. Chronic exposure to inflammation may be quite common in infants born before 30 weeks gestation.

ANTENATAL INFLAMMATION AND POSTNATAL INFLAMMATION

BPD in preterm infants is multifactorial in etiology and results from the interaction of antenatal and postnatal risk factors.[60] In epidemiologic and clinical studies, chorioamnionitis was associated with BPD in some studies[15] but not in others.[7] Multiple reasons for this discrepancy of association between chorioamnionitis and BPD are recognized: (1) Definitions of chorioamnionitis vary (clinical chorioamnionitis versus histologic chorioamnionitis); (2) different consequences may result from chorioamnionitis with different organisms (*Ureaplasma* versus gram-negative organisms); and (3) differing degrees of antenatal and postnatal inflammation are seen in different studies. A way to interpret the interaction between antenatal and postnatal inflammation is by analogy to the "multiple-hit hypothesis" (see Figure 96-1). Antenatal inflammation may "prime" the inflammation, leading to exacerbation of injury from postnatal inflammation.

Experimental evidence from the fetal sheep model supports a "multiple-hit" mechanism. Exposure to intraamniotic endotoxin 30 days before preterm delivery increased postnatal lung inflammation induced by mechanical ventilation in preterm lambs, whereas exposure to endotoxin 4 days before delivery did not amplify the ventilation-induced lung injury response.[61,62] The timing of the onset of antenatal inflammation may be important for modulating injury responses to postnatal inflammation. In another experiment, intraamniotic endotoxin caused a tolerance-type or "down-regulated" endotoxin responsiveness of blood monocytes 2 days after exposure but an amplified endotoxin response 7 to 14 days after exposure.[58] Thus, in a developing fetus, exposure to antenatal infection may cause either innate immune paralysis or augmentation of innate immune responses, depending on the timing of the insult.

Another variable that may contribute to lung injury is the fate of inflammatory mediators that are in the lungs of the infant at delivery. The uninjured fetal lung is quite impermeable to proteins and large-molecular-weight substances such as endotoxin. In two different studies, however, gentle mechanical ventilation of the preterm lamb lung with endotoxin or IL-1 in the air spaces resulted in transfer of the proinflammatory mediators to the systemic circulation, which caused a systemic inflammatory response.[63,64] In an epidemiologic study, the risk of BPD did not increase on exposure to chorioamnionitis but was increased after exposure to chorioamnionitis and mechanical ventilation after birth.[19]

GLUCOCORTICOID EFFECTS ON THE FETAL LUNG

Although antenatal glucocorticoids decrease the incidence of RDS, they do not decrease the incidence of BPD in survivors.[65] This lack of clear benefit for prevention of BPD has been attributed to the increased survival of very preterm infants, who are most at risk for BPD. An alternative possibility, however, is the diminished alveolar septation observed after antenatal glucocorticoid treatment. Exposure of fetal monkeys or sheep to glucocorticoids decreased the lung mesenchyme, thinned the alveolus-capillary barrier, increased potential lung gas volume, but inhibited alveolar septation[42,66] (see Figure 96-4). Monkeys exposed to a relatively high dose of antenatal glucocorticoids had functionally more mature lungs that held more gas after preterm birth. However, when delivery was at term, the lungs were smaller, with fewer and larger alveoli.[67] Alveolar septation also was decreased in the fetal sheep lung by maternal betamethasone.[68] The magnitude of the arrest in alveolar septation was similar for both antenatal intraamniotic endotoxin and maternal betamethasone in sheep.[42] Although the mechanisms resulting in altered alveolar septation are not known, it is provocative that both proinflammatory and antiinflammatory stimuli that induce clinical lung maturation also have as an adverse effect the inhibition of alveolar septation. As with endotoxin, antenatal glucocorticoids may alter the fetal lung responses to injury and initiate the anatomic changes characteristic of BPD.

INTERACTIONS OF ANTENATAL GLUCOCORTICOIDS AND INFLAMMATION

Most women at risk for very preterm delivery with chronic histologic chorioamnionitis and low-grade infection will be asymptomatic. On the basis of current recommendations, such women will receive antenatal glucocorticoids without an amniocentesis to evaluate for infection or inflammation. This clinical practice is based on data from well-performed studies indicating that antenatal glucocorticoids improved neonatal outcomes despite presence of histologic chorioamnionitis or preterm rupture of membranes.[17,69,70] Antenatal glucocorticoids decreased plasma IL-6 and IL-8 in newborns born to mothers with chorioamnionitis, suggesting that the fetal inflammatory response can be suppressed.

Interactions between experimental chorioamnionitis and antenatal glucocorticoids have been minimally explored. Fetal sheep responded to antenatal betamethasone with improved lung function and decreased body weight and thymus gland weight.[71] By contrast, the more striking lung maturation induced by intraamniotic endotoxin occurred without a decrease in body or thymic weight. Exposure of the fetus to antenatal glucocorticoids and intraamniotic endotoxin resulted in a robust lung maturation response without adverse effects on body and thymic weights. In contrast with the additive effects of maternal betamethasone and intraamniotic endotoxin on fetal sheep lung maturation, the two exposures had opposing effects on fetal lung inflammation. Consistent with its widely known role as an antiinflammatory agent, maternal betamethasone initially suppressed the endotoxin-induced inflammation in the fetal lungs.[72] The new and counterintuitive information from experiments in fetal sheep was that maternal betamethasone caused a subsequent rebound in endotoxin-induced lung inflammation (Figure 96-5). The implications of this finding for clinical practice are not clear, but the emerging evidence highlights the complexity of interactions between these common exposures in preterm neonates. No experimental information is available regarding how these combined mediator systems may potentially influence postnatal lung development.

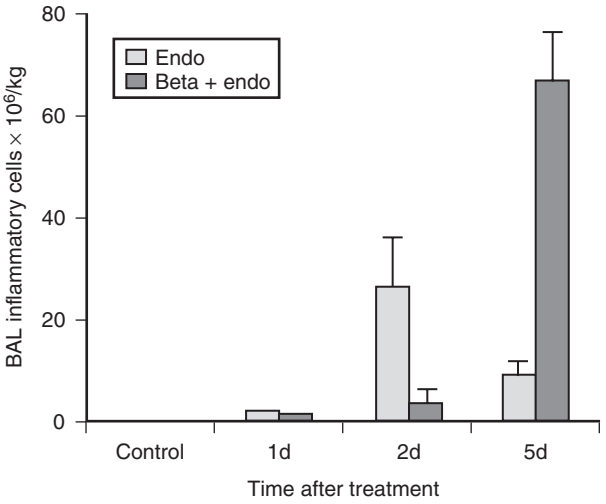

Figure 96-5 The time course of lung inflammation after exposure to intraamniotic endotoxin *(endo)* or maternal betamethasone and endotoxin *(beta + endo).* Of note, betamethasone initially suppressed endotoxin-induced lung inflammation but at 5 days increased the inflammation. *(Data from Kallapur SG, et al: Maternal glucocorticoids increase endotoxin-induced lung inflammation in preterm lambs,* Am J Physiol Lung Cell Mol Physiol *284:L633, 2003.)*

The consequence of less RDS may be more BPD, or greater severity of BPD, if inflammation is accompanied by persistent adverse effects on alveolar septation.

Pathophysiology of Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) is one of the most frequent sequelae in preterm infants who survive after prolonged mechanical ventilation. It is characterized by chronic respiratory failure, and in more severe cases it frequently is associated with pulmonary hypertension and cor pulmonale. The infants with BPD, as described originally, required prolonged mechanical ventilation because of severe respiratory failure resulting from hyaline membrane disease.[1] Today, most infants who have BPD are small premature babies who require prolonged mechanical ventilation because of poor respiratory effort or apnea.[2] Important pathogenic factors that contribute to chronic lung damage include incomplete lung development associated with prematurity, mechanical trauma from positive-pressure ventilation, oxygen toxicity, prenatal and postnatal infections, increased pulmonary blood flow and pulmonary edema secondary to patent ductus arteriosus (PDA), and airway damage and obstruction. The interaction of these and other possible factors leads to the severe morphologic and functional alterations of the lungs observed in these infants. Whereas in the originally described form of BPD the main alterations in lung morphology are emphysema, fibrosis, and marked airway epithelial changes, the more common milder forms of BPD seen today are characterized mainly by an arrest of alveolar and vascular development.[3-7]

Although mechanical trauma and oxygen toxicity are still considered important pathogenic factors in the development of the more severe form of BPD, in recent years, with the increased use of prenatal steroids and the administration of exogenous surfactant, the initial respiratory illness usually is milder, so infants are exposed to much lower airway pressures and oxygen concentrations. Nevertheless, many of the more immature infants, with relatively higher oxygen requirements, will show persistent radiographic changes compatible with BPD. Although positive airway pressure and oxygen exposure at these lower levels may still be sufficient to damage the immature lung, it is likely that other factors also play an important role in the development of the milder lung damage observed in infants today.

Substantial evidence indicates that inflammation plays a major role in the pathogenesis of BPD.[8] The pulmonary inflammatory response can be triggered by a number of factors, including ventilation with excessive tidal volumes,[9] oxygen free radicals,[10-12] increased pulmonary blood flow secondary to a patent ductus arteriosus,[13] and a variety of antenatal and postnatal infections.[14-20] The possible role of antenatal infections has been suggested by published studies showing an increased risk for BPD in infants born to mothers with evidence of chorioamnionitis.[21-23] Several inflammatory cytokines were found in higher

concentrations in the amniotic fluid of mothers of infants who subsequently developed BPD.[24,25] In addition, several reports have suggested a higher risk for BPD in infants whose airways are colonized with *Ureaplasma urealyticum* or other bacteria.[26-29] A significant increase in inflammatory cells, eicosanoids, and various cytokines has been demonstrated in the airways of infants in whom BPD develops subsequently.[30-37] The increase in cytokine concentrations has been documented early after birth, supporting the contention that the inflammatory process can start before birth and is secondary to an infection of the amniotic cavity and the fetal lung. Among the markers of inflammation that have been found in high concentrations in tracheobronchial secretions of infants with later BPD are neutrophils,[30,31] macrophages,[32] leukotrienes,[34] platelet-activating factor (PAF),[33] interleukin (IL)-6,[35,37] IL-8,[36] and tumor necrosis factor (TNF-α).[37] Evidence of pulmonary alveolar macrophage (PAM) activation also has been reported in infants in whom BPD developed subsequently.[38] These activated PAMs have been suggested as a source of neutrophil chemoattractants, especially when exposed to hyperoxia.[39] Neonates with subsequent BPD also have elevated concentrations of fibronectin in lung lavage fluid.[40,41] This large-molecular-weight protein is released from PAMs, epithelial and endothelial cells, and fibroblasts and is associated with the development of pulmonary fibrosis. An increase in elastase and an imbalance between elastase and α_1-proteinase inhibitor (α_1-PI) in the lung also has been postulated as a possible mechanism for the development of neonatal lung injury.[42-45] Urine excretion of elastin degradation products is greater in neonates with subsequent BPD than in control infants.[46] This finding is of particular concern in light of the evidence of a marked reduction in alveolar septation in lungs of infants with BPD.[47,48]

In extremely low-birth-weight infants, the presence of hospital-acquired systemic infections and a symptomatic PDA are strong predictors for the development of BPD.[2,49,50] Furthermore, occurrence of both infection and PDA at the same time produces a synergistic interaction that further increases the risk for developing BPD[51] (Figure 97-1). As a consequence of the left-to-right shunting through the PDA, pulmonary blood flow and lung fluid increases, negatively affecting lung mechanics and gas exchange, thereby increasing the risk for BPD.[52] The presence of a PDA also has been associated with elevated concentrations of myeloperoxidase in the tracheobronchial fluid, suggesting that

the increased pulmonary blood flow may result in damage to the pulmonary endothelium with adhesion and migration of polymorphonuclear leukocytes (PMNs [i.e., polymorphonuclear neutrophils]) into the lung tissue.[13]

Other factors have been proposed to have a role in the pathogenesis of BPD. Because of evidence that vitamin A levels are lower in infants in whom BPD develops than in those who recover without chronic lung damage, vitamin A deficiency has been proposed to play a role in BPD.[53] This possible association is supported by the similarities between some of the airway epithelial changes observed both in BPD and in vitamin A deficiency, and by clinical evidence that vitamin A administration in the first weeks of life affords some degree of protection against BPD.[54,55] Another factor suggested to play a role in the development of BPD in extreme premature infants is early adrenal insufficiency. Among infants with lower cortisol levels in the first week of life, the incidence of lung inflammation and BPD is increased, and early treatment with low-dose hydrocortisone increases survival without BPD.[56-58]

The major difficulty in the prevention of BPD is that as the lung damage progresses, a deterioration in lung mechanics and gas exchange occurs that makes necessary the use of mechanical ventilation with higher peak airway pressures and inspired oxygen concentrations. A vicious circle is thereby created in which the required treatment for the respiratory failure, mechanical ventilation and increased inspired oxygen, induces more lung damage and exacerbates the respiratory impairment. Figure 97-2 summarizes some of the most important pathogenic factors in BPD.

PULMONARY FUNCTION IN INFANTS WITH BRONCHOPULMONARY DYSPLASIA

The alterations in pulmonary function in infants with BPD are nonspecific and reflect the severe disruption of lung growth and architecture that occurs in these infants. The degree of abnormality in lung function may range from mild to severe, paralleling the clinical and radiographic presentation. Very few studies have described the early changes in lung function in infants who subsequently develop BPD, or that have followed longitudinally the course of lung function in these infants.

Lung Function in Early Bronchopulmonary Dysplasia

Infants in whom BPD ultimately develops appear to have worse lung function early in the evolution of their respiratory failure than infants who recover without lung sequelae after their initial RDS. Higher airway resistance was noted during the first weeks of life in infants in whom BPD developed subsequently than in infants who recovered without lung damage.[59,60] This finding suggests that early airway obstruction may be a marker or a predisposing factor for the development of more severe pulmonary damage. Measurements of lung compliance during the first week of life also have shown lower values in infants in whom BPD developed later on.[61-63] For this reason, lung mechanics measurements during the first week of life have been used to improve the accuracy of BPD prediction models.[64,65] Although the added predictive value of pulmonary resistance has been inconsistent, models that include gestational age and

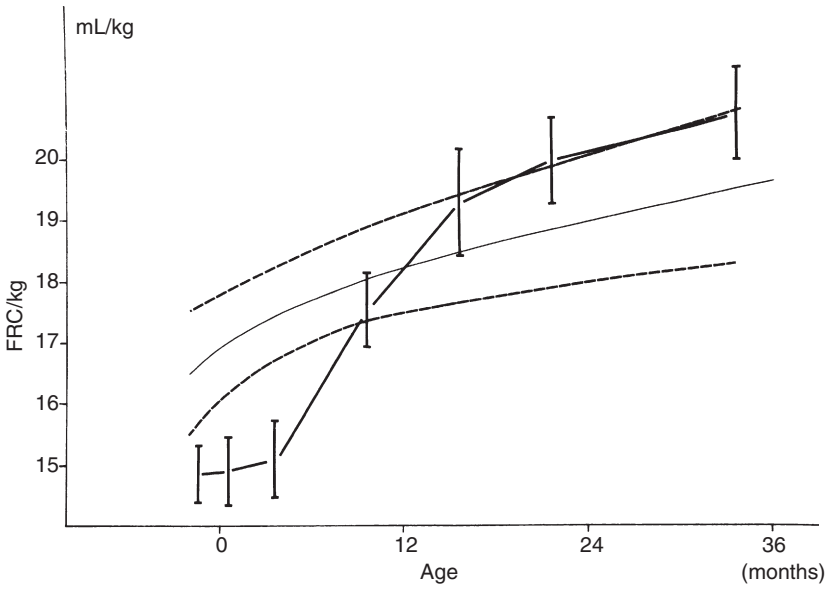

Figure 97-3 Sequential measurements of functional residual capacity *(FRC)* per kilogram in infants with chronic lung disease (mean ± SE) *(heavy line)*. Measurements were shifted to left to correct for preterm birth. For comparison, curve for normal infants *(thin line)* and its 95% confidence limits *(dashed lines)* are shown. *(From Gerhardt T, et al: Serial determination of pulmonary function in infants with chronic lung disease,* J Pediatr *110:448, 1987.)*

pulmonary compliance have displayed the highest predictive accuracy. The worse initial respiratory function in infants with subsequent BPD is most likely to reflect the severity of the initial acute respiratory illness.

Lung Function in Established Bronchopulmonary Dysplasia

Ventilation

Tidal volume is normal or reduced and respiratory rate is increased in most of these infants, resulting in a normal or increased minute ventilation.[66] The increased dead space ventilation that can result will contribute to the hypercapnia observed in infants with severe BPD.

Distribution of Ventilation

The morphologic alterations in the lungs of infants with BPD result in a severe disruption of the relationship between ventilation and perfusion. The damage to the small airways produces different time constants in different areas of the lungs, thereby altering the distribution of the inspired gas.[67] The disturbed ventilation-perfusion relationships lead to an increased arterial-alveolar gradient for carbon dioxide in areas that are ventilated but poorly perfused (high V_A/Q ratio) and an increased alveolar-arterial oxygen gradient caused by poorly or nonventilated areas that receive blood flow (low V_A/Q ratio).[68] Studies evaluating regional excretion of xenon have demonstrated very limited ventilation of the overdistended areas, whereas perfusion was relatively preserved.[69] Nitrogen clearance delay studies have confirmed the presence of slowly ventilated compartments in infants with severe BPD.[67]

Lung Volume

Lung volume measurements in infants with BPD have yielded variable results depending on the age of the infant. Functional residual capacity (FRC) values below normal have been reported during the first month of life, but values increased to above normal by the age of 6 to 16 months[70-72] (Figure 97-3). The later increase in lung volume in infants with BPD may reflect gas trapping secondary to small airway obstruction.

Lung Compliance

Dynamic lung compliance is consistently decreased in infants with BPD[70,71] (Figure 97-4). This decrease may reflect changes in the elastic properties of the lung secondary to fibrosis and interstitial fluid accumulation. Compliance also may be reduced by alterations in surfactant metabolism, which have been described in infants with BPD.[73] The decrease in dynamic compliance also reflects the increase in small airway resistance that produces frequency dependence of compliance. Overdistention of portions of the lung from gas trapping can further contribute to the decrease in compliance.

Therapeutic intervention with diuretics, bronchodilators, and systemic steroids results in a reduction in airway resistance with improved lung compliance in these infants.[74-78] Similar results have been reported after the administration of inhaled nebulized furosemide[79] or beclomethasone.[80]

Airway Resistance

A consistent change in lung function in infants with severe BPD is increased airway resistance (see Figure 97-4). This can lead to severe maldistribution of the inspired gas,[67] lung overdistention from gas trapping, and hypoventilation with hypercapnia secondary to increased work of breathing.

The mechanisms for increased airway resistance include several factors that contribute to airway damage and obstruction. During the initial stages of BPD, histopathologic changes include epithelial cell damage with hyperplasia and squamous metaplasia of the airway epithelial lining. Infection and inflammatory reaction in the airways increase mucus secretion. In addition, clearance of mucus may be decreased as a result of depression of ciliary activity. Infants with severe BPD exhibit hypertrophy of the smooth muscle surrounding the airways[1,81]; this development plays an important role in the increased airway resistance and airway hyperreactivity observed in these infants. Increased production of inflammatory mediators, such as leukotrienes and PAF, also may contribute to airway smooth muscle constriction and increased pulmonary resistance.[34,82,83] A more frequent family history of asthma in infants with BPD raises the possibility that a genetically determined airway hyperreactivity also may contribute to the development of BPD in some cases.[84,85] The increase in airway resistance is not specific to infants with BPD but is observed in most premature infants who receive mechanical ventilation, regardless of whether or not BPD develops subsequently.[86] The increase in airway resistance combined with lower compliance is responsible for a marked increase in the work of breathing and for the alveolar hypoventilation and carbon dioxide retention that are characteristic of these infants. The degree of airway damage is not uniform throughout the lung; this

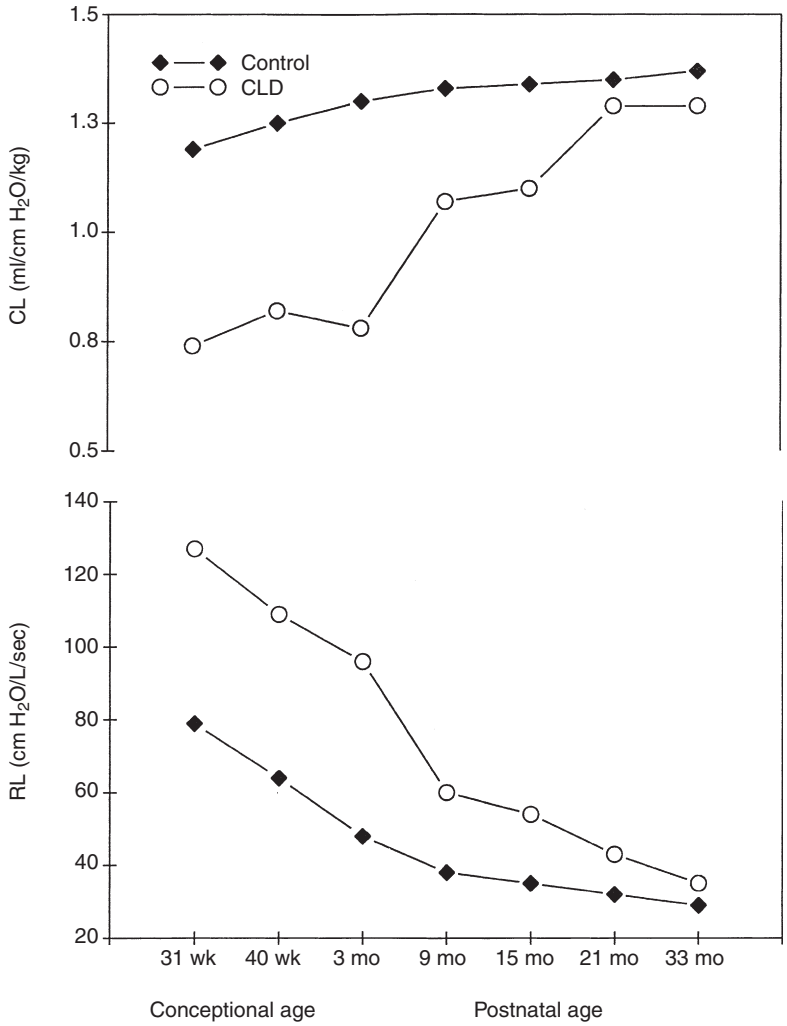

Figure 97-4 Sequential measurements of lung compliance and resistance in infants with chronic lung disease *(CLD)* and in normal controls. *(Modified from Gerhardt T, et al: Serial determination of pulmonary function in infants with chronic lung disease,* J Pediatr *110:448, 1987.)*

variability contributes to the abnormal distribution of ventilation and the development of areas of overdistention alternating with areas of collapse observed in cases of severe BPD.

The exact location of the obstruction has not been defined, but forced expiratory flows at FRC are decreased, suggesting that the main obstruction is at the level of the small airways.[87-89] In infants with severe BPD, large airways also are compromised and may demonstrate increased collapsibility that manifests during active expiration as a result of bronchomalacia.[90,91] This alteration is responsible for the severe deterioration in gas exchange observed in some of these infants during periods of agitation, which results in generation of positive intrathoracic pressure. These episodes can be ameliorated with use of sedation or by maintaining a relatively high positive end-expiratory airway pressure.[92,93]

Of interest are observations that demonstrate increased airway resistance and FRC in infants with BPD in response to a reduction in their inspired oxygen concentration.[94,95] This physiologic response also might explain the episodic airway obstruction often observed in infants with BPD. Cold air or methacholine challenge also produces a marked increase in pulmonary resistance in these patients.[96-98]

The increased airway resistance in infants with BPD is partially reversible with bronchodilators[99-105] and after diuretic therapy.[76,106-110] This dual effect suggests that the increased airway resistance is due to a combination of airway hyperreactivity and interstitial pulmonary edema, both of which may play a role in the obstruction of the small airways. The administration of systemic or inhaled steroids also has been demonstrated to reduce the airway obstruction in infants with BPD.[75,78,80]

Gas Exchange

Most infants with severe BPD exhibit marked hypoxemia and hypercapnia and require supplemental oxygen to maintain a normal Pa_{O_2}. This hypoxemia is due mainly to a reduced ventilation-perfusion ratio and alveolar hypoventilation.[68] The oxygen requirement decreases gradually as the disease process subsides but may increase during sleep, feedings, physical activity, or episodes of pulmonary infection or edema.

The increased Pa_{CO_2} is secondary to alveolar hypoventilation and to an increased arterial-alveolar carbon dioxide gradient produced by a mismatch of ventilation and perfusion and increased alveolar dead space. The chronic hypercapnia is often accompanied by an increase in serum bicarbonate concentration that tends to compensate for the respiratory acidosis. This increase in plasma base can be exaggerated by administration of diuretics, which frequently are used in infants with BPD.

Metabolic Rate

Infants with BPD have an increased metabolic rate.[111] This increase in oxygen consumption is due, at least in part, to the increased work of breathing and is one of the factors that may interfere with normal growth in these infants.[112] The increased metabolic rate also can impose an extra load on the respiratory system, contributing to respiratory failure in infants with severe BPD. This impairment may become evident when carbon dioxide

production is suddenly increased, such as during glucose loading, which can lead to aggravation of hypercapnia in these infants.[113]

Long-Term Lung Function in Infants With Bronchopulmonary Dysplasia

Several studies have evaluated long-term lung function in infants with BPD. Because the initial damage occurs at a critical time when the lung is in one of the most active phases of growth and development, it is now clear that many of the alterations in lung structure and function persist through adulthood.

Gerhardt and colleagues[71] performed serial pulmonary function evaluations in a group of infants up to 3 years of age who had relatively mild BPD. Lung function showed gradual improvement over time, and at the end of the follow-up period, the values for compliance and resistance were close to the normal range (Figure 97-4). In infants who had severe BPD, persistent alterations in lung function have been reported beyond 3 years of age[114-119] whereas in some patients, abnormalities were still present at the end of the first and second decades of life, indicating that the lung damage, when severe, persists into adulthood[96,97] (Figure 97-5).

Morphometric studies performed in lungs from children who died with severe BPD between the ages of 2 and 28 months revealed a striking reduction in the number of alveoli from that typical for the lungs of control subjects.[48] This abnormality results in a significant decrease in the lung surface area available for gas exchange. By contrast, pulmonary function studies done in children with a history of BPD who have reached school age suggest continued lung growth, as indicated by an increase in total lung capacity and improved airway function.[115] Although the decreased lung compliance and changes in lung volume usually normalize over time, the increased airway resistance and flow limitations seem to persist longer and through adulthood in those infants with more severe lung disease.[88,72,116-118] The degree of flow limitation at the age of 11 years has been correlated with the duration and amount of supplemental oxygen received during the neonatal period[119] (Figure 97-6).

Surprisingly, despite these persistent abnormalities in lung function, survivors with BPD do not always have a significant reduction in exercise capacity when compared with healthy term infants or preterm babies without lung disease.[116,120] However, reduced soluble gas transfer at rest and during exercise has been reported in school-aged children with a history of BPD.[121]

Cardiovascular Function in Infants With Bronchopulmonary Dysplasia

Pulmonary Hypertension—Cor Pulmonale

Pulmonary hypertension and right ventricular hypertrophy commonly are observed in infants with severe BPD, and in many instances, pulmonary hypertension is responsible for a gradual deterioration in the clinical condition or the demise of these infants.[81,122] Pulmonary hypertension has been documented by direct pressure measurements during cardiac catheterization and indirectly by echocardiography.[122-124] The specific mechanisms that result in increased pulmonary vascular resistance in these infants are many and include alveolar hypoxia, increased alveolar pressure and overdistention, and release of mediators of inflammation such as PAF and leukotriene B_4.[33]

Postmortem examination of the lungs of infants with severe BPD frequently reveals hypertrophy of the smooth muscle in the pulmonary vessels and muscle extension into intraacinar arteries.[81] Some cases also feature evidence of thromboembolism in the lumina of pulmonary vessels.[125] A derangement in the growth and development of the pulmonary vessels also has been described in these infants and is likely to play a major role in the increased pulmonary vascular resistance observed with severe BPD.[126] The bronchial arteries in infants with BPD are abnormally prominent, and communications exist between those arteries and the pulmonary circulation through precapillary collaterals.[127] These anastomoses may develop in preexisting channels that subsequently dilate, or they may occur in granulation tissue seen in the lungs of patients with BPD. These systemic-to-pulmonary communications may aggravate the existing pulmonary hypertension.

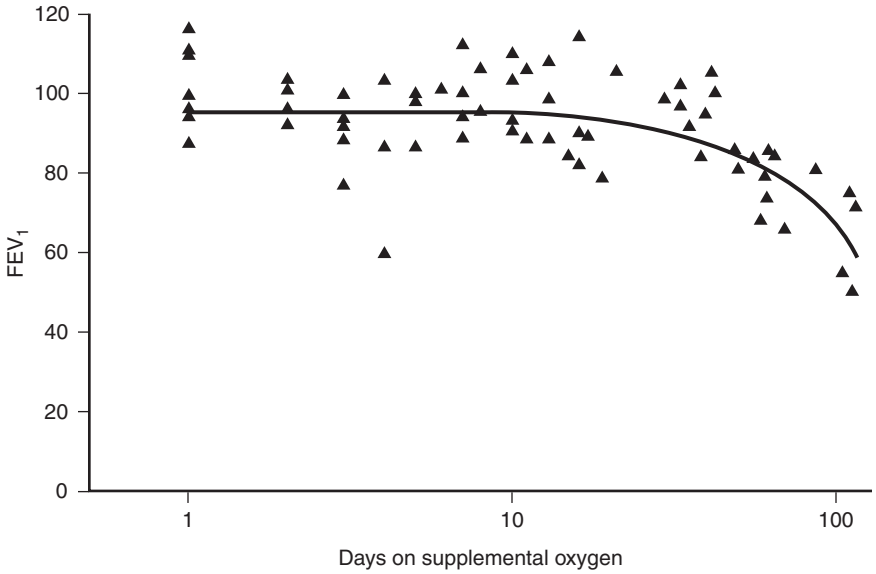

Figure 97-6 Relation between forced expiratory volume in 1 minute (FEV_1) and duration of supplemental oxygen (in log days) during the neonatal period. *Solid line* shows fitted values derived by use of the power function $FEV_1 = \beta_0 + \beta_1 r^{(\text{days on oxygen})}$. *(Modified from Kennedy JD, et al: Effects of birthweight and oxygen supplementation on lung function in late childhood in children of very low birth weight,* Pediatr Pulmonol *30:32, 2000.)*

The pulmonary hypertension in infants with BPD initially is responsive to an increase in the inspired oxygen concentration, demonstrating a reactive pulmonary vascular bed.[123,124,128] Nevertheless, the values frequently remain substantially above normal, reflecting the loss in vascular cross-sectional area secondary to inadequate development or structural remodeling of the pulmonary vascular bed, and in advanced BPD the hypertension becomes unresponsive to all available therapeutic interventions.

Systemic hypertension also has been described in infants with BPD.[129] The mechanism for the systemic hypertension is not clear, but the derangement may contribute to the left ventricular dysfunction and hypertrophy observed in many of these patients.[130] This hypertrophy also can be secondary to an increased afterload of the left ventricle. Left ventricular overload results from the higher negative intrathoracic pressure generated by these infants to overcome the increased mechanical impedance of their respiratory system. Right ventricular hypertrophy also can interfere with left ventricular function, contributing to the hypertrophy of this ventricle. A decreased pulmonary vascular clearance of catecholamines has been reported in infants with severe BPD and also may contribute to the systemic hypertension observed in some of these patients.[131]

The use of vasodilators such as the calcium channel blocker nifedipine can be effective in improving cardiovascular function in infants with severe BPD.[132,133] Inhaled nitric oxide (NO) and phosphodiesterase inhibitors also have been used in infants with BPD to decrease pulmonary vascular resistance and improve ventilation perfusion matching. Although results have not been consistent, some studies have shown an improvement in oxygenation during NO administration.[134-136] NO also may modulate the inflammatory process in the lung, and its early administration in preterm infants with respiratory failure has resulted in reduced incidence of BPD.[137,138] These results are not consistent enough, however, to recommend the routine administration of NO in preterm infants.

98 Liquid Ventilation

Thomas H. Shaffer and Marla R. Wolfson

Respiratory insufficiency during early development, whether resulting from immaturity of pulmonary structure and biochemical processes or from aspiration syndromes, calls for the use of assisted ventilation techniques. Exogenous surfactant replacement therapies have demonstrated improvement in gas exchange, decreased ventilatory requirements, and reduction in mortality. Pulmonary function–guided alterations in conventional ventilatory techniques and high-frequency ventilation can facilitate gas exchange at reduced inflation pressures; aggressive measures such as extracorporeal life support eliminate the requirement for pulmonary inflation pressures. In spite of improved survival of the infant with respiratory insufficiency, significant morbidity persists, resulting from barotrauma leading to chronic pulmonary sequelae.[1] Alternative means to support pulmonary gas exchange while preserving lung structure and biochemical development are still required.

Fluid breathing (liquid-assisted ventilation) uses a liquid to replace nitrogen gas as the carrier for oxygen (O_2) and carbon dioxide (CO_2). The air-liquid interface at the alveolar-capillary surface is eliminated, reducing pressure requirements to inflate the lung. To date, perfluorochemicals (PFCs) are the most promising breathing media liquids because of their specific physiochemical properties of low surface tension and high solubility for respiratory gases, as well as their chemically and biologically inert nature. After more than 30 years of neonatal and adult animal studies of liquid ventilation,[2-8] the clinical investigations have yielded promising results.

With the evolution of gas breathing in land-dwelling vertebrates, the lung replaced the gill as the gas exchange organ. Mammals make the transition from fluid-filled lungs during fetal life, when gas exchange is performed by the placenta, to gas breathing at birth, when the lungs assume responsibility for breathing. If premature delivery, antenatal or perinatal incident, or postnatal pulmonary insult precludes adequate maturation or impedes function of the pulmonary system, gas exchange insufficiency ensues. Because the lungs developed within a fluid environment, it appears logical that restoration of the fluid-filled environment would provide a natural transitional adjunctive therapy, and the fluid-filled lung might provide an experimental tool to understand lung function. This chapter traces the development of fluid breathing and extended applications from its origin to current areas of investigation.

FLUID AS A VENTILATORY MEDIUM

Saline Solution

Saline solution was the first liquid used as a respiratory medium,[9] and it effectively eliminates the gas-liquid interface within the lung. It has been fundamental in elucidating factors that influence alveolar structure, distensibility, stability, ventilation, and pulmonary blood flow.[10-16] Although the detergent-like action of saline solution has proved useful in removing pulmonary debris, it also removes pulmonary surfactant, which is necessary for lung stability. Furthermore, low respiratory gas solubility and excessive diffusion gradients at atmospheric conditions have limited the applicability of saline solution to support pulmonary gas exchange.[17-21] Because the O_2 content of saline solution saturated at 1 atm is only approximately 3 vol%, it cannot support oxygenation under atmospheric conditions. In 1950, it was suggested that saline solution saturated with O_2 dissolved under pressure could potentially sustain submersed mammals.[22] Practical application of this concept was first demonstrated in 1962. Additional studies demonstrated that mammals submerged in hyperbaric-oxygenated saline solution could breathe liquid and resume gas breathing.[18,23-25] Although these studies demonstrated adequate oxygenation, CO_2 retention and profound acidosis occurred, thus rendering saline ventilation physiologically unsound during either normobaric or hyperbaric conditions.

Perfluorochemical Liquids

As an alternative to saline solution, the utility of other liquids as respiratory media was investigated. Experiments with silicone, vegetable oils, and animal oils demonstrated toxic effects.[26,27] PFCs were first produced during World War II as part of the Manhattan Project and, on the basis of the high solubility of this medium for respiratory gases, were first used to support normobaric respiration in 1966 (Figure 98-1).[28] This marked the beginning of the use of PFC as an alternative respiratory medium.

A true PFC is formulated from common organic compounds such as benzene, by replacing all the carbon-bound hydrogen atoms with fluorine atoms through techniques such as vapor-phase fluorination, cobalt trifluoride agitation, or electrochemical fluorination.[27] PFC liquids have a strong carbon-fluorine bond that provides them with extreme thermal, chemical, and physical stability. They can be stored at room temperature indefinitely, they can be subjected to antiseptic conditioning without alteration (i.e., autoclave, small-pore filtering), and they are clear, odorless, nonbiotransformable, and generally insoluble in aqueous media and nonlipid biologic fluids.

The physicochemical profile and structure of various PFC liquids for PFC ventilation are shown in Table 98-1 and Figure 98-2. As a class of liquids, they are unique in two ways: (1) they have the lowest sound speeds of any liquid, and (2) gases are exceptionally soluble in the PFC liquids. PFC fluids are characterized by a cyclic or aliphatic structure consisting of 6 to 14 carbon atoms; the physicochemical profile of each compound is influenced by the particular arrangement of the carbon-fluorine bonds.[27,29-31] Gas solubility differs across PFC liquids and type of gas. It is dependent on the sizes of and steric relationships between the PFC and gas molecules.[32-34] Specific to respiratory gas exchange, O_2 and CO_2 are carried only as dissolved gases with solubilities as much as 16 and three times greater, respectively, in PFC than in water. O_2 solubility ranges from 35 to 70 mL gas per deciliter at 25° C.[35] Although the carrying capacity for CO_2 is known for fewer compounds, reported values of CO_2 solubility are approximately four times greater than those for O_2, ranging from 122 to 225 mL/dL (i.e., perfluorodecalin [APF-140] = 122 mL/dL, perfluoroalkylpentane [FC-75] = 192 mL/dL, perfluorooctylbromide [PFOB] = 225 mL/dL). Fewer data are available regarding the diffusivity of specific gases within the PFC liquids.[34,35] It is known that gases diffuse more slowly in liquids than in a gaseous

medium and that the gas solubility is not related to the diffusivity within the PFC liquid. Although some properties of these liquids vary, their dielectric strength and resistivity are high, they are denser than both water and soft tissue, and they have relatively low surface tension and viscosity.

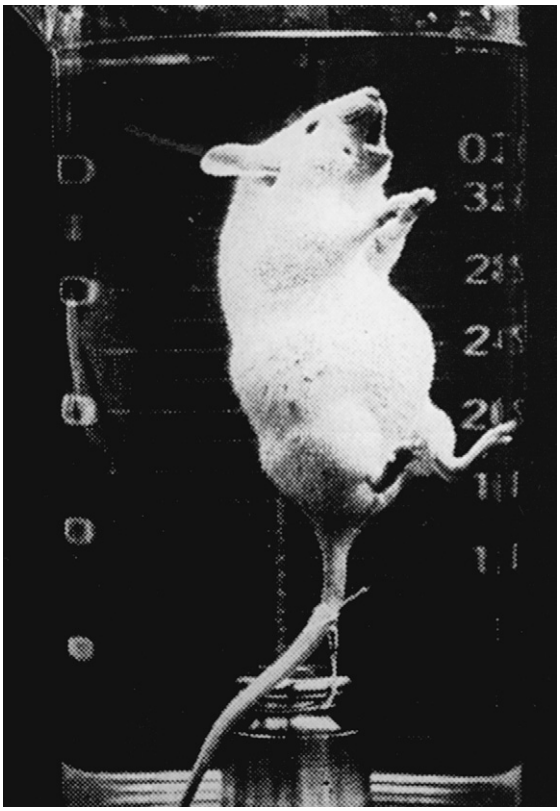

Figure 98-1 The liquid-breathing mouse. This historic mouse is submersed in and breathing a PFC liquid (FC-75; 3M Corporation, St. Paul, Minnesota) saturated with 100% oxygen. *(Courtesy L. C. Clark, Jr., Ph.D.)*

Differences in several of the physicochemical properties of the PFC fluids have relevance to their performance as respiratory media. Fluids of higher vapor pressure (e.g., lower boiling points) tend to volatilize from the lung faster than fluids of lower vapor pressure (e.g., higher boiling points). Fluids of higher spreading coefficients (a parameter related to the surface tension of the liquid and gas-liquid or liquid-liquid interfacial surface tension) may be distributed more readily in the lung than fluids of lower spreading coefficients (i.e., FC-75 > PFOB > APF-140).[36,37] Fluids of higher viscosity or kinematic viscosity (e.g., viscosity-density) may resist redistribution in the lung and therefore maintain contact with more of the alveolar surface and for a longer time than those that stratify more quickly[38,39]; however, they may offer greater flow resistance. Partial liquid ventilation (PLV) with a higher-viscosity, lower–vapor pressure liquid resulted in significant improvement in gas exchange and lung mechanics, as well as significant reduction in inflammatory mediators in the lung tissue after repetitive saline injury compared with conventional mechanical ventilation and PLV with lower-viscosity, higher–vapor pressure fluids.[40,41] Given that PFC evaporative loss and redistribution of PFC is minimized by lower vapor pressure and higher viscosity,[39] these data suggest that, in addition to enhancing lung function, greater lung protection by way of both mechanoprotection and cytoprotection is conferred during PLV with a PFC liquid that remains distributed throughout the entire lung for a longer duration. Both the carrying capacity (i.e., solubility) and the transfer capacity (i.e., diffusivity of gases within the PFC liquid as determined by the diffusion coefficients) of the liquid are important functional criteria in liquid ventilation. Smaller partial-pressure gradients and less time are required for gases to saturate or leave liquids with higher gas diffusion coefficients. The higher the gas solubility, the less fluid volume required to remove or deliver gases. Fluids of higher CO_2 solubility may provide a greater carrying capacity for CO_2 but may require additional ventilation to deplete CO_2 from the reservoir.[42] Each of the physicochemical properties should be considered in the selection of a PFC liquid for specific ventilatory techniques.

Although these fluids are innately nontoxic and weak solvents, material compatibility with ventilator circuitry and endotracheal tubes has been investigated to rule out potential complications associated with leaching of plastics into the PFC and the effect of PFC on the structural integrity of plastic components.

TABLE 98-1

Physicochemical Profile of Various Perfluorocarbons

Perfluorocarbon	Formula	Orientation	O_2 solution (mL/100 mL) (25° C)	Vapor pressure (mm Hg) (37° C)	Boiling point (° C)	Viscosity (cSt) (25° C)	Mol wt (g/mol)	Density (g/mL) (25° C)

Data from references 21, 27, and 34.

PFC liquids have been shown to cause plastic embrittlement of polyvinyl chloride plastics, minimal swelling of polytef (Teflon)–based products, compatibility with medical-grade polyurethane, and solubilization of silicone oil–based materials.[36]

PFC liquids have formed the basis for biologic applications including synthetic bloods, imaging agents, and replacement fluid for the eye.[43-49] Pure medical-grade PFC liquids currently exist for the purpose of liquid ventilation. Various PFCs have been explored in patients as gas transporters in the lung and blood; as ultrasound, oral, and lung contrast agents; to provide intraocular tamponade after vitreoretinal surgery; to enhance oxygenation via peritoneal lavage, for organ preservation and wound healing; and to distend and grow the lungs in patients with congenital diaphragmatic hernia.[2,47,50-66] Over the past three decades, we have pioneered, developed the relevant technology, and used intrapulmonary PFCs in both animal and clinical studies to safely support lung volume recruitment, support gas exchange, decrease pulmonary inflammation and oxidative stress, and preserve lung architecture in multiple causes of respiratory distress.[41,59,67-82] In addition, intrapulmonary use of thermally conditioned PFCs effectively and rapidly induces systemic heating or cooling because of expansive surface area of the pulmonary circulation and thermal capacity of the PFC liquids.[83-87] The feasibility, safety, and efficacy of aerosolizing PFC through the nasopharynx in normal sheep to preferentially induce and maintain brain cooling at rates as great as 10 times faster than by conventional means has been recently demonstrated.[88] This approach minimizes systemic cooling and subsequent systemic adverse effects while selectively providing central hypothermic neuroprotection. Aerosolized PFC significantly increases the heat-carrying capacity of air passing through the nasopharynx. In addition, because of proximity to the cerebral circulation, the nasopharynx is uniquely suited for preferential and homogenous brain cooling. In summary, the nasopharyngeal-PFC approach uses latent heat of vaporization and hematogenous and conductive mechanisms to induce and maintain brain cooling.

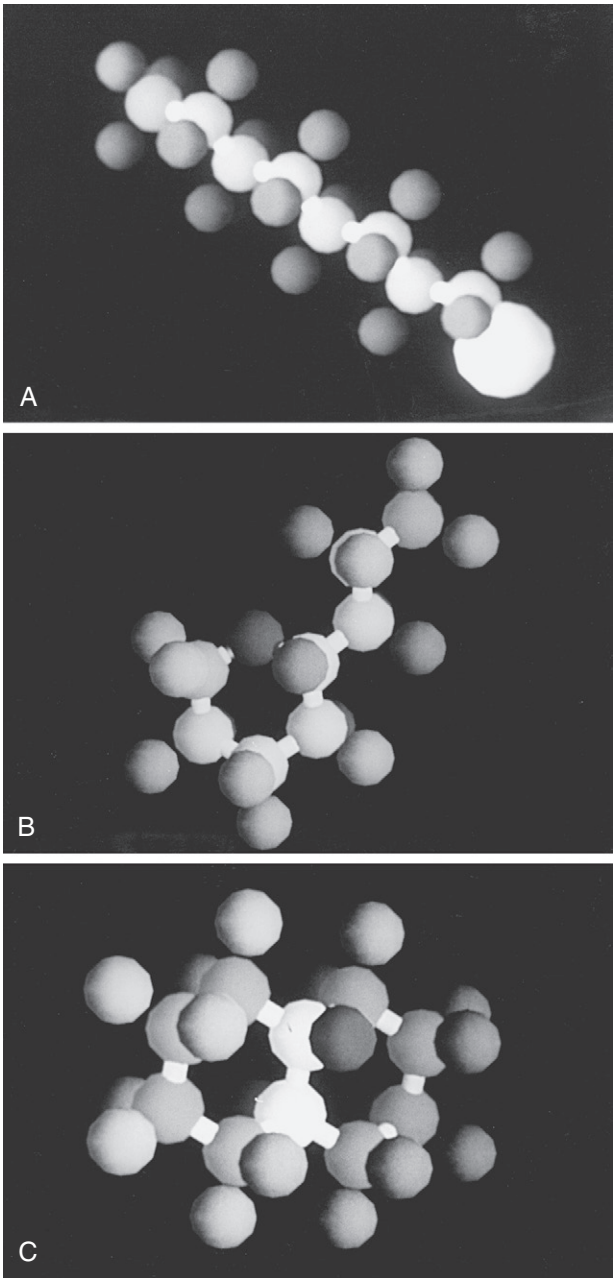

Figure 98-2 Molecular models of PFCs suitable for liquid ventilation. **A,** *Perfluorooctylbromide* (i.e., LiquiVent; Alliance Pharmaceutical Corporation, San Diego, California) consists of an eight-carbon skeleton with surrounding fluorine atoms. Carbon 8 is also bound to a terminal bromide atom. **B,** *Perfluoroalkylpentane* (i.e., a component of RIMAR 101; Miteni Corporation, Milan, Italy; FC-75P; 3M Corporation) consists of a cyclic portion of five fluorinated carbon atoms and one oxygen atom and a chain of three fluorinated carbon atoms. **C,** *Perfluorodecalin* (APF-140; Air Products and Fine Chemicals Corporation, Allentown, Pennsylvania) consists of a bicyclic molecule of 10 fluorinated carbon atoms.

BIOPHYSICAL PROFILE AND PHYSIOLOGIC RESPONSES OF THE FLUID-FILLED LUNG

Figure 98-3 provides a summary of the biophysical profile and physiologic responses of the fluid-filled lung.

Pulmonary Structure and Function

The differential effects of tissue forces from surface-active forces on alveolar distensibility have been identified. One study found that more volume was displaced for the same change in pressure in the saline-filled lung than in the gas-filled lung.[16] This effect was exaggerated when the gas-filled lung with elevated surface tension was filled with saline solution (Figure 98-4). On the basis that saline solution eliminated the gas-liquid interface, and thus

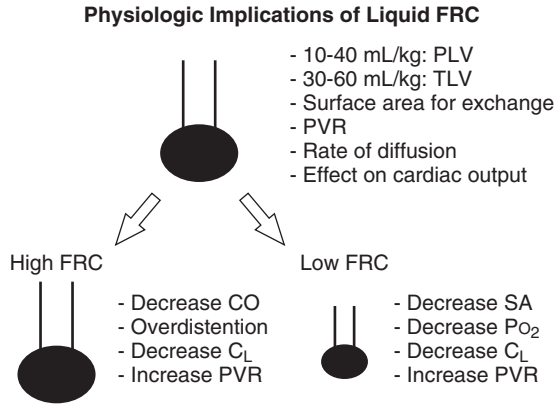

Figure 98-3 Biophysical profile and physiologic responses of the fluid-filled lung. C_L, Lung compliance; *FRC,* functional residual capacity; *PLV,* partial liquid ventilation; *PVR,* pulmonary vascular resistance; *SA,* surface area; *TLV,* tidal liquid ventilation.

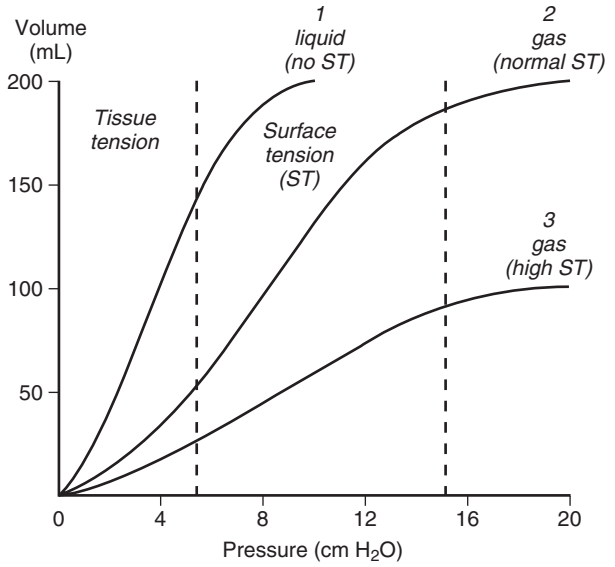

Figure 98-4 Pressure-volume relationship of the gas-filled or liquid-filled lung. *ST,* Surface tension. *(Redrawn from Comroe JH:* Physiology of Respiration*, Chicago, 1977, Year Book Medical Publishers.)*

interfacial tension, it was concluded that the greater pressure requirements in the air-filled normal and abnormal lung resulted from surface forces.

In the gas-filled lung, alveolar pressures are uniform, and vascular pressures are subject to a hydrostatic gradient, but in the saline solution–filled lung, alveolar and vascular pressures are relatively balanced throughout.[89,90] This finding suggests that pulmonary blood vessels would be uniformly distended, resulting in more uniform distribution of blood flow and improved matching of ventilation to perfusion in the saline-filled as opposed to the gas-filled lung. In that regard, ultrastructural studies have shown that the capillaries bulge into the alveolar space in the saline-filled lung, whereas the alveolar surface is relatively smooth in the gas-filled lung.[91] The irregular alveolar surface area is larger in the fluid-filled than in the gas-filled lung of the same volume.

Pulmonary Mechanics

Factors that play a predominant role in maintaining lung volume stability include those attributable to the tissue properties and surface forces acting at the alveolar-capillary interface. Elastin and collagen confer structural integrity, whereas surface forces dictate stability of gas exchange regions over a wide range of lung volume.

Surface tension at the alveolar-capillary interface created by the interface between two phases (i.e., gas and the lung surface) is the force that resists expansion and determines the amount of work required to create additional surface for gas exchange. Because the cohesive forces of molecules within a liquid are stronger than those between liquid (i.e., lung surface) and gas (i.e., within alveolus), more work is required to move molecules from within the liquid to a gas-liquid interface than to a liquid-liquid interface. Addition of a surface-active agent, or *surfactant,* to liquid decreases surface tension and reduces the work needed to increase surface area. Replacement of gas with liquid at the lung surface eliminates surface tension. Applying Laplace's law and the bubble model to the lung, $P = 2T/R$, the radius *(R)* of the alveolus is determined by the pressure gradient *(P)* across the alveolar wall and surface tension *(T)* acting on the alveolus; the pressure required to maintain alveolar size is decreased by lowering surface tension. According to this theory, if alveoli at different sizes are subject to the same transmural pressure, surface tension must vary with size to prevent collapse of smaller into larger alveoli. On this basis, an effective pulmonary surfactant must demonstrate a surface tension that varies with surface area.[92]

Alternatively, evidence from morphometric studies has disputed the bubble model theory. If interior alveoli of different sizes share a common wall, the two alveoli have the same internal pressure; thus there is no driving force to collapse the smaller alveolus. Thus changes in alveolar size over the respiratory cycle are achieved by unfolding of alveolar membranes.[91] In this situation, any agent capable of lowering surface tension would serve to decrease membrane adhesion and allow membrane unfolding; a variable surface tension with varying surface area would not be required.[91,93-95] These principles identify requirements of a modality that would facilitate alveolar stability.

The stabilizing role of pulmonary surfactant originated in 1929. It was shown that less pressure (i.e., work) was required to inflate the saline-filled than the air-filled animal lung. This difference resulted from surface forces at the air-liquid interface of the air-filled lung.[16] It was suggested later that phospholipids in the alveolar surface forces reduced surface forces at the air-liquid interface.[96] Subsequently, it was demonstrated that surface tension changed in relation to surface area,[97] and alveolar material obtained from infants dying of respiratory distress syndrome had decreased surfactant activity.[10] These findings suggested that the lack of pulmonary surfactant predisposed infants to atelectasis. Taken together, these studies established the fundamental basis of subsequent work toward exogenous surfactant replacement therapy to reduce inflation pressures for the treatment of respiratory distress syndrome.

Because of the biophysical similarity between the alveolar lining fluid and saline solution, interfacial tension and surface forces are essentially eliminated in the saline-filled lung. Similar to a completely saline-filled lung, complete insufflation of the lung with a PFC liquid in which gas is carried in the dissolved state eliminates the gas-liquid interface in the lung and reduces, but does not abolish, surface forces. Unlike in the saline-filled lung (and because of physicochemical differences between the alveolar lining fluid and PFC), interfacial tensions remain between alveolar lining fluid and PFC. Therefore alveolar inflation pressures with PFC are lower than those with gas; however, more pressure is required to inflate the PFC-filled lung than the saline-filled lung. Impairment of lung mechanics after PFC ventilation of healthy, surfactant-sufficient adult animals may be attributable to the additional interfacial tension at the PFC-lung surface and the air-PFC surface.[18,80,98-100]

In vivo pulmonary compliance determinations performed in gas-ventilated or PFC-ventilated preterm lambs ranging in age from 106 to 136 days gestation (term approximately 150 days) demonstrated significant age-related differences.[5] Although pulmonary compliance of the PFC-ventilated lamb was consistently higher than that of the gas-ventilated lamb, this difference was not significant until after approximately 120 days gestation. This finding suggests that morphologic and tissue properties predominate over surface properties in determining lung distensibility at the earlier stages of development. In addition, it suggests that the structural development (i.e., elastic, collagen, parenchymal interdependence) of the lung limits the effect of a reduction in interfacial surface tension on increasing lung distensibility.

Numerous in vivo studies in animals and humans with surfactant deficiency or dysfunction, with or without surfactant pretreatment, have demonstrated improvement in respiratory compliance during tidal liquid ventilation (TLV),* on recovery to gas ventilation,[50,111,114,118-120] or during gas ventilation after

*References 5, 6, 72, 76, 79, 101-117.

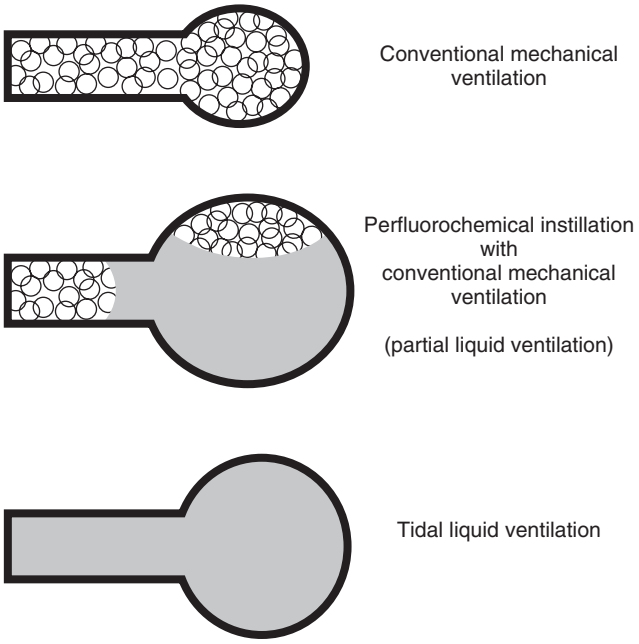

Figure 98-5 Schematic of potential sources of interfacial tensions in the PFC-treated lung during ventilation with tidal volumes of gas (PLV) or PFC liquid (TLV).

instillation of PFC liquid (PLV).[†] The greatest reduction in ventilatory pressure requirements and improvement in specific respiratory compliance were noted after (1) the lung was insufflated with PFC liquid to functional residual capacity (FRC), (2) free gas was vented, and (3) ventilation was achieved by moving tidal volumes of PFC.[79] Figure 98-5 illustrates schematically the various interfacial tensions that may exist in the PFC-treated lung during ventilation with tidal volumes of gas or PFC liquid.

With use of surfactant-deficient excised lungs of preterm lambs, studies have shown that net interfacial tension is lower in the lung filled with an FRC of PFC liquid than in the gas-filled lung; surfactant pretreatment further reduces net interfacial tension in the PFC-filled lung.[146,147] When free gas is introduced into the PFC-treated lung, additional interfacial tensions are created at the free gas–PFC and gas-lung surfaces. Although net interfacial tension is increased in the PFC-treated and gas-ventilated lung relative to the liquid-ventilated lung, tension remains lower than in the gas-filled lung and is reduced by surfactant pretreatment.

Gas Exchange

As reviewed earlier, the need for hyperbaric conditions to oxygenate saline solution adequately, the detergent action of saline solution (removing endogenous surfactant), and the inability to remove CO_2 limit the utility of saline solution as a ventilatory medium. Inadequate CO_2 elimination during saline ventilation has been linked to the slower diffusion rate (greater diffusion coefficients) of CO_2 and the lower maximal expiratory flow associated with elevated density and viscosity in liquids compared with those in gases. These mechanisms were elucidated by theoretic models and experimental data obtained in the saline-filled lung.[17-19,148,149]

One theoretic model viewed the lung as multiple and identical spherical exchange units.[17,18] With each respiratory cycle, the tensions of O_2 and CO_2 change as a function of radial distance from the center of each sphere, diffusion coefficient for the respective gas, and time for diffusion. The partial pressure gradient for each gas decreases over time, resulting in regional differences within each sphere and diffusional dead space (i.e., the center of the sphere has lower CO_2 tensions and higher O_2 tension). Relative to liquid versus gas flow rates, it has been shown that maximal expiratory flow in excised saline-filled animal lungs was one hundredth of that obtainable in the gas-filled lung.[13,14] The reduction in maximal expiratory flow was linked to the increase in density and viscosity of saline solution compared with those of gas and elevated resistive pressures when moving saline solution and gas at comparable rates. Therefore, to overcome such limitations, the respiratory cycle would ostensibly have to be increased in length and depth for adequate alveolar ventilation to eliminate CO_2. Although the potential for adequate ventilation was identified, strategies for ventilating with saline solution were not explored further because of the dependence on achieving hyperbaric oxygenation and the detergent-like action of saline solution in removing native pulmonary surfactant.

There are numerous similarities and differences in the characteristics of PFC liquid and saline solution relative to gas exchange. Although high respiratory gas solubility of the PFC liquids distinguishes these fluids from saline solution to support pulmonary gas exchange, theoretic analysis and in vivo experimentation demonstrated that the low diffusion coefficient for respiratory gases (e.g., gases diffuse into liquids several orders of magnitude slower than into gas) and elevated density and viscosity of liquid (e.g., 10^3 and 10^2 times greater than air) impose rate limitations on alveolar diffusion and expiratory flow.[34,35] Low gas diffusion coefficients and solubilities in PFC have little impact on O_2 exchange because the partial pressure of inspired O_2 can be increased to approximately 700 mm Hg (thereby establishing a sufficient alveolar-arterial O_2 gradient and O_2 content in PFC to meet most metabolic demands). In contrast, the amount of CO_2 removed from the lungs depends primarily on the partial pressure of CO_2 in the blood (usually, 40 mm Hg), thereby limiting the alveolar-arterial CO_2 gradient and CO_2 content. This has been demonstrated experimentally in preterm lambs that showed that the low diffusion coefficient of O_2 in PFC liquid yielded a relatively large gradient between the mean inspired O_2 (496 mm Hg) and the mean alveolar O_2 (335 mm Hg), thus explaining the mean arterial O_2 tensions (170 mm Hg).[67]

Factors contributing to improved matching of ventilation and perfusion in the completely fluid-filled lung also contribute to effective gas exchange during tidal PFC ventilation (see the earlier discussion of pulmonary structure and function). During tidal PFC ventilation, PFC is evenly distributed throughout the lung, and pulmonary blood is redistributed in the completely PFC-filled lung, creating a more homogeneous pattern than during gas breathing.[78,120] The adequacy of gas exchange during gas ventilation of a PFC-filled lung (e.g., PFC-associated gas exchange or PLV) has been related to the "evenness" of bubble oxygenation of PFC and matching of any maldistribution of this pattern to concomitant maldistribution of pulmonary perfusion.[150] Radiographic studies indicate that PFC liquid during gas ventilation is not evenly distributed; stratification occurs, with a primary pattern of gas rising to the nondependent regions and PFC settling to the dependent regions of the lung despite frequent changes in position. Under these conditions, it is currently unknown how much gas exchange occurs in the combined PFC-filled regions of the lung. It is also not known whether improvement in gas exchange in the immature or injured lung occurs in lung regions with only small volumes of PFC liquid (however, these units still may have improved mechanics). Although the high CO_2 solubility in PFC liquids provides an efficient reservoir for CO_2, effective CO_2 elimination during gas ventilation of a PFC-filled lung depends on the distribution of the gas. Nonventilated or poorly ventilated regions and uneven emptying of the lung because of

[†]References 12, 58, 66, 105, 114, 121-145.

airway obstruction or changing lung mechanics present challenges to this ventilatory approach. Studies of gas ventilation of the PFC-filled normal, immature, or injured lung have demonstrated that inspiratory resistance to gas flow may be normal or increased,[119,142,151] and expiratory resistance to gas flow may be elevated.[136] The expiratory flow profile suggests that the lung empties as multiple compartments.[119,150]

Cardiovascular and Metabolic Responses

Less information is available regarding cardiovascular and metabolic responses during liquid ventilation. Early studies performed in normal adult animals reported decreases in cardiac output, O_2 consumption, CO_2 production, and pH and increases in pulmonary vascular resistance (assessed in the isolated-perfused lung), as well as redistribution of cardiac output and pulmonary blood flow.[152-158] These studies suggested that although liquid ventilation techniques could support effective gas exchange, cardiovascular compromise may be an issue when liquid lung volumes and alveolar pressures are increased to more than normal levels. Similar complications have been noted with excessive use of positive end-distending pressure in the gas-filled lung.[159] It was speculated that most of these findings in the PFC-filled lung were related to the effect of the weight of the PFC to compress the heart, great vessels, or pulmonary vasculature in the dependent region of the lung. More recent studies, performed in adult, neonatal, and premature animals with normal or abnormal lungs, have reported less compromise of cardiopulmonary interaction in the PFC-filled lung.[5,11,120,160-162] A recent multicenter trial of TLV in oleic-acid lung–injured adult sheep demonstrated significant improvement in oxygenation, respiratory compliance, cardiac output, stroke volume, physiologic shunt, oxygen delivery, ventilatory efficiency index, lung histomorphology, and reduced lung inflammation (interleukin [IL]-6, IL-8, myeloperoxidase) compared with animals treated with 4 hours of lung-protective mechanical gas ventilation.[59] In a 12-hour study of very-preterm lambs treated with either TLV or repeated dose of surfactant and lung-protective mechanical gas ventilation, animals treated with TLV demonstrated significantly improved compliance, oxygenation index, and ventilatory efficiency index. They required lower ventilatory pressures, had markedly improved histologic outcomes, and demonstrate reduced lung (tumor necrosis factor alpha [TNF-α], IL-6, IL-8, myeloperoxidase) and systemic (plasma TNF-α, IL-6, IL-8)[163] cytokine levels.

Differences between the earlier and more recent studies reflect improvements in ventilator designs and lung volume management during ventilation. In the earlier studies, measurements were performed shortly after PFC instillation, raising the issue of whether the cardiovascular compromise was related to elevated alveolar or intrathoracic pressures associated with liquid compression of resident gas volumes. Preexisting metabolic acidosis complicated interpretation of several of these studies.[152,153,155,157] In a study of normal neonatal piglets, initial elevations in pulmonary artery pressure and pulmonary vascular resistance (which resolved within 40 minutes) were related to early respiratory acidosis rather than to vascular compression.[160] This study demonstrated a small decrease in cardiac output in several animals with no difference in cardiac output between gas and tidal liquid breathing in the remaining animals. It was suggested that application of liquid ventilation of the normal animal may require only modest volume expansion (i.e., a single 10 mL/kg bolus) to support normal cardiac output. Furthermore, the earlier studies were conducted in the normal lung, which transmitted ventilatory pressures more readily to the vasculature than would a stiff lung. In contrast, studies of adult animals with induced acute respiratory distress syndrome have reported no changes in cardiac index during gas ventilation after PFC instillation.[119,161]

Ventilation-perfusion matching is improved during TLV of the poorly compliant lung of preterm animals.[72,76,113,116,120] Increased oxygenation and reduction in preductal to postductal O_2 tension differences indicate improvement in pulmonary blood flow and reduction of right-to-left ductal shunting. Developmental changes in cardiovascular and metabolic function of the TLV-treated lamb (102 days gestation to term) parallel developmental changes reported for fetal or gas-ventilated animals.[5] Left ventricular output, absolute pulmonary blood flow, ductal flow, systemic arterial pressure, heart rate, left ventricular ejection and shortening fraction, and velocity of circumferential fiber shortening remain unchanged, whereas meridional wall stress is reduced during gas ventilation of the PFC-filled lung (10 mL/kg).[11,154] Therefore it is unlikely that the weight of the PFC liquid presents a risk of cardiovascular compromise in the preterm lamb with respiratory distress. As the anteroposterior dimension of the lungs increases, however, hydrostatic pressure gradients may be an issue. Thus, in larger lungs, stratification of gas and PFC liquid during PLV and regional differences in hydrostatic pressure during TLV could play a role in cardiovascular performance.

EXPERIMENTAL AND CLINICAL TECHNIQUES FOR LIQUID-ASSISTED VENTILATION

Figure 98-6 and Table 98-2 illustrate techniques and protective mechanisms associated with liquid-assisted ventilation. The earliest and purest form of respiratory support with PFC liquids is TLV. Early investigations of fluid breathing used either total body immersion or gravity-assisted ventilation, which delivered PFC liquid from a reservoir to an intubated animal. These methods were inadequate for extended ventilation of experimental animals because of problems attributed to the differences between gas and liquid physical properties, such as density, viscosity, and gas diffusion rates.[2,18,28,148] Despite more uniform distribution of blood flow in the liquid-filled lung,[90,158] it was demonstrated that expiratory liquid flow and diffusion limitations could preclude sufficient removal of CO_2 when earlier mechanical ventilation schemes were applied.[69,148]

The concept of demand-regulated liquid ventilation was introduced in the early 1970s.[80-82,164,165] This technique used the respiratory centers of the experimental animal to control the cycling of the respirator, which circulated oxygenated liquid to and from the lungs. This approach reduced the work of breathing. Early experiments with this type of ventilation reported effective oxygenation and better CO_2 removal than immersion or gravity-assisted techniques. Modifications of liquid ventilation systems have evolved, incorporating various designs such as manually controlled flow-assist pneumatic systems[80-82,164]; roller pumps with pneumatic, fluidic, and electronic controls[5,76,116]; gravity-driven systems[110,166,167]; and modified extracorporeal membrane oxygenation circuits.[168] Control strategies incorporating constant pressure or constant flow, time cycling, and pressure (system, airway, or alveolar) or volume (lung volume, tidal volume) limitation have been explored, with the current approach emphasizing microprocessor-based feedback control (Figure 98-7).[42,101]

In general, TLV is achieved by cycling fluid from a reservoir to and from the lung. Warmed and oxygenated PFC liquid is pumped from a fluid reservoir into the lung. During expiration, fluid is pumped from the lung with passive assist of the lung recoil; it is filtered and returned to a gas exchanger for oxygenation and CO_2 scrubbing. O_2 concentration is titrated from the inspired O_2 tension,[42] and fluid is returned to the fluid reservoir. PFC vapor in the expired gas is condensed with high efficiency (at 70% to 80%), and noncondensed PFC loss caused by evaporation is measured and returned to the system.[74,169] During TLV, gas is transported to the alveolar-capillary membrane in dissolved form; O_2 and CO_2 diffuse through the liquid, and the fluid

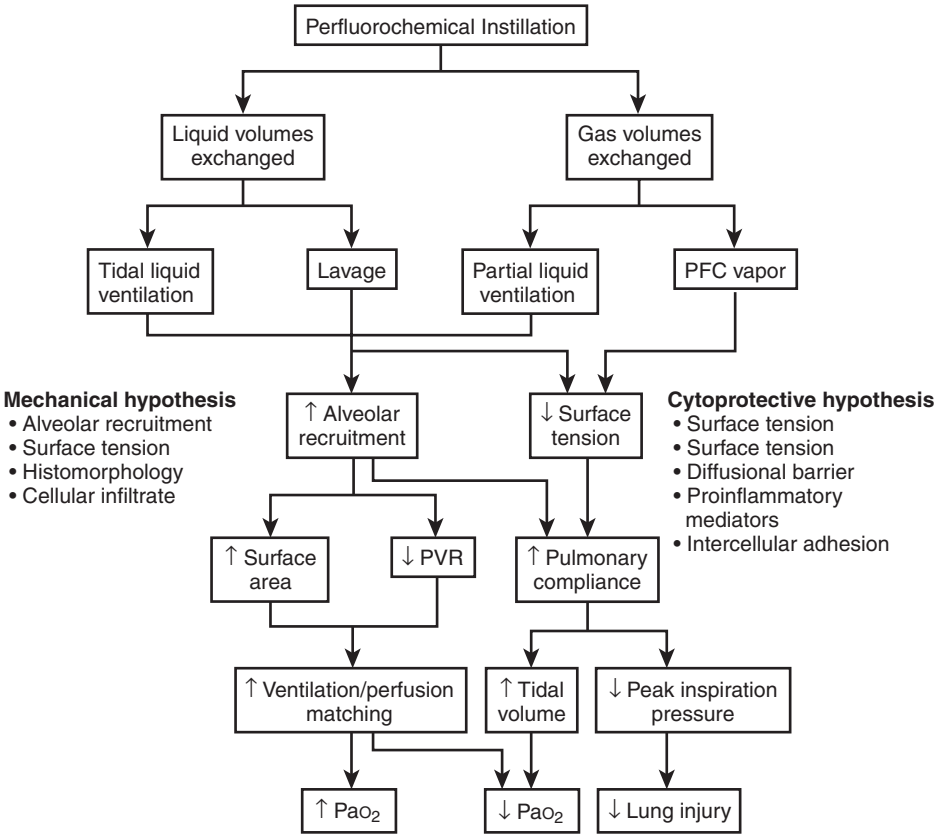

Figure 98-6 Liquid-assisted ventilation techniques and associated lung-protective mechanisms.

TABLE 98-2

Comparison Between Partial and Tidal Liquid Ventilation

Parameter	Partial liquid ventilation (PLV)	Tidal liquid ventilation (TLV)
Dosing—How much perfluorocarbon is in the lung at any given time?	*Unknown* because the perfluorocarbon will evaporate and be expelled with each patient expiration	*Controlled* as a result of the closed circuit established by the liquid ventilator
Pressure changes within the alveoli	*Unknown* because the pressure waveform characteristics vary from the compressible air column in the air ventilator through the incompressible fluid column in the lung	*Controlled* by the liquid ventilator through the incompressible column of perfluorocarbon
Volume changes within the alveoli	*Unknown* as a result of air/fluid compressibility issues noted under pressure changes above	*Controlled* by the liquid ventilator through the incompressible column of perfluorocarbon
Oxygenation at the alveoli	*Unknown* because the transferrence of oxygen delivered by the air ventilator at the meniscus of the perfluorocarbon in the upper airways to the alveoli is indeterminate	*Controlled* by the liquid ventilator which cycles the fluid, scrubbing out CO_2 and establishing O_2 levels
Clearing of debris such as mucus	*Unknown* because any material in suspension within the perfluorocarbon fluid is likely redeposited in the lung when the patient is removed from liquid ventilation and the perfluorocarbon evaporates	*Controlled* by the liquid ventilator which cycles the fluid, filtering any debris from the perfluorocarbon fluid before reintroducing it back into the lung
Equipment	Gas ventilators, PFC vapor condenser, PFC regenerator, PFC vapor analyzer, infusion device	Tidal liquid ventilator

PFC, Perfluorochemical.

is regenerated extracorporeally. Because the lung is entirely fluid filled, heart sounds are more clearly discerned during TLV. Periodic rotation of the patient and suctioning of secretions may be used to facilitate removal of debris. Ventilation-perfusion matching is improved in the lung of a preterm infant with this form of ventilation independent of rotation; however, periodic rotation may further support homogeneous distribution of ventilation and perfusion. This may be more important in larger lungs, in which the effect of hydrostatic pressure has a greater influence on the distribution of pulmonary blood flow.

Repeated trials by different investigators confirmed that when mechanical ventilation is performed properly, oxygenation and ventilation can be maintained effectively in the liquid-filled lung. There is no known physiologic limitation that precludes the

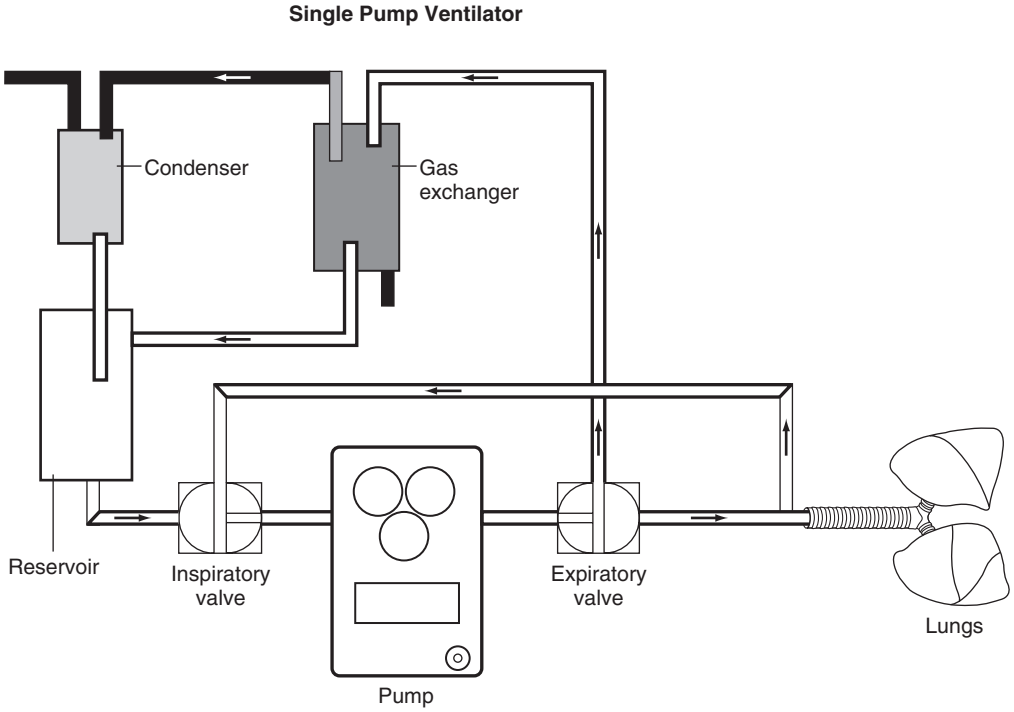

Figure 98-7 Single-pump tidal liquid ventilator. Heater omitted for clarity. *Solid line,* Gas flow; *open line,* PFC liquid flow.

duration of TLV. Term lambs have been ventilated successfully with physiologic gas exchange for up to 24 hours. Gas exchange data from studies of normal or lung-injured preterm, term, and adult animals have reflected improved liquids and ventilation methods. Along these lines, several researchers have reported alternating conventional ventilator therapy with PFC ventilation in various animal preparations and in human patients with respiratory distress ranging in age from extremely premature infants to adults.* This form of combined therapy was well tolerated and in many cases demonstrated improvement in lung mechanics.

This combined ventilation scheme (liquid ventilation and gas ventilation) has since been described as PLV,[66,136] or PFC-associated gas exchange,[154] and is characterized by filling and maintaining the lung with an FRC of PFC liquid while conventional gas ventilation is performed. It has been proposed that the residual PFC liquid within the lung is oxygenated and CO_2 is exchanged in the lung by means of gas movement provided by the conventional gas ventilator. PLV resembles the situation after the TLV-treated lung is returned to gas ventilation.

BIOCHEMICAL, HISTOLOGIC, AND MORPHOLOGIC FINDINGS IN THE LIQUID-VENTILATED LUNG

Since the 1970s, the aftereffects of liquid breathing have been given a substantial amount of attention. In this regard, it has been demonstrated that adult, newborn, and preterm mammals ventilated with PFC liquids for extended periods were able to return safely to breathing gas without long-term negative effects.

Biochemical Findings

Small but significant levels of PFC have been detected in blood samples from animals either ventilated with PFC liquid or after intratracheal instillation of PFC liquids. Across studies, PFC concentration in the blood ranged from 0.25 to 10 μg PFC per milliliter of blood and reached a plateau by 15 to 120 minutes of liquid ventilation, depending on the physical properties of the PFC liquid, the technique of PFC administration, and the species or animal preparation studied (Table 98-3). Although there are differences in experimental conditions across studies, results were similar in that they all noted low concentrations of different PFC compounds in the blood after pulmonary exposure to PFC.[145,172-175]

As reported, the concentration of PFC in the tissues with liquid ventilation is organ dependent, with the highest PFC level typically found in the lungs. In contrast to amounts found in the lungs, there were smaller amounts of PFC reported in other organs. The lowest levels were typically found in organs with low lipid content, and the highest were found in organs with high lipid content.[176] As noted by several investigators,[145,173,174] after return to gas ventilation, there was an overall reduction in PFC levels in organs as a function of gas ventilation duration. This reduction in PFC concentration in tissue was paralleled by a decrease in PFC vapor in expired gas as a function of time after return to gas ventilation.[145,174]

PFC uptake, biodistribution, and elimination were assessed in several infants after liquid ventilation.[175] Similar to results from animal studies, the data demonstrated that PFC uptake and elimination were organ dependent, PFC concentration in the expired gas samples decayed exponentially to within control range by 8 hours after liquid ventilation, and PFC concentration in the blood was relatively saturated by 15 minutes of liquid ventilation. Tissue values revealed highest residual PFC levels in the lung, with variable but small levels in other organs. In infants surviving for an extended period, levels in the lung markedly diminish, and levels in other organs approach control values.

The overall process of PFC uptake, biodistribution, and elimination has been supported by human studies, experimental animal models, and mathematical models of liquid ventilation.* Based on the understanding to date, a conceptual interpretation of this

process is diagrammed in Figure 98-8, and factors influencing this process are outlined in Table 98-4. Because PFC liquid in general is practically insoluble in water, essentially all the PFC in the blood and tissues is dissolved in lipid.[173,174] Therefore small quantities of PFC diffuse into the blood passing through the lungs, where PFC dissolves in blood lipid. The uptake process in the blood is dependent on PFC vapor pressure, permeability coefficients in the lung, PFC solubility in blood lipid, and ventilation-perfusion matching. Similar to the distribution of drugs in the body, biodistribution of PFC to the various organs depends on tissue-blood partition coefficients, tissue blood flow, and tissue compartment volume.[175] Therefore, as shown in previous animal and human studies,[145,175,180] vessel-rich organs with high blood flow are saturated more rapidly, and fat-rich organs have a higher capacity for PFC storage. Finally, PFC liquids may be scavenged by macrophages, and, because of the unique chemical structure of PFC liquids, they are not metabolized. The essential route of elimination is through the lungs by volatilization in the expiratory gases with the potential for transpiration through the skin. In a follow-up study of dogs treated with PFC ventilation,[181] for the first 5 years there were diminishing amounts of PFC as, detected histologically as persistent vacuolated macrophages in the alveoli, interstitium, and hilar lymph nodes, as well as supported by chemical analysis. By 10 years, no evidence of residual PFC was seen, and at no time was evidence seen of fibrosis or untoward structural alterations associated with the residual PFC.

The elimination of PFC liquid from the respiratory system is based on numerous factors and is still under extensive investigation. With use of a PFC vapor analyzer, studies showed that PFC liquid volume loss and evaporation rate from the lungs correlated with time after instillation (Figure 98-9) and were modulated by changes in PFC physical properties, ventilation strategy, lung pathophysiology, distribution of fluid in the lung, repositioning of the subject, and administration of supplemental PFC doses to the lungs.[169]

Histologic and Morphologic Findings

Morphologic studies of newborn rabbits and immature lambs suggest that liquid ventilation actually seems to minimize damage typically incurred as a result of gas ventilation.[5,116,182] Fine structure studies of newborn rabbit lungs ventilated with PFC liquid revealed no indication of damage (Figure 98-10); the integrity of the epithelial cell membranes and bilaminar plasmalemma suggested maintenance of lung ultrastructure.[183] In addition, it is particularly noteworthy that after liquid ventilation, there was thinning of the epithelial septa, and the epithelial cells appeared flattened and more symmetric. As shown in an electron photomicrograph of lung tissue, these findings were reconfirmed in preterm lambs ventilated with PFC (Figure 98-11). The exchange spaces are clear, the air-blood interface is thin walled, the capillaries are intact and thin walled, and the cytoplasm of epithelial cells is relatively smooth. Abundant surfactant exists in lamellar bodies. The salutary effect of PFC ventilation has also been demonstrated in animal preparations of meconium aspiration or hydrochloric acid–induced or oleic acid–induced acute respiratory distress syndrome.[101,103,105,108,109] Histologic differences between the gas-ventilated lung and the TLV-treated lung were profound, reflecting a substantial reduction in pulmonary consolidation, atelectasis, hemorrhage, disruption of the alveolar

capillary membrane, and absence of inflammatory infiltration in the TLV-treated lung. The histology and morphology of lungs from healthy full-term animals after either prolonged TLV or PLV reflected preserved architecture.[79,184,185] Alterations associated with short-term exposure to intrapulmonary PFC liquid could not be detected by histologic or morphologic analysis in human lungs or other tissues.[186] Marked regional differences in pulmonary histology and morphology were noted in the lungs of preterm lambs with respiratory distress syndrome and in neonatal piglets with induced adult respiratory distress syndrome after PLV.[79,184,185] These changes were associated with stratification of the PFC and gas to the dependent and independent regions of the lung. Prolonged (96 hours) PLV of premature baboons resulted in gas exchange and lung mechanics improvements. However, a trend was noted in this study toward delayed pulmonary recovery (based on airway pressures and type II cell immaturity) in animals ventilated with PLV as compared with historical control animals.[187]

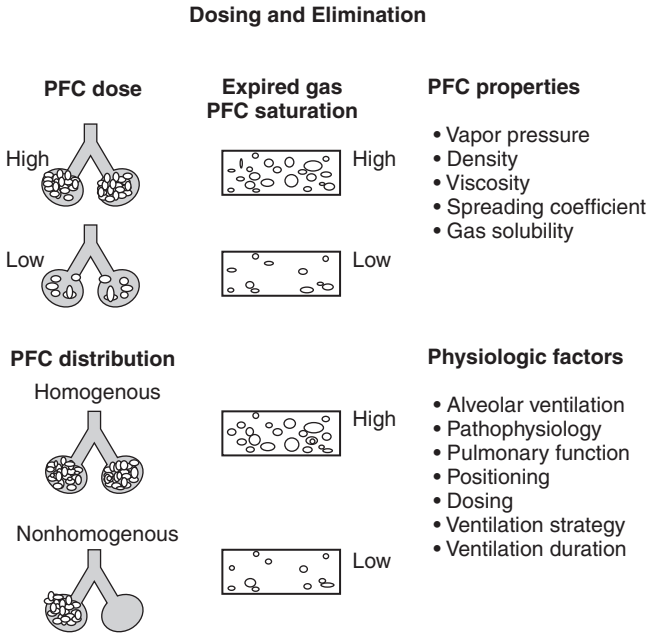

Figure 98-9 Influence of the physicochemical properties, dose, distribution, and physiologic factors of PFC liquids on PFC elimination.

Cellular Findings

In addition to improvement in lung distensibility and gas exchange, studies indicated that, whereas PFC liquids are chemically inert substances, their presence appears to modify certain biologic activity that may reduce pulmonary inflammation and injury associated with respiratory distress syndrome. Pulmonary neutrophil infiltration in rat lungs injured with cobra venom factor or resulting from hemorrhagic shock was significantly reduced during PLV when compared with conventional gas ventilation support.[188,189] Exposure of alveolar macrophages from rabbit and piglet lungs demonstrated that perflubron liquid in vitro decreased the responsiveness of macrophages to potent stimuli.[190] The effects of PFC on neutrophil–epithelial cell interactions have also been evaluated.[191] Neutrophils that were exposed to PFC, washed, and then stimulated retained their ability to generate oxidants, to release proteolytic enzymes, and to adhere to epithelial cells. However, when neutrophils and epithelial cells were simultaneously exposed to PFC, adhesion and target cell injury after stimulation were reduced. The oxidant-generating capacity of cells obtained from PFC-treated humans with acute respiratory distress syndrome was similar to that of peripheral blood neutrophils. Collectively, these findings suggest that the presence of PFC may provide a mechanical barrier to reduce neutrophil-mediated lung inflammation and injury.

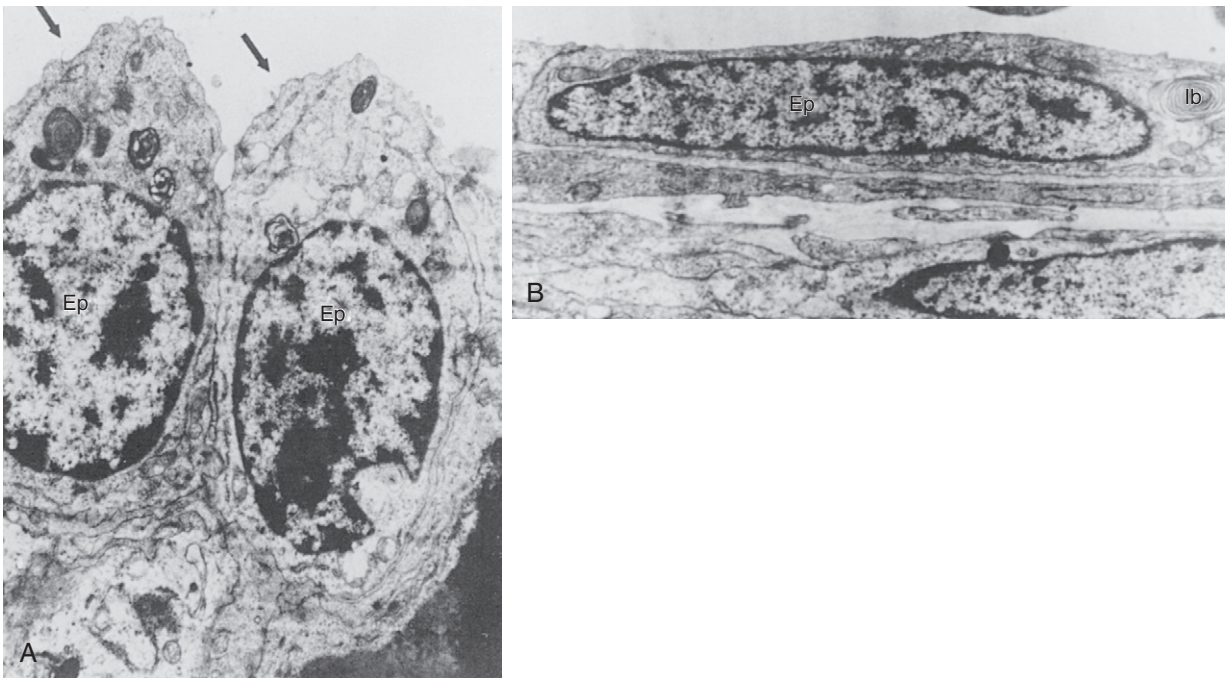

Figure 98-10 Electron micrographs of the lung of a preterm rabbit (27 days gestation). **A,** Unventilated lung. Note rounded contour of lung epithelium borders *(Ep)* (×7752). **B,** Liquid-ventilated lung. Note evenness of the luminal border, the flattened and elongated cells with early differentiation, and the lamellar body *(lb)* (×11,172).

More recent studies compared the cellular effects of PFCs of different properties on human blood cellular elements.[192,193] At the lowest PFC concentrations, which are comparable to the concentrations found in blood during liquid ventilation, PFC liquids seem to be inert and do not induce leukocyte markers associated with inflammation. In the presence of high perflubron concentrations, simulating the condition within the airways and lungs, monocytes may be induced to produce reactive O_2 species.

The permeability of the alveolocapillary membrane was studied in healthy adult rabbits ventilated with gas alone (control) or by PLV with perflubron.[194] Pulmonary clearance of inhaled technetium-labeled diethylenetriamine pentaacetic acid occurred significantly faster in animals treated with PLV than in animals treated with conventional ventilation alone. The investigators concluded that the faster clearance reflected greater alveolocapillary permeability associated with reversible changes in the surfactant system of healthy animals treated with PLV.

The effect of PFC liquid on surfactant function and metabolism has been examined in healthy and injured animal models. In vitro studies have shown that PFC-exposed exogenous surfactant maintains normal surface tension properties.[136,195] In vivo studies of healthy puppies have shown that most of the endogenous surfactant is retained in the lung after a 5-minute PFC lavage.[195] In one study, surfactant synthesis and secretion in surfactant-sufficient lungs were shown to increase after 5 hours of PLV when compared with gas-ventilated controls,[196] whereas the surfactant pool size was unchanged in another study of PLV-treated healthy or injured animals.[197] Preliminary results indicate increased endogenous surfactant phospholipids in bronchoalveolar lavage fluid after 5 hours of PLV in surfactant-deficient lambs.[198]

The effect of PFC ventilation techniques on markers of cell injury, as compared with scheduled physiologically regulated cell death (apoptosis), has been studied in very premature lambs supported with either TLV or conventional mechanical ventilation techniques.[199-201] Animals supported with TLV demonstrated a different pattern of apoptosis than those treated with conventional mechanical ventilation.[199] After conventional mechanical ventilation, apoptotic cells were observed to occlude the lumen of immature air spaces; in contrast, during TLV, apoptosis was limited to small numbers of epithelial cells lining the air spaces, with only a few cells observed within the lumen. No differences in antioxidant enzyme activity were observed.[200] Histologic evidence of barotrauma was less frequent and urinary desmosine levels, an index of elastin turnover, were significantly lower in animals supported with TLV as compared with conventional mechanical ventilation.[77,201] Collectively, these studies suggest that the reduction of barotrauma in premature animals supported with TLV as compared with conventional ventilation could be related to cell-specific apoptosis and appears to be independent of antioxidant enzyme activity.

BIOMEDICAL APPLICATIONS

Treatment of Respiratory Insufficiency

Animal Studies

Respiratory Distress

The hypothesis that PFC liquid would minimize surface forces, recruit and promote alveolar stability, and improve gas exchange at lower inflation pressures than with gas ventilation of the surfactant-deficient lung was first tested in 1976 (Figure 98-12).[113] The first studies were performed with preterm lambs of 132 to 138 days gestation[113,120] with respiratory distress syndrome. The lambs were delivered by cesarean section, initially supported with gas ventilation, and then briefly ventilated with PFC liquid (≤3 hours) and returned to conventional gas ventilation. Inflation pressures and alveolar-arterial O_2 gradients were reduced, and Pa_{O_2} and pulmonary compliance improved during and after rescue liquid ventilation. Pa_{CO_2} remained lower on return to gas ventilation, and the youngest animals with the lowest initial pulmonary compliance and Pa_{O_2} showed the most remarkable improvement in Pa_{O_2} and alveolar-arterial O_2 gradient with TLV. In contrast to the gas-filled lung, the low surface tension and spreading capabilities of PFC allow recruitment of lung tissue, which in itself increases lung compliance. Furthermore, because PFC liquid is incompressible and is not absorbed across the lung surface as is gas, alveolar stability is enhanced, thereby providing a liquid positive end-expiratory pressure. These results indicated that TLV could result in a sustained decrease in intrapulmonary shunting and atelectasis.

The ability to support pulmonary gas exchange while protecting the delicate alveolar epithelium of the immature lung with PFC liquid after delivery was demonstrated in several studies using preterm lambs of 102 to 137 days gestation.[72,76,116] TLV was initiated immediately after birth and was maintained for at least 3 hours. Effective gas exchange and physiologic acid-base status were demonstrated, with little age-related variation observed.[76]

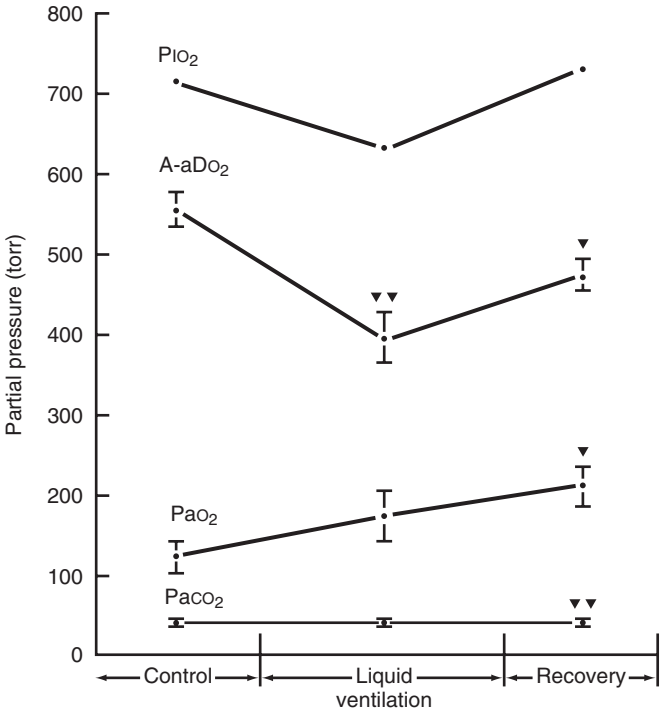

Figure 98-12 Inspired oxygen tension *(P_{IO_2}),* alveolar-arterial oxygen gradient *(A-aD_{O_2}),* arterial oxygen tension *(P_{aO_2}),* and arterial carbon dioxide tension *(P_{aCO_2})* during control gas ventilation, TLV, and recovery to gas ventilation. *(Redrawn from Shaffer TH, Douglas PR, Lowe CA, Bhutani VK: The effects of liquid ventilation on cardiopulmonary function in preterm lambs,* Pediatr Res *17:303, 1983.)*

These studies showed that the alveolar-arterial O_2 gradient during TLV was lower than that reported for gas-ventilated lambs of comparable gestational age, and pulmonary compliance approximated that of older gas-ventilated lambs.

Distinct differences in the clinical, physiologic, and histologic profile between conventional gas-ventilated and liquid-ventilated preterm lambs have been demonstrated (Figures 98-13 and 98-14).[116] Prophylactic TLV techniques supported gas exchange, acid-base balance, and cardiovascular stability throughout the duration of the experiment and improved survival; gas-ventilated animals demonstrated progressive deterioration, high morbidity, and poor survival. Differences in profiles were related to the mechanical characteristics of the respiratory system; respiratory compliance was greater, requiring lower inflation pressures in the liquid-ventilated than in the gas-ventilated animals. Thus maintenance of a liquid-liquid alveolar interface promoted effective cardiopulmonary function and maintenance of the integrity of the pulmonary architecture. These studies suggest that prophylactic TLV (implemented at birth) may decrease intrapulmonary and extrapulmonary shunting and may attenuate the complications associated with perinatal cardiopulmonary instability of the preterm infant. Evidence obtained in preterm lambs (112 to 128 days gestation), ventilated prophylactically with PFC liquid at birth and subsequently ventilated with gas, further supports this notion.[118] These animals demonstrated effective pulmonary gas exchange, acid-base status, and cardiovascular stability during TLV. Furthermore, during the period of gas ventilation, pulmonary compliance was noted to be significantly higher than that reported for animals of comparable or older age that had been gas ventilated since birth. Pulmonary compliance was also greater than that of equivalent-age animals rescue-treated with natural surfactant,[202,203] PFC,[114] or artificial fluorinated surfactant.[204,205] More recent studies performed in very-preterm lambs treated for 12 hours with either TLV or repeated doses of surfactant and lung-protective gas ventilation and in near-term lambs treated with TLV for 72 hours have demonstrated improvement in physiologic markers of gas exchange and lung mechanics, reduced lung inflammation, and improved lung histologic findings.[67,163,180]

In addition to the efficacy of tidal PFC ventilation, that of intratracheal instillation of PFC combined with conventional mechanical ventilation has been explored in animals with respiratory distress. Similar to total liquid ventilation, or the recovery phase of liquid ventilation (i.e., return to gas ventilation), PLV uses the alveolar recruitment capabilities of a fluid of low surface tension to establish an adequate FRC, as well as the ability of residual PFC to stabilize FRC in a surfactant-deficient or impaired lung. This experimental approach has been studied in acute lung injury models (Figure 98-15)* and in neonatal respiratory distress syndrome models (Figure 98-16).† Although the magnitude of responses varied within the different studies (possibly as a result of differences in techniques and degree of lung injury), it was generally shown that maintenance of an FRC with use of PFC combined with conventional gas ventilation provided adequate or improved gas exchange at relatively lower airway pressures than conventional gas ventilation alone. In many cases, the histologic pictures of the lungs were greatly improved compared with use of other forms of respiratory support or with untreated control groups.[143]

Aspiration Syndromes

Efficacy of PFC ventilation for the management of aspiration syndromes has also been demonstrated in neonatal and adult animals.[103,120,121,208] The foundation for this approach is related to removal of caustic substances (i.e., meconium) from the airways and alveolar surface, lung volume recruitment, reduction of surface forces, and improvement in ventilation-perfusion matching. Poor gas exchange, acidosis, and low pulmonary compliance present at birth and during gas ventilation of preterm lambs or induced term animals significantly improved during tidal PFC ventilation[120] or gas ventilation after instillation of PFC liquid (e.g., PLV- or PFC-associated gas exchange).[103,208] Meconium was observed in the expired liquid during tidal PFC ventilation and floated to the top of the endotracheal tube during PLV. Improvements were noted during tidal PFC ventilation in P_{aO_2}, alveolar-arterial O_2 gradient, and pulmonary compliance. Pulmonary blood flow was more uniform and P_{aCO_2} was lower during liquid ventilation. On the basis of these findings, it was concluded that tidal PFC ventilation improved pulmonary perfusion and therefore ventilation-perfusion matching. Similar improvements in pulmonary gas exchange and function have been reported in PLV of term animals with gastric acid–induced or hydrochloric acid–induced acute respiratory distress syndrome with inflammatory processes.[106,121] Similarly, it appears that PFC ventilation has a role in the management of aspiration syndromes. Early intervention may be useful in breaking the cycle of surfactant inactivation and inhibition and inflammatory processes.

Pulmonary Hypoplasia

Several studies have shown the potential of liquid ventilation for supporting gas exchange and lung mechanics in the presence of pulmonary hypoplasia. The basis of this application is related to low-pressure alveolar recruitment and improved ventilation-perfusion matching. Investigation of a lamb preparation of congenital diaphragmatic hernia supported with PLV, either prophylactically at birth or rescued after a period of gas ventilation,

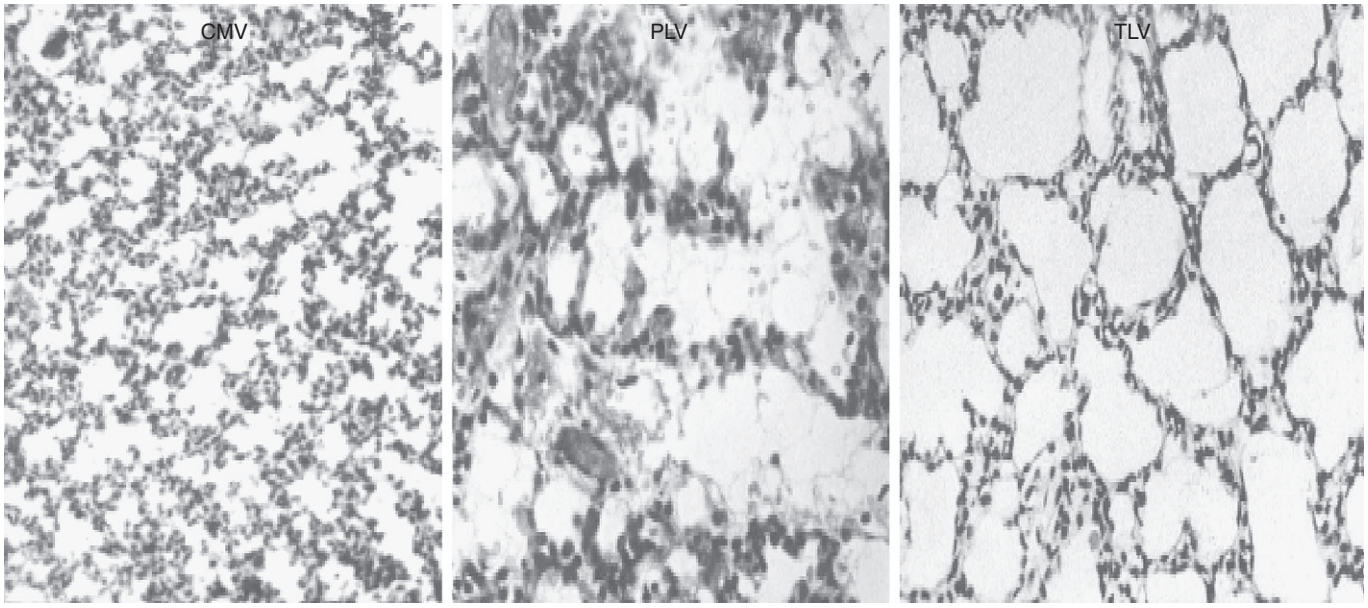

Figure 98-14 Lung histomicrographs of matched regional sections obtained from the surfactant-treated preterm lambs described in Figure 3, after 4 hours of conventional mechanical ventilation *(CMV),* partial liquid ventilation *(PLV),* or tidal liquid ventilation *(TLV).* Ventilation with PFC liquid improved overall expansion; however, marked heterogeneity and alveolar debris were noted after PLV. In comparison, after TLV, lungs were homogenously expanded and free of debris, and had less evidence of inflammatory cells. *(From Wolfson MR, Shaffer TH: Pulmonary applications of perfluorochemical liquids: ventilation and beyond,* Paediatr Respir Rev *6:117-127, 2005.)*

showed improved gas exchange and compliance compared with that of conventional gas ventilation support.[137,209] The congenital diaphragmatic hernia lamb preparation treated prophylactically with PFC at delivery demonstrated improved function and histologic findings compared with rescue treatment.[12,209]

Use of Perfluorochemicals in Infants With Respiratory Distress Syndrome

The first human studies of PFC liquid ventilation for the treatment of respiratory distress were performed in near-death infants with severe respiratory failure in 1989.[9,171] TLV was performed in two 3- to 5-minute cycles separated by 15 minutes of gas ventilation. Although all six infants in these studies ultimately died of their underlying respiratory disease, it was shown that liquid ventilation was able to support gas exchange and residual improvement in pulmonary function after return to gas ventilation in these critically ill patients.[210] Further clinical trials were limited by the need for a medically approved liquid ventilator and medical-grade breathing fluid.

The results of this first human trial and continued success of neonatal and adult animal trials with liquid-assisted gas ventilation promoted initiation of a corporate-sponsored multicenter

trial. This trial was designed to examine the safety and efficacy of PLV with LiquiVent (Alliance Pharmaceutical Corporation, San Diego, California) in the treatment of premature infants with severe respiratory failure in whom conventional therapy had failed.[66] Seven preterm infants 5 days of age or younger (27.8 ± 1.3 weeks gestation; 1000 ± 166 g) who had received two or more doses of surfactant and were at high risk of death were enrolled. During the PLV treatment (Figure 98-17), all patients demonstrated some improvement in oxygenation, and five of seven patients demonstrated improved CO_2 removal and lung compliance; patients with hypercarbia were transferred to high-frequency ventilation. No serious adverse events were related to PLV, and two of the seven patients survived. The remaining infants died of intracranial hemorrhage (n = 2) and bronchopulmonary dysplasia (n = 1). It was concluded that PLV could be achieved for up to several days in critically ill infants without serious adverse events. Additional patients were enrolled in this protocol, and, from the series of 13 infants observed to date, 10 infants received 24 to 76 hours of PLV and 3 infants were withdrawn after a short course to receive high-frequency ventilation with residual PFC in the lung (Alliance Pharmaceutical Corporation, personal communication, 1995). Eight infants were survivors at 28 days, and 7 were discharged. It appears that clinical improvements were clearly demonstrated, with survival in some patients not expected to survive. A number of infants enrolled in this study are currently in their teenaged years. As an adjunct to extracorporeal life support in term neonates (i.e., congenital diaphragmatic hernia, acute respiratory distress syndrome), PLV for up to 7 days has been shown to gradually improve gas exchange and pulmonary compliance without adverse events related to the drug or technique.[109] It is unknown why the response to PLV of the sick term infant is more gradual than in the preterm infant with respiratory distress syndrome. On the basis of the mechanisms of liquid-assisted ventilation (see Figure 98-6), differences in this temporal response are likely due to a relatively rapid reduction in surface tension and volume recruitment in the preterm (within hours) as compared with the term infant in whom improvement in lung function requires removal of debris, which occurs more gradually over days. During the late 1990s, Alliance Pharmaceutical Corporation conducted several clinical trials of PLV with LiquiVent PFC fluid for the treatment of acute respiratory distress syndrome in adults.[58,130,131] In May 2001 Alliance announced the preliminary results from its phase 2 to 3 clinical study, which enrolled 311 adult patients at 56 medical centers in the United States, Europe, and Canada. Results of this trial have only been discussed publicly and not published in complete form to date. Safety data demonstrated that LiquiVent was well tolerated by the patients. Efficacy data revealed that PLV with LiquiVent did not meet the primary study end point for improvement in "ventilator-free days" or the secondary end point of improvement in 28-day mortality. The results of this adult trial suggested that PLV did not provide incremental benefit when compared with the ventilation strategies outlined in the ARDSnet Trial. Given the low mortality in both arms of the adult LiquiVent trial (i.e., 15%-19%) relative to mortality rates between 30% and 50% in most all other acute respiratory distress syndrome studies, failure to meet these end points is not surprising. According to an Alliance Pharmaceutical spokesperson, failure to meet these end points in adults and financial pressures, despite equivalency to existing therapies, precluded further investment in this effort. Although techniques used in the trials in adults had minimal relevance to the neonatal population, all industry-organized trials including those in the neonatal and pediatric groups were suspended. Because there has not been full disclosure of the adult trial results and because corporate support was withdrawn, a sense of uneasiness resulted as an unfortunate consequence of these trials. However, through further questioning, it is important to note that the adult trial continued until completion and was not terminated early on the basis of adverse events, risks associated with this technology, or concerns of the data safety monitoring board (Mark Weidel, personal communication, 1997). Lessons learned from history are applicable: lack of efficacy of exogenous surfactant demonstrated in adult trials did not predict efficacy demonstrated in the neonate. In this regard, equivalency of liquid

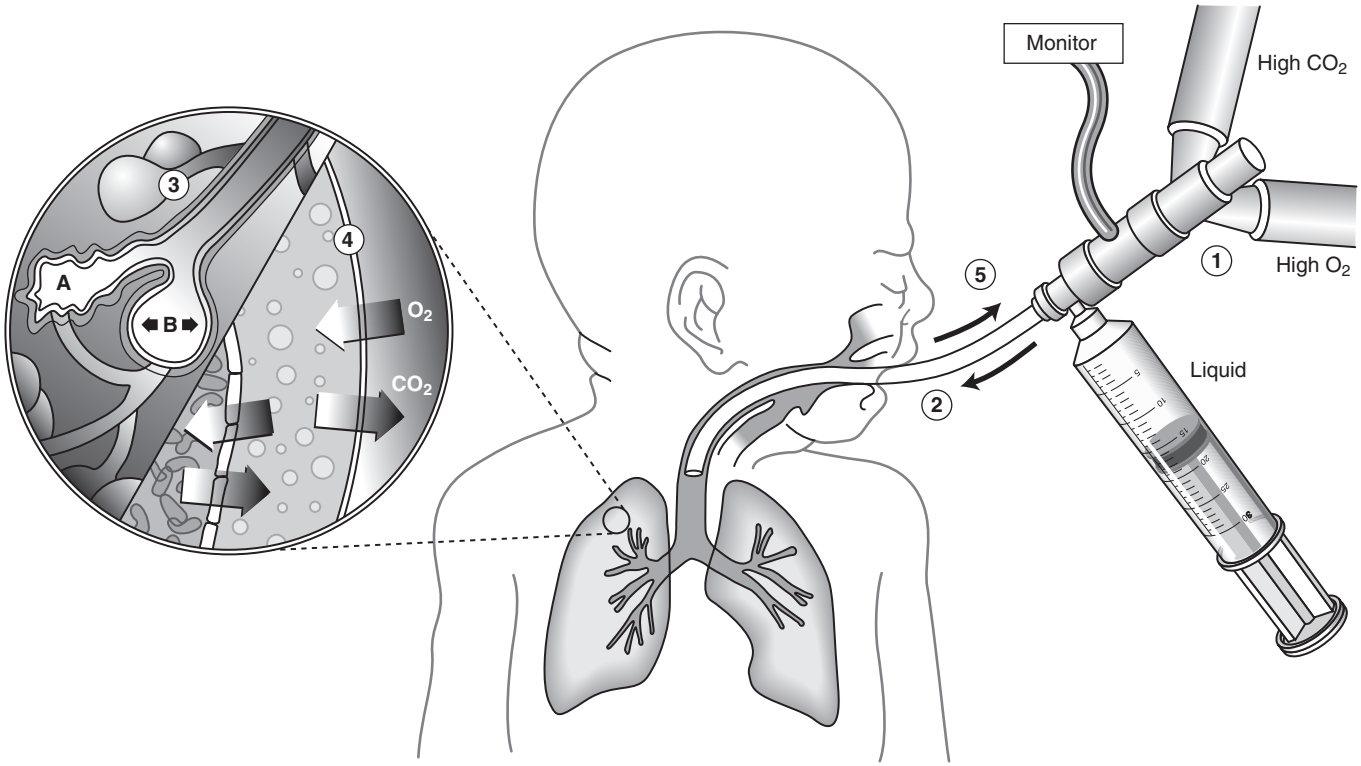

Figure 98-17 Schematic of PFC dosing and conceptualized gas exchange processes during gas ventilation (i.e., PLV). *(Courtesy Jay S. Greenspan, M.D., Thomas Jefferson University Hospital, Philadelphia.)*

ventilation to standard of care in adults rather than exceeding end points should not be used as a deterrent for resumption of clinical trials in the neonate. More recently, Lindemann and colleagues[132] demonstrated that bronchoalveolar lavage with PFC liquid could be performed safely during conventional mechanical ventilation without the additional support of extracorporeal membrane oxygenation in infants with severe alveolar space-occupying material.

Follow-up studies in humans up to 12 years after treatment with PLV have demonstrated no untoward effects of this treatment.[133-135] These imaging studies have demonstrated evidence of residual PFC in the lung, thorax, mediastinum, and retroperitoneum. In addition, they caution against interpreting the high-density opacifications associated with the Hounsfield unit density of some PFCs used with any intrapulmonary application as pulmonary calcification[134] and emphasize the importance of obtaining clinical history when faced with unusual radiographic findings.[135]

Liquid Ventilation as Adjunctive Therapy

The utility of liquid ventilation in the treatment of pulmonary dysfunction extends beyond the lowering of surface tension. In addition to recruiting atelectatic regions of the lung, filling the lungs with PFC has a potential role in delivering both active and inactive agents for treating or diagnosing pulmonary disorders, in preventing further collapse of the lung, and in cleansing the lung, thereby providing a means for improved pulmonary gas transport and mechanics. For these reasons, several investigators have explored the use of liquid ventilation in combination with other forms of respiratory support.

Drug and Tracer Delivery

Several studies have demonstrated the feasibility of using PFC liquid ventilation techniques to deliver aqueous-based pharmacologic agents (i.e., vasopressors, antibiotics) to the lung. Physiologic responses and homogeneous distribution of these agents were demonstrated when they were delivered during tidal PFC ventilation in preterm lambs with respiratory distress syndrome and normal or lung-injured term lambs[78,106,211-216]; limited responses were noted when these agents were delivered during PLV.[212] Despite the lack of miscibility of the aqueous agents in the PFC, the physiologic responses demonstrate that tidal PFC ventilation provided a vehicle to deliver vasoactive agents to the pulmonary and systemic circulation. The delivery of these agents within the PFC tidal volume is consistent with the convective-exchange mechanism[217]; this mechanism is ostensibly absent during PLV.

The physiologic responses to inspired nitric oxide (NO) during PLV were investigated. NO administration in combination with PLV in surfactant-depleted adult pigs produced a significant improvement in gas exchange and decrease in pulmonary artery pressure without deleterious effects on systemic hemodynamic conditions.[218] A study of a congenital diaphragmatic hernia lamb preparation treated prophylactically with PLV demonstrated that NO improved oxygenation and reduced pulmonary hypertension.[209] The ability to deliver NO during PLV is probably related to distribution of NO in the gas-ventilated regions of the lung, the solubility and diffusion of this gas in the PFC, and recruitment of lung volume. These findings on the effective delivery of NO in PFC liquid are consistent with those of earlier studies demonstrating the use of PFC liquid as a vehicle for the delivery of other biologic agents. On the basis of the transport principles previously described, it appears that the absolute amount of NO delivered to the pulmonary structures is dependent not only on the NO in parts per million in the inspired gas, but also on the amount dissolved in the PFC liquid (PFC liquids have high solubility for most gases; solubility data of NO in PFC have not been reported), the stratification pattern of gas and PFC liquid, the amount and distribution of pulmonary blood flow, and ventilation-perfusion matching. Therefore, for equivalent inspired NO

(parts per million), the amount of NO delivered to the pulmonary structures of the PFC-filled lung may be different from the amount delivered by gas ventilation. In addition, the clearance of NO from the PFC-filled lung and potential formation of NO_2 during liquid ventilation may also be different as compared with the gas-filled lung.

These studies suggest that PFC-assisted ventilation may be a useful adjunct in delivering therapeutic levels of other agents (i.e., bronchodilators, exogenous surfactant, antibiotics, steroids, chemotherapeutics, mucolytics, antioxidants, and gene therapy products) directly to the lung while protecting nontargeted organs from pharmacologic effects. Alternate combinations of PFC with biologic or nonbiologic agents such as suspensions, micelles, or liposomes may enhance the therapeutic and diagnostic potential of PFC pulmonary delivery techniques. Overall, it appears that this approach has a promising therapeutic role in the management of various neonatal problems, such as surfactant deficiency, consolidation, exudative processes, persistent or acquired pulmonary hypertension, pneumonia, and airway reactivity.

SECTION XIII

Surfactant

99 Historical Perspective

Mary Ellen Avery

In 1929, a Swiss physician, Kurt von Neergaard,[1] wrote, "New notions on a fundamental principle of respiratory mechanics: The retractile force of the lung, dependent on the surface tension in the alveoli." He speculated that atelectasis of the newborn could result from "considerable retractive force of surface tension in the lungs." He carried out experiments demonstrating that an excised lung inflated with air had considerably greater transpulmonary pressure than the same lung extended to the same volume with liquid.[1] That simple, straightforward experiment was reproduced independently in the 1950s by Mead and associates[2] at the Harvard School of Public Health. The stage was set for understanding what physical and chemical forces were involved in incurring the unique properties of the alveolar lining layer, namely, the ability to augment elastic recoil of the lung at large lung volumes and the ability to reduce surface tension and stabilize air-filled spaces arranged in parallel at low lung volumes (and thus to act as an antiatelectasis factor).[2]

In the late 1940s, Peter Gruenwald[3] and George Anderson with a colleague,[4] both pathologists at Johns Hopkins University, studied lungs at autopsy and commented on the airless state that was seen. They described the lungs as "liver-like" and, in the case of Gruenwald, noted that the lungs could be expanded with liquid without significant change, but when they were expanded with air, they achieved a "Swiss cheese pattern" of overdistended air spaces and atelectasis.[3,4] I had the privilege as a medical student and, later, as a resident of hearing from both Gruenwald and Anderson, and I realized how very important was the contribution of pathologists in stimulating clinicians to relate the baby's clinical course to the findings at autopsy. It was not until the early 1950s that Herbert Miller and colleague[5] at Yale University and Blystad and associates[6] in Boston described the clinical correlations of elevated respiratory rates and retractions that small premature infants showed before their demise from atelectasis with hyaline membranes. It was Herbert Miller and colleagues[5] who first said that membranes could not result from the aspiration of amniotic fluid, as had been previously surmised, because they were not seen in babies who died in the first hours of life but took time after birth to develop. Gitlin and Craig,[7] working in Boston, demonstrated the fibrin content of the membranes and deduced that the proteinaceous material had to come from the circulation.

Independently of these clinical and pathologic observations, the respiratory physiologists at the Harvard School of Public Health were repeating von Neergaard's experiments and were making estimates of lung surface areas on the basis of an assumed surface tension of 50 dyne/cm (the equivalent of serum). The results of those calculations revealed the estimated areas to be one tenth that estimated by histologists, and it was clear a better explanation for the differences had to be found.[8]

The better explanation came from an unlikely source, the Chemical Defense Establishment in Porton, England, where Pattle[9] was assigned. Pattle[9] had been stationed there to study the role of antifoam agents in the prevention of pulmonary edema induced by certain war gases. He needed a measure of bubble stability and expressed bubbles from the lung into a drop of saline to measure their lifespan. He noted that bubbles expressed from the lung seemed to have a much longer lifespan than bubbles from serum, from other tissues, or even from ordinary detergents. He wrote a description of his findings in a now famous article entitled "Properties, Function, and Origin of the Alveolar Lining Layer," published in the *Proceedings of the Royal Society of London* in 1958.[10] He had noted that bubbles expressed from the lungs of fetal guinea pigs did not have the stability of those found in term mammalian lungs and then suggested that one of the difficulties with which a premature baby has to contend is the increased surface forces in the immature lung.

The turning point in all this was the work of John Clements and colleagues,[11] Clements was working at the Army Chemical Center in Edgewood, Maryland. Clements and colleagues proceeded to measure surface tension in a more sophisticated way with a Wilhelmy balance that allowed them to ascertain the changes of surface tension with surface area. Around Christmas-time 1957, I drove to Edgewood and visited Clements. I saw the surface balance, returned to Boston, and decided to explore the reason why lungs of infants who died of hyaline membrane disease never had foam in their airways. It is obvious that the reason they lacked foam was that they did not have surfactants with the capacity to reduce surface tension when surface area was reduced. It was straightforward to demonstrate the deficiency in surfactants on a surface film balance modeled after that of Clements. The following is a quotation from the publication I co-wrote with Mead[12]:

> Low surface tension in the lining of the lung permits stability of the alveoli at end-expiration. Lacking such a material, the lung is predisposed to atelectasis. Measurements of the surface tension of lung extracts confirm the presence of a very surface-active substance in lungs of infants over 1,000 - 2,000 gm and in children and adults. In lung extracts of immature infants and infants dying with hyaline membrane disease, surface tension is higher than expected. This deficiency of surface-active material may be significant in the pathogenesis of hyaline membrane disease.

Meanwhile, Sue Buckingham joined me[13] with the idea that the alveolar type II cells could be the source of production of surface-active lipids because these cells contained osmiophilic lamellar inclusions. We showed a temporal correspondence in mice between the appearance of the osmiophilic bodies and the capacity of lung extracts to lower surface tension. Many studies since then support the concept that the osmiophilic or lamellar bodies are sites of storage for the phospholipids, which are attached to apoproteins that facilitate secretion and spreading on the alveolar surface.

The subsequent years were characterized by work from many laboratories, analyzing the lipid composition of materials expressed from the lung. The finding that lung lipid could be identified in amniotic fluid suggested to Gluck and Kulovich[14] that sampling amniotic fluid in the last trimester of pregnancy may allow ascertainment of the maturity of the lung. The use of the lecithin-sphingomyelin ratio led to the development of an important and clinically useful test to guide obstetricians in the likelihood of an infant being born with or without adequate quantities of pulmonary surfactants. That same year, 1973, Richard King and colleagues[15] identified a surfactant-specific protein that subsequently led to extensive exploration of the three or more proteins that are associated with lipids and can be recovered from lung lavage liquid.

As of early 1995, four surfactant-associated proteins had been discovered and fully defined by identification of their respective genes. Surfactant protein (SP) A is hydrophilic and extensively modified after translation. SP-B is hydrophobic and has been found deficient in congenital alveolar proteinosis. SP-C, the smallest of the peptides, has a covalent linkage with the phospholipids and enhances their uptake by the alveolar type II cells. SP-D resembles SP-A and serves as an opsonin to enhance uptake of bacteria and viruses by macrophages. The sites of synthesis, methods of degradation, and aspects of hormonal regulation have been explored and reviewed extensively.[16-18]

SURFACTANT REPLACEMENT

Glucocorticoids play an essential role in both lung maturation and the synthesis of lipid and protein components of pulmonary surfactants.[19,20] Knowledge of hormonal influences in the timing of organ maturation began with the observations of Moog,[21] who in 1953 described the influence of the pituitary-adrenal system on the differentiation of phosphatase in the duodenum of the suckling mouse. Extensive experience with the use of antenatal glucocorticoids to accelerate lung maturation followed the pioneering observations of Liggins,[22] who in 1969 noted the survival at a younger age of premature lambs of ewes that had received glucocorticoids before delivery. Many controlled clinical trials, which were reviewed in 1990 by Crowley and colleagues,[23] established both the safety and the efficacy of antenatal corticosteroids. It appears that the effects of the combined use of prenatal corticosteroids and postnatal surfactant replacement are additive. It is as if the steroids "condition" the lung by increasing the surface area over which the surfactants, which are instilled as a liquid into the trachea, can spread and exert their effects.

A new chapter in the history of surfactant discovery was written when Fujiwara and colleagues[24] presented their initial experience in an article in *Lancet* in 1980. They and others, notably Forrest Adams in Los Angeles and Goran Enhorning in Toronto,[25,26] spent the previous decade analyzing various mixtures of phospholipids in animal models and then testing them in vitro. They finally decided that mixtures composed only of phospholipids would not have the requisite surface properties to stabilize airways effectively. Fujiwara and colleagues decided to use artificial surfactant (material derived from minced cow lungs), which consisted of lipids and lipid-associated proteins. He enriched the material with added dipalmitoylphosphatidylcholine (DPPC) and called it *TA surfactant,* after Tokyo, where the pharmaceutical house was located, and Akita, where he was working at the time.

The experience of Fujiwara and colleagues was distinguished from that of many investigators who attempted to treat surfactant-deficiency states with aerosolized DPPC; they used natural surfactants from cow lungs, and they instilled them as a liquid into the trachea and enhanced distribution by changing the position of the infant from one side to the other. After the instillation of 3 to 5 mL of material, they could demonstrate distribution in all the lobes of the lung and, impressively, a prompt increase in oxygenation. Thus it was evident that the material was distributed to the gas-exchanging surfaces of the lungs because it resulted in a prompt and sustained improvement in oxygenation. Fujiwara and colleagues demonstrated that, in some infants, a single instillation in the first hour of life or after the diagnosis of hyaline membrane disease could produce improved oxygenation that persisted for 2 to 3 days, which was long enough for the baby to acquire the capacity to synthesize endogenous surfactant.

These observations were not immediately acclaimed because the experience was not a prospective, randomized, controlled study. Nevertheless many investigators in various parts of the world in the mid-1980s were encouraged to conduct prospective, randomized, controlled trials, not only with TA surfactant but also with other mixtures of materials, mostly those derived from calf lung lavage. Other sources of surfactant have included human amniotic fluid, as evaluated by Merritt and colleagues,[27] and porcine lung extracts, which were studied by the Collaborative European Multicenter Study Group[28] in Europe. Meanwhile, TA surfactant was licensed in Japan in 1988 and is widely used. Other preparations, including a totally synthetic mixture, colfosceril, cetyl alcohol, and tyloxapol, also known as colfosceril palmitate, are licensed in the United States. Exosurf was invented by John Clements, who proposed that an alcohol (hexadecanol) be added to the principal phospholipid in pulmonary surfactant, DPPC. He also added tyloxapol to facilitate dispersion.

The natural surfactants from bovine or porcine sources have been used extensively. Short-term benefits are evident with early administration, and continuing evaluation is under way to assess long-term benefits and safety.

Thus, in the years from identification of a deficiency of surfactants in the lungs of infants who died of hyaline membrane disease, to clinical trials, and now to the wide availability of natural and synthetic surfactants for treatment, the odyssey from bench to bedside to pharmacy has been accomplished.

Jeffrey A. Whitsett

Composition of Pulmonary Surfactant Lipids and Proteins

In vertebrates, adaptation to a nonaqueous respiratory environment was achieved by the development of lungs, which provide an extensive surface area for gas exchange. The unique physicochemical boundary between respiratory gases and the respiratory epithelium creates a region of high surface tension, generated by the unequal distribution of molecular forces on water molecules at the air-liquid interface. Unopposed, this surface tension creates collapsing forces that cause atelectasis and respiratory failure. Pulmonary surfactant creates lipid layers separating alveolar gas from the aqueous phase, decreasing these surface forces. It is not surprising that pulmonary surfactant is found in all air-breathing vertebrates studied, including animals as phylogenetically divergent as the lungfish and humans.

Synthesis and secretion of an abundance of phospholipid-rich material accompany the maturation of lung before birth in the human. The lack of pulmonary surfactant in premature infants results in respiratory distress syndrome (RDS) after birth. Likewise, loss of surfactant function related to lung injury causes acute respiratory failure postnatally. Hereditary disorders of surfactant homeostasis cause respiratory failure in newborn infants and children. The specifics of structure and function of the surfactant complex have important implications for treatment of RDS and other pulmonary diseases. This chapter considers the phospholipid and protein components that play critical roles in surfactant function and pulmonary homeostasis.

FORMS OF PULMONARY SURFACTANT

Pulmonary surfactant is composed primarily of phospholipids but also contains proteins and carbohydrates. Pulmonary surfactant is present in distinct macromolecular aggregates whose structural forms probably are conferred by the relative abundance of proteins and phospholipids, as well as by the impact of mechanical forces on the surfactant material accompanying the respiratory cycle. Tubular myelin is a highly surface-active material sedimenting at relatively low gravitational forces and consists primarily of phospholipids and proteins (Figure 100-1). Various lamellar and vesicular forms of surfactant that lack the highly organized structures of tubular myelin also can be isolated from the lung. Although the forms of surfactant may be influenced by procedures designed to isolate or identify them (and thus represent artifactual structures), it is likely that these diverse structures are generated in vivo and play distinct roles in surfactant function and homeostasis.

LIFE CYCLE OF PULMONARY SURFACTANT

Surfactant lipids and proteins are synthesized, stored, and secreted by type II alveolar epithelial cells (Figure 100-2). Surfactant proteins are routed through the endoplasmic reticulum, Golgi complex, and multivesicular bodies before storage in lamellar bodies; the pathway involved in trafficking of surfactant lipids from the site of synthesis in the endoplasmic reticulum to the lamellar body is less clear. The contents of lamellar bodies are secreted into the air space in response to stretch, as well as various secretagogues, including purinoreceptor and adrenergic agonists. As secreted surfactant unravels in the air space, tubular myelin is formed in a process requiring extracellular calcium ions, surfactant lipids, and the surfactant proteins SP-A and SP-B. Tubular myelin is an abundant, large aggregate form of surfactant, probably serving as a reservoir from which surfactant monolayers or multilayers are generated at the alveolar surface. Rapid spreading and stability of these lipid films are determined by the influence of SP-B and the surfant protein SP-C, which serve to maintain phospholipids at the air-liquid interface, thereby reducing surface tension. Small vesicular forms, likely produced by the molecular forces produced during compression and decompression of surfactant during the respiratory cycle, are taken up by type II cells and either reutilized or catabolized. A fraction of surfactant is taken up by alveolar macrophages and degraded in a process requiring signaling by way of granulocyte-macrophage colony-stimulating factor (GM-CSF). Recent evidence demonstrates the important role of both GM-CSF and surfactant protein D (SP-D) in the regulation of surfactant phospholipid concentrations in the alveolus.[1]

ISOLATION OF PULMONARY SURFACTANT

Surface-active material usually is isolated by differential sedimentation of material collected by washing the lung with isotonic saline solutions.[2-4] Centrifugation at low forces is used to remove mononuclear cells, which in the normal lung are

Figure 100-1 Aggregate forms of alveolar surfactant. Lamellar bodies, the intracellular form of surfactant, are secreted into the alveolar lumen as concentrically arranged layers of tightly packed, phospholipid-rich membranes *(large arrow).* Here they are converted into tubular myelin, a lattice-like arrangement of intersecting tubules *(small arrows)* and associated matrix material *(arrowheads).* Image is a transmission electron micrograph of glutaraldehyde–tannic acid–osmium tetroxide fixed material from the neonatal mouse lung. (Magnification ×124,200.)

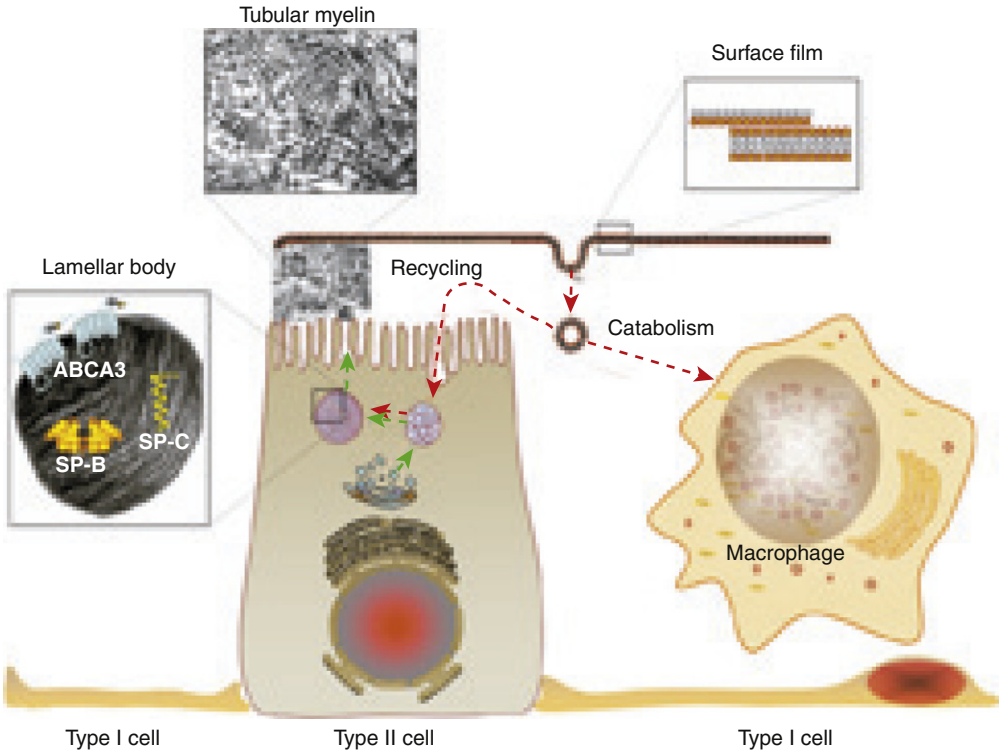

Figure 100-2 Life cycle of pulmonary surfactant. Pulmonary surfactant lipids and proteins are synthesized by type II epithelial cells. Surfactant proteins are transported from endoplasmic reticulum, Golgi complex, and multivesicular bodies to lamellar bodies. Surfactant proteins SP-B and SP-C are proteolytically processed during transit to lamellar bodies, where the active peptides are stored with phospholipids before secretion. After secretion, surfactant membranes unwind and in the presence of extracellular Ca^{2+} and SP-A from tubular myelin (large aggregate surfactant) from which monolayers and multilayers of phospholipids are produced to lower surface tension at the air-liquid interface. Small vesicles produced during the respiratory cycle are taken up and recycled by type II cells or catabolized by alveolar macrophages.

primarily alveolar macrophages. Some surface-active material—specifically, large tubular myelin forms—generally sediments at low gravitational forces. Higher-speed centrifugation or buoyant density separation is then used to isolate subfractions of surfactant containing various physical forms. The organization and separation of pulmonary surfactant are highly dependent on the concentration of calcium used during preparation. Calcium enhances the aggregation of surfactant, creating material with higher buoyant density.[5,6] The dense, tubular myelin-rich material (large aggregate surfactant) is enriched in surfactant-associated proteins SP-A, SP-B, and SP-C and is highly active as a pulmonary surfactant.[7,8] Less surface-active fractions containing primarily smaller or less dense vesicular forms (small aggregate forms) are relatively depleted of protein and are less surface-active than tubular myelin. SP-D is relatively enriched in the small aggregate fraction. These vesicular forms may

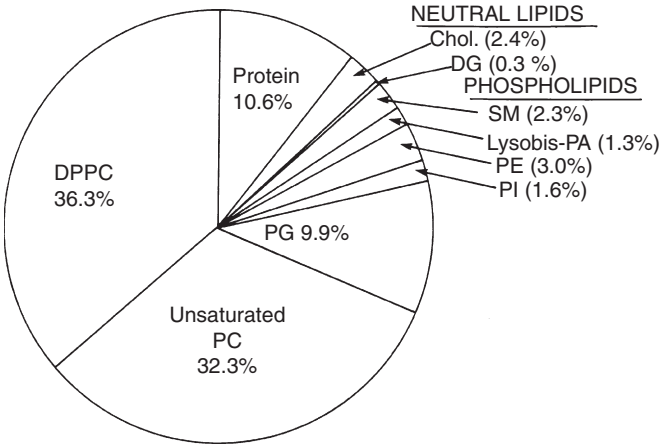

Figure 100-3 Composition of bovine pulmonary surfactant obtained from lung lavage fluid. Components are expressed as % wt. *Chol,* Cholesterol; *DG,* diacylglycerol; *DPPC,* dipalmitoylphosphatidylcholine; *PA,* phosphatidic acid; *PC,* phosphatidylcholine; *PE,* phosphatidylethanolamine; *PG,* phosphatidylglycerol; *PI,* phosphatidylinositol; *SM,* sphingomyelin. *(Modified from Possmayer F, et al: Pulmonary surfactant,* Can J Biochem Cell Biol *62:1121, 1984.)*

represent catabolic products generated from tubular myelin or from the lipids of the surface multilayers and monolayers that are generated during the respiratory cycle and are destined for uptake and catabolism by alveolar macrophages or reutilization by type II epithelial cells.

COMPOSITION OF SURFACTANT

The general composition of lung surfactant has been determined in numerous species, including reptiles, fish, birds, amphibians, and mammals. The composition of pulmonary surfactant is, in general, well conserved among diverse species and is rich in phosphatidylcholine and other lipids; proteins generally contribute less than 10% of its mass. The general composition of mammalian surfactant[9-11] is represented in Figure 100-3.

LIPID COMPONENTS

Surfactant is composed primarily of phospholipid, which represents approximately 80% to 90% of its mass. Lesser amounts of glycolipids and neutral lipids are detected in approximately equal amounts. Phospholipid is the primary surface tension–lowering component of pulmonary surfactant. The phospholipids form multilayered sheets that are derived from tubular myelin or other aggregate forms present in the alveolus. Phosphatidylcholine is the most abundant phospholipid in surfactant and is uniquely enriched in disaturated forms of palmitoylphosphatidylcholine (Table 100-1). In human surfactant isolated from lung minces, phosphatidylcholine represents 80% of the total phospholipid, of which 70% is present as the palmitoylphosphatidylcholine; 55% of this lipid species is in the form of disaturated palmitic acid acyl groups or disaturated phosphatidylcholine (DSPC).[11] Phosphatidylglycerol generally represents 5% to 10% of surfactant phospholipids. Phosphatidylglycerol also is capable of reducing surface tension at an air-liquid interface; however, its precise role in surfactant function remains unclear. Phosphatidylglycerol is not a prerequisite for surface tension–lowering, because surfactant from newborn rabbits lacking this phospholipid is highly functional at birth. It is possible that phosphatidylinositol provides the acidic phospholipid components required for optimal surface properties in the phosphatidylglycerol-deficient lung. Other phospholipids, including phosphatidylinositol, phosphatidylserine, phosphatidylethanolamine, lysophosphatidylcholine, and sphingomyelin, are present in relatively low amounts in pulmonary surfactant. Glycolipids also are present in pulmonary surfactant and have been partially characterized in rabbit surfactant. Neutral lipids are present primarily as cholesterol esters and acylglycerol fatty acids. The biologic functions of these components, present in relatively low amounts, have not been determined with certainty.[9-12]

TABLE 100-1

Phospholipid Composition of Human Surfactant and Lamellar Bodies (% wt/wt)

Component(s)	Surfactant	Lamellar Bodies
Phosphatidylcholine	73	71
Phosphatidylethanolamine	3	8
Phosphatidylglycerol	12	10
Phosphatidylinositol and phosphatidylserine	6	6
Sphingomyelin	4	2
Others	2	3

The molecular structures of phosphatidylcholine and phosphatidylglycerol are represented in Figure 100-4. Several aspects of their structures are critical for surface tension reduction at the alveolar-air interface. Each molecule consists of a three-carbon glycerol backbone. The C_1 carbon is modified by the addition of polar head groups (relatively more hydrophilic residues). In the case of pulmonary surfactant, the most abundant head groups are choline and glycerol. The C_2 and C_3 carbons of the glycerol backbone contain acyl groups of long-chain fatty acids, which are highly hydrophobic and lacking in significant charge. The polar head groups—choline, glycerol, and inositol—of the phospholipids produce charge-dependent interactions among neighboring phospholipid molecules and with water. By contrast, the acyl groups are energetically more stable in a nonaqueous environment and are tightly associated with neighboring phospholipid molecules by interactions between carbon and hydrogen atoms of the acyl chains. Hence these molecules are inherently insoluble in aqueous environments and form a variety of complex structures that include membrane monolayers, bilayers, multilayers, micelles, inverted micelles, and vesicles.

The surface properties of surfactant phospholipids (spreading, stability, and surface tension reduction) are influenced by a number of factors, including the degree of saturation of the acyl chains, which alter the tightness of packing of phospholipid molecules in membranes. The fatty acid composition of the phospholipids in pulmonary surfactants has been determined for various species[10] (Table 100-2). The structure of the acyl chains and the composition of the major phospholipids are important determinants of the organization of the membranes. The acyl chains present in phosphatidylcholine isolated from pulmonary surfactant are uniquely enriched in palmitic acid (C16) with disaturated acyl chains. Enrichment of these phospholipid species at the surface would result in a densely packed monolayer, creating an interface with extremely low surface tension. Saturated acyl chains contain no methylene (C═C) bonds, and the carbon atoms are fully hydrogenated. Membranes containing such lipids pack densely through the hydrophobic interactions of the acyl chains. The ordering of phospholipid molecules in the surfactant membrane also is highly dependent on temperature. Surfactant lipids are present in a gel or crystalline state at the physiologic temperatures of homeothermic

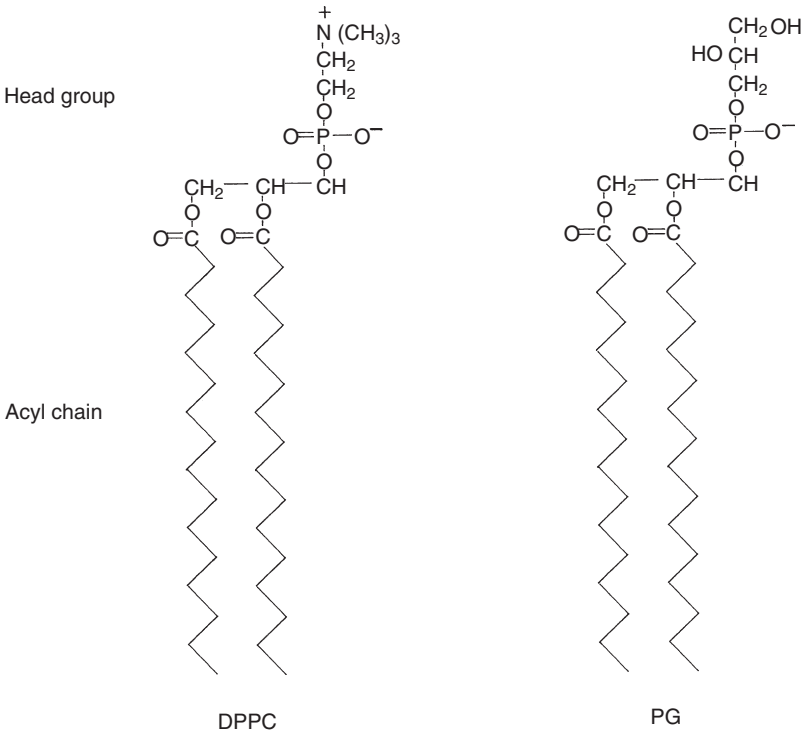

Figure 100-4 Molecular structures of dipalmitoylphosphatidylcholine (DPPC) and phosphatidylglycerol (PG). Phospholipid molecules pack densely, forming membrane monolayers, bilayers, and vesicles and other aggregate forms. Strong molecular interactions occur between polar head groups. Distinct interactions occur between atoms composing the more hydrophobic acyl chains.

organisms because the transition temperature (temperature of melt) of DPPC is approximately 41° C. Therefore DPPC would be present in a relatively rigid state at 37° C. The presence of minor lipids, proteins, and unique phospholipid acyl chains, however, alters the packing characteristics of the phospholipids. The relative abundance of the major lipid classes and their acyl chain length and specific composition, including the proportion of molecular species with unsaturated acyl chains, therefore result in a unique pulmonary surfactant mixture that may alter the surface properties of the surfactant film. The characteristics of rapid adsorption and stability during compression of pulmonary surfactant are not properties inherent in the phospholipids alone, requiring the presence of surfactant proteins as well. The hydrophobic surfactant proteins SP-B and SP-C play critical roles in the organization of phospholipids and are required for full surface-active properties of the lipids in surfactant.

COMPOSITION OF LAMELLAR BODIES

Surface-active material can also be isolated from its primary intracellular storage site in lamellar bodies of alveolar type II cells. Lamellar bodies are highly enriched in phospholipids, generally containing approximately 10 to 12 mg of phospholipid per mg of protein. The limiting membrane of the lamellar body contains at least one ABC transporter, ABCA3, which probably plays an important role in importing surfactant lipids into the lamellar body.[13,14] Mutations in the ABCA3 transporter block the formation of lamellar bodies and cause severe lung disease in newborn infants.[15] Lipid composition of lamellar bodies is similar to that for surfactant isolated from lung lavage fluid.[10] SP-B and SP-C are highly enriched in lamellar bodies and are co-secreted with phospholipids into the air space.

DEVELOPMENTAL CHANGES IN PHOSPHOLIPID COMPOSITION

The phospholipid composition of alveolar lavage material changes during perinatal development. Increased phospholipid synthesis and secretion occur with advancing gestation and are influenced by a variety of hormonal and cellular factors.[12] Because pulmonary secretions contribute a significant volume to amniotic fluid, increased phospholipid in amniotic fluid accompanying advancing gestation has been used for determining the relative maturity of the fetal lung and thus predicting the risk of RDS in premature infants. The phosphatidylcholine content of amniotic fluid increases during the last third of human gestation. The ratio of lecithin (phosphatidylcholine) to sphingomyelin, otherwise known as the L/S ratio, has been useful in the clinical assessment of risk for RDS.[16]

Surfactant content in amniotic fluid can be determined by a number of procedures that predict pulmonary maturity.[17,18] Various amniotic fluid assays are useful in predicting surfactant function or lack of respiratory distress in preterm infants, including the L/S ratio; lamellar body counts; quantitation of phosphatidylglycerol, DSPC, or phosphatidylcholine; and fluorescence anisotropy. Changes in total phospholipid content and in the relative abundance of phospholipid species also accompany respiratory failure in infants and adults.[19]

PROTEINS

The characteristics and nomenclature of surfactant proteins are the subject of several reviews.[20-22] Surface-active fractions isolated from lung lavage by differential sedimentation contain numerous polypeptides, which include both serum and nonserum proteins. At present, four distinct surfactant-associated proteins have been purified from surfactant and their primary structures discerned. These proteins have been termed surfactant proteins SP-A, SP-B, SP-C, and SP-D (Table 100-3). Complementary DNAs and genes encoding these surfactant proteins have been isolated and characterized. The human genes are termed *SFTPA, SFTPB, SFTPC,* and *SFTPD.* The role of each of the proteins in surfactant function and pulmonary homeostasis have been clarified in gene-targeted mice and in clinical observations in children and adults. The precise abundance of each of the proteins in pulmonary surfactant or surfactant subfraction has not been determined with certainty. Nevertheless, SP-A, SP-B, SP-C, and SP-D account for most of the nonserum proteins present in the lipid-associated fraction isolated from lung lavage.

Surfactant Protein A

SP-A is an abundant nonserum lipid-associated protein in pulmonary surfactant.[4] SP-A is a member of a related family of polypeptides termed the *collectins* that includes SP-D, mannose-binding lectin, conglutinin, and collectin-43 (CL-43). These proteins share collagenous and lectin-containing domains that bind complex carbohydrates. SP-A is a glycoprotein of 26,000 to 35,000 Da that undergoes sulfhydryl-dependent oligomerization and other post-translational modifications, accounting for the significant molecular heterogeneity of its isoforms in pulmonary surfactant. Two human *SFTPA* genes have been identified, each consisting of five exons contained within approximately 4.5 kilobases (kb) of DNA.[23] The *SFTPA* locus consists of two coding sequences and a noncoding sequence on human chromosome 10.[24,25] The entire polypeptide sequence of SP-A has been deduced from the gene and complementary DNAs (cDNAs) encoding the human proteins[23] (Figure 100-5). SP-A is first synthesized as a 248 amino-acid precursor peptide from which a small signal sequence is cleaved. The remaining amino-terminal (N-terminal) domain of the mature SP-A peptide contains an extensive collagen-like region of approximately 10,000 Da. A discrete carboxyl-terminal (C-terminal) globular domain is homologous to other mammalian lectins (carbohydrate-binding proteins) and is structurally related to those in SP-D, mannose-binding lectin, and other members of the collectin family of polypeptides.[26] SP-A binds carbohydrates, phospholipids, and glycolipids that are surface components of numerous pathogens, including bacteria, viruses, and fungi.[27,28]

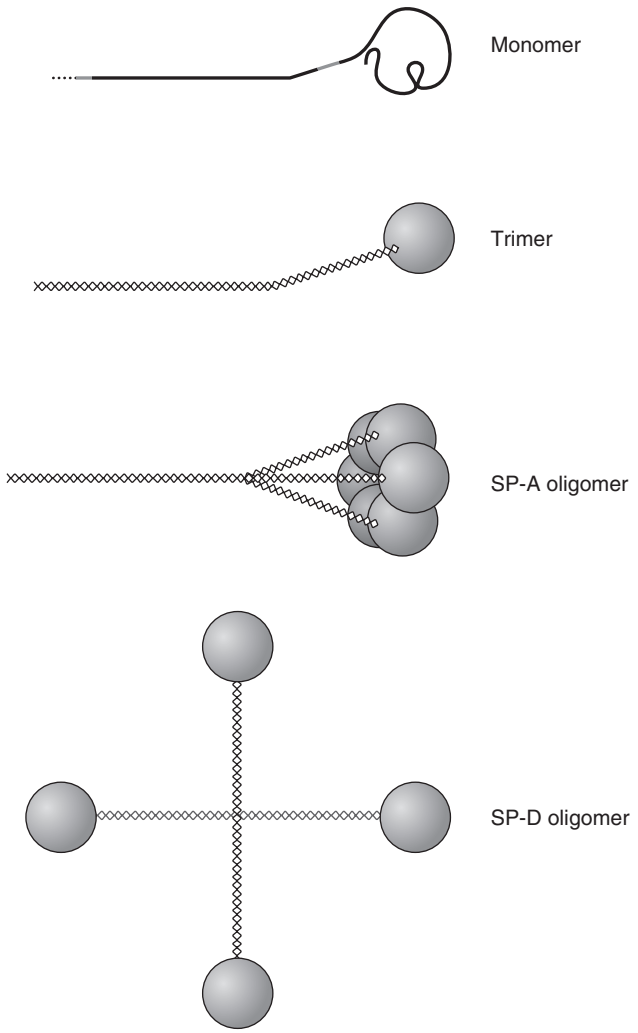

Figure 100-5 Human SP-A is encoded by genomic DNA on chromosome 10. Translocation of the mRNA produced a monomer that forms trimers. Furthermore, oligomerization through the amino-terminal (N-terminal) collagen-like domain *(hatched area)* results in hexamers and larger assembled forms such as octadecamers found in association with tubular myelin in the alveolus. SP-D is formed by a similar process from the SP-D gene locus, also located on chromosome 10; SP-D monomers form trimers that are organized into tetramers and dodecamers.

Functions of Surfactant Protein A

Although the functions of SP-A have not been clarified precisely, in vitro and in vivo studies have demonstrated a wide variety of biologic activities intrinsic to the molecule. SP-A binds carbohydrates and aggregates phospholipids in a calcium-dependent manner.[29-31] Mixtures of phospholipids, SP-A, and SP-B form tubular myelin-like structures in vitro.[32] SP-A enhances the biophysical activity of surfactant phospholipid-rich extracts.[29] In vitro, SP-A binds type II epithelial cells and macrophages and is internalized by receptor-mediated endocytosis.[33,34] After uptake, SP-A is

detected in multivesicular bodies and vesicles closely associated with lamellar bodies.[33] Receptor binding and internalization support the concept that SP-A is reutilized or is involved in cell signaling. Although in vitro findings support a role for SP-A in surfactant homeostasis,[35-37] gene targeting experiments in transgenic mice do not support its importance in surfactant metabolism in vivo.[38] By contrast, a number of studies support a critical role for SP-A in innate host defense of the lung.[27] SP-A is a member of the Ca^{2+}-dependent lectins or "collectins" that serve as opsonins, enhancing binding, phagocytosis, and killing of a variety of bacterial, fungal, and viral pathogens. SP-A enhances binding or uptake of group B streptococci, subtypes of *Haemophilus influenzae, Staphylococcus aureus,* and *Pseudomonas aeruginosa* by alveolar macrophages and is therefore an important defense molecule in the both neonatal and mature lung.[27] SP-A activates alveolar macrophages in vitro and enhances their opsonin-type functions, oxidant production, and killing of pathogens.[39]

Transgenic SP-A–deficient mice, *Sftpa* gene–targeted mice, in which the SP-A gene was disrupted by homologous recombination, survive postnatally.[38] Although SP-A deficient mice do not form tubular myelin, intracellular and extracellular surfactant phospholipid content, uptake of PL by lung tissue, PL secretion, as well as surfactant function are not altered by the absence of SP-A. Thus SP-A plays a critical role in innate host defense of the lung and in the organization of tubular myelin but does not play an important role in surfactant function or homeostasis in vivo.

Control of Surfactant Protein A Content

Like other surfactant proteins, SP-A is synthesized by respiratory epithelial cells in the developing fetal lung and its expression increases in late gestation (reviewed by Ballard[40]). SP-A is detected in nonciliated cells in tracheal bronchial glands, as well as in bronchiolar and alveolar epithelial cells of the lung. In the human, expression of SP-A increases with advancing gestational age in association with the maturation of type II epithelial cells occurring in the latter part of gestation. SP-A appears in increasing concentrations in amniotic fluid during advancing gestation and, like the L/S ratio, is a useful marker of fetal lung maturity in humans.[41,42] SP-A synthesis in human fetal lung cultures is enhanced by a number of hormonal factors, including epidermal growth factor, interferon-γ, interleukin-1, and cyclic adenosine monophosphate (cAMP).[40,44] Glucocorticoids both stimulate and inhibit human SP-A synthesis by distinct mechanisms, which include transcriptional enhancement and decreased messenger RNA (mRNA) stability in vitro.[44] Transcription of the SP-A gene, as well as the genes encoding SP-B and SP-C, are regulated by elements located in the 5′ region of the gene that bind to nuclear transcription factor thyroid transcription factor-1 (TTF-1), a homeodomain–containing member of the Nkx2.1 family of proteins. Binding of TTF-1 confers lung epithelial specificity to SP-A gene transcription. TTF-1 also regulates the transcription of genes expressed exclusively in the respiratory epithelium including SP-A, -B, and -C and the Clara cell secretory protein (CCSP).[45] Inhibitory effects of TGF-β and insulin on SP-A expression have been observed in human fetal lung explant culture.[46,47] SP-A content in alveolar lavage is induced by oxygen exposure, interleukin-4, and silicosis, and SP-A accumulates in the lavage fluid from patients with pulmonary alveolar proteinosis.[48-50] Although GM-CSF–deficient mice develop severe pulmonary alveolar proteinosis with increased surfactant protein content, the relative abundance of surfactant protein mRNAs are not altered, supporting the concept that GM-CSF plays an important role in surfactant clearance.[1,51] Studies in humans demonstrated that pulmonary alveolar proteinosis is associated with neutralizing antibodies against GM-CSF or mutations in the GM-CSF receptor.[52]

In summary, SP-A is an abundant pulmonary host defense protein that is strongly associated with surfactant phospholipids in tubular myelin. SP-A plays important roles in innate defense against bacterial, fungal, or viral pathogens, enhancing opsonization and killing of respiratory pathogens by alveolar macrophages.[27] SP-A also is expressed at lower levels in extrapulmonary cells, and infection of newborn SP-A–deficient mice results in significant mortality associated with gastrointestinal tract disease.[53]

Surfactant Protein D

SP-D is another member of the collectin family of polypeptides, sharing structural motifs with SP-A and other family members.[27,28] A single human SP-D gene *(SFTPD)* is located in close proximity to the SP-A genes on chromosome 10. SP-D is slightly larger than SP-A, being composed of 43-kDa monomers containing an approximate 15,000-kDa collagenous region that forms trimers and higher-ordered complexes that are found in the alveoli (see Figure 100-5).

Unlike that of SP-A, SP-B, and SP-C, the expression of SP-D is not restricted to cells within the lung. SP-D mRNA and protein have been detected in various organs, including the gastrointestinal tract, pancreas, bile duct, cervical glands, and other sites.[54] In the lung, SP-D is expressed by type II epithelial cells in the alveoli, nonciliated bronchiolar, and tracheal-bronchial epithelial cells, including cells lining tracheal-bronchial glands. SP-D is less abundant and is not associated with large aggregate forms of surfactant. SP-D is, however, associated with small lipid vesicles (small aggregate surfactant) but is not required for the formation of tubular myelin or lamellar bodies.[55]

Role of Surfactant Protein D in Innate Host Defense of the Lung and Regulation of Surfactant Homeostasis

The C terminus of SP-C consists of a globular carbohydrate recognition domain (CRD) that binds molecules on the surface of bacterial, viral, and fungal pathogens. SP-D has high affinity for various bacterial lipopolysaccharides (LPSs), complex carbohydrates, and phosphoinositol.[28] SP-D binds and agglutinates various bacteria (including *Escherichia coli*, *Salmonella*, and *Pseudomonas*), fungal, as well as viral pathogens (influenzavirus A, adenovirus, and respiratory syncytial virus), enhancing their uptake and killing by alveolar macrophages.[27,28] Thus SP-D serves an important role in pathogen recognition critical to innate defense of the lung against infection. In vivo, SP-D–deficient (*Sftpd* gene–targeted) mice are susceptible to various bacterial and viral pathogens. SP-D enhances the clearance and suppresses inflammatory responses following viral and bacterial infection of the lung.[27] SP-D also plays important roles in the regulation of surfactant phospholipid pool size and in the suppression of oxidant production by alveolar macrophages in the lung.[56] Deletion of SP-D in transgenic mice caused emphysema, macrophage activation, accumulation of oxygen reactive species, and a pulmonary lipidosis. Alveolar and tissue surfactant lipid pool sizes were markedly increased in the absence of SP-D. Thus SP-D plays a critical role in the regulation of surfactant lipid homeostasis, the inflammatory responses, and innate host defense of the lung. Because SP-D influences inflammation and cytokine responses after exposure to various pulmonary pathogens, it also is highly likely that SP-D influences subsequent acquired immune responses after infection.

Regulation of Surfactant Protein D

SP-D is expressed at high levels in the lung, where it is regulated by C/EBPα (*C*CAAT/*e*nhancer-*b*inding *p*rotein-α), nuclear factor of activated T cells (NFAT), and TTF-1.[57] SP-D also is expressed in many other organs and in various cell types.[54] SP-D content in fetal lung and amniotic fluid increases with advancing gestational age, and its content is enhanced by glucocorticoids in experimental models. SP-D expression is enhanced by allergens and interleukins (IL-4 and IL-13). SP-D concentrations in alveolar

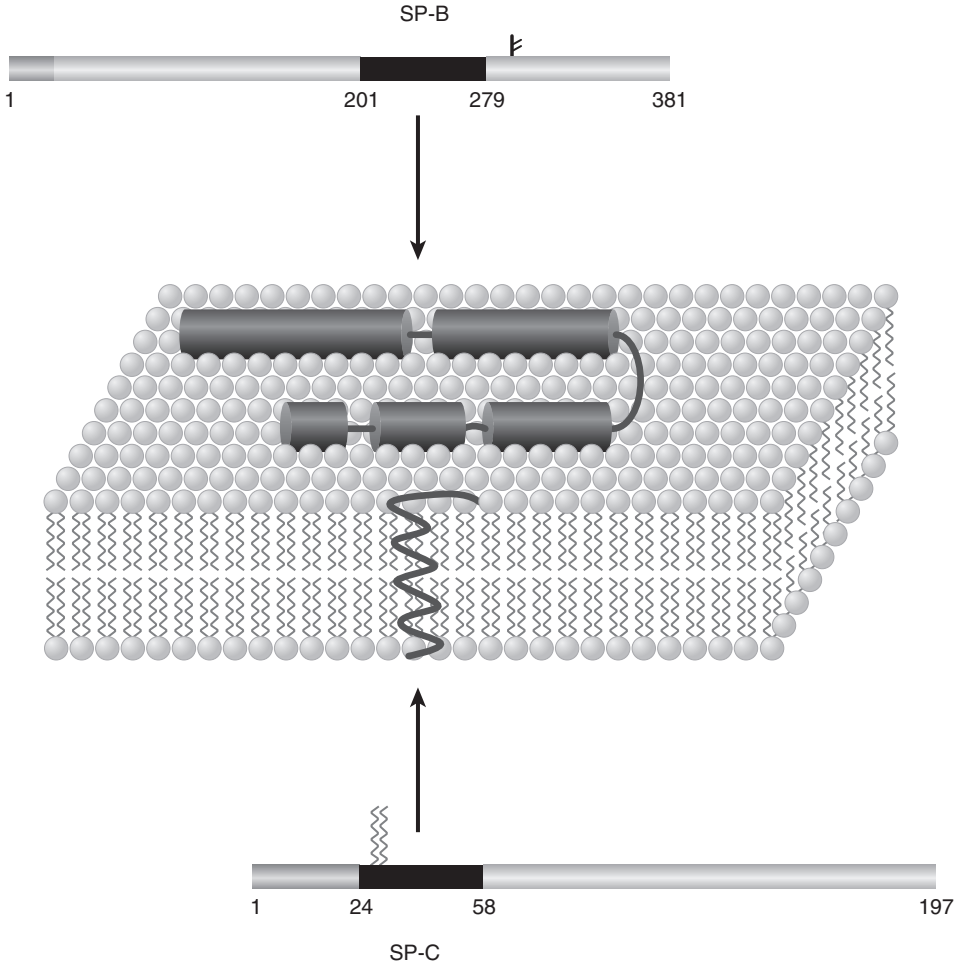

Figure 100-6 Human SP-B is encoded by a single gene located on chromosome 2 and comprises approximately 9.5 kb of genomic DNA. The active peptide comprises 79 amino acids. The messenger RNA (mRNA) is approximately 2.0 kb in length and is translated to a preproprotein of approximately 39,000 Da that is proteolytically processed and glycosylated. The active peptide is generated from proSP-B during proteolytic processing to form the 79–amino acid peptide (M_r of 8000), that forms oligomers are tightly associated with phospholipids in the airway. Human SP-C is encoded by a gene located on chromosome 8 that compries approximately 3.5 kb of genomic DNA. The active peptide, comprising 35 or 36 amino acids, is encoded by a single exon and is palmitoylated. The mRNA is approximately 0.9 kb long and is translated to proSP-C (M_r of approximately 22,000), which is proteolytically processed to an M_r = 3800 monomer, and its oligomers found in the airway. SP-B and SP-C are tightly associated with phospholipid membranes in the alveolus. M_r, Molecular weight.

fluid are decreased in various clinical conditions associated with pneumonitis, including cystic fibrosis.[27,58] Like other surfactant components, SP-D accumulates in the pulmonary alveolar proteinosis associated with GM-CSF deficiency and silicosis.[1]

Surfactant Protein B

SP-B is a small hydrophobic polypeptide comprising 79 amino acids (Figure 100-6). SP-B structure and function have been reviewed in detail by Weaver and Conkright[59]; a brief summary follows.

A single human SP-B gene *(SFTPB)* is composed of 10 exons, spanning approximately 10 kb of DNA located on chromosome 2.[60] Analysis of cDNAs encoding SP-B demonstrate that the SP-B polypeptide is produced by proteolytic processing of an approximately 40,000- to 46,000-Da glycosylated precursor comprising 381 amino acids.[61-63] The active peptide found in the airway forms sulfhydryl-dependent oligomers that include dimers and tetramers. Proteolytic processing of the precursor proSP-B occurs in type II epithelial cells, during routing of the proSP-B from endoplasmic reticulum to multivesicular bodies and during transport from MVB and lamellar bodies before secretion. Immunostaining with antibodies generated against SP-B co-localize with apical intracellular inclusions in type II cells and stain material in the lumen of alveolar and airway structures.[64,65] Although the functions of SP-B have not been elucidated with certainty, SP-B is tightly associated with surfactant phospholipids and is required for formation of tubular myelin in the presence of SP-A, phospholipids, and calcium.[32] SP-B is highly fusogenic,[66] generating phospholipid membranes from vesicular lipid forms and enhancing spreading and stability of surfactant. SP-B is required for conversion of vesicular lipids in the lumen of multivesicular bodies to the tightly packed membrane sheets observed in the lamellar bodies.[67] Although SP-B enhances the uptake of phospholipid vesicles by type II epithelial cells in vitro, when present with SP-A, SP-B enhances formation of tubular myelin, a form of surfactant that remains in the alveolus.[68] Increasing evidence supports the concept that SP-B is critical for the enhancement of surface properties of surfactant phospholipids. SP-B is an important component of surfactant replacement mixtures made by organic solvent extraction of pulmonary surfactant or lung minces.

Surfactant Protein B Is Required for Lung Function at Birth: Hereditary SP-B Deficiency

Studies in SP-B gene (*Sftpb)*–targeted mice, and in full-term infants bearing mutations in *SFTPB*, demonstrated that SP-B is required for pulmonary function at birth.[67,69] Although pulmonary structure is normal, mice lacking SP-B die in respiratory distress immediately after birth. Decreased lung volumes, lack of hysteresis and atelectasis were associated with the lack of lamellar bodies and accumulation of aberrant multivesicular bodies with type II cells. Decreased surfactant activity, lack of tubular myelin, and the synthesis of an abnormal proSP-C precursor demonstrated that SP-B is required for both intracellular and extracellular routing of surfactant lipids and proteins. Full-term human infants with mutations in *SFTPB* generally demonstrate respiratory distress within hours after birth, with clinical and radiologic features typical for RDS in preterm infants. Respiratory failure generally is progressive and is not responsive to exogenous surfactant replacement therapy, affected infants dying of respiratory failure despite intensive ventilatory support. In SP-B–deficient infants, alveolar spaces are filled with proteinaceous material[69] that consists primarily of surfactant proteins and abnormally processed proSP-C. The disorder generally is inherited in an autosomal recessive manner.

The most common mutation, $SP\text{-}B_{121ins2}$, creates an unstable mRNA, resulting in lack of SP-B protein production. More than 15 distinct mutations in the SP-B gene have been associated with respiratory failure in infants.[70] The disorder generally is fatal in the first months of life but has been treated by lung transplantation. SP-B is required for lung function and survival in adult animals.[71]

In summary, SP-B is required for packaging and processing of surfactant lipids and proteins intracellularly and for organization, function, and homeostasis of surfactant lipids and proteins in the alveolar space.

Regulation of Expression of Surfactant Protein B

The abundance of SP-B mRNA increases with advancing gestation in the human fetal lung, being expressed in both type II alveolar cells and nonciliated respiratory epithelial cells lining distal portions of the respiratory tract.[72] In fetal lung, SP-B synthesis is stimulated by cAMP, IL-1β, and glucocorticoids.[40,43,73,74] The concentration of SP-B in human amniotic fluid increases with advancing gestation in association with increased L/S ratio and phosphatidylglycerol.[75] As with other surfactant proteins, the SP-B expression is regulated by the homeodomain-containing nuclear protein TTF-1, that controls transcription of the SP-B gene.[45,57]

Surfactant Protein C

SP-C is the most hydrophobic protein isolated from pulmonary surfactant[21,22] (see Figure 100-6). Like SP-A and SP-B, SP-C is relatively abundant in the dense surfactant fractions obtained by lung lavage. SP-C consists of 35 amino acids, most of which are hydrophobic residues valine, leucine, and isoleucine.[76] Complementary DNAs and genomic DNA encoding SP-C *(SFTPC)* have been isolated and characterized.[77,78] In humans, the SP-C gene comprises approximately 3 kb of contiguous DNA and consists of 6 exons located on chromosome 8. Allelic variations and differential RNA splicing are likely to account for the molecular heterogeneity at these loci.[79] The precursor contains neither an N-terminal signal sequence nor amino acid sequences predicting the addition of asparagine-linked carbohydrate. SP-C is palmitoylated and is transported through the endoplasmic reticulum to multivesicular bodies with proSP-B. Both proSP-C and proSP-B are processed during transport to lamellar bodies, SP-B being required for proteolytic processing of proSP-C. The active 35–amino acid SP-C peptide is stored in lamellar bodies and is associated with surfactant lipid in the alveolus. In the lung, synthesis of SP-C is restricted to type II alveolar cells.

SP-C or mixtures of SP-B and SP-C enhance the rate of absorption of surfactant phospholipids and confer important surfactant-like properties to the lipids.[21,22,59,80] Evidence from studies in *Sftpc* gene–targeted mice demonstrates that SP-C is not required for formation of lamellar bodies or tubular myelin. SP-C is taken up by alveolar epithelial cells; addition of SP-C peptides enhances uptake of phospholipid vesicles by type II epithelial cells in vitro.[68,81] SP-C is highly enriched in organic solvent extracts of surfactant and, like SP-B, is present in the surfactant extracts used for replacement therapy of RDS in infants.

Role of Surfactant Protein C in Surfactant Function and Homeostasis

Studies in SP-C gene–targeted mice and in humans bearing mutations in the SP-C gene demonstrate the important role of SP-C in surfactant function and pulmonary homeostasis.[80] Although SP-C gene–targeted mice survive perinatally, abnormalities in the stability of surfactant film formed from SP-C–deficient mice, demonstrate the role of SP-C in recruiting phospholipids to monolayers/multilayers, SP-C is required for the stability of phospholipid films during dynamic compression.[82] Formation of lamellar bodies and tubular myelin are not perturbed in SP-C deficient mice. However, SP-C–deficient mice develop strain-dependent interstitial lung disease associated with emphysema, epithelial cell dysplasia, and inflammation.[80] Humans bearing mutations in the SP-C gene *(SFTPC)* develop various forms of acute and chronic pulmonary disease including acute respiratory distress syndrome (ARDS) and idiopathic pulmonary fibrosis.[83,84] *SFTPC* mutations generally are inherited as an autosomal dominant trait and have been associated with the histopathologic diagnoses of usual interstitial pneumonitis, nonspecific interstitial pneumonitis, and desquamating interstitial pneumonitis.

Regulation of Surfactant Protein C Synthesis

SP-C synthesis and mRNA content increase in association with type II cell maturation in fetal lung, and its expression is restricted to type II cells in the postnatal lung.[40,73,74] SP-C mRNA is detected early in embryonic lung development—by postconception day 10 in the mouse and at 10 to 12 weeks gestation in the human.[85] SP-C mRNA are increased by glucocorticoids and cAMP.[73,74] The transcription of the *Sftpc* gene is lung epithelial cell–specific and requires TTF-1.[45,57]

Role of Surfactant Proteins in Surfactant Replacement Preparations

The structures of each of the major surfactant proteins are quite distinct, supporting the concept that each plays a unique role in the structure and function of surfactant. Surfactant phospholipids themselves, although providing the molecules critical for the reduction of surface tension in the alveolus, do not have the properties inherent in pulmonary surfactant. At physiologic temperatures, surfactant lipid is in a highly organized gel-crystalline state that is not capable of rapidly forming a surface film. Phospholipid molecules alone fail to rapidly spread and respread during compression and decompression. Their adsorption rates to surfaces are slow and do not generate the surface tension–lowering film necessary to maintain surface forces during the respiratory cycle. SP-B and SP-C interact with surfactant phospholipids to produce surfactant with unique physicochemical properties, allowing formation and stability of the surfactant film during the respiratory cycle.

Both SP-B and SP-C confer important surfactant-like activity to phospholipids and are included in preparations used for treatment of surfactant-deficient states.[86-89] Preparations containing SP-A have not been used widely for clinical studies. Human surfactant isolated from amniotic fluid, containing SP-A, SP-B, or

SP-C, as well as a variety of other human proteins, was previously used for exogenous surfactant replacement. Surfactant extracts based on organic solvent extracts of lung or surfactant preparations contain SP-B and SP-C (but not SP-A).[86] Survanta, Curosurf, Alveofac, and Infasurf are examples of such preparations.[90] SP-B and SP-C, when mixed with phospholipids, appear to be sufficient to generate the surface-active properties of pulmonary surfactant and may therefore be useful in future development of surfactant replacement preparations for treatment of surfactant-deficient states. Protein-free (Exosurf, Coltosceril) and synthetic peptide–based (Lucinactant) surfactant preparations have been developed, although their current use is limited.[91]

DISORDERS OF SURFACTANT HOMEOSTASIS

Mutations in genes encoding the surfactant proteins SP-B and SP-C (*SFTPB* and *SFTPC*) and the lamellar body–associated lipid transporter protein *(ABCA3)* are a rare cause of severe pulmonary disease in newborn infants and children,[15] as reviewed by Whitsett and associates.[92] Although each protein has distinct structures and functions, these mutations generally cause acute respiratory failure in newborn infants or chronic interstitial lung disease in children. Most infants with mutations in *SFTPB* or *ABCA3* are born at term and present in the immediate neonatal period with progressive respiratory failure and clinical and radiologic abnormalities consistent with respiratory distress and typically fail to respond to surfactant replacement therapy and supportive care. *SFTPB*- and *ABCA3*-related diseases are inherited as autosomal recessive traits. Most patients with mutations in *SFTPC* present with the respiratory signs and symptoms later in infancy, but some have been symptomatic at birth.

Histopathologic analysis of lung tissue from patients with mutations in *SFTPB, SFTPC,* or *ABAC3* reveals interstitial lung disease, consistent with chronic pneumonitis of infancy, nonspecific interstitial pulmonary disease, or desquamating interstitial pneumonitis. Abnormalities in surfactant lipid content associated with these disorders include decreased phosphatidylcholine and phosphatidylglycerol content. Mutations in *SFTPC* generally are inherited as an autosomal dominant trait with variable penetrance. These mutations cause the synthesis of a misfolded protein that in turn causes alveolar type II cell injury, disrupting the production of the active SP-C peptide. Although *SFTPC* mutations may be associated with disease manifestations in the newborn period, most affected patients present in infancy or childhood with chronic respiratory disease, often exacerbated by respiratory infection. Clinical, histopathologic, and immunohistochemical criteria are useful for identifying patients with disorders of surfactant homeostasis. Definitive diagnosis requires identification of the mutations underlying the disorder.

OTHER ALVEOLAR PROTEINS

Detailed analysis of material obtained at lung lavage, such as by two-dimensional gel electrophoresis or sensitive silver staining techniques, reveals hundreds of serum and nonserum proteins. Precise abundance, the cellular source, and the role of each of these proteins in lung function have not been determined. The alveolar fluid contains a number of molecules that may play a role in host defense: fibronectin, lysozyme, antiproteases, immunoglobulins (particularly IgA), defensins, mucins, and Clara cell proteins. Products from type I and type II epithelial cells, alveolar macrophages, and lymphocytes are likely to contribute to the heterogeneity of proteins found in alveolar lavage fluid from the normal lung; however, the identity and functions of these proteins have not been clarified. It also is increasingly apparent that surfactant homeostasis may be disrupted by the presence of blood or serum proteins, including albumin and fibrin.[93-95] Thus homeostatic mechanisms that exclude nonsurfactant proteins from the alveolus are likely to be highly critical for the function of surfactant and thus for gas exchange after birth.

Physicochemical Aspects of Pulmonary Surfactant

When an infant is born, he or she must clear the lungs of fetal pulmonary fluid, inflate the alveoli with air, and establish air breathing. These functions are facilitated by the presence of pulmonary surfactant. By lowering the surface tension in the lung to low values, surfactant reduces the work of breathing and stabilizes the terminal air spaces, particularly at low lung volumes. The net effect is to increase air space and thereby to enhance gaseous exchange. The obvious success of surfactant replacement therapy for prematurely delivered infants with respiratory distress syndrome (RDS), who lack sufficient surfactant of their own, emphasizes the critical role of surfactant during the neonatal period.[1-3] Surfactant is also being used to treat meconium aspiration and to help wean infants during treatment with extracorporeal membrane oxygenation[4-8] (see Chapter 106). Considerable evidence indicates that surfactant dysfunction contributes to pulmonary instability in acute lung injury and acute RDS and that surfactant therapy could prove beneficial.[6,9-15]

It is generally appreciated that the physicochemical properties of pulmonary surfactant are critical for normal lung function. However, the mechanisms by which this lipid-protein complex adsorbs to form a surface active film that stabilizes the lung are still not completely understood. Improved insights into the mechanisms by which surfactant lowers surface tension in the lung could lead both to superior "designer" surfactants and to improved applications of clinical management. Since the 1960s, it has generally been concluded that surfactant stabilizes the lung by generating a surface monolayer highly enriched in the disaturated lecithin, dipalmitoyl-*sn*-phosphatidylcholine (DPPC). More recently new techniques and approaches have combined to indicate that this paradigm not only is oversimplified but may be flawed. As elaborated in a later section, certain surfactant properties can best be explained in terms of multilayers rather than monolayers. In addition, it has become apparent that under appropriate circumstances, the low surface tensions required to stabilize terminal air spaces can be attained with unsaturated phosphatidylcholine (PC) in the absence of gel-phase disaturated phospholipids such as DPPC. This chapter summarizes current understanding of pulmonary surfactant compositional function in vitro and in vivo.

SURFACTANT COMPOSITION

Natural Pulmonary Surfactants

Surfactant can be isolated using bronchoalveolar lavage followed by centrifugation. Although some variation exists among species and with different disease states,[16-20] the composition shown in Figure 101-1 for bovine surfactant is representative. Mammalian surfactants normally contain 80% to 85% phospholipid, 5% to 10% neutral lipids, and 5% to 10% weight/weight-specific surfactant apoproteins. Phospholipid classes include PC 80%, phosphatidylglycerol (PG) plus phosphatidylinositol 10% to 15%, and phosphatidylethanolamine 1% to 3%, with lesser amounts of sphingomyelin, lyso-*bis*-phosphatidic acid, and lyso-PC. The neutral lipid fraction includes cholesterol, cholesterol esters, diacylglycerol, triacylglycerol, and some free fatty acids.[18,20] The surfactant-associated proteins (SPs) consist of SP-A and SP-D, which are hydrophilic glycoproteins, and SP-B and SP-C, which are low-molecular-weight hydrophobic proteins that dissolve with the lipids in organic solvents such as chloroform:methanol.[21-24]

Electrospray ionization mass spectroscopy and high-pressure liquid chromatography analyses have been used to estimate molecular species distribution of individual phospholipids in pulmonary surfactant for numerous animal species.[20,25,26] PC and PG molecular species for bovine surfactant are listed in Table 101-1. Such analyses show the PC fraction for different animal surfactants is high in DPPC (35% to 55%), with significant amounts (5% to 20%) of palmitoyl-myristoyl PC, palmitoyl-palmitoleoyl PC, palmitoyl-oleoyl PC (POPC), and palmitoyl-linoleoyl PC. PG molecular species are high in palmitoyl-oleoyl PG (POPG) (25% to 35%), with substantial amounts of dipalmitoyl PG (DPPG) and palmitoyl-linoleoyl PG.

Surfactant Proteins

The SPs are described in detail in Chapter 100. In the human, SP-A is a 228–amino acid hydrophilic protein. As a result of glycosylation and other secondary modifications, apparent molecular weights of 28 to 36 kDa are observed with polyacrylamide gel electrophoresis under reducing conditions. SP-A contains four functional domains: a short amino-terminal (N-terminal) region involved in sulfhydryl-dependent oligomerization, a collagen-like region, a neck region that forms coiled-coil oligomers, and an approximately 130–amino acid carboxyl-terminal (C-terminal) globular carbohydrate recognition domain.[27] SP-A forms trimers resulting from triple helical formation within the collagen-like domain, coiled-coil interactions within the neck region, and sulfhydryl-dependent and perhaps other interactions in the short N-terminal region. Furthermore, six of these triple-helix subunits combine to form a bouquet-like structure containing 18 monomers. Collagen consists of Gly-X-Y repeats where Y is often hydroxyproline. The collagen-like region of SP-A contains an extra amino acid that produces a kink in this structure. As a result of this kink, the collagenous region forms the stalks and stems of the bouquet. The C-terminal carbohydrate recognition domain forms structures resembling three-petaled flowers. The resulting oligomeric form is approximately 20 nm long and at its widest point is approximately 20 nm wide.[28] Polyacrylamide gel electrophoresis of SP-A under nonreducing conditions shows that SP-A recovered from the alveolus is predominantly present as large oligomers of up to 640 kDa. SP-A is a member of the C-type lectin (carbohydrate-binding) superfamily, which contains mannose-binding protein and the collectins (*col*lagen-*lectins*).[27,29] SP-A binds lipids and is isolated with natural surfactant. Its role in the biophysical functions of surfactant is discussed in a later section.

SP-D also contains collagenous and calcium-dependent lectin domains, and like SP-A, is a member of the C-lectin superfamily.[21,30,31] As in the case of SP-A, the collagen-like and neck-like regions of SP-D promote trimerization. SP-D contains four of these trimers, which are bound at their N terminus through disulfide bonds. The resulting structure of SP-D forms a cruciform oligomer consisting of 4 trimers in a total of 12 subunits.

TABLE 101-1

Major Molecular Species for Phosphatidylcholine and Phosphatidylglycerol in Bovine Lipid Extract Surfactant*

Molecular Species	% Total
Phosphatidylcholine (PC)	
Palmitoyl, myristoyl-PC (16:0, 14:0)†	9.2 ± 0.3
O-palmityl, palmitoyl-PC (16:0a,14:0)‡	5.4 ± 0.7
Palmitoyl, palmitoleoyl-PC (16:0, 16:1)	13.0 ± 1.0
Palmitoyl, palmitoyl-PC (16:0, 16:0)	40.0 ± 1.7
Palmitoyl, linoleoyl-PC (16:0, 18:2)	4.6 ± 0.7
Palmitoyl, oleoyl-PC (16:0, 18:1)	22.8 ± 1.0
Stearoyl, linoleoyl-PC (18:0, 18:2), plus oleoyl, oleoyl-PC (18:1, 18:1)	2.7 ± 0.7
Stearoyl, oleoyl-PC (18:0, 18:1)	1.8 ± 0.4
Phosphatidylglycerol (PG)	
Palmitoyl, palmitoleoyl-PG (16:0, 16:1)	6.4 ± 0.6
Palmitoyl, palmitoyl-PG (16:0, 16:0)	23.1 ± 0.6
Palmitoyl, linoleoyl-PG (16:0, 18:2)	7.6 ± 0.5
Palmitoyl, oleoyl-PG (18:0, 18:1)	48.2 ±3.4
Stearoyl, linoleoyl-PG (18:0, 18:2) plus oleoyl, oleoyl-PG (18:1, 18:1)	7.0 ± 0.7
Stearoyl, oleoyl-PG (18:0, 18:1)	7.7 ± 0.7

Unpublished data from the work of Capote KR, Possmayer F.
*As determined by electrospray ionization spectrometry.
†Numeric representations for the fatty acyl groups are given in *parentheses.*
‡Alkyl, acyl-PC.

Some SP-D is present in larger oligomeric forms (6 to 8 trimers). Each monomer has a molecular weight of approximately 43 kDa, yielding an overall molecular weight of 500 kDa or more. SP-D does not bind to surfactant lipids as well as SP-A and is predominantly found in the supernatant arising after centrifugation of lung lavages. SP-D exhibits different lectin properties from SP-A and selectively binds phosphatidylinositol rather than DPPC. SP-D has a relatively weak biophysical role compared with SP-A. SP-A and SP-D have important roles in the innate host defense system.[21,32]

SP-B is a low-molecular-weight hydrophobic protein, 79 amino acids long, present in surfactant as a disulfide-dependent dimer of approximately 18 kDa. Mature SP-B is produced by N-terminal and C-terminal proteolytic processing of a larger proprotein of approximately 42 kDa.[33-38] SP-B is cysteine rich and is very basic (positively charged). The 18-kDa SP-B dimer appears to be a membrane-associated protein that binds to the surface of lipid bilayers.[24,35,39] SP-B deficiency arising from natural human mutations or deliberate gene disruption in mice results in neonatal respiratory distress leading to death.[10,24,40,41]

Pro–SP-C (approximately 21 kDa) is also proteolytically processed. Mature SP-C is present in surfactant as a monomer of 35 amino acids with a molecular weight of 4.2 kDa. SP-C is not only the most hydrophobic protein known, but it also contains two palmitic acid moieties that are acylated to two adjacent cysteine groups near the N terminus. In some species, such as mink and canine, SP-C contains only one cysteine and, corespondingly, a single palmitate. SP-C has a short, 12–amino acid moderately hydrophilic N-terminal region, terminating in positively charged arginine and lysine groups. The remaining 23 amino acids form a hydrophobic α-helix composed primarily of aliphatic amino acids (leucine, isoleucine, and valine). This α-helix is of appropriate length to act as a membrane-spanning domain.[24,42,43] SP-C appears to be unique in that no similar protein has yet been identified.

Therapeutic Surfactants

As indicated previously, SP-B and SP-C can dissolve in organic solvents and are isolated with the lipids in lipid extracts of pulmonary surfactant. Organic solvent lipid extracts, containing SP-B and SP-C but not SP-A, are the basis of the so-called second-generation clinical preparations. These surfactants should not be called "natural" or "animal" surfactants. Rather, they should be referred to as "modified natural" or "animal-based" surfactants,[44] and because of processing differences, such preparations are not equivalent.[1,13,45] Survanta, also known as Beractant (Abbott Laboratories, United States), Curosurf (Chiesi Pharmaceuticals, Italy), and HL-10 (Leo Pharmaceuticals, Denmark) are obtained from minced bovine or porcine (Curosurf) lung. Alveofact (Boehringer-Ingelheim, Germany), BLES (bovine lipid extract surfactant) (BLES Biochemicals, Canada), and Infasurf, also referred to as CLSE (calf lung surfactant extract) (Forest Laboratories, United States) are obtained by lavage or foaming (BLES) techniques. Infasurf is obtained from neonatal calves, whereas the other bovine preparations are from mature calves or adult cows. Because neutral lipids (mainly cholesterol) reduced the ability to attain low surface tensions during compression with the available techniques, they were removed from BLES, Curosurf, and Survanta. Survanta has little SP-B compared with the other animal-based surfactants, but palmitic acid and tripalmitin are added to enhance surface film formation.[46-49] The available animal experimental literature would suggest that Infasurf promotes a faster and more effective response than Survanta, although a head-to-head clinical trial comparing these surfactants showed no difference in death or incidence of pneumothorax (air leak).[50]

In addition to these modified animal surfactants, two protein/peptide-based surfactants have been developed.[51] Surfaxin (Discovery Laboratories, United States) contains KL4 (a 21–amino acid peptide containing a series of 5 amino acid repeats, each with a lysine followed by 4 leucines), DPPC, dioleoyl-PC, and palmitic acid. Although designed to mimic SP-B, a surface membrane protein, KL4 acts as a transmembrane peptide.[52] Venticute (Byk Gulden Pharmaceuticals, Germany) contains recombinant human SP-C (rSP-C) produced in *Escherichia coli*, plus DPPC, dioleoyl-PC, and palmitic acid. Palmitic acid enhances phospholipid adsorption and can enhance the ability of these preparations to attain low surface tensions in vitro. However, the effectiveness of adding palmitate has been questioned because this fatty acid is taken up almost instantaneously by lung tissue.[53]

At least two artificial, wholly synthetic, protein-free surfactants, Pneumactant, also known as ALEC (artificial lung expanding compound, Britannia Pharmaceuticals, United Kingdom) and Exosurf (Burroughs-Wellcome, United States) are available. ALEC, which contains DPPC:POPG (7:3), was named for Dr. Alec Bangham of Cambridge, who developed this artificial preparation. Exosurf, developed by Dr. John A. Clements, a pioneer in the surfactant field, consists of DPPC, hexadecanol (a long-chain alcohol that acts as a spreading agent), and tyloxapol, a detergent introduced to ensure consistent formulations. Clinical trials show that these surfactants have biologic activity with premature neonates, but the effects are slow compared with those of the lipid extract surfactants, a finding consistent with a secondary effect arising from phospholipid uptake and recycling by type II cells.[51] Exosurf recovered from premature lungs possesses enhanced surface activity consistent with the equilibration with endogenous surfactant apoproteins.[54] Comparisons indicate that natural surfactant-based extracts are more effective than the wholly synthetic preparations in reducing death and morbidity.[2,55]

LUNG BIOLOGY OF PULMONARY SURFACTANT

The present view of the life cycle of pulmonary surfactant is depicted in Figure 101-2. Surfactant is produced in the type II cells of the alveoli and assembled and stored in lamellar bodies.[56-61] These organelles are composed of a limiting membrane and concentric or parallel phospholipid lamellae apparently composed primarily of phospholipid bilayers. Lamellar bodies contain surfactant lipids, SP-B, and SP-C, but relatively low amounts of SP-A.[62-64] SP-A is also secreted from type II cells via the normal constitutive secretory pathway, which bypasses lamellar bodies.[65] Once secreted into the alveolar hypophase, lamellar bodies interact with calcium and SP-A to form the unique structure known as *tubular myelin*.[56,59,66-68] Tubular myelin consists of long, rectangular, stacked tubes composed mainly of phospholipid bilayers. The corners of these tubes appear fused, giving cross-sections of tubular myelin a lattice-like appearance (Figure 101-3). Tubular myelin-enriched surfactant fractions adsorb readily to form a film at the air-liquid interface, a finding suggesting that this structure acts as an important monolayer-generating source.[61,69] The surfactant monolayer is ultimately responsible for lowering surface tension at the air-liquid interface.

As described elsewhere, surfactant obtained through lung lavage (washing) can be separated into numerous fractions by density gradient or differential centrifugation. Two major fractions, known as large surfactant aggregates (LAs) and small surfactant aggregates (SAs), also known as heavy and light surfactant subtypes, are readily isolated.[61,70,71] The heavy LA subtype contains lamellar bodies, tubular myelin, and multilamellar vesicles of various sizes. The light subtype is composed mainly of small unilamellar vesicles. Time course studies conducted shortly after birth and pulse-labeling experiments have established that the small vesicles are metabolic products of the larger, heavier forms. These observations support the view that SAs, presumably generated from the surface film during repeated compression and expansion, represent spent surfactant in transit to the type II cells. Surfactant lipids are taken up by type II cells and are partially degraded, presumably by lysosomes, but they are also recycled into lamellar bodies. Considerable recycling of surfactant constituents occurs with newborn animals, and this feature likely explains in part the success of surfactant therapy for RDS. Certainly, without recycling, more frequent retreatment would be required. Compositional studies have shown the LA and SA surfactant subtypes exhibit similar phospholipid profiles, but only the heavier subtype possesses significant amounts of the surfactant apoproteins.[72,73] Not surprisingly, the heavier LA forms show superior surface activity.[74,75]

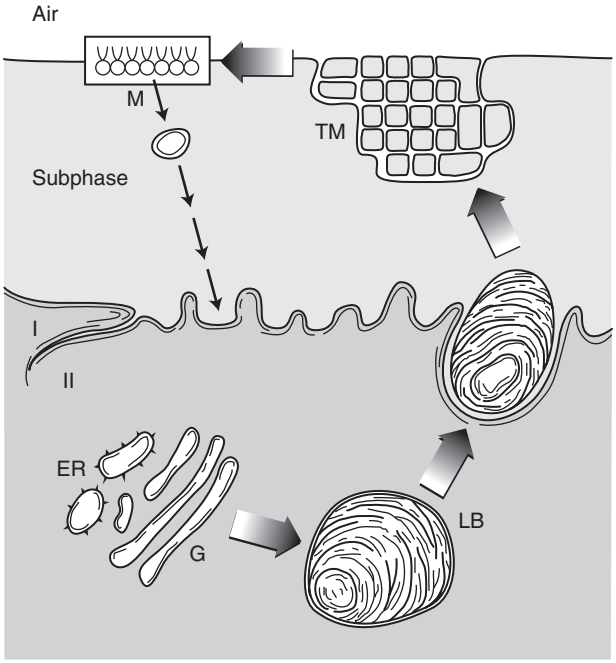

Figure 101-2 Diagrammatic representation of the biologic life cycle of pulmonary surfactant. Pulmonary surfactant is synthesized in type II alveolar cells and assembled into lamellar bodies *(LB)*. After exocytosis, lamellar bodies form tubular myelin *(TM)*, which is thought to be a major source of the surface film. TM consists of long rectangular hollow tubes composed of phospholipid bilayers that are fused together at the corners. A cross-sectional view with a lattice-like appearance is shown. TM is thought to be the major source for phospholipid adsorption to create a film at the air-water interface. Although shown as a single monolayer *(M)*, evidence of surfactant multilayers is seen. The surface monolayer reduces surface tension. Vesicles formed from the surface during repeated compression and expansion are taken up by the type II cells for degradation and recycling into lamellar bodies. *I,* Type I cell; *II,* type II cell; *ER,* endoplasmic reticulum; *G,* Golgi apparatus. *(From Possmayer F, Yu SH, Weber JM, Harding PG: Pulmonary surfactant,* Can J Biochem Cell Biol *62:1121, 1984; modified from Goerke J: Lung surfactant,* Biochim Biophys Acta *344:241, 1974.)*

SURFACE TENSION AND LUNG MECHANICS

Initial evidence of the importance of surface tension in pulmonary function was reported in 1929 by von Neergaard,[76] who observed that a greater pressure difference was required to keep lungs inflated with air than with fluid. Figure 101-4 shows data from a more recent pressure-volume relationship study on excised lungs.[77,78] When air is introduced stepwise into a lung, the initial increase in lung volume is modest, followed by a more rapid elevation to total lung capacity. As the pressure difference is lowered, considerably more air remains in the lungs at any given pressure than during inflation. This is known as *hysteresis* (literally, "lagging behind"). Furthermore, at zero pressure, a new initial volume is obtained that is larger than the volume observed during the initial inflation. Filling the lung with saline eliminates surface tension forces. Under these circumstances, the lung expands readily and uniformly, and little hysteresis is observed.

This simple experiment permits us to draw three important conclusions. First, the work done against surface tension forces constitutes a major part of the effort required to inflate the lung.[76] Assuming that the pressure required to inflate the lung

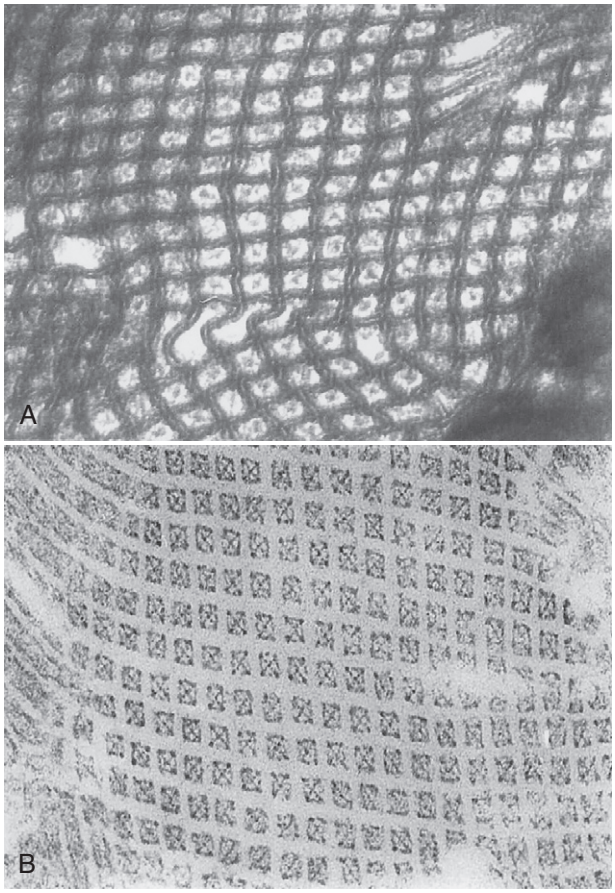

Figure 101-3 Tubular myelin. A, Electron micrograph showing cross-section of tubular myelin from bovine surfactant. Tubular myelin consists of fused tubes that, in this case, extend perpendicular to the plane of the image. The squares are approximately 50 nm across. **B,** Structures remaining after acetone washing to remove phospholipids. The X-shaped structures are thought to be surfactant-associated protein As that interact with the phospholipids via their carbohydrate recognition domains. *(From Nag K, Munro JG, Hearn SA, et al: Correlated atomic force and transmission electron microscopy of nanotubular structures in pulmonary surfactant,* J Struct Biol *126:1, 1999.)*

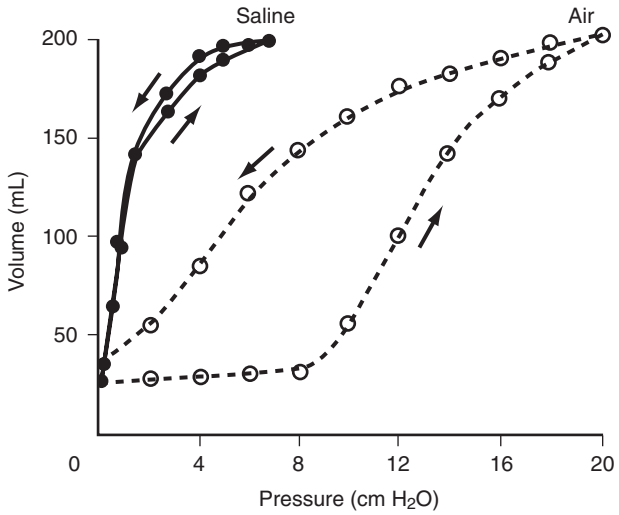

Figure 101-4 Pressure-volume relationships in cat lungs. Air filling *(open circles)*: A considerable pressure is required before the lungs begin to expand to maximum volume. On deflation, the lung remains more open than during inflation. This effect is known as hysteresis. Some air is left in the lung at zero pressure. Saline filling *(closed circles):* The lung inflates from zero pressure to a similar maximum volume as with air. Little hysteresis is present during deflation. *(From Clements JA: Surface phenomena in relation to pulmonary function,* Physiologist *5:11, 1962, and Radford EP Jr: Recent studies of mechanical properties of mammalian lungs. In Remington JW, editors:* Tissue Elasticity, *Bethesda, MD, American Physiological Society, 1957, pp 177-190.)*

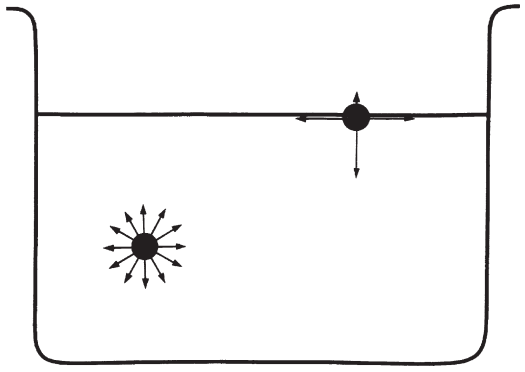

Figure 101-5 Diagrammatic representation of surface tension. A molecule of water within the bulk phase is attracted by all molecules surrounding it, but molecules of water at the surface experience a net attraction into the bulk phase *(From Possmayer F, Yu SH, Weber JM, Harding PG: Pulmonary surfactant,* Can J Biochem Cell Biol *62:1121, 1984.)*

to half-maximal volume with air represents both surface forces and tissue elasticity, whereas the pressure needed to achieve this volume with saline functions primarily against tissue elasticity, it can be seen that more than two thirds of the work can be accounted for by lung surface tension resistance. Second, the difference in the pressure-volume relationships during inflation and deflation indicates surface tension changes during this cycle. Finally, the observation that the air-filled lung retains some air on deflation suggests that surface tension must be low at low lung volumes.[77,79,80]

SURFACE TENSION

Surface tension arises from the attractive forces between molecules.[81-85] A molecule in the bulk phase is subject to attractive forces from the molecules around it, resulting in a net force of zero (Figure 101-5). Molecules at the surface are attracted by the molecules below (and to either side) but in the upward direction only by the weak attractive forces of water vapor and air. As a result, all the molecules at the surface experience a net attraction (downward) into the bulk phase. Work is required to move a molecule from its lower energy state in the bulk phase to the more energetic state at the surface. With water, the work or the energy required to move sufficient molecules to the surface to expand it by 1 cm^2 at 37° C is 70 mJ/cm^2 or 70 erg/cm^2. Because of the difference in energy of surface molecules, the most stable situation arises with a minimum surface area. This is why materials with high surface tension, such as water or mercury, form spherical droplets. Surface tension may also be thought of in terms of a thin elastic film of liquid at the surface that resists expansion (or works toward contraction) of the surface area.

This may be more readily understood by considering a bubble blown in water. The pressure difference across the surface of such a bubble is described by the well-known law of Young and Laplace:

$$\Delta P = 2\gamma / r$$

where P = pressure in millinewtons per meter squared (mN/m^2), r = the radius in meters, and γ = the surface tension in millinewtons per meter (mN/m). Because of the attractive forces on molecules at the surface, a force or a tension in the surface film resists expansion of the bubble and consequently acts to contract the surface area. This contractive force is known as the *surface tension* and has a value of 70 mN/m or 70 dyne/cm for water at 37° C (72 mN/m at 25° C).

Surface tension can be altered by the presence of a second substance in the liquid. Because of hydrogen bonding, water has a high γ. The γ of ethanol is less than that of water. With a water:ethanol solution, the water molecules interact less strongly with ethanol than with one another, and hydrogen bonding is reduced. Consequently, a molecule of ethanol at the surface of a water:ethanol solution will experience less attraction into the bulk phase than a water molecule. This replacement of some surface water with ethanol molecules results in a reduction in γ. The difference in attractive forces between surface molecules of water and ethanol results in a second effect. Because ethanol molecules at the surface experience less attraction into the bulk phase, a small but definite net accumulation of ethanol molecules at the surface will result. The resulting increase in the surface concentration of ethanol generates slightly lower γs than would be predicted from the bulk concentrations. Conversely, the presence of substances such as sodium chloride in water produces a slight increase in γ, probably because water molecules have a stronger association to the sodium and chloride ions in the bulk phase. Therefore water molecules require even more potential energy to attain the surface than with pure water.

The surface tension–reducing capacity of surfactant is the result of its phospholipid constituents. Phospholipids contain *hydrophilic* (water-attracting) polar head groups and *hydrophobic* (water-repelling) fatty acyl groups. Such molecules are known as *amphipathic* (literally, "feeling both ways"). Phospholipids are essentially insoluble, existing in aqueous dispersions as aggregates such as liposomes. Figure 101-6 shows a monomolecular film of PCs or lecithins spread at the air-liquid interface. Numerous different PC molecular species, with palmitate (16:0) at the *sn*-1 position but differing in the fatty acids at the *sn*-2 position of the glycerol moiety, are depicted (*sn* = stereospecific numbering). The polar phosphorylcholine groups interact with water, whereas the hydrophobic fatty acyl moieties extend toward the air. Interactions between these molecules are weaker than the attractive interactions between water molecules. As in the case of ethanol, these lipids reduce γ by displacing water from the surface.

PC monolayers can be formed by spreading the lipids at the air-water interface using an organic solvent such as chloroform. As more phospholipid is spread, γ falls until a surface tension of approximately 23 mN/m is attained. Application of additional phospholipids will not decrease γ further. Although PC dispersions adsorb to form a monolayer relatively slowly, under appropriate conditions and with long time periods, γs of approximately 23 mN/m can be obtained. Because of the presence of the SPs, surfactant adsorbs quite rapidly, again to a final γ of approximately 23 mN/m. This value of approximately 23 mN/m is known as the *equilibrium surface tension* for phospholipid monolayers. At equilibrium surface tension the air-liquid interface can no longer spontaneously accept more phospholipid molecules (i.e., the surface is "saturated" with phospholipid). The precise equilibrium surface tension depends on the composition of the film and the temperature, but 23 mN/m is used for discussion purposes.

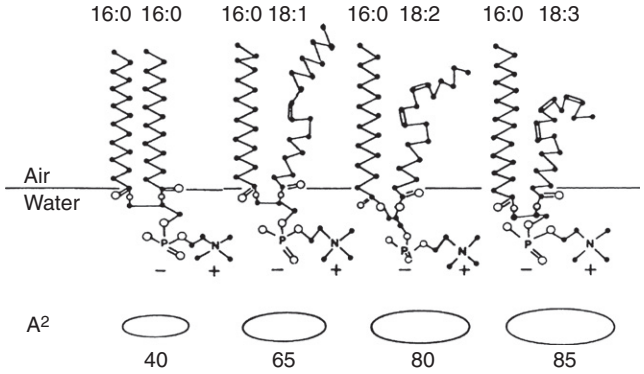

Figure 101-6 Orientation of various molecular species of phosphatidylcholine *(PC)* at the air-water interface. The hydrophobic fatty acyl groups extend into the air, whereas the hydrophilic polar phosphorylcholine groups interact with water via their positive and negative charges. Because of kinks at the double bonds, PCs with unsaturated fatty acids occupy a larger average molecular size, as indicated by *ovals* below the molecules. Unsaturated PCs cannot pack as well as dipalmitoylphosphatidylcholine, the molecule on the *extreme left*. *(From Possmayer F, Yu SH, Weber JM, Harding PG: Pulmonary surfactant,* Can J Biochem Cell Biol *62:1121, 1984.)*

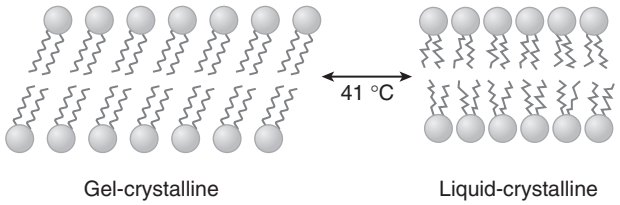

Figure 101-7 Diagrammatic representation of the phase transition from the gel-crystalline to the liquid-crystalline state of a bilayer of dipalmitoylphosphatidylcholine *(DPPC).* The hydrophobic palmitates interact together, and the polar phosphorylcholine groups interact with the water. At 41° C, the acyl groups gain sufficient thermal energy to twist, rotate, and move laterally. This "fluidity" permits the individual DPPC molecules to diffuse relative to one another while remaining in the same leaflet.

Dry or partially hydrated DPPC crystals placed on a water surface or mixed as a dispersion will spread to form a monolayer, again to a final equilibrium surface tension of 23 mN/m. It appears that as the DPPC head groups become fully hydrated, they can either remain at the surface, where they spread to form a monolayer, or they can form vesicles with other hydrated DPPC molecules. The rate of monolayer formation from DPPC increases many-fold at 41° C.[86-89] This temperature dependence of monolayer formation can be understood by considering bilayer structure, which is the molecular basis of biologic membranes (Figure 101-7). As hydrated DPPC bilayers are heated, the palmitic acids change from a relatively ordered state in which all carbon-carbon bonds are extended in the all-*trans* configuration to a disordered fluid state in which some of the carbon bonds are in the *gauche* configuration. Below the critical transition temperature (T_c) of 41° C, the acyl groups are packed together in a regular pattern, and the phospholipid molecules are relatively motionless, although they may rotate in an axis roughly perpendicular to the bilayer. At T_c, the fatty acyl groups gain sufficient thermal energy, so the ordered acyl

chains start to move and become disordered and fluid (i.e., the chains "melt"). The individual phospholipid molecules become more mobile, allowing them to diffuse rapidly relative to one another in their plane of the bilayer.

It is clear from cell biology studies that membrane fluidity is essential for life. Membrane lipids possess high proportions of phospholipids with unsaturated phospholipids at their *sn*-2 position. As shown in Figure 101-6, double bonds introduce a kink in the fatty acid. This reduces the ability of the phospholipid to pack closely in monolayers or bilayers. Consequently, T_c for phospholipids containing unsaturated fatty acids is much lower than for saturated phospholipids with fatty acids of similar length. Reducing the chain length of saturated fatty acids also lowers T_c. The concept of ordered and fluid fatty acyl chains is important for understanding the principles involved in alveolar stabilization as explained in the next section.

In summary, surface tension arises from the difference in attractive forces on molecules at an interface. The term *surface tension* is applied to air-liquid interfaces; *interfacial tension* is used for other interfaces. Molecules at a surface possess excess potential energy relative to molecules in the bulk phase. All the molecules at the surface experience an attraction into the bulk phase. This force is perpendicular to the surface. Clearly, the most stable situation arises with a minimum surface area. This is why water and mercury form droplets. One can think of γ in terms of the work required to expand the surface area. One can also consider γ in terms of an elastic film of surface molecules, in which the attraction of molecules into the bulk phase resists expansion and works toward minimizing surface area. This contractile force produces a pressure difference across bubbles or alveoli, which is equal to twice the surface tension divided by the radius (law of Young and Laplace; see Equation 1). The surface tension of water at 37° C is 70 mN/m.

A monolayer of phospholipids at the air-liquid interface (see Figure 101-6) lowers γ by replacing water at the surface. Phospholipids are amphipathic molecules possessing hydrophilic polar head groups and hydrophobic fatty acyl chains. Phospholipids such as PC are essentially insoluble in water and readily form lipid bilayers, which are the structural basis of biologic membranes. The gel-to-liquid crystalline T_c marks the temperature at which the fatty acyl groups in a bilayer change from an ordered state to a disordered fluid state (see Figure 101-7). Membrane fluidity is essential for membrane processes compatible with life. Below T_c, PC forms monolayers either from crystals placed at the surface or from dispersions in the bulk phase at an extremely slow rate. T_c is lowered by reducing the acyl chain length or introducing double bonds. Mixing DPPC, which has a T_c of 41° C, with unsaturated phospholipids reduces T_c and allows increased adsorption at 37° C.[90-93] However, such adsorption is still insufficient to stabilize the alveoli.

The equilibrium surface tension of 23 mN/m is attained when all available sites at the air-water interface are "fully" occupied by PCs. Equilibrium surface tension is the lowest γ that can be achieved by spreading sufficient phospholipid on the surface with an organic solvent. A similar γ is achieved when natural surfactant, which adsorbs rapidly, is injected below the subphase. Under equilibrium conditions, phospholipids cannot spontaneously enter the monolayer unless a similar amount of phospholipid leaves the surface.

REDUCTION OF SURFACE TENSION BY PULMONARY SURFACTANT

An important physicochemical difference exists between soluble and insoluble surface films. The γ of a bubble blown in a 50% ethanol solution is 30 mN/m. (The surface concentration of ethanol is slightly higher than the bulk concentration.) Increasing the bubble size does not affect γ because ethanol molecules are soluble and move into the surface film almost instantaneously. Likewise, reducing the bubble surface area does not affect the surface concentration of ethanol or γ. However, phospholipid films are insoluble, and reducing the size of the bubble leads to lateral compression of the monolayer. Slow *dynamic* (in the sense of continuous) *lateral compression* of the PC film depicted in Figure 101-6 results in closer packing of the surface phospholipids and a fall in γ because the phospholipid molecules are forced closer to one another and more water is excluded from the surface. However, phospholipid films such as that in Figure 101-6, which contain a high proportion of unsaturated fatty acids, are not very stable at 37° C. Because of the fluid nature of the fatty acids, such films can withstand limited dynamic compression only to a γ of approximately 20 mN/m.[85,94-96] Further reduction in surface area does not produce a concomitant reduction in γ, but it results in the expulsion of PCs from the two-dimensional monolayer (into a collapse phase of uncertain structure). With dynamic compression, γ can be driven slightly below equilibrium, but when dynamic compression ceases (i.e., surface area is held constant), γ returns to its equilibrium state. This increase in γ is thought to arise from loss of unsaturated PC molecules from the surface, thereby relieving the strain resulting from film overcompression. Such molecules can form bilayer structures such as vesicles, which are lost from the surface. However, as discussed in a later section, it is clear that, especially with surfactant, some of the lipid material can remain associated with the surface monolayer.

In contrast to unsaturated PCs, films of DPPC are stable at 37° C and can be compressed until γ approaches 0 mN/m. This film stability is attributed to the ability of the saturated palmitic acids to pack closely, thus allowing the DPPC molecules to organize into a highly ordered, two-dimensional surface gel at this temperature. Experimental evidence of the differences in the physicochemical properties of gel and fluid phospholipid monolayers is outlined in Figure 101-8, which depicts the effects of compressing DPPC (see Figure 101-8, *A*) or 1-stearoyl,2-oleoyl-PC (SOPC) (see Figure 101-8, *B*) monolayers on a Langmuir-Wilhelmy surface balance (see Figure 101-8, *C*). The Langmuir-Wilhelmy surface balance introduced by John Clements[79] provided some of the first direct experimental evidence of pulmonary surfactant. Figure 101-8, *A,* shows a so-called *compression isotherm* (i.e., compression at constant temperature) for DPPC monolayers spread at low surface concentration with organic solvent, which is then allowed to evaporate. Compressing the film from "lift off," the point on the right side of the graph at which a significant decrease in γ is first noted, results in a slow progressive decrease in γ. At a certain point (γ of approximately 60 mN/m [70% surface area] for the curve at 25° C), the decrease in slope is sharp. This leads to a slowly increasing plateau, which then curves upward as surface area is reduced further. As the monolayer is compressed still further, surface tension falls to approximately 0 mN/m, at which the DPPC monolayer collapses. At 37° C, because of increased mobility of the acyl groups, greater compression is required to reach the initial plateau, but the curves become identical as γ declines.

This DPPC isotherm contrasts with that for SOPC, which has a T_c of 6° C. With this unsaturated PC at 37° C, the gradual plateau at low γ is not observed (see Figure 101-8, *B*). Furthermore, it is apparent that SOPC monolayers cannot withstand sufficient lateral pressure to lower the surface tension to very low levels. At approximately 20 mN/m, further compression squeezes SOPC molecules out of the monolayer into a collapse phase. The lowest surface tension attained (approximately 20 mN/m) is only slightly below the equilibrium surface tension of 23 mN/m. Electron microscopic studies indicate that compressed DPPC monolayers near 0 mN/m are relatively solid and collapse as structures resembling small ice floe sheets as

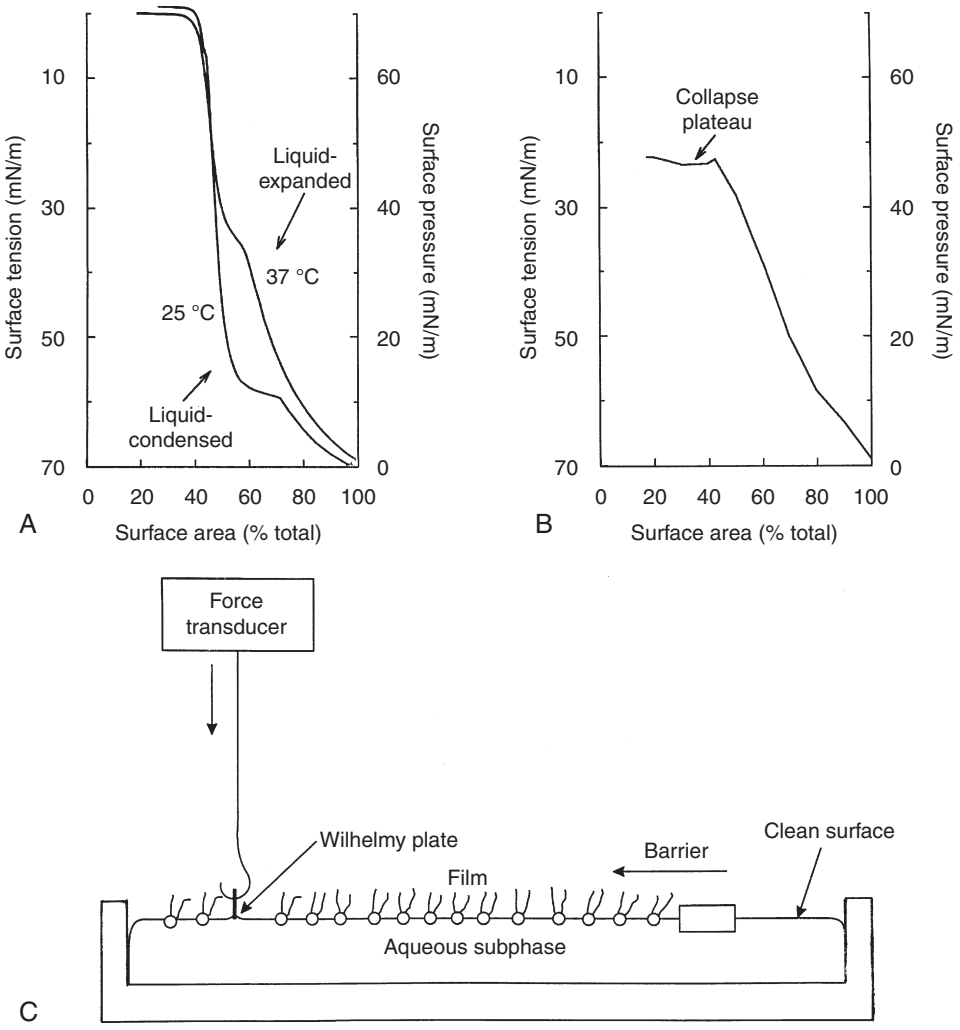

Figure 101-8 Effect of compression on surface tension of a dipalmitoylphosphatidylcholine *(DPPC)* monolayer or a monolayer of 1-stearoyl, 2-oleoylphosphatidylcholine *(SOPC)* on a Langmuir-Wilhelmy surface balance. A, Surface tension/surface pressure relationship for DPPC monolayers at 25° and 37° C. The liquid-expanded (LE) and liquid-condensed (LC) phase regions are indicated. Because of thermal agitation at 37° C, the liquid-expanded region extends to a lower γ (higher surface pressure). Surface tensions of approximately 0 mN/m are attained with both monolayers at approximately 50% original area. **B,** Surface tension/surface pressure versus area curve for SOPC at 37° C. Only the liquid-expanded state is observed, before the collapse point is attained at approximately 45% surface area reduction. Further surface area reduction results in a collapse plateau at which surface tension is not lowered further. **C,** Diagrammatic representation of a Langmuir-Wilhelmy surface balance. The barrier is used to compress the film. The Wilhelmy plate is used to monitor surface tension. *(**A** and **C,** Modified from Goerke J, Clements JA: Alveolar surface tension and lung surfactant. In Fishman AP, editors:* Handbook of Physiology, Section 3: The Respiratory System, *vol. III, part 1. Bethesda, MD, American Physiological Society, 1986, pp 247-261. **B**, Modified from Hawco MW, Davis PJ, Keough KM: Lipid fluidity in lung surfactant: Monolayers of saturated and unsaturated lecithins,* J Appl Physiol *51:509, 1981.)*

the barrier progresses near 0 mN/m. SOPC monolayers collapsing at γ approximately 20 mN/m appear more like fluid pools.[97]

The behavior of DPPC and SOPC monolayers can be readily understood in terms of the generalized phase diagram for phospholipids below T_c depicted in Figure 101-9. The interpretation of such curves is based on extensive work with fatty alcohols and fatty acids, as well as phospholipids.[89,98-102] At low surface concentrations, DPPC molecules act as a two-dimensional gas and have no discernible effect on γ. As surface area decreases to approximately 120 Å^2/molecule, the DPPC molecules interact with each other such that they become more erect. This marks the *liquid-expanded* (LE) state, which continues to approximately 80 Å^2, at which some of the molecules become compressed into the *liquid-condensed* (LC) state, giving rise to an LE/LC coexistence plateau. As more of the LE molecules become tightly packed and assume the LC state, γ decreases more rapidly with surface area reduction. This continues until γ approaches 0 mN/m at approximately 40 Å^2, at which the monolayer acts like a solid LC gel. Because SOPC at 37° C is far above T_c, only the LE phase is observed during monolayer compression, and the monolayer collapses near equilibrium surface tension. Below its T_c of 6° C, SOPC can be compressed to low γs.[95] It has been suggested that, at high compression, DPPC monolayers can be transformed to a more tightly packed LC solid state by altering head group orientation to create less tilt in the molecules, but this is controversial.[99,100,103]

Our appreciation of the molecular interactions occurring during monolayer compression has been greatly improved by the development of fluorescence imaging microscopy, Brewster angle microscopy, and atomic force microscopy. DPPC films in

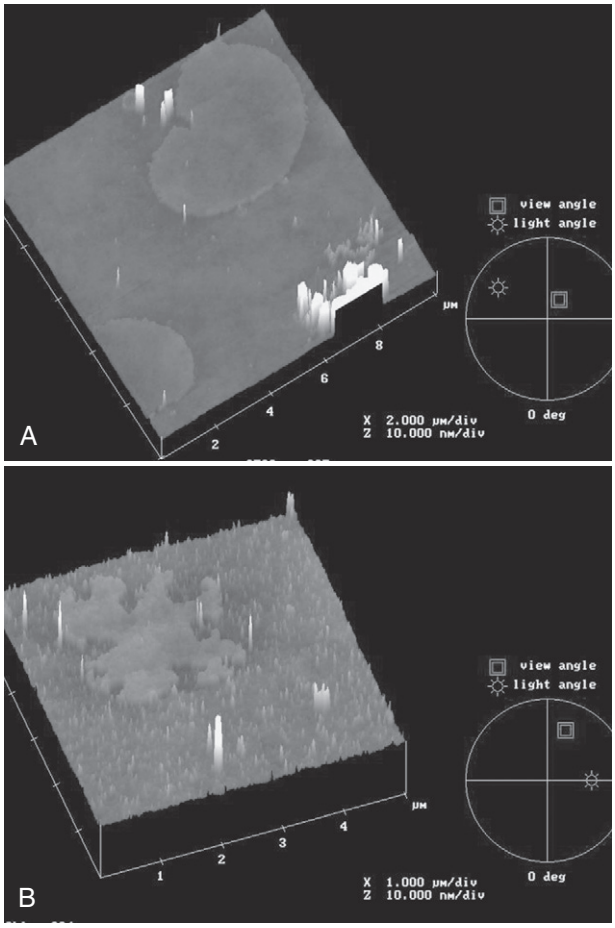

Figure 101-10 Atomic force microscopy images of dipalmitoylphosphatidylcholine (DPPC) (A) and bovine lipid extract surfactant (BLES) **(B)** monolayers in the liquid-expanded (LE): liquid-condensed (LC) coexistence region. The kidney bean-shaped LC structure in **A** is approximately 6 µm long and extends approximately 1.2 nm above the plane of the LE phase. The BLES LC structure in **B** is approximately 7 nm long and is floral shaped. It extends approximately 1.7 nm above the LE phase. The nature of the small spikes in the *insert* is not known. *SP-A,* Surfactant-associated protein A. *(Unpublished data from the work of Nag K, Peterson N, Possmayer F.)*

the LE/LC coexistence plateau can be examined directly on the monolayer to reveal kidney bean-shaped LC condensed structures as dark probe-excluding regions with fluorescence imaging microscopy and thickened monolayer regions with Brewster angle microscopy. Such structures can also be observed on *Langmuir-Blodgett films* deposited from the monolayer as elevated regions using atomic force microscopy (Figure 101-10). Although the kidney bean structure in Figure 101-10, *A* is obviously an LC gel-phase structure, some explanation is needed for the BLES floral-shaped structure in Figure 101-10, *B.* This is also an LC gel-phase structure that arises through segregation (i.e., phase separation) of the gel-phase phospholipids DPPC and DPPG. Fluid constituents remain in the LE phase.[104-106] The kidney bean shape of the DPPC LC structures (see Figure 101-10, *A*) and the floral shape of the BLES LC structures (see Figure 101-10, *B*) observed using atomic force microscopy arise through line tension, which is the two-dimensional equivalent of surface tension. Water and mercury form spherical droplets because of high surface tension (large interfacial tension between air and water). A high line tension would cause the shape of the domain to be spherical.[102] In fact this occurs with CLSE, which has cholesterol. DPPC and BLES domains have low line tensions between LE and LC, and as a result, their domains take up a longer perimeter.

The manner in which surfactant films benefit the lung can be considered in terms of both high lateral surface pressure and low surface tension. High surface pressure resists decreases in alveolar surface area by acting as a monomolecular surface "splint." Low surface tensions stabilize the lung by reducing the pressure gradient across the alveolar lining layer. This may also function to reduce transudation of interstitial fluid into alveolar spaces.[107,108] Surface pressure is related to surface tension by the followingequation, which states that the surface pressure, π, is equal to the surface tension of a clean surface (γ_o) minus the surface tension of the surface containing the film (γ):

$$\pi = \gamma_o - \gamma$$

It should be evident from this equation that applying a lateral pressure on a monolayer produces a corresponding decrease in surface tension. For historical reasons, surfactant specialists normally express this kind of information as surface tension (left axis in Figure 101-8), whereas physical chemists normally use surface pressure (right axis). As indicated earlier, films compressed to surface tensions below equilibrium[82,84,109,110] (23 mN/m for phospholipids) are no longer in thermodynamic equilibrium and are theoretically capable of returning to their equilibrium surface tension by shedding molecules from the compressed monolayer. However, although inherently metastable, films containing a high proportion of DPPC can remain at surface tensions near 0 mN/m for long periods (i.e., many minutes). This is more than sufficient to stabilize the alveoli during breathing.

As discussed further later on, it is clear that the surface tension of the alveolar lining layer in vivo falls to values very near 0 mN/m during expiration. This low surface tension is important for stabilizing the alveoli and preventing their collapse. Such low surface tensions could not be achieved experimentally through compression of fluid phospholipid films such as those with compositions similar to that of pulmonary surfactant on Langmuir-Wilhelmy balances (see Figure 101-8, *C*). This led to the concept that the alveolar surface lining must be covered by a film highly enriched in DPPC, which is the major tenet of the classical model mentioned at the beginning of this chapter.[48,49,107,109-113] Because removing surfactant from the lung disrupts the surface film, this enrichment could not be directly measured by chemical analysis but was inferred from physical measurements. It is generally held that the fluid lipid components could contribute to the surfactant adsorption, which is very slow at 37° C for DPPC. However, DPPC:unsaturated phospholipid mixtures adsorb relatively slowly in the absence of surfactant apoproteins. The fluid lipid constituents could also be important for the transport of surfactant components within the type II cells and for secretion of lamellar bodies.

In summary, phospholipids are amphipathic molecules that contain hydrophilic polar head groups and hydrophobic acyl chains. Amphipathic molecules form insoluble monolayers in which surface concentration can be increased by dynamic lateral compression. Dynamic compression can be exerted by a barrier, as with the Langmuir-Wilhelmy surface balance (see Figure 101-8, *C*). Lateral compression also increases when the surface area of a bubble (or an alveolus) is reduced by decreasing the volume. In either case, the resulting increase in the surface concentration of the amphipathic molecules produces a decrease in γ.

Dynamic compression of DPPC monolayers results in highly ordered, closely packed, gel-like LC films. Compressed DPPC monolayers can reduce γs to near 0 mN/m. Furthermore, such monolayers can remain at low γs for long periods (i.e., these films are very stable). In contrast, monolayers composed of phospholipids with bilayer gel to liquid-crystalline T_cs significantly lower than 37° C cannot be compressed to low surface tensions with conventional balances at biologic temperatures. Such fluid films collapse at surface tensions only slightly below their equilibrium tension of approximately 23 mN/m and tend to return to equilibrium once dynamic compression ceases.[114-117]

It can be shown that the surface pressure of a monolayer is equal to the surface tension of the clean surface minus the surface tension of the surface containing the film (see Equation 2). For water, which has a surface tension of 70 mN/m at 37° C, surface pressure can vary, ranging from 0 mN/m (for a clean surface) to near 70 mN/m (corresponding to a surface tension of 0 mN/m).

ROLE OF SURFACTANT IN ALVEOLAR STABILITY

Theoretical calculations based on measurements of transpulmonary pressure and morphologic considerations with normal and saline-filled lungs indicate that surface tension varies during lung inflation and deflation and falls to very low values during expiration.[77,79,118-120] Studies in detergent-rinsed and fluorocarbon-filled lungs, in which surface tension is altered by the remaining detergent or fluorocarbon, support the view of low alveolar surface tension.

More direct evidence was obtained by Schürch and coworkers[119,121-124] by monitoring the spreading properties of fluorocarbon or silicone oil test droplets deposited on the lung's alveolar surfaces in situ.[119,121-124] Such droplets spread to form a thin lens when surface tension of the droplet is similar to that of the underlying phase. When surface tension of the underlying substrate is lower than the test droplet, the droplet adopts a more nearly spherical shape (this is the reason water forms droplets on Teflon-coated materials). Calibration of the test droplets with DPPC monolayers on the Langmuir-Wilhelmy surface balance allowed precise estimation of the surface tension of the alveolar lining layer in situ. These microdroplet studies revealed that lung volume alterations corresponding to quiet breathing (e.g., between 40% and 50% total lung capacity) were associated with only modest increases in γ from 1 to 5 mN/m. Large inflations to total lung capacity resulted in alveolar surface tensions of approximately 30 mN/m, slightly higher than the equilibrium value of 23 mN/m. When lung volume was reduced to functional residual capacity, which is 40% of total lung capacity, γ fell to less than 1 mN/m. Furthermore, when the lung was held at this volume, surface tension remained at this low value for several minutes before increasing gradually. Even after 1 hour, γ at functional residual capacity remained at less than 10 mN/m. These measurements showed that the surface film covering the alveolar lining layer is very stable in the sense that it returns to equilibrium surface tension only very slowly. This property would minimize pressure differences between small and large alveoli and would prevent collapse of the smaller units. These observations reinforced the view that the endogenous surface monolayer must be highly enriched with DPPC and were considered consistent with the classical model of surfactant function.

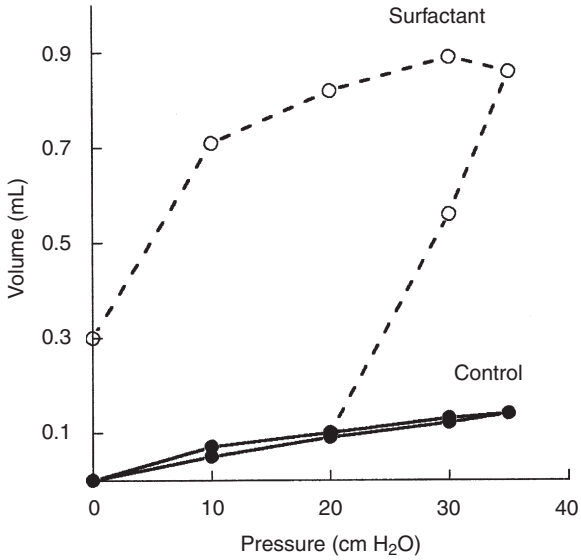

Figure 101-11 Pressure-volume maneuvers with prematurely delivered rabbit fetuses of 27 days gestation (term, 31 days). Control inflation (*closed circles*) shows little increase in lung volume or hysteresis. Lipid extract surfactant administration (*open circles*) results in a marked increase in lung volume and prominent hysteresis. *(Data from Metcalfe IL, Pototschnik R, Burgoyne R, Enhorning G: Lung expansion and survival in rabbit neonates treated with surfactant extract,* J Appl Physiol *53:838, 1982.)*

The functional significance of the presence of a lipid-protein complex capable of generating low surface tensions within the lungs can be readily demonstrated through surfactant supplementation of surfactant-deficient lungs. Treatment of prematurely delivered rabbit fetuses of 27 days gestation (term, 31 days) with natural or lipid extract surfactant increases survival. Surfactant administration results in a four- to five-fold increase in inflation during pressure-volume loops[125-127] (Figure 101-11) (see Chapter 106). Similar observations have been made with prematurely delivered fetuses of other species and with adult lungs made surfactant deficient through lavage. Administration of lipid mixtures similar to those present in surfactant has little immediate effect. This finding emphasizes the role of the SPs in surfactant function.[1,49,51,128]

Studies in which surfactant-deficient animals or prematurely delivered infants are treated with natural or lipid extract surfactants in vivo prove more difficult to interpret but clearly indicate increased compliance that results in an increase in lung volume.[1,125,129] Clinically, this can readily be monitored by a rapid increase in arterial oxygen tension, a finding indicating enhanced gaseous exchange.[130] Studies by Bachofen and Schürch[131] indicate that, in addition to promoting lung expansion, surface tension reduction of the alveolar lining layer influences lung alveolar morphology. At low lung volumes, alveolar septa are elongated, thereby maximizing alveolar surface area. At high surface tensions of 20 to 30 mN/m, these septa are contracted through extensive folding, resulting in 30% to 50% decreases in alveolar surface area. The combined abilities of surfactant to increase compliance and optimize alveolar surface area would appear to explain the rapid increases (within 30 minutes) in gaseous exchange often noted on treatment of surfactant-deficient infants and would have important implications for acute RDS.

TECHNIQUES FOR INVESTIGATING SURFACTANT FUNCTION

Discussion of the mechanisms involved in surfactant function requires a brief introduction into the technical approaches used and their limitations.

Langmuir-Wilhelmy Balance

The Langmuir-Wilhelmy surface balance illustrated earlier (see Figure 101-8, *C*) is an excellent tool for examining spread films because film composition and the amount of material deposited can be controlled accurately.[49,132] This approach is readily combined with other techniques, such as fluorescence imaging, Brewster angle microscopy, and grazing angle x-ray diffraction. By drawing mica sheets, glass slides, or cover slips perpendicular to the plane of the film, one can deposit *Langmuir-Blodgett films,* which are useful for atomic force microscopy, time-of-flight secondary ion mass spectroscopy, or autoradiography. Because of the large subphase, the Langmuir-Wilhelmy approach is not convenient for studying adsorbed films. Temperature control at 37° C is difficult. Compression rates can be altered, but experimentally productive compression and expansion rates are limited. In addition, Langmuir-Wilhelmy studies require considerable expertise and scrupulous cleanliness, and they take a long time to conduct. However, the major limitation of the Langmuir-Wilhelmy balance studies is that it has become apparent that, at the high surface pressures required to generate γs approaching 0 mN/m (values critical for surfactant function in vivo), film material "creeps" onto the Teflon barriers and walls.[115,133] This difficulty is particularly problematic with spread monolayers containing cholesterol and becomes more significant at physiologic temperatures. This situation is often referred to as "leakage" because frank film leakage did occur with early balance studies before Teflon tapes were introduced.

Pulsating Bubble Surfactometer

The pulsating bubble surfactometer (PBS), introduced by Enhorning,[134,135] is an artificial alveolus model. The key component is a small cuvette in which a bubble communicating with the atmosphere is drawn into the surfactant suspension to be tested.[49,85,132,136] This device can be thought of as a bubble on a tube model. With the commercial version of this apparatus, the pulled bubble diameter is maintained for 10 seconds to measure adsorption and then is pulsated at 20 cycles per minute with 50% surface area change. Bubble radius and the pressure difference across the bubble are recorded. Using the law of Young and Laplace (see Equation 1), a microchip controls bubble radius and generates γ at a minimum and maximum radius.

An important feature of the PBS is that it monitors surface activity at compression rates and ratios comparable to those in the alveolus in vivo. In practice, the Enhorning PBS is an easily learned, rapid method for testing small (approximately 25 μL) surfactant samples at 37° C for physiologically important parameters. It is therefore superb as a screening device, especially for animal or clinical samples. An apparent disadvantage is that, at γs approximating zero, the bubble tends to flatten, thus losing its spherical shape. This can affect calculation of γ, although the error appears to be small. In any case, γ is clearly low.[136] The major difficulty is that it has become apparent that some fluid can remain in the capillary when the bubble is created. This produces a variable increase in effective surface area.[137] This effect would be particularly serious for samples containing hydrophilic nonsurfactant proteins, for example in inhibitory studies. As with the Langmuir-Wilhelmy balance, leakage can occur in which material creeps up the polyacrylamide capillary. This leakage limits the usefulness of the PBS for mechanistic studies, although it is useful for monitoring surfactant effectiveness.

Captive Bubble Tensiometer

The captive bubble tensiometer (CBT) or surfactometer combines many of the advantages of the Langmuir-Wilhelmy balance with those of the PBS. With this device, introduced by Schürch,[119,133,138] an air bubble is introduced into the surfactant sample in an air-tight chamber where it floats up to a hydrophilic agar ceiling. The agar gel is highly hydrated and so cannot accept phospholipid material from the adsorbed film. Film leakage appears to be negligible. The CBT can be used to study adsorption, after which quasistatic or dynamic compression and expansion curves can be generated by increasing and decreasing pressure in the chamber. Surface area and surface tension are obtained from bubble shape, which is recorded with a video camera.[139]

The original CBT designed by Schürch used an air-tight syringe. More recent versions using gas-type plastic cuvettes have been introduced that are convenient for film spreading experiments. With such studies, it is important to change the subphase numerous times to remove the organic spreading solvent. Although both experiments and analysis with the CBT are slow, the availability of an apparently leak-proof system for studying surfactant at any temperature is an important advantage. This device has proved pivotal in studies challenging the classical model for surfactant function.

ROLE OF SURFACTANT-ASSOCIATED PROTEINS IN THE PHYSICOCHEMICAL FUNCTIONS OF PULMONARY SURFACTANT

As indicated by the law of Young and Laplace (see Equation 1) the pressure difference across an alveolus is inversely related to the radius. If the surface tension in the alveolus were 70 mN/m, the surface tension of water at 37° C, the pressure difference across the alveolus would be considerable, promoting alveolar instability. The mechanical properties of the lung suggest that the alveoli are covered with a phospholipid monolayer highly enriched in DPPC. However, at less than the bilayer T_c of 41° C, DPPC adsorbs and spreads only slowly at the air-liquid interface.[87-91,109,140,141] Thus, as demonstrated by the classical model, surfactant must contain fluid lipids and other substances (i.e., apoproteins) that facilitate rapid adsorption and spreading of DPPC without interfering with the ability of this disaturated phospholipid to reduce the surface tension to near 0 mN/m when the surface film is under dynamic compression during expiration.

In vitro studies indicate that surfactant apoproteins augment the surface activity of surfactant lipids in three distinct ways. First, they promote adsorption and spreading of surfactant lipids at the air-water interface. This forms a surface-active film that lowers γ toward equilibrium. Second, SPs modify the properties of the surface film and facilitate its ability to attain low surface tensions near 0 mN/m during film compression. Third, SPs enhance respreading or reinsertion of phospholipids from collapse phase.

Adsorption

The processes by which phospholipids adsorb (i.e., form surface-active films) at the air-water interface are poorly understood. Long chain molecules such as phospholipids have low critical micellar concentrations. The critical micellar concentration for DPPC of approximately 10^{-10} mol/L[109] means that DPPC in excess of this low concentration forms aggregates. The tendency of phospholipids to form aggregates arises from the so-called hydrophobic effect, which states that the high energetic cost of water:hydrocarbon interactions drives lipids to adopt specific aggregate forms in which water–fatty acid contact is minimized. Phospholipids such as saturated PC and unsaturated PC are shaped like cylinders with similar diameters for the polar head group and the hydrophobic diacylglycerol moieties.[142] Hydration of phospholipid films dried on the walls of a test tube with water or saline greater than T_c results in the formation of planar bilayer sheets that minimize water:hydrocarbon contact. If these sheets had ends (i.e., if the structures remained *open*), water:hydrocarbon interactions would still occur. However, such sheets curve to produce vesicles (also known as liposomes), which are *closed* structures. Depending on the preparative conditions, multilamellar vesicles of various sizes are generated, but in each case the structures are closed, engulfing some of the aqueous phase. Below T_c, hydration proceeds very slowly. This is why it is often stated that DPPC alone cannot be an effective pulmonary surfactant. Introducing short-chain phospholipids, unsaturated phospholipids (which have low T_cs), or cholesterol will decrease T_c of the mixture. In each case, the resulting vesicles are closed structures. Applying energy in the form of ultrasound using bath or probe sonicators will convert multilamellar vesicles into smaller unilamellar vesicles. This results in an increase in the surface area of the vesicle available for adsorptive processes, as reviewed by Hope and colleagues.[142]

In view of the foregoing considerations, it should not be surprising that surfactant film formation is thought to proceed not through individual phospholipid molecules, but through mechanisms whereby vesicles interacting with the surface rapidly donate many of their phospholipids to the interface. Observations by Schürch and co-workers[143] indicate that the porcine lipid extract surfactant Curosurf adsorbs in discrete, sudden bursts, corresponding to approximately 10^{14} phospholipid molecules.[143] This finding suggests a cooperative mechanism whereby film formation involves the collective transport of subphase material into the surface film. The collective transport of large amounts of lipid into the surface monolayer does not imply that all the lipids in a particular surface vesicle will become incorporated into the monolayer. As elaborated later, it has become evident that considerable amounts of lipid can remain associated with the monolayer as functional multilayers.

Phospholipid Adsorption

Studies of surfactant phospholipid adsorption are considered both in the absence and in the presence of surfactant apoproteins. Phospholipid adsorption characteristics change dramatically at the bilayer transition temperature T_c. Below T_c, dried phospholipid films hydrate extremely slowly, and, as a result, DPPC alone fails to generate surface-active films at physiologic temperatures lower than the T_c of 41° C. In addition, vesicles of saturated PCs prepared at temperatures higher than their T_c adsorb very slowly at temperatures less than their T_c. This rate increases slowly as a function of temperature and increases markedly once T_c is attained. For example, DPPC vesicles (prepared at greater than 41° C) at 1.0 mmol/L do not attain equilibrium in 15 minutes at less than 41° C, but they achieve equilibrium in approximately 1.5 minutes at all temperatures greater than T_c.[140] Likewise, dimyristoyl PC vesicles prepared at greater than the T_c of 23.5° C attain equilibrium at significant rates only at this temperature or greater. DPPC adsorption at 37° C can be enhanced by addition of fluid-phase phospholipids, such as unsaturated PC, unsaturated phosphatidylethanolamine, unsaturated phosphatidylinositol, or unsaturated PG, which lowers T_c of the mixture to less than 41° C.[84,144,145] PG is particularly effective in increasing DPPC adsorption.[146] Dialkyl phosphono analogues of DPPC, which are diethers rather than diacyl phospholipids, adsorb more readily than DPPC.[147]

It has long been thought that cholesterol present in mammalian surfactant at 2% to 10% weight/weight (which corresponds to 8% to 20 mol%) could play a critical role in surfactant phospholipid adsorption. In this context, it has been known for some time that cholesterol interacts with saturated PC, sphingomyelin, and sphingoid-based glycolipids to form a liquid-ordered L_o phase, which possesses properties between LE and LC.[148,149] This distinct liquid-ordered phase is the physicochemical basis of membrane rafts and caveolae, plasma membrane (and likely other cellular membrane) structures with numerous important roles, including cell signaling.[150,151] As mentioned earlier, cholesterol is removed from Curosurf and BLES and is not included in any of the current artificial synthetic surfactants. At present, no distinct physiologic functions or advantages can be attributed to this sterol in replacement surfactants. Adding (returning) cholesterol to BLES enhances adsorption and surface activity on the PBS at 25° C, but this difference is negated at 37° C.[93] The cholesterol content of rat and human surfactant is changed during vigorous exercise, although the physiologic significance is unknown.[20,152,153] Cholesterol levels also are altered in animals in torpor (induced by temporary programmed decreases in body temperature), but again, the significance is not clear.[20,154]

Addition of certain other lipids such as palmitic acid, hexadecanol, or dipalmitoylglycerol to DPPC markedly enhances adsorption in vitro.[155,156] As indicated earlier, palmitic acid is added to Surfactant-TA and Survanta, whereas hexadecanol is used as a spreading agent in Exosurf. However, as explained later, because of nonsurfactant protein inhibition, the in vivo efficacy of monolayer formation is dubious.

In addition to bilayers, certain phospholipids and phospholipid mixtures can form nonbilayer phases.[142] It has been suggested that a hexagonal II phase could be involved in surfactant adsorption. DPPC:phosphatidylethanolamine mixtures that can form a hexagonal II phase do adsorb rapidly.[157,158] However, evidence of a role for a hexagonal II phase in surfactant adsorption is lacking.[159]

Phospholipid Adsorption With Surfactant Proteins

The increased fluidity arising from introduction of non–gel-phase phospholipids and cholesterol can explain, in part, the rapid adsorption of pulmonary surfactant. However, the overall effects are relatively small. This has led to the conclusion that the ability of natural and modified pulmonary surfactant to adsorb sufficiently rapidly to stabilize the terminal air spaces can be attributed to the low-molecular-weight hydrophobic proteins SP-B and SP-C. Early studies demonstrating organic solvent extracts adsorbed rapidly were instrumental in the development of the modified natural surfactant used clinically.[129,145,156,159-163] Such preparations contain SP-B and SP-C, but not SP-A. SP-B and SP-C, alone or together, greatly enhance

adsorption of DPPC-containing mixtures to the equilibrium γ of 23 mN/m.[156,164-170] Whether SP-B or SP-C is more effective depends on the experimental conditions, but SP-B appears to have a greater effect with phospholipid mixtures closely mimicking natural surfactant.[168,169,171,172] SP-A has only a minor effect on adsorption of DPPC or DPPC-containing lipid mixtures but greatly enhances film formation of mixtures containing SP-B in a calcium-dependent manner.[166,173-175] The carbohydrate recognition domain of SP-A is important for this function.[27] SP-A does not influence phospholipid adsorption rate in the presence of SP-C.

The manner by which either SP-B or SP-C promotes adsorption of surfactant phospholipids is not known. These low-molecular-weight hydrophobic proteins can be thought of as bilayer breakers, which disrupt the bilayer structure in such a way that they permit cooperative flow of bilayer phospholipids to the surface monolayer. It is likely separate mechanisms are involved. The 79–amino acid SP-B has three intrapeptide and one interpeptide disulfide bonds. Each monomer has four or five amphipathic helices with hydrophobic amino acids on one face of the protein and hydrophilic amino acids on the other side. SP-B thus acts as a membrane surface protein, with the hydrophobic face buried in the membrane, whereas the hydrophilic residues can interact with phospholipid head groups or with the surrounding water. In addition to the intermolecular disulfide bridge at Cys 48 of the homodimer, SP-B (a dimer) is stabilized by salt bridges (Glu 51 of one SP-B monomer and Arg 52 of the other chain, and vice versa).[176,177] The dimeric nature of SP-B is important for its surface activity.

Several properties of SP-B could contribute to its bilayer-disrupting propensity. SP-B surfactant lipid mixtures can form discoidal disks approximately 50 nm in diameter,[178] similar to those observed in serum high density lipoprotein fractions.[179] These disks are thought to represent bilayer sheets with SP-B dimers associating with the fatty acyl perimeters to minimize aqueous contact. Discoidal fractions have been reported in natural surfactant and in reconstituted systems. Whether these discoidal particles are directly involved in phospholipid adsorption is not known.

SP-B possesses *fusogenic properties* that could contribute to its ability to enhance phospholipid adsorption. Phospholipid vesicles containing SP-B aggregate through membrane:membrane interactions and allow the phospholipids in the outer bilayer leaflets to flow onto the corresponding leaflet of the adjacent vesicle.[35,180] Lipid mixing should be distinguished from true fusion, in which the surface bilayers of the two vesicles combine to become a single membrane and the intravesicular aqueous compartments form a common pool.[142,181] Thus SP-B-mediated lipid mixing is correctly referred to as *hemifusion.* Because air is considerably less polar than water, vesicular hemifusion with the air-water interface could generate a monolayer. However, the molecular details are still vague. SP-B enhancement of DPPC adsorption is greater in the presence of acidic phospholipids such as PG. SP-B contains eight conserved positive residues, but only one conserved negative residue and so could interact with PG. Calcium also promotes adsorption of systems containing SP-B.[92,169,180]

SP-A, SP-B, DPPC, and calcium can combine to reconstitute tubular myelin, a natural surfactant form consisting of stacked square tubules hemi-fused at the corners[179,182] (see Figure 101-3). Tubular myelin may represent the most active form for surfactant adsorption because the rate at which natural surfactant preparations adsorb varies with tubular myelin content.[69] However, because it is not possible to purify this surfactant form, this conclusion cannot be validated.

PL adsorption is also enhanced in the presence of SP-C. SP-C is a 4.2-kDa monomeric protein with a short, 12–amino acid N terminus, ending in Lys-Arg, which marks initiation of a 23–amino acid α-helical segment, terminating in Met 35.[42] It has been reported that removal of the two palmitates esterified to Cys 4 and Cys 5 hampers the ability of SP-C to promote phospholipid adsorption to variable extents.[183-185] Depalmitoylated SP-C can dimerize readily and forms large β-sheet aggregates that could account, in part, for the difference in activity.[186-188] Neutralizing the membrane surface lysine initiating the α-helix greatly diminishes SP-C surface activity.[189,190]

To this point, the adsorption of surfactant phospholipids to a clean surface has been considered. Phospholipid adsorption to a partially occupied surface can occur by a different mechanism. In these experiments, DPPC:PG mixtures containing SP-B or SP-C were spread to a surface tension of 50 mN/m.[191,192] This surface film accelerated subsequent incorporation of lipids from DPPC:PG unilamellar vesicles and resulted in rapid lowering of surface tension to equilibrium. Lipid insertion was triggered by injecting calcium ions into the subphase. This triggering effect arose because calcium ions neutralize the negative charge on PG and thus minimize charge repulsion between surface and subphase phospholipids. SP-B is considerably more effective than SP-C in promoting the "pulling up" of lipids into the surface film. This mechanism could involve interaction of surface lipids with the nonlamellar structures discussed earlier. Such a mechanism could be important in lipid insertion during inspiration when surface tension rises to more than the equilibrium value. The dimeric nature of SP-B enhances surface properties.[193] Removal of the palmitates from SP-C has little effect on SP-C-mediated incorporation of lipids from DPPC:PG into the monolayer. Surprisingly, lipid insertion from neutral DPPC:PC unilamellar vesicles into DPPC:PG:SP-C–containing monolayers was slower with palmitoylated SP-C.[194]

Surface Tension During Film Compression

Surfactant apoproteins modify the properties of model surfactant films and facilitate their ability to attain low γ during film compression. In this context, the term *surface activity* is defined as the ability to reduce surface tension, and the same term is used for γ reduction through adsorption (i.e., 70 mN/m to equilibrium 23 mN/m) and for γ reduction during film compression (i.e., to values lower than equilibrium). The term *compressibility* can be used to describe the degree to which surfactant films lower γ during surface area reduction. Unsaturated phospholipids at equilibrium surface tension are highly compressible: Little reduction in γ occurs with large decreases in surface area. Thus compressibility is inversely related to the slope of the γ versus surface area reduction curve. Good surfactants have low compressibility: γ falls markedly during surface area reduction. The low compressibility of good surfactant films resembles DPPC. This is why the classical model concluded that surfactant monolayers were enriched in DPPC. Addition of the low-molecular-weight apoprotein SP-B or SP-C leads to decreased compressibility, so smaller surface area reductions are required to lower γ from equilibrium to near zero.[171,175,195-197] As in the case of adsorption, SP-A decreases compressibility of surfactant films containing SP-B but not films with SP-C. The manner in which SPs contribute to decreased surfactant compressibility is not understood.

The classical model of surfactant function argues that, for a film to achieve the low γs near 0 mN/m required to stabilize the terminal air spaces, the surface monolayer must be highly enriched with DPPC. Two mechanisms have been proposed for producing this purported DPPC enrichment: (1) the squeeze-out of non-DPPC fluid phospholipids during film compression and (2) selective DPPC adsorption.

Squeeze-Out

The squeeze-out model proposes that, during surface area reduction, gel-phase phospholipids are retained, whereas fluid-phase lipids are selectively expelled from surface monolayers.

This hypothesis arose primarily from Langmuir-Wilhelmy balance studies showing that DPPC is the only major lipid component in surfactant that could sustain sufficient surface pressure to generate γ near zero with surface balances. DPPC monolayers at equilibrium require approximately 12% surface area reduction to lower γ to near zero.[133] Both spread and adsorbed surfactant model systems lacking SP-B and SP-C exhibit high compressibility and require high compression ratios (surface area reduction) to attain low γ. As indicated earlier, compressibility is markedly reduced by the presence of the hydrophobic apoproteins.

Selective DPPC Adsorption

Selective DPPC adsorption means that the initial adsorbed surfactant monolayer contains a higher proportion of DPPC than the bulk phase surfactant. The basis of this proposed phenomenon can be best understood by comparing theoretical and experimental surface area reductions required to compress surfactant monolayers from equilibrium surface tension to γs less than 2.0 mN/m during the initial compression. DPPC monolayers require approximately 12% surface area reduction to lower γ from 23 mN/m to less than 2 mN/m.[129,133] Theoretically, DPPC:PG (70:30) mixtures with 1% SP-B or SP-C at equilibrium would require 30% surface area reduction for squeeze-out of the fluid PG (assumes perfect squeeze-out), resulting in a pure DPPC film (Figure 101-12). A further 12% surface area reduction of the remaining DPPC (70%) in the monolayer would require an 8.4% (0.12 × 70) area reduction to approach zero, resulting in a total area reduction of 38.4% (30 + 8.4). Applying the same reasoning to BLES, which contains approximately 35% DPPC, it would require at least 65% (100% total phospholipid, 35% DPPC) surface area reduction to expel the non-DPPC components from the monolayer. To achieve γ of zero, the remaining DPPC would have to be compressed 4.2% (35 × 0.12) of the surface area. Thus a minimum total surface area reduction of 69.2% (65 + 4.2) would be required to achieve low γ. Table 101-2 shows that the surface area reductions observed during the first quasistatic compression of films adsorbed on a CBT are considerably lower than theoretical.[129] Interpreted in terms of the classical theory, these studies suggest that SP-B and SP-C promote selective DPPC adsorption. This corresponds to a change in surface monolayer composition. However, these inferences are indirect, and the results could indicate a change in surface film organization.

Surface Tension During Film Expansion

Compression of spread DPPC monolayers at equilibrium results in a reduction in γ to near zero. However, with repeated compression and expansion cycles, greater compression ratios are required, particularly if compression is allowed to continue once low γ is attained. This results from low reinsertion of DPPC molecules into the monolayer after collapse. Addition of non-DPPC phospholipids improves respreading, although larger compression ratios are required for the squeeze-out of the non-DPPC components. However, in the absence of the low-molecular-weight hydrophobic proteins, respreading remains poor.[132,171,196-199] These observations demonstrate that SP-B and SP-C promote reinsertion of surfactant lipids. In addition, in the presence of these apoproteins, compressibility decreases during cycling. For example, CBT studies show that Curosurf or BLES films adsorb at low concentrations, requiring 50% to 60% surface area reduction to attain γ near zero during the first quasistatic compression, but approximately 20% during the fifth compression.[129,175,200] The ability of SP-B and SP-C to augment surface activity during cycling can be observed with spread monolayers, but it is more pronounced with surfactant material in excess of a single monolayer. These observations are best explained by the presence of surfactant multilayers, as discussed in the next section.

Evidence Counter to the Classical Model for Surfactant Function

The classical model argues that surfactant adsorption results in monolayers containing DPPC and non-DPPC lipids. This model suggests that repeated compression and expansion of the monolayer result in refining because of squeeze-out of fluid non-DPPC lipids, resulting in enrichment in DPPC.[107,113,201] This process would require incorporation of fresh surfactant during cycling to replace material lost by squeeze-out. The classical model readily explained observations with the Langmuir-Wilhelmy surface balance and the PBS in which repeated compression and expansion cycles led to lowering of γ to low values. The squeeze-out hypothesis was proposed to explain the original classical model when it was introduced.[107,113,201] The selective adsorption model, conversely, arose only because more recent observations with the CBT indicated that the surface activity of adsorbed films during the first compression could not be explained by the DPPC content of natural surfactant or its extracts[112,116,119,129] (see Table 101-2).

Although the classical model considers surfactant from the perspective of a single monolayer, considerable more recent experimental evidence is most readily explained in terms of functional multilayers, which can provide surfactant phospholipids to the surface monolayer.[132,159,200,202] Multilayers can be characterized as *adsorption reservoirs*, generated during film formation, and *compression reservoirs*, generated during film surface area reduction.

Adsorption Reservoirs

Figure 101-13 presents a CBT washout experiment that presents evidence for the formation of functional multilayers during surfactant adsorption.[200] A bubble was introduced into a BLES-1% SP-A (1.0 mg/mL) dispersion in saline 1.5 mmol/L calcium chloride. After adsorption to equilibrium, the CBT chamber was sealed, and the subphase was washed repeatedly to remove surfactant material not associated with the surface film. An initial quasistatic compression (see Figure 101-13, point 1) was then performed to γ approximately 1.0 mN/m. Quasistatic expansion of the bubble led to increases in γ to just above equilibrium. This γ was maintained even though the surface area was expanded well beyond the original value. Because the subphase had been depleted of surfactant, the excess material required to maintain γ near equilibrium must originate from a *surface-associated surfactant reservoir.* After relaxation, a second quasistatic compression (see Figure 101-13, point 2) was performed, followed by a second expansion. Again, γ remained near equilibrium. This also occurred with a third compression, but after the fourth maneuver, γ increased above equilibrium, indicating that the surface-associated reservoir was being depleted. Surface area reduction to attain γ near zero for each compression was 20% to 25%, although BLES contains approximately 35% DPPC. The final compressed monolayer was approximately five-fold larger than that obtained with the initial compression, a finding indicating the reservoir formed during adsorption contained functional surfactant corresponding to at least four monolayers.

Further evidence of the existence of the surface-associated multilayers that can act as surfactant reservoirs has been obtained through electron microscopy of surfactant systems in rabbit and guinea pig lung in situ[138,200] and in vitro.[203] The presence of a surface-associated reservoir has also been deduced from autoradiographic examination of Langmuir-Blodgett films from model and lipid extract surfactants and from radioactive studies on monolayers spread from adsorbed BLES films using filter paper-supported wet bridges.[204,205] These studies indicate the presence of surface-associated lipid aggregate complexes that are generated during adsorption.[206,207] Existence of a surfactant reservoir created during adsorption would serve to explain the remarkable bulk concentration dependence of surfactant observed in numerous studies.[173,175,200] For example, whereas

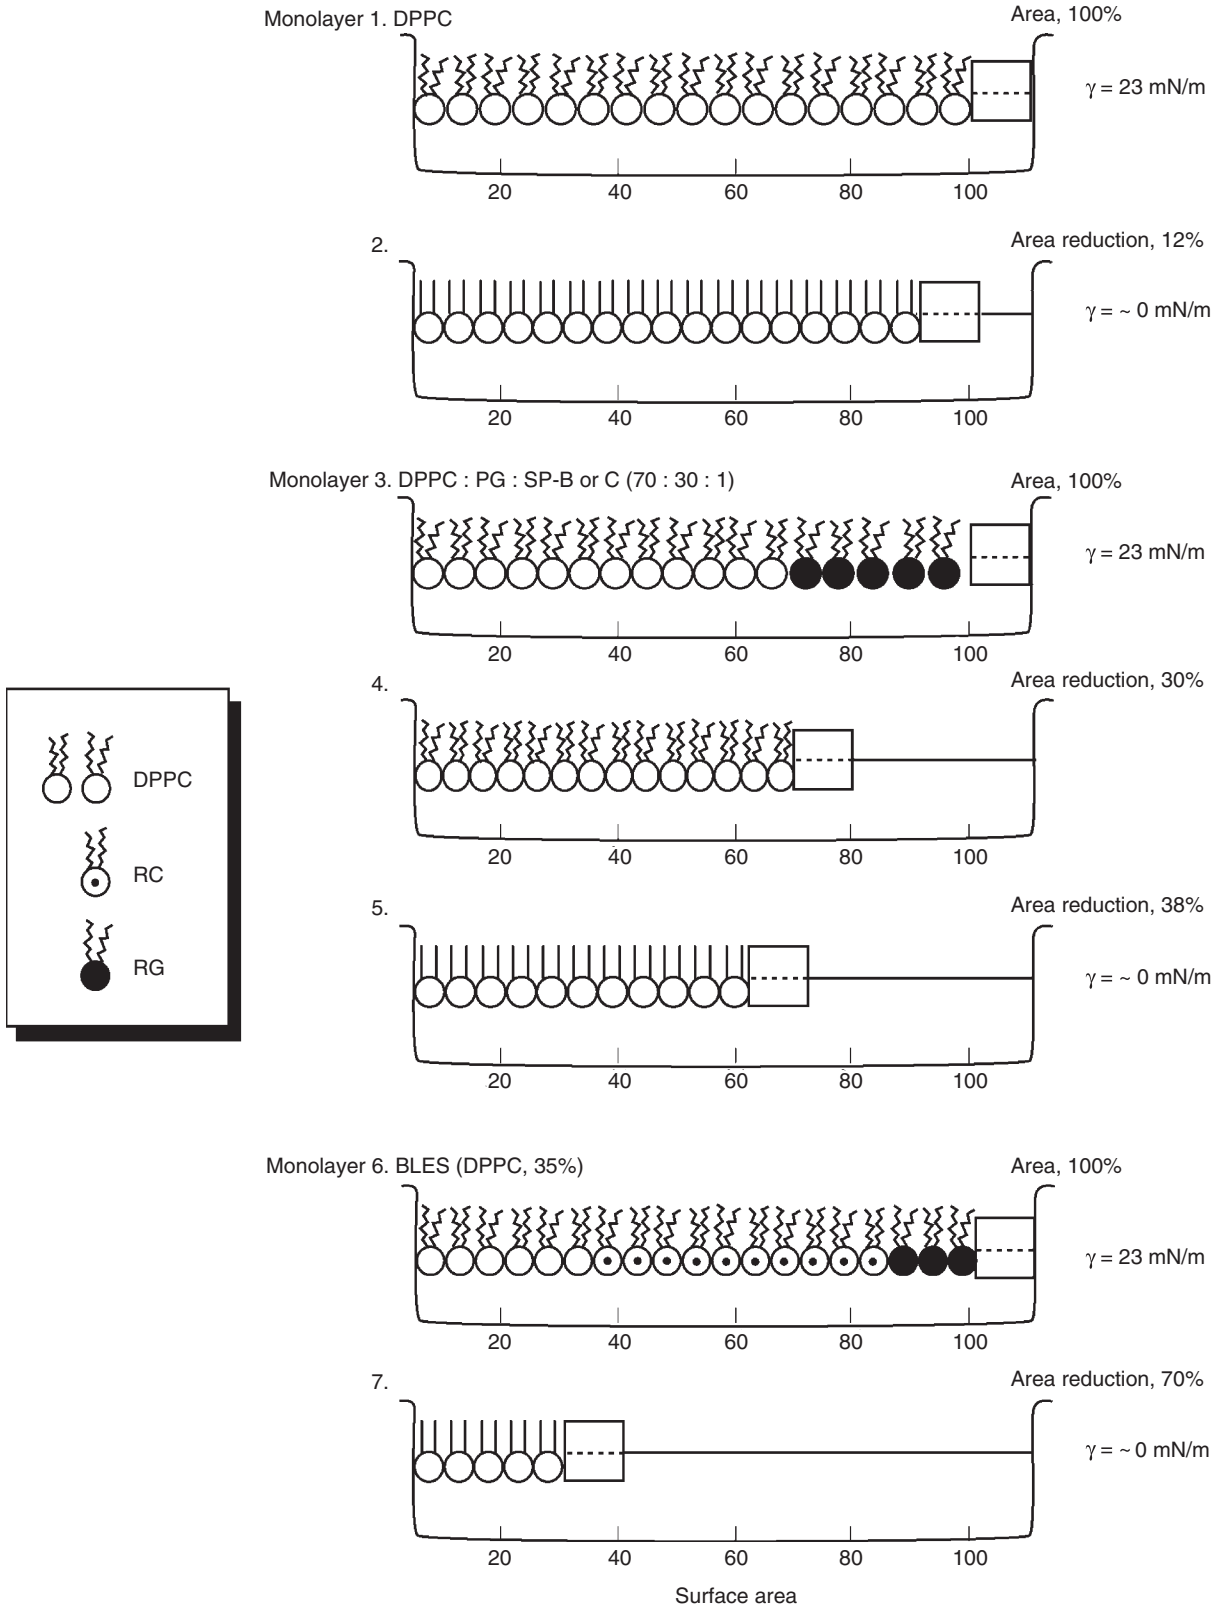

Figure 101-12 Representation of the theoretical surface area reductions required for various monolayers to reduce surface tension from approximately 23 mN/m (equilibrium) to near 0 mN/m. See text for explanation of calculations. *Monolayer 1*, Dipalmitoylphosphatidylcholine *(DPPC)* alone at equilibrium, 23 mN/m. Surface area reduction of approximately 12% leads to *monolayer 2*, which shows DPPC alone after compression to near 0 mN/m. *Monolayer 3,* DPPC:phosphatidylglycerol *(PG)* (70:30) with 1% surfactant-associated protein B *(SP-B)* or SP-C at 23 mN/m. Surface area reduction of 30% leads to *monolayer 4*, after squeeze-out of PG. Only DPPC remains. Compressing monolayer 4, an additional 12% leads to *monolayer 5*, which contains DPPC alone after squeeze-out of PG and compression to near 0 mN/m. *Monolayer 6*, Bovine lipid extract surfactant *(BLES)* at 23 mN/m. Compression of 70% leads to *monolayer 7*, showing BLES after squeeze-out of unsaturated phosphatidylcholine *(PC)* and PG and compression to near 0 mN/m. *(Modified from Possmayer F, Nag K, Capote KR, et al: Surface activity in vitro: role of surfactant proteins,* Comp Biochem Physiol A Mol Integr Physiol *129:209, 2001.)*

TABLE 101-2

Theoretical and Observed Surface Area Reductions Required to Reduce Surface Tension from Equilibrium (23 mN/m) to <2 mN/m

	SURFACE AREA REDUCTION REQUIRED (%)	
Film Composition	***Theoretical***	***Observed***
DPPC	—	12
DPPC/PG/SP-B (70:30:1)	38	20
DPPC/PG/SP-C	38	30
BLES	69	30
BLES plus SP-A	69	25

BLES, Bovine lipid extract surfactant; *DPPC,* dipalmitoylphosphatidylcholine; *PG,* phosphatidylglycerol; *SP,* surfactant-associated protein.

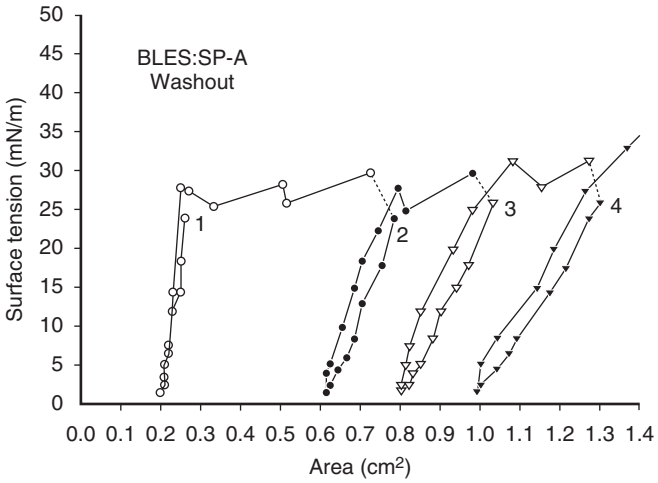

Figure 101-13 Physicochemical evidence for the adsorption surface-associated reservoir. After washing the subphase *(1),* the film *(open circles)* compressed to low tension.The bubble surface tension increases as surface area is increased but remains close to equilibrium.After a brief relaxation period *(2),* the film *(closed circles)* is compressed to low tension a second time.The bubble is again expanded, allowed to relax, and expanded a third time *(3, open triangles).* After the fourth compression, surface area expansion *(4, closed triangles)* leads to high surface tension, indicating that the surface-associated reservoir has been depleted (see text for further details). *BLES:SP-A,* Bovine lipid extract surfactant:surfactant-associated protein A. *(From Schürch S, Qanbar R, Bachofen H, Possmayer F:The surface-associated surfactant reservoir in the alveolar lining,* Biol Neonate *67:61, 1995.)*

50% to 60% surface area reduction is required to reduce γ from equilibrium to near zero during the first compression with BLES at 50 μg/mL, only 22.5 to 25% surface area reduction is required to reduce γ to near zero at bulk concentrations of 250 to 300 μg/mL. Addition of SP-A to BLES at low concentration greatly improves surface activity.[175,200,208]

Compression Reservoirs

The existence of surface-associated reservoirs, formed during film compression, that could supply phospholipid to the surface monolayer during film expansion would provide an efficient means for surfactant respreading. Evidence of such reservoirs is available from fluorescence imaging and atomic force microscopy. For example, fluorescence imaging studies reveal that compression of model systems such as DPPC:DPPG, DPPG:POPG, and DPPC:POPC:POPG results in loss of material from the surface into the bulk phase during collapse. Inclusion of either SP-B or SP-C (or synthetic analogues thereof) results in film buckling and formation of large folds or buds that extend into the subphase.[197,209-217] As the surface is expanded again, the folds are incorporated into the surface monolayer with minimal loss of material over many compression and expansion cycles. Examination of Langmuir-Blodgett films deposited under compression reveals large irregular plates divided by thin spaces with phospholipid multilayers containing protein.[189,197,212,215-218] In addition to the folds noted earlier, buds that grew into stacked bilayers have been noted, particularly with lipid extract surfactants and similar systems.[104-106,219]

Compression reservoirs that function in phospholipid reinsertion into the monolayer during film expansion not only provide a plausible function for SP-B and SP-C, but also explain why adsorbed films and films spread in excess of a single monolayer remain more surface active during cycling. SP-B and SP-C also promote uptake of phospholipid vesicles from the bulk phase.[192,193] Such uptake can occur only when γ rises above equilibrium.

Phase Transitions and the Classical Model

Further evidence incompatible with the classical model arises from fluorescence imaging studies. Dark probe-excluding regions, apparently LC domains, are observed during compression of DPPC:1% fluorescent probe on Langmuir-Wilhelmy balances (see previous section). Probe-excluding LC domains can also be observed with natural surfactant, lipid extract surfactants, and the phospholipid fraction from the calf surfactant CLSE. The classical model would imply that compression to high surface pressures (low γ) would result in nearly complete elimination of fluid probe-containing LE phase, leaving only dark LC phase in the monolayer. Fluorescence imaging studies with CLSE and porcine surfactant lipid extracts reveal probe-excluding domains that appear at γ near 60 mN/m and attain 33% to 40% total surface area at γ near 40 mN/m. However, these LC domains diminish and disappear at γ near 30 to 40 mN/m.[104,106,159,219] This behavior suggests that lateral phase separation occurs at high γs (low surface pressures), but it is followed by a loss of LE and LC phases resulting from phospholipid remixing at lower γs (higher surface pressures). This phase remixing (codissolving) can be attributed to the cholesterol present in these extracts. Cholesterol appears to serve to maintain the monolayer in a more fluid phase capable of reaching relatively (but not very) low γ. These studies provided no evidence for generalized exclusion of non-DPPC lipids leading to monolayer enrichment in DPPC as required by the classical model.

Further evidence contrary to the classical model was obtained with fluorescence studies employing BLES or the phospholipid fraction from CLSE (no cholesterol). Such films readily attain γ near zero during compression while containing less than 40% surface area probe-excluding regions.[159,220] This level of LC phase is comparable to the DPPC mole fraction. The ability of LE:LC-containing phospholipid monolayers to achieve γ of approximately zero in the presence of more than 60% LE phase is incompatible with the classical model, which would predict that only LC phase would be present at low γs.

The classical model evolved from the observations that DPPC was the only major surfactant component that could achieve and maintain surface tensions below equilibrium during monolayer compression. Such studies were normally conducted using the Langmuir-Wilhelmy balance introduced by Clements.[79] Studies by Hall's group have demonstrated that the ability to achieve γ near zero depends not only on monolayer composition but also on the rate at which the film is compressed. As stated earlier, phospholipid monolayers can be compressed dynamically to surface tensions below their equilibrium surface tensions, but above T_c, surface tension will rapidly return to equilibrium.

However, compressing POPC (T_c = −6° C) or dimyristoyl PC (DMPC) (T_c = 24.5° C) at rates of 32% of initial area/second permits such films to reduce to approximately 2 mN/m.[221,222] Furthermore, such rapidly compressed films can maintain γ below equilibrium for many minutes. Once compressed rapidly across the equilibrium γ of approximately 23 mN/m threshold, monolayers can be compressed or expanded more slowly without losing this remarkable property. Such rates are inaccessible on the Langmuir trough, which is normally compressed at approximately 3% total surface area/minute, but are readily attainable with the pulsating and captive bubble surfactometers and correspond to those in the lung. As emphasized in a later discussion, films below γ equilibrium are metastable (also true for DPPC) but remain at low tensions for periods much longer than required to stabilize the terminal air spaces during breathing or with high-frequency (fixed-volume) ventilation.

The mechanism by which spread monolayers of fluid-phase phospholipid attains this remarkable metastable state is not understood. Piknova and co-workers[159] suggested that as fluid LE monolayers are compressed beyond equilibrium, they can either collapse to three-dimensional multilayers or form a disordered phase that, although thermodynamically metastable, is kinetically trapped for long periods. A possible analogy for this kinetically trapped metastable phase may be glass, which is an amorphous (nonordered) solid. The observation that single-component fluid phospholipid monolayers can be compressed into viscous metastable phases raises the question of whether either the gel-phase lipid DPPC or surfactant apoproteins may be required in the lung. A possible explanation is that these surfactant components facilitate transformation of LE phase to the viscous state. Such an interpretation would be consistent with evidence from compression and expansion cycles as described. Regardless of the interpretation, it should be clear that the rapid compression studies provide further strong evidence against the absolute requirement for a monolayer highly enriched in gel-phase phospholipids such as DPPC, as argued by the classical model. (After tornadoes, straws are sometimes reported to be found stuck through barn boards. It thus appears that rapid motion can alter physical stiffness.)

In summary, it is evident that surfactant apoproteins play essential roles in the biophysical functions of pulmonary surfactant. These low-molecular-weight hydrophobic proteins enhance surfactant lipid adsorption so surfactant can form phospholipid films at the rates required by the lung. Observations have suggested that surfactant films can act as functional multilayers. Evidence has been obtained for both adsorption reservoirs and compression reservoirs that can provide surfactant phospholipids to the surface monolayer during film expansion. SP-B, SP-C, and SP-A plus SP-B contribute to the formation of these reservoirs, but the mechanisms involved are not clear. The classical model for surfactant function implies that, during film compression, LC regions consisting primarily of DPPC increase and coalesce as a single gel-phase monolayer at γ near zero. Fluorescence studies on porcine and calf surfactant extracts do not observe a large increase in LC phase. Rather, at a critical surface pressure, LC phase lipids appear to dissolve again (remix) with the fluid components. This behavior is not predicted by the classical model.

Other studies have demonstrated that monolayers consisting of the phospholipid fraction from calf surfactant can be compressed to low surface tensions without the anticipated large increase in LC gel phase. The observation that low surface tensions (high surface pressures) can be achieved in the presence of LE and LC phases is counter to the classical theory.

Finally, studies using CBT have shown that monolayers of fluid lipids such as DMPC and POPC can achieve γs near zero at 37° C when compressed at rapid rates that are similar to those occurring in the lung. It is suggested that when fluid monolayers are compressed slowly, they collapse. However, when compressed rapidly enough, fluid monolayers can be kinetically trapped as an amorphous solid that collapses very slowly. Such monolayers, although metastable by definition (they are below equilibrium γ), could stabilize the alveoli. The existence of such metastable monolayers is opposite to the requirement for the DPPC-enriched monolayer proposed by the classical model.

SURFACTANT INACTIVATION

In addition to surfactant deficiency, such as occurs in neonatal RDS, alveolar stability can also be compromised through surfactant inactivation. Numerous natural and synthetic materials including meconium (fetal feces), lysophospholipids (produced by phospholipase A_2), pulmonary edema fluid, and nonsurfactant proteins can inhibit surfactant function in vitro.[11,49,155,223-230] Although the importance of surfactant inhibition in acute RDS is recognized, the mechanisms are not well understood. Considerable effort has been devoted toward examining the effects of serum proteins on surfactant function. Acute lung injury arising from certain insults results in disruption of the capillary-endothelial integrity, leading to increased protein influx into alveolar spaces.[11,71,230] The enhanced permeability and increased protein oncotic pressure antagonize the efforts of the alveolar epithelium to remove fluid from the alveoli. In addition, by inhibiting surfactant function, serum proteins increase the hydrostatic pressure gradient across the alveolar surface, possibly further promoting pulmonary edema. Perhaps not surprisingly, wholly artificial surfactants lacking surfactant apoproteins are highly susceptible to protein inhibition.[155,231,232] The ability of several clinical preparations to resist protein inhibition correlates with their SP-B content.[233-235] SP-C–based surfactant preparations show resistance to meconium.[224]

SP-A is not present in the lipid extract surfactants used clinically. However, addition of SP-A to lipid extract surfactant effectively reverses in vitro inhibition resulting from serum proteins.[174,236] SP-A does not block surfactant inhibition resulting from nonprotein inhibitors such as lysophospholipids. Lysophospholipids can sensitize lipid extract surfactant to inhibition by proteins.[228] SP-A deletion knockout studies demonstrate that SP-A is not essential for normal lung function. Evidence indicates that this collectin can play a role in reversing surfactant inhibition by proteins in vivo[237-240] as well as in vitro, but this remains controversial.

Surfactant inactivation varies with both the particular serum protein examined and the surfactant preparation employed. This finding indicates that protein inactivation could involve several mechanisms. Some proteins— albumin, for example— appear to inhibit surfactant by adsorbing rapidly, thereby monopolizing the air-water interface. Surfactant inhibition is readily reversed by increasing the concentration of lipid extract surfactant. This reversal of protein inhibition is nonstoichiometric and cannot be readily explained by competition.[230,241] Albumin binds free fatty acids, but whether this property is involved in surfactant inhibition is not known. Studies indicate albumin interferes with surfactant respreading from compression reservoirs.[213] However, this interference and the ability of albumin to compete with surfactant for the air-water interface only occur at surface tensions higher than those observed in the lung.[121,124,133] A possible explanation is that several inhibiting mechanisms occur during acute lung injury and acute RDS. For example, lyso-PC at low concentration does not inhibit surfactant but can sensitize it to protein inhibition.[228,242] The C-reactive peptide, an acute phase protein, can bind the phosphorylcholine-head groups of PC and DPPC.[243] Inhibition by C-reactive protein can be reversed by phosphorylcholine, which is water soluble. The reason that C-reactive protein can inhibit surfactant, whereas SP-A, which also binds DPPC, blocks protein inhibition, is not understood.

Fibrinogen and fibrin monomers are particularly effective in inactivating surfactant.[11,229] These proteins appear to inactivate surfactant by sequestering surfactant constituents, such as surfactant apoproteins, in the hyaline membranes characteristic of respiratory distress.[244-246] Procoagulant activity increases in RDS and acute RDS. The ability of the lung to remove fibrin-based clots is also compromised in acute RDS. These observations further emphasize the complexity of the relationship between lung injury and surfactant inactivation. Studies in vitro have reported surfactant inhibition by proteins and meconium can be reversed by high-molecular-weight dextran[247] or polyethylene glycol.[248] Attempts to overcome surfactant inactivation in vivo have been variable.[249,250] Surfactant is also inactivated by oxidative stress. Superoxide and hydroxyl radicals likely react with surfactant lipids and SPs.[251-253] SPs can also be affected by nitration.[254,255] SP-A (and SP-D) has been reported to block lipid oxidation by free radicals.[252] In addition, SP-A can reverse the inhibitory effects of surfactant oxidation.[256]

Artificial surfactant preparations lacking surfactant apoproteins are susceptible to inactivation by serum proteins. Addition of the low-molecular-weight hydrophobic proteins, particularly SP-B, results in resistance to inhibition by serum proteins. SP-A is capable of resisting surfactant inactivation by serum proteins in vitro, and this may be important in vivo. SP-A may also be important in preventing and reversing surfactant inactivation during oxidative stress.

CONCLUSION

The physicochemical principles governing surfactant function reviewed in this chapter provide insight into the design of exogenous surfactants for clinical use. It is apparent that different optimizing strategies will be required to develop exogenous surfactants for treating neonatal and adult respiratory distress. However, the precise requirements for acute lung injury and acute RDS must still be defined.

It is clear an effective exogenous surfactant must adsorb rapidly at 37° C and spread quickly to form a surface film with an equilibrium surface tension of approximately 23 mN/m. Excellent spreading within the terminal air spaces is important for exogenous surfactant to ensure adequate distribution.[257] In addition to rapid adsorption and good spreading, exogenous surfactants should achieve low surface tensions with the dynamic compressions produced during normal breathing or mechanical ventilation. The highest γs that can be attained during inspiration and expiration while still compatible with adequate lung function are not known.[121] Effective exogenous surfactants must resist inactivation by serum proteins, other inhibitors, and oxidative stress. This is particularly true for acute lung injury and acute RDS. Therapeutic surfactants should also be resistant to film overcompression at low surface tensions. In addition, considerable benefit would accrue if the exogenous preparations could resist conversion from the highly active LA subtype to the poorly active SA form. Exogenous surfactants could also contribute by modulating conversion of endogenous surfactant, thereby maintaining a high proportion in the active LA form.

The artificial synthetic surfactants used clinically can become "activated" in the lung through interaction with endogenous surfactant apoproteins.[1,54] This interaction should be optimized in the design of exogenous preparations. The ability of exogenous surfactant to act as "substrate" for recycling into lamellar bodies and secretion as "new" surfactant must also be considered. It is thought that recycling of artificial surfactant components and mixing with endogenous surfactant apoproteins explain their effectiveness in RDS. Their inability to act directly may explain why artificial surfactants have not proven effective with acute RDS. The use of synthetic lipid molecules that resist degradation by secreted phospholipids or cellular catabolic systems could prove useful.[147] However, such lipid analogues must be recycled appropriately and should not accumulate within cells.

It has become evident that peptides or peptoids that can mimic the activities of specific surfactant apoproteins are required for exogenous treatment, especially for the treatment of acute RDS.[39,258-261] Therefore this chapter closes with a recapitulation of the nature of the surfactant apoproteins and emphasizes their proposed roles in surfactant function. SP-A by itself has little effect on phospholipid adsorption. However, SP-A markedly enhances the phospholipid adsorption observed in the presence of SP-B and calcium.[92,166,208,236] In the presence of SP-B, SP-A counteracts serum protein inhibition of surfactant function. SP-A preferentially binds gel-phase lipids demonstrating a very high preference for DPPC.[27,28] Although only small amounts are present in lamellar bodies, SP-A is an important constituent of tubular myelin. Tubular myelin structures can be formed in vitro with DPPC, PG, SP-A, SP-B, and calcium.[179,183] Its ability to interact with DPPC would explain the role of SP-A in maintaining the integrity of LAs. SP-A also could contribute to formation of a surface-associated surfactant reservoir.[200]

SP-A and SP-D are members of the collectin superfamily and have important roles in the innate host defense system.[21,22,29,31,32] In vitro studies indicate that SP-A can play an important role in regulating alveolar levels of surfactant lipids, but this is controversial because SP-A–deficient knockout mice have normal surfactant levels and turnover.

SP-B is a low-molecular-weight hydrophobic protein that is an important constituent of the lipid extract surfactant used clinically.[24,35,132] SP-B deficiencies resulting from gene disruption in mice or human SP-B mutations are associated with neonatal pulmonary complications and death.[10,40] SP-B enhances the adsorption of surfactant lipids. In addition to promoting adsorption to clean surfaces, SP-B present in partially filled monolayers can assist in the "incorporation" of phospholipid from vesicles in the subphase. SP-B can stabilize surface monolayers at low surface tensions hindering the return to the equilibrium surface tension of 23 mN/m. With DPPC-PG, SP-A, and calcium, SP-B is involved in the formation of tubular myelin in vitro. The ability of SP-B to promote hemifusion of phospholipid vesicles indicates that SP-B may be responsible for forming the lattice corners of tubular myelin. SP-B contributes to the formation of adsorption and compression reservoirs.

Like SP-B, SP-C is present in the lipid extract surfactants used clinically.[42] Recombinant SP-C is the only apoprotein present in the synthetic SP-C-containing surfactant Ventacute. SP-C enhances phospholipid adsorption. Surface SP-C can also promote the uptake of phospholipid vesicles into the surface film until equilibrium is attained. SP-C contributes to the mechanical stability of surface films compressed to low surface tensions. SP-C also promotes the uptake of phospholipids from a surface-associated surfactant reservoir during monolayer expansion. This property appears to resist the decrease in surface activity of surfactant films subjected to repeated overcompression at low surface tensions. The palmitoyl groups esterified to N-terminal cysteines of SP-C appear to be important for these latter functions.

This chapter reviews the physicochemical functions of pulmonary surfactant with emphasis on the SPs. Although a great deal has been learned about the nature and properties of these apoproteins, further experimentation is required to confirm some of the suggested mechanisms proposed in this chapter. A more complete understanding of these mechanisms is clearly essential for producing optimal surfactants for clinical application.

Structure of Alveolar Epithelial Cells and the Surface Layer During Development

This chapter describes the developmental anatomy of the alveolar epithelium and the alveolar interfacial (surfactant) layer. When possible, it includes data from human studies, but the fundamental process of alveolar epithelial maturation appears to be common to most mammals, and the chapter also draws freely from animal data. Several developmental anomalies affect in utero development of the pulmonary epithelium, but comprehensive discussion of them is beyond the scope of this chapter (see Stocker[1] and Chapter 78).

HISTORICAL PERSPECTIVE

In 1953, Low resolved a riddle of the lung: Are alveolar capillaries exposed directly to alveolar air? With the new technology of electron microscopy, he conclusively demonstrated the presence of a thin alveolar membrane consisting of capillary endothelium, lung interstitium, and a continuous covering of (type I) epithelium (Figure 102-1).[2] Even before Low's anatomic work, physiologic considerations predicted the presence of a surface-active alveolar lining layer. Terry[3] had proposed, in 1926, that a thin film overlaid the alveolar epithelium. By 1929, von Neergaard's experiments[4] had proved that surface forces had a profound influence on the mechanical properties of lungs, and evidence mounted during the next 30 years that surface tension at the alveolar air-liquid interface must be extraordinarily low,[5] especially at low lung volumes. Macklin[6] hypothesized that the alveolar lining film functioned to remove particulates, maintain a favorable surface tension, protect the alveolar septa from desiccation, and suppress invading microorganisms. Early histologists had recognized the granular pneumonocyte (now known as the type II cell) as a lung secretory cell, and Macklin correctly proposed that it was the source of an alveolar lining layer. He speculated that ". . . [the film's] mechanism of production insured a constancy of volume, thickness, weight and solid content. . . ."[6] Despite the soundness of the physiologic experiments, the morphology of the surfactant layer remained controversial because it could not be demonstrated microscopically. Light microscopy was unable to resolve whether the observed carbohydrate-rich lining of alveoli was due to a mucoid surface layer or to cell membranes. Electron microscopy initially failed because aqueous solutions and organic solvents used for tissue processing washed away the lipid-rich lining layer. By using perfusion fixation methods, Weibel and Gil[7] were finally able to demonstrate remnants of the interfacial film in situ. Later refinements[8] showed details of an unbroken superficial alveolar lining, probably a pure phospholipid monolayer, on top of an aqueous hypophase containing reserves of newly secreted material and pools of surfactant desorbed from the air-liquid interface (Figure 102-2).

IN UTERO DEVELOPMENT OF THE ALVEOLAR EPITHELIUM

The mammalian lung begins as a tiny foregut pouch formed at the level of the pharynx. During early organogenesis, the lung anlage consists of clumps of endodermally derived, multipotent, columnar to cuboidal epithelial cells, which are surrounded by mesenchyme. Important developmental signals are exchanged between the mesenchyme and the epithelium. During the lung bud stage, direct contact of cardiac mesoderm with foregut ventral endoderm is required to induce

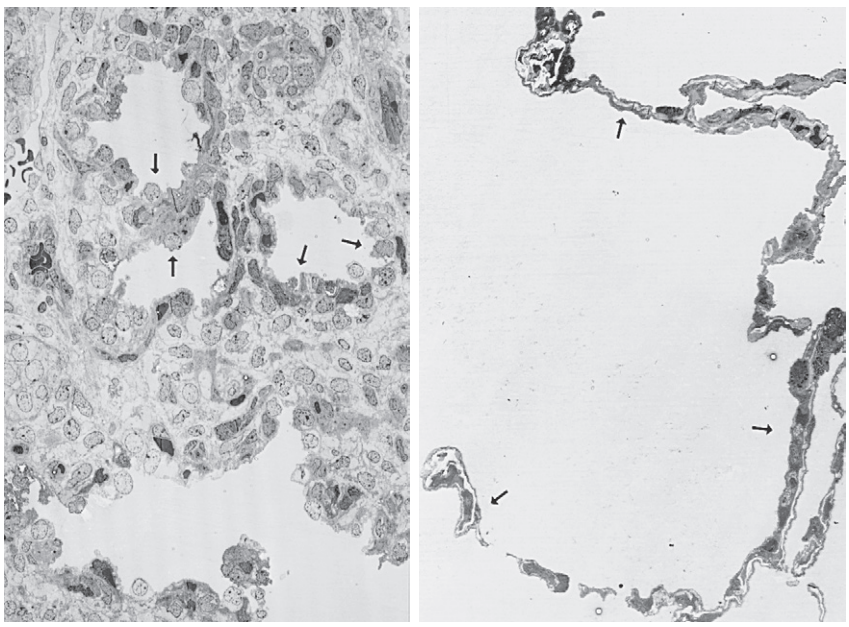

Figure 102-1 Electron micrographs of fetal (week 25, *left panel*) and adult human lungs *(right panel)* at equal magnification. The dramatic expansion of the air spaces, thinning of the interstitium, and the extreme thinning of the epithelial cells *(arrows)* are some of the critical developmental changes enabling efficient gas exchange.

lung-specific genes.[9] Tissue recombination experiments using slightly later embryos have shown that branching morphogenesis of the bronchial tree is dependent on surrounding mesenchyme and that regional-specific epithelial cytodifferentiation is also dependent on intimate contact with its corresponding mesenchyme[10,11] (see Chapter 78).

The stages of human lung development[12] (see Chapter 78) serve as a useful framework to describe important steps in epithelial cell development (Figure 102-3). The *glandular* (or pseudoglandular) stage of human lung development ends at 16 weeks gestation. At this time, conducting airways to the level of the terminal bronchioles are surrounded by a loose investment of mesenchyme, which includes blood vessels. The airways are lined with multipotent, glycogen-rich, and morphologically undifferentiated epithelial cells that have a columnar to cuboidal shape. Sixteen weeks of gestation marks the onset of the *canalicular* period, during which the respiratory bronchioles and alveolar ducts of the gas exchange region of the lung are formed. The mesenchyme becomes more condensed, blood vessels proliferate, and the epithelium overlying capillaries thins, which is the hallmark of type I epithelial cell differentiation.

After 24 to 28 weeks, the *saccular* period begins. Primitive forms of the future alveoli are present (hence the term *saccular*) and are lined by squamous type I cells and cuboidal type II cells. At approximately 25 weeks gestation, the human lung has the potential to support gas exchange, although successful unassisted ventilation is unlikely because the lung and its surfactant system are still underdeveloped.

Significant species differences exist in the timing of alveolar epithelial cell differentiation. In laboratory rodents and in lambs, the first appearance of type II cell lamellar bodies occurs at approximately 80% of gestation, whereas in humans their appearance at 24 weeks marks 60% of gestation. The most remarkable maturational timing belongs to the marsupials, in which type II cell lamellar bodies appear in time for the marsupial's precocious transition to air breathing, often occurring at less than 20% of gestation when lung development has not progressed beyond the canalicular stage.[13] Lamellar bodies appear in female offspring slightly earlier than they appear in males, partly because androgens exert an inhibitory influence on alveolar epithelial maturation.[14] Molecular mechanisms that govern epithelial phenotype have been identified (reviewed by Mendelson[15] and Warburton and colleagues,[16] and see Chapter 81). Human type II cells at 24 weeks gestation or rat type II cells at 19 days of gestation (term = 21 days) can be recognized morphologically by their cuboidal shape, apical intercellular junctions, microvilli, and a few lamellar bodies. They have a large and dispersed cytoplasmic pool of glycogen that displaces organelles toward the cell periphery. Glycogen likely serves as a precursor for the production of surfactant phospholipids[17] (also see Chapter 103). The cells are rich in the organelles of synthesis, such as granular endoplasmic reticulum, polyribosomes, and the Golgi apparatus with its associated vesicles. Impressive changes in type II cell morphology occur during late gestation, with a rapid loss

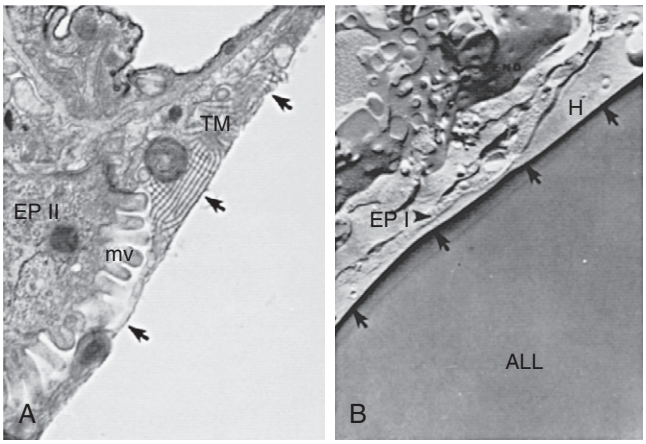

Figure 102-2 A, Electron micrograph of a perfusion-fixed adult rat lung. A type II cell *(EP II)* can be seen with microvilli *(mv),* and the alveolar lining layer is visible *(arrows)*. Lamellar forms *(L)* are present in the hypophase fluid, and tubular myelin *(TM)* is in contact with the surface. **B,** Freeze fracture micrograph, en face view, of the lining layer *(ALL),* hypophase fluid *(H),* and a type I cell *(EP I). Figure 102-3 A highly schematized illustration of the light microscopic appearance of human lung during the glandular **(A, B)**, canalicular **(C, D)**, and saccular **(E, F)** stages of in utero development. Undifferentiated columnar cells of the early bronchi **(B)** rest on a basal lamina, which has been emphasized. Mesenchymal cells and capillaries are present below the basal lamina. **D** shows that the epithelium overlying proliferating blood vessels thins to a squamous type I morphology and that the most distal cells retain a cuboidal shape. At the saccular stage **(E, F)**, thinner septa are lined by differentiated type I and type II cells. The low- and high-magnification drawings are shown at approximately the same magnification in each panel.

of the glycogen pool and proliferation of the cellular structures used for surfactant production and secretion (Figure 102-4).

Biochemical markers are valuable in the study of lung development and have been used to study cellular parental lineage and the timing of cellular differentiation of the lung's distal epithelium. Wuenschell and co-workers[18] demonstrated epithelial coexpression of markers characteristic of neuroendocrine cells, Clara cells, and type II cells during the glandular stage of lung development when only conducting airways were present. Later, these markers were restricted to their respective cell lineages. The early expression of the Clara cell marker secretoglobin 1A1 (SCGB1A1, also known as Clara cell-specific protein and sometimes abbreviated CCSP or CC10) or the type II cell marker surfactant protein C (SFTPC) enables the generation of triple transgenic mice with inducible genetic modifications of specific populations of lung epithelial cells.[19,20] These mice have revealed cell lineage patterns, and this approach has general applicability as a research tool for inducible, lung epithelial-specific genetic manipulation in mice.

Williams and co-workers[21] described a monoclonal antibody directed against a surface marker of type I cells, T1α. Their studies demonstrated expression of T1α on distal bronchial epithelial cells early during development, when no squamous cells and only cuboidal cells were present. This finding suggests a direct lineage of the early saccular epithelium to type I cells in addition to the more accepted transformation of type II to type I epithelial cells. Genetic deletion of T1α inhibited type I cell differentiation and enhanced epithelial and mesenchymal cell proliferation resulting in a neonatal lethal phenotype.[22] Additional type I cell markers (Table 102-1 and reviewed by Williams[23]) include the water channel aquaporin 5 and the epithelial sodium channel, indicating a likely role for type I cells in alveolar fluid homeostasis (see Chapter 82).

Type II cells are considered the usual precursors of type I cells both during development and during repair of the injured epithelium in adults.[24,25] Before the identification of specific surface antigens, morphology was the principal method for classifying type I cells, which cover more than 90% of the adult lung alveolar surface area.[26] The cytoplasm of type I cells is so thin that most organelles appear to be clustered within the perinuclear region. The volume of a type I cell is approximately five times greater than that of a type II cell, consisting mainly of cytoplasm. Although mitochondria or rough endoplasmic reticulum content is reduced per unit volume of type I cell cytoplasm, the absolute volume of organelles per cell is equivalent to that of type II cells.[27]

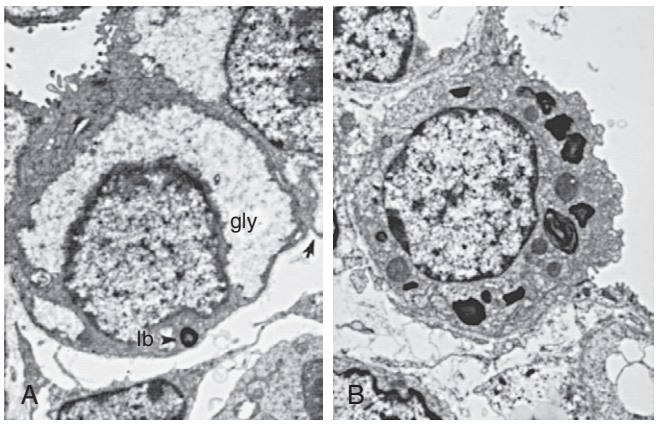

Figure 102-4 Electron micrographs of rat lung illustrating type II cells during development. The earliest morphologically recognizable type II cell **(A)** has large pools of glycogen *(gly)* and small lamellar bodies *(lb)*. A foot process *(arrow)* can be seen perforating the basement membrane. At the time of birth **(B)**, the type II cell undergoes a rapid depletion of glycogen and acquires many lamellar bodies.

INTRACELLULAR METABOLISM OF SURFACTANT

Details of the biochemistry and biosynthesis of surfactant lipids and the four surfactant-related proteins are given in Chapters 100, 101, and 103. De novo lipid biosynthesis occurring in the endoplasmic reticulum of type II cells has been demonstrated by in vivo injection of tritiated choline. After surfactant lipids are synthesized in the endoplasmic reticulum, they are transported to lamellar bodies. Early autoradiographic studies demonstrated that [^{3}H]choline radiolabel appears in multivesicular bodies after the endoplasmic reticulum but before it is found in lamellar bodies.[28] Thus morphologic and biochemical evidence places the multivesicular body in the pathway leading to lamellar body genesis, yet its role remains poorly understood.[29] Two morphologic types of multivesicular bodies are visible in type II cells: one with vesicles plus an electron-lucent background and another composed of vesicles within an electron-dense matrix (Figure 102-5). An intermediate, possibly immature form of lamellar bodies, termed the composite body, contains both lamellae and vesicles. Mature lamellar bodies do not contain vesicles but have a limiting membrane, a thin rim of granular material, many phospholipid-rich lamellae, and often a central core of granular material (Figure 102-6). (see also Figure 102-4.)

Lamellar bodies belong to a family of lysosome-related organelles, also including platelet dense granules and melanosomes, that are affected in Hermansky-Pudlak syndrome, a genetically heterogeneous condition, the diathesis of which includes lamellar body abnormalities and interstitial lung disease (see Online Mendelian Inheritance in Man, http://www.ncbi.nlm.nih.gov/omim/203300). Mutations in Hermansky-Pudlak syndrome, and in its animal models,[30] alter biogenesis, trafficking, secretion, or reuptake pathways regulating homeostasis of lysosome-related organelles.

Pathways of protein biosynthesis and cellular packaging by type II cells have been determined and appear to be similar to those noted in other cell types, with the exception of a possible synthetic, rather than degradation, role for the multivesicular body.[28] Proteins for export, including surfactant apoproteins, are synthesized in the endoplasmic reticulum, and several studies indicate extensive posttranslational protein modifications in the *trans*-Golgi.[28,31,32]

Biochemical studies indicate extensive uptake and recycling of surfactant lipid and protein by type II cells.[33,34] Morphologic descriptions of recycling pathways suggest that endocytosed components are directed into lamellar bodies, presumably for resecretion. Multivesicular bodies appear to be part of the endocytic pathway and may function as a nexus between synthetic, recycling, and degradation systems.[35] Electron-lucent multivesicular bodies are the first structures to receive freshly

TABLE 102-1

Selected Alveolar Epithelial Cell Markers, Their Function, and Knockout Phenotype

	Marker	Function	Knockout
Type I cell	T1α	Unknown	Dysmorphic alveoli
	ENaC	Na^+ transport	Alveolar flooding
	AQP5	H_2O transport	No phenotype
Type II cell	SP-A	Surfactant	Innate immunity
	SP-B	Surfactant	Lethal at birth
	SP-C	Surfactant	Interstitial fibrosis
	SP-D	Surfactant	Lipid storage, emphysema

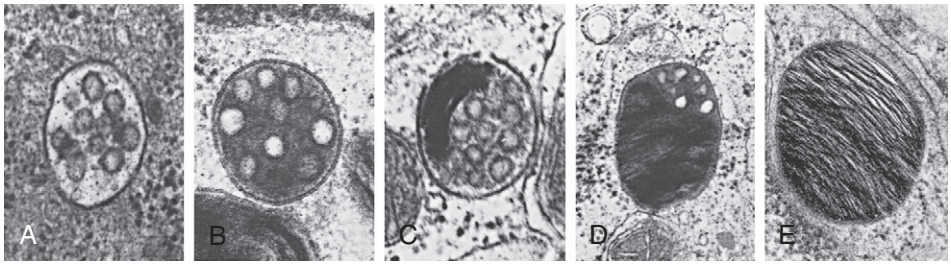

Figure 102-5 Electron micrographs of multivesicular bodies **(A, B)** and composite forms **(C, D)** from rat lung type II cells. The mature lamellar body **(E)** contains no vesicles. The magnifications vary, multivesicular bodies are approximately 0.2 μm, composite forms are approximately 0.5 μm, and lamellar bodies average approximately 1 μm in diameter. *(From Young SL, Fram EK, Craig BL: Three-dimensional reconstruction and quantitative analysis of rat lung type II cells: a computer-based study,* Am J Anat *174:1-14, 1985.)*

endocytosed membrane markers such as cationic ferritin or lectins.[29] About 30 minutes later, the markers are found within lamellar bodies, the mature secretory and storage granules of the type II cells. Autoradiographic studies[35,36] of radiolabeled lipid and surfactant protein instilled into rat lungs revealed recycling of both components, although lipid and protein were differently localized to electron-dense (protein) and electron-lucent (lipid) multivesicular bodies, and lamellar bodies later received both labels.

ORGANIZATION OF THE TYPE II CELL DURING DEVELOPMENT

Three-dimensional views of type II cells obtained from rats from gestational day 20 to adulthood demonstrate dynamic spatial reorganization of organelles during differentiation and maturation. At day 20, composite bodies, which may represent immature lamellar bodies, and a few mature lamellar bodies were localized to the basal side of the cell. Later in life, lamellar bodies increased and were distributed throughout the cell.[37] Composite forms were polarized toward the basal aspect, away from the alveolar air border. Composite body number peaked at the time of the rapid appearance of lamellar bodies, around the time of birth in rats, consistent with their putative role as lamellar body precursors.[28]

GESTATIONAL CHANGES IN ALVEOLAR BASAL LAMINA

The basal lamina influences overlying epithelial cells and is likely an important mediator of epithelial-mesenchymal interactions. On gestational day 19 in rats, the basal lamina is continuous, but, as cellular maturation proceeds, type II cells extend cytoplasmic foot processes, which become closely apposed to interstitial lipofibroblasts, through interruptions of the basal lamina (see Figure 102-4).[38-40] Foot processes increase during late gestation and in the early postnatal period, in parallel with increasing cellular lipid synthesis and cytodifferentiation. Steroids accelerate foot process appearance and enhance type II cell differentiation and surfactant lipid and apoprotein synthesis. Foot processes rapidly decrease after birth but reappear during repair of the injured alveolar epithelium in human adults.[41] These observations imply that foot processes are a platform for epithelial-mesenchymal communication.

The basal lamina underlying the alveolar epithelium in adults is polyanionic.[39] The anionicity of the basal lamina decreases with increasing gestational age in rats, and a shift of anionic sites takes place from the interstitial side of the basement membrane to the epithelial side of the basement membrane.[39] The basal lamina is more anionic beneath type I than type II cells. The biochemical composition of the alveolar basal lamina varies between species and as a function of development.[42] The causes and molecular details of alveolar basal lamina variation are largely unknown but are likely important in view of the substantial effects of different substrates on type II cell differentiation in vitro.[42-44]

Figure 102-6 Freeze fracture of rat lung type II cell lamellar body. The folding of the lamellae is seen at the *arrows. (From Williams MC: Ultrastructure of tubular myelin and lamellar bodies in fast-frozen adult rat lung,* Exp Lung Res *4:37, 1982.)*

BIRTH AND THE TRANSITION TO AIR BREATHING

Secretion of surfactant begins in utero, and serial analysis of amniotic fluid reflects increasing production of surfactant lipids and apoproteins, which are released into fetal alveoli (saccules) and are carried out of the lung by evolving lung liquid.

Immediately after birth, the lung must function as the organ of gas exchange, and dramatic events convert the newborn lung from fluid filled to gas filled in moments. Fluid adsorption and surfactant production are two major tasks for the alveolar, and possibly the bronchiolar, epithelium, and both must occur to achieve normal gas exchange after birth. Fluid adsorption from the fetal alveolar space begins in early labor and is augmented by adrenergic hormones.[45] Pathways of solute and fluid transport are being clarified by transporter expression studies and testing of their function in vitro (Kemp and colleagues[46] and see Chapter 82). There are few morphologic correlates of fluid transport across the alveolar epithelium, although ultrastructural studies suggest the possibility of a paracellular route through cell junctions, a transcellular route via the endocytic vesicles of type I cells, or a basolateral exit in which lung fluid is transported by alveolar epithelial cells or by Clara cells.[47]

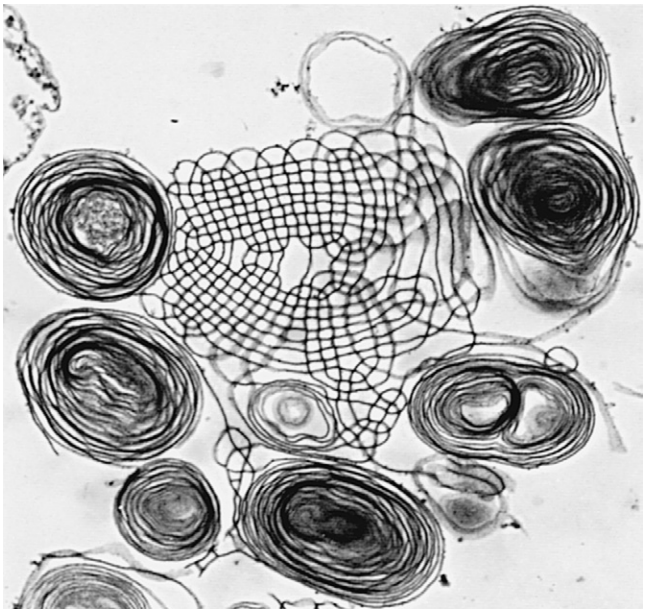

Figure 102-8 Transmission electron micrograph of lamellar bodies forming tubular myelin in the (fluid-filled) air space of a fetal rat.

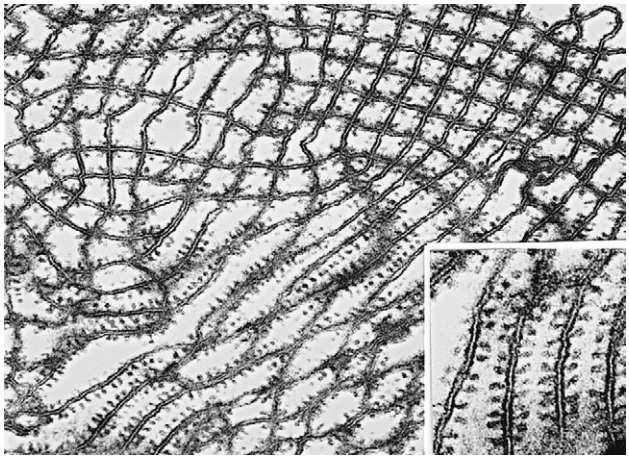

Figure 102-9 Transmission electron micrograph of tubular myelin. The regularly spaced globular profiles on short stalks that decorate the lipid bilayers are probably SP-A (*inset* shows a section parallel to the tubular structure at higher magnification). *(Courtesy C. Kuhn III, MD.)*

At term, the newborn rat lung has two times as many type II cells per gram of dry tissue as the adult lung, and each type II cell contains approximately half the adult volume of lamellar bodies. At birth, or at any time during the postnatal period in normal animals, intracellular lamellar body pools do not become depleted.[48,49] However, alveolar surfactant lipid pools increase substantially, representing accumulation of newly synthesized surfactant.[49] Thus flux through the system must be dramatically increased.[50]

Surfactant exists in several recognizable morphologic forms, although technical concerns over lipid preservation create potential artifacts that make quantitation challenging. The best-recognized form of surfactant is the intracellular lamellar body. (See also Figures 102-4 and 102-5.) The characteristic lamellae likely represent a large phospholipid bilayer sheet, draped and folded to appear almost circular in some profiles. Freeze fracture, which does not fix or extract lipids, demonstrates complete filling of the lamellar body with lamellae, suggesting that large globular proteins are not embedded in the lipid membranes within the granule (Figure 102-6). Lamellar bodies have a limiting outer bilayer membrane, the components of which are becoming better defined. The lipid-transporting adenosine triphosphate binding cassette (ABC) superfamily member ABCA3 is localized to the lamellar body outer membrane, and mutation of ABCA3 leads to fatal neonatal respiratory distress.[51] Although there are some variations, lamellar bodies contain a thin rim of granular material beneath the bounding membrane plus pools of granular material within a central core. A comprehensive view of lamellar body subcompartment biochemical composition does not yet exist, although the lamellae probably represent lipid and the core material contains protein and enzyme activities, such as acid phosphatase. The presence of acid phosphatase is consistent with the lamellar body being in the family of lysosome-related organelles. Surfactant proteins are localized to lamellar body granular cores and to type II cell cytoplasmic vesicles.[52]

THE SECRETORY EVENT

During exocytosis of lung surfactant (reviewed by Dietl and colleagues[53]), the limiting membrane of the lamellar body fuses with the apical plasma membrane of the type II cell, and a dense band of F-actin forms at the cytoplasmic face of the lamellar body being secreted[54] (Figure 102-7). Between 15 and 50 lamellar bodies are secreted per rat type II cell per hour, although the cell is capable of much faster secretion after β-adrenergic stimulation.[55,56] The freshly secreted lamellar body, stripped of its surrounding membrane, enters the acidic, calcium-rich alveolar hypophase liquid.[57] A series of morphologic transformations occurs within a few hundred milliseconds by unknown, but presumably spontaneous, mechanisms. Several lamellar bodies (from a few to at least 24) contribute closed tubular sheets of membranous material to the lung-specific structure known as tubular myelin (Figure 102-8). This unique and highly ordered array has an absolute requirement for calcium ions and is reversibly disassembled by ethylene glycol tetraacetic acid.[58] Electron micrographs of tubular myelin reveal regularly spaced small globular profiles on short stalks ("lollipops") decorating the lipid bilayers (Figure 102-9). These images are consistent with rotary

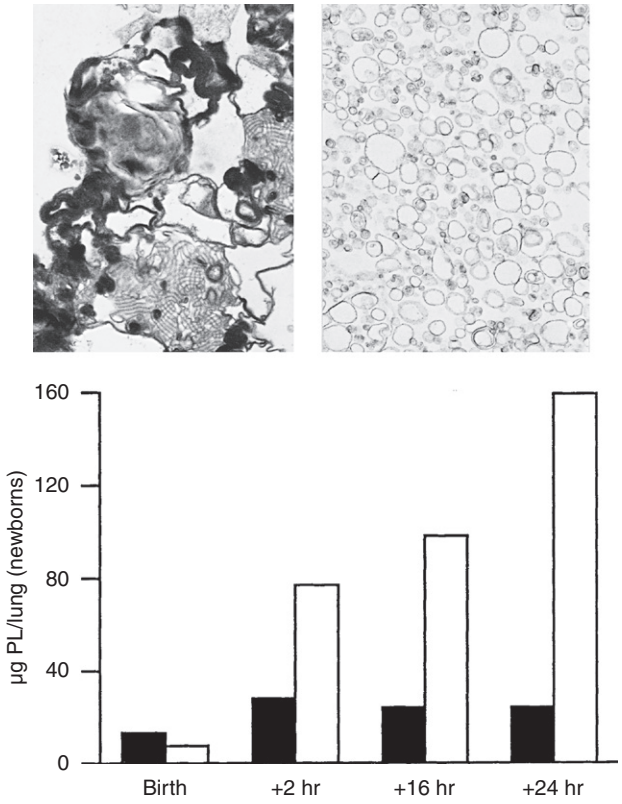

Figure 102-10 The onset of air breathing at birth produces large changes in the alveolar pool of phospholipids.The electron micrographs show the highly aggregated forms of newly secreted surfactant *(upper left panel)* and the vesicular forms that are probably spent surfactant *(upper right panel)*.The amount of phospholipid in each fraction is shown in the bar graph with an equal amount of aggregated *(dark bars)* and vesicular forms *(open bars)* at birth to a marked increase in the vesicular forms after a few hours of air breathing. *(From Spain CL, Silbajoris R, Young SL:Alterations of surfactant pools in fetal and newborn rat lungs,* Pediatr Res *21:5, 1987.)*

shadowing images of pure surfactant protein A (SP-A) oligomers,[59] and immunolocalization suggests that SP-A is localized at the "corners" of tubular myelin.[60] Reconstitution experiments also reveal lollipop decorations of phospholipid membranes when SP-A is added to phospholipid mixtures. Fully developed tubes with 90-µm intersecting membranes can be generated by addition of SP-A plus SP-B to phospholipid mixtures.[61]

ESTABLISHMENT OF THE AIR-LIQUID INTERFACE

Freeze fracture and transmission electron micrographic images are in agreement about the structure of tubular myelin, and serial section reconstructions indicate that tubular myelin collections may contain uninterrupted tubes greater than 12 µm in length.[62] Large tubular myelin aggregates are easily sedimented at low centrifugal force. Tubular myelin is an unstable form of surfactant that may be specialized to enhance lipid insertion into the alveolar interfacial film. Rapid adsorption rates of lipids from tubular myelin likely permit insertion of saturated phospholipids into the interfacial film within a single breath cycle. Lipid insertion into the surfactant film uses a mechanism involving direct contact of the tubules with the surface layer, and at least one of the apoproteins, SP-A, is dissociated from the lipid during adsorption.[63,64]

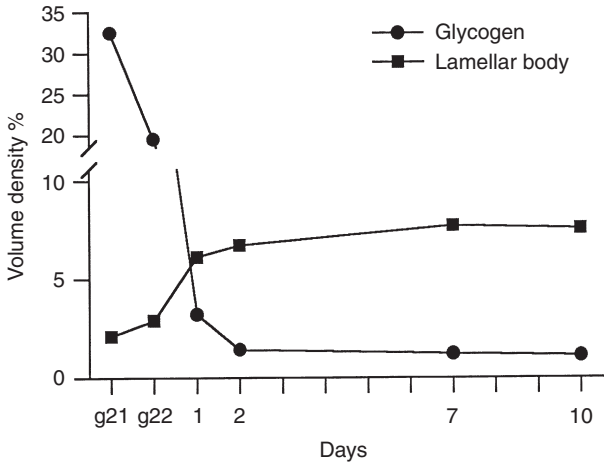

Figure 102-11 Changes in the percent composition of glycogen and lamellar bodies in type II cells. *(Modified from Massaro GD, Clerch L, Massaro D:Perinatal anatomic development of alveolar type II cells in rats,* Am J Physiol *251:R470-R475, 1986.)*

DESORPTION AND RECYCLING OF SURFACTANT

The interfacial film of surfactant is subject to high pressures (low surface tension) at low lung volumes, promoting desorption of surfactant lipid. The morphologic forms representing desorbed surfactant are poorly understood, but there is evidence that surfactant material for recycling is shaped like collapsed disks or liposomal vesicles.[33,65] Studies in adult rats demonstrated an increase in small vesicular surfactant forms in the alveolar pool after a period of large tidal volume ventilation.[66] The morphologic forms of desorbed surfactant that are taken up and recycled by type II cells are not well understood. In addition to uptake by type II cells, extracellular cycling of surfactant may include reincorporation into tubular myelin and other aggregated forms that are then reinserted in the interfacial monomolecular film.[33]

CHANGES IN ALVEOLAR SURFACTANT AT THE START OF AIR BREATHING

The in utero, fluid-filled lung has no air-liquid interface, and the initiation of air breathing at birth must be accompanied by formation and maintenance of an adequate interfacial surfactant layer. Experiments with newborn rats and rabbits demonstrated 10-fold increases in the amount of phospholipid recoverable from bronchial lavage during the first postnatal day (Figure 102-10).[49,50] The separation of lavageable phospholipids into classes by differential centrifugation showed that aggregated forms, including tubular myelin, represented a relatively stable amount of lipid but that the class of lavageable lipid in nonaggregated liposomal forms increased greatly until a stable adult ratio was achieved by the end of the first postnatal day (see Figure 102-10). These observations are consistent with the hypothesis that newly secreted surfactant is highly aggregated and that spent surfactant produced by respiratory cycling appears as small vesicles.

POSTNATAL MATURATION

At the end of normal gestation in rats, the glycogen content of maturing type II cells decreases rapidly, and lamellar body and mitochondrial volumes increase. The type II cell at birth generates a higher surfactant content per gram of dry lung weight than at any other time of life, but the type II cell is still immature, and in rats the volume of lamellar bodies nearly doubles from birth to adulthood[67] (Figure 102-11). Clara cells undergo

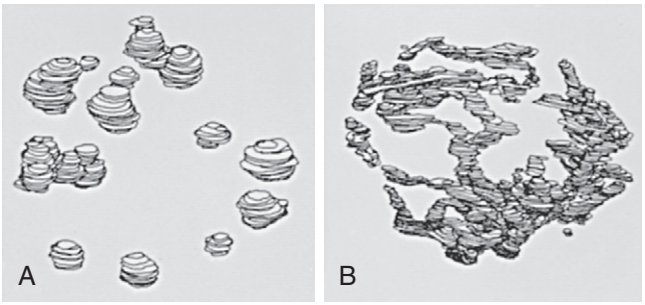

Figure 102-12 Three-dimensional reconstructions of the mitochondria of single type II cells from a rat on the day of birth **(A)** and an adult rat **(B)**. Both panels are approximately the same magnification.

a differentiation process similar to that of the type II cell but somewhat later.[68] Nuclear size, glycogen content, and granular endoplasmic reticulum content decrease, and agranular endoplasmic reticulum, mitochondria, and secretory granule content increase; most of the changes occur after birth.

An interesting postnatal change occurs in type II cell mitochondria. As noted in morphometric studies, mitochondrial volume density increases after birth, but the changing shapes and configuration of mitochondria have not been readily appreciated. Three-dimensional studies reveal dramatic conversion of type II cell mitochondria from isolated spherical organelles at gestational day 22 to a branched, interconnected morphology in adults (Figure 102-12).[37] These changes are similar to those found in mitochondria from widely divergent cell types in which transitions between metabolically quiescent and active states occur, such as exponentially growing algae[69] or housefly flight muscle during metamorphosis.[70]

Regulation of Surfactant-Associated Phospholipid Synthesis and Secretion

Lung surfactant is composed largely of lipids, of which phospholipids account for at least 80% of the total. Phosphatidylcholine (PC) is by far the most abundant phospholipid in surfactant and accounts for approximately 80% of its total phospholipid. At least 50% and often as much as 85% of the PC in surfactant preparations consist of the disaturated, surface-active species.[1] Phosphatidylglycerol is the second most abundant phospholipid in surfactant. It represents approximately 13% of the total phospholipid. In some situations, phosphatidylglycerol is replaced by phosphatidylinositol, and the relationship between the amounts of these two acidic phospholipids in surfactant appears to be reciprocal. The focus in this chapter is on the biosynthesis of the major surfactant phospholipids—PC and disaturated PC. Biosynthesis of the acidic phospholipids—phosphatidylglycerol and phosphatidylinositol—is also discussed. The biosynthesis of other typical membrane phospholipids found in low amounts in surfactant—phosphatidylethanolamine, sphingomyelin, phosphatidylserine, and cardiolipin—is beyond the scope of this chapter but is discussed elsewhere.[2]

Even though surfactant has a characteristic phospholipid composition, it contains no unique phospholipid component. Although present in relatively large amounts in surfactant, disaturated PC and phosphatidylglycerol are also found in nonsurfactant fractions of the lung[1] and, indeed, in other organs of the body.[3] Thus it is difficult to study the synthesis of surfactant-associated phospholipids specifically. Of course, rates of substrate incorporation into phospholipids in surfactant-enriched fractions (e.g., lamellar bodies) can be measured, but this is of little help when enzyme activities are to be determined. Studies can be carried out in isolated type II pneumocytes, which are the cellular sites of surfactant phospholipid biosynthesis, but even the type II cell synthesizes phospholipid for membranes as well as for surfactant. Therefore in most studies it has not been possible to distinguish between synthesis of membrane phospholipids and synthesis of those associated with surfactant, and the data must be interpreted accordingly. In contrast, secretion of specific surfactant-associated phospholipids can be studied relatively easily because membrane phospholipids are not secreted to any appreciable extent. Thus the lipids secreted by cultured type II cells have the typical profile of surfactant-associated phospholipids.[1] This is also true of lipids recovered in lung lavage.[1]

PATHWAYS IN THE BIOSYNTHESIS OF PHOSPHOLIPIDS AND FATTY ACIDS

The pathways in the biosynthesis of PC, phosphatidylglycerol, and phosphatidylinositol are illustrated in Figure 103-1. Phospholipid biosynthesis begins with the biosynthesis of phosphatidic acid (PA). This phospholipid occupies a central position in glycerolipid biosynthesis; it is the common lipid precursor of all other glycerophosphatides as well as acylglycerols. The glycerophosphate backbone of PA originates from the triose phosphate, dihydroxyacetone phosphate, an intermediate in glycolysis. Dihydroxyacetone phosphate is metabolized to 1-acylglycerol 3-phosphate by two pathways: acylation followed

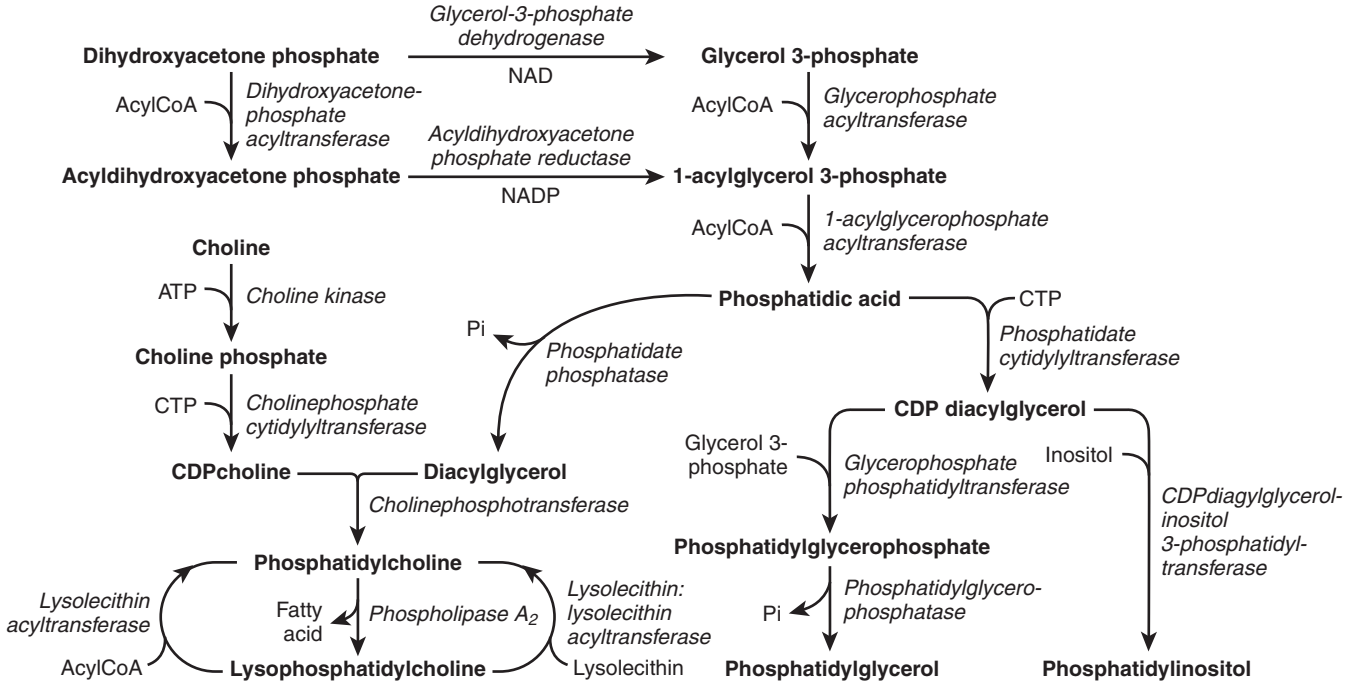

Figure 103-1 Pathways in the biosynthesis of phosphatidylcholine, phosphatidylglycerol, and phosphatidylinositol. *(From Rooney SA: The surfactant system and lung phospholipid biochemistry,* Am Rev Respir Dis *131:439, 1985.*

by reduction or reduction followed by acylation. Evidence shows that both pathways exist in the lung and are involved in the synthesis of PC and phosphatidylglycerol in type II cells.[4] PA is subsequently synthesized by further acylation of 1-acylglycerol 3-phosphate.

Numerous nonlipid precursors can be incorporated into phospholipids during the biosynthesis of PA.[1] Glucose, derived from dietary sources through the blood or from glycogen degradation in the lung, can be incorporated into phospholipids through the glycolytic pathway and dihydroxyacetone phosphate. Glycerol can be incorporated after phosphorylation to glycerol 3-phosphate by the action of glycerol kinase. Fatty acids are incorporated into phospholipids during the previously described acylation steps, as well as in subsequent reacylation reactions.

PC and the acidic phospholipids, phosphatidylglycerol and phosphatidylinositol, are synthesized from PA by different mechanisms. In the case of PC biosynthesis, PA is first dephosphorylated, and the resulting diacylglycerol (DAG) is combined with cytidine diphosphocholine (CDPcholine) to form PC. CDPcholine arises from choline after initial phosphorylation and subsequent transfer to cytidine triphosphate in reactions catalyzed by choline kinase and choline-phosphate cytidylyltransferase (CCT), respectively. Choline is essentially a vitamin in that it is not synthesized in the body but is obtained from dietary sources, often in the form of PC.[5,6]

Although disaturated PC can be synthesized by the foregoing de novo mechanism, evidence shows that it also can be synthesized by remodeling of the 1-saturated-2-unsaturated molecular species. At least half of lung and type II cell disaturated PC is synthesized by remodeling.[4,7] As shown in Figure 103-1, at least two remodeling mechanisms have been described. Both involve initial deacylation of de novo synthesized 1-saturated-2-unsaturated PC. The resulting 1-acyl-2-lysophosphatidylcholine (lysolecithin) is then either reacylated by reaction with a saturated acyl-coenzyme A or transacylated in a reaction in which two molecules of lysophosphatidylcholine react to form one molecule each of PC and glycerophosphocholine. Of the two

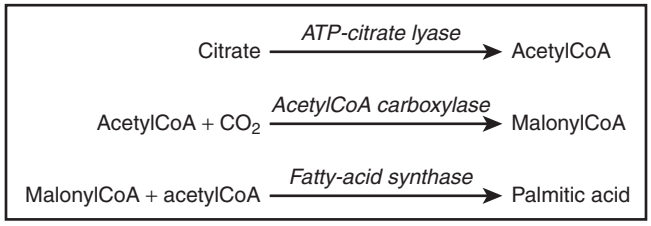

Figure 103-2 Enzymes involved in fatty acid biosynthesis.

remodeling mechanisms, only the reacylation pathway is of any quantitative importance.[4,7,8]

In the synthesis of phosphatidylglycerol and phosphatidylinositol, PA reacts with cytidine triphosphate to form CDPdiacylglycerol. This intermediate then reacts with either inositol or glycerol 3-phosphate to form phosphatidylinositol or phosphatidylglycerophosphate, respectively. The last substance does not accumulate but is immediately dephosphorylated to phosphatidylglycerol.

Fatty acids are clearly integral components of phospholipids and consequently of surfactant. Fatty acids may be synthesized de novo in the lung or supplied from extrapulmonary sources by the blood.[9,10] Although fetal and adult lungs can synthesize fatty acids de novo, the relative contributions of de novo synthesis and exogenous sources to the supply of fatty acids for surfactant synthesis are not known.[7,9] In view of the poor blood supply to the lungs during fetal life, it is likely that de novo synthesis is of quantitative importance at that stage of development. The fatty acid biosynthesis pathway is illustrated in Figure 103-2. Starting from citrate, an intermediate in the Krebs cycle, long-chain fatty acid biosynthesis is accomplished by just three enzymes: adenosine triphosphate (ATP)-citrate lyase, acetyl-coenzyme A carboxylase, and fatty acid synthase (FAS). FAS catalyzes seven distinct biochemical reactions, four of which are repeated for the addition of each two-carbon unit. In bacteria and plants, the seven reactions are carried out by separate proteins, but

in animals and yeasts, they are carried out by single multifunctional proteins.[11,12] The 16-carbon fatty acid, palmitic acid, is the usual product of de novo fatty acid biosynthesis in mammals. All the reactions illustrated in Figures 103-1 and 103-2 have been shown to occur in the lung. Most of the enzymes listed have been assayed in isolated type II cells.[1]

DEVELOPMENTAL AND HORMONE-INDUCED CHANGES IN LUNG PHOSPHOLIPID CONTENT AND BIOSYNTHESIS

Normal Development

Surfactant production increases toward the end of gestation as the fetus prepares for extrauterine life.[1] The amount of total and disaturated PC in lung lavage from fetal rabbits increases 10-fold between days 27 and 31 (full term) of gestation, and a further increase of similar magnitude occurs immediately after birth (Table 103-1). At the same time, the composition of the phospholipids recovered in lung lavage changes substantially. As shown in Figure 103-3, PC increases from less than 30% of the total phospholipid at 27 days gestation to approximately 70% at term and to 80% or more after birth. During this period, sphingomyelin decreases from approximately 40% of the total at 27 days gestation to less than 10% at term and to 1% to 2% after birth. As shown in Table 103-1, this results in a dramatic increase in the ratio of PC (lecithin) to sphingomyelin (L/S ratio). Because fetal lung fluid contributes to amniotic fluid, measurement of the L/S ratio in human amniotic fluid, obtained by amniocentesis, is widely used to predict the degree of fetal lung maturity and hence the optimal time for elective delivery.[13,14] A developmental increase occurs in the amount of phosphatidylglycerol in late-gestation fetal lung lavage,[15] and measurement of this phospholipid in human amniotic fluid can provide an additional assessment of the extent of fetal lung maturity.[13]

The prenatal increase in surfactant PC appears to be largely the result of increased synthesis, whereas the massive increase immediately after birth is caused by increased secretion in response to labor and ventilation (see later discussion). The rate of incorporation of radiolabeled choline into total or disaturated PC in fetal lung has been used extensively to assess the rate of synthesis of these phospholipids. A major problem in the interpretation of such data is that unless the intracellular pool sizes of choline, choline phosphate, and CDPcholine are known, rates of radiolabeled choline incorporation are not necessarily synonymous with rates of synthesis. Despite this caveat, rates of choline incorporation into PC in fetal lung have correlated well with other parameters of synthesis, such as increased mass of PC and increased enzyme activities.[8] As shown in Figure 103-4, a developmental increase in the rate of choline incorporation into PC occurs in fetal rat lung, and this continues into newborn life. Similar developmental increases have been reported in other species.[1,8] CCT is a major rateregulatory enzyme in the biosynthesis of PC,[2,16] and a developmental increase in its activity in the lung occurs either at the end of gestation or immediately after birth.[8] A developmental increase in CCT activity has also been reported in isolated type II cells,[17] and the increase in activity is accompanied by increased enzyme mass, mRNA content, and mRNA stability,[18,19] a finding indicating increased expression of the CCT gene.

A developmental increase in lung fatty acid biosynthesis occurs during late fetal life. The rate of de novo fatty acid biosynthesis can be assessed by measuring the rate of ^3H_2O incorporation into fatty acids. The problem of pool size does not arise in this situation because intracellular and extracellular water become equally labeled. A developmental increase in the rate of fatty acid synthesis in fetal rat lung has been reported using this method.[20,21] As shown in Figure 103-4, the increase occurs between days 19 and 21 of gestation and is followed by a decrease after birth. The increase in fatty acid biosynthesis coincides with the increase in PC biosynthesis (see Figure 103-4). The increase in de novo fatty acid synthesis in fetal rat lung is accompanied by a similar developmental increase in FAS activity.[22,23] The increase in FAS activity results from increased gene expression because a corresponding developmental increase occurs in the level of FAS mRNA.[24,25] A similar developmental increase in FAS expression occurs in late-gestation fetal rabbit lung.[26] In contrast to FAS, no changes or minor and inconsistent developmental increases in the activities and mRNA levels of ATP-citrate lyase and acetyl-coenzyme A carboxylase have

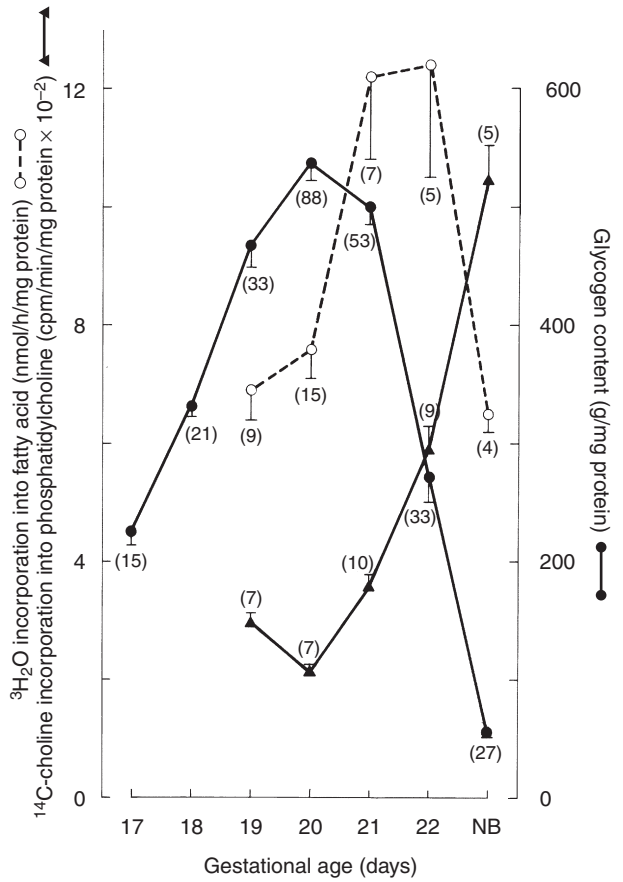

Figure 103-4 Developmental changes in glycogen content and in rates of ^3H_2O incorporation into fatty acids and of [^{14}C] choline incorporation into phosphatidylcholine in developing fetal rat lung. *(From Rooney SA, Gobran LI, Chu AJ: Thyroid hormone opposes some glucocorticoid effects on glycogen content and lipid synthesis in developing fetal rat lung,* Pediatr Res *20:545, 1986.)*

been reported.[20,22-25] Therefore the developmental increase in de novo fatty acid biosynthesis is mediated by the increase in FAS expression.

As is also shown in Figure 103-4, a developmental increase is followed by a decrease in lung glycogen content of fetal rat lung. Similar developmental changes in lung glycogen have been reported in other species.[1] Parallel developmental changes in the enzymes controlling glycogen synthesis and degradation have also been reported.[22,27,28] The temporal relationship between glycogen depletion and increased PC synthesis, which has also been reported in isolated fetal type II cells,[29] prompted speculation that glycogen provides substrate or energy for surfactant phospholipid biosynthesis in the fetal lung.[27,29,30] However, a direct relationship between glycogen depletion and increased phospholipid synthesis has not been proven. The reciprocal relationship that exists between fetal lung glycogen content and PC biosynthesis also exists between glycogen and fatty acid biosynthesis (see Figure 103-4). Glycogen is therefore just as likely to provide substrate or energy for the biosynthesis of fatty acids as for that of phospholipids.

Influence of Hormones

Lung maturation and surfactant production in the fetus can be accelerated by certain hormones and growth factors.

Glucocorticoids

In 1969, Liggins[31] reported that administration of dexamethasone to fetal lambs resulted in delivery of live animals as early as 117 to 123 days of gestation, although term is approximately 147 days. Because such premature fetuses were born alive and had partly expanded lungs, he suggested that the hormone "accelerated appearance of pulmonary surfactant, possibly as a result of premature activity of enzymes involved in a biosynthetic pathway." That the glucocorticoid did increase the amount of surfactant was soon demonstrated by deLemos and colleagues,[32] who measured lung pressure-volume relationships and the surface activity of lung extracts in the same species. Shortly thereafter, similar findings were reported in the rabbit,[33] a species in which accelerated morphologic maturation of the fetal lung was also observed.[34] Within 3 years of the initial observation, Liggins and Howie[35] reported the first successful use of glucocorticoids in the prevention of respiratory distress syndrome (RDS) in human infants. Since that time, investigation has been intense in many laboratories into the mechanism by which glucocorticoids accelerate fetal lung maturation and stimulate surfactant production.

The influence of glucocorticoids on surfactant phospholipid synthesis and the related biochemical parameters of fetal lung maturation were studied in several species. Experimental models included intact animals and explants of fetal lung in organ culture. Direct injection of fetal rabbits with cortisol or administration of betamethasone to pregnant rabbits results in an increase in the amount of surfactant phospholipid in fetal lung lavage. An increase occurs in the amount of total phospholipid and PC, an increase in PC as a percentage of the total phospholipid, and an increase in the L/S ratio.[36,37] Similarly, glucocorticoid administration in vivo increases the rate of PC biosynthesis in fetal rabbit,[37] rat,[21] mouse,[38] baboon,[39] and human[40] lung; culture of fetal rat,[41] rabbit,[42] baboon,[43] and human[44] lung explants in the presence of the hormone results in the same effect and also increases the amounts of total PC,[44,45] disaturated PC,[45,46] and phosphatidylglycerol.[45] Glucocorticoids also stimulate fatty acid biosynthesis in fetal lung. They increase the rate of de novo fatty acid biosynthesis in fetal rat,[21] rabbit,[47] and human[48] lung. In addition the hormone has been reported to accelerate the glycogen developmental profile (see Figure 103-4) in fetal lung. Thus glucocorticoids increase lung glycogen content at the time of the normal developmental increase in this parameter[21] and decrease it later in gestation at the time of the normal developmental decrease.[21,37,38]

Despite the early prediction by Liggins[31] that glucocorticoids accelerate enzyme activity, initially considerable controversy and confusion occurred with respect to the effects of glucocorticoids on enzymes of lipid biosynthesis in the fetal lung. Eventually it was established that the hormones increase the activity of two lipogenic enzymes in fetal lung in late gestation-CCT and FAS. CCT activity increases in fetal rabbit,[36,37,49] rat,[46,50,51] and mouse[38] lung tissue and in fetal rat type II cells[52] after injection of the mother with glucocorticoids. It also increases in fetal rabbit,[53] rat,[54] and human[55] lung explants treated with glucocorticoids in culture. Similarly, FAS activity increases in fetal rat lung tissue[22] and in isolated type II cells[56] after maternal injection with dexamethasone and in response to the same hormone in cultured explants of fetal rat[25] and human[57] lung. However, unlike in rats and humans, it has been reported that betamethasone does not increase FAS activity in fetal lamb lung.[58] Whether that is the result of a species difference or a function of gestational age needs to be investigated. Glucocorticoids do not increase the activities of ATP-citrate lyase[25] or acetyl-coenzyme A carboxylase.[22] Thus, as is the case in normal development, the glucocorticoid-induced increase in fetal lung fatty acid biosynthesis is entirely the result of increased FAS activity.

The situation with respect to other enzymes of phospholipid synthesis is less clear. Fetal lung phosphatidate phosphatase activity has been reported to increase with glucocorticoid administration in the rabbit and mouse but not in the rat.[8,59] Glucocorticoids were also shown to increase cholinephosphotransferase activity in a few studies, but it was not a consistent finding.[8,59] Similarly, lysolecithin acyltransferase, lysolecithin:lysolecithin acyltransferase, and glycerophosphate phosphatidyltransferase activities have been reported to increase in some studies, but not in others.[59]

The finding that glucocorticoid effects occur in cultured explants indicates that the hormone acts directly on the lung. Glucocorticoid receptors have been demonstrated in fetal and adult lung,[60] and data indicate that the effects of glucocorticoids on PC synthesis and CCT and FAS activities are directly mediated by the receptor. Stimulation of PC synthesis in the rat,[61] rabbit,[42] and human[44] and of CCT[54,55] and FAS[48,62] activities in the rat and human depends on glucocorticoid concentration. The EC_{50} values (concentration at which 50% of the maximal stimulation is achieved) are of the same order of magnitude,[42,44,54,63] or even lower,[62] than the dissociation constant (K_d) values for specific binding of the glucocorticoid to the nuclear receptor. Furthermore, the order of potency of various steroids in producing the previously described effects is the same as that of their binding to the receptor.[42,54,62] Glucocorticoid stimulation of PC synthesis[42] and of CCT[64] and FAS[62,64] activities in fetal lung explants is not apparent until after exposure to the hormone for approximately 12 hours. Maximal stimulation is achieved in 20 to 36 hours. This time course is consistent with induction of new protein synthesis. The stimulatory effects of the hormone are antagonized by actinomycin D[42,54,62] and cycloheximide,[42,65] and this finding again shows that the action of the hormone involves increased transcription and induction of new protein synthesis.

Glucocorticoid stimulation of CCT activity (a direct effect on the lung) is clearly receptor mediated and dependent on mRNA and protein synthesis. However, quantification by immunotitration[66] and Western blotting[51] revealed that the amount of the CCT protein is not increased by the hormone. Similarly glucocorticoids have no effect on CCT mRNA content,[19] although small increases have been reported in some studies.[43,67] As discussed in detail later, the preponderance of the evidence suggests that the effect of the hormone results from the activation of existing enzyme, rather than increased expression of the CCT gene.

Conversely the glucocorticoid-induced increase in FAS activity in fetal lung is clearly the result of increased gene expression. The increase in activity is accompanied by an increase in the amounts of FAS protein[56,57,62,68] and mRNA[25,56,57,69] in the rat and human, whereas lung FAS mRNA content is decreased in glucocorticoid-insufficient fetal mice.[70] The glucocorticoid-induced increase in FAS mRNA results from both increased transcription[56,57,68] and mRNA stability.[57,71] Increased transcription is the predominant mechanism in the rat, whereas increased mRNA stabilization predominates in the human.[57,68,71] Glucocorticoid-induced transcription of the FAS gene has been reported to be mediated by an 89–base pair fragment in the promoter region.[72] It is therefore clear that the increase in FAS activity in fetal lung is the result of increased expression of the FAS gene. FAS is the only enzyme involved in lipid synthesis that is induced by glucocorticoids in fetal lung. Consistent with a role for FAS in surfactant production, the glucocorticoid-induced increase in its expression is more pronounced in type II cells than in other lung cells.[56,57] As discussed later, evidence exists that increased FAS activity accounts for the stimulatory effects of glucocorticoids on PC synthesis and CCT activity.

Although maternal injection with glucocorticoid results in increased CCT[52] and FAS[56] activities in fetal type II cells (the site of surfactant synthesis within the lung), this action of the hormone is not the result of a direct effect on the type II cell. Adult type II cells contain glucocorticoid receptors,[73] and glucocorticoids have stimulatory effects on some parameters in type II cells,[74-76] including stimulation of surfactant secretion (see later discussion). However, glucocorticoids have little effect on parameters of PC synthesis when either adult[77] or fetal[67,78] type II cells are cultured with the hormone. Data indicate that the effects of glucocorticoids on surfactant lipid synthesis are mediated by mesenchymal factors. The maximum effect of cortisol on FAS expression in fetal rat type II cells requires a fibroblast-conditioned medium.[67] In early studies,[79] a factor released from fibroblasts, fibroblast-pneumonocyte factor, was proposed to mediate the effect of glucocorticoids, but fibroblast-pneumonocyte factor has never been isolated or characterized. However, other factors are known to be released from fibroblasts, and one or more of those may be the active ingredient in a fibroblast-conditioned medium. Indeed, keratinocyte growth factor (KGF), also called fibroblast growth factor-7, stimulates surfactant phospholipid synthesis, CCT activity, and FAS expression in fetal rat type II cells.[80] Administration of KGF in vivo also increases the amount of disaturated PC in the lungs of preterm rabbits.[81] Dexamethasone increases KGF expression in fetal lung fibroblasts, and an anti-KGF antibody blocks the glucocorticoid-induced increase in PC synthesis in fetal rat type II cells cultured with fibroblast-conditioned medium.[82] Although involvement of other factors is also possible,[82] such data suggest that KGF may have a major role in mediating the effects of glucocorticoids on stimulation of surfactant synthesis.

Thyroid Hormone

Thyroid hormone has been reported to accelerate surfactant phospholipid production in several species. Direct injection of fetal rabbits with thyroxine (T_4) results in accelerated morphologic lung maturation, as well as increased amounts of surfactant in lung lavage.[8,83] T_4 also increases the L/S ratio in fetal lamb tracheal fluid.[84] Administration of triiodothyronine (T_3) to pregnant rats results in increased biosynthesis of total and disaturated PC as well as increased CCT activity in the fetal lung.[46] The effect of thyroid hormone is a direct effect on the lung because both PC synthesis and CCT activity are increased in fetal rat lung explants exposed to T_3 or T_4 in culture.[41,46,61] T_3 also increases PC synthesis in explants of fetal rabbit[85] and human[44] lung. Fetal lungs of genetically hypothyroid mice are less mature and contain less surfactant than normal.[86,87]

Thyroid hormone receptors are present in adult and fetal lung and in type II cells.[88] Half-maximal stimulation of PC synthesis in fetal rabbit and human lung explants is achieved at a concentration of T_3 that is almost identical to the Kd for binding of the hormone to the nuclear receptor.[44, 85] The relative potencies of various thyroid hormone analogues in stimulating PC biosynthesis and in binding to the receptor are also the same,[44,85] and the stimulatory effect of T_3 is abolished by actinomycin D and cycloheximide.[85] These data indicate that the stimulatory effect of thyroid hormone in fetal lung is receptor mediated and involves increased gene expression. The gene or genes induced by thyroid hormone remain to be identified.

Several of the stimulatory effects of thyroid hormone in fetal lung are similar to those of glucocorticoids. However, the effects of the two hormones on certain parameters of surfactant phospholipid synthesis have been reported to be additive,[44,61,85,89] a finding suggesting that glucocorticoids and thyroid hormone act through different mechanisms. Furthermore, these two hormone types have opposite effects on other developmental parameters in fetal lung. Thyroid hormone and glucocorticoids both accelerate the normal developmental decrease in fetal lung glycogen content; however, the normal developmental increase in glycogen (which occurs earlier in gestation [see Figure 103-4]) is accelerated by glucocorticoids

but is prevented by thyroid hormone in the fetal rat.[21] Furthermore the glucocorticoid-accelerated increase is antagonized by thyroid hormone.[21] Similarly, although dexamethasone accelerates the normal developmental increase in de novo fatty acid biosynthesis in fetal rat lung, both the normal increase and the stimulatory effect of the glucocorticoid on this parameter are antagonized by thyroid hormone.[21] T_3 does not stimulate de novo fatty acid biosynthesis or FAS activity in fetal rat or human lung explants.[22,48,62] Furthermore it diminishes the stimulatory effect of glucocorticoid on FAS activity in fetal rat[22,62] but not human[48] lung.

A major difficulty in studying the effects of thyroid hormone on the fetal lung in vivo is that, in most species, T_4 does not easily cross the placenta. In early studies, therefore, T_4 was administered directly to the fetus.[83] However, directly injecting the fetus, even with saline, causes stress, which itself stimulates surfactant production,[36] so in that model some effects of thyroid hormone may have been masked. Administration of a relatively high dose of T_3 to pregnant rats results in elevated levels of the hormone in the fetal serum, and this model has been employed to examine effects of thyroid hormone on surfactant synthesis in vivo.[46] In the same in vivo model, antagonism between the effects of glucocorticoids and thyroid hormone on fatty acid biosynthesis, FAS activity, and glycogen accumulation has been observed[21,22] In contrast, although the stimulatory effect of T_3 on PC synthesis in cultured fetal lung[44,61,85] occurs at a concentration consistent with receptor mediation, the inhibitory effect of thyroid hormone on FAS in the same model requires a much higher hormone concentration.[62] The physiologic relevance of the inhibitory effects of thyroid hormone is therefore not clear.

Thyrotropin-Releasing Hormone

In an effort to overcome the problem of poor placental transfer of thyroid hormone, thyrotropin-releasing hormone, a tripeptide that readily crosses the placenta, was administered to pregnant rabbits and was found to increase the amount of surfactant phospholipid in lung lavage from the fetuses.[90] Thyrotropin-releasing hormone has been reported to have a similar effect in the fetal lamb,[91] and it has also been noted to accelerate functional and morphologic lung maturation in the fetal rabbit.[92] A combination of thyrotropin-releasing hormone and cortisol is more effective than either hormone alone in the fetal rabbit[93] and lamb.[91,94] However, a combination of thyrotropin-releasing hormone and betamethasone is no more effective than betamethasone alone in prevention of RDS in premature human newborns[95-97] (see Chapter 108). Although data are contradictory on its effect on PC biosynthesis,[43,90] thyrotropin-releasing hormone was reported to increase CCT mRNA content markedly in fetal baboon lung explants.[43]

Estrogen

Clinical data suggest that low estrogen levels are associated with an increase in the incidence of RDS,[8,98,99] and in one early study, administration of estrogen to pregnant women resulted in an increase in the amniotic fluid L/S ratio.[100] In that study, estrogen was just as effective as dexamethasone.[100] In animal studies, estrogen has been reported to stimulate surfactant production in the late-gestation fetal rabbit[101-104] and rat[105,106] but not in the lamb.[107] The most dramatic changes are found in the fetal rabbit when the hormone is administered to the pregnant doe. In this model, the hormone increases the amount of surfactant phospholipid in lung lavage[101] and the rate of PC synthesis[102,104] and CCT activity in the lung.[102,104,108] In addition, it decreases lung glycogen content.[53,103] in vivo administration of estrogen also accelerates morphologic maturation of the fetal rabbit[103] and rat[106] lung.

Estrogen increases PC synthesis[53,105,109] and CCT activity[53] and decreases glycogen[105] in organ cultures of fetal rat and rabbit lung. However, the effects in organ culture are less pronounced than those occurring in vivo, they are apparent only at relatively high hormone concentrations,[53,105] and they do not appear to be mediated by an estrogen receptor.[53] It is therefore not clear that the stimulatory effects of estrogen occur directly on the lung. Thus, although estrogen clearly stimulates fetal lung surfactant synthesis, particularly in the rabbit, the mechanism by which this occurs and its physiologic significance are not known.

Prolactin

A developmental increase occurs in blood prolactin levels, and infants with RDS have lower levels of this hormone than controls at the same gestational age.[8,110] Although a temporal relationship does not prove cause and effect, such clinical observations led to the hypothesis that prolactin has a role in fetal lung maturation and surfactant production. Support for this theory comes from the observation that administration of prolactin to fetal rabbits led to an increase in the amounts of total phospholipid, total PC, and disaturated PC in fetal lung tissue.[111] Lung lavage was not examined, so surfactant-associated phospholipids were not specifically measured.[111] In other studies, prolactin had no effect on lung PC content or synthesis in the fetal rabbit[112] or on surfactant content in the fetal rabbit[113] or lamb.[112] The lung has prolactin receptors,[114,115] and prolactin was reported to stimulate PC synthesis in cultured explants of fetal rat[116] but not fetal rabbit[117] or human[118] lung. In the rat and human systems, it enhanced the stimulatory effect of glucocorticoids.[116,118] In view of these conflicting data in both in vivo and cultured lung systems, a role for prolactin in regulation of surfactant production has not been established.

Other Hormones and Growth Factors

In addition to KGF,[80-82] other hormones and growth factors that have been reported to stimulate surfactant phospholipid production in fetal lung include corticotropin,[8] corticotropin-releasing hormone,[43] epidermal growth factor,[119,120] parathyroid hormone,[121] leptin,[122] insulin-like growth factor,[123] and gastrin-releasing peptide.[123] Platelet-activating factor has been reported to decrease lung glycogen in the fetal rabbit in vivo,[124] and a temporal relationship exists between the decrease in glycogen content and increased platelet-activating factor concentration in cultured human fetal lung explants.[125] However, a role for platelet-activating factor in regulation of surfactant phospholipid synthesis has not been established. Cyclic adenosine monophosphate (cAMP), which is clearly involved in regulation of surfactant secretion (see later discussion), may also have a regulatory role in its synthesis.[8] cAMP increases FAS expression in human[126] but not in rat[68] fetal lung explants. Vitamin D was reported to stimulate surfactant synthesis in fetal rat type II cells[127] but it did not increase FAS expression.[68]

Numerous agents have been reported to inhibit surfactant phospholipid synthesis in the late-gestation fetal lung. Infants of mothers with diabetes are particularly prone to RDS.[128] In animal models, fetuses of rats and rabbits made diabetic by administration of streptozotocin and alloxan exhibit delayed lung maturation and decreased surfactant, as determined by several criteria.[129-132] However, although the infants of mothers with diabetes are hyperinsulinemic and hyperglycemic, in the animal models the fetuses generally have high glucose levels, but insulin levels are often normal. It is therefore not clear whether the delayed lung maturation is the result of the increased insulin or the high glucose concentration. Infusion of insulin into fetal rhesus monkeys leads to hyperinsulinemia without elevated glucose levels, but no evidence of delayed lung maturation in such animals is available.[133] Conversely hyperinsulinemia with hypoglycemia in the fetal rat[134] and lamb[135] does reduce surfactant production. In cultured fetal

lung systems, insulin does not decrease PC synthesis,[136,137] but it diminishes the stimulatory effect of glucocorticoids on both PC synthesis[137] and CCT activity.[138] A high glucose concentration has also been reported to decrease surfactant production and morphologic maturation in cultured fetal rat lung explants.[139,140]

It is known that premature male infants are more prone to RDS than female infants.[141] The lungs of female fetuses tend to be approximately 1 week more mature than those of males as determined by the amniotic fluid L/S ratio and disaturated PC content.[142] Evidence is available of this female advantage in fetal lung maturation and surfactant synthesis in rats[143-145] and, to a lesser extent, in rabbits,[146,147] but not in monkeys.[148,149] This maturational difference may result from inhibition of surfactant production in male fetuses by androgens.[150,151] More recent studies suggest that the androgen effect is caused by enhancement of lung morphogenesis and branching earlier in gestation,[152] and it may be mediated by changes in the relative amounts of epidermal growth factor and transforming growth factor-β receptors in fibroblasts.[153]

Transforming growth factor-β_1 was reported to antagonize the dexamethasone-induced increase in FAS expression in human fetal lung explants,[154] an effect that appears to be mediated at the transcription level.[72] Retinoic acid was reported to antagonize the stimulatory effect of glucocorticoids on FAS expression in fetal rat lung explants, but retinoic acid on its own had no effect.[68] In contrast, retinoic acid was reported to increase the amount of fetal lung surfactant phospholipid and rate of PC synthesis.[155] Vitamin A–deficient fetal rats were reported to have a reduced amount of surfactant phospholipid, an effect accompanied by decreased FAS expression but normal CCT activity.[156]

MECHANISM OF REGULATION OF FETAL LUNG PHOSPHATIDYLCHOLINE BIOSYNTHESIS

Numerous studies in the developing fetal lung, in isolated type II cells, and in other organs established that CCT is a major rate-regulatory enzyme in de novo PC biosynthesis.[2,4,16] As shown in Figure 103-1, CCT catalyzes the conversion of choline phosphate to CDPcholine. The size of the choline phosphate pool is larger than that of choline or CDPcholine in both whole lung and type II cells.[4] As discussed earlier, a developmental increase in CCT activity occurs in association with increased PC biosynthesis in the developing lung. Glucocorticoids, thyroid hormone, and estrogen, which stimulate PC synthesis and increase PC content in fetal lung, also increase CCT activity.

The developmental increase in fetal lung CCT activity is largely the result of increased expression of the CCT gene,[18,19] although activation of existing enzyme may also be involved.[157,158] In contrast, although the stimulatory effect of glucocorticoids on fetal lung CCT activity is dependent on new protein and mRNA synthesis, CCT is not the protein that is induced by the hormone; CCT enzyme mass[51,66] and mRNA content[19] are not increased by glucocorticoids in the fetal lung. The effect of glucocorticoids on CCT activity is caused by activation of existing enzyme, rather than by synthesis of new CCT. How is CCT activated?

CCT belongs to a group of proteins called amphitropic[159] or ambiquitous,[160] the activities of which are regulated by interconversion between a soluble and a membrane-bound form. Considerable evidence shows that CCT activity is regulated by reversible membrane association; the membrane-bound form is active, whereas the soluble form is inactive and requires lipid for activation.[2,161] The curvature and other physical properties of the membrane are critical in the interaction with CCT.[162,163] Physiologic activation of CCT in many systems is thought to involve translocation of the enzyme from the cytosol to membranes.[164] Translocation from cytosol to microsomes has been reported in association with increased PC synthesis in choline-depleted type II cells.[165] However, translocation is not always involved in CCT activation because activation without translocation has been reported.[2,166] Little evidence is available that translocation has a role in hormonal stimulation of CCT activity in the fetal lung. The stimulatory effects of dexamethasone on CCT in the fetal rat[54] and of estrogen in the fetal rabbit[108] are clearly not the result of translocation. The bulk of the enzyme is in the cytosolic fraction, and the subcellular distribution is not altered by the hormones. Estrogen increases only the CCT activity in the cytosol and has no effect on activities in the microsomal or mitochondrial fractions.[108] Similarly dexamethasone does not alter the subcellular distribution of CCT in fetal lung type II cells, although in that study, most of the activity was in the microsomal fraction.[52]

It is clear, however, that hormonal activation of CCT is mediated by endogenous lipids. Fetal lung CCT activity can be increased several-fold by inclusion of fatty acids,[167] as well as phospholipids,[108,168,169] in the assay mixture, and when the enzyme is assayed in the presence of sufficient lipid to achieve maximal activation in vitro, the stimulatory effects of glucocorticoids,[46,51,54,64,66] T_3,[46] and estrogen[102,104,108] are considerably reduced or completely abolished. Because the lipids would be expected to activate any newly synthesized CCT just as much as existing enzyme, these data are consistent with the concept that it is the catalytic activity, rather than the amount of CCT, that is increased by the hormones. CCT activity in fetal lung cytosol is markedly decreased by extraction of lipids with solvents that do not cause protein denaturation.[51,108,157] Lipid extraction under the same conditions completely abolishes the stimulatory effects of betamethasone in the rat[51] and of estrogen in the rabbit.[108] CCT activity and the stimulatory effects of the hormones are fully restored on re-addition of the appropriate lipid extract.[51,108] Furthermore the stimulatory effects of the hormones can be switched from the treated to the control groups by interchanging the added lipids.[51,108] Such data establish that the stimulatory effects of those hormones are mediated by a lipid factor. Indeed betamethasone elevates the levels of some phospholipids and fatty acids in fetal rat lung.[51] Estrogen also increases phospholipid levels in fetal rabbit lung, but its effect on fatty acids has not been examined.[108]

As discussed earlier, glucocorticoids enhance fatty acid biosynthesis and increase expression of the FAS gene in late-gestation fetal lung. Indeed FAS is the only gene for a lipogenic enzyme that is known to be induced by glucocorticoid in fetal lung. Inhibition of fatty biosynthesis in fetal rat lung explants completely abolishes the stimulatory effect of dexamethasone on CCT activity.[64] This finding suggests that the stimulatory effect of glucocorticoids on CCT activity in fetal lung is mediated by induction of the FAS gene. Whether FAS induction also accounts for the estrogen- and thyroid hormone–induced increases in CCT activity is a question that remains to be investigated.

It is not clear at present whether the glucocorticoid effect on CCT activity is mediated by free fatty acids, by the lipids into which they become incorporated, or possibly by other fatty acid metabolites. The observations that linoleic acid was the fatty acid that was increased to the greatest extent by betamethasone in fetal rat lung and the same fatty acid was the most effective in activating CCT in vitro led to the suggestion that glucocorticoid stimulation of fetal lung CCT activity is mediated by linoleic acid.[170] However, linoleic acid is an essential fatty acid that is not synthesized by mammals. It is consequently difficult to reconcile the notion that glucocorticoid activation of CCT is mediated by induction of FAS with the concept that it is also mediated by linoleic acid. In summary, although evidence is compelling that the stimulatory effect of glucocorticoids on CCT activity results from increased FAS expression and

is mediated by endogenous lipids, the precise identity of the activator(s) remains to be established.

Three CCT isoforms exist: α, β_1, and β_2. The β isoforms are splice variants of the same gene, but CCTα is encoded by a different gene.[166,171] Some sequence differences exist among the three isoforms, but the catalytic and membrane-binding domains are highly conserved.[166] All three isoforms are enzymatically active and are regulated by reversible membrane association.[166] The membrane-bound form of CCTα has been reported to be largely associated with the nucleus in some systems,[2,16,166] but it is also found in association with endoplasmic reticulum,[171] especially in the lung, where it is entirely extranuclear.[172,173] In contrast, CCTβ_1 and CCTβ_2 are associated with the endoplasmic reticulum.[16,171] CCTα is widely expressed,[171] and it is the most extensively investigated of the three isoforms. The three CCT isomers are expressed in fetal lung, but only CCTα is expressed in adults.[171] Therefore an interesting question that has not yet been addressed is whether one or both of the CCTβ isoforms may have a role in regulation of PC synthesis during fetal lung development.

Although the glucocorticoid-induced increase in CCT activity appears to be primarily the result of enzyme activation, the possibility of increased synthesis cannot be discounted entirely. In contrast to the effect of estrogen in fetal rabbit lung, in which stimulation of CCT is completely abolished by inclusion of phosphatidylglycerol in the in vitro assay mixture,[102,104,108] glucocorticoid stimulation of CCT activity in rat and mouse lung is not completely abolished by inclusion of activating lipids.* Indeed, although markedly reduced, the stimulatory effect of dexamethasone remained statistically significant even in the presence of phosphatidylglycerol.[38,54] In human lung explants, increased CCT activity in response to dexamethasone was even more pronounced and became statistically significant only when phosphatidylglycerol was included in the assay mixture.[55] That the stimulatory effect of the hormone was apparent when the enzyme was maximally activated in vitro suggests an increase in enzyme mass. As discussed earlier, CCT mRNA was reported to be increased in some studies,[43,67] although that was not a consistent finding.[19]

Apart from CCT, it is possible that other enzymes have regulatory roles in phospholipid biosynthesis, at least under some circumstances. In one study,[174] mice overexpressing CCT in the lungs had only modest increases in PC synthesis and content, a finding suggesting that other steps in the PC biosynthetic pathway may also be important in its regulation. As discussed earlier, activities of fetal lung phosphatidate phosphatase, cholinephosphotransferase, lysolecithin acyltransferase, lysolecithin:lysolecithin acyltransferase, and glycerophosphate phosphatidyltransferase have been reported to be increased in some studies either during normal development or after hormone treatment. Data suggest that glycerophosphate acyltransferase, an enzyme catalyzing an early step in glycerophospholipid synthesis (see Figure 103-1), has a regulatory role in type II cells isolated from adult rats[175] and rabbits.[176] Evidence also exists that choline kinase and phosphatidate phosphatase are regulatory enzymes in other organs.[2] However, rate-regulatory roles for these and other enzymes have not been established in the fetal lung.

SECRETION OF SURFACTANT-ASSOCIATED PHOSPHOLIPIDS

Lamellar inclusion bodies are the secretory organelles of the type II pneumocyte. The phospholipid composition of isolated lamellar bodies is virtually identical to that of surfactant.[1] After their biosynthesis, surfactant phospholipids are stored in lamellar bodies and are finally secreted into the alveolar lumen by the process of regulated exocytosis.[177-181] A lamellar body in the process of exocytosis is shown in Figure 103-5. It is possible that there is also some constitutive secretion of surfactant lipids; the basal secretion of phospholipids that is observed in isolated type II cells cultured without secretagogues may well be a constitutive process. However, secretion of surfactant appears to be a slow process, with little difference between regulated and constitutive mechanisms.[182]

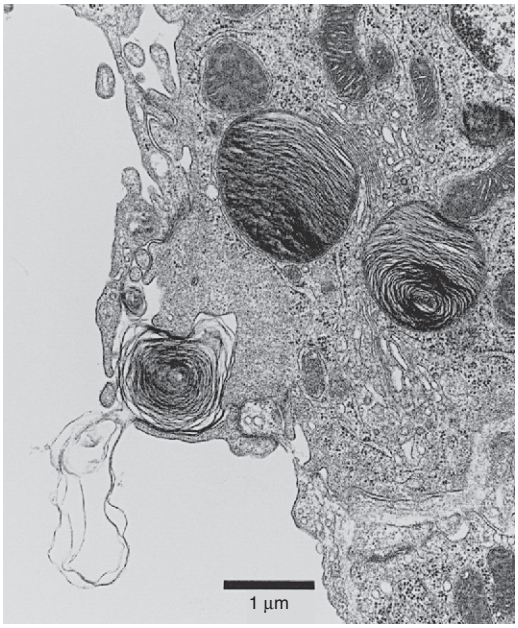

Figure 103-5 Exocytosis of a lamellar body by an adult rat type II cell. This electron micrograph was generated by Dr. Stephen L. Young at Duke University. *(From Rooney SA, Young SL, Mendelson CR: Molecular and cellular processing of lung surfactant,* FASEB J *8:957, 1994.)*

Surfactant secretion has been measured in several systems ranging from intact animals in vivo to isolated type II cells in culture.[177-180] Isolated type II cells have been the model of choice for most studies on the regulation of surfactant secretion. Most such studies have been carried out on type II cells isolated from adult animals, but surfactant secretion in fetal and newborn type II cells[76,183-185] has also been investigated. In most studies, secretion of surfactant phospholipid has been assessed biochemically by labeling the intracellular PC pool with [^{3}H] choline during overnight culture of the cells and then measuring the amount of [^{3}H]PC or disaturated PC released into the medium. However, cell physiologic and fluorescent techniques have been used to study surfactant secretion and membrane fusion kinetics in single type II cells.[182,186-189]

Various physiologic and pharmacologic agents stimulate surfactant secretion in isolated type II cells, and some agents inhibit it.[177-180] Well-established surfactant secretagogues in cultured type II cells include the following: β-adrenergic, adenosine A_{2B}, and $P2Y_2$ receptor agonists; agents such as tetradecanoylphorbol acetate (TPA); cell-permeable DAGs; forskolin and cholera toxin, which bypass receptors and activate downstream signaling steps; and the ionophores ionomycin and A23187, which promote calcium (Ca^{2+}) influx into the cell (Figure 103-6).

A working model of the signal-transduction mechanisms that mediate surfactant secretion is shown in Figure 103-6. The signaling mechanisms consist of three distinct pathways, although overlap and interactions exist among them.[177,190] The first mechanism involves activation of adenylate cyclase

*References 38, 46, 51, 54, 64, 66

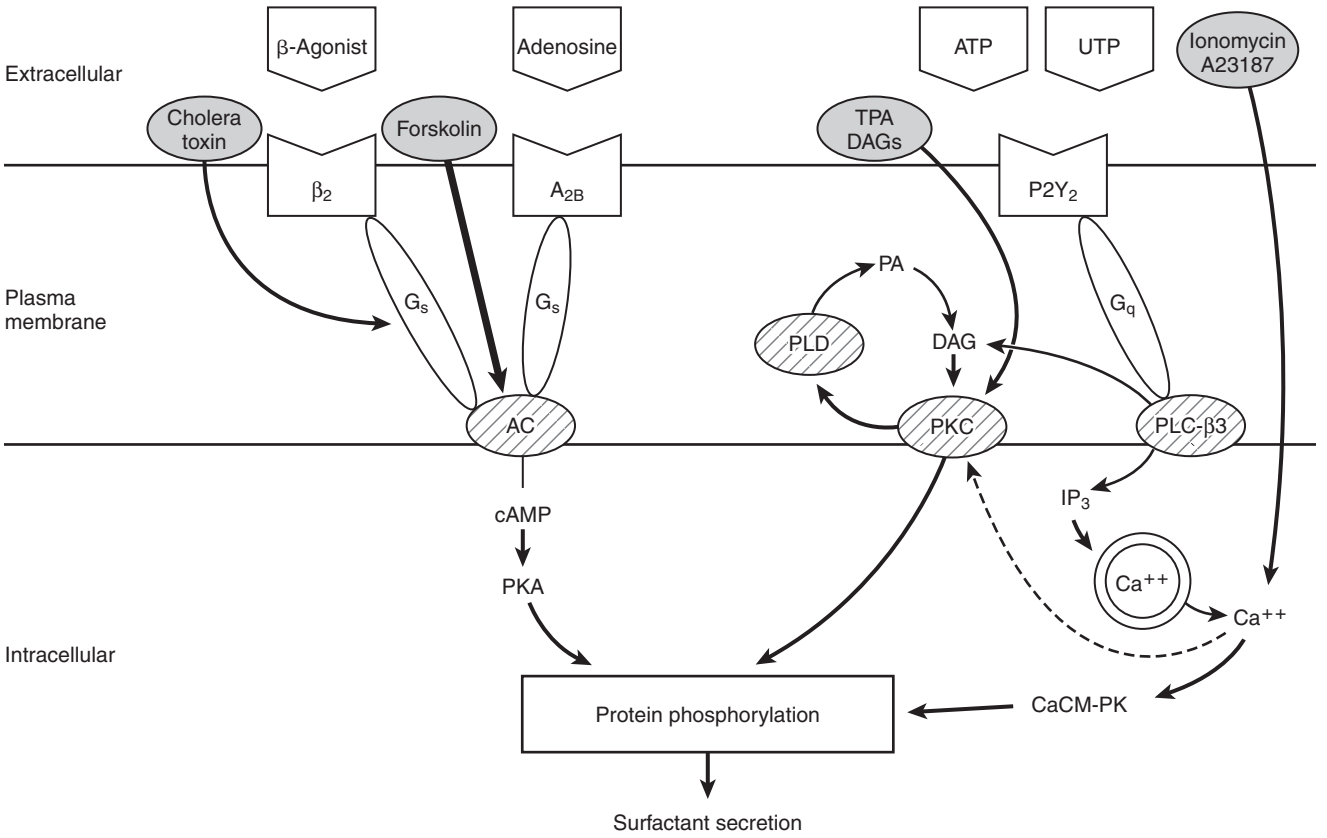

Figure 103-6 Schematic representation of signal transduction mechanisms mediating surfactant phospholipid secretion in type II cells. See text for explanation and abbreviations. *(Modified from Rooney SA, Young SL, Mendelson CR: Molecular and cellular processing of lung surfactant,* FASEB J *8:957, 1994.)*

(AC), generation of cAMP and subsequent activation of cAMP-dependent protein kinase (protein kinase A). This pathway is activated by agonists such as terbutaline and the adenosine analogue *N*-ethylcarboxyamidoadenosine that bind to β-adrenergic and adenosine A_{2B} receptors, respectively, both of which are coupled to AC through the G-protein G_s. The AC pathway is also activated by cholera toxin, which permanently activates G_s, and by forskolin, which directly activates AC.

The second mechanism involves direct or indirect activation of protein kinase C (PKC). TPA and cell-permeable DAGs directly activate PKC. ATP and uridine triphosphate (UTP) activate PKC by binding to $P2Y_2$ receptors that are coupled to phospholipase C-β_3 (PLC-β_3) through G_q. Activation of PLC-β_3 results in hydrolysis of phosphatidylinositol bisphosphate and formation of DAG, which then activates PKC. PKC, in turn, activates phospholipase D (PLD),[191] which hydrolyzes PC to form choline and PA. Phosphatidate phosphatase converts PA to DAG (see Figure 103-1), which further activates PKC. The PLD loop may provide a mechanism whereby surfactant secretion is sustained for a prolonged period. PA itself may also have a signaling role,[192] although that possibility has not been investigated in the type II cell. In addition to acting through $P2Y_2$ receptors, ATP also stimulates surfactant secretion by the cAMP pathway; ATP, but not UTP, promotes cAMP formation in the type II cell.[193] This effect of ATP is not the result of direct action at the adenosine A2B receptor.[177] Whether it is caused by catabolism to adenosine with consequent activation of A_{2B} receptors[194] or by activation of an unidentified AC-coupled receptor[177,195] has not been established.

The third mechanism involves elevation of intracellular Ca^{2+} levels. This can be accomplished by increasing the level of inositol triphosphate, the other product of the action of PLC-β_3; inositol triphosphate promotes mobilization of Ca^{2+} from intracellular stores.[196] It can also be accomplished by ionophores that promote Ca^{2+} influx into the cell from the medium. Ca^{2+} activates a Ca^{2+}/calmodulin-dependent protein kinase (CaCM-PK) and may also act synergistically with DAG to activate some PKC isoforms. Protein phosphorylation by protein kinase A, PKC, or CaCM-PK ultimately leads to surfactant secretion.

Secretion is an indispensable step in the overall homeostasis of surfactant.[179,197] Failure of secretion would likely lead to a drastic deficiency in surfactant. Because severe surfactant deficiency is probably incompatible with life, it is likely that there is sufficient redundancy so a fatal defect in surfactant secretion does not occur. This would account for the number of potential physiologic agonists that can stimulate surfactant secretion and would also explain the multiple signaling mechanisms.

There is a developmental increase in agonist-induced surfactant secretion in fetal and neonatal rat Type II cells.[183,185] The response to the $P2Y_2$ agonist UTP is negligible in early newborn cells, but it increases with age,[185] and the response to ATP, terbutaline, *N*-ethylcarboxyamidoadenosine, and TPA also increases with age.[183] Dexamethasone significantly increases the response to terbutaline, *N*-ethylcarboxyamidoadenosine, ATP, and UTP in early newborn rat type II cells while causing a small decrease in the basal rate of surfactant secretion.[76] This effect is mediated by the glucocorticoid receptor and is probably the result of induction of a signaling step downstream of the receptors that is common to the different signaling pathways.[76] Thus, in addition to stimulation of surfactant synthesis, regulation of its secretion may be an additional function of glucocorticoids in the developing lung.

There are many subtypes and isomers of the receptors and other signaling proteins shown in Figure 103-6, and there is increasing information on the identity of those involved in surfactant secretion. Of the three β-receptors, β_3 is not expressed in the lung,[198] but the β_1 and β_2 genes are both expressed in the type II cell.[199,200] However, pharmacologic data suggest that surfactant secretion is regulated by the β_2 receptor.[201,202] There are four subtypes of adenosine receptors, A_1, A_{2A}, A_{2B}, and A_3,[203] and all four are expressed in the type II cell.[199] Agonist and antagonist potency data and the observation that adenosine agonists that stimulate surfactant secretion also enhance cAMP formation make it clear that it is the adenosine A_{2B} receptor that regulates surfactant secretion.[195] P2 receptors are divided into two major groups: P2X receptors are ion channels, whereas P2Y receptors are metabotropic and are coupled to G-proteins.[204] To date, seven mammalian P2X and seven P2Y receptors have been cloned.[205,206] Evidence is good that the P2 purinoceptor responsible for stimulation of surfactant secretion is $P2Y_2$,[177,195] which was termed P_{2u} in an older nomenclature system.[204] The $P2Y_2$ receptor is expressed in the type II cell,[193,199,207] ATP and UTP are equally potent at $P2Y_2$ receptors,[204] and both nucleotides stimulate surfactant secretion in type II cells with similar EC_{50} values.[193] Additional agonist potency order data are also consistent with involvement of the $P2Y_2$ receptor in surfactant secretion.[193,208,209]

Mammalian PLC is divided into four subfamilies of: β, γ, δ, and ε.[210] $P2Y_2$ receptors are coupled to PLC-β,[211] of which there are four isoforms: β_1, β_2, β_3, and β_4.[212] PLC-β_3 is the only PLC-β isomer expressed in the type II cell[199] and therefore the one involved in regulation of surfactant secretion. The $P2Y_2$ receptor is also coupled to PLC-β_3 in other systems.[211] Twelve PKC isoforms are currently known to exist: α, βI, βII, δ, ε, γ, η, θ, ζ, λ/i, μ, and ν.[213] PKCμ and PKCν are structurally different from the other PKCs[214,215] and have been designated as a new class of protein kinases, protein kinase D (PKD), of which there are currently three members.[216] In this system, PKCμ becomes PKD1. The α, βI, βII, δ, η, θ, and ζ isoforms of PKC as well as PKD1 are expressed in the type II cell.[199,217] PKD1 is activated by the $P2Y_2$ agonists ATP and UTP as well as by TPA and a cell-permeable DAG, dioctanoylglycerol, in the type II cell.[218] This finding suggests a physiologic role for PKD1 in regulation of surfactant secretion. TPA and dioctanoylglycerol also activate PKCs α, βI, βII, δ, and η[217,218]; however, because both agonists are nonphysiologic, the significance of this in terms of regulation of surfactant secretion is not clear. PKD is involved in several signaling pathways and has been reported to be downstream of PKC.[216] However, in type II cells, no evidence is available that any PKC isomers other than PKD1 are activated by $P2Y_2$ agonists.[218]

The specific isomers of other signaling proteins (see Figure 103-6) involved in regulation of surfactant secretion have not been identified. Two mammalian PLDs exist, PLD1 and PLD2,[219] and both are expressed in the type II cell.[181] However, the PLD isomers involved in surfactant secretion are not known. Eight of the nine membrane-associated mammalian AC isoforms are expressed in the lung,[220,221] and AC-II and AC-IV, but not AC-I, are expressed in the type II cell.[222] Whether other ACs are also expressed in the type II cell is not known, and the AC isoforms involved in surfactant secretion have not been identified. Currently no information is available about the subunits or isomers of protein kinase A[223] and CaCM-PK[224, 225] that are expressed in the type II cells or are involved in surfactant secretion.

Other signaling mechanisms may also be involved in surfactant secretion.[181] For instance, data suggest involvement of phospholipase A_2 as well as a PC-specific PLC in ATP- and TPA-mediated secretion.[177] High- and low-density serum lipoproteins stimulate PC secretion by activation of receptors coupled to PKC through G_i.[226,227] Mastoparan, an agent that activates several signaling mechanisms, is a powerful surfactant secretagogue, and there are indications that its effect is also mediated in part by G_i.[228] Mitogen-activated protein (MAP) kinase activation is not involved in surfactant secretion, although this enzyme is often downstream of PKC activation,[229] and it is activated by $P2Y_2$ agonists in numerous systems.[181,230,231] Although ATP and TPA activate the MAP kinase cascade in type II cells,[232] MAP kinase inhibitors do not antagonize agonist-stimulated PC secretion.[181,232,233] Involvement of the MAP kinase cascade in surfactant-associated protein (SP)-A inhibition of surfactant secretion has also been discounted.[180,233] Experiments with inhibitors similarly suggest that tyrosine kinase signaling does not have a role in regulation of surfactant secretion,[181] although it is involved in P2 receptor signaling in other systems.[231]

Distal steps in the surfactant secretory pathway have been incompletely studied. As shown in Figure 103-6, all the signal-transduction pathways are believed to result in phosphorylation of proteins after activation of specific protein kinases. Virtually no information is available on the identity of the proteins phosphorylated in response to surfactant secretagogues, although TPA[234] and terbutaline[235] were reported to promote phosphorylation of certain proteins in type II cells. Relatively little is known of the steps beyond protein phosphorylation that ultimately result in exocytosis of lamellar bodies[177]; essentially no information is available about whether the SNARE (soluble NSF [*N*-ethylmaleimide–sensitive fusion protein] attachment protein receptor) paradigm of vesicle (lamellar body) docking and membrane fusion[236,237] applies to surfactant secretion.[177] However, some of the proteins involved in the SNARE exocytosis mechanism are phosphorylated,[236,237] and it is possible that such proteins are the site of action of the protein kinases involved in surfactant secretion. Also evidence exists of a role for synexin in fusion of lamellar bodies with the cell membrane in type II cells,[238,239] and it has been suggested that both synexin and the SNARE mechanism may be independently involved in mediating surfactant secretion.[239]

Little is known about the physiologic regulation of surfactant secretion.[177,181] Two physiologic factors are known to stimulate surfactant secretion in vivo: ventilation/exercise, which stimulates secretion in both adults[240-243] and newborns,[244,245] and labor, which stimulates secretion in newborns.[246] Ventilation-induced surfactant secretion is thought to result from a direct mechanical effect on the lung,[247] and in vitro experiments have shown that stretch increases surfactant secretion in type II cells.[248] Ventilation causes stretch of type I cells, and the type I cell then acts as a mechanotransducer to stimulate surfactant secretion by the type II cell.[189] The amount of literature is extensive on the mechanisms by which the effects of physical forces are transduced.[247] Evidence shows the involvement of at least three signaling pathways: activation of AC, PLC, and MAP kinase. Although, as discussed earlier, MAP kinase is not involved in regulation of surfactant secretion,[181,232,233] both AC and PLC are involved (see Figure 103-6).

There is direct evidence of a physiologic role for the AC signaling mechanism in regulation of surfactant secretion. A physiologic role for β-receptor activation is suggested by the finding that the stimulatory effects of ventilation[241] and labor[249] are antagonized by β-antagonists. A similar role for the adenosine A_{2B} receptor is suggested by the finding that the ventilation-induced increase in surfactant secretion in newborn rabbits is attenuated by an adenosine receptor antagonist.[244] Finally, although atropine blocks the effect of ventilation in vivo,[240,244,245] a finding suggesting cholinergic regulation, evidence is substantial that cholinergic regulation of surfactant secretion is mediated by activation of β-receptors on the type II cell in response to catecholamines released from the adrenal

medulla.[177] β-agonists,[241,250] cholinergic agonists,[240,244,250] and adenosine[251] all stimulate surfactant secretion in vivo.

No direct evidence is currently available that PLC activation has a physiologic role. As shown in Figure 103-6, PLC-β_3 is central to both the PKC and CaCM-PK signaling pathways. Apart from ATP, UTP, and possibly lipoproteins,[227] the only well-established surfactant secretagogues that activate the PKC signaling pathway are the nonphysiologic agonists TPA and cell-permeable DAGs, whereas those that activate the CaCM-PK pathway are the equally unphysiologic ionophores ionomycin and A23187. It is highly likely that some physiologic agonist activates those signaling mechanisms, and it is tempting to speculate that ATP or UTP may be such an agonist. Currently, no information is available on whether the $P2Y_2$ receptor on the type II cell has a physiologic role in regulation of surfactant secretion, but evidence is good that the $P2Y_2$ receptor has such a role in many other systems.[204,205,252,253] Activation of P2Y receptors is one of the mechanisms by which the effect of mechanical force is transduced[254]; a mechanical stimulus promotes release of ATP and UTP in airway epithelial and other cells.[254-256] The nucleotides then activate P2Y receptors on either the same or adjacent cells in an autocrine or paracrine manner.[253,254,256] Mechanical stimulation activates PLC in airway epithelial and other cells,[257,258] and the stretch-induced increase in surfactant secretion in type II cells is accompanied by elevated intracellular Ca^{2+} levels.[248] Thus possibility is reasonable that the stimulatory effect of ventilation on surfactant secretion is mediated by the type II cell $P2Y_2$ receptor and therefore by the PKC or CaCM-PK signaling pathways. Based on tissue culture data, ATP levels in bronchoalveolar lavage fluid[259] are sufficient to stimulate surfactant secretion.

SECRETION OF SURFACTANT PROTEINS

Secretion of the protein components of surfactant has been less extensively investigated than that of the phospholipids. Lamellar bodies are enriched in the hydrophobic proteins, SP-B and SP-C,[260] and these organelles have a central role in the overall processing of both proteins.[261] Secretion of SP-B and SP-C in rat type II cells is stimulated by the same agonists that stimulate PC secretion: terbutaline, *N*-ethylcarboxyamidoadenosine, ATP, TPA, and ionomycin.[262] A combination of agonists and a PKC inhibitor have the same effects on secretion of SP-B and SP-C as on that of PC.[262] In addition evidence shows that in vivo secretion of SP-B and PC have similar kinetics.[263] Therefore secretion of surfactant phospholipids and of hydrophobic proteins is similarly regulated, and secretion of both involves exocytosis of lamellar bodies.

In contrast secretion of SP-A and SP-D occurs by a different mechanism. Although data are conflicting with respect to the distribution of SP-A between lamellar bodies and other compartments of the type II cell,[180,264-266] it is general agreed that secretion of SP-A occurs independently of lamellar bodies. SP-A secretion in isolated type II cells is usually not stimulated by agonists that stimulate PC secretion,[184,262,265,267] although in two studies it was stimulated by TPA.[268,269] Furthermore, both in vivo[270,271] and tissue culture[266] experiments suggest that newly synthesized SP-A is secreted independently of lamellar bodies. Lamellar bodies are devoid of SP-D,[272,273] and secretion of SP-D is not stimulated by surfactant phospholipid secretagogues in isolated type II cells.[262,267,268]

In summary, secretion of surfactant phospholipids, SP-B, and SP-C occurs largely by regulated exocytosis of lamellar bodies, whereas secretion of SP-A and SP-D occurs independently of lamellar bodies and is either not regulated or is regulated by a different mechanism from that of the phospholipids and hydrophobic proteins.

Pathophysiology of Respiratory Distress Syndrome and Surfactant Metabolism

The pathophysiology of the respiratory distress syndrome (RDS) and the surfactant system were linked by the recognition of abnormal surfactant in RDS by Avery and Mead in 1959.[1] This chapter focuses on the pathophysiology of RDS from the perspective of surfactant metabolism and function. The effects of surfactant treatment on the initial pathophysiologic events and on surfactant metabolism also will be reviewed. Clinical aspects of surfactant treatment for RDS and its resolution will be covered in another chapter.

LUNG STRUCTURE OF THE PRETERM WITH RESPIRATORY DISTRESS SYNDROME

Lung structure is the substrate on which surfactant functions. The preterm lung changes structure as it matures, and the structural maturation of the lung affects the responses of the lung to surfactant and the lung complications that may occur after preterm birth. The lung of the term infant contains approximately 30% of the 500 million alveoli that are present in the adult lung[2,3] (Figure 104-1). The fetal lung at the margin of viability at 24 weeks gestation has just matured beyond the canalicular stage to be in the early saccular stage of lung development.[4] The saccular lung has undifferentiated distal air saccules with a poorly developed capillary microvasculature. The potential surface area for gas exchange of the developing human lung does not increase much before 30 weeks gestation, and alveolar septation of the distal saccules does not begin until after 32 weeks. However, the rate of septation to form alveoli then is high until term. After birth, the rate of alveolar septation decreases until alveolar development ceases at 18 to 24 months of age. A slow process of alveolar septation and lung remodeling may continue throughout life. The early lung maturation that commonly occurs in preterm infants with maternal glucocorticoid treatment or with exposure to chorioamnionitis will accelerate mesenchymal involution and increase surfactant but may delay alveolar septation.[5,6] A major factor determining how the preterm lung will respond to treatment and injury is the structural maturation of the lung at delivery.

OVERVIEW OF SURFACTANT METABOLISM

The general scheme of surfactant metabolism as it is understood in the adult lung is the basis for the discussion of surfactant metabolism in the preterm lung with RDS[7] (Figure 104-2). More extensive descriptions of the surfactant lipids and proteins, the biophysics of surfactant function, and regulation of synthesis and secretion are found in other chapters in this section. Surfactant lipids are synthesized from precursors, such as palmitic acid, that are made by type II cells or are transported to the type II cells from the circulation. The lipids are processed via the Golgi to multivesicular bodies that associate with the surfactant-associated protein (SP)-B and SP-C and are stored in the form of membrane-enclosed lipid and protein structures called lamellar bodies. Lamellar bodies are localized to the apical (air) surface of the type II cell and are secreted by exocytosis either constitutively or when type II cells are stimulated by secretogogues such as β-agonists and purines or by mechanical stretch. The other surfactant proteins SP-A and SP-D are secreted primarily independently of the lamellar bodies.

Surfactant also has an extracellular "life cycle" once secreted to the thin fluid hypophase of the healthy lung. The SP-A associates in the hypophase with the lipids plus SP-B and SP-C secreted as lamellar bodies to form tubular myelin and other loose lipid arrays that are macroaggregated lipoprotein forms.[8] These large lipoprotein aggregates are the forms of surfactant that facilitate adsorption to the air-water interface. The surfactant film is multilayered and continuously replenished from surfactant in the hypo-phase.[9] Lipids are cleared from the airspaces as small liposomal vesicles that contain the phospholipids, but essentially no surfactant proteins. The surfactant proteins also are cleared by macrophages and type II cells, but their forms for clearance have not been characterized. Approximately half of the surfactant components are catabolized by alveolar macrophages in the adult mouse lung and the other half are catabolized by type II cells.[10] However, the type II cells also take up phospholipids, SP-B, SP-C, and SP-A and recycle them via multivesicular bodies back to lamellar bodies for resecretion.

The surfactant lipids and proteins are dynamically cycling from type II cells to the surfactant layer and back to type II cells. In the adult rabbit lung, the rate of synthesis of surfactant phosphatidylcholine is 1.5 μmol/kg • hr, 0.5 μmol/kg • hr is recycled back from the airspace, and approximately 2 μmol/kg • hr is secreted into an alveolar pool of approximately 10 μmol/kg.[11] Approximately 25% of the phospholipids are recycled in the adult. At steady state, the alveolar surfactant pool is replaced every 5 hours. Thus surfactant pool is very metabolically active. The airway clearance rates and efficiencies of recycling for SP-A, -B, and -C are similar to the lipids in the adult lung.[12-14] As will be apparent, the recycling pathways are important for surfactant treatment strategies.

CHARACTERISTICS OF SURFACTANT IN THE PRETERM

Composition

The composition of surfactant and the characteristics and function of the surfactant proteins are discussed extensively in the chapters in this section. We focus on the composition of surfactant in the preterm. The surfactant recovered from the air spaces of preterm animals with RDS has less saturated phosphatidylcholine relative to total phospholipids.[15] The lower amount of saturated phosphatidylcholines will result in a surfactant with decreased surface activity. The surfactant of a mature animal or man contains approximately 8% phosphatidylglycerol and little phosphatidylinositol. In contrast surfactant from the preterm contains much more phosphatidylinositol than phosphatidylglycerol.[16] These two acidic phospholipids are interchangeable in terms of surfactant function, but the lack of phosphatidylglycerol in surfactant indicates lung immaturity or injury to the type II cells. The changes in the lecithin/sphingomyelin (L/S) ratio in amniotic fluid with advancing gestation result primarily from the contributions of fetal lung fluid to amniotic fluid. The L/S ratio increases after at approximately 34 weeks gestation

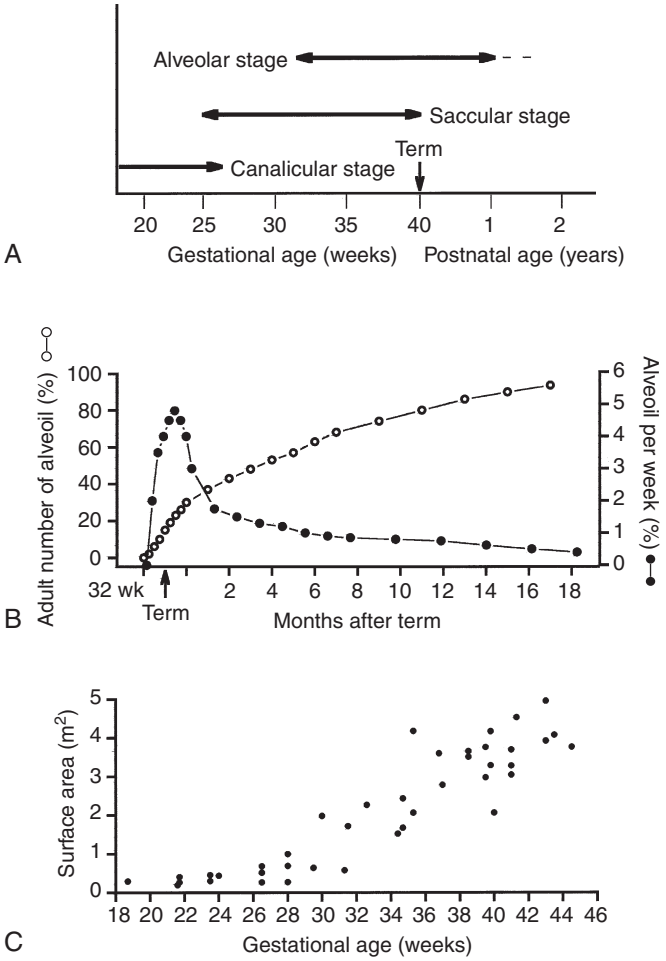

Figure 104-1 Lung structural maturation. A, The stages of lung development from 20 weeks gestation to 2 years. **B,** Alveolar number and weekly rate of accumulation of alveoli are expressed as percentage of the adult number of alveoli. The curves assume that the term infant has 30% of the adult number of alveoli. **C,** The large increase in lung surface area does not occur until after the saccular lung begins to alveolarize. *(**A,** Modified from Burri PH: Structural aspects of prenatal and postnatal development and growth of the lung. In McDonald JA, editor:* Lung Growth and Development, *New York, 1997, Marcel Dekker, pp 1-35;* **B,** *Modified from Hislop AA, Wigglesworth JS, Desai R: Alveolar development in the human fetus and infant,* Early Hum Dev *13:1, 1986;* **C,** *Modified from Langston C, Kida D, Reed M, et al: Human lung growth in late gestation and in the neonate,* Am Rev Respir Dis *129:607, 1984.)*

in normal pregnancies, indicating progressive lung maturation.[17] The L/S ratio measures primarily saturated phosphatidylcholine relative to sphingomyelin, a lipid not specific to the fetal lung surfactant. The phosphatidylinositol content of amniotic fluid increases after 28 weeks gestation to peak at 35 weeks gestation, and phosphatidylglycerol does not begin to increase until after 34 weeks gestation.[16] Infants with early lung maturation caused by fetal stress or fetal exposure to inflammation can increase the amounts of saturated phosphatidylcholine, decrease phosphatidylinositol, and increase phosphatidylglycerol in amniotic fluid to have a surfactant composition comparable to a mature lung. Infants recovering from RDS have increasing amounts of phosphatidylglycerol in the surfactant. In contrast RDS that progresses to bronchopulmonary dysplasia (BPD) results in surfactant with a delayed appearance of phosphatidylglycerol, presumably because of injury to type II cells.[18]

The surfactant specific protein content of surfactant from the preterm lung is low relative to the amount of lipid. Type II cells with lamellar bodies appear in the human lung after approximately 22 weeks, but very little surfactant protein mRNA is expressed until later in gestation. The timing of gene expression and protein secretion in the normal human preterm fetus can be inferred from the increases in the proteins in amniotic fluid.[19] SP-A increases after 32 weeks gestation; SP-B increases after 34 weeks gestation. In animal models SP-A and SP-B mRNA expression is low until late in gestation and then increases rapidly to term. SP-B protein must be extensively processed before it enters lamellar bodies. With induced lung maturation in fetal sheep, both the mRNA and the protein processing of SP-B increase in parallel.[20] SP-D mRNA in the lung also is low until late gestation, and amniotic fluid levels of SP-D do not change much with advancing gestation.[21] SP-A and SP-D in amniotic fluid may also come from nonpulmonary sources because these innate host defense proteins are made in locations other than the lung.

In contrast to other surfactant proteins, SP-C mRNA is highly expressed at the tips of branching airways during early lung development.[22] SP-C mRNA also is expressed in the developing type II cells before SP-C is found in the fetal airways. Incompletely processed SP-C is in tissue before mature SP-C is measurable in the secreted surfactant in the fetal rabbit, and the ratio of mature SP-C to saturated phosphatidylcholine increases 10-fold over 2 days gestation in the rabbit.[23] SP-C has not been measured in amniotic fluid from humans.

Surfactant Pool Size

During normal gestation, the lungs store progressively larger amounts of surfactant in the maturing type II cells. The appearance of surfactant in fetal airspaces lags behind the accumulation of surfactant in fetal lung tissue. After approximately 34 weeks, surfactant is secreted by the fetus and large amounts of surfactant can be isolated from amniotic fluid at term. The term infant has a large excess of surfactant that facilitates rapid pulmonary adaptation to air breathing. The amount of surfactant in the lung saccules in infants younger than 32 weeks and in the developing alveoli and small airways after 32 weeks depends on the physiologic events experienced by the fetus or newborn. With labor and the stress of delivery, some of the lamellar bodies are secreted into the fetal lung fluid, and surfactant concentration increases as fetal lung fluid volume decreases.[24] More surfactant is secreted after the initiation of ventilation in response to stretch, increased catecholamines, and purinoceptor agonists. In the preterm sheep, the fetal surfactant stores in the type II cells are secreted within approximately 30 minutes of ventilation after birth.[25]

The only direct measurements of surfactant pool sizes of infants were made by alveolar lavage of lungs of infants who died of RDS soon after birth and in the era before mechanical ventilation was available.[26] The lavages contained approximately 5 mg/kg surfactant. Measurements by bronchoalveolar lavage in preterm rabbits and lambs with severe RDS yield values less than 3 mg/kg. Preterm lambs can be supported with continuous positive airway pressure if their surfactant pool size is approximately 3 mg/kg.[27] Smaller pool sizes result in severe respiratory failure. The differences in phospholipid composition between exogenous surfactant given as treatment and the endogenous surfactant have been used to estimate the pool size in infants with RDS. By measuring the change in phosphatidylglycerol composition, Hallman and colleagues[28] estimated a surfactant pool size of approximately 9 mg/kg for infants with RDS.

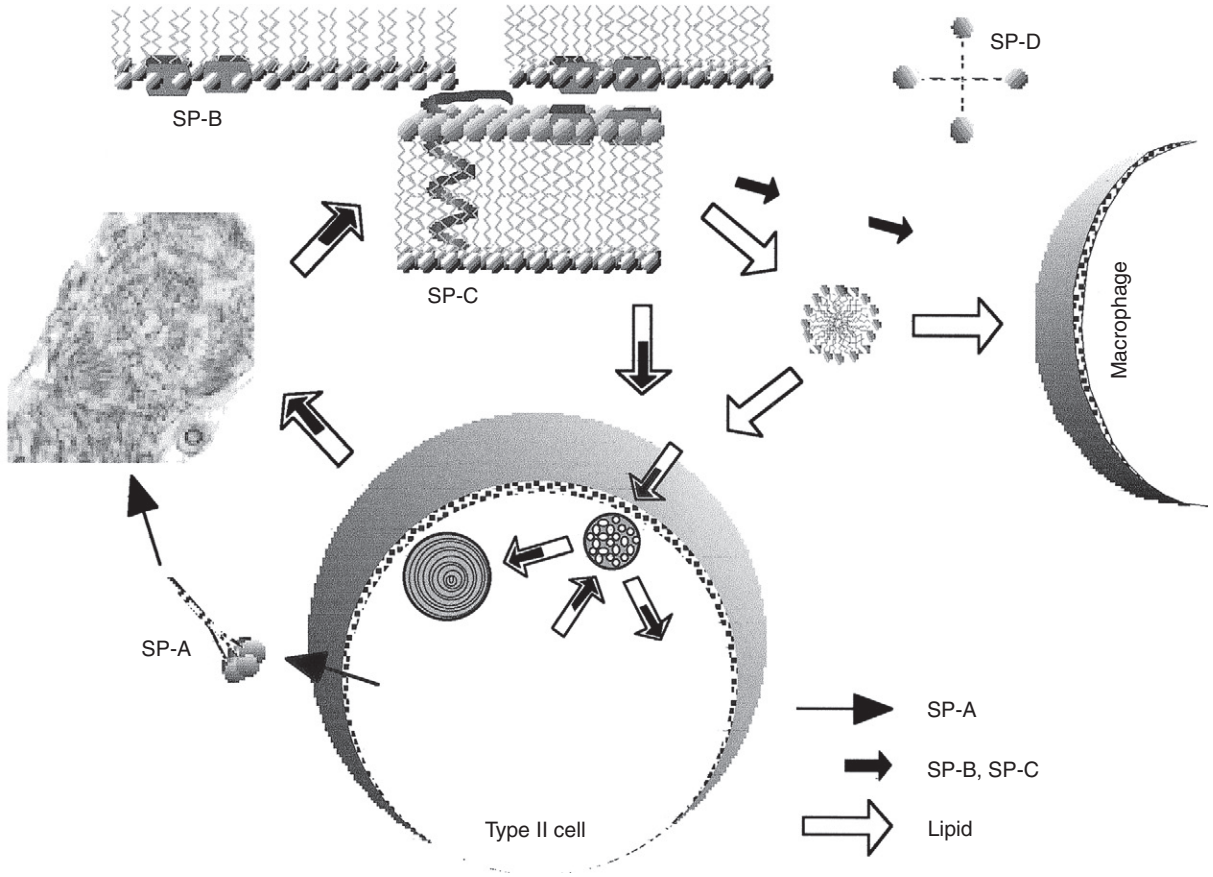

Figure 104-2 Major metabolic pathways of surfactant. Surfactant components are synthesized and packaged into lamellar bodies in type II cells.The lamellar bodies are secreted to the hypophase and surfactant is adsorbed to the air fluid interface. Surfactant components are cleared from the airspaces primarily by type II cells and macrophages. *SP,* Surfactant-associated protein.

Similar measurements by Griese and colleagues[29] yielded a surfactant pool size estimate of 20 mg/kg. A more recent measurement using stable isotope-labeled dipalmitoylphosphatidylcholine yielded a value of 5.6 mg/kg.[30] These techniques assume good mixing of the treatment surfactant with the endogenous pool, no loss of the treatment surfactant from the alveolar pool, and that airway aspirates represent what is in the distal lung. These assumptions are not strictly valid, and the techniques used clinically will overestimate the endogenous pool size by at least two-fold.[25]

The endogenous pool size of surfactant is the major determinant of lung compliance in preterm animals[31,32] (Figure 104-3). Very preterm infants with severe RDS probably have surfactant pools of less than 5 mg/kg. Although not measured in humans, term newborn animals have surfactant pools of approximately 100 mg/kg. In contrast the surfactant pool size in the adult human is only approximately 4 mg/kg.[33] Therefore preterm infants have perhaps 5% of the amount of surfactant in the term newborn lung, but they have amounts comparable to the healthy adult human. This issue will be addressed relative to surfactant function later in this chapter.

Changes in Surfactant Pool Size After Birth

The pool sizes of surfactant that can be recovered by alveolar lavage increase slowly after birth in preterm ventilated monkeys and sheep. In monkeys recovering from RDS, the surfactant increases from approximately 5 mg/kg toward term values by 3 to 4 days of age[34,35] (Figure 104-4). No direct measurements of surfactant pool sizes as infants recover from RDS are available. The changes in surfactant concentration in airway samples will, in part, reflect pool sizes. The concentration of surfactant was similar for infants without RDS and for infants with RDS who were treated with surfactant.[36] Infants with RDS had a progressive increase in surfactant concentration during approximately 4 days.

Surfactant treatments with the commonly used dose of 100 mg/kg do not result in large or sustained increases in alveolar surfactant pool size. Soon after administration, the majority of the lipids can no longer be recovered by lavage. For example, in sheep only approximately 25% of the treatment dose is recovered 5 hours after treatment.[37] In preterm ventilated baboons, approximately 20% of the treatment amount of surfactant was recovered 24 hours later.[38] Infants with RDS had a mean surfactant pool size of 17 mg/kg 33 hours after an initial 100 mg/kg surfactant treatment, as estimated with stable isotopes.[30] The increase in alveolar surfactant that accompanies the resolution of RDS does not occur in preterm ventilated baboons that are developing BPD.[39] In these animals, the alveolar pool size after surfactant treatment at birth and 6 days of ventilation was approximately 30 mg/kg, which had not increased after a second surfactant treatment and a further 8 days of ventilation. The alveolar content of the surfactant proteins SP-A and SP-D also were low in these preterm baboons.[40] Nevertheless, the lung tissue content of saturated phosphatidylcholine increased approximately four-fold, and the tissue content of SP-A and SP-D increased, indicating a defect in surfactant processing and secretion in the early phases of BPD.

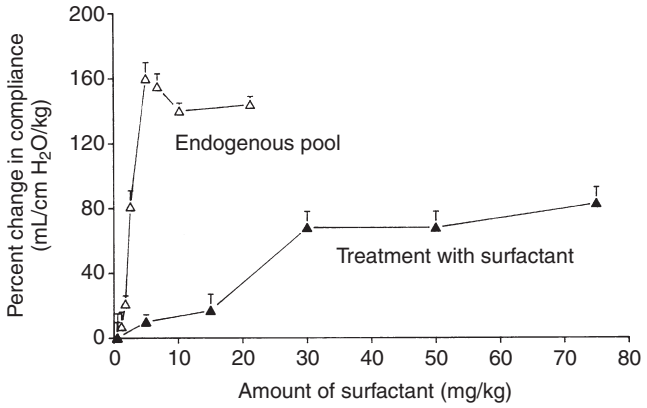

Figure 104-3 Compliance changes in relation to surfactant pool sizes. The curve for the endogenous pool was measured for alveolar washes of ventilated preterm rabbits that were 27 to 29 days gestational age at delivery.The increase in compliance includes a surfactant effect as well as spontaneous lung structural maturation that occurred in the 2-day interval.The curve for treatment with surfactant gives the responses of 27-day gestation rabbits to different treatment doses of surfactant. *(Data from Ikegami M, Jobe AH, Yamada T, et al: Relationship between alveolar saturated phosphatidylcholine pool sizes and compliance of preterm rabbit lungs, the effect of maternal corticosteroid treatment,* Am Rev Respir Dis *139:367, 1989 and Seidner S, Pettenazzo A, Ikegami M, et al: Corticosteroid potentiation of surfactant dose response in preterm rabbits,* J Appl Physiol *64:2366, 1988.)*

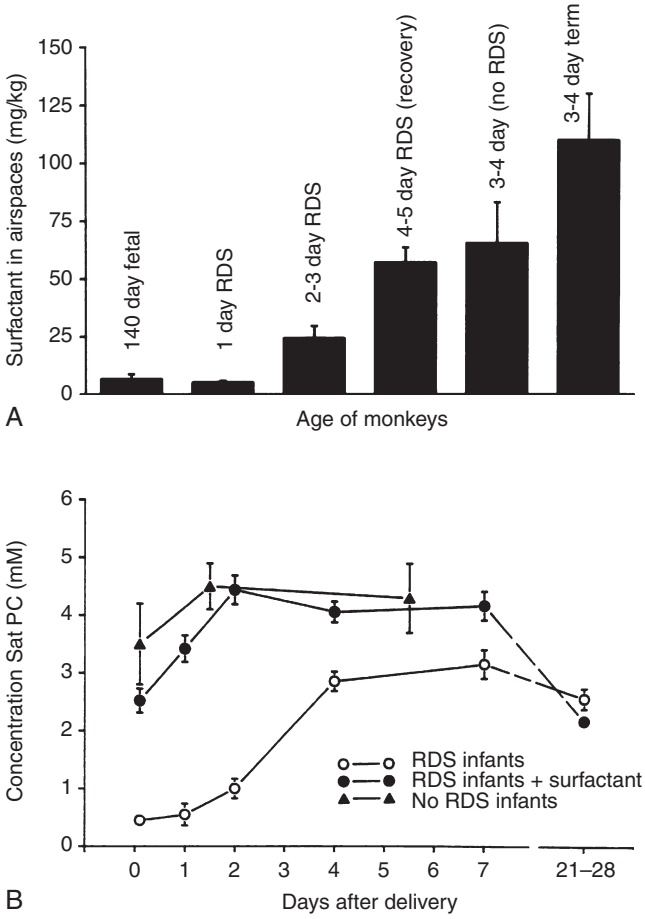

Figure 104-4 Surfactant pool sizes with resolution of respiratory distress syndrome (RDS). A, The amount of surfactant recovered by alveolar lavage from mechanically ventilated preterm monkeys with RDS is shown relative to age and stage of the disease. **B,** The concentrations of saturated phosphatidylcholine *(Sat PC)* in airway samples from infants with RDS, infants with RDS treated with surfactant, and infants without RDS are graphed relative to age from birth.The concentrations of Sat PC approached values for healthy preterm infants by 4 to 7 days. *(**A,** Data from Jackson JC, Palmer S, Truog WE, et al: Surfactant quantity and composition during recovery from hyaline membrane disease,* Pediatr Res *20:1243, 1986, and Jackson JC, Palmer S, Flandaert T: Developmental changes of surface active material in newborn non-human primates,* Am Rev Respir Dis *129:A204, 1984.* **B,** *Data from Hallman M, Merritt TA, Akino T, et al: Surfactant protein-A, phosphatidylcholine, and surfactant inhibitors in epithelial lining fluid: correlation with surface activity, severity of respiratory distress syndrome, and outcome in small premature infants,* Am Rev Respir Dis *144:1376, 1991.)*

Surfactant Metabolism in the Preterm

To understand how the alveolar surfactant pool is maintained in the lung, it is helpful to divide metabolism into the anabolic components of synthesis and secretion and the catabolic activities of uptake, degradation, and recycling. Surfactant components labeled with stable isotopes were used to evaluate surfactant metabolism in infants. Although these measurements have a number of limitations, they provide information that corroborates the more complete measurements that have been made in term and preterm animals. Most metabolic studies have focused on saturated phosphatidylcholine because it is the major component of surfactant and is primarily responsible for the biophysical properties of surfactant.

Measurements of synthesis of surfactant phospholipids generally involve the intravascular injection of labeled precursors. The labeled precursors are taken up by type II cells and incorporated into phosphatidylcholine, which is transacylated to increase the amount of saturated phosphatidylcholine. The surfactant lipids together with SP-B and SP-C are processed and packaged via multivesicular bodies to become the storage-secretion granule, the lamellar body[41] (see Figure 104-2). Secretion can be measured by recovering the labeled surfactant components from the airspaces, which evaluates the overall kinetics of synthesis and secretion. The absolute amount of a surfactant component that is synthesized cannot be easily determined because the radiolabeled precursor is diluted into the plasma pool and is further diluted by the precursor pool in the type II cell. However, the net kinetics of synthesis and secretion provide critical information for understanding why surfactant deficiency requires days to resolve in infants with RDS.

After term delivery and ventilation of lambs, an intravascular injection of radiolabeled palmitic acid is incorporated into lung phosphatidylcholine within minutes.[42] However, radiolabeled surfactant is not detected in the air spaces for approximately 5 hours, and the amount of radiolabeled surfactant continues to accumulate in the airspaces for 30 to 40 hours[43] (Figure 104-5). A similar curve for accumulation of de novo synthesized surfactant was measured for ventilated preterm lambs with mild RDS. Subsequent surfactant treatment of these preterm lambs caused a large dilution of the endogenous surfactant. Surfactant lipids labeled with ^{13}C-glucose could not be detected in airway samples of surfactant-treated very preterm baboons until 24 hours of age, after a ^{13}C-glucose infusion for the first 24 hours after birth.[44] The peak accumulation of ^{13}C-glucose in phosphatidylcholine was at approximately 100 hours. The curve for the preterm baboon has a longer delay in detection than the curve for the preterm sheep because the radiolabel was not given as

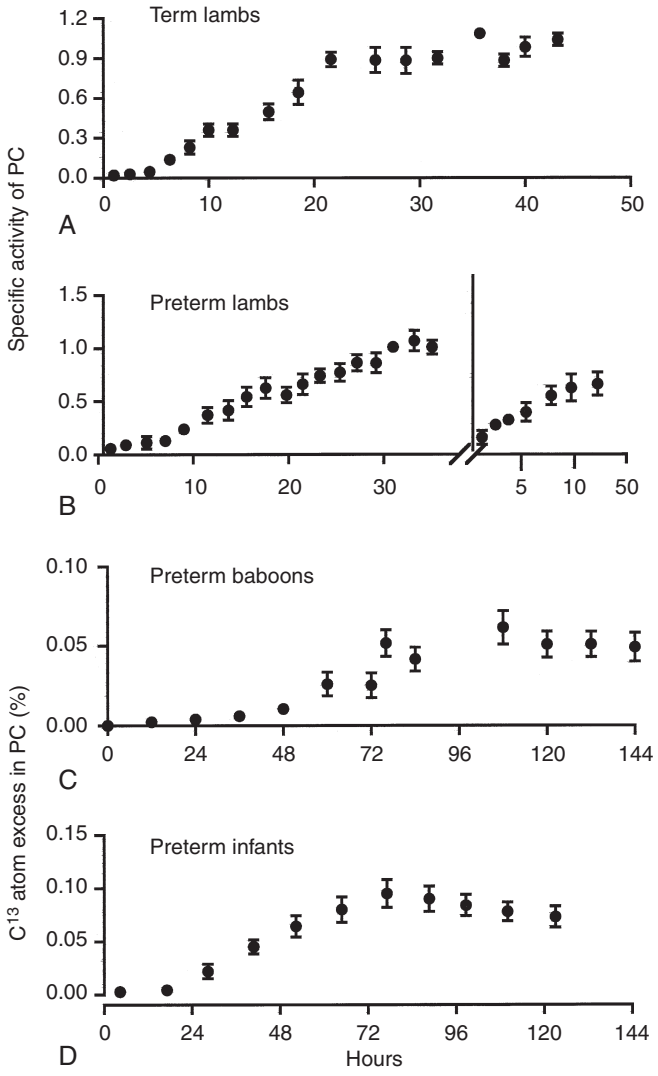

Figure 104-5 Time course of appearance of de novo synthesized surfactant phosphatidylcholine (PC) in airway samples of term lambs, preterm lambs, preterm baboons, and preterm infants. **A,** Labeling of saturated PC in airway samples of ventilated term lambs given ^{3}H-palmitic acid as a bolus intravascular injection at birth. Data are means ± SE of specific activities (counts per minute/μmol PC) normalized to the maximal values for each animal. **B,** Labeling of saturated PC in airway samples of ventilated preterm lambs given a single intravascular injection of ^{3}H-palmitic acid at birth and not treated with surfactant until approximately 38 hours of age.The discontinuity in the curve demonstrates the fall in the specific activity after treatment with surfactant (dilution of surfactant pool with treatment dose of surfactant). **C,** Labeling of PC in airway samples of preterm surfactant-treated baboons that were ventilated for 6 days. The animals received ^{13}C-glucose by intravascular infusion for the first 24 hours of age and the ^{13}C in the palmitate of PC is expressed as ^{13}C-atom percent excess. **D,** Labeling of PC in airway samples of preterm surfactant treated and mechanically ventilated infants with RDS following an intravascular infusion of ^{13}C-glucose for the first 24 hours of life.The label in the PC is expressed as atom percent excess. *(***A** *and* **B,** *Data from Jobe AH, Ikegami M, Glatz T, et al: Saturated phosphatidylcholine secretion and the effect of natural surfactant on premature and term lambs ventilated for 2 days,* Exp Lung Res *4:259, 1983.* **C,** *Data from Bunt JE, Carnielli VP, Seidner SR: Metabolism of endogenous surfactant in premature baboons and effect of prenatal corticosteroids,* Am J Respir Crit Care Med *160:1481, 1999.* **D,** *Data from Bunt JE, Carnielli VP, Darcos Wattimena JL, et al: The effect in premature infants of prenatal corticosteroids on endogenous surfactant synthesis as measured with stable isotopes,* Am J Respir Crit Care Med *162:844, 2000.)*

a pulse label and time was required to get enough label into the airspace to be detected. Preterm surfactant-treated infants given infusions of ^{13}C-palmitic acid and ^{13}C-glucose have curves similar to the baboons for the detection of surfactant lipids in airway samples[45] (see Figure 104-5). The conclusion is that secretion is delayed for hours after synthesis, and surfactant made shortly after birth is secreted gradually over a prolonged period of time. The curves are not altered much by surfactant treatment or by age after birth when the labeled precursor is given.[44] Antenatal glucocorticoids may increase lipid synthesis, but this conclusion is not unequivocal because precursor pools may be altered by the glucocorticoids.[45] Surfactant treatment does not inhibit de novo synthesis of lipids or the surfactant proteins in the preterm lungs. Surfactant treatment also does not alter the ultrastructure of type II cells or the volume fraction of lamellar bodies in type II cells.[46] The timing of phosphatidylcholine secretion measured with stable isotopes was similar for infants with RDS ventilated with conventional or high frequency oscillatory ventilation.[47]
