Fetal and Neonatal PHYSIOLOGY

FOURTH EDITION / VOLUME 1

Richard A. Polin, MD

Professor of Pediatrics
College of Physicians and Surgeons
Columbia University
Director, Division of Neonatology
Morgan Stanley Children's Hospital of New York–Presbyterian
Columbia University Medical Center
New York, New York

William W. Fox, MD

Professor of Pediatrics
Division of Neonatology
University of Pennsylvania Perelman School of Medicine
Medical Director
Infant Breathing Disorder Center
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Steven H. Abman, MD

Professor of Pediatrics
University of Colorado School of Medicine
Director, Pediatric Heart Lung Center
The Children's Hospital
Denver, Colorado

No part of this publication may be reproduced or transmitted in any form or by any means, electronic or mechanical, including photocopying, recording, or any information storage and retrieval system, without permission in writing from the publisher. Details on how to seek permission, further information about the Publisher's permissions policies and our arrangements with organizations such as the Copyright Clearance Center and the Copyright Licensing Agency, can be found at our website: www.elsevier.com/permissions.

This book and the individual contributions contained in it are protected under copyright by the Publisher (other than as may be noted herein).

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Dedicated to

Our spouses –
Helene Polin, Laurie Kilpatrick, and Carolyn Abman

Our children –
Allison Polin Steinbrenner, Mitchell Polin, Jessica Moseley, and Gregory Polin
Will Fox, Jon Fox, James Fox, Lauren Fox, and James Hunt
Ryan Abman, Lauren Abman, Mark Abman, and Megan Abman

And our grandchildren –
Lindsey Steinbrenner, Eli Steinbrenner, Willa Polin, Jasper Polin, and Casey Moseley
Sarah Fox, Jane Fox, Charles Fox, Nola Fox, and Colton Fox

CONTRIBUTORS

Soraya Abbasi, MD
Associate Professor of Pediatrics, University of Pennsylvania School of Medicine; Neonatologist, Division of Neonatology, Pennsylvania Hospital/The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Evaluation of Pulmonary Function in the Neonate

S. Lee Adamson, PhD
Professor of Obstetrics and Gynecology, University of Toronto Faculty of Medicine; Senior Scientist, Samuel Lunenfeld Research Institute of Mount Sinai Hospital, Toronto, Ontario, Canada
Regulation of Umbilical Blood Flow

Anne M. Ades, MD
Associate Medical Director, Newborn/Infant Intensive Care Unit, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Developmental Aspects of Pain

N. Scott Adzick, MD, MMM
C. Everett Koop Professor of Pediatric Surgery, Department of Surgery, University of Pennsylvania School of Medicine; Surgeon-in-Chief, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Pathophysiology of Neural Tube Defects

Kurt H. Albertine, PhD, FAAA
Professor, Department of Pediatrics, Associate Dean for Faculty Administration, School of Medicine, Director, Research Microscopy Facility, Health Sciences Center, University of Utah; Editor-in-Chief, *The Anatomical Record,* Salt Lake City, Utah
Impaired Lung Growth After Injury in Premature Lung

Steven M. Altschuler, MD
President and Chief Executive Officer, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Development of the Enteric Nervous System

Ruben E. Alvaro, MD, FAAP
Associate Professor, Department of Pediatrics, Director of Neonatology, St. Boniface General Hospital, Director of Sleep Lab, Department of Pediatrics, Health Sciences Centre, University of Manitoba, Winnipeg, Manitoba, Canada
Control of Breathing in Fetal Life and Onset and Control of Breathing in the Neonate

Russell V. Anthony, PhD
Hill Professor, Department of Biomedical Sciences, Colorado State University, Fort Collins, Colorado
Angiogenesis

Shankari Arulkumaran, BSc, MB, BS
Clinical Research Fellow, Parturition Research Group, Imperial College Faculty of Medicine, Institute for Reproductive and Developmental Biology, Hammersmith Hospital Campus, London, United Kingdom
Pathophysiology of Preterm Birth

Richard L. Auten Jr., MD
Professor of Pediatrics, Department of Pediatrics, Duke University, Durham, North Carolina
Mechanisms of Neonatal Lung Injury

Mary Ellen Avery, MD, ScD (Hon)
Thomas Morgan Rotch Professor of Pediatrics, Emeritus, Harvard University School of Medicine, Children's Hospital, Boston, Massachusetts
Historical Perspective

Ellis D. Avner, MD
Associate Dean for Research, Professor of Pediatrics and Physiology, Department of Pediatrics (Nephrology), Medical College of Wisconsin; Director, Children's Research Institute, Children's Hospital Health System; Attending Physician, Pediatric Nephrology, Department of Pediatrics, Children's Hospital of Wisconsin, Milwaukee, Wisconsin
Embryogenesis and Anatomic Development of the Kidney

H. Scott Baldwin, MD
Professor of Cell and Developmental Biology, Katrina Overall McDonald Professor of Pediatrics, Division Chief of Pediatric Cardiology, Vice Chair of Pediatric Laboratory Services, Vanderbilt University Medical Center, Nashville, Tennessee
Molecular Determinants of Embryonic Vascular Development

Philip L. Ballard, MD, PhD
Professor Emeritus, Department of Pediatrics, University of California San Francisco, San Francisco, California
Hormonal Therapy for Prevention of Respiratory Distress Syndrome

Eduardo Bancalari, MD
Professor and Director, Division of Neonatology, Department of Pediatrics, University of Miami Miller School of Medicine; Chief, Newborn Service, Department of Pediatrics, Jackson Memorial Hospital, Miami, Florida
Pathophysiology of Bronchopulmonary Dysplasia

David J.P. Barker, MD, PhD, FRS
Professor in Cardiovascular Medicine, Oregon Health and Science University, Portland, Oregon; Professor of Clinical Epidemiology, University of Southampton, Southampton, United Kingdom
Fetal Origins of Adult Disease

Damien Bates, MD, PhD
Chief Medical Officer, Organogenesis, Inc., Canton, Massachusetts
Developmental Basis of Congenital Limb Differences

Frederick C. Battaglia, MD
Professor Emeritus of Pediatrics, University of Colorado at Denver and Health Sciences Center, Perinatal Research Center, Aurora, Colorado
Circulatory and Metabolic Changes Accompanying Fetal Growth Restriction

†Karl Bauer, MD
Professor, Neonatology, Klinikumder Johann Wolfgang-Goethe Universitat, Frankfurt, Germany
Fluid Distribution in the Fetus and Neonate

Gary K. Beauchamp, PhD
Director, Monell Chemical Senses Center, Philadelphia, Pennsylvania
Development of Taste and Smell in the Neonate

Corinne Benchimol, DO
Assistant Professor, Department of Pediatrics, Mount Sinai School of Medicine, New York, New York
Potassium Homeostasis in the Fetus and Neonate

Laura Bennet, PhD
Associate Professor, Department of Pediatrics, University of Auckland, Auckland, New Zealand
Responses of the Fetus and Neonate to Hypothermia

Phillip R. Bennett, MD, PhD, FRCOG
Professor of Obstetrics and Gynecology, Parturition Research Group, Imperial College Faculty of Medicine, Institute for Reproductive and Developmental Biology, Hammersmith Hospital Campus, London, United Kingdom
Pathophysiology of Preterm Birth

Robert A. Berg, MD
Division Chief, Critical Care Medicine, Russell Raphaley Endowed Chair, Department of Anesthesiology and Critical Care Medicine, Professor of Anesthesiology and Critical Care Medicine and Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Developmental Pharmacology of Adrenergic Agents

Melvin Berger, MD, PhD
Senior Medical Director, CSL Behring, King of Prussia, Pennsylvania; Adjunct Professor of Pediatrics and Pathology, Case Western Reserve University, Cleveland, Ohio
The Complement System of the Fetus and Newborn

Monica Bhatia, MD
Assistant Professor of Pediatrics, Division of Pediatric Blood and Marrow Transplantation, Columbia University College of Physicians and Surgeons, New York, New York
Neonatal Neutrophil Normal and Abnormal Physiology

Vinod K. Bhutani, MD, FAAP
Professor of Pediatrics, Stanford University School of Medicine, Division of Neonatal and Developmental Medicine, Stanford, California
Vitamin E Metabolism in the Fetus and Newborn Infant

Stan R. Blecher, MD, FCCMG
Professor, Department of Molecular Biology and Genetics, University of Guelph, Guelph, Ontario, Canada
Genetics of Sex Determination and Differentiation

Arlin B. Blood, PhD
Associate Professor, Department of Pediatrics, Division of Neonatology, Center for Perinatal Biology, Loma Linda University School of Medicine, Loma Linda, California
Perinatal Thermal Physiology

David L. Bolender, PhD
Associate Professor, Department of Cell Biology, Neurobiology, and Anatomy, Medical College of Wisconsin, Milwaukee, Wisconsin
Basic Embryology

Rada Boskovic, MD
Senior Fellow and Clinical Co-Investigator, Division of Clinical Pharmacology and Toxicology, The Hospital for Sick Children, Toronto, Canada
Maternal Drug Abuse: Effects on the Fetus and Neonate

Robert D.H. Boyd, MB, FRCP
Visiting Professor, Department of Maternal and Fetal Health Research Centre, University of Manchester, Manchester, United Kingdom
Mechanisms of Transfer Across the Human Placenta

Robert A. Brace, PhD
Professor, Department of Obstetrics and Gynecology, Oregon Health and Science University, Portland, Oregon
Fluid Distribution in the Fetus and Neonate

Eileen D. Brewer, MD
Renal Pediatrics, Baylor College of Medicine, Texas Children's Hospital, Houston, Texas
Urinary Acidification

Delma L. Broussard, MD
Director, Regulatory Affairs International, Merck & Company Inc., West Point, Pennsylvania
Development of the Enteric Nervous System

Laura D. Brown, MD
Instructor, Pediatrics, University of Colorado at Denver and Health Sciences Center, Aurora, Colorado
Fetal Requirements and Placental Transfer of Nitrogenous Compounds

Douglas G. Burrin, PhD
Professor of Pediatrics, U.S. Department of Agriculture Children's Nutrition Research Center, Section of Pediatric Gastroenterology, Hepatology, and Nutrition, Department of Pediatrics, Baylor College of Medicine, Houston, Texas
Trophic Factors and Regulation of Gastrointestinal Tract and Liver Development

Bridgette M.P. Byrne, MD, MRCPI, MRCOG
Senior Lecturer, Royal College of Surgeons in Ireland; Consultant Obstetrician and Gynecologist, Coombe Women's Hospital, Dublin, Ireland
Regulation of Umbilical Blood Flow

Anne Grete Byskov, MSc, PhD, DSc
Professor Emeritus, Consultant, Laboratory of Reproductive Biology, Rigshospitalet–Copenhagen University Hospital, Copenhagen, Denmark
Differentiation of the Ovary

Mitchell S. Cairo, MD
Professor of Pediatrics, Medicine, Pathology, Microbiology, and Immunology, and Cell Biology and Anatomy, New York Medical College; Chief, Pediatric Hematology, Oncology, and Stem Cell Transplantation, Director, Children's & Adolescent Cancer and Blood Diseases Center, Maria Fareri Children's Hospital, Valhalla, New York
Neonatal Neutrophil Normal and Abnormal Physiology

Barbara Cannon, PhD
Professor, The Wenner-Gren Institute, The Arrhenius Laboratories F3, Stockholm University, Stockholm, Sweden
Brown Adipose Tissue: Development and Function

†Deceased

Michael Caplan, MD
Clinical Professor of Pediatrics, University of Chicago Pritzer School of Medicine; Department of Pediatrics, North Shore University Health System, Chicago, Illinois
Pathophysiology and Prevention of Neonatal Necrotizing Enterocolitis

Luke C. Carey, PhD
Department of Obstetrics and Gynecology, The Center of Research for Obstetrics and Gynecology, Wake Forest University School of Medicine, Winston-Salem, North Carolina
Development of the Corticotropin-Releasing Hormone–Corticotropin System in the Mammalian Fetus

Susan E. Carlson, PhD
A.J. Rice Professor of Nutrition, Department of Dietetics and Nutrition, University of Kansas Medical Center, Kansas City, Kansas
Long-Chain Fatty Acids in the Developing Retina and Brain

David P. Carlton, MD
Associate Professor, Department of Pediatrics, University of Wisconsin School of Medicine; Chief, Division of Neonatology, University Hospital, Madison, Wisconsin
Regulation of Liquid Secretion and Absorption by the Fetal and Neonatal Lung
Pathophysiology of Edema

William J. Cashore, MD
Associate Chief of Pediatrics, Women's and Infants' Hospital, Providence, Rhode Island
Neonatal Bilirubin Metabolism

Yang Chai, MD
Center for Craniofacial Molecular Biology, School of Dentistry, University of Southern California, Los Angeles, California
Regulation of Embryogenesis

Carol L. Cheatham, MD
Assistant Professor, Department of Psychology, The University of North Carolina at Chapel Hill, Chapel Hill, North Carolina; Scientist, Nutrition Research Institute, University of North Carolina, Kannapolis, North Carolina
Long-Chain Fatty Acids in the Developing Retina and Brain

Sylvain Chemtob, MD, PhD, FRCPC, FAAP
Professor of Pediatrics, Ophthalmology, and Pharmacology, University of Montreal; Neonatologist, Department of Pediatrics, Centre Hospitalier Sainte-Justine; Research Chair, Vision Science, Department of Ophthalmology, Hospital Maisonneuve-Rosemont, Montréal, Québec, Canada
Basic Pharmacologic Principles

Robert L. Chevalier, MD
David Harrison Professor of Pediatrics, Department of Pediatrics, University of Virginia; Attending Pediatrician, University of Virginia Health System, Charlottesville, Virginia
Functional Development of the Kidney In Utero
Response to Nephron Loss in Early Development

Sadhana Chheda, MD
Pediatrix Medical Group, El Paso, Texas
Immunology of Human Milk and Host Immunity

Robert D. Christensen, MD
Medical Director, Neonatology, Urban North Region, Director of Neonatology Research, Intermountain Healthcare, Ogden, Utah
Developmental Granulocytopoiesis

David H. Chu, MD, PhD
Staff Physician, Division of Dermatology and Cutaneous Surgery, Scripps Medical Group, La Jolla, California
Structure and Development of Skin and Cutaneous Appendages

Robert Ryan Clancy, MD
Professor, Department of Neurology and Pediatrics, University of Pennsylvania Perelman School of Medicine; Senior Physician, Department of Neurology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Electroencephalography in the Premature and Full-Term Infant

M. Thomas Clandinin, PhD
Distinguished Professor of Nutrition, Department of Agricultural Food and Nutritional Science, Professor Emeritus, Alberta Institute of Human Nutrition, University of Alberta, Edmonton, Alberta, Canada
Accretion of Lipid in the Fetus and Newborn

David A. Clark, MD
Chairman, Department of Pediatrics, Division of Neonatology, Albany Medical Center, Albany, New York
Development of the Gastrointestinal Circulation in the Fetus and Newborn

Jane Cleary-Goldman, MD
Maternal Female Medicine, Department of Obstetrics and Gynecology, New York Presbyterian/Weill Cornell, New York, New York
Physiologic Effects of Multiple Pregnancy on Mother and Fetus

Ronald I. Clyman, MD
Professor of Pediatrics and Senior Staff, Cardiovascular Research Institute, Department of Pediatrics, University of California San Francisco, San Francisco, California
Mechanisms Regulating Closure of the Ductus Arteriosus

Susan S. Cohen, MD
Instructor, Pediatrics, The Warren Alpert Medical School of Brown University; Fellow, Neonatal-Perinatal Medicine, Department of Pediatrics, Women & Infants Hospital of Rhode Island, Providence, Rhode Island
Development of the Blood-Brain Barrier

John Colombo, PhD
Director, Schiefelbusch Life Span Institute, Professor, Department of Psychology, University of Kansas, Lawrence, Kansas
Long-Chain Fatty Acids in the Developing Retina and Brain

Howard E. Corey, MD
Director, The Children's Kidney Center of New Jersey, Goryeb Children's Hospital, Morristown, New Jersey
Renal Transport of Sodium During Early Development

Robert B. Cotton, MD
Professor of Pediatrics, Vanderbilt University School of Medicine, Nashville, Tennessee
Pathophysiology of Hyaline Membrane Disease (Excluding Surfactant)

Beverly J. Cowart, PhD
Monello Chemical Senses, Philadelphia, Pennsylvania
Development of Taste and Smell in the Neonate

Richard M. Cowett, MD, FAAP
National Medical Director, Neonatal Resource Services, OptumHealth Care Solutions, United Health Group, Amherst, Massachusetts
Role of Glucoregulatory Hormones in Hepatic Glucose Metabolism During the Perinatal Period

Leona Cuttler, MD
William T. Dahms Professor of Pediatrics, Director, The Center for Child Health and Policy, Division Chief, Pediatric Endocrinology, Diabetes, and Metabolism, Rainbow Babies and Children's Hospital, Case Western Reserve University, Cleveland, Ohio
Luteinizing Hormone and Follicle-Stimulating Hormone Secretion in the Fetus and Newborn

Mary E. D'Alton, MD
Division of Maternal Fetal Medicine, Columbia University, New York, New York
Physiologic Effects of Multiple Pregnancy on Mother and Fetus

Enrico Danzer, MD
Fetal Surgery Research Fellow, Center for Fetal Diagnosis and Treatment, University of Pennsylvania School of Medicine; Division of General, Thoracic, and Fetal Surgery, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Pathophysiology of Neural Tube Defects

Elmer S. David, MD
Associate Professor of Pediatrics, Department of Pediatrics, University of Medicine and Dentistry of New Jersey–New Jersey Medical School; University Hospital, Department of Pediatrics, University of Medicine and Dentistry of New Jersey, Newark, New Jersey
Bile Acid Metabolism During Development

Diva D. De León, MD
Division of Endocrinology, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Growth Factor Regulation of Fetal Growth

Maria Delivoria-Papadopoulos, MD
Professor of Pediatrics, Physiology, and Obstetrics and Gynecology, Drexel University College of Medicine; Chief, Division of Neonatal–Perinatal Medicine, St. Christopher's Hospital for Children, Philadelphia, Pennsylvania
Oxygen Transport and Delivery

Raye-Ann Odegaard deRegnier, MD
Attending Physician, Neonatology, Marion Robinson Heise PhD Chair in Neonatal Development, Associate Professor of Pediatrics, Northwestern University Feinberg School of Medicine, Chicago, Illinois
Fetal and Neonatal Iron Metabolism

Thomas G. Diacovo, MD
Associate Professor, Departments of Pediatrics and Pathology, Director of Neonatal Research, Columbia University Medical Center, New York, New York
Platelet–Vessel Wall Interactions

George A. Diaz, MD, PhD
Associate Professor, Department of Genetics and Genomic Sciences, Department of Pediatrics, Mount Sinai School of Medicine, New York, New York
Advances in Molecular Genetics: Developmental and Clinical Implications

Chris J. Dickinson, MD
Division of Pediatric Gastroenterology, University of Michigan Medical Center, Ann Arbor, Michigan
Development of Gastric Secretory Function

John P. Dormans, MD, FACS
Professor, Department of Orthopaedic Surgery, University of Pennsylvania; Chief, Department of Orthopedic Surgery, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
The Growth Plate: Embryologic Origin, Structure, and Function

Kerry McGarr Empey, PharmD, PhD
Assistant Professor, Department of Pharmacy and Therapeutics, Center for Clinical Pharmaceutical Sciences, University of Pittsburgh, Pittsburgh, Pennsylvania
Neonatal Pulmonary Host Defense

Offer Erez, MD
Perinatology Research Branch, NICHD/NIH/DHHS; Department of Obstetrics and Gynecology, Wayne State University School of Medicine, Detroit, Michigan
Fetal and Maternal Responses to Intrauterine Infection

Robert P. Erickson, MD
Professor, Department of Pediatrics, University of Arizona College of Medicine, Tucson, Arizona
Genetics of Sex Determination and Differentiation

Bulent Erol, MD
Department of Orthopaedic Surgery, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
The Growth Plate: Embryologic Origin, Structure, and Function

Mohamed Abdelmonem Fahim, PhD
Professor of Physiology and Director of Medical Sciences, Department of Physiology, Faculty of Medicine and Health Sciences, United Arab Emirates University, Al-Ain, United Arab Emirates
Functional Development of Respiratory Muscles

Leonard G. Feld, MD, PhD, MMM
Clinical Professor of Pediatrics, Department of Pediatrics, The University of North Carolina School of Medicine, Chapel Hill; Chief Medical Officer, Sara H. Bissell and Howard C. Bissell Endowed Chair in Pediatrics, Department of Pediatrics, Levine Children's Hospital at Carolinas Medical Center, Charlotte, North Carolina
Renal Transport of Sodium During Early Development

Miguel Feldman, MD
Director of Neonatal Intensive Care Unit, Hillel-Iaffe Medical Center, Hadera and Raanana, Israel
Accretion of Lipid in the Fetus and Newborn

Ronaldo P. Ferraris, PhD
Professor, Departments of Pharmacology and Physiology, and Pediatrics, University of Medicine and Dentistry of New Jersey, Newark; Department of Nutritional Sciences, Rutgers University, Cook College, New Brunswick, New Jersey
Bile Acid Metabolism During Development

Douglas G. Field, MD
Assistant Professor of Pediatrics, Pennsylvania State University College of Medicine; Attending, Department of Pediatrics, Division of Pediatric Gastroenterology and Nutrition, Pennsylvania State Children's Hospital, Milton S. Hershey Medical Center, Hershey, Pennsylvania
Fetal and Neonatal Intestinal Motility

Delbert A. Fisher, MD
Vice President, Science & Innovation, Nichols Institute, Quest Diagnostics, San Juan Capistrano, California
Fetal and Neonatal Thyroid Physiology

Jennifer Frances, MD
Department of Orthopedic Surgery, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
The Growth Plate: Embryologic Origin, Structure, and Function

Hans-Georg Frank, MD
Privatdozent, Department of Anatomy II, University Hospital, University of Technology Aachen, Aachen, Germany
Placental Development

Philippe S. Friedlich, MD, MS Epi, MBA
Associate Professor of Pediatrics & Surgery, USC Division of Neonatal Medicine, Keck School of Medicine; Section Head, CHLA Operations; Medical Director, Newborn & Infant Critical Care Unit, Children's Hospital Los Angeles, Los Angeles, California
Pathophysiology of Shock in the Fetus and Neonate
Regulation of Acid-Base Balance in the Fetus and Neonate

Aaron L. Friedman, MD
Vice President for Health Sciences, Dean, University of Minnesota Medical School, Minneapolis, Minnesota
Transport of Amino Acids During Early Development

Joshua R. Friedman, MD, PhD
Assistant Professor of Pediatrics, Division of Gastroenterology and Nutrition, University of Pennsylvania School of Medicine, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Pathophysiology of Gastroesophageal Reflux

Marianne Garland, MB, ChB
Division of Pediatric Neonatology, Columbia University College of Physicians and Surgeons, New York, New York
Drug Distribution in Fetal Life

Michael K. Georgieff, MD
Vice Chair and Martin Lenz Harrison Land Grant Professor, Director, Division of Neonatology, Director, Center for Neurobehavioral Development, Department of Pediatrics, University of Minnesota; Director and Neonatologist, Department of Neonatology, University of Minnesota Amplatz Children's Hospital, Minneapolis, Minnesota
Fetal and Neonatal Iron Metabolism

Peter D. Gluckman, KNZM, FRS, FMedSc, FRSNZ
University Distinguished Professor, Liggins Institute, The University of Auckland, Auckland, New Zealand; Program Director, Singapore Institute for Clinical Sciences, Agency for Science, Technology, and Research, Singapore
Growth Hormone and Prolactin

Armond S. Goldman, MD
Professor Emeritus, Department of Pediatrics, University of Texas Medical Branch, Galveston, Texas
Immunology of Human Milk and Host Immunity

Roberto Ariel Gomez, MD
Harrison Distinguished Professor of Pediatrics and Biology, Department of Pediatrics, University of Virginia Health Sciences Center, Charlottesville, Virginia
Development of the Renin-Angiotensin System

Francesca Gotsch, MD
Perinatology Research Branch, NICHD/NIH/DHHS, Bethesda, Maryland, and Detroit, Michigan
Fetal and Maternal Responses to Intrauterine Infection

Denis M. Grant, PhD
Professor and Chair, Department of Pharmacology & Toxicology, University of Toronto, Toronto, Ontario, Canada
Pharmacogenetics

Lucy R. Green, BSc, PhD
Reader in Developmental Physiology, Institute of Developmental Sciences, University of Southampton, Southampton, United Kingdom
Developmental Effects on Fetal Circulation

Adda Grimberg, MD
Associate Professor, Department of Pediatrics, University of Pennsylvania School of Medicine; Scientific Director, Diagnostic and Research Growth Center, Division of Pediatric Endocrinology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Hypothalamus: Neuroendometabolic Center

Justin C. Grindley, PhD
Research Instructor, Division of Pediatric Cardiology, Vanderbilt University School of Medicine, Nashville, Tennessee
Molecular Determinants of Embryonic Vascular Development

Ian Gross, MD
Professor, Department of Pediatrics, Yale School of Medicine; Director, Newborn Special Care Unit, Yale New Haven Children's Hospital, New Haven, Connecticut
Hormonal Therapy for Prevention of Respiratory Distress Syndrome

M. Brad Guffey, MD
Instructor, Medicine and Pediatrics, Adult and Pediatric Infectious Diseases, Centre for Infectious Disease Research, Zambia; University of Alabama at Birmingham, Birmingham, Alabama
Host Defense Mechanisms Against Viruses

Jean-Pierre Guignard, MD
Honorary Professor of Pediatrics, Lausanne University Medical School, Lausanne, Switzerland
Postnatal Development of Glomerular Filtration Rate in Neonates

Alistair Jan Gunn, MBChB, PhD
Head, Department of Physiology, University of Auckland; Pediatrician, Department of Pediatric Endocrinology, Starship Children's Hospital, Auckland, New Zealand
Responses of the Fetus and Neonate to Hypothermia

Gabriel G. Haddad, MD
Professor and Chair, Department of Pediatrics, University of California San Diego, La Jolla; Physician-in-Chief and Chief Scientific Officer, Rady Children's Hospital San Diego, San Diego, California
Basic Mechanisms of Oxygen Sensing and Response to Hypoxia

J. Nathan Hagstrom, MD
Division of Pediatric Hematology/Oncology, University of Connecticut School of Medicine, Connecticut Children's Medical Center, Hartford, Connecticut
Developmental Hemostasis

J. Nina Ham, MD
Assistant Professor, Pediatrics, Section of Endocrinology and Metabolism, Baylor College of Medicine, Houston, Texas
Growth Factor Regulation of Fetal Growth

K. Michael Hambidge, MD, ScD
Professor Emeritus, Department of Pediatrics, University of Colorado; Staff Pediatrician, Digestive Diseases and Nutrition, The Children's Hospital, Denver, Colorado
Zinc in the Fetus and Neonate

Margit Hamosh, PhD
Professor Emeritus of Pediatrics, Georgetown University School of Medicine, former Chief, Division of Developmental Biology and Nutrition, Georgetown University Medical Center, Washington, District of Columbia
Human Milk Composition and Function in the Infant

Mark A. Hanson, MA, DPhil
Director, Developmental Origins of Health and Disease, University of Southampton; Professor of Cardiovascular Science, British Heart Foundation, Southampton, United Kingdom
Developmental Effects on Fetal Circulation

Richard Harding, PhD, DSc
Professorial Fellow, Department of Anatomy and Developmental Biology, Monash University, Melbourne, Australia
Physiologic Mechanisms of Normal and Altered Lung Growth Before and After Birth

Olga T. Hardy, MD
Division of Endocrinology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Pathophysiology of Hypoglycemia

Mary Catherine Harris, MD
Professor of Pediatrics, Division of Neonatology, Department of Pediatrics, University of Pennsylvania Perelman School of Medicine; Senior Attending Physician, Newborn Intensive Care Unit, Division of Neonatology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Cytokines and Inflammatory Response in the Fetus and Neonate

Musa A. Haxhiu, MD, PhD
Director, Developmental Lung Neurobiology Laboratories, Case Western Reserve University School of Medicine, Rainbow Babies & Children's Hospital, Cleveland, Ohio
Regulation of Lower Airway Function

William W. Hay, Jr., MD
Professor, Department of Pediatrics/Neonatology, University of Colorado, Aurora, Colorado
Fetal Requirements and Placental Transfer of Nitrogenous Compounds

William C. Heird, MD
Children's Nutrition Research Center, Department of Pediatrics, Baylor College of Medicine, Houston, Texas
Protein and Amino Acid Metabolism and Requirements

Emilio Herrera, PhD
Professor of Biochemistry and Molecular Biology, Faculties of Pharmacy and Medicine, University of San Pablo–CEU, Madrid, Spain
Maternal-Fetal Transfer of Lipid Metabolites

Harry R. Hill, MD
Professor, Department of Pathology, Pediatrics, and Medicine, University of Utah, Salt Lake City, Utah
Host Defense Mechanisms Against Bacteria

A. Craig Hillemeier, MD
Professor and Chair, Department of Pediatrics, Pennsylvania State University College of Medicine; Vice Dean for Clinical Affairs and Medical Director, Pennsylvania State Children's Hospital, Milton S. Hershey Medical Center, Hershey, Pennsylvania
Fetal and Neonatal Intestinal Motility

Kurt Hirschhorn, MD
Department of Pediatrics, Mount Sinai School of Medicine, New York, New York
Advances in Molecular Genetics: Developmental and Clinical Implications

Steven B. Hoath, MD
Professor of Pediatrics-Neonatology, University of Cincinnati College of Medicine; Medical Director, Skin Sciences Program, Children's Hospital Medical Center, Cincinnati, Ohio
Physiologic Development of the Skin

Stuart B. Hooper, PhD
Professor and Principal Research Fellow, The Ritchie Centre, Monash Institute for Medical Research, Monash University, Melbourne; Professor and Principal Research Fellow, Department of Obstetrics and Gynecology, Monash University, Monash Medical Centre, Clayton, Victoria, Australia
Physiologic Mechanisms of Normal and Altered Lung Growth Before and After Birth

Tracy E. Hunley, MD
Assistant Professor, Department of Pediatrics, Vanderbilt University School of Medicine; Attending Physician, Monroe Carell Jr. Children's Hospital at Vanderbilt, Nashville, Tennessee
Pathophysiology of Acute Renal Failure in the Neonatal Period

Shahid M. Husain, MD
Senior Lecturer and Honorary, Consultant Neonatologist, Centre for Pediatrics, Barts and The London School of Medicine and Dentistry; Neonatal Unit, Homerton University Hospital, London, United Kingdom
Calcium, Phosphorus, and Magnesium Transport Across the Placenta

Susan M. Hutson, MD
Professor, Department of Human Nutrition, Foods, and Exercise, Virginia Polytechnic Institute, Blacksburg, Virginia
Vitamin K Metabolism in the Fetus and Neonate

Machiko Ikegami, MD, PhD
Division of Pulmonary Biology, Cincinnati Children's Hosptial, Cincinnati, Ohio
Pathophysiology of Respiratory Distress Syndrome and Surfactant Metabolism

Terrie E. Inder, MD, MBChB
Professor, Department of Pediatrics, Washington University in St. Louis; Department of Pediatrics, St. Louis Children's Hospital, St. Louis, Missouri
Intraventricular Hemorrhage in the Neonate

John Lynn Jefferies, MD, MPH
Department of Pediatrics (Cardiology), Baylor College of Medicine, Texas Children's Hospital, Houston, Texas
Cardiomyopathies in Infants and Children

Alan H. Jobe, MD, PhD
Division of Pediatric Neonatology, Cincinnati Children's Hospital, Cincinnati, Ohio
Antenatal Factors That Influence Postnatal Lung Development and Injury
Pathophysiology of Respiratory Distress Syndrome and Surfactant Metabolism
Surfactant Treatment

Lois H. Johnson, MD
Section on Newborn Pediatrics, Pennsylvania Hospital, Philadelphia, Pennsylvania
Vitamin E Metabolism in the Fetus and Newborn Infant

Sonja E. Johnson, PhD
Postdoctoral Fellow, Masonic Cancer Center, University of Minnesota, Minneapolis, Minnesota
B-Cell Development

Michael V. Johnston, MD
Professor of Neurology and Pediatrics, Kennedy Krieger Institute, Johns Hopkins University School of Medicine, Baltimore, Maryland
Development of Neurotransmitters

Richard B. Johnston, Jr., MD
Associate Dean for Research Development, Department of Pediatrics, University of Colorado School of Medicine, Denver, Colorado
Host-Fungi Interactions Relevant to the Newborn Infant

Deborah P. Jones, MD
Department of Pediatrics, University of Tennessee Medical Group, Memphis, Tennessee
Developmental Aspects of Organic Acid Transport

Peter Lloyd Jones, PhD
Division of Pediatric Critical Care and Developmental Lung Biology, University of Colorado Health Science Center, Denver, Colorado
The Extracellular Matrix in Development

Rebecca L. Jones, PhD
Lecturer in Maternal and Fetal Health, Department of Maternal and Fetal Health Research Centre, University of Manchester, Manchester, United Kingdom
Mechanisms of Transfer Across the Human Placenta

Pedro A. Jose, MD, PhD
Professor, Department of Pediatrics and Medicine, George Washington University School of Medicine and Health Sciences; Director, Center for Molecular Physiology Research, Children's Research Institute, Washington, District of Columbia
Postnatal Maturation of Renal Blood Flow

Satish C. Kalhan, MD, MBBS, FRCP, DCh
Professor, Department of Molecular Medicine, Cleveland Clinic Lerner College of Medicine of Case Western Reserve University; Staff, Department of Pathobiology, Cleveland Clinic, Lerner Research Institute, Cleveland, Ohio
Metabolism of Glucose and Methods of Investigation in the Fetus and Newborn

Suhas G. Kallapur, MD
Division of Neonatology and Pulmonary Biology, Cincinnati Childrens' Hospital Medical Center, Cincinnati, Ohio
Antenatal Factors That Influence Postnatal Lung Development and Injury

Stanley Kaplan, PhD
Professor Emeritus, Department of Cell Biology, Neurobiology, and Anatomy, Medical College of Wisconsin, Milwaukee, Wisconsin
Basic Embryology

Heidi Eigenrauch Karpen, MD
Assistant Professor, Department of Pediatrics, Baylor College of Medicine; Attending Neonatologist, Department of Pediatrics and Neonatology, Texas Children's Hospital, Houston, Texas
Bile Formation and Cholestasis

Saul J. Karpen, MD, PhD
Professor of Pediatrics, Department of Pediatrics/ Gastroenterology, Hepatology & Nutrition, Baylor College of Medicine, Director, Texas Children's Liver Center, Houston, Texas
Bile Formation and Cholestasis

Sudha Kashyap, MD
Division of Neonatology, Babies Hospital, Professor of Clinical Pediatrics, Columbia University College of Physicians and Surgeons, New York, New York
Lipids as an Energy Source for the Premature and Full-Term Neonate
Protein and Amino Acid Metabolism and Requirements

Frederick J. Kaskel, MD, PhD
Vice Chair of Pediatrics, Director of Pediatric Nephrology, Fellow in Pediatric Nephrology, Department of Pediatrics, Children's Hospital at Montefiore/Albert Einstein College of Medicine, Bronx, New York
Role of the Kidney in Calcium and Phosphorus Homeostasis

Lorraine E. Levitt Katz, MD
Division of Endocrinology and Diabetes, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Growth Factor Regulation of Fetal Growth

Susan E. Keeney, MD
Pediatric Neonatology, University of Texas Medical Branch, Children's Hospital, Galveston, Texas
Immunology of Human Milk and Host Immunity

Omar S. Khwaja, MD, PhD
Instructor in Neurology, Director, Rett Syndrome Program and Neurogenetics, Department of Neurology, Harvard Medical School; Director, Fetal Neurology Program, Department of Neurology, Children's Hospital Boston, Boston, Massachusetts
Development of the Nervous System

Laurie E. Kilpatrick, PhD
Associate Professor of Physiology, Temple University School of Medicine, Philadelphia, Pennsylvania
Cytokines and Inflammatory Response in the Fetus and Neonate

David Winston Kimberlin, MD
Professor, Department of Pediatrics, University of Alabama at Birmingham, Birmingham, Alabama
Host Defense Mechanisms Against Viruses

John P. Kinsella, MD
Division of Pediatric Neonatology, University of Colorado Health Sciences Center, Denver, Colorado
Physiology of Nitric Oxide in the Developing Lung

Jay K. Kolls, MD
Professor of Genetics and Pediatrics, Department of Genetics, Louisiana State University Health Sciences Center, New Orleans, Louisiana; Adjunct Professor of Pediatrics, Department of Pediatrics, Children's Hospital of Pittsburgh, University of Pittsburgh, Pittsburgh, Pennsylvania
Neonatal Pulmonary Host Defense

Valentina Kon, MD
Professor of Pediatrics, Vanderbilt University School of Medicine; Attending Physician, Monroe Carell Jr. Children's Hospital at Vanderbilt, Nashville, Tennessee
Pathophysiology of Acute Renal Failure in the Neonatal Period

Ernest A. Kopecky, PhD, MBA
Senior Director, Head, Pain, and Neuroscience Therapeutic Area, Clinical Development and Medical Affairs, Department of Research and Development, Endo Pharmaceuticals Inc., Chadds Ford, Pennsylvania; Fellow, Division of Clinical Pharmacology and Toxicology, Hospital for Sick Children, Toronto, Ontario, Canada
Maternal Drug Abuse: Effects on the Fetus and Neonate

Gideon Koren, MD, FRCPC, FACMT
Professor, Department of Pediatrics, Pharmacology, Pharmacy, and Medical Genetics, University of Toronto; Director, Motherisk Program, Hospital for Sick Children, Toronto, Ontario, Canada
Maternal Drug Abuse: Effects on the Fetus and Neonate

Nancy F. Krebs, MD, MS
Professor of Pediatrics, Head, Section of Nutrition, University of Colorado at Denver, Aurora, Colorado
Zinc in the Fetus and Neonate

Thomas J. Kulik, MD
Senior Associate in Cardiology, Children's Hospital Boston; Associate Professor of Pediatrics, Harvard Medical School, Boston, Massachusetts
Physiology of Congenital Heart Disease in the Neonate

Juhi Kumar, MD, MPH
Assistant Professor of Pediatrics, Weill Cornell Medical College; Assistant Attending Pediatrician, NewYork–Presbyterian Hospital, New York, New York
Role of the Kidney in Calcium and Phosphorus Homeostasis

Juan Pedro Kusanovic, MD
Perinatology Research Branch, NICHD/NIH/DHHS, Bethesda, Maryland, and Detroit, Michigan; Department of Obstetrics and Gynecology, Wayne State University School of Medicine, Detroit, Michigan
Fetal and Maternal Responses to Intrauterine Infection

Jessica Katz Kutikov, MD, FAAP
Attending Physician, Children's Emergency Department, Children's Hospital of Philadelphia at Virtua, Voorhees, New Jersey
Hypothalamus: Neuroendometabolic Center

Timothy R. La Pine, MD
Professor, Department of Pediatrics and Pathology, University of Utah; Director, Department of Neonatology, St. Mark's Hospital, Salt Lake City, Utah
Host Defense Mechanisms Against Bacteria

Miguel Angel Lasunción, PhD
Associate Professor, Department of Biochemistry and Molecular Biology, University of Alcalá, Alcalá de Henares; Head of Department, Service of Biochemistry-Investigation, Ramón and Cajal Hospital University, IRYCIS; Member, CIBER "Fisiología de la Obesidad y Nutrición" (CIBERobn), Madrid, Spain
Maternal-Fetal Transfer of Lipid Metabolites

Tucker W. LeBien, PhD
Vice Dean for Research, Professor of Laboratory Medicine and Pathology, Associate Vice President for Research, Academic Health Center, University of Minnesota Medical School, Minneapolis, Minnesota
B-Cell Development

Mary M. Lee, MD
Professor of Pediatrics and Cell Biology, Chief, Pediatric Endocrine Division, University of Massachusetts Medical School, Worchester, Massachusetts
Testicular Development and Descent

Matthew K. Lee, MD
Assistant Professor, Center for Craniofacial Molecular Biology, University of Southern California, Los Angeles, California
Regulation of Embryogenesis

Fred Levine, MD, PhD
Professor and Director, Sanford Children's Health Research Center, Sanford-Burnham Medical Research Institute, La Jolla; Attending Physician, Department of Genetics, Rady Children's Hospital, San Diego, California
Basic Genetic Principles

Chris A. Liacouras, MD
Director, Center for Pediatric Eosinophilic Diseases, Division of Gastroenterology and Nutrition, The Children's Hospital of Philadelphia, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Pathophysiology of Gastroesophageal Reflux

[†]Michael A. Linshaw, MD
Division of Pediatric Nephrology, Massachusetts General Hospital for Children, Boston, Massachusetts
Concentration and Dilution of the Urine

Steven Lobritto, MD
Pediatric Medical Director, Center for Liver Disease Transplantation, New York Presbyterian Hospital-Columbia University, New York, New York
Organogenesis and Histologic Development of the Liver

Cynthia A. Loomis, MD, PhD
Assistant Professor, Departments of Pathology, Dermatology, and Cell Biology, New York University School of Medicine, New York, New York
Structure and Development of Skin and Cutaneous Appendages

Maria Luisa S. Sequeira Lopez, MD
Assistant Professor of Pediatrics, University of Virginia School of Medicine, Charlottesville, Virginia
Development of the Renin-Angiotensin System

John M. Lorenz, MD
Professor of Clinical Pediatrics, Department of Pediatrics, Columbia University College of Physicians and Surgeons; Attending Neonatalogist, Morgan Stanley Children's Hospital of New York–Presbyterian, New York, New York
Fetal and Neonatal Body Water Compartment Volumes With Reference to Growth and Development

Felicia M. Low, PhD
Research Fellow, Liggins Institute, The University of Auckland, Auckland, New Zealand
Growth Hormone and Prolactin

Ralph A. Lugo, PharmD
Department of Pharmacy Practice, University of Utah, Salt Lake City, Utah
Basic Pharmacokinetic Principles

[†]Deceased

Akhil Maheshwari, MD
Instructor, Division of Pediatric Neonatology, University of South Florida College of Medicine, St. Petersburg, Florida
Developmental Granulocytopoiesis

Shadi N. Malaeb, MD
Assistant Professor, Pediatrics, Tufts University; Assistant Professor, Pediatrics, Tufts Medical Center, Boston, Massachusetts
Development of the Blood-Brain Barrier

Carlos B. Mantilla, MD, PhD
Associate Professor, Department of Anesthesiology and Physiology, Consultant, Department of Anesthesiology, Mayo Clinic, Rochester, Minnesota
Functional Development of Respiratory Muscles

M. Michele Mariscalco, MD
Department of Pediatrics, Children's Nutritional Research Center, Baylor College of Medicine, Houston, Texas
Integrins and Cell Adhesion Molecules

László Maródi, MD, PhD
Professor of Pediatrics, Head, Department of Infectology and Pediatric Immunology, University of Debrecen, Medical and Health Science Center, Debrecen, Hungary
Host-Fungi Interactions Relevant to the Newborn Infant
T-Cell Development

Karel Maršál, MD, PhD
Department of Obstetrics and Gynecology, University Hospital, Lund University, Lund, Sweden
Fetal and Placental Circulation During Labor

Richard J. Martin, MD
Professor, Department of Pediatrics, Physiology, and Biophysics, Case Western Reserve University; Drusinsky-Fanaroff Chair in Neonatology, Rainbow Babies and Children's Hospital, Cleveland, Ohio
Regulation of Lower Airway Function
Pathophysiology of Apnea of Prematurity

Dwight E. Matthews, PhD
Professor, Departments of Chemistry and Medicine, University of Vermont, Burlington, Vermont
General Concepts of Protein Metabolism

Alan N. Mayer, MD
Division of Pediatric Gastroenterology, Rush University Medical Center, Chicago, Illinois
Development of the Exocrine Pancreas

Jane E. McGowan, MD
Visiting Associate Professor, Division of Pediatric Neonatology, Johns Hopkins University Medical Center, Baltimore, Maryland
Oxygen Transport and Delivery

James L. McManaman, PhD
Professor and Chief, Division of Basic Reproductive Sciences, Department of Obstetrics and Gynecology, University of Colorado Anschutz Medical Campus, Aurora, Colorado
Physiology of Lactation

Tim C. McQuinn, MD
Professor, Department of Pediatrics, University of Washington; Director, Heart Center Inpatient Services, Heart Care Center, Seattle Children's Hospital, Seattle, Washington
Cardiovascular Development

Huseyin Mehmet, MD
Merck and Co, Inc., Whitehouse Station, New Jersey; Weston Laboratory, Institute of Reproductive and Developmental Biology, Division of Paediatrics, Obstetrics, and Gynaecology, Imperial College Faculty of Medicine, Hammersmith Hospital Campus, London, United Kingdom
Apoptotic Cell Death

Julie A. Mennella, PhD
Monell Chemical Senses Center, Philadelphia, Pennsylvania
Development of Taste and Smell in the Neonate

Martha J. Miller, MD, PhD
Department of Pediatrics, Rainbow Babies' and Children's Hospital, Case Western Reserve University, Cleveland, Ohio
Pathophysiology of Apnea of Prematurity

Helen A. Mintz-Hittner, MD, FACS
Alfred W. Lasher III Professor of Ophthalmology, Department of Ophthalmology and Visual Science, The University of Texas Health Science Center, Houston Medical School; Robert Cizik Eye Clinic, Houston, Texas
Retinal Development and the Pathophysiology of Retinopathy of Prematurity

Paul Monagle, MD, MBBS, MSc, FRACP, FRCPA, FCCP
Head of Department, Department of Pediatrics, The University of Melbourne; Head of Department and Pediatric Hematologist, Clinical Hematology Department, Acting Director, Department of Children's Cancer Centre, Royal Children's Hospital; Honorary Fellow, Department of Critical Care and Neurosciences, Murdoch Children's Research Institute, Melbourne, Australia
Developmental Hemostasis

Iona M. Monteiro, MD
Associate Professor, Department of Pediatrics, University Hospital, University of Medicine and Dentistry of New Jersey, Newark, New Jersey
Bile Acid Metabolism During Development

Jacopo P. Mortola, MD
Department of Physiology, McGill University School of Medicine, Montréal, Québec, Canada
Mechanics of Breathing

Glen E. Mott, PhD
Professor, Department of Pathology, University of Texas Health Science Center, San Antonio, Texas
Lipoprotein Metabolism and Nutritional Programming in the Fetus and Neonate

Maka Mshvildadze, MD
Neonatologist, Georgian Institute of Perinatal Medicine, Tbilisi, Georgia; Visiting Research Scholar, University of Florida, Gainesville, Florida
Digestive-Absorption Functions in Fetuses, Infants, and Children

M. Zulficar Mughal, MBChB, FRCP, FRCPCH, DCH
Consultant in Paediatric Bone Disorders, Department of Paediatric Endocrinology, Royal Manchester Children's Hospital, Manchester, United Kingdom
Calcium, Phosphorus, and Magnesium Transport Across the Placenta

Susan E. Mulroney, PhD
Professor, Department of Pharmacology & Physiology, Director, Special Master's Program, Member, Center for the Study of Sex Differences in Health, Aging, and Disease, Georgetown University Medical Center, Washington, District of Columbia
Role of the Kidney in Calcium and Phosphorus Homeostasis

Upender K. Munshi, MD
Assistant Professor of Pediatrics, Neonatology-Perinatology, Albany Medical Center, Albany, New York
Development of the Gastrointestinal Circulation in the Fetus and Newborn

Leslie Myatt, PhD
Department of Obstetrics and Gynecology, University of Cincinnati, Cincinnati, Ohio
Regulation of Umbilical Blood Flow

Margaret Myers, MD
Associate Clinic Director, Newborn Infant Center, Division of Pediatric Neonatology, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Developmental Aspects of Pain

Ran Namgung, MD, PhD
Professor, Department of Pediatrics, Yonsei University College of Medicine; Chief, Department of Pediatrics, Severance Children's Hospital, Seoul, Korea
Neonatal Calcium, Phosphorus, and Magnesium Homeostasis

Sumana Narasimhan, MD
Assistant Professor of Pediatrics, Division of Pediatric Endocrinology and Metabolism, Rainbow Babies and Children's Hospital, Case Western Reserve University, Cleveland, Ohio
Luteinizing Hormone and Follicle-Stimulating Hormone Secretion in the Fetus and Newborn

Heinz Nau, MD
Zentrum für Lebensmitelwissenschaften, Zentrumsabteilung Lebensmitteltoxikologie, Tierärztliche Hochschule Hannover, Hannover, Germany
Physicochemical and Structural Properties Regulating Placental Drug Transfer

Jan Nedergaard, PhD
Department of Zoology, The Wenner-Gren Institute, The Arrhenius Laboratories F3, Stockholm University, Stockholm, Sweden
Brown Adipose Tissue: Development and Function

Josef Neu, MD
Professor, Department of Pediatrics, University of Florida, Gainesville, Florida
Digestive-Absorption Functions in Fetuses, Infants, and Children

Margaret Cobb Neville, PhD
Professor Emerita, Departments of Physiology and Biophysics, and Obstetrics and Gynecology, University of Colorado Denver School of Medicine, Aurora, Colorado
Physiology of Lactation

Heber C. Nielsen, MD
Professor, Departments of Anatomy and Cell Biology, and Physiology, Sackler School for Biograduate Medicine, Tufts Medical School; Professor, Department of Pediatrics, Floating Hospital for Children at Tufts Medical Center, Boston, Massachusetts
Homeobox Genes

Lee Niswander, PhD
Professor, Lee Niswander Lab, Developmental Biology, Howard Hughes Medical Institute, University of Colorado, Aurora, Colorado
Developmental Basis of Congenital Limb Differences

Lawrence M. Nogee, MD
Professor of Pediatrics, Eudowood Neonatal Respiratory Division, Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, Maryland
Genetics and Physiology of Surfactant Protein Deficiencies

Shahab Noori, MD
Senior Fellow in Neonatology, Division of Pediatric Neonatology, Keck School of Medicine, University of Southern California, Childrens Hospital Los Angeles, Los Angeles California
Pathophysiology of Shock in the Fetus and Neonate

Victoria Fay Norwood, MD
Robert J. Roberts Professor of Pediatrics, Department of Pediatrics, University of Virginia; Chief, Pediatric Nephrology, University of Virginia Children's Hospital, Charlottesville, Virginia
Functional Development of the Kidney in Utero

Luigi D. Notarangelo, MD
Jeffrey Modell Chair of Pediatric Immunology Research, Director, Research and Molecular Diagnosis Program on Primary Immunodeficiencies Division of Immunology, Professor of Pediatrics and Pathology, Children's Hospital, Harvard Medical School, Boston, Massachusetts
T-Cell Development

Edward S. Ogata, MD, MBA, CPharm
Chief Medical Officer, Children's Memorial Hospital #2, Chicago, Illinois
Carbohydrate Metabolism During Pregnancy

Robin Kjerstin Ohls, MD
Professor, Department of Pediatrics, University of New Mexico; Director of Pediatric Integration, Clinical Translational Science Center, University of New Mexico Health Sciences Center, Albuquerque, New Mexico
Developmental Erythropoiesis

Taher I. Omari, PhD
National Health and Medical Research Council Senior Research Fellow, Gastroenterology Unit, Children, Youth, and Women's Health Service; Affiliate Senior Lecturer, School of Pediatrics and Reproductive Health, University of Adelaide, Adelaide, Australia
Gastrointestinal Motility

James F. Padbury, MD
Department of Pediatrics, Brown University School of Medicine, Women and Infants' Hospital of Rhode Island, Providence, Rhode Island
Developmental Pharmacology of Adrenergic Agents

Mark R. Palmert, MD, PhD
Associate Professor, Department of Pediatrics and Physiology, The University of Toronto; Head, Division of Endocrinology, Department of Pediatrics, The Hospital for Sick Children, Toronto, Ontario, Canada
Luteinizing Hormone and Follicle-Stimulating Hormone Secretion in the Fetus and Newborn

Prabhu S. Parimi, MD
Professor, Department of Pediatrics, Chief, Division of Neonatology, Kansas University Medical Center, Kansas City, Kansas
Metabolism of Glucose and Methods of Investigation in the Fetus and Newborn

Elvira Parravicini, MD
Division of Pediatric Neonatology, Columbia University, New York, New York
Neonatal Neutrophil Normal and Abnormal Physiology

Gilberto R. Pereira, MD
Neonatologist, Professor Emeritus of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania
Nutritional Assessment

Jeffrey M. Perlman, MD, MB, ChB
Professor of Pediatrics, Division Chief, Newborn Medicine, Weill Cornell Medical College, NewYork–Presbyterian Hospital, New York, New York
Cerebral Blood Flow in Premature Infants: Regulation, Measurement, and Pathophysiology of Intraventricular Hemorrhage

Anthony F. Philipps, MD, FAAP
Professor and Chair, Department of Pediatrics, University of California–Davis; UC Davis Medical Center, Sacramento, California
Oxygen Consumption and General Carbohydrate Metabolism of the Fetus

Arthur S. Pickoff, MD
Professor and Chair, Department of Pediatrics and Community Health, Wright State University Boonshoft School of Medicine; The Children's Medical Center of Dayton, Dayton, Ohio
Developmental Electrophysiology in the Fetus and Neonate

Grisha Pirianov, PhD
Honorary Research Associate, Division of Surgery, Oncology, Reproductive Biology, and Anesthetics, Department of Surgery and Cancer, Imperial College of London, London, United Kingdom
Apoptotic Cell Death

David Pleasure, MD
Professor, Neurology and Pediatrics, University of California Davis, Davis, California
Trophic Factor and Nutritional and Hormonal Regulation of Brain Development

Jeanette Pleasure, MD
Professor, Clinical Pediatrics, University of California Davis, Davis, California
Trophic Factor and Nutritional and Hormonal Regulation of Brain Development

Sabine Luise Plonait, MD
Berlin, Germany
Physicochemical and Structural Properties Regulating Placental Drug Transfer

Daniel H. Polk, MD
Division of Neonatology, Children's Memorial Hospital, Chicago, Illinois
Fetal and Neonatal Thyroid Physiology

Scott L. Pomeroy, MD, PhD
Bronson Crothers Professor, Department of Neurology, Harvard Medical School; Chair and Neurologist-in-Chief, Department of Neurology, Children's Hospital Boston, Boston, Massachusetts
Development of the Nervous System

Fred Possmayer, MD
Professor Emeritus, Department of Obstetrics and Gynecology, University of Western Ontario, London, Ontario, Canada
Physicochemical Aspects of Pulmonary Surfactant

Martin Post, PhD
Program Head, Physiology and Experimental Medicine, Departments of Pediatric Physiology, Laboratory Medicine, and Pathology, Hospital for Sick Children, Toronto, Ontario, Canada
Molecular Mechanisms of Lung Development and Lung Branching Morphogenesis

Brandon S. Poterjoy, DO
Assistant Professor of Pediatrics, Division of Newborn Medicine, Drexel University College of Medicine, Philadelphia, Pennsylvania
Developmental Megakaryocytopoiesis

Gordon G. Power, MD
Professor, Department of Physiology and Internal Medicine, Loma Linda University, Loma Linda, California
Perinatal Thermal Physiology

Jorge A. Prada, MD
Division of Maternal Fetal Medicine, Department of Obstetrics and Gynecology, University of Cincinnati College of Medicine, Cincinnati, Ohio
Calcium-Regulating Hormones

Lawrence S. (Lance) Prince, MD, PhD
Assistant Professor of Pediatrics, Division of Neonatology, Vanderbilt University School of Medicine, Nashville, Tennessee
The Extracellular Matrix in Development

Guy Putet, MD
Professor of Pediatrics, Université Claude Bernard; Head of Neonatal Unit, Hôpital de la Croix-Rousse; Coorindator of Neonatal Departments, Hospices Civils de Lyon, Lyon, France
Lipids as an Energy Source for the Premature and Full-Term Neonate

Theodore J. Pysher, MD
Professor and Division Chief, Pediatrics Pathology, Department of Pathology, University of Utah School of Medicine; Head, Department of Pathology, Primary Children's Medical Center, Salt Lake City, Utah
Impaired Lung Growth After Injury in Premature Lung

Marlene Rabinovitch, MD
Division of Pediatric Cardiology, Stanford University School of Medicine, Stanford, California
Developmental Biology of the Pulmonary Vasculature

Scott H. Randell, PhD
Associate Professor, Department of Cell and Molecular Physiology, The University of North Carolina at Chapel Hill, Chapel Hill, North Carolina
Structure of Alveolar Epithelial Cells and the Surface Layer During Development

Timothy Robert Hume Regnault, PhD
Assistant Professor, Department of Obstetrics and Gynecology, University of Western Ontario, London, Ontario, Canada
Angiogenesis
Fetal Requirements and Placental Transfer of Nitrogenous Compounds

Jann Rhodes, PhD
Fellow, Department of Biomedical Sciences, Colorado State University, Fort Collins, Colorado
Angiogenesis

Michael J. Rieder, MD, PhD, FRCPC, FAAP, FRCP (Glasgow)
Professor, Departments of Pediatrics, Physiology and Pharmacology, and Medicine, Schulich School of Medicine and Dentistry, University of Western Ontario; Children's Hospital of Western Ontario, London, Ontario, Canada
Drug Excretion During Breast Feeding

Henrique Rigatto, MD
Division of Pediatric Neonatology, University of Manitoba Faculty of Medicine; Children's Hospital, Winnipeg, Manitoba, Canada
Control of Breathing in Fetal Life and Onset and Control of Breathing in the Neonate

Natalie E Rintoul, MD
Clinical Associate in Neonatology, University of Pennsylvania School of Medicine; Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Pathophysiology of Neural Tube Defects

Roberto Romero, MD
Perinatology Research Branch, NICHD/ NIH/DHHS, Bethesda, Maryland, and Detroit, Michigan
Fetal and Maternal Responses to Intrauterine Infection

Seamus A. Rooney, PhD, ScD
Professor Emeritus of Pediatrics, Yale University School of Medicine, New Haven, Connecticut
Regulation of Surfactant-Associated Phospholipid Synthesis and Secretion

James C. Rose, PhD
Frank C. Greiss Jr. Professor, Department of Obstetrics and Gynecology, Wake Forest University School of Medicine, Winston-Salem, North Carolina
Development of the Corticotropin-Releasing Hormone–Corticotropin System in the Mammalian Fetus

Charles R. Rosenfeld, MD
George L. MacGregor Professor of Pediatrics, Professor of Obstetrics/Gynecology and Anesthesiology, Department of Pediatrics, University of Texas Southwestern Medical School at Dallas; Attending, Department of Women and Infants, Parkland Memorial Hospital; Attending, Neonatal Medicine, Children's Hospital of Dallas, Dallas, Texas
Regulation of the Placental Circulation

Arthur J. Ross III, MD, MBA
Dean, School of Medicine, Professor of Surgery and Pediatrics, West Virginia University, Morgantown, West Virginia
Organogenesis of the Gastrointestinal Tract

Colin D. Rudolph, MD, PhD
Chief, Division of Pediatric Gastroenterology and Nutrition, Professor of Pediatrics, Medical College of Wisconsin, Milwaukee, Wisconsin
Gastrointestinal Motility

Martin Rutter, PhD
Hospital for Sick Children Research Institute, Physiology and Experimental Medicine Program; Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada
Molecular Mechanisms of Lung Development and Lung Branching Morphogenesis

Thor Willy Ruud-Hansen, MD, PhD
Professor of Pediatrics, Neonatologist, Neurologist, Department of Neonatology, Women's and Children's Division, Oslo University Hospital-Rikshospitalet, University of Oslo, Oslo, Norway
Mechanisms of Bilirubin-Induced Brain Injury

Rakesh Sahni, MD
Professor of Clinical Pediatrics, Morgan Stanley Children's Hospital of New York–Presbyterian, New York, New York
Temperature Control in Newborn Infants

Harvey B. Sarnat, MS, MD, FRCPC
Professor of Pediatrics, Pathology, (Neuropathology), and Clinical Neurosciences, University of Calgary Faculty of Medicine, Alberta Children's Hospital, Calgary, Alberta, Canada
Ontogenesis of Striated Muscle

Lisa M. Satlin, MD
Professor and Chair, Department of Pediatrics, Mount Sinai School of Medicine; Pediatrician-in-Chief, Mount Sinai Medical Center, New York, New York
Potassium Homeostasis in the Fetus and Neonate

Ola Didrik Saugstad, MD, PhD
Professor of Pediatrics, Director, Department of Pediatric Research, University of Oslo; Consultant, Department of Women and Children's Health, Oslo University Hospital, Oslo, Norway
Physiology of Resuscitation

Kurt R. Schibler, MD
Perinatal Institute, Division of Pediatric Neonatology, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio
Developmental Biology of the Hematopoietic Growth Factors
Mononuclear Phagocyte System

Frank C. Schmalstieg, MD
Professor, Department of Pediatrics, Director, Pediatric Immunology Diagnostic Laboratory, University of Texas Medical Branch, Galveston, Texas
Immunology of Human Milk and Host Immunity

Karl Schulze, MD
Associate Professor of Clinical Pediatrics, Children's Hospital of New York, New York, New York
Temperature Control in Newborn Infants

Jeffrey Schwartz, MD
Discipline of Physiology, School of Molecular and Biomedical Sciences, University of Adelaide, Adelaide, Australia
Development of the Corticotropin-Releasing Hormone–Corticotropin System in the Mammalian Fetus

Gunnar Sedin, MD, PhD
Department of Paediatrics, University Children's Hospital, Uppsala, Sweden
Physics and Physiology of Human Neonatal Incubation

Jeffrey L. Segar, MD
Professor and Director, Division of Neonatology, Department of Pediatrics, University of Iowa Carver College of Medicine, Iowa City, Iowa
Neural Regulation of Blood Pressure During Fetal and Newborn Life

Istvan Seri, MD, PhD, HonD
Professor of Pediatrics, Keck School of Medicine, University of Southern California; Director, Center for Fetal and Neonatal Medicine, Head, USC Division of Neonatal Medicine, Children's Hospital Los Angeles, Los Angeles, California
Pathophysiology of Shock in the Fetus and Neonate
Regulation of Acid-Base Balance in the Fetus and Neonate

Thomas H. Shaffer, MD, MSE, PhD
Director, Respiratory Physiology Section, Department of Physiology, Temple University School of Medicine, Philadelphia, Pennsylvania
Upper Airway Structure: Function, Regulation, and Development
Liquid Ventilation

Philip W. Shaul, MD
Professor and Director, Division of Pulmonary and Vascular Biology, Department of Pediatrics, University of Texas Southwestern Medical Center; Attending Physician, Neonatal-Perinatal Medicine, Parkland Health and Hospital System, Dallas, Texas
Physiology of Nitric Oxide in the Developing Lung

Jayant P. Shenai, MD
Professor of Pediatrics, Director, Educational Affairs, Vanderbilt University School of Medicine; Vanderbilt Children's Hospital, Neonatology, Vanderbilt University Medical Center, Nashville, Tennessee
Vitamin A Metabolism in the Fetus and Neonate

Colin P. Sibley, PhD
Professor, Child Health and Physiology, Maternal and Fetal Health Research Centre, University of Manchester; Head of Research and Innovation Division, Central Manchester University Hospitals NHS Foundation Trust, Manchester, United Kingdom
Mechanisms of Transfer Across the Human Placenta

Gary C. Sieck, PhD
Vernon F. and Earline D. Dale Professor and Chair, Department of Physiology and Biomedical Engineering, Dean, Research Academic Affairs, Mayo Clinic, Rochester, Minnesota
Functional Development of Respiratory Muscles

Theresa M. Siler-Khodr, PhD
Scientist and Director, Center for Investigation of Cell Regulation and Replication, San Antonio, Texas
Endocrine and Paracrine Function of the Human Placenta

Rebecca Anne Simmons, MD
Associate Professor, Department of Pediatrics, University of Pennsylvania Perelman School of Medicine; Attending Neonatologist, Department of Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Cell Glucose Transport and Glucose Handling During Fetal and Neonatal Development

Emidio M. Sivieri, MS
Biomedical Engineer, Neonatal Pulmonary Function Laboratory, Pennsylvania Hospital; University of Pennsylvania Perelman School of Medicine, Philadelphia, Pennsylvania
Evaluation of Pulmonary Function in the Neonate

Harold C. Slavkin, DDS
Professor of Dentistry, Division of Biomedical Sciences, Herman Ostrow School of Dentistry, University of Southern California Center for Craniofacial Molecular Biology, Los Angeles, California
Regulation of Embryogenesis

Brian S. Snarr, MD, PhD
Department of Pediatrics, University of Texas Southwestern Medical Center, Dallas, Texas
Cardiovascular Development

Evan Y. Snyder, MD, PhD, FAAP
The Sanford-Burnham Medical Research Institute, Program in Stem Cell and Regenerative Biology, Department of Pediatrics, University of California–San Diego, La Jolla, California
Stem Cell Biology

Jeanne M. Snyder, PhD
Department of Anatomy and Cell Biology, University of Iowa Medical Center, Iowa City, Iowa
Regulation of Alveolarization

Martha Sola-Visner, MD
Assistant Professor of Pediatrics, Division of Newborn Medicine, Children's Hospital Boston and Harvard Medical School, Boston, Massachusetts
Developmental Megakaryocytopoiesis

Michael J. Solhaug, MD
Associate Dean of Admissions, Professor of Pediatrics, Associate Professor of Physiology, Eastern Virginia Medical School, Norfolk, Virginia
Postnatal Maturation of Renal Blood Flow

Charles A. Stanley, MD
Professor, Department of Pediatrics, University of Pennsylvania Perelman School of Medicine; Director, Hyperinsulinism Center, Attending Physician, Division of Endocrinology and Diabetes, The Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Pathophysiology of Hypoglycemia

F. Bruder Stapleton, MD
Professor and Chair, Associate Dean, Department of Pediatrics, University of Washington School of Medicine; Chief Academic Officer, Seattle Children's Hospital, Seattle, Washington
Developmental Aspects of Organic Acid Transport

Barbara S. Stonestreet, MD
Professor of Pediatrics, The Warren Alpert Medical School of Brown University; Staff Neonatologist, Director, Fellowship Program in Neonatal–Perinatal Medicine, Department of Pediatrics, Women and Infants Hospital of Rhode Island, Providence, Rhode Island
Fluid Distribution in the Fetus and Neonate
Development of the Blood-Brain Barrier

Dennis M. Styne, MD
Professor and Yocha Dehe Endowed Chair of Pediatric Endocrinology, Department of Pediatrics, Section of Endocrinology, University of California Davis Medical Center and School of Medicine, Sacramento, California
Endocrine Factors Affecting Neonatal Growth

William E. Sweeney, Jr., MD
Assistant Professor, Children's Kidney Disease Research Center, Milwaukee, Wisconsin
Embryogenesis and Anatomic Development of the Kidney

Deanna T. Taylor, MD
Department of Cellular and Molecular Neuroscience, Division of Neuroscience and Mental Health, Imperial College, Hammersmith Campus, London, United Kingdom
Apoptotic Cell Death

Paul S. Thornton, MB, BCh
Division of Pediatric Endocrinology, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Ketone Body Production and Metabolism in the Fetus and Neonate

Jeffrey A. Towbin, MD
Chief, Pediatric Cardiology, Professor, Departments of Pediatrics (Cardiology), Cardiovascular Sciences, and Molecular and Human Genetics, Baylor College of Medicine, Texas Children's Hospital, Houston, Texas
Cardiomyopathies in Infants and Children

William E. Truog, MD
Division of Pediatric Neonatology, University of Missouri–Kansas City; Children's Mercy Hospital, Kansas City, Missouri
Pulmonary Gas Exchange in the Developing Lung

Reginald C. Tsang, MD
Department of Pediatrics, University of Cincinnati Medical Center, Cincinnati, Ohio
Calcium, Phosphorus, and Magnesium Transport Across the Placenta
Neonatal Calcium, Phosphorus, and Magnesium Homeostasis

Nicole Ullrich, MD, PhD
Assistant Professor of Neurology, Director of Neurooncology, Department of Neurology, Children's Hospital Boston, Harvard Medical School, Boston, Massachusetts
Development of the Nervous System

Edi Vaisbuch, MD
Perinatology Research Branch, NICHD/NIH/DHHS, Bethesda, Maryland, and Detroit, Michigan
Fetal and Maternal Responses to Intrauterine Infection

John E. Van Aerde, MD
Neonatologist, Edmonton, Alberta, Canada
Accretion of Lipid in the Fetus and Newborn

Carmella van de Ven, MA
Division of Pediatric Oncology, Columbia University, New York, New York
Neonatal Neutrophil Normal and Abnormal Physiology

Johannes (Hans) B. van Goudoever, MD, PhD
Professor, Department of Pediatrics, University of Amsterdam Academic Medical Center; Director, Emma Children's Hospital, Amsterdam Medical Center; Head, Department of Pediatrics, VU University Medical Center, Amsterdam, The Netherlands
General Concepts of Protein Metabolism

Minke Van Tuyl, PhD
Programme in Lung Biology Research, Hospital for Sick Children, Toronto, Ontario, Canada
Molecular Mechanisms of Lung Development and Lung Branching Morphogenesis

Robert C. Vannucci, MD
Professor, Department of Pediatrics and Pediatric Neurology, Milton S. Hershey Medical Center, Pennsylvania State College of Medicine, Hershey, Pennsylvania
Perinatal Brain Metabolism

Susan J. Vannucci, PhD
Professor of Neuroscience in Pediatrics, Research Director, Newborn Medicine, Department of Pediatrics, Weill Cornell Medical College, New York, New York
Perinatal Brain Metabolism

Matteo Vatta, PhD
Department of Pediatrics (Cardiology), Baylor College of Medicine, Texas Children's Hospital, Houston, Texas
Cardiomyopathies in Infants and Children

Daniela Virgintino, MD, PhD
Professor of Human Embryology, Department of Human Anatomy and Histology, University of Bari "Aldo Moro" Medical School, Bari, Italy
Development of the Blood-Brain Barrier

Joseph J. Volpe, MD
Bronson Crothers Distinguished Professor of Neurology, Harvard Medical School; Neurologist-in-Chief Emeritus, Children's Hospital Boston, Boston, Massachusetts
Intraventricular Hemorrhage in the Neonate

MaryAnn V. Volpe, MD
Associate Professor of Pediatrics, Division of Newborn Medicine, Department of Pediatrics, Floating Hospital for Children at Tufts Medical Center and Tufts University School of Medicine, Boston, Massachusetts
Homeobox Genes

Reidar Wallin, PhD
Professor Emeritus, Department of Internal Medicine, Section on Molecular Medicine, Wake Forest University School of Medicine, Winston-Salem, North Carolina
Vitamin K Metabolism in the Fetus and Neonate

David Warburton, MD, OBE, DSc, MMM, FRCP, FRCS, FRCPCH
Professor, Department of Pediatrics, Surgery, and Craniofacial Biology, Keck School of Medicine and Herman Ostrow School of Dentistry, University of Southern California; Director, Developmental Biology and Regenerative Medicine Program, Director, California Institute for Regenerative Medicine Training Program and Stem Cell Core Facilities, Children's Hospital Los Angeles, Los Angeles, California
Regulation of Embryogenesis

Robert M. Ward, MD
Director, Pediatric Pharmacology Program, University of Utah School of Medicine, Salt Lake City, Utah
Basic Pharmacokinetic Principles

Kristi L. Watterberg, MD
Professor and Chief, Division of Neonatology, Department of Pediatrics, Albuquerque, New Mexico
Fetal and Neonatal Adrenocortical Physiology

Steven L. Werlin, MD
Professor, Department of Pediatrics, Medical College of Wisconsin; Department of Pediatric Gastroenterology, Children's Hospital of Wisconsin, Milwaukee, Wisconsin
Development of the Exocrine Pancreas

Lynne A. Werner, PhD
Professor, Department of Speech and Hearing Sciences, University of Washington, Seattle, Washington
Early Development of the Human Auditory System

Susan E. Wert, PhD
Associate Professor, Department of Pediatrics, University of Cincinnati College of Medicine; Director, Molecular Morphology Core, Divisions of Neonatology, Perinatal Biology, and Pulmonary Biology, Cincinnati Children's Hospital Research Foundation/ Perinatal Institute, Cincinnati, Ohio
Normal and Abnormal Structural Development of the Lung

Andy Wessels, PhD
Department of Cell Biology and Anatomy, Department of Pediatrics, Division of Pediatric Cardiology, Medical University of South Carolina, Charleston, South Carolina
Cardiovascular Development

[†]Lars Grabow Westergaard, MD
Fertility Clinic Trianglen, Hellerup, Denmark
Differentiation of the Ovary

PREFACE

It has been nearly 7 years since the third edition of *Fetal and Neonatal Physiology* was published. During that interval, thousands of publications have focused on various aspects of fetal or neonatal physiology. The challenge faced in the preparation of this edition was to provide an exhaustive update without allowing the size (and cost) of the textbook to escalate. To further this end, each of the authors has been asked to incorporate relevant new material, but to remain within the page limitations of the previous edition. We have also eliminated clinical information that can easily be found in one of the many standard textbooks on neonatology, without sacrificing our goal of making the book a comprehensive reference text. Notably, there are several new chapters in this edition, and all chapters from the previous edition have been extensively revised.

As with any large textbook, there are a number of individuals we need to acknowledge. First, we wish to thank the hundreds of authors who contributed chapters to this fourth edition. We realize that the "academic" benefits of writing a chapter are limited, and that both new chapters and revisions require enormous time and effort. Only through the generosity of these contributors and their desire to educate has this edition been able to go forward. We wish to thank Heidi Kleinbart for her superb editorial assistance and Melissa Dudlick at Elsevier for her tremendous help in the development and organization of the book. Finally, we want to thank Judy Fletcher at Elsevier, who has been our senior editor since the first edition of *Fetal and Neonatal Physiology*, and who has challenged us to make this edition ever better.

ACKNOWLEDGMENTS

We acknowledge with great sadness the passing of Michael Linshaw, MD, the renowned pediatric nephrologist who contributed the chapter "Concentration and Dilution of the Urine" to this text for several editions. He was a beloved teacher and mentor who enjoyed solving the mysteries of the kidneys. His passion and tenacity for doing so improved the lives of many children and their families.

We also wish to acknowledge the many scientific contributions of Karl Bauer, MD, whose research on energy expenditure and body composition were fundamental to understanding changes in body water compartments that occur in the transition to postnatal life. Dr. Bauer was awarded the Czerny Prize of the German Society of Pediatrics for his research on the genetics of lymphocytes in the newborn. He served as director of the department of neonatology of the University of Frankfurt and was president of the German Society of Perinatal Medicine.

Fred Levine

Basic Genetic Principles

PRIMARY STRUCTURE OF NUCLEIC ACID

The two kinds of nucleic acid—deoxyribonucleic acid (DNA) and ribonucleic acid (RNA)—both are composed of recurring monomeric units called *nucleotides.* Each nucleotide has three components (Figure 1-1, *A*): (1) a phosphate group linked to (2) a five-carbon atom cyclic sugar group, which, in turn, is joined to (3) a purine or a pyrimidine base. DNA and RNA are distinguished by their base components and the makeup of their sugar-phosphate backbones. DNA consists of four deoxyribonucleotides that differ in their base components. The four bases are the purine derivatives adenine (A) and guanine (G) and the pyrimidine derivatives cytosine (C) and thymine (T) (see Figure 1-1, *B* and *C*). Similarly, four different ribonucleotides are the major components of RNA; they contain the purine bases adenine and guanine and the pyrimidine bases cytosine and uracil (U). Thus the major difference in base composition between RNA and DNA is that RNA contains uracil, whereas DNA contains thymine. The other difference between RNA and DNA is in their sugar-phosphate backbones: RNA contains ribose, and DNA contains 2-deoxyribose. In both DNA and RNA, the nucleotides are joined together by phosphodiester bonds linking the phosphate group of one nucleotide to a hydroxyl group on the sugar of the adjacent nucleotide. The purine and pyrimidine bases of the nucleotide constitute distinctive side chains and are not present in the backbone structure of nucleic acids.

By analyzing x-ray diffraction patterns of purified DNA and by building models, Watson and Crick deduced that native DNA consists of two antiparallel chains in a structure that can be conceptualized as resembling a spiral staircase, the *double helix* (Figure 1-2, *A*). The two strands are held together by hydrogen bonds between pairs of bases on the opposing strands, similar to the steps on the staircase (see Figure 1-2, *B*). The bonding is specific: A always pairs with T, and C always pairs with G. As Watson and Crick noted, a pair of purines would be rather large to fit inside a double helix (which has a thickness of 2 nm), and a pair of pyrimidines would be too far apart to form stable hydrogen bonds with each other. The base pairs AT and GC, however, proved to be similar not only in size but also in shape. Overall, the discovery of the structure of DNA was one of the most important events in biology because it not only provided an explanation for how genetic information is carried but also indicated how this information is propagated. As a consequence of the hydrogen bonding between the two DNA strands, also known as *base pairing* or *hybridization,* a DNA molecule can replicate precisely by separation of the two chains followed by synthesis of two new complementary strands.

In contrast with the regular structure of DNA, most RNA molecules are single-stranded. Base pairing, however, occurs between regions of an RNA strand with complementary sequences, with AU pairs instead of AT, giving RNA molecules a complex secondary structure that is poorly understood in most cases but plays an important role in cellular metabolism (e.g., as has been described for transfer RNA [tRNA]).

GENOMIC ORGANIZATION

Chromosomes

Each cell in a human being contains an enormous amount of DNA. With the completion of the human genome sequence, we know now that the genome contains 3.24475×10^9 base pairs per haploid genome. Obviously, the cell must be able to organize such a large amount of DNA in a compact manner. This organization is accomplished by packaging the DNA into large macromolecular complexes called *chromosomes.* A major distinguishing feature of eukaryotic organisms such as humans versus prokaryotic organisms such as bacteria is the presence of a nucleus, the main function of which is to contain the chromosomes.

Of the 46 chromosomes in the human nucleus, 44 are *autosomes;* the remaining 2 are the *sex chromosomes*—those involved in sex determination. In the human karyotype (an organized microphotographic array of all of the chromosomes), the autosomes can be seen to exist in homologous pairs, which are numbered from 1 to 22 in order of decreasing size, with one member of each pair inherited from one parent. The two sex chromosomes are designated X and Y. Normally, females have two X chromosomes, whereas males have one X and one Y. A small segment of the Y chromosome includes the gene for the testis-determining factor (TDF) responsible for male development. The lack of this factor results in female development, so it is the presence or absence of the Y chromosome that actually determines gender. The *TDF* gene encodes a sequence-specific DNA binding protein named SRY (for "sex-determining region Y").

Each chromosome consists of one large DNA molecule complexed with large amounts of two types of protein, called *histone* and *nonhistone chromosomal proteins,* which serve to condense the DNA into an orderly, compact structure. The five principal histone types—H1, H2a, H2b, H3, and H4—interact specifically with one another and with DNA to form structures called *nucleosomes.* Each nucleosome consists of a disk-shaped histone core plus a segment of DNA that winds around the core. The core contains two copies of H2a, H2b, H3, and H4, and the DNA wrapped around the histone core is approximately 140 base pairs in length. H1 binds to the DNA just next to the nucleosomes. The nonhistone proteins are much more diverse and complex; 12 to 18 major and many additional minor species have been identified. Nonhistone proteins play important roles, including as chromosomal structural elements and in the control of gene expression, for example, posttranslational modification of histones by acetylation and deacetylation. The complex of DNA and histones, called *chromatin,* forms coils to produce a fiber with a larger diameter. Histone-depleted metaphase chromosomes have been shown to consist of a nonhistone protein scaffold that has the shape characteristic of a metaphase chromosome surrounded by a halo of DNA. In this model of chromosome organization, the nucleoprotein fibers form radially oriented loops that converge to the central scaffolding. Most chromatin fibers

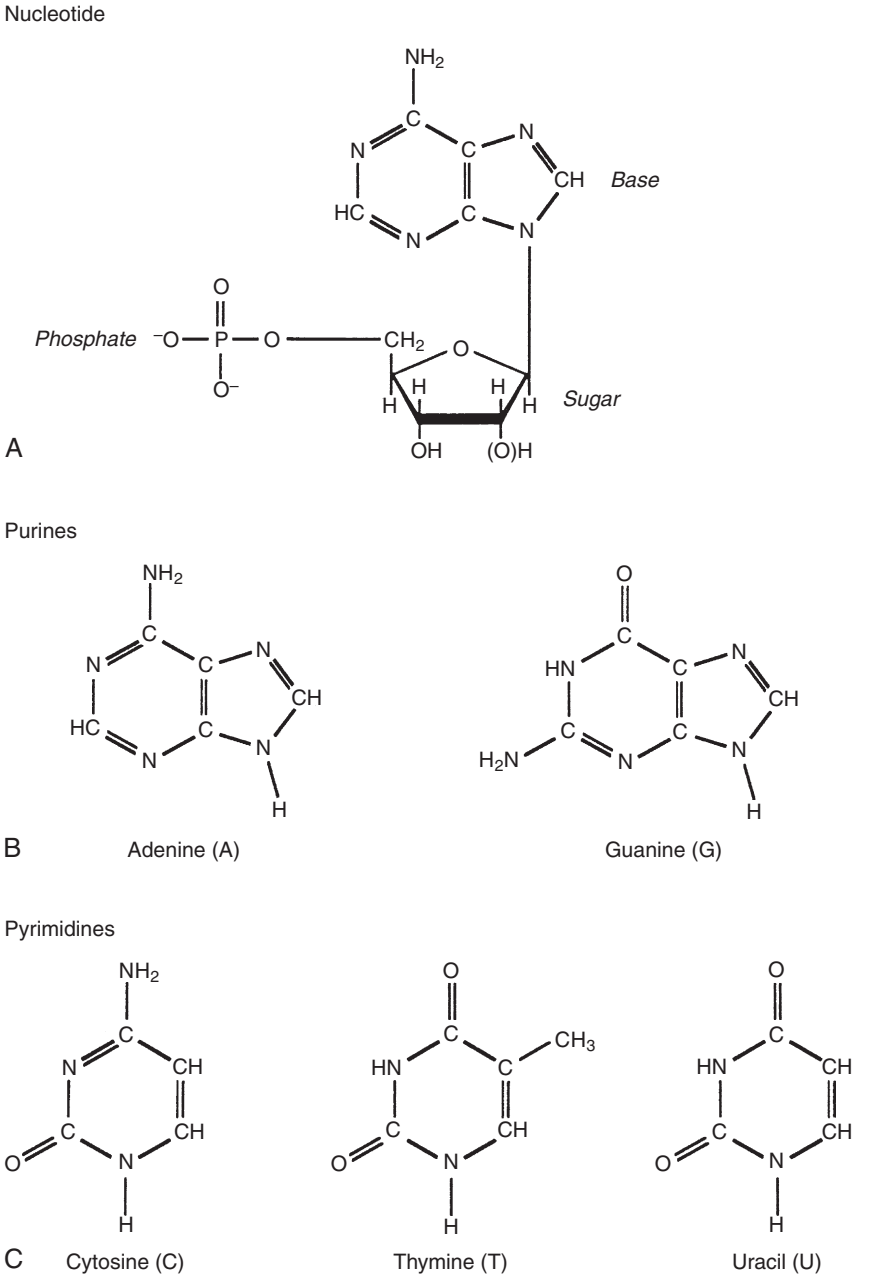

Figure 1-1 Nucleotide structure. A, General structure of nucleotides, consisting of a purine or pyrimidine base (in this case, adenine), a five-carbon atom sugar, and a phosphate group. The oxygen in *parentheses* in the sugar is present in the ribose of RNA but is absent in the deoxyribose of DNA. The plane of the sugar is perpendicular to that of the other subunits. **B,** Structures of the two purines in DNA and RNA. **C,** Structures of the three pyrimidines in nucleic acids. Cytosine is found in both DNA and RNA, thymine is unique to DNA, and uracil is unique to RNA.

undergo a transition between dispersed and condensed configurations during the cell cycle. Before cell division, most chromatin is in the condensed form, with limited but functionally important transcriptional activity. Between cell divisions, the bulk of the chromatin in most cells is dispersed within the nucleus for events such as DNA replication and gene transcription.

Gene Structure

All hereditary information is transmitted from parent to offspring through the inheritance of genes, which are defined as the DNA sequences necessary to produce a functional protein or RNA sequence. It is thought that approximately 25,000 genes are present on human chromosomes, although this number is the subject of controversy, even with the completion of the human genome sequence. A surprising finding on completion of the genome sequence was that the number of genes in human beings is not substantially greater than that in lower organisms. Thus, evidently it is not the number of genes that accounts for increased complexity, but rather the manner in which they are regulated.

Genes in eukaryotic cells are divided into regions called *expressed sequences (exons)* and *intervening sequences (introns),* of which only the exon sequences are present in mature messenger RNA (mRNA) and actually code for proteins (Figure 1-3, *top*). Although some introns play a role in the control of gene expression, the function of most is unknown, but they can greatly expand

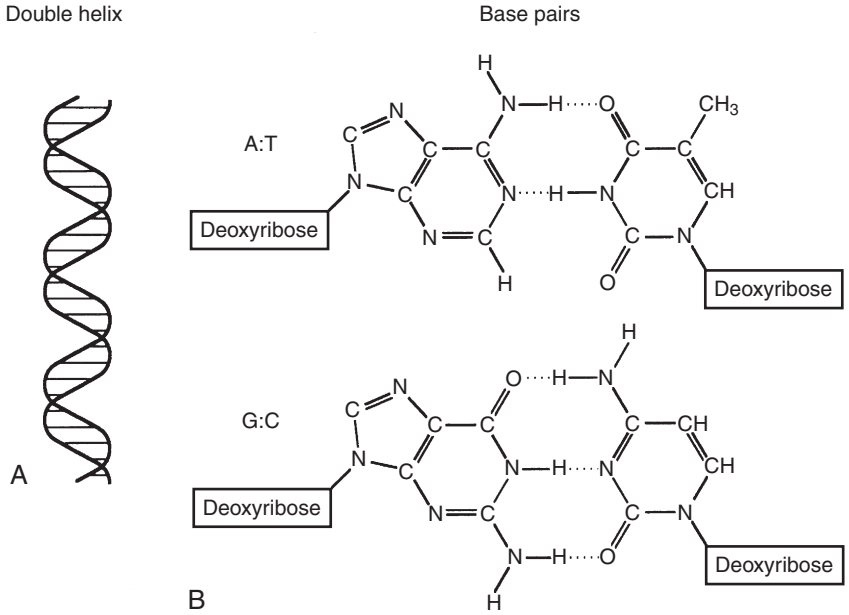

Figure 1-2 DNA structure and base pairing. A, Schematic representation of the double helical DNA molecule. **B,** Base pairing of purines and pyrimidines in DNA. Hydrogen bonding between the pairs is indicated by *dotted lines.* The AT and GC base pairs are identical in size and nearly identical in shape. Note that the GC base pair has an additional hydrogen bond and therefore is held together more strongly.

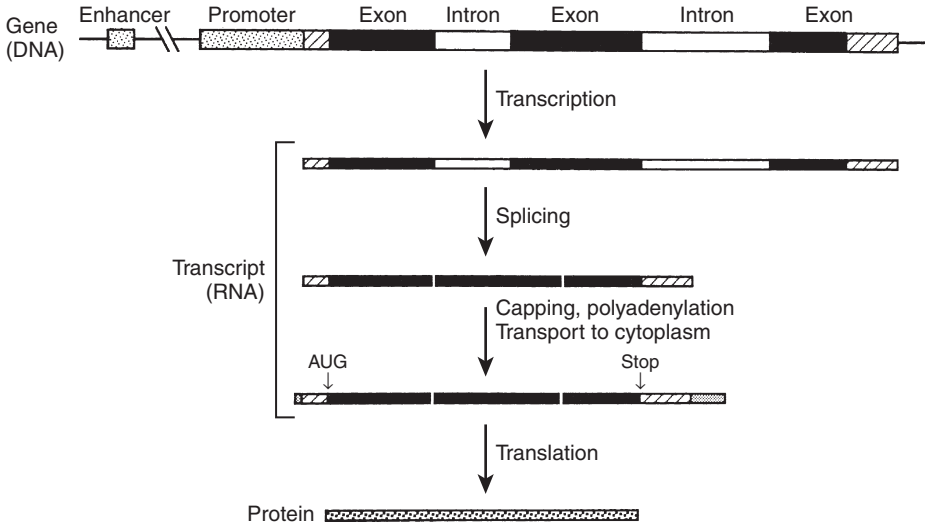

Figure 1-3 Gene structure *(top)* and the flow of genetic information from DNA to protein. *Cross-hatched boxes* indicate the regions of exons that do not encode amino acid sequences; *shaded boxes* indicate posttranscriptional modifications. AUG is a codon that specifies the amino acid methionine and is also used to specify the first amino acid of a protein.

the size of genes. For example, the dystrophin gene, involved in Duchenne muscular dystrophy, is approximately 2300 kilobase (kB) pairs of DNA in length and includes 79 exons accounting for only 14 kB, with the remainder consisting of introns, some more than 100 kB long. By contrast, the α-globin gene, 835 base pairs long, includes two introns that total 261 base pairs.

In addition to the exons and introns of genes, most of the eukaryotic genome consists of long DNA stretches that are not part of genes. In fact, it has been estimated that genes make up only 10% of the human genome, and the actual protein-coding regions account for only 1% of the genome. It is not understood why these long DNA stretches are present. Although some of them may play a role in DNA replication, chromosome pairing, and recombination, most of these stretches apparently serve no obvious function.

Interspersed throughout the noncoding DNA stretches are many repeated sequences, which are either clustered together or evenly distributed throughout the genome. These sequences can be short and consist only of 5 to 10 nucleotides, or they can be as long as 5000 to 6000 nucleotides. Whether these repeats have important functions or are mere players in an intragenomic evolutionary battle for self-preservation and expansion remains largely a mystery. Some of the longer repeats, such as the so-called Alu sequences or long interspersed nuclear elements (LINEs), have features similar to those of viruses and have been shown to be able to move from place to place in the genome. Other repeats are short, consisting of a stretch of two bases, such as CACACA. It has been known for some time that short repeats exhibit extreme variability from individual to individual. This variability

can be used to generate a type of fingerprint to uniquely identify any given individual. Such genetic "fingerprinting" is a powerful tool for gene mapping studies as well as in forensic applications such as paternity testing and criminal investigations. More recently, longer repeats and large regions of chromosomes have been found to exhibit copy number variation. This large-scale variation will almost certainly be found to contribute to genetically determined individual variation in human populations.

HOW GENES FUNCTION

Flow of Genetic Information

Transcription

Because DNA stores genetic information in the nucleus of eukaryotic cells, whereas protein synthesis occurs in the cytoplasm, a mechanism by which the information is carried to the cytoplasm is essential. The first step in gene expression is the production of an RNA molecule from the DNA template. This RNA acts as a molecular messenger, carrying the genetic information out of the nucleus. The synthesis of mRNA is called *transcription* because the genetic information in DNA is transcribed without being changed into a new language. During the process of transcription, the two DNA strands separate, and one functions as a template for the synthesis of single-stranded RNA molecules by the action of enzymes called *RNA polymerases.* The initial RNA transcripts are quite long because they include both intron and exon sequences from the gene (see Figure 1-3). The intron sequences are cut out by specific enzymes, and the remaining exons are spliced together. To form the mature mRNAs that leave the nucleus, a methylated guanine nucleotide called a *cap* is added to the beginning; a string of 200 to 250 adenine bases usually is added to the end (see Figure 1-3). The cap is important for ribosomal binding in the initiation of protein synthesis, whereas the polyadenosine stretch at the end of the mRNA plays a role in the stability of the mRNA.

In addition to mRNA, other major classes of RNA are transcribed from DNA: ribosomal RNA (rRNA), tRNA, and micro-RNAs (miRNAs). In contrast with mRNA, these classes of RNA do not code for proteins. Ribosomal RNAs and tRNAs are required for protein synthesis. The recently discovered miRNAs play complex and as yet poorly understood roles in posttranscriptional regulation of gene expression. A subclass of small RNA molecules, termed small interfering RNAs (siRNAs), have homology to specific mRNAs in the cell. Binding of a target mRNA by an siRNA results in its being degraded, with a consequent decrease in the production of the encoded protein. This phenomenon is widely used by researchers to shut down the expression of target genes. Ultimately, the hope is that this approach can be used therapeutically to target genes that may be involved in diseases such as cancer; as with other forms of gene therapy, however, the major problem remains efficient delivery to specific target cells in the body.

Unlike prokaryotic cells, in which a single RNA polymerase makes all types of RNA, eukaryotic cells have three different RNA polymerases that transcribe different classes of RNA: The precursors to 18S and 28S rRNA are made by RNA polymerase I; the precursors to mRNA are made by RNA polymerase II; and 5S rRNA and tRNA are synthesized by RNA polymerase III. RNA polymerase I functions in a specialized region within the nucleus called the *nucleolus.*

Translation and the Genetic Code

The production of protein from an mRNA template is called *translation* because the genetic information that is stored in DNA as a sequence of nucleotides is translated into a sequence of amino acids. The method of storing genetic information is called the *genetic code.* Each member of the code, called a codon, consists of three adjacent bases. Each codon specifies a particular amino acid. Thus the linear nature of the codons in a DNA sequence specifies the sequence of amino acids in a protein. Because each of the three sites in a codon can be one of four possible nucleotides, a total of 4^3, or 64, different codons can be generated. Three of these 64 possible codons, UAA, UAG, and UGA, are called nonsense or termination codons because they do not code for amino acids, but rather serve to mark the end of a protein, that is a stop signal. The remaining 61 codons specify one of the 20 amino acids. Because each amino acid is specify by more than codon, the genetic code is said to be degenerate. A consequence of degeneracy in the genetic code is that some mutations do not result in a change in the amino acid sequence.

The three types of rRNA—28S, 18S, and 5S—associate with more than 50 proteins to form the ribosomes, which are the cytoplasmic sites of translation. The tRNAs are small molecules approximately 80 nucleotides long whose function is to position the correct amino acid for incorporation into the polypeptide. Before an amino acid can be incorporated into a polypeptide chain, it is first coupled to an appropriate tRNA by an aminoacyl-tRNA synthetase, which is specific for each amino acid–tRNA combination. A three-nucleotide region of each tRNA, designated the *anticodon,* includes a base sequence complementary to the appropriate mRNA codon and therefore hybridizes to it. In this way, each amino acid is brought into proper position and is added sequentially to the growing polypeptide chain by peptidyl transferase, an enzyme that is an integral part of the ribosome. Initiation of transcription almost always occurs at an AUG codon, which codes for methionine (see Figure 1-3). In many proteins, the initiation methionine is removed posttranslationally. Translation is terminated when a ribosome encounters a nonsense codon (see Figure 1-3). In the presence of the appropriate factors, the polypeptide chain is released from the last tRNA, and the ribosome disengages from the mRNA to start the cycle of protein synthesis over again.

Regulation of Gene Expression

The ability to control the production of proteins is central to the development and functioning of every organism. Although this control occurs at every stage of protein production, the most important level of control occurs at the level of mRNA production (i.e., transcriptional control). Transcriptional regulation is accomplished via the action of proteins that act on DNA, either by modifying it (e.g., cytosine methylation) or by binding to specific DNA sequences to activate or repress transcription from a gene.

In higher eukaryotes such as humans, two major types of DNA sequences regulate gene expression: promoters and enhancers. *Promoters* are located immediately adjacent to the start site of transcription, whereas enhancers can be located at large distances from the transcribed regions of the gene (see Figure 1-3). Several types of regulatory sequences have been identified in promoters that are important in transcriptional initiation by RNA polymerase II, including the *TATA box,* so called because it consists of a run of T and A base pairs. The TATA box is located approximately 30 bases before the transcription start site and functions as the binding site for a large, multisubunit complex of transcription factors, which includes RNA polymerase. Other sequence elements that are common to many genes transcribed by RNA polymerase II include the CAAT sequence, or *CAT box,* which lies between 50 and 100 bases before the transcription start site, and the GGGCGG sequence, or *GC box.* As with the TATA box, the function of these sequence elements is to serve as binding sites for proteins that are involved in transcriptional control.

Enhancer sequences serve to increase the level of transcription from promoters and have been shown to play pivotal roles in gene regulation, particularly for highly expressed genes such as viral genes and the globins. Many mammalian enhancers are tissue specific in their action. For example, enhancers from the pancreatic amylase, chymotrypsin, and trypsin genes function only in exocrine pancreas, and enhancers from immunoglobulin genes function only in lymphoid cells. As noted, in contrast with promoters, which have fixed positions relative to the transcription start site, enhancers exist in widely varying positions,

including before the promoter, after the coding region, within introns, and at great distances from the coding sequence, as in the case of the globin enhancer. Another property of enhancers that distinguishes them from promoters is their ability to function in a position-independent and orientation-independent manner relative to the gene. In addition to enhancer elements, which increase the levels of transcription, similar elements called *silencers* decrease the level of transcription. Combinations of these elements allow for precise control of the level of gene transcription.

Transcription is regulated by interactions among proteins bound to enhancer and promoter sequences. Such proteins can have either stimulatory or inhibitory functions. For example, the receptors for steroid hormones such as the glucocorticoids, estrogen, and androgens have been isolated and shown to bind to specific sequences near steroid-responsive genes such as vitellogenin and lactalbumin. In addition to the classic transcription factors that bind to specific sequence elements in genes, other proteins play important roles in the control of gene expression. For example, methylases and demethylases regulate the methylation of cytosine residues to affect gene expression. Mutations in MeCP2, a protein that binds to methylated DNA, cause Rett syndrome, an X-linked neurodegenerative disease. Rubinstein-Taybi syndrome is caused by mutations in a protein called CREB-binding protein (CBP), which acts to acetylate the histone proteins that are major components of chromatin, illustrating the fact that posttranslational modifications of chromatin proteins play central roles in regulating gene expression. Overall, it is the complex interplay of positive and negative effects between factors bound to different sites, both near and far from the coding region of a gene, that determines the pattern of gene expression.

In addition to transcriptional control, posttranscriptional mechanisms play important roles in controlling the level of gene product. Regulation takes place at virtually every level, including alternative splicing, transport of RNA from the nucleus to the cytoplasm, persistence of mRNA in the cytoplasm, translational efficiency, and regulation of the rate of protein degradation. Individual mRNA species differ widely with respect to metabolic stability. The half-lives of some mRNAs span several hours or even days, whereas those of others are extremely short. The rate of turnover of some mRNAs can vary dramatically in response to changes in the cell cycle and in response to treatment with certain hormones. Protein binding and mRNA structural features also have been shown to influence susceptibility to decay. The significance of posttranscriptional influences on protein levels has given rise to the field of *proteomics,* in which techniques for measuring protein levels on a global and high-throughput scale are used to define the *proteome* (i.e., the total complement of proteins) within a cell.

Stem Cells and Development

Development, in general terms, is the process by which a single fertilized egg becomes a complete organism. Central to development is the process of *differentiation,* whereby cells acquire different properties to carry out specific functions in separate tissues. To a large extent, differentiation is reflected in the production of tissue-specific proteins that, of course, is the result of specific gene expression. A fundamental question in development is how a group of genetically identical cells comes to express sets of genes in a tissue-specific manner. Much progress in this area has come from the striking similarities between the process of development in organisms such as *Drosophila* and *Caenorhabditis elegans* and in humans. Important principles of development, such as the role of morphogen gradients, were first described in lower organisms but have proved to be relevant in humans as well. A number of transcription factors are recognized to form concentration gradients that are critical in determining the pattern of body formation.

In addition to knowledge gained from lower organisms, a revolution in understanding of human development and human genetic disease has come from advances in the ability to manipulate mice genetically. Originally, this was done by introducing genetic material into mice by microinjection of fertilized eggs. The injected eggs give rise to mature animals that integrate the injected genes into their genome; such transgenic animals will pass the introduced genetic material through the germline to their offspring. In many cases, the introduced genes are expressed, allowing the effect of overexpression or ectopic expression of a gene product to be studied.

Inactivation of specific genes in mammals can be done by genetically manipulating embryonic stem (ES) cells derived from the blastocyst (Figure 1-4). A *stem cell,* by definition, is any cell that can both self-renew (i.e., replicate) and also give rise to more differentiated progeny. ES cells usually are derived from blastocysts, although ES cell lines have been derived even from eight-cell embryos. They can be grown in culture while retaining the ability to differentiate into all somatic tissues and the germline of mature mice. Thus a single cell grown in culture can be used to create a living mouse. Because ES cells can be grown in culture and genetically manipulated, mutations can be created in DNA using recombinant techniques, the resulting DNA introduced into ES cells where it is incorporated into DNA by homologous recombination (Figure 1-5), and the resulting ES cells carrying a specific mutation used to create mutant mice. To do that, the genetically manipulated ES cells are injected into blastocysts, giving rise to chimeric adult mice (Figure 1-4). Some of these mice contain the genetically manipulated cells in their germline and will produce genetically altered, nonchimeric offspring.

In many instances, gene mutations result in nonviable organisms; such genes are said to possess embryonic lethality. This characteristic is useful in genetic studies. For example, a common investigational technique is to knock out genes in a particular

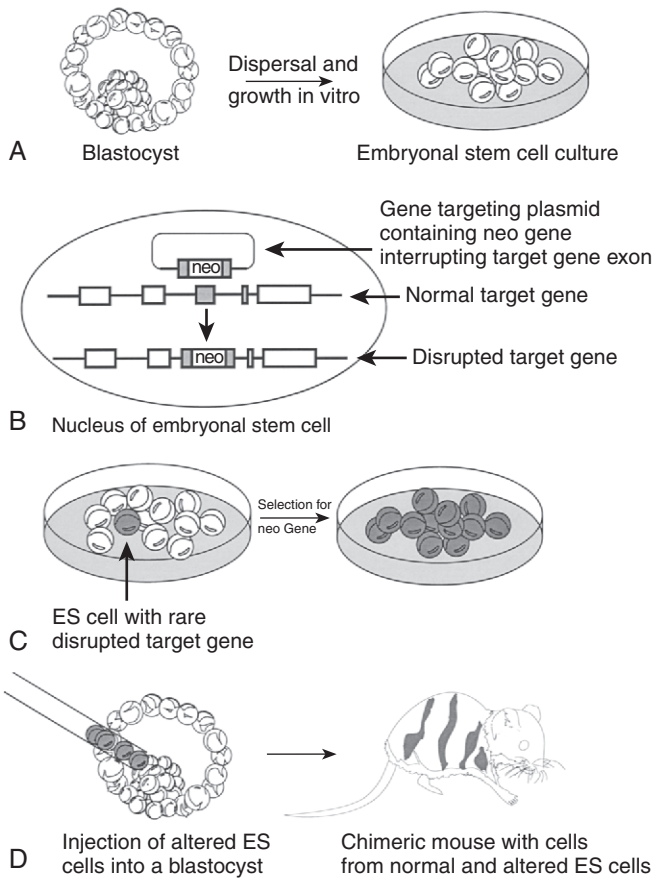

Figure 1-4 Genetic alteration of mice by homologous recombination.

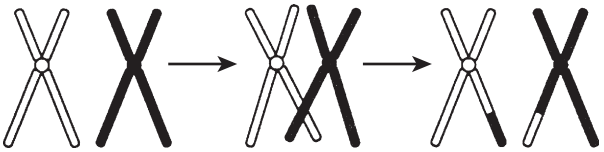

Figure 1-5 Recombination. In this simplified view of recombination, the two members of a homologous pair of chromosomes line up during the first meiotic prophase. Segments of the two chromosomes "cross over," and breakage and rejoining of the DNA strands occur.

tissue through modification of the target gene by flanking it with 34–base pair DNA sequences called *lox sites* that are the substrates for a recombinase enzyme derived from the bacteriophage P1 Cre recombinase. In mice, when Cre (for "cyclization recombination") is expressed from a tissue-specific promoter element, the affected mouse will demonstrate deletion of the target gene only in cells expressing the tissue-specific promoter.

CELL DIVISION AND RECOMBINATION

Cell Cycle and Mitosis

The *cell cycle* is the process by which the cell divides to form two daughter cells. In *mitotic division,* the normal complement of 46 chromosomes is maintained through a process of DNA replication and subsequent separation of the chromosomes. Additionally, the cytoplasm of the eukaryotic cell cleaves into two approximately equal halves. Mitotic division takes up only a small part of the cell cycle. A complete cell cycle consists of four phases: G_1 (growth or gap 1), S (synthesis), G_2, and M (mitosis). The cycle of each type of cell varies considerably in total duration, from minutes in some cells to weeks or months in others. The G_1 phase begins immediately after a cell division. It is followed by the S phase, during which DNA replication occurs, as described earlier. Immediately after the S phase, the cell has a tetraploid chromosome content, instead of the usual diploid number, so there are 92 chromosomes divided into 46 pairs of sister chromatids. Cells then pass into the premitotic G_2 phase, which ends with the onset of mitosis or actual cell division. The G_1, S, and G_2 phases are called *interphase* because despite continued growth and synthesis of macromolecules, such as DNA, RNA, and proteins, cell division takes place only during mitosis. DNA and the histone components of the chromatin are synthesized only during the S phase, whereas RNA, the cytoplasmic proteins, and organelles are synthesized continuously during all of interphase. The cell finally divides in the M phase, during which the synthesis of RNA and protein is greatly reduced.

During interphase, chromosomes are not visible by light microscopy because chromatin is dispersed throughout the nucleoplasm. The beginning of mitosis is signaled by the appearance of chromosomes as thin threads inside the nucleus. Mitosis is divided somewhat arbitrarily into four phases: prophase, metaphase, anaphase, and telophase. During *prophase,* the nuclear envelope begins to break up, and each chromosome can be seen to consist of two identical or sister chromatids held together at specific regions called *centromeres.* Another structure that is important for proper segregation of chromosomes is the centriole, an organelle just outside the nuclear membrane. Each cell normally has a pair of centrioles, arranged opposite one other, but they are duplicated early in the S phase. During mitotic prophase, the two pairs of centrioles separate and migrate to define the poles of the cell. During *metaphase,* the chromosomes move to the equatorial plane of the cell and become attached to the spindle fiber apparatus, which is a structure consisting of microtubules of protein that radiate from the centrioles at either pole and extend from pole to pole. Each chromatid has near its centromere a dense granule called a *kinetochore* to which the spindle fibers attach. Because of the kinetochores and attached spindle fibers, the two sister chromatids are pulled toward opposite poles. During *anaphase,* the centromeres divide, and the two chromatids of each pair, now free of each other, move toward their respective poles by the contraction of spindle fibers. In *telophase,* the chromosomes and spindle fibers disperse and disappear, and new nuclear envelopes are assembled to surround the two sets of daughter chromosomes. Simultaneously, separation and segregation of the cell cytoplasm occur, a process called *cytokinesis,* which results in the formation of a complete membrane around the cell and constitutes the end of the process of forming a new cell.

Progress through the cell is controlled by a complex set of phosphorylation and dephosphorylation steps, mediated by many interacting kinases and phosphatases. Proteins called *cyclins,* so called because their expression is limited to specific stages of the cell cycle, control the initiation of the kinase-phosphatase cascade. That cascade, in turn, ultimately controls the ability of the cell to progress through the major cell cycle control points called *checkpoints,* at the G_1-S and G_2-M boundaries. Many of the proteins involved in cell cycle control are, not surprisingly, involved in the loss of cell cycle control that is the hallmark of carcinogenesis and so can be classified as oncogenes or tumor suppressor genes, depending whether their normal role is to promote or inhibit proliferation. In addition to the proteins that are directly involved in cell cycle control, proteins that are important in DNA repair also have been found to be important in carcinogenesis. Most prominently, the *TP53* tumor suppressor gene, which seems to be the central monitor of genomic damage, is also the most commonly mutated gene in human cancer, and it has a role in a high percentage of all human cancers.

Meiosis

Meiosis is the process by which germline cells form gametes. In contrast with mitosis, in which a single cell division and an exact duplication of the genetic material in the parent cell occur, meiosis involves two separate cell divisions from a diploid parent cell and a random reassortment and reduction of genetic material so that each of the four daughter cells has a haploid DNA content (i.e., 23 chromosomes). In this way, meiosis yields four haploid gametes, the sperm and the egg cells, which support sexual reproduction and a new generation of diploid organisms.

The first meiotic division, as with mitosis, is separated into four stages: prophase, metaphase, anaphase, and telophase. Before meiosis begins, the chromosomes in the cell are replicated to produce two pairs of sister chromatids, and each pair of sister chromatids remains together throughout the first meiotic division. In metaphase, the spindle fibers attach to chromosomes, and the paired chromosomes align themselves in the equatorial plane of the cell. In anaphase, the paired homologous chromosomes separate and move toward their respective poles. The daughter chromatids, however, remain attached to their centromeres. In telophase, the chromosomes arrive at the poles. One of the sets of chromosomes forms the first polar body, which eventually is lost. Because the number of chromosomes in each daughter cell is reduced by half, the first mitotic division is called the *reduction division.* This polar body can be removed from the unfertilized egg and the purified DNA amplified by polymerase chain reaction (PCR) techniques (described further on) and used for preimplantation genetic diagnosis.

The second meiotic division is completed after fertilization and occurs without DNA replication. A second polar body, containing a complete set of chromosomes, is extruded, leaving the egg with a single remaining set (i.e., it is haploid). The second polar body is also useful for preimplantation genetic diagnosis, particularly when recombination has occurred during the first meiotic division.

Recombination

During prophase of the first meiotic division, homologous pairs of chromosomes are held together by a protein-containing framework called a *synaptonemal complex,* which extends along the entire length of the paired chromosomes. Recombination between chromatids of the homologous chromosomes occurs at this stage, resultin in the exchange of DNA between the original parental chromosomes (see Figure 1-5). In males, the X and Y chromosomes are associated only at the tips of their short arms during meiotic prophase. This short associated region is called the *pseudoautosomal region* because recombination between the X and Y chromosomes occurs there (so it behaves as an autosome in terms of mendelian inheritance). This region probably plays an important role in sex chromosome pairing and segregation, as well as in male fertility. Recombination, in conjunction with mutation (see later), is important for generating genetic diversity through the exchange of DNA between different chromosomes, and it plays a critical role in gene mapping studies.

MUTATION AND GENETIC HETEROGENEITY

Mutation is defined broadly as any change in the sequence of DNA. Because most of the human genome does not consist of genes, most mutations are of no apparent functional consequence and thus are termed *silent.* Only mutations that affect the expression or function of a gene or its product are phenotypically apparent. Of these, many are not clinically relevant but instead contribute to normal population heterogeneity. Variations in hair and eye color, for example, originally arose through mutation. Thus the term *mutation* may be defined differently at the molecular genetic, biologic, and clinical levels. Along with recombination, mutation is a central element in producing the population diversity that is the substrate for evolution. The mutation rate in humans has been measured at 2.5×10^{-8} mutation per nucleotide site per generation. This translates to 175 new mutations in every person. The mutation rate and the types of mutations that occur, however, can vary dramatically among different loci. The consequence of this rate of mutation is that variations in the human genome occur, on average, approximately once per 1000 base pairs. Hence, each genome differs from others at millions of sites. Although mutations occur in both germline and somatic (nongermline) cells, only mutations affecting the germline are inherited. Somatic cell mutations also are of major medical importance, particularly in the development of cancer.

Single-Gene Mutations

Mutations can range from those affecting only a single base pair to major alterations in chromosome structure. Mutations that affect only one nucleotide are called *point mutations* and involve the substitution of one nucleotide for another (Figure 1-6, *A*). Accordingly, such mutations also are referred to as single-nucleotide polymorphisms (SNPs). When a point mutation occurs in a part of the gene that codes for a protein and alters the protein by changing the codon of which it is a part, it is called a *missense mutation.* Because the genetic code is degenerate, it is possible to have a point mutation that does not change the amino acid that is encoded. This is called a *silent mutation.* Insertion or deletion of a nucleotide in the protein-coding portion of a gene is called a *frameshift mutation* because it changes the entire reading frame of the gene at every codon distal to the site of the mutation. *Nonsense mutations* are those point mutations that result in the formation of one of the three codons (UAA, UAG, UGA) that do not code for an amino acid and so produce truncated proteins, which usually have little or no activity. Point mutations occurring near the boundaries between introns and exons

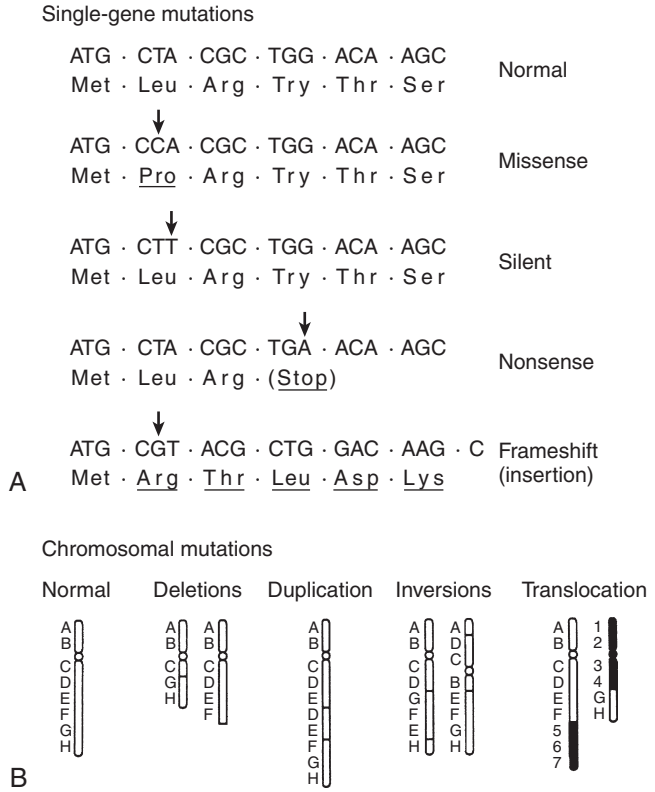

Figure 1-6 Mutation. A, Single-gene mutations. A prototypical normal gene sequence is shown on the first line, with the corresponding amino acid sequence. Examples of four types of common mutations also are shown. The substituted or inserted nucleotides are indicated by *arrows,* and the affected amino acids are *underlined.* **B,** Chromosomal mutations. A prototype normal chromosome is shown, with genes A through H. Examples of gross chromosomal mutations are shown to the *right,* and their effects on gene content and arrangement are indicated. In the translocation example, the two chromosomes are not members of a homologous pair.

can cause improper splicing of mRNA precursors, resulting in RNA instability or the production of truncated proteins, or both.

Regulation of gene expression also can be affected by mutations occurring in control elements such as promoters and enhancers. Although the effect of such mutations usually isthe production of less protein, such as occurs in some forms of thalassemia, some mutations also result in the increased production of a gene product, as in hereditary persistence of fetal hemoglobin.

An interesting mutational mechanism involves the expansion of triplet repeat sequences. More than 10 disorders have been found to be caused by an increase in the number of copies of CCG or AGC repeats in or near a gene, including myotonic dystrophy, fragile X syndrome, and Huntington disease. In these disorders, the repeat number tends to increase with succeeding generations. As the repeat number increases, so does the severity of the disease, giving rise to the phenomenon of *anticipation.* First described in myotonic dystrophy, anticipation refers to an increase in disease severity within succeeding generations of an affected family.

Chromosomal Mutations

Mutations involving large alterations in chromosome structure are visible microscopically by karyotypic analysis (see Figure 1-6, *B*). These include deletions, duplications, inversions, and

translocations from one chromosome to another. Because chromosomal aberrations usually result in the disruption of multiple genes, they often have profound clinical consequences. *Terminal chromosomal deletions* result from a single chromosomal break with subsequent loss of the piece of chromosome without a centromere. *Duplications* occur when a segment of a chromosome is repeated, either from inappropriate recombination or as a result of meiosis involving chromosomes with inversions or translocations. Most other chromosomal rearrangements, such as interstitial deletions, require multiple break-and-reunion events, so they usually are less common. Some common genetic diseases, however, such as Duchenne muscular dystrophy, result primarily from small interstitial deletions—demonstrating that chromosomal regions vary greatly in their propensity to undergo different types of mutational events.

Inversions result from two chromosome breaks followed by reversal of the broken piece of chromosome and subsequent rejoining to form an intact but rearranged chromosome. Although the inversion in and of itself does not have any clinical consequences unless one of the breakpoints affects gene expression, significant effects are seen in subsequent generations. When chromosomes with inversions (either pericentric, in which the inverted region includes the centromere, or paracentric, in which the centromere is not involved) go through meiosis and recombination with normal homologues, gametes may be formed that contain duplications and deletions of parts of the involved chromosomes. *Translocations* result from the exchange of genetic material between two nonhomologous chromosomes. Similar to inversions, they do not cause any clinical disease unless the breakpoints occur in a gene. Persons in whom a translocation is present but who have a normal amount of genetic material are called *balanced translocation carriers.* Like inversions, however, translocations can have severe effects in offspring, resulting from the consequent duplication or deficiency syndromes (or both).

GENETIC DISORDERS

Approximately 4500 inherited disorders have been described thus far. More than half of these have been genetically mapped, and the molecular defect is being identified in a rapidly increasing number. Genetic disorders can be classified into three general categories: simple mendelian, chromosomal, and multifactorial. This section discusses these categories of disease as well as factors that contribute to disease heterogeneity.

Mendelian Disorders

Mendelian disorders are caused by mutation of a single gene, so they display the simple patterns of inheritance dictated by the mendelian laws. Mendelian disorders can be classified as being of either autosomal dominant (AD), autosomal recessive (AR), or X-linked inheritance. X-linked disorders result from mutations on the X chromosome; by contrast, AD and AR disorders are the result of mutations on the autosomes. The demonstration that a particular disease or syndrome exhibits simple mendelian inheritance implies that the pathogenesis, no matter how seemingly complex it may be, is an alteration at a single genetic locus. In many cases, a single mutation can lead to numerous, seemingly unrelated defects, a phenomenon known as *pleiotropy.* It has been estimated that approximately 1% of people in the general population have a monogenic disorder. The simple pattern of inheritance has made it relatively straightforward to isolate genes for monogenic disorders. Virtually all common monogenic disorders and an increasingly large number of quite rare disorders have had the responsible genes isolated and studied.

Autosomal Dominant Disorders

AD disorders are those in which a patient manifests clinical symptoms when only a single copy of the mutant gene is present (i.e., the patient is heterozygous for the mutation). Inheritance of AD disorders follows several general principles (Figure 1-7, *A*):

- Each affected person has an affected parent.
- Affected persons, on average, have equal numbers of affected and unaffected children.
- Normal children of affected parents have only unaffected children.
- Males and females are affected in equal proportions.
- Each sex is equally likely to transmit the disorder to male and female children.
- Vertical transmission of the disorder occurs through successive generations.

These general rules of AD inheritance are based on the assumption, not always valid, that no new mutations occur. In fact, in some disorders the incidence of new mutations is quite high. For example, up to 50% of the cases of von Recklinghausen neurofibromatosis are estimated to result from new mutations.

Dominant mutations involve types of gene products in which an abnormality in 50% of the protein leads to disease. Although mutation of genes with many different functions results in AD inheritance, three classes of proteins frequently are involved: (1) proteins that regulate complex metabolic pathways, such as membrane receptors and rate-limiting enzymes in pathways under feedback control; (2) structural proteins; and (3) proteins with alterations that cause a dominant negative function, that is, in which the mutant protein interferes with the function of the protein expressed from the normal allele. Examples of AD disorders are familial hypercholesterolemia, which is caused by mutations in the low-density lipoprotein receptor; osteogenesis imperfecta, caused by mutations in some members of the collagen gene family; and Huntington disease, caused by a triplet repeat expansion in the Huntington gene.

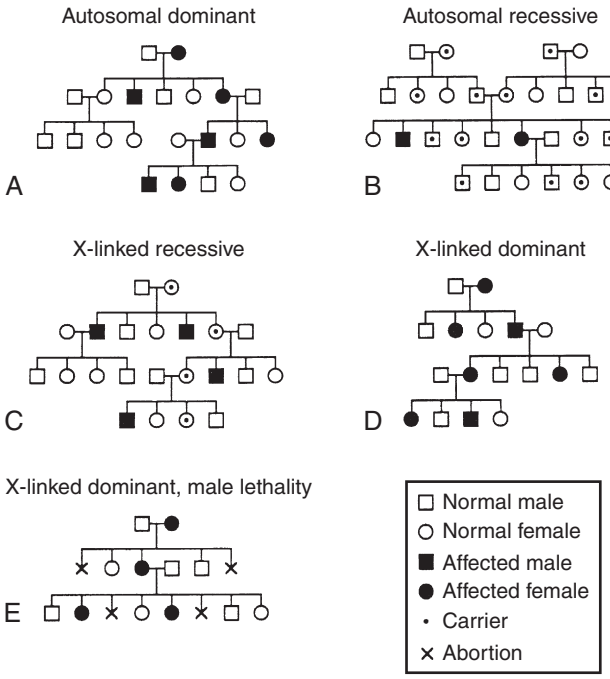

Figure 1-7 A-E, Pedigrees for disorders exhibiting the various mendelian modes of inheritance. These are idealized pedigrees, assuming full penetrance and no new mutations.

A characteristic of many AD disorders is *incomplete penetrance,* whereby not all persons carrying the relevant gene(s) exhibit a specific trait. A particular gene defect can therefore manifest with widely variable severity. For example, tuberous sclerosis, one of the neurocutaneous disorders, can be clinically silent. Some persons are diagnosed with this disorder only when they have multiple severely affected children. At that point, careful examination may reveal subtle evidence of tuberous sclerosis, such as a minor abnormality on a computed tomography scan of the head. Similar observations have been made for many different dominant diseases. Incomplete penetrance is a manifestation of the interaction of other gene products with the product of the disease gene. Increasingly, this phenomenon is being recognized as a step in the continuum between simple completely penetrant monogenic disorders and so-called complex disorders in which no single gene mutation is sufficient to cause disease.

The phenomenon of *germline mosaicism* is a complicating factor in incomplete penetrance. Germline mosaicism occurs when a mutation is present in some of the germ cells but not in most other cells. The affected person is completely healthy but is at risk for having multiple affected children. Germline mosaicism is fairly common in Duchenne muscular dystrophy and occurs in other disorders as well. It can sometimes be difficult to distinguish between germline mosaicism and incomplete penetrance, thereby making accurate genetic counseling and prenatal diagnosis difficult unless a direct assay for the presence of a mutated gene is available.

Autosomal Recessive Disorders

AR disorders are those that are clinically apparent only when the patient is homozygous for the disease (i.e., both copies of the gene are mutant). The following general principles of inheritance are recognized for AR disorders (see Figure 1-7, *B*):

- The parents of affected children may be clinically normal (i.e., carriers).
- Assuming that the carrier frequency in the population is low, only siblings are affected, and vertical transmission does not occur; the pattern therefore tends to appear horizontal.
- Males and females are affected in equal proportions.
- When both parents are heterozygous carriers of the mutation, 25% of their children are affected, 50% are carriers, and 25% are normal.

Every person is a carrier of certain AR mutations. Fortunately, the carrier frequency for most of these mutations is so low that the likelihood that carriers will have affected children is low.

Recessive mutations frequently involve enzymes, as opposed to regulatory and structural proteins. This is because 50% of the normal level of enzyme activity usually is sufficient for normal function. Complete enzyme deficiency produces an accumulation of one or more metabolites preceding the enzymatic block, such as the buildup of phenylalanine in phenylketonuria, and a deficiency of metabolites distal to the block. Either, or both, of these abnormalities may be responsible for the disease phenotype. Although many recessive disorders involve enzymes, two of the most common disorders with AR inheritance are cystic fibrosis, resulting from a mutation in a chloride channel, and sickle cell anemia, resulting from a mutation in the β-globin gene.

The terms *dominant* and *recessive* refer to phenotypes only and have their greatest application at the clinical level. At the gene level, "dominance" and "recessiveness" do not exist. Persons heterozygous for a recessive disorder may be clinically normal, but the reduced level of functional or immunoreactive protein usually is detectable analytically and may lead to other biochemical abnormalities that have no obvious effect on the person's health. In addition, patients homozygous for dominant mutations usually are more severely affected than are heterozygous patients, as is true in familial hypercholesterolemia. In many cases, the homozygous condition results in embryonic lethality, so the clinical disorder is never seen. Huntington disease stands out as a major exception in that homozygous patients are not clinically different from heterozygous patients.

X-Linked Disorders

With X-linked disorders, the mutation occurs on the X chromosome, of which females have two copies and males have only one. Thus, for these disorders, clinical risk and disease severity will differ for males and for females.

The following rules of inheritance apply for X-linked recessive disorders (see Figure 1-7, *C*):

- In contrast with the vertical pattern of inheritance seen on pedigrees for AD disorders and the horizontal pattern for AR disorders, the inheritance pattern tends to be oblique, because patients have unaffected parents but affected cousins and uncles.
- Male-to-male transmission of the disorder does not occur, because fathers transmit X chromosomes only to daughters.
- Male children of carrier women have a 50% chance of being affected.
- All female children of affected men are heterozygous carriers.
- Unaffected men do not transmit the disease to any children.

Examples of X-linked recessive disorders are hemophilia, color blindness, and Lesch-Nyhan syndrome (hypoxanthine-guanine phosphoribosyltransferase [HPRT] deficiency).

Although X-linked recessive disorders generally are observed only in male patients, X-linked dominant disorders are approximately twice as frequent in females as in males and are characterized by transmission of the disorder from affected men to all daughters but to no sons (see Figure 1-7, *D*). Relatively few X-linked dominant disorders have been described, but one example is hypophosphatemia (vitamin D–resistant rickets), in which males and females are equally affected even though females carry a normal as well as an abnormal gene. Several X-linked dominant disorders demonstrate embryonic lethality in hemizygous males (and presumably in homozygous females). In these disorders, affected mothers transmit the trait to half of their daughters but to no sons (see Figure 1-7, *E*). A high incidence of spontaneous abortions has been recognized, and the male-to-female ratio in children is significantly less than 1. Disorders that appear to have this mode of inheritance include focal dermal hypoplasia, incontinentia pigmenti, and orofaciodigital syndrome type I. Aicardi syndrome is a neurodegenerative disorder consisting of agenesis of the corpus callosum with chorioretinal abnormalities that has been described only in female patients, suggesting X-linked dominant inheritance. Because of the severity of the phenotype and low reproductive fitness of affected persons, however, it is difficult to define the pattern of inheritance. Presumably, virtually all cases result from new mutations.

An important feature of X-linked disorders is the wide range of clinical expression in heterozygous females. In contrast with the incomplete penetrance of AD disorders, which probably results from interactions among different genes, variability in X-linked disorders is significantly affected by the process of X-inactivation, or lyonization (after its discoverer, Mary Lyon). Because females carry two copies of the X chromosome and males carry only one, a mechanism called *dosage compensation* has evolved to equalize the amount of gene product that is produced from genes on the X chromosome. It is possible to envision many ways in which this could be accomplished. For example, X-linked genes in females could be transcribed at half the rate of those genes in males, as occurs in insects. The mechanism that operates in humans, however, involves the random inactivation of one of the X chromosomes in every cell of the body. Therefore, only one X chromosome is active in each cell. This observation has major implications for X-linked diseases. Because the process of

inactivation is random, on average, half of the cells inactivate the X chromosome carrying the normal gene and half inactivate the abnormal X chromosome. Unfortunately, in some cases, significant deviation from an equal ratio may be seen. Female patients in whom X chromosome inactivation has occurred in a high percentage of the body's normal cells may demonstrate significant symptoms. This may be one reason for the significant percentage of female carriers of the fragile X syndrome who exhibit some degree of mental retardation.

It also is important to distinguish between actual X-linked disorders and sex-influenced disorders. The latter category consists of disorders encoded by autosomal genes that are differentially expressed in the two sexes. Male pattern baldness, for example, is the result of an AD mutation that requires high testosterone levels to become manifest.

Chromosomal Disorders

Chromosomal disorders fall into two general categories: those involving incorrect chromosome number, called *aneuploidy,* and those that result from large chromosomal mutations, as described earlier. Aneuploidy is the result of nondisjunction during meiosis, in which both members of a homologous pair of chromosomes move to the same daughter cell. As a result of nondisjunction, the fertilized egg receives either one or three copies of the chromosome instead of the usual two. Because they involve numerous genes, with disturbance in the normal genomic balance, most disorders affecting chromosome number are lethal in the embryonic or fetal period, particularly if the defect is loss of a chromosome. Disorders that are not lethal usually result in sterility, because they prevent meiosis from proceeding normally. The best known and most common chromosomal disorder is Down syndrome, which generally results from trisomy of chromosome 21 but also can be caused by a duplication or translocation of a specific region of chromosome 21. Trisomies of chromosome 13 or 18 also occur but are much less common than Down syndrome. Turner syndrome occurs in women who receive only a single X chromosome, whereas Klinefelter syndrome occurs in men who receive two X chromosomes in addition to the Y chromosome.

Deletions that are too small to be visible using standard cytogenetic techniques (but that still result in the deletion of multiple genes) are called *microdeletions,* and the resulting disorder is termed a microdeletion syndrome or *contiguous gene syndrome.* Such deletions sometimes can be detected using advanced cytogenetic techniques, such as prometaphase banding, in which cells are arrested in mitosis at an earlier stage, so that instead of the usual 300 to 400 bands (each containing about 1 megabase of DNA), more than 1000 bands can be visualized. With the availability of cloned genetic markers covering much of the genome, the technique of fluorescence in situ hybridization (FISH) can be used to detect small deletions. In the FISH technique, a cloned DNA probe is labeled with a fluorescent molecule and is then hybridized to a standard chromosome preparation on a microscope slide. The presence of two normal chromosomes can be visualized by the appearance of two fluorescent dots, whereas a heterozygous microdeletion appears as a single dot. Examples of microdeletion syndromes are the DiGeorge syndrome, characterized by T cell immunodeficiency and cardiac anomalies and caused by a microdeletion of chromosome 22, and Prader-Willi syndrome, characterized by mental retardation, infantile hypotonia, and a compulsive eating disorder and frequently caused by a microdeletion of chromosome 15. A clinically unrelated disorder, Angelman syndrome, characterized by severe mental retardation, seizures, and a movement disorder, also can be caused by a microdeletion in the same region of chromosome 15 as that affected in Prader-Willi syndrome. In Prader-Willi syndrome, the deletion is always on the chromosome inherited from the father, whereas in Angelman syndrome, the deletion is always on the maternally inherited chromosome. Both Prader-Willi and Angelman syndromes can arise from *uniparental disomy,* which means that both chromosomal homologues are derived from one parent, with no contribution from the other. For example, in approximately 15% of patients with Prader-Willi syndrome, both copies of chromosome 15 are maternally derived, whereas in Angelman syndrome, both copies can be from the father.

Parent-of-origin effects on the occurrence of a genetic disease are a reflection of the phenomenon of *imprinting.* Imprinting refers to a process of transcriptional inactivation of a region of a chromosome derived from only one parent. The mechanism of this transcriptional inactivation involves methylation of cytosine residues during development. The reason for the existence of imprinting is not known, but it is clear that proper imprinting is necessary for normal development.

Mitochondrial Disorders

Mitochondria, cytoplasmic organelles whose major function is to serve as the sites of oxidative phosphorylation and energy production for the cell, also contain their own genetic material in the form of a small circular piece of DNA. The structure of the mitochondrial genome is similar in this way to that of bacterial genomes—a finding contributing to the theory that mitochondria originally developed from bacteria that established a symbiotic relationship within eukaryotic cells.

Many different clinical entities are now recognized to be caused by mutations in mitochondrial DNA. Mitochondrial diseases frequently affect organs that are highly dependent on energy production and use, such as the central nervous system, muscle, and also pancreatic beta cells. Examples of mitochondrial diseases are myoclonic epilepsy with ragged red fibers (MERRF) syndrome; mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS) syndrome; and Kearns-Sayre syndrome, which has heart block and retinal disease as prominent components. Many of the mutations in the mitochondrial DNA have been defined, with both point mutations and deletions described. The inheritance of mitochondrial DNA is unique because only maternal mitochondria are transmitted to the zygote. Therefore, although males and females can be equally affected by disorders caused by defects in mitochondrial DNA, the mutation can be passed only through the maternal lineage. This is called *maternal* or *cytoplasmic inheritance,* because the mitochondria are located in the cytoplasm.

Multifactorial Disorders

Multifactorial disorders, which are by far the most common form of genetic disease, do not show clear-cut mendelian patterns of inheritance but tend to run in families. These disorders include common chronic diseases of adults, such as atherosclerosis, hypertension, diabetes, peptic ulcers, and schizophrenia, as well as birth defects, including cleft lip and palate, spina bifida, and congenital heart disease. Multifactorial disorders are thought to result from the interaction of multiple genes with environmental factors, leading to the observed familial clustering. The polygenic component of these disorders consists of a series of genes interacting in a cumulative manner. A particular combination of genetic and environmental factors pushes vunerable persons past a threshold at which they are at risk for the disease. The genes that contribute to a particular polygenic trait such as atherosclerosis can be difficult to define, but advances in gene mapping techniques, combined with increasing understanding of the pathophysiology of these disorders, are leading to rapid progress in elucidation of the ways in which genes and the environment interact to cause multifactorial disorders.

Heterogeneity in Genetic Disorders

As discussed earlier, genetic disorders are quite heterogeneous as a result of the complex interactions between multiple genetic loci and environmental factors. This is true for diseases that segregate as simple mendelian traits as well as for multifactorial disorders. In numerous single-gene disorders, identical mutations are recognized to cause widely varying phenotypes. Nongenetic factors also can play roles in mendelian disorders, leading to heterogeneity. Several disorders result from interactions between a mutant gene and an environmental factor. For example, patients with xeroderma pigmentosum are unusually sensitive to sunlight, whereas persons with α_1-antitrypsin deficiency, who have a predisposition to develop emphysema, are more sensitive to the deleterious effects of tobacco smoke.

Of particular interest for the clinician, inherited single-gene mutations may produce potentially serious inappropriate responses to certain drugs. These pharmacogenetic disorders exhibit all three mendelian modes of inheritance. The most common is glucose-6-phosphate dehydrogenase deficiency, inherited as an X-linked recessive disorder, which may induce hemolytic anemia in response to various drugs. Without exposure to these drugs, such patients otherwise appear to be normal. Genetic differences in drug metabolism are increasingly recognized as important in determining pharmacokinetics. This finding has spurred interest of pharmaceutical companies in the burgeoning field of pharmacogenomics, which is directed at understanding the genetic contribution to pharmacology. Genetic testing for certain alleles of cytochrome P-450 that affect drug metabolism is already commercially available.

In addition to the interactions between genetic and nongenetic components in both mendelian and multifactorial disorders, other factors serve to increase the heterogeneity of genetic disorders. As stated earlier, AD disorders often are characterized by varying severity and incomplete penetrance. It is likely that the specific disease locus interacts with the genetic background of the individual patient. Some combinations of genes at other loci may minimize the pathologic consequences of the mutation, whereas other combinations may accentuate them. In addition, disease heterogeneity results from multiple mutant alleles for a single locus. For example, Duchenne muscular dystrophy is caused by mutations in the dystrophin gene that usually lead to complete absence of the protein. The less severe Becker muscular dystrophy results from mutations at the same locus that lead to shortened dystrophin molecules. In addition, mutations that lead to partial deficiency of hypoxanthine-guanine phosphoribosyltransferase (HPRT) activity cause gout, whereas mutations that abolish HPRT activity lead to the severe neurologic manifestations of the Lesch-Nyhan syndrome. These examples of allelic variation and disease are akin to the normal allelic variation that gives rise to the rich diversity of life.

An additional reason for heterogeneity in genetic disease is that mutations in different genes can sometimes have quite similar clinical manifestations. Certain forms of hemophilia, for example, are caused by mutations in either the gene for factor VIII, responsible for classic hemophilia, or the gene for factor IX, the cause of Christmas disease. Both of these genes are on the X chromosome, and both conditions are inherited as X-linked recessive disorders. Additional bleeding disorders result from mutations in other genes. Other diseases caused by mutations in multiple gene loci have different modes of inheritance in different families. For example, spastic paraplegia, Charcot-Marie-Tooth disease, and retinitis pigmentosa all have AD, AR, and X-linked recessive inheritance forms.

MOLECULAR GENETICS AND MEDICINE

Molecular Genetic Methods

The field of molecular genetics has developed explosively since Watson and Crick's discovery of the structure of DNA in 1953. Two developments in particular made possible recombinant DNA research: the discovery of bacterial restriction enzymes and the invention of blot hybridization methods. Subsequently, the development of DNA and RNA amplification techniques based on PCR revolutionized virtually every area of biology dealing with nucleic acids and had far-reaching effects on society as a whole; for example, forensic DNA testing has had a dramatic effect on criminal investigations.

Restriction Enzymes

Restriction enzymes recognize a specific DNA sequence, most commonly 4 or 6 base pairs long, and they cleave DNA at this site (Figure 1-8). Restriction enzymes recognizing many different sequences have been isolated from numerous species and strains of bacteria. Most of these recognition sites are inverted palindromes, meaning that they have the same sequence on both DNA strands. In addition, most restriction enzymes cut the two strands of DNA in a staggered fashion, leaving two to four bases of single-stranded DNA on both segments of DNA (see Figure 1-8).

Because of the inverted palindromic nature of most recognition sites, these single-stranded regions are complementary and hybridize to each other whenever pieces of DNA cut with the same enzyme are mixed together, temporarily joining two segments. If an enzyme called *DNA ligase* also is present, it covalently links the hybridized segments. Thus the discovery and isolation of restriction enzymes allowed molecular geneticists to cleave DNA at specific sites and to reconnect the segments in specific arrangements, thus allowing for the creation of *recombinant DNA,* popularly known as genetic engineering.

Blot Hybridization

Various methods, collectively known as *blot hybridization,* have been developed to allow the rapid identification of a segment of nucleic acid containing a particular nucleotide sequence. As first described by Southern in 1975, in blot hybridization, DNA is digested with a restriction enzyme. The now fragmented DNA is separated according to size by electrophoresis through an agarose gel matrix, in which smaller fragments move faster than larger ones. The DNA is then transferred to a filter under conditions that cause the two DNA strands to come apart. The filter is incubated with a radiolabeled RNA or DNA probe including the desired nucleotide sequence. The probe hybridizes to the

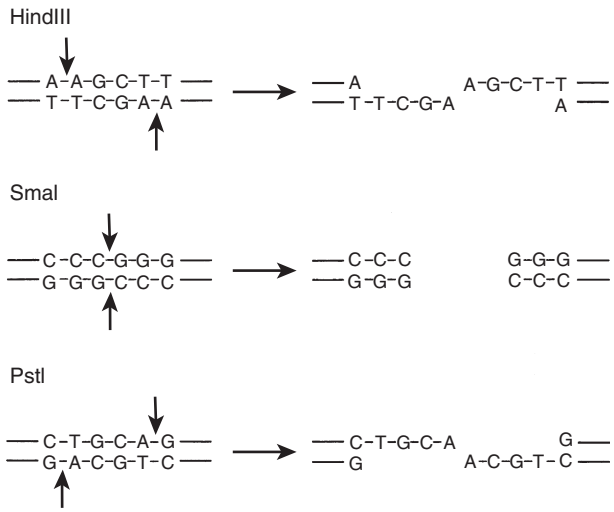

Figure 1-8 Restriction enzymes. The recognition sequences for three common restriction enzymes are shown at *left.* The *vertical arrows* indicate the sites at which each strand is cleaved to produce two ends, depicted on the *right.* There are three types of cut ends, differing in which strand, if any, is single-stranded.

complementary sequence on the filter, and the labeled DNA band is then visualized by autoradiography (i.e., exposing x-ray film to the filter). This method of identifying DNA sequences is called *Southern blotting*, after its inventor (Figure 1-9). A similar method has been developed to identify RNA sequences and is called, by playful analogy, *Northern blotting.* (*Western blotting,* in which antibodies directed against specific proteins are used to detect those proteins on blots of cellular extracts, also exists.)

Cloning

The ability to clone genes has greatly facilitated the ability to understand the pathogenesis of inherited disease at the molecular level. In molecular genetics, *cloning* means isolating a particular gene in a form that allows its DNA to be amplified and manipulated. A major breakthrough in the ability to clone genes came with the discovery of the enzyme reverse transcriptase, which is essential in the life cycle of a class of viruses called *retroviruses.* These viruses, which have single-stranded RNA genomes, include the human immunodeficiency virus (HIV). The function of reverse transcriptase is to make a DNA copy of the viral genome that can integrate into the cellular DNA and can be replicated. The designation *reverse transcriptase* was chosen because the enzyme functions counter to the normal DNA-to-RNA direction of transcription. Researchers commonly use reverse transcriptase to make single-stranded DNA molecules complementary to mRNA sequences and therefore called *complementary DNA* (*cDNA).* The single-stranded molecules are converted to normal double-stranded cDNA using DNA polymerase and are then inserted into cloning vectors. This permits the isolation or cloning, in the form of cDNA, of any region of the genome that is transcribed into RNA. Even with recently acquired knowledge of the complete human genome sequence, the technology of generating cDNA from RNA remains invaluable for determining the complement of genes that are expressed in a particular cell type. The general approach to cloning gene sequences is summarized in Figure 1-10.

Polymerase Chain Reaction

The development of the *PCR technique,* which allows amplification of selected pieces of DNA by many orders of magnitude, revolutionized both basic and clinical genetics (Figure 1–11). Oligonucleotide primers that flank the section of DNA to be amplified are hybridized to a DNA-containing sample. The intervening segment of DNA is then filled in by a heat-stable DNA polymerase derived from bacteria that are adapted to extremely hot environments. The sample is then heated to separate the strands and is cooled, and the cycle is repeated. In this way, the desired segment of DNA is exponentially amplified, resulting in million-fold increases in the number of copies of a desired segment of DNA after 30 to 40 cycles. This technology has become central to virtually every aspect of genetics and many areas of medicine and biology, including gene mapping, gene cloning, analysis of gene transcription (using reverse-transcribed mRNA as a starting material), prenatal diagnosis (including preimplantation diagnosis from a single cell of an eight-cell embryo), infectious disease detection, and forensic medicine.

Microarrays

The ability to produce nucleic acids in large quantities using amplification technologies such as PCR or direct chemical synthesis, combined with technology such as photolithography and nanodroplet deposition used in the computer industry, has enabled the production of high-density arrays of nucleic acids (Figure 1-12). In this way, arrays can be produced that are composed of up to a million distinct nucleic acids, each with a different sequence, and each placed in a distinct location. These nucleic acid "targets," which are tethered to the surface of the array (composed of glass or a variety of other materials), can be hybridized with a nucleic acid "probe," consisting of a biologic sample that has been modified to incorporate a fluorescent label.

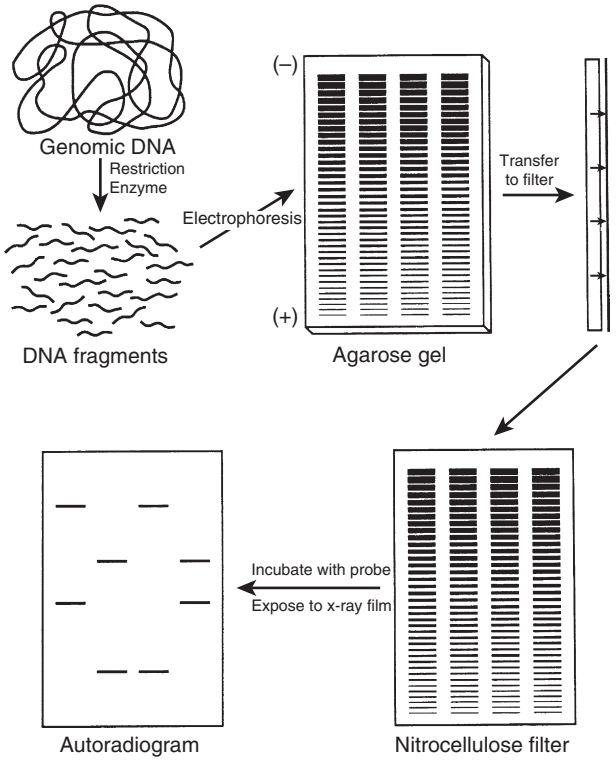

Figure 1-9 Southern blotting. Cellular DNA is cut with a restriction enzyme to produce small fragments. The cut DNA is separated by size by means of electrophoresis through an agarose gel. Because DNA is an acid and therefore has a negative charge, it migrates toward the positive electrode, the smaller fragments migrating faster than the larger. The DNA is transferred to a nitrocellulose (or charged nylon) filter, usually by buffer flow (as shown in an *edge view*), to produce a replica of the gel. The filter is incubated with a radioactive DNA or RNA probe and then washed, followed by exposure of x-ray film to the filter. The resulting autoradiogram indicates DNA bands that have sequence homology with the probe.

Uses of microarrays are many and varied, depending on the sequences of the nucleic acids that are used to produce the array. Diagnostic arrays containing nucleic acid targets from pathogenic microorganisms as well as research arrays containing sequences from all known genes of a particular organism are available. Probes can range from diagnostic samples such as blood that may contain a virus to mRNA isolated from a particular cell type to determine the pattern of genes expressed in that cell. Use of microarrays that distinguish between different SNPs in the genome is now the predominant technology for genetic mapping studies. Microarrays are even being used in conjunction with a technique called comparative genomic hybridization (CGH) to measure the number of copies of particular genes. This technology has the potential to supplant conventional chromosomal karyotypes and to detect microdeletions that are below the limit of sensitivity of current banding techniques.

Biomedical Applications of Molecular Genetics

Production of Clinically Useful Proteins

Once a gene has been cloned, it is possible to produce virtually unlimited quantities of the encoded protein by introducing the clone (in an appropriate expression vector) into bacterial, yeast,

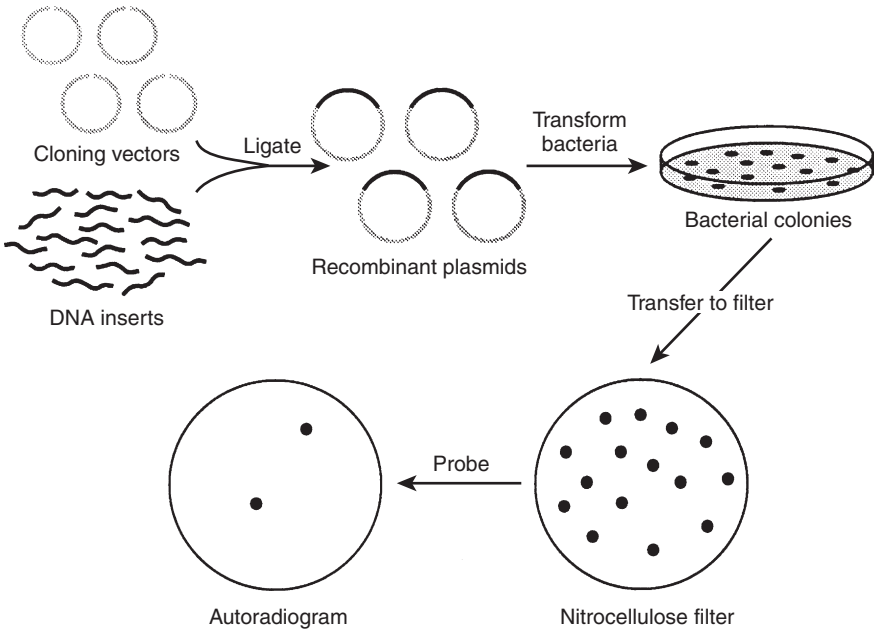

Figure 1-10 Cloning. The desired DNA inserts, either genomic DNA cut with a restriction enzyme or cDNA produced from mRNA, are ligated into cloning vectors that have been cut to accept the inserts. The resulting recombinant plasmids are introduced into bacteria, a process called *genetic transformation,* producing a genetic library. Bacterial colonies grown from the library are transferred to a nitrocellulose filter by simply overlaying the plate. The filter is then probed, either with DNA or RNA, as described for Southern blotting, to look for colonies with homologous sequences, or with labeled antibodies, to look for specific protein production. The resulting autoradiogram uses x-ray film to indicate the position of colonies containing the desired sequence.

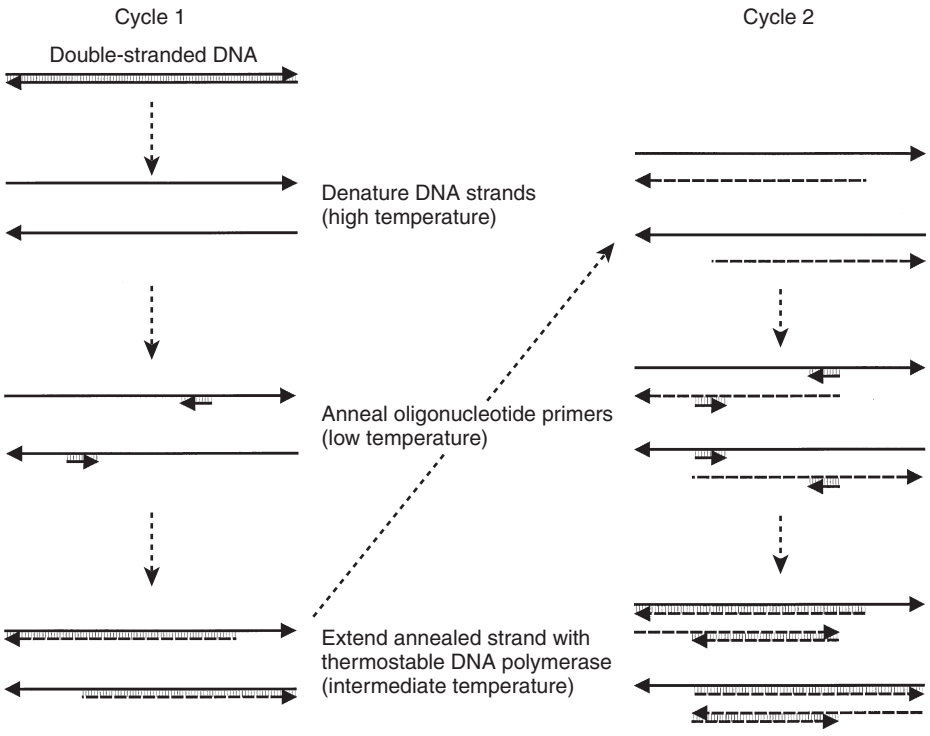

Figure 1-11 Polymerase chain reaction (PCR) amplification of DNA. Double-stranded DNA is subjected to cycles of denaturation, annealing with short, single-stranded, oligonucleotide DNA primers, and extension using a thermostable DNA polymerase. Typically, 20 to 40 cycles of PCR are performed, resulting in exponential amplification of the DNA sequence between the two primers. The high specificity of primer annealing allows a short sequence (typically <1 kilobase [kB]) to be amplified from the 3 million kB present in the human genome. The advantage of a thermostable polymerase is that it can withstand the extreme temperatures (close to boiling) necessary to denature the DNA strands.

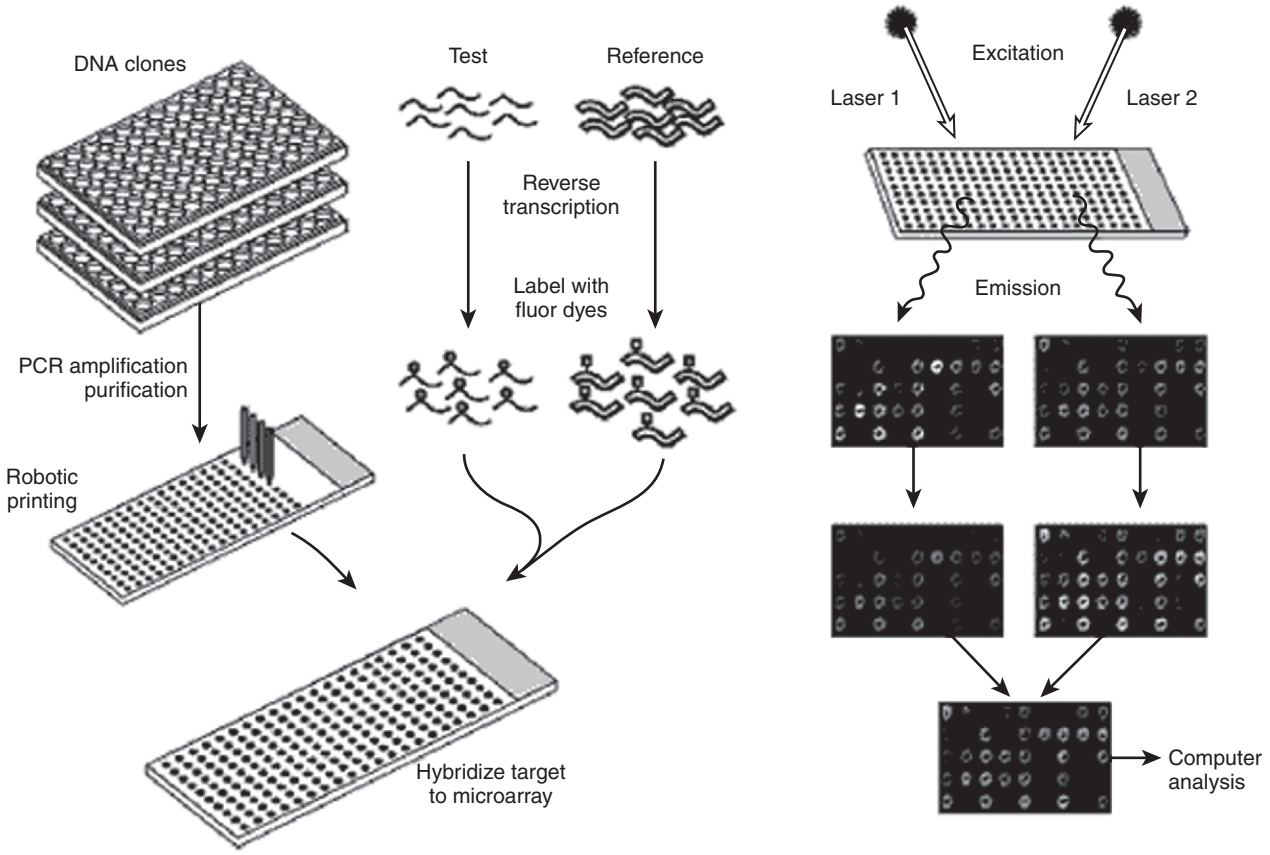

Figure 1-12 Complementary DNA (cDNA) microarray schema. Templates for genes of interest are obtained and amplified by PCR. After purification and quality control, aliquots (~5 nL) are printed on coated glass microscope slides using a computer-controlled, high-speed robot. Total RNA from both the test and reference samples is fluorescently labeled with either Cye3–dUTP or Cye5–dUTP using a single round of reverse transcription. The fluorescent targets are pooled and allowed to hybridize under stringent conditions to the clones on the array. Laser excitation of the incorporated targets yields an emission with a characteristic spectrum, which is measured using a scanning confocal laser microscope. Monochrome images from the scanner are imported into software in which the images are pseudo-colored and merged. Information about the clones, including gene name, clone identifier, intensity values, intensity ratios, normalization constant, and confidence intervals, is attached to each target. Data from a single hybridization experiment are viewed as a normalized ratio (that is, Cye3/Cye5) in which significant deviations from 1 (no change) are indicative of increased (>1) or decreased (<1) levels of gene expression relative to the reference sample. In addition, data from multiple experiments can be examined using any number of data mining tools. *dUTP,* deoxyuridine-5′-triphosphate; *PCR,* polymerase chain reaction. *(From Duggan DJ, Bittner M, Chen Y, et al: Expression profiling using cDNA microarrays,* Nat Genet *21:10-14, 1999.)*

mammalian, or other cells. Because many eukaryotic proteins undergo posttranslational modification, including glycosylation, phosphorylation, acylation, and carboxylation, which frequently are required for normal protein function, it is often preferable to express proteins in mammalian cells. Rapidly increasing numbers of recombinant human proteins are in clinical use, including insulin, growth hormone, clotting factors VIII and IX, erythropoietin, hematopoietic colony-stimulating factors, and tissue plasminogen activator, among others. A number of lysosomal storage diseases such as Gaucher disease are now treated by infusion of recombinant enzymes. In addition to simple replacement therapy, monoclonal antibodies directed against cell surface proteins expressed on tumors are revolutionizing cancer treatment.

Genomics and the Genome Project

Perhaps one of the most significant scientific achievements in human history is the complete sequencing of the human genome. The *Human Genome Project* is still ongoing, and further sequencing and gene identification remain to be done before the sequence will be truly complete—a process that may take many more years. This genome project was made possible by development of the techniques of molecular genetics described earlier as well as automated sequencing machines. Such machines made it possible to achieve the economies of scale necessary to sequence the 3 billion base pairs in the human genome.

In addition to the human genome, the genomes of other organisms, including many important human pathogens such as *Mycobacterium tuberculosis,* have been sequenced. Sequencing the genomes of other mammalian and nonmammalian species has led to the recognition that most human genes have homologues in other species, including lower organisms such as yeast and worms, thereby justifying the enormous effort that has been devoted to studying those model organisms over the years. The ultimate impact of the genomics revolution has yet to be felt. Much more DNA sequencing and analysis will be required to obtain a complete understanding of how organisms differ from one another at the interspecies and intraspecies level. Undoubtedly, however, the end result, an understanding of the genetic basis of human variability and predisposition to disease, will produce enormous benefits for human health.

Gene Mapping

Linkage mapping in humans involves examining pedigrees to determine the frequency of co-inheritance of specific traits. As described previously, recombination between chromatids of

homologous chromosomes occurs in meiosis, so sections of chromosomes are exchanged with each other. Thus, recombinant chromosomes are produced that contain a segment derived from each of the original homologous chromosomes. The closer together two genes are located on the same chromosome, the less likely it is that recombination will occur between them during meiosis, and the more likely it is that particular alleles of these genes will be inherited together. Thus, it is possible to use the recombination frequency between two genes to determine their distance from each other and hence to construct a genetic map.

A 1% recombination frequency between two loci is defined as 1 map unit, or 1 centimorgan (cM). Genes located on separate chromosomes are inherited independently and are therefore unlinked. Genes located on the same chromosome but that are so far apart that recombination occurs between them 50% of the time (i.e., 50 cM apart) are also considered unlinked. Although 1 cM corresponds to approximately 1 million base pairs, this physical distance must be considered to represent only a rough estimate, because recombination does not occur purely randomly throughout the genome—instead, the genome has "hot" and "cold" spots. Regions of decreased recombination give rise to the phenomenon of *linkage disequilibrium,* in which alleles of linked loci are found on the same chromosome more frequently than one would expect with normal levels of recombination occurring over time. Linkage disequilibrium also can arise from selective pressure for the maintenance of linked alleles, as seems to occur for the human leukocyte antigen (HLA) major histocompatibility complex. The implication of linkage disequilibrium is that two alleles that are not in close physical proximity may nonetheless be co-inherited. A set of alleles inherited as if on a single locus is referred to as a *haplotype.*

The ability to detect and to assay for sequence variations in DNA made feasible the construction of sets of markers that cover the entire genome. Current gene mapping strategies take advantage of SNPs. Because each person differs from every other at millions of individual loci, increasingly dense SNP maps have been constructed. As the number of polymorphic markers increases and the expense of genotyping decreases, diseases can be mapped with increasing resolution and complex polygenic diseases can be attacked. Once an approximate map location is determined for a gene, the genome sequence can be used to search for candidate genes known to have sequence elements or biologic functions suggesting that they may be involved in the disease being studied. Moreover, the approximate map locations can serve as the starting point for more detailed studies using a higher density of polymorphic markers from the specific region being studied. Both approaches have been greatly facilitated by the completion of the human genome sequence.

Linkage analysis and, more recently, direct mutation detection have revolutionized prenatal diagnosis. Fetal cells are obtained from amniotic fluid, and blood or skin samples are obtained from parents and siblings. Analysis of DNA from these samples can then determine in many cases whether the fetus has inherited the disease. This approach was first used for the prenatal diagnosis of sickle cell anemia. It is now used for diagnosis of various other inherited disorders and can be applied to any condition for which a linked polymorphic marker or, even better, the pathogenic mutation has been identified. The same principles involved in prenatal diagnosis also apply to presymptomatic diagnosis in disorders with late onset and to carrier detection in X-linked and AR disorders. The most sophisticated application of prenatal diagnosis is preimplantation genetic diagnosis, in which genetic material from an early embryo or even from the polar bodies of the egg are used to detect the presence of a particular genetic trait.

Gene and Cell Therapy

The available therapies for most human diseases, and particularly genetic diseases, are inadequate. Treatments such as enzyme replacement for Gaucher disease or dietary restriction as in disorders of amino acid metabolism have serious limitations, such as high cost or low efficacy. Additionally, protein replacement is applicable to only a few diseases in which delivery into the circulation is efficacious; this approach is problematic when it is necessary to deliver a missing component directly to cells, particularly when tissue specificity is necessary. The ultimate treatment for many inherited disorders is to use DNA itself as a pharmacologic agent to treat the actual defect—the gene mutation. The development of sophisticated gene transfer methods has made this gene therapy approach a reality.

It is important to distinguish between gene therapy affecting the germline and therapy affecting only somatic tissues. Germline gene therapy would allow genetic modifications to be transmitted to future generations. Even if such modifications were limited to treating specific diseases, serious moral and ethical questions would arise. This situation is further complicated because it would theoretically be possible to alter traits to produce more "desirable" children. Because somatic cell therapy affects only the person treated, the ethical considerations are greatly simplified. All current gene therapy protocols in humans are limited to somatic cell experiments.

Although inherited mutations exist in every cell in the body, most genes are expressed in specific tissues, and, in most cases, gene therapy needs to be directed only toward the proper tissue. Even when a gene is expressed in all tissues, only one tissue may need be treated to ameliorate the disease phenotype. The effectiveness of this approach has already been proved for maple syrup urine disease, in which liver transplantation is effective despite the fact that the enzyme is expressed in other tissues as well. For some diseases, such as hemophilia, any cell that can secrete a protein into the circulation is a potential target for gene therapy, even if it is not the normal site of protein production.

The most desirable methods of gene therapy allow for gene transfer directly into the patient (i.e., in vivo gene therapy) (Figure 1-13). For some tissues, such as the central nervous system, this is likely to be the major mode of gene transfer. For organs such as the bone marrow, however, cells can be removed easily, manipulated in vitro, and reintroduced into the patient (i.e., ex vivo gene therapy) (see Figure 1-13).

In the ideal gene therapy system, the normal gene would be introduced into cells in vivo in such a way that it would replace the defective gene through site-specific recombination. This would result in the gene's being in the proper position relative to the various transcriptional regulatory elements. Unfortunately, efficient techniques for site-specific integration are not yet available, and all current methods of gene transfer result in predominantly random integration. Because of this limitation, gene *replacement* therapy is not yet possible. Instead, gene *augmentation* therapy has been pursued, in which the normal gene supplements the defective gene from a distal site. Although simpler, this method suffers from the risk of insertional mutagenesis, in which the transducing vector affects the expression of genes in the region in which it integrates. This phenomenon led to the development of leukemia in a number of patients enrolled in a gene therapy trial for severe combined immunodeficiency in which bone marrow was removed and transduced with a retroviral vector expressing the adenosine deaminase gene and the transduced cells were reintroduced into the patient. Although the augmentation therapy achieved its goal, the severe complication of leukemic transformation by insertional mutagenesis has raised questions about the risk-benefit ratio of the procedure.

Various biochemical and physical methods have been developed to introduce DNA into mammalian cells, referred to as *transfection* (i.e., *trans*formation + in*fection*). These methods generally suffer from the serious limitation that only a few of the treated cells are permanently genetically modified. Direct injection of DNA into some tissues such as muscle results in gene transfer and expression, but this method is inefficient, with only

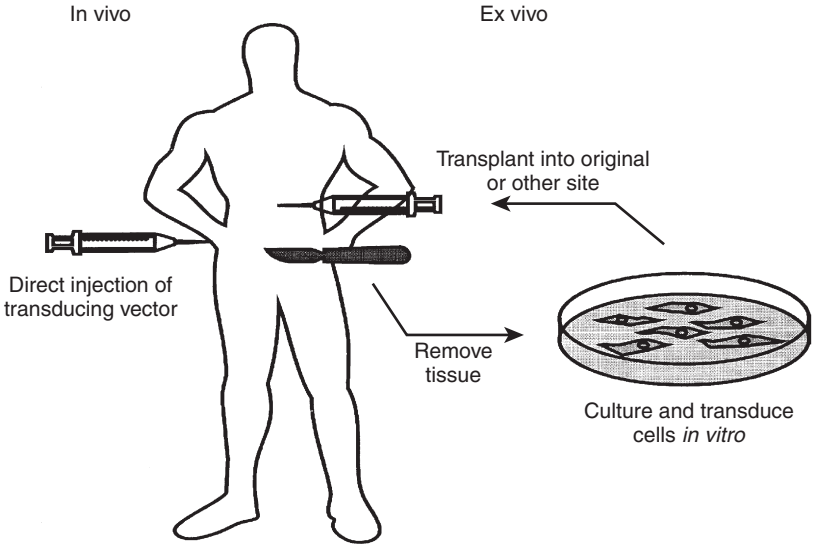

Figure 1-13 Models for human gene therapy. In vivo gene therapy involves direct introduction of a transducing vector into the patient. Ex vivo gene therapy involves removal of tissue and transduction in vitro.

a small number of cells taking up the injected DNA. Nevertheless, this approach is well suited by virtue of simplicity and low cost to vaccine development.

To increase the efficiency of gene transfer, most gene therapy studies have instead used replication-defective genetic transducing vectors derived from viruses. Numerous different viruses have been used, including adenovirus adeno-associated virus, murine retroviruses, and even lentiviruses such as HIV. Viral vectors can infect various cell types from several species at efficiencies often approaching 100%.

Although the initial thrust of research in gene therapy was to correct single-gene defects such as in hemophilia and adenosine deaminase deficiency, work in the field has shifted toward applying gene transfer technology to more common polygenic diseases such as cancer and coronary artery disease. Viral vectors are being used to deliver cytotoxic genes to cancer cells. In some cases, the vectors are designed specifically to target the cancer cells—a so-called magic bullet. Other experiments are using gene transfer techniques to enhance angiogenesis in ischemic cardiac tissue. The appeal of using gene therapy for common polygenic diseases is that these techniques can be applied to many more patients than would be the case if gene therapy were limited to the much rarer monogenic disorders.

Stem Cells

As described previously, ES cells from mice have revolutionized the study of mammalian development and disease. In addition to basic science applications, stem cells are now being studied to determine if they can be used to treat diseases in which replacement of malfunctioning cells or cells that have been destroyed is an attractive approach. Examples are type 1 diabetes, in which the pancreatic beta cells are destroyed, and Parkinson disease, in which the dopaminergic neurons die. The isolation and extended culture in vitro of human ES cells in 2000 by Thompson and colleagues at the University of Wisconsin raised the hope that such cell-based therapies could be developed and marked the advent of a new area of medicine termed *regenerative medicine.*

Although ES cells have enormous potential in terms of being able to differentiate into any cell type in the body, major problems are still to be overcome. One such problem is achieving the ability to direct ES cells along a particular lineage so that only the desired cell types are produced. Another is to find ways to stimulate the cells that are formed to incorporate functionally into the target organ. For instance, dopaminergic neurons derived from ES cells must be properly integrated into the substantia nigra so that dopamine release is properly regulated. Finally, transplanted cells will be rejected by host immune responses unless they are genetically identical to the host's. This fact has stimulated interest in a technique called somatic cell nuclear transfer, in which the nucleus from an adult is transferred into an egg in place of the egg nucleus, resulting, albeit with great inefficiency, in the formation of an ES cell line that is genetically identical to that of the donor of the adult nucleus. This technology has been used to create a variety of cloned mammals, most notably Dolly the sheep. Thus far, it has not been done successfully with human cells, and serious ethical issues continue to swirl around the entire field.

In addition to ES cells, which are not found postnatally, so-called adult stem cells have been isolated from a number of tissues. By far the best characterized is the hematopoietic stem cell, which gives rise specifically to blood cells. Other widely studied types of adult stem cells include neural stem cells and mesenchymal stem cells. In general, adult stem cells give rise to a restricted range of mature cell types—for example, a neural stem cell can give rise to neurons but not cardiomyocytes. An advantage of using adult stem cells is that they are already programmed to give rise to specific cell types. Also, because they exist normally in many tissues and function in tissue regeneration, they already "know" how to incorporate functionally into the organ to which they give rise. Significant problems include the fact that adult stem cells have not been identified for many organs, and the signals that control the regenerative process are poorly understood for the most part—the hematopoietic system being a notable exception.

Advances in Molecular Genetics: Developmental and Clinical Implications

MOLECULAR GENETICS TOOLS

The explosive advances in human genetics of the past few decades have been fueled by a powerful set of tools built on a small number of critical scientific developments. The more important of these techniques and principles are reviewed briefly in this opening section.

Recombinant DNA Technology

The identification and characterization of enzymes involved in DNA replication, repair, and sequence-specific endonuclease digestion (Table 2-1) have led to the development of tools that allow convenient manipulation of DNA. Restriction endonucleases are a class of enzymes that recognize specific DNA sequences, typically 6– to 8–base-pair palindromes, and usually cut the DNA backbone at a symmetric point within the recognition sequence on both strands. Digestion of purified genomic DNA with a restriction enzyme yields a collection of fragments with identical end sequences and discrete sizes corresponding to the distances between recognition sites in the DNA sequence. The termini of fragments resulting from a restriction digestion may be single-stranded and self-complementary over several bases or completely double-stranded, depending on the cleavage site. By using a different enzyme, DNA ligase, digested fragments with using can be spliced together, even if the two pieces were not initially contiguous, generating a recombinant molecule.

Library Construction

The enzymatic tools just described allow the direct manipulation of DNA, but additional methods had to be developed to permit efficient amplification of specific fragments. Small, circular DNA molecules that replicate autonomously in bacterial cells (plasmids) have been characterized and developed as vectors to propagate DNA sequences of interest. These reagents make it possible to ligate restriction enzyme–digested DNA fragments into digested plasmids, introduce the recombinant plasmid into bacterial cells, and then select for the presence of a plasmid-encoded antibiotic resistance gene. DNA isolated from the resulting colonies is then analyzed by restriction analysis or sequencing to identify plasmids containing DNA of interest. Cells containing the desired plasmid can then be propagated or stored frozen indefinitely. This process is known as *cloning*.

When complex mixtures of DNA are ligated into a recipient plasmid, the resulting recombinant molecules represent a *library* of plasmids containing different fragments. Libraries can be generated from digested genomic DNA or from complementary DNA (cDNA) produced by reverse transcription from mRNA. Genomic DNA libraries were critical reagents in the sequencing of the human genome, with improvements made over time in the cloning vectors used (yeast or bacterial artificial chromosomes [YACs or BACs, respectively]) and in the stability of the cloned inserts. In contrast with the goal that genomic libraries represent the full genetic complement of an organism, cDNA libraries are designed to represent the tissue-specific spectrum of genes expressed in the mRNA source tissue. In the creation of such libraries, hybridization methods (see further on) are used to normalize the contribution of highly expressed ubiquitous housekeeping genes.

Libraries have been generated from a wide range of tissue types and from samples obtained in different disease states. Sequence data from clones derived from different libraries, so-called expressed sequence tags (ESTs), have been catalogued in publicly available databases. Identification of transcripts whose expression is restricted to a specific tissue type is a powerful tool for understanding the genetic basis of tissue-specific function. The ability to work with nucleic acids, which are easily manipulated, rather than with the encoded proteins, allowed a significant acceleration in the understanding of many biologic phenomena.

Polymerase Chain Reaction

The use of thermostable DNA polymerases derived from bacteria that live in extremely high-temperature environments represented a revolutionary twist on the use of nucleic acid polymerases. These enzymes retain activity even after heating to temperatures sufficient to denature DNA strands (higher than 96° C), allowing multiple cycles of primer annealing and chain elongation to be carried out in a single reaction. Each cycle of primer annealing and chain elongation results in double the number of template molecules for the next cycle of primer binding and extension, so amplification of the input template DNA occurs exponentially.

Polymerase chain reaction (PCR) methodology thus makes possible the amplification of large amounts of product from trace amounts of starting material, overcoming the technical limitations imposed by the relatively limited number of copies of genomic DNA available in a given human tissue specimen. The extensive range of uses for which PCR amplification is essential, from basic molecular biology research to infectious disease diagnostics and forensic applications, attests to the power of this technique.

Nucleic Acid Hybridization

Alterations in thermal or ionic conditions can disrupt the hydrogen bonding interactions in a DNA double helix, resulting in single-stranded DNA. Complementary strands can reanneal with great specificity when reaction conditions are adjusted appropriately, a property that has been exploited to use a cloned DNA as a probe for the presence of related sequences among a mixture of single-stranded DNA or RNA. Target molecules are first separated based on size by gel electrophoresis, transferred to a support matrix, such as a nylon membrane, and then probed with a DNA fragment labeled with a radioisotope or some other reporter molecule. This procedure is known as a Southern blot (Figure 2-1) after its inventor, Edward Southern. When applied to RNA, the procedure is called a "Northern blot." Alternatively, a collection of bacterial colonies representing a cDNA library grown

on agar plates can be transferred and lysed directly on nylon filters, allowing screening of the entire library for sequences of interest. The thermal energy required to disrupt DNA hydrogen bond interactions is related to the base composition of the nucleic acid duplex, allowing approximate calculations of the melting and annealing temperature of a known sequence. Under appropriate hybridization conditions, even small synthetic oligonucleotides can be used as high-specificity probes to detect single-base mismatches.

Differences between single- and double-stranded nucleic acids in binding to positively charged matrices have been exploited in subtractive hybridization approaches. Single-stranded cDNA from a differentiated or diseased tissue can be hybridized with excess cDNA strands from nondifferentiated precursor or normal tissue. Genes transcribed in both states will be readily available for hybridization with the excess cDNA pool, whereas those induced only in the differentiated or disease condition will remain single-stranded. By binding double-stranded molecules on an affinity column, state-specific transcripts can be isolated and enriched in the final library. Modifications of the principles of subtractive hybridization also allow identification of low abundance transcripts whose expression is associated with developmental changes or disease states.

Hybridization-based approaches continue to be used in a variety of high-throughput methods, such as those based on so-called DNA chips, in which the hybridization reaction occurs in parallel at an enormous number of individual sites on a small solid support (Figure 2-2, *A*). Technologies involving the performance of massive numbers of hybridization reactions in a small volume, with data obtained in a digital format are being applied in research settings to assess differences in transcription patterns between normal and diseased tissue or to score for the presence or absence of polymorphisms in genomic DNA. The introduction of such techniques to the clinical arena offers the promise of therapeutic interventions tailored to an individual patient's genotype—for example, by aggressive measures for disease prevention (e.g., testing for BRCA1/BRCA2 and breast and ovarian cancer) or by adjusting medication exposure or dosing based on the presence or absence of polymorphisms affecting the function of metabolic enzymes. This type of approach also has been used to perform molecular characterization of pathologically indistinguishable cancerous cells by the pattern of gene expression exhibited by different specimens on microarray analysis, suggesting a potentially useful application as a diagnostic and prognostic tool (Figure 2-2, *B*).

Expression Libraries

An early effort in the effort to catalogue the complete set of human genes involved the generation of libraries of reverse-transcribed and cloned transcripts from various tissues. These clones were subjected to limited sequencing and the resulting data were stored in a repository of transcript sequences (expressed sequence tags [ESTs]). An important limitation of this approach is the difficulty of obtaining cDNA from all tissues, as well as in all developmental stages, but this repository (dbEST) has proved extremely useful in mapping exonic sequences onto the complete genome sequence data.

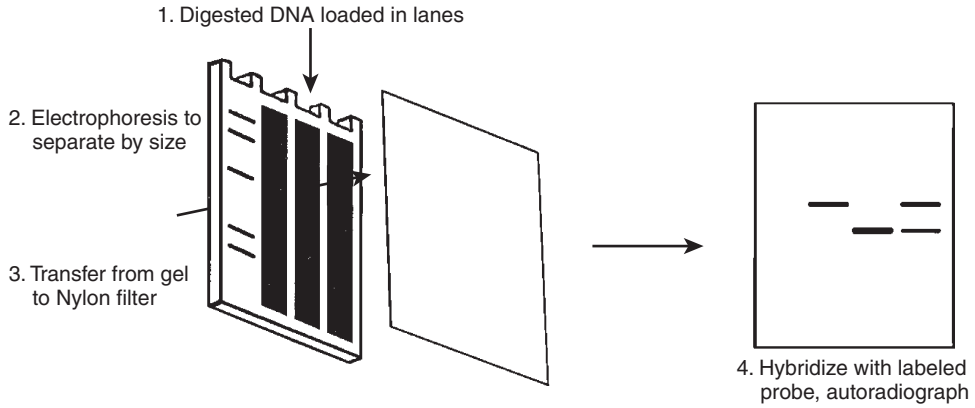

Figure 2-1 Southern blot analysis. Hybridization of labeled DNA probes to immobilized DNA affixed to a solid support was developed by Dr. Edward Southern. The technique involves separating different-sized DNA fragments produced by restriction enzyme digestion by electrophoresis through a porous gel. After the fragments are separated, the DNA is migrated out of the gel in a perpendicular direction by capillary flow, or in a second electrophoretic event, and onto a positively charged membrane (nitrocellulose or nylon). DNA affixed to this membrane can then be hybridized with a rabiolabeled probe and the filter used to expose x-ray film in order to detect bands containing DNA sequences related to the probe.

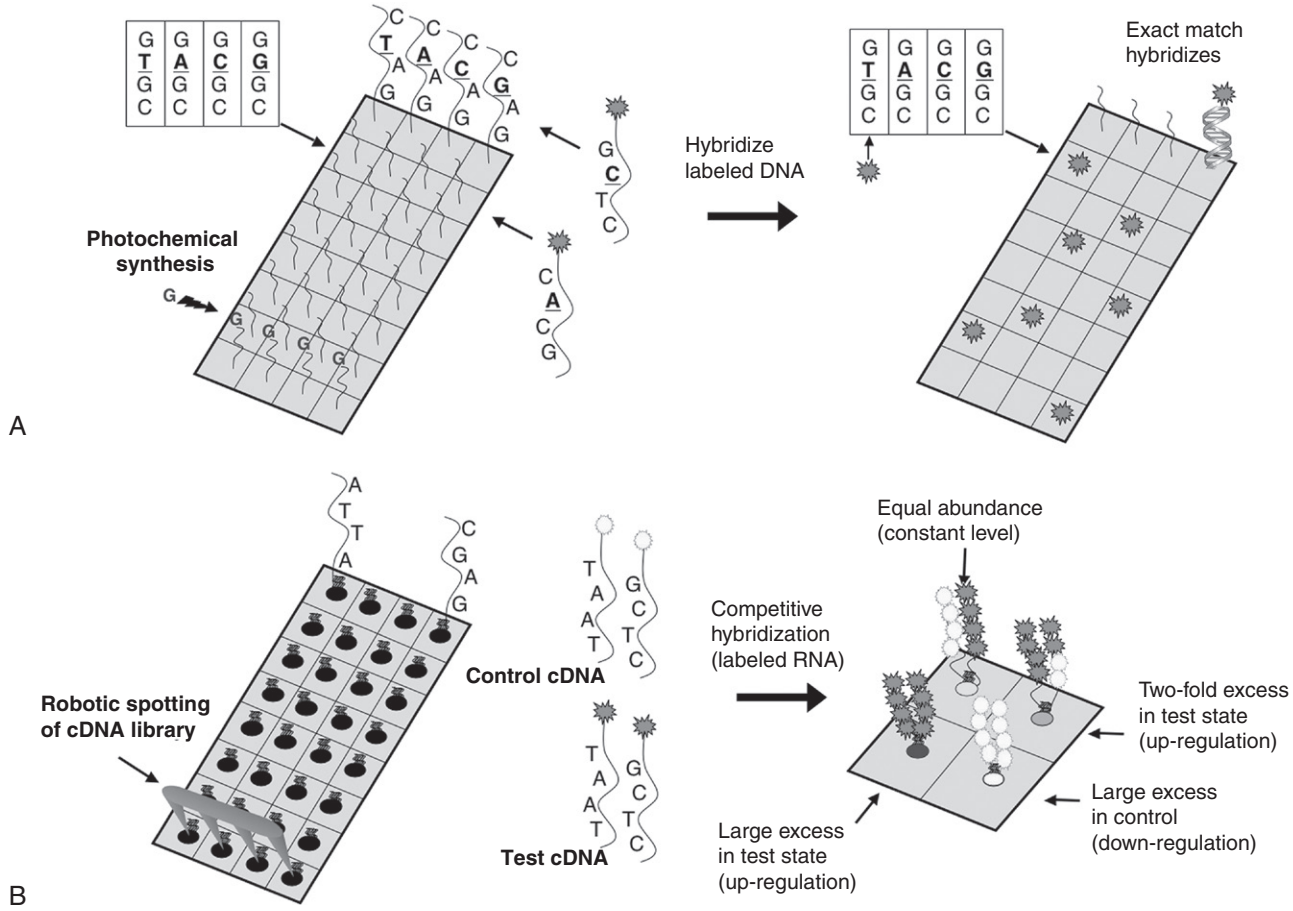

Figure 2-2 Microarrays. The general principles behind two different types of microarrays. **A,** Oligonucleotides are synthesized directly on a chip surface by photochemical techniques, allowing a series of overlapping sequences to be produced with each row containing all possible single base substitutions introduced at each given position. The DNA sequence to be analyzed (resequenced) is labeled with a fluorochrome and hybridized to the array, producing a pattern of hybridization that allows the detection and identification of any point mutations occurring within the portion of a gene represented by the overlapping oligonucleotide array. **B,** Complementary DNA (cDNA) arrays are produced by spotting characterized cDNA clones onto slides at high density. The expression levels of the genes placed on the array are then assayed by generating cDNA from RNA samples from a tissue of interest and from a matched control sample (e.g., normal versus malignant). The two samples are labeled fluorescently in two different colors, and equivalent amounts of the cDNAs are mixed and used for competitive hybridization to the targets on the microarray. The expression level of a gene in the test sample relative to the control can be calculated by determining the intensity of each of the fluorescent label at spots corresponding to hybridization targets for that cDNA.

HUMAN GENOME PROJECT

The most significant development in molecular genetics of the late 20th century was the commitment to sequence and then identify all of the genes in the complete genome of humans and other important model organisms and pathogens. Use of the basic tools described previously at an industrial level culminated in the development of highly detailed linkage, physical, and sequence maps of the human genome. This section describes some of the methods that were required to complete the mapping and sequencing of the human genome.

Polymorphic Markers

Although identity at the DNA sequence level between any two humans is greater than 99.9%, a large number of interindividual differences exist. These sequence polymorphisms have been exploited as tools to track the segregation of chromosomal loci through generations in human pedigrees. The first such markers were single-base changes or small insertions or deletions that created or destroyed a restriction enzyme site (restriction fragment length polymorphisms [RFLPs]), detectable by Southern blot analysis as bands of altered mobility. The discovery of variable number tandem repeat (VNTR) markers provided reagents that were more abundant and more informative (with more alleles, corresponding to differences in the number of repeats found in the population). The size of the repeat units typically identified was such that different alleles could differ in size by thousands of base pairs, making Southern blotting a requisite step for genotyping. The type of marker used most extensively in the creation of human genetic linkage maps was the short tandem repeat (STR), in which runs of two to four nucleotides (e.g., CA, AAT, GATA) were repeated approximately 10 to 30 times. Size differences in alleles as little as two base pairs in PCR products ranging from approximately 80 to 300 base pairs in length were resolved easily by electrophoresis in polyacrylamide sequencing gels. Compared with Southern blotting, this process required significantly less labor and sample DNA, substantially facilitating large-scale genotyping.

The most recently developed type of polymorphic marker is the *single-nucleotide polymorphism* (SNP). SNPs are single-base

changes that occur on average once every 750 base pairs. SNPs have fewer alleles and are therefore less informative than the repeat-type markers, but their sheer abundance is anticipated to make them powerful tools in the effort to elucidate the genetic basis of common complex diseases, such as hypertension and asthma, as well as quantitative traits that have an impact on fetal health, such as birth weight, at the molecular genetic level.

Linkage Analysis

The ability to map genes to specific chromosomal locations was developed in experimental organisms such as *Drosophila melanogaster* in the early 20th century. The construction of genetic maps in model systems required the identification of individuals with traits of interest (e.g., mutations in eye color or wing shape) and subsequent selective mating to generate numbers of progeny suitable for quantitative analysis. This approach was not applicable to humans, limiting the success of early mapping studies to those diseases in which the genetic locus was tightly linked to the few available polymorphic loci, such as the ABO blood group antigen locus. The discovery of abundant DNA polymorphisms with significant levels of interindividual variation made linkage mapping feasible in humans.

Linkage analysis is a statistical method in which genotyping data from a pedigree are evaluated for the probability that two loci (markers) are inherited together because they are in physical and thus genetic proximity, compared with the probability that the data can be explained by the null hypothesis that the markers are not linked and are being inherited independent of each other. The statistic commonly used is the LOD ("logarithmic odds") score, which represents the logarithm of the probability of linkage divided by the probability of no linkage. An LOD score greater than 3.3 traditionally is taken as the threshold to declare linkage, because it represents a 1000:1 probability ratio in favor of linkage, corresponding to a p value of approximately .05.

Genetic and Physical Map

An extensive set of polymorphic markers was used to genotype a collection of large multigenerational pedigrees for the construction of a human genetic linkage map. In contrast with the mapping of genes responsible for physical traits in model organisms, the human genetic map established genetic distances between anonymous polymorphic markers. These markers were concurrently mapped to physical locations by a variety of methods such as fluorescence in situ hybridization (FISH) mapping (see later on), allowing the coordination of genetic loci to physical chromosomal locations. The mapping of markers onto genomic clones—YACs or BACs—by hybridization or PCR amplification allowed the identification of clones containing common markers that were therefore overlapping. Collections of overlapping clones were organized by computational analysis into large contiguous assemblages ("contigs") that allowed the ordering of data generated by sequencing the cloned DNA.

Complexity in Eukaryotic Genomes

Among the interesting facts to emerge from the Human Genome Project was that the total number of genes, as defined by transcribed open reading frames, was not significantly higher in humans than in lower organisms such as the fruitfly, *D. melanogaster,* or the roundworm, *C. elegans.* The greater complexity of mammals is attributable in part to more flexible utilization of the available exons in a transcriptional unit. By alternatively splicing a common set of exons, transcripts encoding proteins with distinct or even opposing activities can be generated. In addition, proteins can be modified in numerous ways that may affect localization or function (e.g., glycosylation, phosphorylation, lipidation, proteolysis). Thus, the complement of proteins generated from the genome—the proteome—is much larger than the number of genes, or discrete transcriptional units.

The study of the proteome, or *proteomics,* has become a new focus of interest in the "postgenomic" world. Recent innovations in protein separation technologies—tandem mass spectrometry, multidimensional gel electrophoresis, and protein tissue array analysis—have accelerated the ability to identify and characterize the protein complement of cells or tissues of interest, as well as their modifications, localization, and interactions. The ability to isolate and characterize individual proteins and to profile protein changes qualitatively and quantitatively from tissues of interest (healthy versus diseased), in conjunction with genome-scale characterization of diseased and normal tissue (e.g., expression profiling, cataloguing sequence polymorphisms), is anticipated to facilitate the identification of protein biomarkers, the discovery of candidate therapeutic drug targets, and discrimination of individual patient responses to a given treatment. Proteomics complements other functional genomics approaches, including microarray-based profiles, systematic phenotypic profiles at the cell and organism level, systematic genetics, and small molecule–based arrays. As these approaches migrate from the research laboratory to the clinic, they will provide the tools for the practice of more personalized medicine.

Regulatory RNA

Efforts to characterize the complete set of expressed RNAs in humans and higher mammals identified a set of transcripts in the EST database that did not contain identifiable open reading frames (ORFs). These noncoding RNAs, which initially were thought to represent truncated transcripts or cloning artifacts, more recently have been recognized to correspond to a significant fraction of mammalian transcribed sequences, and to play important roles in the regulation of gene expression.[1] Regulatory RNAs in mammalian cells, particularly micro-RNA and small interfering RNA (siRNA) sequences, are now known to possess the ability to down-regulate gene expression—something previously observed only in simpler eukaryotes. This property has been widely exploited at the level of preclinical basic research, and RNA-mediated down-regulation is now being considered as a therapeutic approach for a number of diseases.

GENETIC BASIS OF HUMAN DISEASE

Identification of Disease-Associated Gene Mutations

Currently available molecular tools allow the efficient mapping and identification of loci underlying single-gene (mendelian) disorders. Families transmitting a disease of interest can be genotyped using polymorphic markers spaced at equal intervals (approximately 10 cM) across all chromosomes to determine the inheritance of maternal and paternal alleles. The probability that a given marker is close to the disease locus can then be calculated by comparing the inheritance of marker alleles and disease affectation status by linkage analysis. To identify the genetic basis of the trait under study, candidate genes near the disease locus are analyzed for mutations, with priority given to genes having an expression pattern or known function relevant to the disease manifestations. Before the availability of sequence and map information produced by the Human Genome Project, this latter stage required the construction of a physical map of a YAC or BAC contig spanning the minimal genetic interval containing the locus. These clones were then used to identify new polymorphic markers and to map candidate genes onto the region of interest. By eliminating the need to perform these last two laborious and time-intensive steps, the sequence and map information produced by the Human Genome Project has dramatically accelerated the rate at which genes underlying mendelian diseases

are being identified by this positional cloning approach. These endeavors have resulted in the identification of disease-causing mutations both in well-studied and well-characterized genes as well as in genes without previously known functions.

Atypical Inheritance

As increasing numbers of genetic disease loci have been characterized at the molecular level, it has become apparent that numerous diseases can result from mutations at any of several genes; such diseases are said to possess genetic heterogeneity. Mutation analysis studies of genetically heterogeneous diseases have led to the discovery of interesting exceptions to traditional mendelian inheritance. Aganglionic megacolon (Hirschsprung disease) is a heterogeneous disease that can show autosomal dominant, recessive, or complex inheritance. In rare cases, inheritance has been found to result from double heterozygosity for single mutant alleles at each of two different genes that can independently cause the phenotype in a mendelian fashion.[2,3] In some cases of Bardet-Biedl syndrome, a syndrome of mental retardation and obesity, disease expression requires mutation of both alleles of one gene and a single mutant allele at one of two other genes—an example of triallelic inheritance.[4] In both disorders, genetic complexity is intermediate between simple monogenic disease inheritance and multigene complex inheritance.

Complex Inheritance

The inheritance of complex traits is thought to involve multiple loci, with environmental factors contributing to phenotypic expression. Trait expression can involve quantitative features like weight and blood pressure that are distributed in a gaussian fashion in the population, or qualitative features that are either present or absent, such as cleft lip and palate. The former are thought to result from interactions between multiple genes with alleles that contribute positively or negatively to the expression of the final phenotype. The favored model for the latter involves the contributions of multiple liability loci, in which variants at each locus contribute additively to the expression of the disease phenotype until a critical liability threshold is passed and the trait is expressed. Examples of such traits are spina bifida and pyloric stenosis. In this model, traits with marked gender differences in incidence are assumed to reflect gender-specific differences in the liability threshold for disease expression. Occurrence of the condition in the less commonly affected gender implies inheritance of a greater burden of liability alleles, so the recurrence risk for subsequent siblings is higher than if the affected child is of the more commonly affected gender.

Because of the involvement of multiple loci whose relative contribution may differ from pedigree to pedigree, linkage studies have been largely unsuccessful in dissecting the genetic basis of complex traits. However, if a single locus contributes substantially to the heritability of a trait, the locus may be detectable by standard linkage analysis. The first successful example of disease gene discovery for a complex trait was the identification of variants in the gene *NOD2* contributing to the expression of Crohn disease.[5,6] Additional complex disease-associated variants have been successfully identified by association and linkage studies, particularly by investigators focusing on relatively genetically isolated populations. These successes are setting the stage for future diagnostic and therapeutic advances in the future.

The International HapMap Project

After the completion of the Human Genome Project, a new effort was organized to characterize the genetic variations present in different human populations as discrete blocks of co-inherited polymorphisms, or haplotypes (Figure 2-3). This effort, the International HapMap Project, is a multinational collaborative effort to collect genetic data from four populations derived from Africa, Asia, and Europe. By determining which polymorphisms are likely to be inherited as a distinct haplotype in these populations, the HapMap holds the potential to streamline the discovery of genetic variants that contribute to the susceptibility for complex disorders. Recently, HapMap data were used in documenting the rapid spread of polymorphisms that confer survival advantages through human populations (e.g., the evolutionary origin of lactose tolerance in Northern Europeans and isolated tribes in Africa), illustrating that the potential benefits of the effort are rapidly becoming a reality.[7,8]

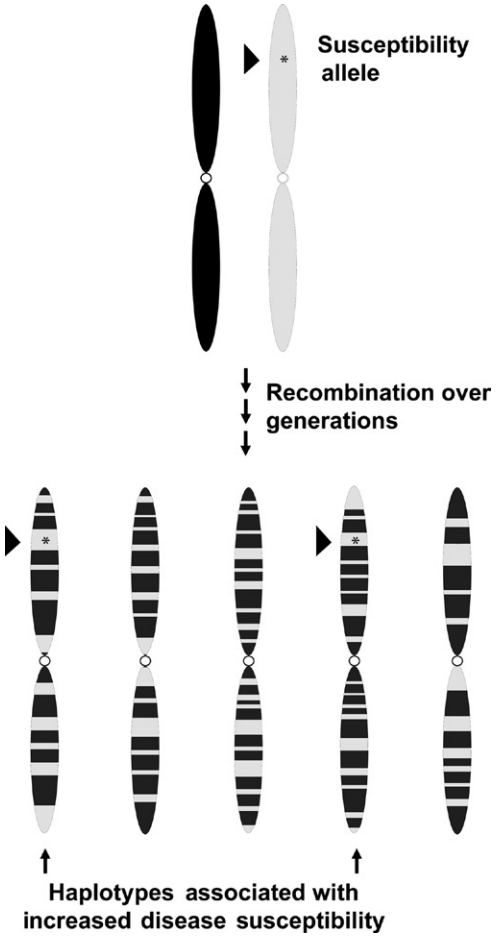

Figure 2-3 Ancestral disease susceptibility alleles exist on conserved haplotype blocks. Genetic variants predisposing to disease susceptibility (*, indicated by arrows) arose on ancestral chromosomes that have subsequently undergone recombination through meiosis over succeeding generations. In contemporary populations, the disease-predisposing variants occur on haplotype blocks conserved from the ancestral chromosomes.

DISEASE INHERITANCE AND MOLECULAR PATHOGENESIS

Diseases caused by mutations of single genes may be inherited in either dominant or recessive fashion. The observed inheritance pattern will depend on the effect of the mutation on the encoded protein. Mutations may inactivate, dysregulate, or enhance protein function. By cataloguing the distribution and types of mutations (e.g., missense, nonsense) causing a given disease phenotype, the effect on protein function can sometimes be deduced.

Null Alleles

Mutations that abolish protein expression or function produce a *null allele.* Potential mechanisms include mutations that interfere with transcription (promoter mutations), prematurely terminate the open reading frame (nonsense, frameshift, splicing mutations), or alter catalytically or structurally critical residues (point mutations, small in-frame insertion or deletions). If cellular function is not compromised by the diminished abundance of wild type protein, a recessive inheritance pattern is seen. Carriers of a single null allele of a gene encoding an enzyme are usually healthy, but mutation of single alleles encoding structural proteins or transcription factors may cause disease, as discussed further on.

Familial cancer syndromes caused by mutations in tumor suppressor genes are an interesting exception to the rule that mutations in genes for which a single allele is sufficient for normal cellular function will manifest recessive inheritance. Cells carrying a null mutation in a tumor suppressor gene grow normally. Uncontrolled growth occurs when the remaining wild type allele is mutated by a second, independent event. Because both alleles must be impaired for expression of the phenotype, this is an example of a recessive mechanism at the cellular level. At the organismal level, the large number of total cells makes the probability of a second mutation event in at least one cell quite high. Thus, despite the recessive mechanism observed at the cellular level, familial cancer syndromes caused by loss of tumor suppressor genes usually are inherited in a dominant fashion.

Haploinsufficiency

For some proteins, such as those expressed as part of highly regulated developmental programs, total abundance may be critical to the execution of their function. When a single copy of an allele is inadequate for normal function or development, carriers of null mutations are symptomatic—a mechanism known as *haploinsufficiency*. Examples are transcription factor mutations, in which decreased transcript abundance results in secondary diminution of downstream effector protein levels, and heteromeric structural protein mutations, such as in collagens, in which the proper stoichiometry of the component subunits is important. Transmission of the null allele is sufficient to cause disease, so dominant inheritance is observed.

Dominant Negative Mutations

Mutations may abolish protein function in a domain-specific manner so that some activities are lost, while others are maintained. Potential mechanisms include missense mutations or in-frame deletions that affect a single functional domain and truncations that ablate distal domains. Mutant proteins retaining some aspect of function can be more deleterious for cellular function than complete absence of an allele if the mutant prevents the available wild type protein from performing its function. This mechanism is exemplified by mutation of a transcription factor so that transactivation is lost but DNA binding is normal, thereby preventing the protein encoded by the wild type allele from binding to the recognition sequence and activating transcription. Proteins that are components of a multimeric complex, such as the individual collagen chains forming a heterotrimeric collagen fibril, can have dominant negative effects when the incorporation of a mutant subunit impairs the assembly of the functional unit.

Activating Mutations

Mutations can directly (by active site alteration) or indirectly (by disabling a regulatory domain) enhance the activity of a protein. In the case of signal transduction proteins such as kinases, inappropriately regulated enzymatic activity may initiate a signaling cascade that stimulates cell division and sets the stage for cellular transformation. As the abnormal activity of the mutant allele overrides the properly regulated activity of the wild type allele, dominant inheritance is observed.

TRADITIONAL AND MOLECULAR CYTOGENETICS

Chromosomal abnormalities, both numeric and structural, are the leading cause of fetal loss, developmental and congenital abnormalities, and apparent infertility. Although some of these result in live births, many are responsible for lack of embryonic implantation, growth, or survival. Of the numeric abnormalities, the only ones associated with the potential for survival are trisomies 21, 13, 18, 22, and rarely 9, along with the sex chromosome abnormalities (XXX, XXY, XYY). The only monosomy that permits survival (although more than 95% of affected fetuses abort in the first trimester) is 45,X. Because virtually all of these abnormalities are the result of meiotic nondisjunction, observation oftrisomies and monosomies of every chromosome would be expected. A few trisomies can be found among spontaneous abortions, especially trisomy 16. Calculation of the expected frequency of the discovered and the nonviable trisomies and monosomies predicts that approximately 75% of fertilized ova are chromosomally abnormal, most of which never implant or result in miscarriage early in pregnancy, appearing as "late" menstrual periods. In a study by Wells and colleagues,[9] 9 of 10 polar bodies studied by comparative genomic hybridization (CGH) (discussed further on) had either one too many (i.e., 24) or one too few (i.e., 22) chromosomes—a proportion not dissimilar from the theoretical prediction. Among the chromosomes involved, some were identified that are never seen in viable fetuses, even those studied after spontaneous abortions. Another form of numeric abnormality leading to multiple congenital malformations and fetal demise, stillbirth, or, rarely, neonatal death is triploidy (69 chromosomes). This abnormality can result from dispermy in a single ovum or one sperm with two female germ cells, probably an ovum and a polar body.

Numeric abnormalities also can result from mitotic, postfertilization events, which generally lead to mosaicism. *Mosaicism* should be distinguished from *chimerism,* resulting from fusion of two separate embryos into one individual embryo. In the latter condition, the affected infant is born alive and exhibits generally normal development but can be infertile or a true hermaphrodite if the two initial embryos are of different genders. Mosaicism, on the other hand, results from either mitotic nondisjunction or anaphase lag. If the abnormal event occurs in the first cell division after fertilization, an embryo with two cell lines will result: In the case of mitotic nondisjunction, they both will be abnormal (45 and 47 chromosomes each, with monosomy and trisomy for the nondisjoined chromosome); in the case of anaphase lag, one cell line will be normal and the other will be missing a chromosome. Anaphase lag is the cause of many cases of mosaic Turner syndrome, when the involved chromosome is an X or a Y. The source of the nondisjoined chromosome has clinical significance because if it was a Y, the resulting mosaic individual may have Turner syndrome with testicular rests leading to a risk for gonadal tumors. If mitotic nondisjunction occurs later in embryonic development, the affected individual will have three cell lines—normal, trisomic, and monosomic. This mechanism accounts for mosaic Down syndrome cases (46 and 47 chromosomes, the latter with trisomy 21); in affected persons, the predicted monosomy 21 cell line dies off because of nonviability of autosomal monosomic cells.

The other major category of chromosomal abnormalities is structural alteration of one or more chromosomes. A single chromosome may be abnormal as a consequence of a deletion or a duplication of a piece of chromosomal material ranging in

size from a few genes to whole chromosomal arms. The resulting abnormalities and viability of the fetus will vary depending on the amount and genetic content of the material deleted and duplicated. Breakage and recombination of fragments between two or occasionally more chromosomes also will result in structural variation. If the exchange is achieved without loss or gain of material, the translocation is balanced and should not result in abnormalities unless a gene is damaged at the breakpoints. Of note, however, a normal carrier of such a balanced translocation can produce gametes that have duplications of one of the exchanged fragments, along with deficiency of the other (unbalanced translocation). Because the number of possible rearrangements is virtually infinite, the phenotype can range from one characterized by essentially normal features or mild anomalies to one featuring severe anomalies and death in utero or after birth.

Chromosomal Basis of Nonmendelian Disease

Over the past several years it has become apparent that nonmendelian behavior of chromosomes and their genes can be the result of a variety of mechanisms. Some of these mechanisms and their alterations lead to a variety of developmental defects. Among these are genetic imprinting, uniparental disomy, the formation of neocentromeres, and mitochondrial inheritance.

Imprinting results in the expression of certain genes exclusively from the chromosome derived from one of the two parents in a gender-specific fashion. The allele derived from the parent of the opposite gender is silent (imprinted). This parent of origin–specific expression appears to involve differential methylation of the regions controlling imprinted genes during formation of gametes. It is this phenomenon that accounts for the lack of viability of embryos derived from a single parent. Embryos with a chromosomal complement derived only from the male have poorly functioning placentas, whereas those with entirely female-derived chromosomes do not develop properly develop fetal tissues which may lead to formation of a hydatidiform mole. Absence of the active allele by deletion or mutation results in abnormalities of the offspring. The type of abnormality is determined by which of the imprinted genes is absent. For example, the proximal long arm of chromosome 15 has two adjacent areas, one of which is paternally imprinted and the other maternally imprinted. Deletion of the paternal imprinted genes results in Prader-Willi syndrome, whereas absence of the maternal genes results in Angelman syndrome, both associated with distinct patterns of developmental defects. Disturbances in an imprinted gene in the short arm of chromosome 11, most commonly caused by relaxing imprinting and allowing both alleles to be expressed in an imprinted area, results in an overgrowth syndrome, Beckwith-Wiedemann syndrome, which also is associated with tumor formation and other abnormalities. This disorder appears to be due to overexpression of a growth factor in the usually imprinted region. Chromosomal regions known to contain imprinted genes are shown in Figure 2-4.

One of the mechanisms by which absence of the active allele at an imprinted locus or a double expression of the active allele can occur is *uniparental disomy*. In uniparental disomy, both members of a chromosome, in some cases, a part of a pair of chromosomes, are derived from the same parent. If imprinted genes exist in this pair, the phenotypic result will depend on whether the pair derives from the mother or the father, and on which parent contributes the imprinted gene. As an example, with maternal uniparental disomy of chromosome 15, the active allele that is derived from the father will be absent, and the result will be Prader-Willi syndrome, as if the paternal allele had been deleted. Similarly, with paternal uniparental disomy of chromosome 15, the active maternal allele at the Angelman locus will be absent, and Angelman syndrome will result, just as if the maternal allele had been deleted.

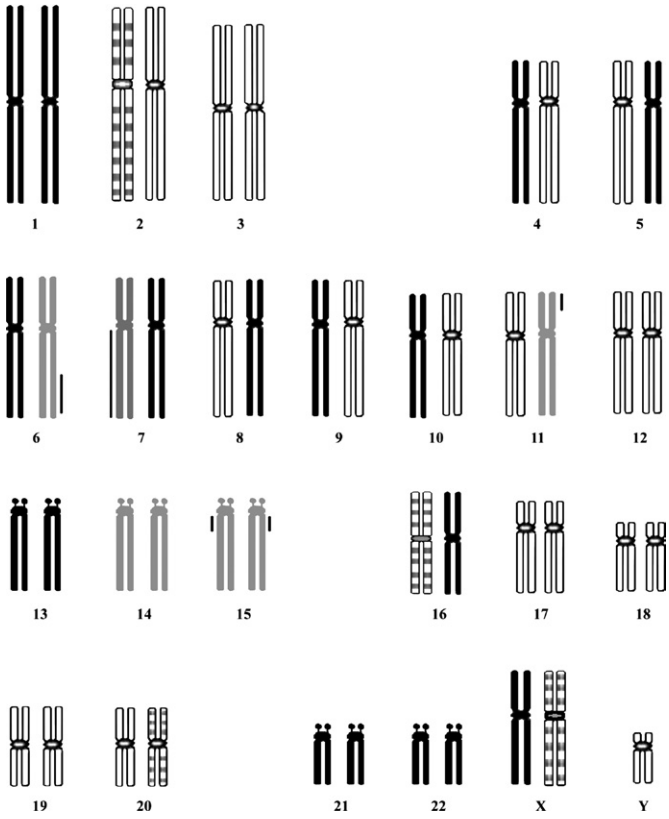

Figure 2-4 Imprinted chromosomal regions. Data are from a survey summarizing areas of human chromosomes that are known to be imprinted *(gray)* with the imprinted region indicated by adjacent bars is applicable. Chromosomes that are possibly imprinted are hatched, those unlikely to be imprinted are indicated in *shaded in black*, and those without any UPD cases reported are *unshaded*. Maternal chromosomes are shown at left of each pair. The figure can be viewed as an interactive webpage document (http://genes.uchicago.edu/upd/) with links to citations supporting the summary data. *(Courtesy Dr. David Ledbetter, with permisssion.)*

Uniparental disomy comes in two forms. Uniparental *heterodisomy* occurs if the embryo inherits both members of a pair of chromosomes from one parent, whereas in uniparental *isodisomy,* two copies of a single chromosome from the pair are transmitted. In addition to the effect on imprinted genes, uniparental isodisomy also results in homozygosity for the entire chromosome or for the part that is disomic, including any mutant genes that happen to be on that chromosome. In fact, the first proven case of human uniparental isodisomy was in a child with cystic fibrosis who had received both members of a single maternal chromosome 7 that happened to contain the cystic fibrosis mutation. The child also was unusually short, because of the presence of an imprinted gene with a strong impact on growth.

None of these observations would be possible without the technical advances allowing detailed examination of the chromosomes. After discovery of methods to produce specific banding patterns in the early 1970s, permitting identification of each chromosome and its major parts, additional breakthroughs led to the ability identify increasingly smaller parts of chromosomes by fluorescence in situ hybridization (FISH) (Figure 2-5), identification of each chromosome in a single karyotype by multicolor FISH, and most recently, CGH. CGH is done by double hybridization of patient DNA labeled with one fluorochrome and normal DNA labeled with a different fluorochrome with normal

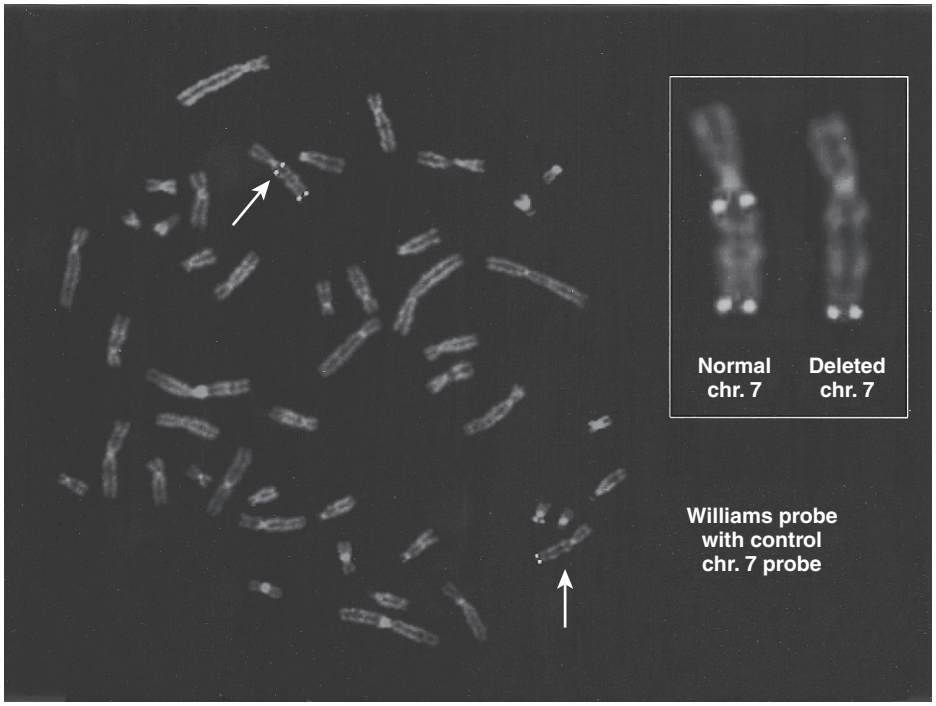

Figure 2-5 Fluorescence in situ hybridization (FISH). Diagnosis of chromosomal microdeletion syndromes has been revolutionized by molecular cytogenetic techniques allowing metaphase chromosomes to be analyzed for the presence of specific sequences using fluorescently labeled cloned DNA as probes. In this example, a telomeric probe is seen hybridizing to each replicated pair of chromosome 7; a probe specific for a region that is recurrently deleted in patients with Williams syndrome is absent from one pair of sister chromatids *(arrows). (Courtesy Dr. Brynn Levy.)*

metaphase chromosomes on a slide. Using a computerized camera and microscope, this technique permits the discovery and exact identification of missing and extra material in any sample, even when the sample cannot be grown in culture (as with products of conception, for example). More recent application of CGH to DNA probes on microarrays has allowed the discovery of the smallest duplications and deletions, even from a single cell. These new techniques have rapidly led to far more accurate delineation of the causes of developmental and congenital abnormalities.

Genomic Disorders and Gene Dosage

A number of human genetic disorders are now known to result from loss or gain of genetic material on a smaller scale than that for disorders caused by cytogenetically observable events (i.e., in the range of hundreds of kilobases to several megabases). Deletions and duplications as small as 100 base pairs were rendered easily detectable with the advent of FISH technology. This advance set the stage for the molecular characterization of diseases in which a recurrent deletion of a specific genomic interval caused a characteristic phenotype, such as in DiGeorge syndrome. Studies of this syndrome and other diseases caused by deletion or duplication of genomic segments (see Table 2-1) have identified the features in the genomic DNA that predispose to these events.

The presence of low-copy DNA repeats having relatively high levels of sequence conservation may predispose to deletion or duplication events if the repeats occur in the same orientation (tandem repeats) or to inversion events if the repeats are in opposite orientations (inverted repeats). Unlike the more abundant high-copy repeats present in human DNA (e.g., *Alu* retrotransposon insertions), low-copy repeats exist as duplicated segments with extensive homology over relatively long distances (up to tens of thousands of base pairs). Inappropriate pairing between repeat elements at meiosis could thus result in the loss or gain of intervening genomic DNA segments as long as several million base pairs. Such an event would not necessarily change the coding sequence of genes on the deleted chromosome but would change the copy number of genes in the affected interval, leading to haploinsufficiency for all of the genes contained within the deleted interval. Conversely, in a duplication event, the dosage for all of the affected genes would be increased. Both aspects of this principle have been well illustrated in the case of neurologic disease caused by gain or loss of the peripheral myelin gene, *PMP22* (reviewed by Inoue and Lupski[10]). *Deletion* of the locus results in type 1 Charcot-Marie-Tooth disease. *Duplication* of the locus leads to increased dosage of *PMP22,* resulting in hereditary susceptibility to neuropathy and pressure palsies (HNPP). Of interest, persons who are homozygous for such a duplication (gene dose of four instead of two) are more severely affected than those heterozygous for the mutation. Proof of the principle is further provided by gain-of-function mutations in *PMP22,* in which the gene dose is unchanged but the clinical phenotype mirrors the effect of a duplication.

The change in gene copy number is necessarily deleterious in events detected in patients with genetic diseases, but copy number changes also have been found to occur as polymorphisms in human populations. The contribution of these copy number changes to disease burden is not yet known, but in at least one case, gene copy number polymorphisms have been shown to modulate the course of a common human disease. The copy number of the inflammatory chemokine gene, *CCR3L1,* is polymorphic across and within different human populations, resulting in differences in serum CCR3L-1 protein levels. Cohort studies of humsn immunodeficinecy virus (HIV)-infected patients have revealed that *CCR3L1* copy number higher than the mean observed in a given population was associated with decreased infection rates and slower progression of HIV disease and acquired immunodeficiency syndrome (AIDS). This effect, presumably mediated by increased CCR3L-1 ligand occupancy of the HIV co-receptor, CCR5, was most evident in the setting of CCR5 alleles associated with enhanced disease progression.[10] This first example of gene copy number polymorphisms modulating human pathologic states is unlikely to be the last.

CONCLUSION AND FUTURE DIRECTIONS

The massive amount of information made available by the Human Genome Project has already shown its power in allowing the mapping of many hundreds of disease genes and the cloning of

a high proportion of these. The methods developed by the project, such as high-throughput genotyping, have become widely used and are beginning to be applied to a much broader set of genes associated with susceptibility to common diseases, such as cardiovascular disease, diabetes, and obesity. Clearly, a number of conditions applicable to fetal development will fall into this effort, including prematurity, intrauterine growth restriction (IUGR), and birth weight. The search for such genes until now has been conducted primarily by association studies, many of which have not been replicated or replicable. As noted in a review by Hirschhorn and colleagues,[12] of approximately 200 such associations found in more than 600 references in the literature, only 5 were clearly replicable, with highly suggestive results for another 20 or so. Nevertheless, with application of increasingly powerful methodologies to the search for associations between alleles for specific genes and disease susceptibility, this number is likely to grow steadily.

Another potentially highly useful application of such studies is in the field of pharmacogenomics. A number of genes have already been identified in which polymorphisms lead to large differences in individual responses to therapeutic agents. It is suspected that some of these may even be related to whether or not a particular drug is teratogenic in a particular fetus. The ability to tailor types and amounts of medications to different patients would be an enormous benefit to therapeutic interventions by reducing risks of drug reactions or side effects.

Finally, the long-hoped-for practical use of gene therapy may grow in the near future. The successful treatment of several children with X-linked severe combined immunodeficiency[12] has given hope for the application of treatment of deleterious mutations by gene replacement. The first success has definitely been helped by the fact that corrected immune cells have a selective advantage over the abnormal cells and therefore replace them to produce a cure of the disease. This success was predictable from previous findings that reversion of deleterious mutations in such cells led to a reversion to relative normality in an otherwise fatal illness.[14] Prenatal gene therapy has been attempted in immunodeficiency with some apparent success, but the occurrence of lymphoproliferative disease caused by insertion of transgenes upstream of proto-oncogenes has tempered the initial enthusiasm for this approach. Until methods for gene replacement are worked out for many other diseases, advances in product replacement, particularly for lysosomal storage diseases, are expanding.

3 Prenatal Diagnosis

Louise Wilkins-Haug

Currently, the prenatal diagnosis of a fetal genetic disorder or a chromosome abnormality requires invasive testing; all of the tests in use carry small but recognized risks of miscarriage (0.5% to 2%). Accordingly, an important aspect of prenatal care is screening to identify those women who face an increased risk of a pregnancy complicated by a genetic disease or congenital malformation. Such screening modalities include review of the clinical history for both the patient and her partner, evaluation of maternal serum markers, and ultrasound examination in both the first and second trimesters. Ultimately, however, the definitive diagnosis of a genetic condition or chromosome abnormality in the fetus requires fetal nucleic acids obtained by chorionic villus sampling (CVS), amniocentesis, or percutaneous umbilical blood sampling (PUBS). Under investigation are new methods of assessing fetal DNA in the maternal serum, which could provide, for the first time, prenatal diagnosis without the risk for miscarriage.

SCREENING

Because women with "positive screens" (risk greater than a predetermined cutoff), indicating increased risk, often proceed to an invasive prenatal diagnostic test with an inherent risk of miscarriage, screening methods should strive for a high level of detection with the lowest screen-positive rate. Concepts such as *screen-positive rate* (the number of women with an increased risk among those undergoing testing identified on the screening test), *positive predictive value* (the chances of an abnormal result among the screen-positive group), and *detection rate* (number of abnormal fetuses identified from within the screened population) provide useful parameters to compare screening approaches. Additionally, knowledge of the gestational age at which screening can be performed is important and may influence pregnancy options.

Parental Clinical History

Parental Age

A long-recognized increase in aneuploidy as women become older is a cornerstone of prenatal diagnosis. For women who are 35 years of age at delivery, the chance of having a newborn with Down syndrome (trisomy 21) frequency is approximately 1 in 308 pregancies. Because trisomy 21 is associated with increased risk for miscarriage and stillbirth, for a 35-year-old woman the chances are actually higher that at amniocentesis (1 in 258) or CVS (1 in 175) Down syndrome will be diagnosed. Although maternal age was the first screening criterion for Down syndrome, it performs poorly when assessed at a population level. Approximately 15% of women have children at age 35 years or older (screen-positive rate), and the likelihood in this subgroup women that a pregnancy is complicated by Down syndrome (positive predictive value) is only 1% to 3%. Furthermore, the detection rate is only approximately 20%; less than one fourth of Down syndrome infants are born to women in this older maternal age subcategory. When evaluated by these screening parameters, the utility of maternal age over 35 years alone as an indication for an invasive prenatal diagnostic test has been challenged.[1] Genetic conditions associated with the father's age are more difficult to delineate but include an increased risk for dominant mutations as exemplified by achondroplasia.[2]

Reproductive History

Assessment of the couple's reproductive history also may signal an increased genetic risk to the pregnancy. A history of repeat miscarriages (2 or more) is associated with an increased risk for parental balanced translocation (6.8%). Other reproductive outcomes such as a previous malformed stillbirth along with a single miscarriage also are associated with an increased risk for a parental balanced translocation, (5.4%).[3] A history of three or more consecutive first-trimester abortions carries a 9.6% risk of a parental balanced translocation. [4] Similarly, repeated failure of vitro fertilization cycles (for more than 10 cycles) attributable to poor implantation is associated with an increased risk of a parental balanced translocation of 2.5%.[4] By comparison, the overall rate of balanced translocations in newborns is 0.2%.[5] A balanced translocation increases the person's risk that offspring may inherit an unbalanced complement of chromosomes, with associated implications for mental and physical delays.

In addition to previous pregnancies, a diagnosis of infertility warrants closer examination of the identified etiologic disorder and the possible recommendation of prenatal diagnostic testing. Balanced translocations and sex chromosome aneuploidy occur in 14.3% and 6.5% of men with absent and low sperm counts, respectively.[6] In addition, with male factor infertility related to obstructive azoospermia, congenital absence of the vas deferens (CBAVD) is a common diagnosis. Of men with CBAVD, almost two thirds carry at least one mutation in the gene responsible for classic cystic fibrosis (i.e., the cystic fibrosis transmembrane receptor gene [*CFTR*]). Almost half (54.5%) of the men are double heterozygotes, possessing two mutations for classic cystic fibrosis, although most often the second mutation is a variant specifically associated with infertility and not classic cystic fibrosis.[7] Because men with CBAVD can father children through assisted reproduction using intracytoplasmic sperm injection, carrier screening of the female partner is critical in view of the relatively high carrier frequency—1 in 25 in the white population. Couples in which both members carry a *CFTR* mutation face a 25% risk of having a child with cystic fibrosis; this finding emphasizes the importance of delineating the specifics of male factor infertility.

Female factor infertility also may have an underlying genetic etiology with subsequent risk to the offspring. In particular, poor ovarian reserve and oligomenorrhea or amenorrhea may reflect a premutation of fragile X. Classically, 3% of cases of sporadic premature ovarian failure (POF) and 13% of cases of familial POF are associated with a premutation fragile X.[8] Of significance for female factor infertility, earlier menopause in women with a premutation of fragile X heightens the possibility that these women will seek infertility evaluation and treatment with a diagnosis of poor ovarian reserve.[9] In view of an overall frequency of fragile X premutations in the general population of approximately 1 in 200 women, many infertility centers now are more likely to offer screening for fragile X to women. For fragile X premutation carriers, the implications for the offspring reflect the degree of expansion of the fragile X site (as discussed next under family history screening).

Family History

Finally, review of the clinical history for both parents includes an assessment of family history. Ethnicity and country of origin are now routinely ascertained at preconception and prenatal visits. Various diseases of an autosomal recessive nature occur with increased frequency among specific populations reflecting historical physical or cultural constraints to gene migration. For some disorders, disease distribution is widespread and warrants screening in essentially all individuals. Cystic fibrosis is an example of such an autosomal disease. Current recommendations are to offer *CFTR* carrier screening to all women, ideally in the preconception period, with education regarding disease frequency and sensitivity of testing within the patient's specific ethnicity (Table 3-1). In persons of Northern European heritage, the carrier frequency is 1 in 25, with screening detecting 88% of the carriers. However, in populations in which cystic fibrosis is less common, such as Asians (carrier frequency of 1 in 94), screening detects only 49% of carriers. In any population, screening can reduce but not totally negate the presence of a *CFTR* carrier.

Several autosomal recessive disorders occur more frequently within specific populations, and screening is then specifically directed by the individual patient's race or ethnicity. For example, hemoglobinopathies are more common in people of African, Mediterranean, or Asian origin. The carrier state for sickle cell occurs in approximately 1 in 12 persons of African American ancestry, and hemoglobin electrophoresis is the preferred method of screening. In some populations, further assessment for a hemoglobinopathy is warranted in the presence of a low mean corpuscular volume (MCV). β-Thalassemia will be detected by hemoglobin electrophoresis, whereas low MCV without iron deficiency and with a normal hemoglobin electrophoresis is suggestive of α-thalassemia. Further diagnosis of this carrier state would require molecular diagnostic testing based on the individual patient's country of origin. Among persons of Ashkenazi Jewish heritage, the American College of Obstetrics and Gynecology recommends carrier screening for Tay-Sachs disease, cystic fibrosis, Canavan disease, and familial dysautonomia.[10] For each of these disorders, the carrier frequency is sufficiently increased and the molecular diagnostic tests are sufficiently sensitive to meet the criteria for a prenatal screening test. As with all autosomal recessive disorders, any offspring would have a 25% chance of inheriting the disease in question if both parents are carriers.

For couples in which only one person is of Eastern European Ashkenazi Jewish heritage, the recommendation remains to offer screening but with the knowledge that in non–Ashkenazi Jewish populations the carrier frequency is lower and typically is not established. Furthermore, among non–Ashkenazi Jewish persons, the sensitivity of the molecular diagnostic tests for specific disease mutations is substantially less. For example, in screening for Tay-Sachs disease carriers in a non–Ashkenazi Jewish population, the recommendation is to use a functional assay with 98% detection, compared with detection by molecular diagnostic tests of only 50%. Persons of Ashkenazi Jewish heritage also may avail themselves of information regarding additional autosomal recessive diseases (Table 3-2). For couples in which only one member is of Ashkenazi Jewish heritage, however, the constraints of accurate screening in the non–Ashkenazi Jewish persons remain, with functional assays available only for Tay-Sachs disease. For couples in which both members are carriers for these autosomal recessive disorders, prenatal diagnosis is possible with use of the same molecular diagnostic tests on fetal cells obtained by either amniocentesis or CVS.[11]

Of relevance to prenatal diagnosis, a family history of mental retardation of unknown etiology or significant developmental delay or autism represents a positive screen for fragile X syndrome. Fragile X syndrome is the most common inherited cause of mental retardation and manifests with a spectrum of mental disability. The specific characteristics result from expansion of the fragile X mental retardation (FMR-1) region on the X chromosome. In most cases, 40 or fewer CGG repeats are present within FMR-1, and the region remains stable when passed from either parent to their offspring. Of note, however, some persons have inherited expansions of this repeat region, either slight (41 to 60—"intermediate range") or larger (61 to 200—"premutation range").[12] Approximately 1 in 200 women (1 in 113 to 1 in 350) carry a premutation for fragile X syndrome. When this unstable CGG repeat region expands to greater than 200 repeats ("full mutation"), increased methylation impairs translation, resulting in lack of production of the fragile X mental retardation protein (FMRP). The size of the maternal premutation allele directly influences whether further expansion occurs during meiosis.[13] (Table 3-3). Sons who inherit a full mutation have characteristics of typical fragile X syndrome. In daughters who inherit the full mutation, features of the syndrome are unpredictable because of the normal random silencing of one X chromosome (Lyon hypothesis). As many as two thirds of daughters with a full fragile X mutation may have mild to moderate retardation. Although general population screening for the premutation carrier state in women is not currently advocated, with a relatively high frequency of premutation carriers (1 in 200) and implications for disability, judicious review of the family history for characteristics of fragile X syndrome is encouraged.[14]

The family history of both partners also can yield important information regarding adult-onset dominant disorders such as Marfan syndrome, polycystic kidney disease, myotonic dystrophy, and Huntington disease. Such dominant, adult-onset disorders may be noted in one or more seemingly remote family members, with no perception of the significance for the current pregnancy. Non–disease-related death of affected persons before disease manifestation and the later age at onset of symptoms can cloud the inheritance pattern in a family. Additionally, especially in women with myotonic dystrophy, the most common adult-onset muscular dystrophy, the occurrence of congenital myotonic dystrophy with symptoms more severe than those typical of the adult-onset disease should be addressed. Disorders of recessive inheritance require attention with testing of the individual at risk for the specific DNA mutation known to be segregating within the family. Lack of knowledge of the specific mutation within a family does not prevent testing the person at risk but will limit the assurance of exclusion of the carrier state. For example, in a woman with a brother who has cystic fibrosis arising from the most common mutation, homozygosity for delta508, a negative result. for the most common cystic fibrosis mutations (which include delta508) changes her risk of being a carrier from 2 in 3 (unaffected sibling of a patient with an autosomal recessive disease) to 1 in 208 (background residual risk that any Northern European individual has for undetected carrier status for cystic fibrosis). By comparison, if her brother had not been tested, perhaps dying before molecular diagnosis, and neither parent was available, then her two-thirds empiric carrier risk could be reduced to only 1 in 15 (as a result of residual undetectable cystic fibrosis mutations in a Northern European person).

TABLE 3-1

Cystic Fibrosis Detection and Carrier Rates Before and After Testing

Racial or Ethnic Group	Detection Rate %	Carrier Rate (Before Testing)	Approximate Carrier Risk (After Negative Test Result)
Ashkenazi Jewish	94	1/24	1/400
Non-Hispanic white	88	1/25	1/208

Screening for Down Syndrome in the Second Trimester

	Screen-Positive Rate	**Detection Rate**
Maternal age >35 years	15%	20%
Triple test*	5%	75%
Quad test†	5%	80%
"Soft marker"‡ on fetal survey ultrasound examination	13%	50%
≥ two markers, thickened nuchal fold, or structural anomaly	6%	75%

*Triple test: maternal age + alpha-fetoprotein, β-human chorionic gonadotropin (β-hCG), and estriol assays.

†Quad test: triple test + inhibin assay.

‡Defined as increased nuchal fold, echogenic bowel, shortened femur, echogenic cardiac focus, or renal pelvis dilatation.

Maternal Serum Screening for Aneuploidy Risk

With recognition of maternal age as a poor screening instrument for the risk of aneuploidy in a pregnancy, various approaches evolved to refine an individual woman's risk for having an infant with Down syndrome. These approaches consist of identification of protein and hormonal markers from the fetus or the placenta and can be assessed in a sample of the mother's blood. On average, when the fetus has trisomy 21, lower levels of alpha fetoprotein and estriol and increased levels of human chorionic gonadotropin (hCG) are present. As these values change during gestation, standardization to a specific week is achieved with multiples of the median (MoM) for each gestational week from 15 to 22 weeks. For an individual woman, the maternal age risk is modified by the likelihood that changes in each of these three independent markers are more likely to occur in a Down syndrome fetus. Determination of levels of these three markers, in combination with the maternal age, constitutes a "triple test." Approximately 5% of women will have a positive triple test result, with detection of 75% of fetuses with Down syndrome within this screen-positive group. Addition of a fourth marker, inhibin, converts the screen to a "quad test," with a 5% screen-positive rate and detection of 80% of trisomy 21 fetuses. These results are markedly improved over those for maternal age alone, which yields a 15% screen-positive rate and a 20% detection rate (Table 3-4).

TABLE 3-5

Common Ultrasound Findings in Fetuses With Chromosome Abnormalities

Abnormality	Ultrasound Findings
Trisomy 21	Ventriculomegaly, brachycephaly Nuchal thickening Cardiac defect—AV canal Duodenal atresia, echogenic bowel Renal pyelectasis Shortened femur/humerus; clinodactyly involving fifth digit, sandalfoot
Trisomy 18	CNS—agenesis of corpus callosum, meningomyelocele, ventriculomegaly Cystic hygroma Cardiac anomalies Congenital diaphragmatic hernia Omphalocele Clenched hands with overlapping digits IUGR with polyhydramnios
Trisomy 13	CNS—holoprosencephaly, agenesis of corpus callosum, meningomyelocele, microcephaly Cleft lip/palate, midface hypoplasia, cyclopia, microophthalmia Nuchal thickening Cardiac anomalies Omphalocele, echogenic bowel Echogenic kidneys Radial aplasia, polydactyly
Turner	Cystic hygroma Cardiac defects (coarctation of the aorta) Horseshoe kidneys Hydrops
Triploidy	CNS—holoprosencephaly, agenesis of corpus callosum, meningomyelocele, Dandy-Walker malformation Hypertelorism, micrognathia Syndactyly involving third and fourth fingers Cardiac defects Omphalocele Early-onset IUGR affecting skeleton more than head Placental abnormalities—enlarged, or small and calcified

Risk data are estimates, which are influenced by gestational age at detection and the resolution of ultrasound images in reported studies.

AV, Atrioventricular.

Prenatal Ultrasound Examination

As maternal serum screening during the second trimester gained popularity during the 1990s, advances in ultrasound resolution also occurred. For the more common aneuploidies, characteristic patterns of ultrasound findings emerged (Table 3-5). Even when isolated malformations exist, the risk for aneuploidy can range from a few percent to greater than 50% (Table 3-6). Some of the increased risk associated with isolated ultrasonography-detected malformations is attributable to the possibility that further subtle dysmorphia or other minor malformations undetectable even by high-resolution ultrasound techniques will be present in the newborn.

As ultrasound survey in the second trimester increasingly became used for assessment of structural malformations, various minor ultrasound features gained new importance. "Soft markers" for aneuploidy include findings such as increased dimension to the nuchal fold, echogenic bowel, shortened femur, echogenic cardiac focus, choroid plexus cysts, and renal pelvis dilatation. These findings typically are transient and if not associated with aneuploidy have no functional significance in the fetus. The one exception is echogenic bowel, which may be associated with cystic fibrosis or fetal infection (typically cytomegalovirus infection). The use of a genetic sonogram, with recommendation for amniocentesis if any one of these soft markers is present, is evolving. When this modality is used as a screening tool for aneuploidy, the screen-positive rate (based on the presence of any one of these subtle markers as a positive result) is relatively high (13.0%), with a detection rate for Down syndrome of approximately 50%.[15] One modification of this approach is to offer amniocentesis if any of the following is present: two or more markers, an increased nuchal fold, or a structural anomaly. This approach decreases the screen-positive rate to 5.7% with a 75% detection rate for Down syndrome.[16] Incorporation of maternal age into this approach increases the screen-positive rate to 27.1% but also increases the detection rate for Down syndrome to 86.8%.[17]

First-Trimester Screening for Aneuploidy

With improvements in ultrasound resolution, greater clarity of fetal structures in the first trimester emerged. Between 11 and 14 weeks of gestation, visualization of additional fluid collection at the nape of the fetal neck (nuchal lucency) is a sensitive indicator of aneuploidy in the fetus. In initial studies, 70% detection of Down syndrome was predicted, with only 5% of the population considered screen-positive (increased nuchal lucency more than 2 standard deviations for gestational age). The addition of maternal serum markers, primarily pregnancy-associated plasma

TABLE 3-7

Detection Rates for Down Syndrome With First-Trimester Screening

*In the first trimester.
NA, Not applicable.

protein-A and hCG, brought the screen-positive rate in line with 5%, with a detection rate of 80% for trisomy 21 in the fetus.[18] The striking difference is that this screening can be performed in the first trimester, allowing earlier diagnosis. Ductus venosus measurements and the assessment of the nasal bone are two additional first-trimester ultrasound parameters to further decrease screen-positive rates without loss of detection.[19,20]

Although first-trimester screening with a combination of ultrasound examination and maternal serum screen yields high detection and low screen-positive rates, an alternative approach of so-called *integrated testing* also has been supported. Integrated testing consists of first-trimester ultrasound examination and measurement of serum markers in combination with select second-trimester serum markers. With an integrated testing, the screen positive rate is lower by a few percent and the detection rate is above 95%.[21] This methodology, however, delays screening results until the second trimester. A compromise between first-trimester screening alone and integrated testing is reached with *sequential screening*. Sequential approaches may be stepwise or contingent; both release high-risk screen results in the first trimester. Further screening is done in the second trimester for all (in the stepwise approach) or only a proportion of the women (in the contingent approach)[22,23] (Table 3-7). Either sequential approach maintains a, low screen-positive rate with (<5.0%) with a detection rate for Down syndrome above 90%. Currently, the American College of Obstetrics and Gynecology recommends offering women of all ages screening for aneuploidy in pregnancy, with initiation of screening in the first trimester optimal.[1]

Of fetuses with increased nuchal lucency but a normal karyotype, a majority proceed through gestation without complication. As the degree of first-trimester nuchal edema increases, however, the risk of other structural malformations detected on the second-trimester ultrasound or at birth also increases. Although a relatively low risk of 2.7% is present for fetuses with mild nuchal edema (nuchal latency 3.0 mm), risk reaches 35.6% for those fetuses with markedly enlarged nuchal translucency (7.0 mm).[24] Although many of the identified abnormalities are cardiac malformations, other disorders such as congenital diaphragmatic hernia, skeletal dysplasias, fetal akinesis, and metabolic storage disease also are reported.[25] Persistence of markedly increased nuchal edema into the second trimester represents perhaps the greatest risk, with almost one half (40.9%) of fetuses experiencing an adverse outcome such as structural malformation, hydrops, or in utero demise.[26] Conversely, for fetuses with mild increases (2.5-3.0 mm) in first-trimester nuchal fold, a majority continue through gestation without adverse outcome, and the risk for structural abnormalities or disability in the newborn period or early childhood is not significantly increased.[27]

DIAGNOSTIC TESTING

Although use of screening modalities for genetic disease and aneuploidy during pregnancy avoids the risk of miscarriage, none of the available tests provide a definitive answer. For diagnosis, fetal DNA needs to be studied; currently, appropriate samples can be obtained only through invasive testing: The placenta (CVS), amniotic fluid (amniocentesis), or fetal blood (percutaneous blood sampling [i.e., PUBS]) may be used. When patients are counseled regarding each of the diagnostic modalities, the miscarriage rate frequently is quoted, but other concerns such as fetal morbidity from the procedure and the likelihood of technical complications also should be considered.

Chorionic Villus Sampling

Available from 10 weeks of pregnancy onward, CVS currently affords the earliest diagnostic possibility. Trophoblast cells obtained from the placenta can be studied for specific genetic mutations as well as chromosome analysis. CVS is performed under ultrasound guidance with the passage of a catheter into the placenta, either transcervically or through the maternal abdomen. Based on large multicenter collaborative studies from the 1990s, with either transcervical or transabdominal CVS, an approximate 1.0% risk of miscarriage has been reported.[28] Concerns related to fetal morbidity include fetal infection (from maternal disease such as HIV), isoimunization, and fetal damage. With regard to fetal injury, initial reports of higher rates of limb reduction defects among newborns after first-trimester CVS sampling have been extensively investigated. At this time, the risk of such fetal complications is considered rare, 5.2 to 5.7 per 10,000 after CVS, compared with 4.8 to 5.97 per 10,000 without CVS.[29] Technical concerns also have surfaced with CVS. The procurement of the sample is technically different from an amniocentesis, and the learning curve is longer. In addition, with multifetal pregnancies, assurance of sampling each individual fetus is possible but can be more problematic than with amniocentesis. Finally, although both CVS and amniocentesis will provide information concerning the chromosomal makeup of the fetus, CVS also may detect aneuploidy, which is confined to the placenta. Occurring in approximately 1% to 2% of CVS samples, confined placental mosaicism reflects a combination of karyotypically normal and abnormal cells. In two thirds of the cases, the abnormal cell line is confined to the placenta, although further evaluation of the fetus by amniocentesis or PUBS is warranted. An additional outcome associated with confined placental mosaicism is fetal growth restriction, which is likely to be dependent on the specific chromosome abnormality.[30]

Early Amniocentesis (at 9 to 11 Weeks of Gestation)

In order to provide diagnostic results in the first trimester, early amniocentesis was investigated. From 10 to 18 weeks of gestation, however, the amniotic fluid volume is rapidly expanding such that the removal of 20 mL at 11 weeks represents as much as a third of the total volume. The same 20 mL removed at 18 weeks represents less than 10% of the total volume. An initial trial to assess the safety of early amniocentesis was halted owing to an increased miscarriage rate.[31] When compared with CVS, early removal of amniotic fluid carries a significantly higher relative risk for miscarriage of 1.92 (95% confidence interval [CI], 1.14 to 3.23).[32] Additionally, increased fetal morbidity was noted, with a higher rate of clubfoot, which was unrelated to whether or not rupture of membranes had occurred.[33] Technical concerns also arose, with increased rates of culture failure, and efforts to decrease the amount of amniotic fluid removed were associated with an even greater chance of technical culture failure.

Standard Amniocentesis at 15 Weeks or Later

Removal of 15 to 20 mL of amniotic fluid in the second trimester is associated with a small risk of miscarriage. Collaborative studies in the 1990s noted a miscarriage rate of approximately 0.5% above the background rate. The definitive prospective, randomized study by Tabor in 1986 revealed a 1.0% risk of miscarriage above the background rate. This study was performed in low-risk women with both case and control groups of subjects of comparable gestational ages. In the amniocentesis and control groups, miscarriage rates between 16 and 24 weeks were 1.7% and 0.7%, respectively, with a relative risk of 1.72 (95% CI, 1.06 to 2.81). [34] More recently, analyses of data perhaps more reflective of the current practice of amniocentesis suggest that the loss rate may be less than that previously noted. Additionally, risk factors may be present that increase a particular woman's miscarriage rate after amniocentesis. When women with repeated miscarriages or bleeding in the current pregnancy are compared with women without these risk factors, increased odds ratios of 3.03 and 2.4, respectively, have been reported.[35] If such predisposing risk factors are considered, the risk of miscarriage in the woman without significant history is only minimally and not significantly increased above the background rate.[36]

Fetal morbidity after amniocentesis also should be considered. In pregnant women who are Rh-negative, the combination of an Rh-positive fetus and an invasive diagnostic test carries a small risk for fetal-maternal hemorrhage. For this reason, RhoGAM is given as a prophylactic measure to all Rh-negative women unless the partner is known to be Rh-negative and the woman declines RhoGAM. For women with other red blood cell antigen incompatibilities with their partners, any invasive diagnostic test increases the risk for antibody formation and the effects of isoimmunization in the fetus. These risks also exist for CVS, although they are theoretically lower, because amniocentesis can avoid the placenta. Similarly, infectious disease in the mother poses a theoretical risk. Transmission of hepatitis B in women who are chronic carriers does not appear to increase the risk for subsequent carriage in their infants. Likewise, although transmission of HIV through amniocentesis remains a theoretical possibility, testing by amniocentesis in women with low viral load is considered reasonable.

Fetal morbidity also is associated with rupture of membranes occurring after amniocentesis. In approximately 1% of procedures, the amniotic membranes do not promptly reseal, and amniotic fluid leakage occurs. In a majority of such instances (90%), the amniotic fluid will reaccumulate to normal levels, although the mean duration of the recovery period has been reported to be 3 weeks. Amniocentesis-related rupture of membranes with failure to reseal is associated with increased risk for intrauterine growth restriction and prematurity.[37] By contrast, spontaneous rupture of the membranes in the second trimester carries a poor prognosis, with only a limited chance of regaining normal fluid levels.

Technical issues arise with amniocentesis when the genetic diagnosis being pursued relies on molecular genetic studies. All amniotic fluid samples contain a small number of maternal cells, probably obtained as the needle passes through the maternal skin and uterus. When cultured amniotic fluid cells are evaluated, the chance of overgrowth by the maternal cells, with consequent assessment of the karyotype of the mother and not the fetus, is low. Nevertheless, when molecular diagnostic studies are initiated on direct, uncultured amniotic fluid, certainty that the fetal genome is being assessed is needed. This can be accomplished either by (1) clearing the initial 1 or 2 mL from the needle before obtaining the amniotic fluid sample or (2) simultaneous evaluation of maternal blood for additional polymorphic markers to ensure that the amniotic fluid sample represents a discretely different genome (maternal cell contamination study).

Percutaneous Umbilical Blood Sampling

Percutaneous umbilical blood sampling (PUBS) is performed at 18 weeks or later in gestation by the removal of a blood sample from the umbilical cord under ultrasound guidance. The procedure is accompanied by an approximate 1% to 2% risk of pregnancy loss, which is higher with fetuses with other risk factors such as hydrops. Nevertheless, PUBS can provide rapid and often more extensive information than that obtained by CVS or amniocentesis. Karyotype analysis yields results within 48 hours, because the rapidly dividing peripheral blood cells do not require the extensive, often 2-week period of culture needed for both CVS and amniocytes. Additionally, molecular genetic studies are possible on the extracted DNA as well as functional assessment of the bone marrow, immune system, and hepatic system. Fetal anemia can be diagnosed and treated by umbilical vessel transfusion in situations in which the hematologic suppression is expected to be transitory, such as parvovirus infection. Polymerase chain reaction (PCR) analysis for specific viruses such as parvovirus and cytomegalovirus also can be performed using fetal blood. Altered hepatic or bone marrow function may point to an underlying metabolic disease, guiding more specific molecular testing in the fetus.

NEW AVENUES FOR PRENATAL DIAGNOSIS

Preimplantation Genetic Diagnosis

After in vitro fertilization, directed assessment of a single cell from a blastocyst before transfer to the uterus—preimplantation genetic diagnosis (PGD)—can reveal single-gene disorders as well as chromosome abnormalities. For persons with a balanced chromosome translocation, single blastomeres can be studied with fluorescence in situ hybridization (FISH)—a method to determine copy number for specific, predefined segments of DNA in nondividing cells. With probe combinations designed for the specific translocation carried by the individual, couples proceed through assisted reproduction and in vitro fertilization. On day 3 after fertilization, single cells are removed from each blastocyst and assessed within 12 to 24 hours with the translocation-specific FISH probes. On completion of the FISH analysis, the information obtained is used to guide selection of blastocysts to transfer to the woman. This methodology also allows determination of chromosome copy number and was initially applied as preimplantation genetic screening (PGS) in women at increased risk related to increased maternal age, previous anueploidy, or repeat miscarriage. Development of the optimal panel of probes remains challenging, because increases in the number of chromosomes studied are associated with higher technical error rates and the potential for eliminating from

consideration for transfer a blastocyst that may indeed be chromosomally normal.[38] As currently performed, PGD is a screening method to decrease the chance that the pregnancy will be complicated by a chromosome abnormality but does not improve outcomes for women of advanced age or habitual miscarriage. Application of CGH array technology may be helpful in this area.

Various factors can contribute to the approximate 10% error rate, including the lack of possibility of retesting owing to use of a single cell, the existence of mosaicism in the early blastocyst, and the inherent technical difficulties of resolution with FISH probes. Approaches using a molecular approach to chromosome number (such as microarray or PCR methods) are likely to address this concern in the future.

Similarly, individual patients or couples at risk for a single-gene disorder that is inherited in either a recessive or dominant fashion may be candidates for PGD. As the technology continues to progress and the accuracy of PGD improves, current indications range from diagnosis of autosomal recessive disorders associated with childhood lethality to autosomal dominant disorders of adult onset. Uses of PGD that represent areas of ethical controversy in this field are screening for cancer genes, human leukocyte antigen (HLA) matching for an affected sibling, and family balancing.

Cell-Free Fetal DNA

In the late 1990s, Lo and colleagues identified the presence of cell-free fragments of fetal DNA (cff DNA) in the circulation of pregnant women.[39] As opposed to the earlier search for fetal cells in the maternal circulation, methods for retrieving cff DNA are proving to be reproducible and sensitive in numerous laboratories. Additionally, cff DNA has the advantage of rapid clearance from the maternal circulation, with essentially none remaining within hours of the infant's delivery.

Applications for this methodology initially focused on settings in which the paternal and, potentially, the fetal genotypes differ from the mother's. The primary example of such a condition is Rh isoimmunization. Because the mother's genotype is Rh-negative, the presence of any Rh-positive DNA in her circulation denotes a fetus with the Rh-positive gene from the father and for whom the risks of isoimmunization exist.[40] The methodology is reproducible and sensitive such that cff DNA is used in the management of Rh disease. When a woman is isoimmunized to Rh antigen and produces antibodies, the Rh status of the fetus becomes an important piece of information in the management of this disease. An Rh-negative fetus would not require the extensive surveillance and testing indicated for the Rh-positive fetus with other risk factors.[41] Before the advent of cff DNA, fetal Rh status could be established only by determining the genotype of the fetal cells, typically obtained by amniocentesis. Further studies are under way assessing cff DNA for RhD as a component of determining which women should receive RhoGAM. Additional uses of cff DNA for aneuploidy assessment and determination of other molecular genetic disorders will follow as specific markers for differentiation of fetal DNA from that of the mother emerge.[42] Knowledge of quantitative alterations in cell-free nucleic acids in the maternal circulation as a reflection of placental integrity is growing and is likely to form the basis for important tools for the presymptomatic assessment of a range of pregnancy complications such as preeclampsia.[43]

SUMMARY

Prenatal genetic diagnosis currently is possible only by means of invasive procedures, with their inherent risk of miscarriage as well as fetal morbidity and technical constraints. CVS, amniocentesis, and PUBS each can provide the fetal DNA needed for the assessment of a wide range of genetic and chromosome disorders. However, although the risks from any one of these procedures is relatively low, preconception and prenatal screening to identify which women face an increased risk of genetic disease is appropriate. Clinical history including parental ages, reproductive history, and family history each have value in screening for genetic and chromosome risks. During pregnancy, both maternal serum markers and ultrasound examination are productive screening tools used primarily to assess Down syndrome risk. Ideally, such screening should be initiated in the first trimester. Finally, new methods of prenatal diagnosis are emerging. Most important, further developments in the assessment of cell free fetal DNA will allow prenatal genetic diagnosis from a maternal blood sample and remove the need for more invasive testing.

4 Basic Embryology

David L. Bolender and Stanley Kaplan

The human embryo begins as a single large cell, approximately 0.1 mm in diameter, just visible to the unaided eye. During the 266 days of gestation following fertilization, this cell increases in size, weight, and surface area in a rapid and markedly nonlinear fashion. From newly fertilized egg to newborn, length increases by a factor of 5000, surface area by a factor of 61 million, and weight by a factor of nearly 6 billion.[1] During this process the fertilized egg divides and differentiates into more than 200 different morphologically recognizable cell types. Orchestration of the increase in size and specialization in cellular function is a complex process about which much remains unknown. It has been argued, however, that the principles of development have been established and that details are missing only at the molecular level.[2] This claim is undoubtedly an overstatement; nevertheless, during the last decade or so, understanding of the molecular control of development has increased substantially. That human embryonic development occurs normally in most pregnancies is a tribute to the design of the control mechanisms that are operating. This chapter presents a brief description of the growth and differentiation of the human embryo, along with a limited discussion of certain factors that play a part in control of these activities.

GAMETES AND THEIR MATURATION

The human egg and sperm are two highly specialized cells that share little in common with the other cells of the adult body. They are different in both form and function. Like other cells, however, they must achieve a degree of maturity before they can perform their function (i.e., combining to form the zygote). The steps as well as the chronology leading to this maturation are quite different in the male and in the female, and such differences reflect the diverse pathways of the two sexes beginning early in human development.[3]

Origin of the Gametes

The human egg and sperm are derived from large, round primordial germ cells that can be identified in the wall of the yolk sac as early as 24 days after fertilization.[4] As the yolk sac begins to be incorporated into the embryo, the germ cells migrate along the dorsal mesentery of the hindgut to the gonadal ridges, which they reach by the end of the fourth or early fifth week (Figure 4-1). This migration has been observed in vitro in pieces of hindgut, mesentery, and gonadal ridges of mouse embryos.[5] It is facilitated in humans by a striking ameboid shape (which persists even after the cells have reached the gonad[6]) and pseudopodia typical of those found in ameboid cells. The pseudopodia disappear later after the migration is complete.[5,7] In humans, these cells contain glycogen stores that diminish over time and disappear when the cells have reached their destination in the gonad, suggesting that the glycogen may be the energy source for their journey.[8]

Organization of the Gonad

The coelomic epithelium covering the medial aspect of the gonadal ridges undergoes proliferation about week 7 of gestation. As these cells multiply, they grow into the underlying mesenchyme in a series of fingerlike cords of cells called primitive sex cords. The primordial germ cells associate with these cords. If the embryo is to become a male, these cords continue to be prominent and eventually develop into the seminiferous tubules and rete testis. The early male gonad can also be recognized by the separation of the cords from their parent epithelial covering by a fibrous connective tissue layer, the tunica albuginea, that forms just under the epithelium. If the gonad is to become an ovary, the primitive sex cords remain rudimentary. The origin of the follicle cells of the ovary remains unclear, but likely candidates are cells from the coelomic

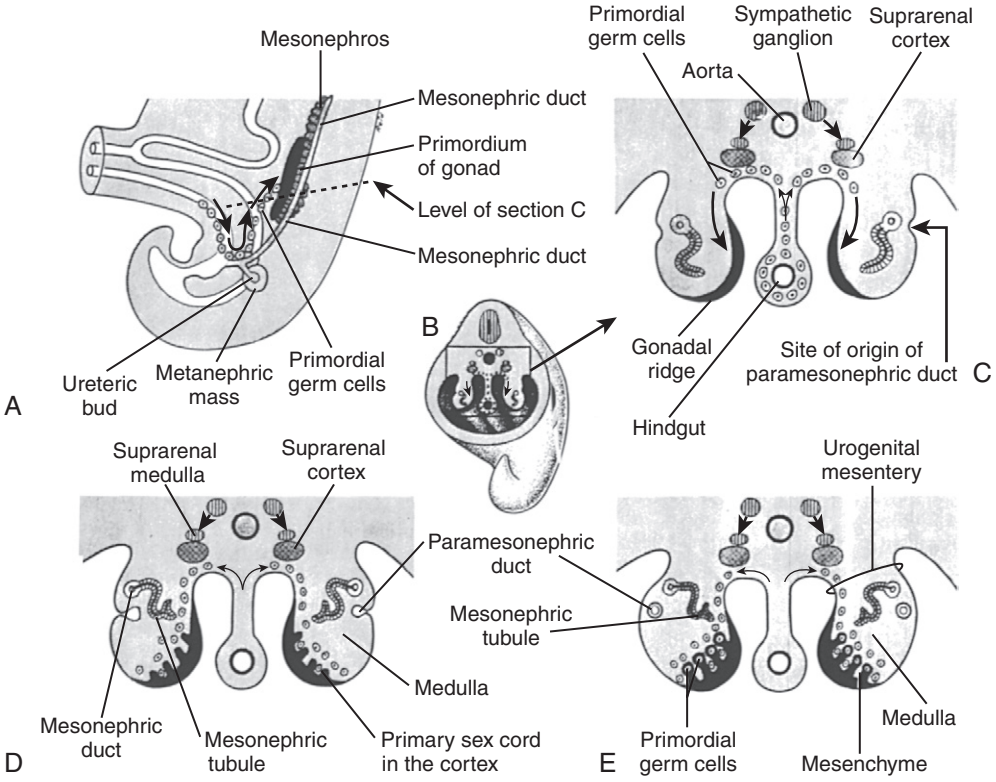

Figure 4-1 **A,** Sketch of a 5-week embryo, illustrating the migration of primordial germ cells from the yolk sac. **B,** Three-dimensional sketch of the caudal region of a 5-week embryo, showing the location and extent of the gonadal ridges on the medial aspect of the urogenital ridges. **C,** Transverse section showing the primordium of the suprarenal (adrenal) glands, the gonadal ridges, and the migration of primordial germ cells into the developing gonads. **D,** Transverse section through a 6-week embryo, showing the primary sex cords and the developing paramesonephric ducts. **E,** Similar section at a later stage showing the indifferent gonads and the mesonephric and paramesonephric ducts. *(From Moore KL, Persaud TVN: The Developing Human: Clinically Oriented Embryology, 5th ed, Philadelphia, WB Saunders, 1993, p 281.)*

epithelium and the mesonephros. The follicle cells associate with the primordial germ cells to form primordial ovarian follicles.[8]

Development of the Female Gamete (See Chapter 184)

If the gonad develops into an ovary, the primordial germ cells become oogonia and continue mitotic division.[9] Mitotic division of these cells has been observed in humans up to the seventh fetal month[10] but ceases sometime shortly before birth. No oogonia form subsequent to the birth of the infant after a normal full-term pregnancy.

In both males and females, the germ cells form a syncytium while dividing.[11,12] These intercellular connections permit communication and facilitate the high degree of synchrony that has been observed during both mitotic and meiotic divisions.[13-15]

By the eighth or ninth week after fertilization, some oogonia enter prophase of meiosis I and become primary oocytes.[9-16] Meiosis begins first deep to the surface of the human ovary and then expands toward the surface. Thus, at an appropriate fetal stage, oogonia are found superficially, oocytes deep to the surface, and small follicles at the inner part of the ovarian cortex.[9] It has been suggested that a diffusible meiosis-activating substance is secreted by rete cells (derived from the mesonephros), which lie in the center of the ovary, and good experimental evidence is available to support this hypothesis.[17-20]

The oocyte goes through the leptotene, zygotene, and pachytene stages of meiosis I, and it then arrests at the diplotene stage. At this point the oocyte becomes surrounded by a single, incomplete layer of flat follicular cells[9]; this unit is called a *primordial follicle.* The follicle's large central nucleus is known as the germinal vesicle. A crescent-shaped assembly of cellular organelles containing mitochondria, endoplasmic reticulum, the Golgi complex, lysosomes, and annulate lamellae (stacked parallel membrane arrays with pores) remain clustered adjacent to the nucleus.[15,21] Once it has been incorporated into a primordial follicle, the oocyte enters a long period of quiescence, beginning before birth in humans and ending in either atresia or ovulation.

Once sexual maturity is attained, a small number of oocytes begins the process of folliculogenesis or follicle maturation during each menstrual cycle.[22] The oocyte grows and eventually becomes one of the largest cells in the human body.[23] The organelles disperse throughout the cytoplasm and the germinal vesicle (nucleus) enlarges. It increases its complement of nuclear pores, facilitating transport of molecules between nucleoplasm and cytoplasm. The follicular cells resume mitosis and increase markedly in size, changing in shape from squamous to cuboidal, and the follicle becomes surrounded by a basement membrane. Those follicles containing an oocyte surrounded by a single layer of cuboidal follicular cells are known as unilaminar primary follicles, to distinguish them from earlier or later stages.[3]

During further growth of the primary follicle, a thick, acellular coat, the *zona pellucida,* begins to form between the oocyte and the follicular cells. Mitotic activity increases the number of follicle cell layers, and the follicle is now called a multilaminar primary follicle. The expanding follicle compresses the surrounding ovarian stoma, which organizes into a compact layer adjacent to the basement membrane of the follicle. This layer of stromal cells is called the theca interna, and its cells have the capacity to produce androgens when stimulated by luteinizing hormone activity (Figure 4-2). The theca interna is vascularized, but the epithelial layers of follicle cells remain avascular.

The zona pellucida is important in the process of fertilization because it contains sperm receptors, takes part in induction of the acrosome reaction, and becomes a block to polyspermy. It also may act after fertilization as a smooth, slippery envelope to contain the sticky ball of cells of the morula-stage embryo; these are free to adhere to the uterine endothelium when the zona breaks down, just before implantation.

The zona pellucida is made up of three separate filamentous glycoproteins, ZP1 through ZP3, which differ in molecular weight and isoelectric point and account for virtually all protein in the zona pellucida. ZP1 cross-links these filaments, resulting in a three-dimensional matrix that is permeable to large macromolecules. ZP3 serves as a species-specific sperm receptor and also

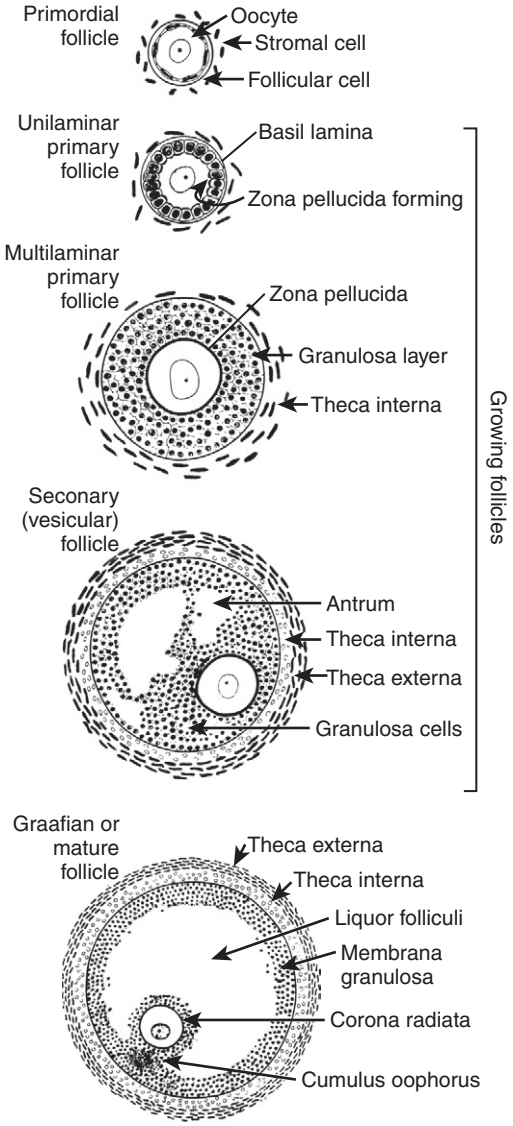

Figure 4-2 Schematic drawing of development of ovarian follicles, starting with the primordial follicle and ending with mature follicles. *(From Junqueira LC, et al:* Basic Histology, *7th ed, Norwalk, CT, Appleton & Lange, 1992.)*

induces the acrosome reaction in sperm at contact. At or shortly after fertilization, these two characteristics are lost, reducing the likelihood of polyspermy.[24-26] The ZP3 gene has been cloned; it is expressed only in oocytes, and then only during the growth phase of oogenesis.[27] The human genes for ZP2 and ZP3 are located on chromosomes 16 and 7, respectively,[28] but the location of ZP1 remains unknown. The interesting story of these zona pellucida proteins has been the subject of a popularized account[29] as well as several reviews.[28,30,31] Radiolabeling studies in mice indicate that all three glycoproteins are synthesized by the oocyte itself, rather than by the follicular cells.[32] Furthermore, immunofluorescence studies show that zona pellucida antigens are present within human oocytes but not in follicular cells.[33] Studies in species other than the mouse, however, suggest that the granulosa cells that surround the oocyte also may play a role in the synthesis of zona pellucida components.[30]

Numerous cytoplasmic projections of the follicular cells penetrate the zona pellucida to contact the cell membrane of the oocyte. In humans, these filopodial extensions of the follicular cell may actually lie deeply buried in the oocyte, in straight invaginations or pits.[34] These pits are lined by the oocyte cell membrane; however, no cytoplasmic continuity exists between the two cell types. Animal studies have demonstrated the presence of gap junctions along the association of these two cell membranes, permitting transfer of small molecules (molecular weight of approximately 1000) between them.[22]

As the primary follicle enlarges, the follicular cells begin to produce follicular fluid, which collects within the intercellular spaces between follicle cells. These spaces coalesce to form a large fluid-filled cavity called the antrum, which is characteristic of the secondary (vesicular) follicle. The antrum expands, and the oocyte becomes located on one side of the follicle, where it is embedded within a mound of follicle cells known as the cumulus oophorus. The layers of follicular cells immediately surrounding the oocyte are termed the corona radiata. Because of its increased size, the follicle further compresses the surrounding ovarian stroma. A looser, less organized layer of flattened stromal cells encircles the follicle superficial to the theca interna. This is called the theca externa, and its cells have no steroid-secreting activity (see Figure 4-2). A few days before ovulation, one secondary follicle becomes dominant and inhibits the growth of the remaining secondary follicles. The dominant follicle, now called a *graafian follicle,* can reach several centimeters in diameter. The oocyte is approximately 100 μm in diameter at this stage. Approximately a day before ovulation, its nuclear membrane breaks down, the nucleolus disappears, and the first polar body forms, containing one of the two sets of chromosomes. Meiosis I is completed, and the oocyte proceeds to meiosis II, but it again arrests on reaching metaphase. In most mammalian species including humans, meiosis II resumes only after the oocyte is penetrated by a sperm.[35,36] Completion of meiosis in the fertilized oocyte results in production of the second polar body.

Follicles of any stage can undergo atresia. Atresia begins in the fetus and continues into menopause until all follicles have disappeared. At birth, approximately 2 million primordial follicles are present within the two ovaries. It has been estimated that half of the 2 million follicles present at birth are atretic at that time.[10] In humans, follicular growth starts before birth, and the newborn ovary contains multilaminar primary follicles as well as primordial follicles. Follicular growth and subsequent atresia are continuous during human childhood, and it has been clearly stated that "quiescent ovaries in which follicular growth is absent do not occur in normal children."[37]

Little is known about control of atresia. For example, it is not known whether atresia is initiated by action of the follicular cells, by that of the oocyte, or by both.[22] The process of atresia, however, can be manipulated experimentally.[37] Approximately 40,000 follicles are present in the two ovaries of a young adult woman, indicating a reduction to 2% of the pool originally present at birth.[38]

These stages, up to and including the newly fertilized mature ovum, are summarized in Table 4-1. Most or all of the RNA and protein found in a mature oocyte are synthesized during oocyte growth. Those macromolecules present in the oocyte of an atretic follicle are degraded and the degradation products subsequently used for new synthesis.[23]

As estimated from an assumed fertility span of 30 years, approximately 400 eggs are shed during a woman's lifetime.[35] Thus, approximately 1 in every 100 of the eggs present in a young adult completes maturation and is ovulated; the rest degenerate. A human female has her full complement of eggs, albeit immature, on the day she is born. This is not the case for sperm development in males.

Early Development of Male Gametes (See Chapter 185)

In male humans, the primordial germ cells migrate into the gonadal ridges as outlined earlier (see Figure 4-1). Once they have reached the gonad, they divide to form a pool of spermatogonia.[39]

TABLE 4-1

Summary of the Developmental Characteristics of the Human Female Germ Cell

Name	Approximate First Recognizable Time (Postfertilization)	Location	Approximate Total Number (Both Ovaries)	Size, Shape, Characteristics	Relevant Study(ies)
Primordial germ cell	During 4th week	Caudal yolk sac, among endoderm cells	500	Large, round, 15-20 μm in diameter	Witschi, 1948[4]; Fujimoto et al, 1977[7]
	During 5th week	Dorsal mesentery of hindgut and gonadal ridges	500	Ameboid shape, migrating, with pseudopodia; >20-30 μm in long axis; alkaline phosphatase–positive	Witschi, 1948[4]; Fujimoto et al, 1977[7]
Oogonium	During 6th week	Sexually indifferent gonad	100,000	Rapid mitosis increases numbers (mitosis signals name change)	Witschi, 1948[4]; Byskov, 1980[9]
	During 7th week	Gonad recognizable as ovary	100,000	Mitosis continues; almost all primordial germ cells are now in the gonad	Fujimoto et al, 1977[7]; Moore and Persaud, 1998[38]
Oocyte (in primordial follicle)	Weeks 8-9	Ovary	?	Meiosis begins; ~19 μm diameter	Dvorak and Tesarik, 1980[16]
Quiescent oocyte in primordial follicle	16 weeks	Ovary	?	Arrest of meiosis I at diplotene; 50-70 μm; round to ovoid; vitelline body present	Baca and Zamboni, 1967[34]
	2 months	Ovary	600,000		Baker, 1963[10]
	5 months	Ovary	6,800,000		Baker, 1963[10]
	7 months	Ovary		Mitosis of oogonia ceases	Baker, 1963[10]
	Birth	Ovary	2,000,000 (50% atretic)		Baker, 1963[10]; Moore and Persaud, 1998[38]
	7 years	Ovary	300,000		Baker, 1963[10]
Primary to mature (graafian) follicles	Puberty on	Ovary	40,000 and declining	From oocyte to mature: comes out of meiotic arrest and enters metaphase of meiosis II, then arrests again	Moore and Persaud, 1998[38]
Mature ovum	Puberty on	Uterine tube	1 per month	Meiosis is completed and the 2nd polar body is extruded when penetrated by a sperm	Moore and Persaud, 1998[38]

Both spermatogonia and their supporting cells—the Sertoli cells—can be identified as early as 48 days after fertilization.[40] The germ cells and the supporting cells combine to form seminiferous tubules.

Spermatogonia are located next to the basement membrane of the seminiferous tubule, where they lie quiescent until puberty. Experimental studies with mice have shown that male primordial germ cells are kept in that state by a meiosis-preventing substance, which also can arrest female germ cells in meiosis. Conversely, the female gonad secretes a meiosis-inducing substance, which can induce male germ cells to enter meiosis.[19]

At puberty, the spermatogonia begin differentiation into sperm (spermatogenesis). The process of spermatogenesis occurs in three phases. In the first phase, the spermatogonia divide mitotically. In the second phase, some spermatogonia differentiate into primary spermatocytes and undergo meiosis. In the third phase, spermatids proceed through spermiogenesis to form spermatozoa. In contrast with the female, the cycle of differentiation of gametes in men is essentially continuous throughout life. Studies in which tritiated thymidine was injected into healthy male volunteers indicate that the complete cycle takes approximately 74 days.[41] The various stages of spermatogenesis, however, are not synchronized along the length of the coiled seminiferous tubule in humans: Different stages are found at different positions.

FERTILIZATION

Development begins with the fusion of the male and female gametes at fertilization, which takes place in the distal third of the oviduct. Although fertilization is an "internal" process in humans and other mammals, the development of culture systems that support fertilization has made detailed study of the sperm-oocyte interaction possible, as well as providing a basis for in vitro fertilization for clinical ends. As a result, the precisely ordered events comprising a "fertilization pathway" have been identified (Figure 4-3). The mechanisms involved in the fertilization pathway have been the subject of investigation at the molecular level.[29,31,42] Most studies on fertilization have been done using mice, but comparative data suggest that the pathway is similar in all mammals, including humans.

The pathway of fertilization begins with binding of the sperm to the surface of the zona pellucida (see Figure 4-3). On the surface of every sperm are thousands of copies of an egg-binding protein; these are recognized by thousands of copies of sperm receptors on the zona pellucida.[43] Binding is relatively species-specific and requires a complete plasma membrane (i.e., an acrosome-intact sperm).[44,45] Once bound to the zona surface, the sperm undergoes a series of dynamic membrane fusions known as the acrosome reaction (see Figure 4-3).[46] During this phase, the plasma membrane at the apical end of the sperm fuses with the outer membrane of the acrosome, forming a series of membrane-bound vesicles. These are eventually sloughed, which exposes the inner acrosomal membrane and its complement of enzymes.[31,47]

As a result of enzyme modification of the zona, the sperm is able to tunnel its way through. The first sperm to penetrate the perivitelline space (between the zona pellucida and the oocyte plasma membrane) and fuse with the plasma membrane triggers activation of the egg (see Figure 4–3). Oocyte activation is a dynamic, multistep process that includes mechanisms to prevent polyspermy, completion of meiosis by the oocyte, engulfment of the sperm, formation of male and female pronuclei and initiation of the first mitotic division of the embryo. Prevention of fertilization by more than one sperm (polyspermy—a potentially lethal condition) is thought to be a biphasic reaction, although the first phase is not well documented in humans. The first phase is rapid and consists of hyperpolarization of the oocyte plasma membrane. The second phase may take several minutes and involves the release of enzymes from the cortical granules that alter the structure of the zona pellucida. As a result, the plasma membrane and the zona pellucida become refractory to further penetration by other sperm.

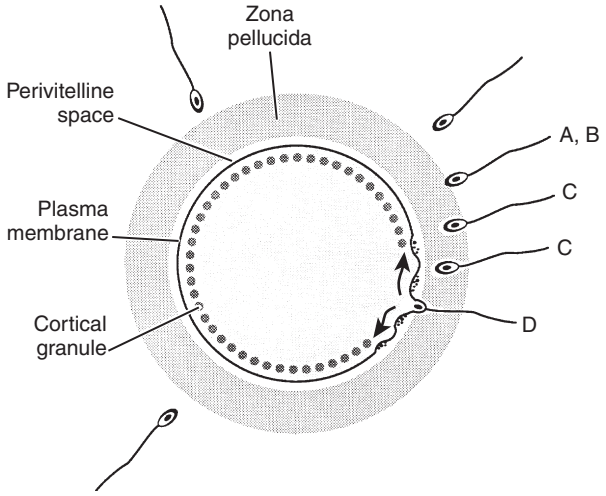

Figure 4-3 Pathway of fertilization. *A* and *B* show sperm binding and the acrosome reaction, exposing the zona to acrosomal enzymes. *C* depicts penetration of the enzyme-modified zona pellucida by the sperm. *D* shows activation of the egg, including oocyte membrane hyperpolarization and release of enzymes by the cortical granules. *(Modified from Wassarman PM: Fertilization in Mammals,* Sci Am *259:82, 1988.)*

Studies at the molecular level have revealed that a component of the zona pellucida is a key substance in the fertilization pathway. As mentioned earlier, the zona pellucida is an acellular coat that surrounds the oocyte and consists of three glycoproteins—ZP1, ZP2, and ZP3—arranged in an interlacing filamentous network.[43,48] Of interest, one of them, ZP3, functions as the sperm receptor, initiates the acrosome reaction, and participates in the zona reaction.[48] Sperm binding is mediated by a subset of the *O*-linked oligosaccharides associated with ZP3, whereas a segment of the polypeptide backbone is needed to induce the acrosome reaction.[29,49]

Several important events necessary for development of the embryo—initially called a *zygote* after fertilization—are accomplished as a result of fertilization.[38] First, the diploid chromosome number is restored by fusion of the two haploid gametes. Normally, half of the chromosomes come from each parent, and the new complement of chromosomes in the zygote promotes species variation. In addition, the genetic sex of the zygote is determined by the type of sperm that participates in fertilization. Sperm that bear a Y chromosome produce a genetically male zygote (XY), whereas an X-bearing sperm produces a female zygote (XX). Finally, fertilization initiates cleavage, the mitotic division of the zygote. Apposition of the male and female pronuclei forms a metaphase plate, and the first cleavage soon begins. In contrast with some animal species, the human male and female pronuclei never fuse (i.e., form a complete nucleus). Instead, they immediately enter mitotic metaphase.[50]

Parthenogenesis is activation of the unfertilized oocyte, leading thereafter to varying degrees of successful development of the zygote and embryo. In some animal species, this process is well known to occur and may even produce viable offspring. No verified human cases, however, have been reported in the scientific literature.[38]

MORPHOGENESIS

The mechanisms mediating the transformation of a fertilized oocyte into a three-dimensional embryo are complex and still not completely understood. Studies on human embryos have been, for the most part, limited to observations of static images or serial reconstructions on preserved specimens of different developmental stages. Therefore most knowledge of the mechanisms controlling development has come from animal studies.

During development, cells of different genetic backgrounds are constantly interacting with each other and with a variety of molecules within their extracellular environment. The processes involved in these interactions consist of many well-recognized phenomena of cell biology, including cell division, adhesion, secretion, cytodifferentiation, motility, and cell death. Although the complex interactions that occur during morphogenesis may appear to be unorganized, they are recognized to occur not stochastically but rather in a precisely ordered sequence of events resulting in recognizable patterns of histogenesis and organogenesis. In the past decade, an abundance of molecular studies have provided a much clearer picture of the complex signaling activity that controls embryonic development.[8]

As a result of fertilization, the zygote undergoes a series of mitotic divisions termed *cleavage.* The cells derived from these repeated mitotic divisions are called *blastomeres.* The first divisions result in a solid mass of blastomeres that are still surrounded by the zona pellucida. Starting at the 8- to 16-cell stage, intercellular spaces between blastomeres coalesce to form a central cavity. The embryo, now termed a *blastocyst,* consists of a regionalized clump of cells termed the *inner cell mass,* that projects into the blastocyst cavity and is surrounded by an outer layer of trophoblast cells (Figure 4-4, *A* and *B*). Initially the blastocyst floats freely within the uterine cavity. After shedding the zona pellucida, the blastocyst attaches and implants within the uterine endometrium.[38]

Studies on embryos suggest that the earliest cleavage divisions appear to be driven by maternal messages stored within the oocyte cytoplasm.[51] In mammals (including humans), the embryonic genome is activated by the two- to four-cell stage and begins to synthesize proteins on its own. This functional maturation is reflected in the steady rise in the synthesis of many intracellular proteins such as actin.[52-54]

During cleavage, several changes fundamental to embryonic development occur at the molecular level. One of the most important processes is the generation of cell diversity. Initially, all blastomeres express a specific transcription factor, oct-4, which reflects the undifferentiated state of these cells. If separated from the others at this stage, each of the blastomeres has the capacity to form a complete embryo. By the 8- and 16-cell stage the embryo is a solid mass of cells called a *morula.* At this time, the outer cells of the morula are distinguishable from the inner cells because the outer cells no longer express oct-4.[8] The outer cells, now designated the *trophoblast,* also begin to exhibit epithelial polarity.[55] As a result, the first embryonic tissue (trophoblast epithelium) is formed. Subsequent cytodifferentiation of the trophoblast results in a double-layered membrane, which is a progenitor tissue of the chorion, the fetal portion of the placenta (see Figure 4-4, *C*). The inner cellular layer is called the *cytotrophoblast,* and the outer layer the *syncytiotrophoblast.* The latter structure, which secretes human chorionic gonadotropin (hCG) and proteolytic enzymes, is critical to implantation.[38]

During the second week of development, the cells of the inner cell mass that face the blastocyst cavity become flattened, forming a second layer of epithelium.[38] The upper layer, located next to the trophoblast, is now designated the epiblast, whereas the bottom layer of flattened cells is called the primary endoderm or hypoblast (see Figure 4-4, *C*). Cells of the epiblast become organized into an epithelial disk, the progenitor of all embryonic tissues, as well as the extraembryonic mesoderm, amnion, and yolk sac.[53] The cells forming the extraembryonic mesoderm apparently arise from the presumptive caudal end of the epiblast and coat the internal surface of the cytotrophoblast.[56] The extraembryonic mesoderm combined with the trophoblast constitutes the chorion. Even at this early stage of development, it is possible to determine that the surface of the epiblast adjacent to the trophoblast represents the dorsal side of the embryo.[57]

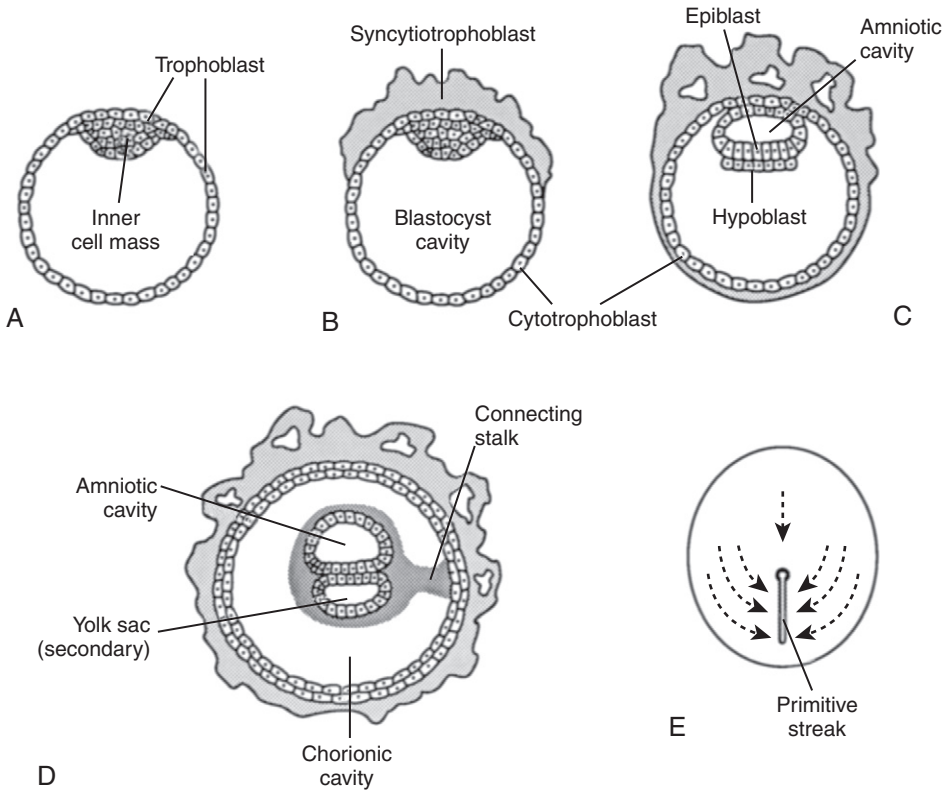

Figure 4-4 Development of the blastocyst embryonic disk. **A,** Blastocyst stage human embryo, exhibiting the inner cell mass as a regionalized mass of cells projecting into the blastocyst cavity. The cavity is surrounded by trophoblast cells. **B,** Slightly older blastocyst than that seen in **A.** At this time, the inner cell mass and trophoblast cells are capped by cells of the syncytiotrophoblast, which are buried in the endometrial stroma (not shown). The cellular layer of trophoblast is now called the cytotrophoblast. **C,** An older blastocyst stage human embryo. The cavity is now surrounded by a double-layered membrane, and the inner cell mass has developed into a bilayered embryonic disk capped by a cavity (amniotic cavity). **D,** This somewhat older, completely implanted embryo now exhibits cavities both above and below the embryonic disk, the amniotic cavity, and the yolk sac. No axial features are present in the disk at this time; cephalic and caudal regions cannot be discerned. **E,** Surface view of the embryonic disk, showing the primitive streak. This midline thickening of epiblast cells occurs during the early part of the third week after fertilization and produces a landmark (the primitive streak) that delineates the midline of the embryo and reveals the future cephalic and caudal ends. The thickening of epiblast cells in the midline (primitive streak) is actually an increased population of cells in this region, resulting from both a high mitotic rate in the midline and migration of a subpopulation of epiblast cells to a midline position. The *arrows* indicate migration of the epiblast cells.

Rearrangement of some of the epiblast cells results in the formation of a small amniotic cavity.[58] It is unclear whether the amnion is derived from epiblast cells adjacent to the newly formed cavity[58] or from the cytotrophoblast.[59] Primary endoderm cells of the hypoblast proliferate and migrate onto the inner surface of the cytotrophoblast, forming the yolk sac or umbilical vesicle.[60] Therefore, by the end of the second week of development, the embryo consists of a circular bilaminar disk located between two fluid-filled cavities (see Figure 4–4, *C* and *D*). At this time, no axial features are visible within the embryonic disk.

At the outset of the third week of development, dynamic cell movements result in extensive rearrangement of the epiblast cells. In most species, this period, called *gastrulation,* is characterized by morphogenetic movements and the changes resulting from them. A midline thickening of the now elongated epiblast becomes visible, designating the future posterior end of the embryo.[53] This thickening is the *primitive streak* (see Figure 4-4, *E*). Cellular activity at the streak results in another fundamental process of morphogenesis, epithelial-mesenchymal transformation. This process begins when some epiblast cells enter the streak while others remain within the epiblast to become the embryonic ectoderm.[61] The transformation from epithelium to mesenchyme consists of a cascade of cellular dynamics, including loss of intercellular connections, cell shape changes, and eventual freedom from the confines of the epiblast. Thus, at the primitive streak, subsets of polarized epithelial cells within the epiblast transform into nonpolarized free cells termed *mesenchyme,* the second embryonic tissue. These events are thought to be mediated by modulation of adhesive molecules located on the cell surface,[62] as well as by cytoskeletal rearrangements. In addition, variable expression of homeobox genes as well as of many other signaling molecules also occurs during gastrulation,[8] leading to patterning of axial and nonaxial structures

The primitive streak provides a means by which subsets of epiblast cells can ingress and be distributed to more ventral regions of the embryo as the endoderm and the mesoderm.[61] The first cells through the streak probably represent the definitive embryonic endoderm. These are followed by a solid cord of cells, the notochordal process, which extends cranially from the streak. These cells form the notochord, which defines the axis of the embryo and plays a significant role in the induction of the nervous system. Studies suggest that the notochord is an important signaling center for organizing the embryo. It secretes several important morphogenetic signaling molecules such as retinoic acid and Sonic hedgehog.[8,62] Another important signaling center, the prechordal plate, forms just cranial to the notochord. The prechordal plate is an important organizing center for the head of the embryo.[8] Just cranial to the prechordal plate, the endoderm fuses to the to the

overlying ectoderm. This region of fused ectoderm and endoderm is the site of the future mouth.[63] The remainder of the cells that pass through the streak become the intraembryonic mesoderm and come to lie between the endoderm and the ectoderm. Thus, the primitive streak provides the embryo with a means to organize epiblast cells, perhaps already partially fate-specified, into three primary germ layers—ectoderm, mesoderm, and endoderm.

As a consequence of cleavage and gastrulation, subpopulations of cells in various states of determination are brought together in new spatial relationships, which permits new tissue interactions. Subsequent histogenesis and organogenesis are driven by these tissue interactions, defined as the action of one dissimilar group of cells on another, resulting in the alteration of cell behavior of one of the component groups in a developmentally significant direction.[64] Tissue interactions often result in induction in which signals from one cell group mediate the change in developmental direction of another group of cells that are competent to respond to the inductive signals. These interactions are mediated by a variety of signaling molecules such as growth factors, secreted factors, and transcription factors, produced by cells and often concentrated in the extracellular matrix.[8]

EMBRYOLOGY OF THE ORGAN SYSTEMS

The following brief account of the development of some of the major organs provides an overview of some of the complex processes that occur as the embryo is built from raw materials. It is an amazing and precisely timed process. That it happens properly in most conceptions is even more remarkable. For a much more complete account, several other excellent and current texts are recommended,[8,38,63] as well as appropriate chapters elsewhere in this book.

Nervous System (See Chapter 160)

The human nervous system begins to form approximately 18 days after fertilization,[64,65] making it the first of the organ systems to initiate development. It begins as a thickening of the ectodermal layer along the craniocaudal axis of the embryo in the area destined to become the cervical region (Figure 4-5, *B*). This thickening is the result of an increase in the height of the ectodermal cells as they change shape from cuboidal to tall columnar, as well as intercalatory movements within the local population of cells. The result is an oval or keyhole-shaped area of thickened ectoderm known as the *neural plate.* Two ridges of this neural plate on each side of the midline undergo accelerated growth giving rise to two longitudinal neural folds with a neural groove between. Before this folding, a mesencephalic flexure forms in the cranial portion of the neural plate.[63] This flexure demarcates the future prosencephalon, mesencephalon, and rhombencephalon. These neural folds increase in height, curve toward each other, touch, and fuse to form the rudiment of the neural tube midway along the embryonic axis (see Figure 4-5, *B*). This fusion then proceeds in both cranial and caudal directions, as if two zipper fasteners were operating simultaneously but in different directions.

The remaining unfused ends of the neural folds at each end of the embryo are called the *cranial* and *caudal neuropores* because the neural tube is open at these sites. The cranial neuropore closes on day 25 and the caudal neuropore on day 27 of development.[64,65] This folding and shaping of the neural tube occur through both intrinsic (cell cycle, cell shape) and extrinsic (proliferation of adjacent tissue) mechanisms.[66,67] Shortly after fusion of the neural folds in a given region of the embryo, the neural tube separates from the ectoderm and becomes buried in the mesenchyme below the surface.

During this process of neural tube formation, an epithelial-mesenchymal transformation occurs, resulting in formation of a group of cells derived from the crests of the neural folds. These

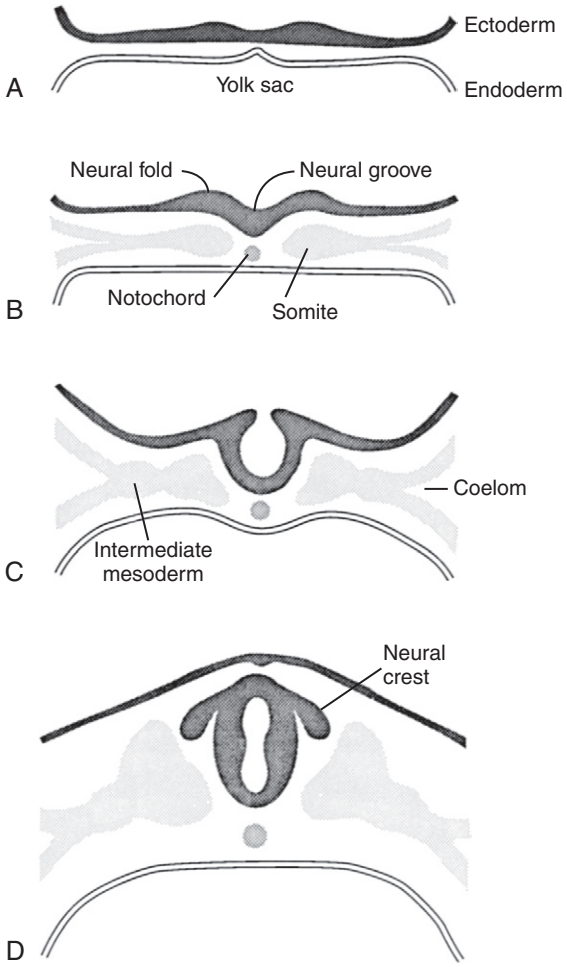

Figure 4-5 Development of the neural tube. Approximate ages: **A,** 15 days; **B,** 18 days; **C,** 20 days; **D,** 23 days. All sections are transverse, approximately midway along the embryonic axis. Note that although the neural tube is completely closed in the section shown in **D,** both the rostral and the caudal neuropores remain open in an embryo of this age. They do not close until near the end of the fourth week.

neural crest cells come to lie on the superolateral margins of the tube. The neural tube proper goes on to form the central nervous system, which consists of the brain and spinal cord, whereas the neural crest forms much of the peripheral nervous system, consisting of portions of autonomic, cranial, and spinal ganglia and nerves. The lumen of the neural tube becomes the central canal of the spinal cord and the ventricles of the brain.

Further Development of the Central Nervous System

The spinal cord develops from that part of the neural tube caudal to the cervical flexure, one of two unambiguous bends in an embryo about 30 days old that give the embryonic axis a C-shaped profile in lateral views (Figure 4-6). The wall of the tube thickens and soon stratifies into a ventricular zone that borders the central canal, an intermediate zone, and a marginal zone. The intermediate zone is created by migration of neurons from the ventricular zone. These neurons then send out processes that create the marginal zone, later to become the white matter of the cord.

Proliferation of the cells of these zones is greatly influenced by the somites, mesodermal structures that lie lateral to the neural tube along its craniocaudal axis. Later, the roof and floor of the neural tube become thin, while the lateral walls thicken. Studies

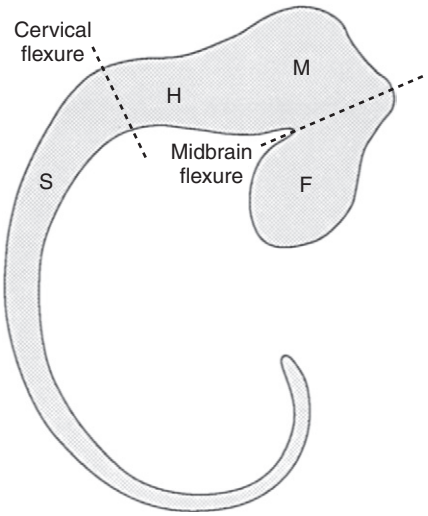

Figure 4-6 Lateral view of the isolated central nervous system of a 28- to 30-day embryo, showing the two flexures *(dotted lines)* and the resulting divisions of the brain and spinal cord at this age. *F,* Forebrain; *H,* hindbrain; *M,* midbrain; *S,* spinal cord.

in animals show that this particular organization around the circumference of the neural tube is under the influence of an inductive substance from the somites.[68] Experimental manipulation of the number, size, or position of somites influences the cross-sectional profile of the tube, including the keyhole-shaped profile of the neural canal (Figure 4-7).

The sulcus limitans is a groove that divides the more dorsal alar plate from the ventral basal plate. The former develops into the dorsal gray horns associated with sensory (afferent) input. The basal plate gives rise to the ventral and lateral gray horns, which function in motor (efferent) output. The floor plate secretes morphogenetic molecules (e.g., retinoic acid, Sonic hedgehog), which control the patterning of dorsal sensory and ventral motor elements.[8,69]

The spinal cord extends the entire length of the developing vertebral column during the embryonic period. The spinal cord grows more slowly than the vertebral column, however, so that in the fetal period and beyond, these two structures change position with respect to each other. At 24 weeks, the spinal cord extends caudally to the level of the first sacral (S1) vertebral body. In the newborn, it extends to the third lumbar vertebral body (L3), and in the adult to L1. This aspect of spinal development is important clinically with respect to lumbar punctures and other procedures that require knowledge about where the cord ends.

The brain is divided into forebrain (prosencephalon), midbrain (mesencephalon), and hindbrain (rhombencephalon) when the midbrain flexure appears (see Figure 4-6). These three divisions of the brain quickly become five by the partitioning of the forebrain into telencephalon and diencephalon and the separation of the hindbrain into metencephalon and myelencephalon. The formation of divisions and their adult derivatives are summarized in Table 4-2. Two distinct signaling centers apparently organize the cranial portion of the neural tube. One center organizes the forebrain and the other the hindbrain; each produces its own set of signaling factors. Another important source of signaling molecules for brain regionalization comes from the midbrain-hindbrain signaling center.[8]

The Eye (See Chapter 170)

At approximately 4 weeks of development, two outpouchings of the forebrain (diencephalon) expand laterally to form the optic vesicles (Figure 4-8, *A* and *B*), progenitors of the eyes. Inductive

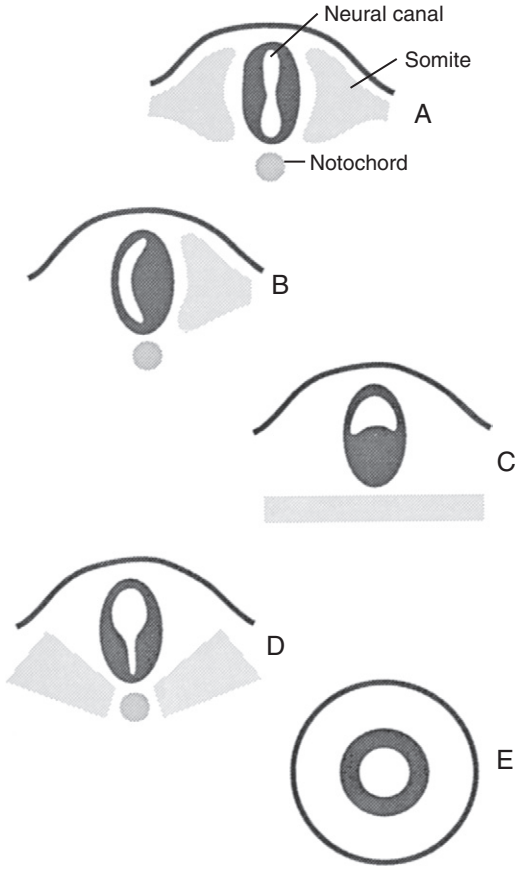

Figure 4-7 Influence of somite mesoderm *(lightly stippled areas)* **on neural tube and neural canal shape. A,** Normal. **B,** One somite removed. **C,** Somite mesoderm transplanted to the ventral surface of the neural tube. **D,** Somite mesoderm transplanted to the ventrolateral surface of the neural tube. **E,** Complete absence of somite mesoderm. *Clear areas* between structures contain non-somite mesoderm. *(Modified from Saxen L, Toivonen S:* Primary Embryonic Induction, *London, 1962, Logos Press.)*

interaction takes place between the optic vesicles and the head ectoderm, which lies closest to the vesicles.[70] The first manifestation of this interaction is the formation of a thickened plate in the head ectoderm, the lens placode (see Figure 4-8, *B*). At approximately the same time, the lateral surface of the optic vesicles begins to invaginate to form the double-layered optic cup. The lens placode also invaginates creating a lens pit (see Figure 4-8, *C*). The pit continues to deepen as it follows the profile of the increasingly concave optic cup. Finally the deeply pitted placode pinches off, forming the lens vesicle (see Figure 4-8, *D*). By this time point (approximately 30 days), the double walls of the optic cup appose each other; fusion of these two layers is completed during the fetal period. The inner layer forms the neural retina, and the outer becomes the pigment epithelium of the retina. The peripheral margin of the optic cup forms the iris and ciliary apparatus, whereas the optic nerve is formed from the optic stalk. Mesoderm surrounding the optic cup forms the inner vascular choroid and the fibrous outer sclera.

The Ear (See Chapter 171)

The inner ear begins to develop in the fourth week after fertilization as a recognizable thickening of surface ectoderm on either side of the myelencephalon, known as the otic placode (Figure 4-9, *A*). As with the lens vesicle, the placode invaginates to form

TABLE 4-2

Brain Vesicles and Their Derivatives

Early Division	Later Divisions	Wall Derivatives	Lumen Derivatives
Forebrain (prosencephalon)	Telencephalon	Cerebral hemispheres	Lateral ventricles, rostral part of 3rd ventricle
	Diencephalon	Epithalamus, thalamus, hypothalamus, pineal	Most of 3rd ventricle
Midbrain (metencephalon)	Mesencephalon	Midbrain	Cerebral aqueduct
Hindbrain (rhombencephalon)	Metencephalon	Pons, cerebellum	Superior part of 4th ventricle
	Myelencephalon	Medulla	Inferior part of 4th ventricle

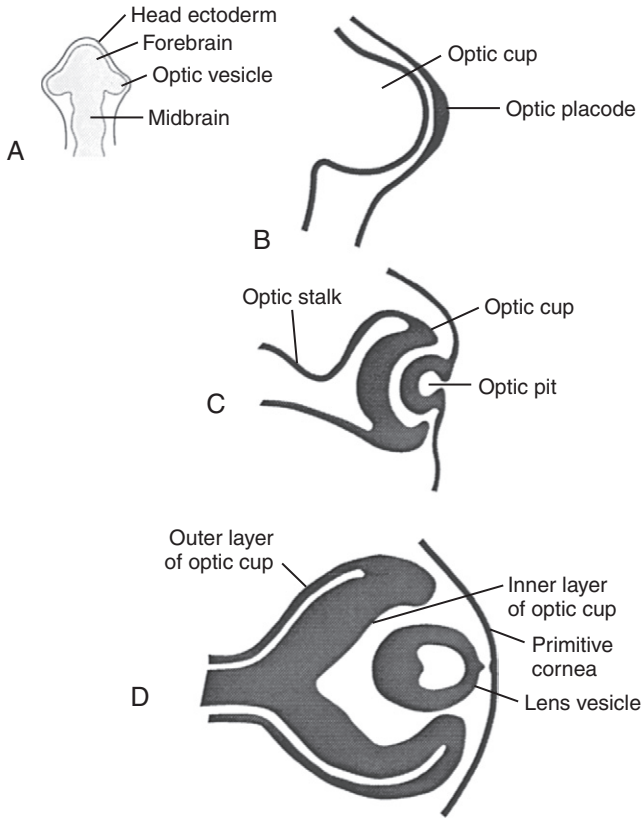

Figure 4-8 Development of the eye. A, Dorsal view showing the head, optic vesicles, and overlying head ectoderm. **B-D,** Magnified view of the right optic vesicle at successively older stages, illustrating the development of the lens placode, pit and vesicle, and the optic cup.

the otic pit) (see Figure 4-9, *B*) and pinches off to form the otic vesicle (see Figure 4-9, *C*). Small diverticula soon bud from each vesicle to form the endolymphatic sac. As growth of the hollow vesicle proceeds, additional regional morphogenesis yields the utricle, semicircular ducts, saccule, and cochlear ducts, as well as other sensory receptors and primary sensory neurons (see Figure 4-9, *C*).

Cardiovascular System (See Chapters 63 and 64)

Heart

Cells destined to form the primitive heart tube are located within two oval areas of mesoderm (Figure 4-10) on either side of the midline of the embryo.[71-73] Organized as discrete clusters of cells between the ectodermal and endodermal layers, this precardiac mesoderm migrates cranially and fuses in the midline just cranial to the oral membrane. The cell clusters form two more or less parallel solid cords of cells on reaching the area just forward of the oral plate (see Figure 4-10). These soon canalize to form endocardial tubes. The tubes swing together because of lateral body folding and fuse to form the primitive heart tube, which then undergoes additional growth, morphogenesis, and changes in position with time. Initially the primitive chambers of the heart tube are arranged in a linear series, with inflow at the caudal end and outflow at the cranial end.

The heart begins beating approximately 22 days after fertilization, and weak circulatory movement of fluid begins in adjacent vessels about a day later. At this time, the embryo can be compared to an aggregate of cells approximately 1 × 1 × 2 mm. Tissue culture studies indicate that cells in the center of a mass thicker than approximately 0.5 mm die of oxygen deprivation, because

the simple diffusion of oxygen into the core is not sufficient to support cell metabolism. Thus it appears that the formation of a functional circulatory system is requisite for the continued life of the embryo. Indeed, the circulatory system is the first organ system to become functional in the human embryo.[74,75]

Good evidence from animal experiments indicates that the first contractions of the embryonic heart are initiated by stretching of the heart tube as fluid pressure builds in the developing circulatory system. Isolated hearts do not begin beating on time unless artificially produced fluid pressure is maintained within the lumen of the heart. Moreover, the heart in intact embryos can be induced to begin beating earlier than normal by the introduction of small amounts of fluid into the lumen, thereby increasing intraluminal pressure and causing stretching of the walls of the heart.[76,77]

Almost as soon as the primitive heart tube forms, sulci on its external surface deepen markedly. This begins a process called *cardiac looping,* in which the inflow and outflow regions are brought into approximation. The mechanisms behind the control of looping are poorly understood.

Several concurrent events occur after looping that lead to partitioning of the heart into separate chambers and outflow channels. The sinus venosus, which initially receives all incoming venous blood from the embryo, is remodeled so that all blood enters what will later become the right atrium. Resorption of the sinus venosus forms the smooth area of the definitive right atrium and contributes to atrial septation. Much of the definitive left atrium is formed by resorption of the pulmonary veins.

Separation of the atria begins during week 5, when a sickle-shaped membrane, the septum primum, grows from the roof of the atrium toward the atrioventricular canal. This canal is simultaneously being divided into right and left channels by the fusion of the enlarging superior and inferior endocardial cushions. The opening between right and left sides of the common atrium, now partially divided by the growing septum primum, is called the *foramen* (or *osteum*) *primum.*

Soon the lower edges of the septum primum fuse with the endocardial cushions, and further growth of both the septum and the cushions closes the foramen primum. Before it closes completely, however, several perforations appear in the superior portion of the septum primum. These perforations fuse to form the foramen secundum. Thus, communication between the right and left atrial cavities is maintained during this complex morphogenetic process.

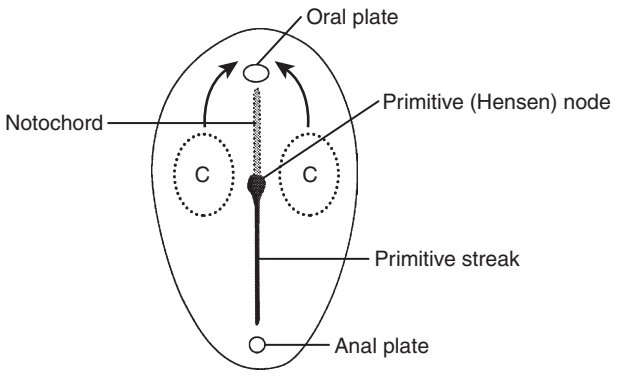

Figure 4-10 Surface view of an embryo at approximately 16 to 17 days after fertilization. This view is of the ectodermal surface. Structures below the surface are outlined with *dotted lines.* The anal and oral plates are areas in which the ectoderm and endoderm are in tight contact, as in a "spot weld," with no mesoderm between. Mesoderm is present in other areas. At *C* lie the mesodermal cell clusters that migrate *(arrows)* to an area forward of the oral plate, to form the cardiogenic cords. These two *oval areas* contain precardiac mesoderm cells.

Another septum (the septum secundum) begins to form at about the time the foramen secundum becomes well defined. This septum forms to the right of the septum primum as a crescentic ridge. Further growth produces a thick membrane, but the oval opening in this membrane persists as the foramen ovale. This arrangement of two parallel septa (primum and secundum) with offset holes (secundum and ovale) produces a flap valve between the two atria, ensuring unidirectional flow of blood from right to left.

Fusion of the endocardial cushions (composed of cardiac mesenchyme) forms the septum intermedium. This structure not only divides the atrioventricular canal into right and left portions but also acts as a central attachment point and reference center for several septation events, as already described. The cushion tissue of the septum intermedium contributes to the formation of the membranous portion of the interventricular septum, as well as to the development of the atrioventricular valves and to the fibrous cardiac skeleton. It also serves as a fusion point for the cushion tissue–derived ridges, which divide the proximal outflow region of the heart.

Even though the heart is enlarging while septation proceeds, the dimensions in this central region around the septum intermedium remain constant. A significant enlargement in this region at this time could lead to congenital heart defects.

Partitioning of the ventricle is accomplished primarily by fusion of trabeculae, which form a muscular interventricular septum. Ventricular septation is completed by formation of the membranous portion of the septum from an outgrowth of endocardial cushion tissue. This morphogenetic process occurs simultaneously with division of the proximal outflow area. Initially, no direct communication is present between the right atrium and the right ventricle. Remodeling activities in the inner curvature of the heart create this communication by mechanisms which are still obscure.

Division of the outflow tract is complex and still not completely understood. The proximal portion of the outflow tract is subdivided into the conus and truncus regions, both of which are divided into left and right halves by ridges of endocardial cushion tissue called the conotruncal or bulbar ridges. Septation of the conus region forms an outflow segment for each ventricle, whereas in the truncus region, distinct aortic and pulmonary valves develop. A portion of the conal septum extends down and attaches to the muscular interventricular septum, partially closing the interventricular foramen. Complete closure of the foramen is accomplished by downgrowth of cushion tissue from the septum intermedium. In the distal outflow tract (the aortic sac), a wedge of mesenchyme (the aorticopulmonary septum) develops between the fourth and sixth aortic arches. This mesenchyme (thought to be of neural crest origin[78]) grows downward and then penetrates and fuses with the conotruncal ridges.

Vessels

During the third week of development, groups of extraembryonic mesodermal cells in the yolk sac and chorion, known as *angioblasts,* aggregate to form isolated, solid masses called *angioblastic clusters* or *blood islands.* These soon cavitate (Figure 4-11), and those cells on the periphery of the hollow blood islands differentiate into endothelial cells. Blood cells are formed from those angioblasts remaining in the lumen, as well as by cell division and budding from the primitive endothelial lining. Growth and fusion of the isolated hollow blood islands form tubes, and the tubes fuse to form long interconnected channels. Lateral buds from tubes and channels also may extend the developing vasculature into adjacent areas.

This sequence, based on observations of sectioned embryos, constitutes the basic template for how vessels form. It does not explain how the pattern of vessels develops. Little is known concerning how the intricate pattern of anastomosing vessels is established in the early embryo.

The Musculoskeletal System (See Chapter 175)

Muscular System

The three types of muscle tissue—skeletal, smooth, and cardiac—are largely derived from cells of the mesodermal germ layer. Skeletal muscle forms from paraxial mesoderm, whereas cardiac muscle is a derivative of splanchnic mesoderm. Most smooth muscle is derived from splanchnic mesoderm. It seems likely, however, that all mesenchyme, whether derived from mesoderm or from neural crest (as in head mesenchyme), has the potential to form vascular smooth muscle. The dilator and sphincter smooth muscles of the iris as well as the myoepithelial cells that surround sweat glands and mammary glands are thought to be of neural crest origin.

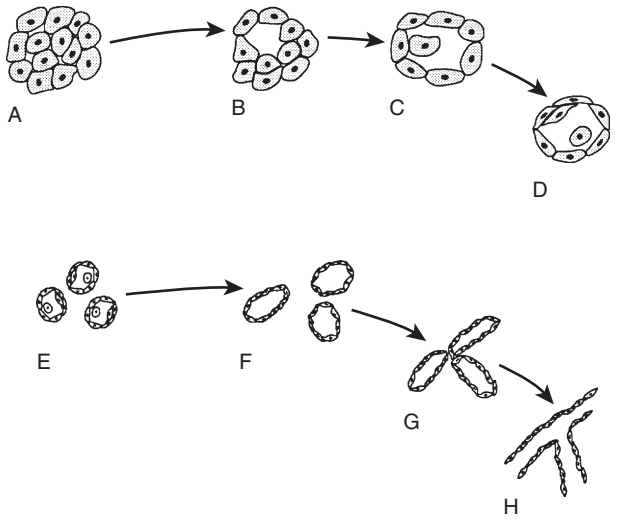

Figure 4-11 Vasculogenesis. A-D, Formation of hollow blood islands from solid clusters of angioblasts. **E-H,** Formation of a portion of a primitive vascular network by fusion of blood islands. Budding *(not shown)* also contributes to vascular pattern growth.

Skeletal Muscle

Mesenchyme cells that are to develop into skeletal muscle elongate and lose their multiple processes. The earliest cell that can be identified as a skeletal muscle precursor is a fusiform cell called a *myoblast* (Figure 4-12). These cells become postmitotic and fuse into cylindric, multinucleated myotubes. These myotubes start producing actin and myosin myofilaments, which adds to girth. Growth of myotubes also may occur by fusion of additional myoblasts. The skeletal muscles of the head and neck develop from paraxial mesoderm represented by somitomeres in the early embryo. Trunk musculature is derived from the myotome portion of the somites (Figure 4-13).

Somites themselves are interesting structures—serially repeated paired blocks of condensed (closely packed) paraxial mesoderm cells. Approximately 44 pairs of somites eventually develop in humans, beginning between days 19 and 21.[64] These can be seen in a surface view of the embryo because they produce bulges in the overlying sheet of ectoderm. Each member of a pair of somites lies lateral to the neural tube (see Figure 4-13). Myoblasts of the myotome portion of each somite divide and spread out deep to the embryonic skin, where they form the musculature. Various morphologic processes including fusion, tangential splitting of layers, reorientation of muscle fibers, and formation of tendon intersections are responsible for the final morphologic form of the named muscles.

The musculature of the limb also is derived from the myotome portion of the somites. These myoblasts migrate into the elongating limb buds and arrange into dorsal and ventral muscle masses, which later become subdivided into the definitive limb muscles.

Cardiac Muscle

Cardiac type of muscle develops from splanchnic mesoderm adjacent to the pericardial or transverse portion of the intraembryonic coelom. Myocardial precursor cells undergo mass migration and do not fuse to form myotubes. Rather, the myoblasts differentiate as discrete cells, with closely applied end-to-end junctions, which persist as the adult intercalated disk. They form a layer around the endothelial tube of the heart, which eventually becomes the myocardial or muscular wall of the heart.

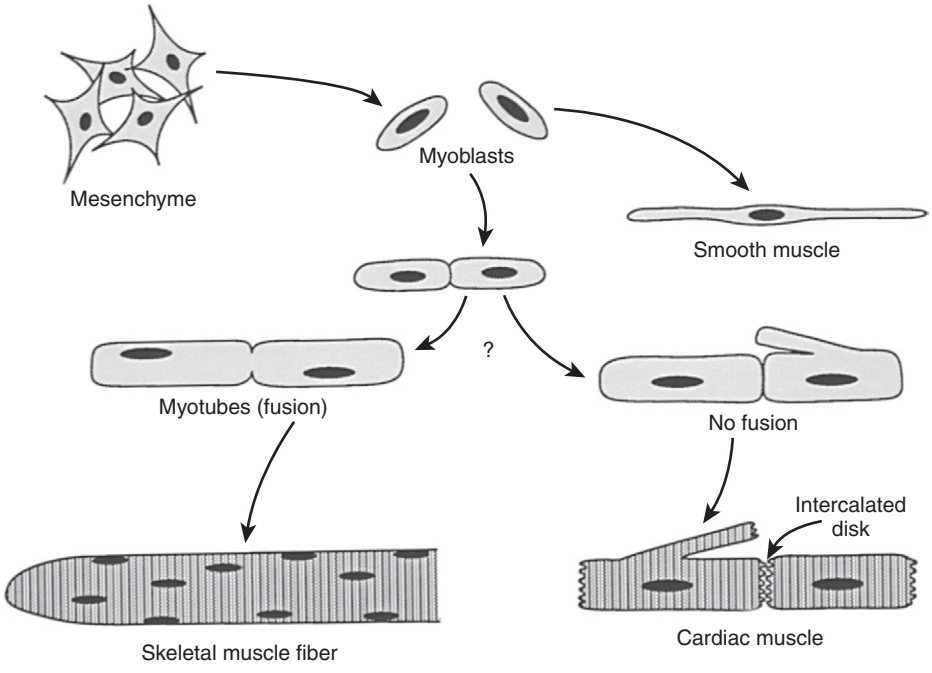

Figure 4-12 Schematic representation of the development of the three types of muscle cells—skeletal, smooth, and cardiac. Some question exists regarding the precursor cells—that is, a current hypothesis is that mesenchyme gives rise to a cell type that develops into cardiac and smooth muscle, but that it gives rise to another cell type that develops into skeletal muscle.

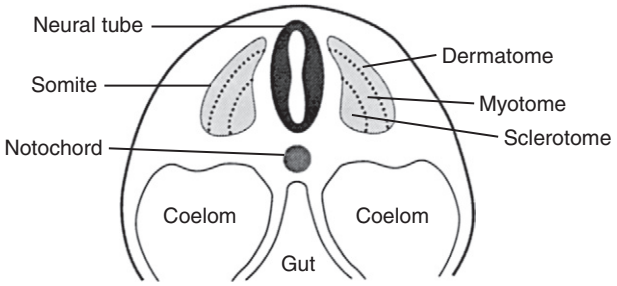

Figure 4-13 Fate map of the somite, showing regions from which cells developing into dermis, muscle, and cartilage and bone are derived.

Smooth Muscle

Smooth muscle cells form from myoblasts derived primarily from splanchnic mesoderm (see Figure 4-12).

Skeletal System (See Chapter 173)

Cartilage develops from mesodermally derived mesenchyme, except in some areas of the head and neck, where it is of neural crest origin. Chondroblasts aggregate, condense, and begin to produce collagen fibers and ground substance. In the embryo, bone tissue is formed in either of two distinct ways, depending on the site and type of bone growth. The first is de novo bone formation, in which mesoderm cells (or, in the case of some skull bones, neural crest cells) first condense (pack) into sheets or membranes. Cells in these sheets then differentiate into osteoblasts, which secrete prebone or osteoid. Osteoid is the extracellular matrix onto which hydroxyapatite crystals (a unique calcium phosphate mineral) form. Once the mineral is present and integrated into the collagen of the matrix, the tissue is considered to be bone. This type of bone formation is called intramembranous ossification because the osteogenesis occurs within these sheets or membranes of condensed mesenchyme. Some of the bones of the cranial vault, face, and jaws form in this way.

The second manner in which bone forms in the embryo is called *endochondral ossification.* As implied by the name, bone forms in this case only in sites where preexisting cartilage models are found. The cartilage does not turn into bone. Rather, bone replaces the preexisting cartilage model in a sequence of steps, as follows. Cartilage cells hypertrophy and calcify in an area where bone is to form, that is, they become large and undergo metabolic changes, which lead to infiltration of the surrounding cartilage extracellular matrix with insoluble calcium salts. In this way, the cartilage cells become partitioned from their surroundings by an environment that is presumed to cut off their supply of oxygen and nutrients, and they die. At the same time, local osteoblasts begin to produce osteoid, which then becomes mineralized as described in intramembranous ossification. Once bone has formed in the embryo, it can be remodeled by changes in the balance between addition of more bone by osteoblasts and removal of bone by osteoclasts.

Respiratory System (See Chapter 78)

During the fourth week of development, the embryo forms a C shape, and the primitive gastrointestinal tube is already divided into a foregut, midgut, and hindgut (Figure 4-14). A groove, the respiratory (laryngotracheal) diverticulum, arises as an evagination of the ventral surface of the foregut, close to the region destined later to become the stomach. As the foregut elongates a wedge of mesoderm, the tracheoesophageal septum, separates the foregut (portion that will become esophagus) from the future lungs. This early association of developing lung and stomach leads to the occasional finding of ectopic lung and cartilage tissue near the esophageal-gastric junction.[79]

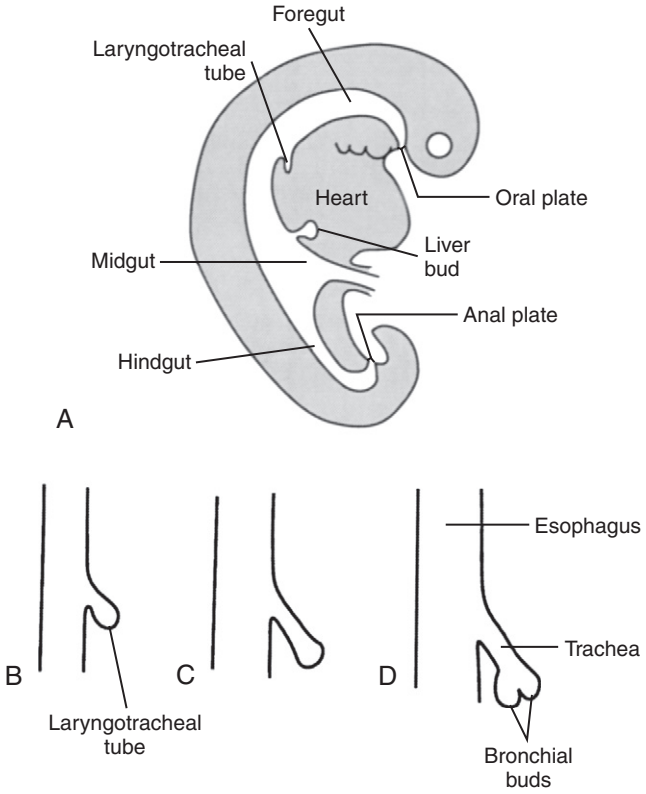

Figure 4-14 Development of the respiratory system. The laryngotracheal (respiratory) tube buds off from the ventral surface of the foregut, as shown in **A.** The tube elongates and splits into two bronchial buds **(B-D),** each of which ultimately gives rise to the epithelial lining of one lung.

The respiratory diverticulum grows caudally and soon splits into two bronchial buds. Each of these buds subdivides to form primitive secondary or lobar bronchi. On the left side, two secondary bronchi supply the developing superior and inferior lobes of the left lung. On the right, the inferior secondary bronchus divides into two, providing a total of three secondary bronchi to supply the three lobes on this side. The third-order branches form the bronchopulmonary segments. Altogether, approximately 17 generations of branches form. Differentiation of the respiratory passages begins in the fetal stage and proceeds from distal to proximal along the branches of the respiratory diverticulum. Alveolar formation begins toward the end of the fetal period and continues until the age of 2 to 3 years.[53]

Of note, the endoderm of the foregut gives rise to the epithelial lining of the trachea, bronchi, and lungs, including the alveoli. The surrounding splanchnic mesoderm develops into the cartilage and fibrous connective tissue of the larger airways as well as the blood vessels and supporting tissues of the smaller airways and alveoli.

Digestive System (See Chapters 108 and 109)

The lining of the gastrointestinal tube arises primarily from endoderm, whereas the muscle coats and connective tissue elements usually are derived from splanchnic mesoderm. Toward the end

of the third week the embryo folds craniocaudally and laterally, forming a inner gut tube of endoderm that is subdivided into the foregut, midgut (still connected to the degenerating yolk sac), and the hindgut.

Oral Cavity and Anal Regions

Throughout most of the developing gastrointestinal tube, the epithelium and derivative glands arise from the endodermal germ layer, which lines the foregut, midgut, and hindgut (see Figure 4-14). Cranial to the foregut and caudal to the hindgut, the relationship of embryonic structure to adult derivatives is less obvious. For example, the oral membrane, which is a fusion of ectoderm and endoderm, is the cranial boundary of the foregut (in the adult this boundary is at the level of the tonsillar fauces). The oral cavity develops cranial to the oral membrane from an ectodermal depression, the stomodeum, bounded by the first pharyngeal arch and the frontal process. Three groups of salivary glands develop in this region. The sublingual and submaxillary glands develop from endoderm, as might be expected, but the parotid is derived from head ectoderm.[38] Similarly, structures below the pectinate line in the adult anal canal are derivatives of the proctodeum, an ectodermal depression in the caudal end of the embryo that is sealed off from the gut tube by the anal plate until the end of the eighth or beginning of the ninth week. Thus the anal columns (of Morgagni), located above the pectinate line, are of endodermal origin, whereas the anocutaneous (white) line and surrounding epithelial structures are from ectoderm.

Liver (See Chapter 118)

The hepatic diverticulum (or liver bud) arises as an outpouching of the lumen of the distal foregut during the fourth week of development (see Figure 4-14). The liver bud gives rise to the gallbladder and bile ducts as well as to the parenchyma of the liver. The liver bud grows toward the anterior body wall, at first completely buried in the mesenchyme of the septum transversum. Rapid growth causes the liver bud to bulge into the abdominal cavity, freeing it on all but the cephalic surface. There it remains in contact with the septum transversum as the latter forms part of the diaphragm. After development is complete, this area of contact between the liver and the diaphragm is known as the "bare area of the liver" because it is not covered with capsule or peritoneum.

The liver is connected on its anterior surface to the anterior body wall by the ventral mesentery, which becomes the falciform ligament. The hepatocytes are derived from endoderm, as are the bile canaliculi and the epithelial linings of the intrahepatic biliary ducts. The liver sinusoids, larger blood vessels, and connective tissue stroma of the liver all are derived from the mesenchyme of the septum transversum, which is of mesodermal origin.

Pancreas (See Chapter 114)

Most of the pancreas develops from the dorsal pancreatic bud, which arises as an outpouch of the dorsal surface of the future duodenum at the caudal end of the foregut. It grows into the mesenchyme of the dorsal mesentery at this site. The ventral pancreatic bud starts as an outgrowth of the future common bile duct, but it fuses with the dorsal pancreatic bud when rotation of the gut brings these two components of the pancreas into contact. Both exocrine and endocrine (islets of Langerhans) elements of the pancreas are derived from endoderm, whereas the blood vessels and connective tissue components arise from splanchnic mesoderm.

Esophagus

The esophagus is a short regional specialization of the embryonic foregut tube that elongates with growth of the body. During the middle of the embryonic period, its lumen is obliterated by proliferation of the endoderm-derived lining cells, but cell death (a normal developmental process in many areas of the human embryo) reestablishes the lumen by early fetal life.

Stomach

The stomach begins as a simple fusiform dilation of the foregut. Growth of the dorsal wall of the stomach surpasses that of the ventral wall, leading to the greater curvature and driving a clockwise rotation of the gut that brings the greater curvature (original dorsal surface) to the left and the lesser curvature (original ventral surface) to the right. As a result of differential growth, the cardiac region (cranial) of the stomach moves inferiorly and to the left, and the pyloric (caudal) end moves superiorly and to the right. Ultimately, this rearrangement results in the almost horizontal axis seen in the adult stomach.

Duodenum

The duodenum develops from both the caudal end of the foregut and the cranial end of the midgut. It rapidly elongates into a loop, the bend of which is toward the ventral body wall. As the stomach rotates to the right, so does the duodenal loop, bringing it to lie against the dorsal wall of the body cavity. There it fuses with the dorsal wall, and most of it comes to lie in a retroperitoneal position. As in the esophagus, the duodenal lumen is transiently obliterated by growth of the endoderm-derived lining cells until the beginning of the fetal period.

Lower Gastrointestinal Tract

Much of the remaining gastrointestinal tube—jejunum, ileum, cecum, ascending colon, and half of the transverse colon—develops from the midgut. The elongating midgut also forms a distinct loop the of which is closest to the anterior body wall. This U-shaped loop herniates (normally) into the extraembryonic coelom of the umbilical cord. While herniated, the loop rotates 90 degrees counterclockwise. Thus the cranial branch of the U-shaped loop moves to the right. At the same time, growth and elongation create several additional subloops in the cranial portion of the U-shaped loop; these later give rise to the jejunum and ileum.

The herniated small intestine with its subloops returns to the body cavity first. As the large intestine follows, it rotates an additional 180 degrees, bringing the cecum and appendix to their final position in the lower right quadrant of the abdomen.[80] Little is known about how these complex morphogenetic events are controlled. Nevertheless, a thorough knowledge of these events as they occur in a normal embryo can help to explain the numerous anatomic variations and congenital malformations that have been observed. The hindgut contributes to the distal half of the transverse colon, the descending and sigmoid colon, the rectum, and the anal canal down to the white line.

Urinary System (See Chapter 123)

Near the end of the third week after fertilization, the intermediate mesoderm appears as a solid cord of condensed mesenchyme just lateral to the paraxial (somite-forming) mesoderm (see Figure 4-5, *C*). The intermediate mesoderm is bilateral and extends along the length of the body axis as far as the somites do; it gives rise to components of the urinary and genital system.

The intermediate mesoderm is displaced ventrally to a position lateral to the dorsal aorta and notochord when the embryo becomes tubular, owing to growth and formation of the lateral body folds. During this movement, the connection between the somites and intermediate mesoderm is broken. Once this connection is lost, the two bars of intermediate mesoderm are called nephrogenic cords.

The traditional description of kidney development suggests that three successive sets of kidneys form in the embryo—the

pronephros, mesonephros, and metanephros. The concept of a pronephros, however, is not relevant in humans.[81] Beginning at the level of the eighth or ninth somite,[82] the mesonephric kidney contains primitive tubules associated with glomeruli that empty into a mesonephric (wolffian) duct. The cephalic tubules begin to degenerate even before the more caudal tubules are starting their development. In males, the mesonephric duct becomes associated with the primitive gonad and gives rise to the epididymis, ductus deferens, and ejaculatory ducts; some of the mesonephric tubules persist as the efferent ductules. In females, the mesonephric duct distal to the ureteric bud degenerates. The mesonephros actively produces urine as early as the sixth week of development and continues into the early fetal period.

During the fifth week, the metanephros begins as a small diverticulum near the caudal end of the mesonephric duct—the ureteric bud. The mesoderm at the caudal aspect of the nephrogenic cord condenses around the ureteric bud, forming a metanephric blastema. The ureteric bud plus the metanephric blastema form the metanephric or definitive kidney (see Figure 4-1, *A*). The nephron from the renal corpuscle to the collecting duct is derived from the metanephric blastema whereas the collecting system and ureter are derived from the ureteric bud. Development of the metanephric kidney depends on mutual inductive signals from the metanephric blastema and the ureteric bud.[68] Signals from the bud result in mesenchymal-epithelial transformation of the metanephric blastema mesenchyme, leading to formation of an epithelial vesicle. The vesicle remodels into a tubule, the proximal end of which attaches to the ureteric bud, whereas the distal end becomes associated with vascular precursors of the glomerulus. Signals from the metanephric mesoderm cause the ureteric bud to branch, forming the collecting system. If for some reason the ureteric bud does not grow to meet the metanephric blastema, the blastema does not develop nephrons, and renal agenesis results. If the blastema is absent, the ureteric bud does not develop into the collecting system of the kidney.[83]

By the end of the first trimester, the fetal kidneys begin to produce urine.[84] At that time, they have been displaced from their initial pelvic location to the abdomen, and they lie in a retroperitoneal position close to the adrenal glands. The latter develop from coelomic mesoderm (cortex) and neural crest cells (medulla) that have become associated in the abdominal cavity, cephalic to the final position of the kidneys.

The urogenital sinus is an endoderm-lined cavity from which are derived the epithelium of the urinary bladder, all of the female urethra, and most of the male urethra. The muscular coats and connective tissue elements of all of these structures are of splanchnic mesoderm origin.

GROWTH AND MATURATION OF THE EMBRYO AND FETUS

Human embryonic development is a continuous process that averages 266 days, or 9½ months, when counted from the day of fertilization. Clinically, the start of gestation is determined by counting from the date of the last menstrual period (LMP). Estimated this way, it averages 280 days or 10 lunar months.[85] Human prenatal development commonly is divided into two periods or phases: the embryonic period and the fetal period (Figure 4-15). The first 8 weeks after fertilization constitute the *embryonic period.* It has been subdivided into 23 developmental stages (Carnegie stages).[53] During the embryonic period, the single-celled zygote is transformed into an embryo. With respect to human embryology, the term *embryo* means "an unborn human in the first 8 weeks" from fertilization.[53] This period is characterized by several developmental milestones, including cell division of the zygote, formation of a blastocyst, implantation, formation of three primary germ layers, segmentation and axis formation, and initial morphogenesis of organ systems.

It is thought that during the first 2 weeks of development, the embryo is relatively insensitive to the action of agents that cause congenital malformations (teratogens). Retrospective human studies as well as studies in animals suggest that low to medium doses of teratogens will not cause abnormal development during the first 2 weeks, but that a large dose will kill the embryo. Duringthis 2-week period, defects also may develop

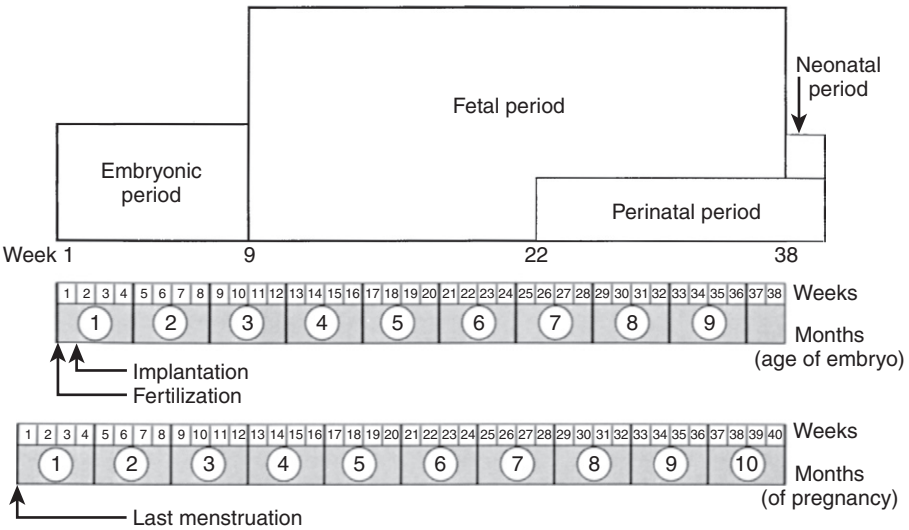

Figure 4-15 Human development. The *upper portion* of the schematic diagram shows human development divided into periods. The embryonic period extends from fertilization through week 8. The remainder of pregnancy (week 9 through birth) is termed the fetal period. The perinatal period extends from the prenatal week 22 until 4 weeks after birth. The neonatal period is the first 4 weeks after birth. In the *bottom portion* of the diagram, the ages of the embryo/fetus are shown on two time scales. The lower of the two is a clinical scale, with *pregnancy* counted from the date of the last menstrual period. Above it are weeks and months of *development,* counted from fertilization. Note that the 2-week difference, with pregnancy lasting 40 weeks. *(Modified from Kaplan S:* Congenital Defects: An Overview: An Introduction to the Principles of Teratology, *Chapel Hill, NC, 1981, Health Sciences Consortium.)*

after treatment with the teratogenic agent if for some reason it remains available to the embryo throughout the period—for example, because of slow metabolism or excretion. It is during the third to eighth week of development, however, that morphogenesis of most organ systems begins and, for many systems, ends. This is the portion of the embryonic period in which the organs, and therefore the embryo as a whole, are most sensitive to the actions of teratogens. For example, a kidney will fail to develop only if, during morphogenesis, the ureteric bud fails to send the proper signals to the metanephric blastema. Moreover, a limb will be abnormally foreshortened only if long bones fail to form during that time when the bony elements are due to undergo their primary morphogenesis. Therefore weeks 3 to 8 of the embryonic period constitute the critical period in human development with regard to the action of teratogenic agents.

During the *fetal period* (beyond the end of the eighth week after fertilization, or beyond the tenth week of post-LMP pregnancy—see Figure 4-15), the fetus becomes increasingly resistant to the action of teratogens. This decreasing susceptibility does not mean that no organ system can become malformed during fetal life. An example of such an organ is the brain, which exhibits the longest developmental period of any organ; it continues both physical and functional development throughout the fetal period and beyond, well after birth.[86] This extended development also prolongs its period of susceptibility; more major congenital defects occur in the brain than any other organ.[87]

Organ systems other than the brain also continue morphogenesis into the fetal period (e.g., palate, ear, external genitalia, lungs). In contrast with the brain, however, most other organ systems essentially complete morphogenesis by the end of the embryonic period.

The fetal period is characterized by rapid growth in weight and size of the conceptus as a whole (Figure 4-16), which reflects growth in individual organs. All organs expand and undergo histogenesis, or differentiation of the cell populations of which they are composed, but the particular pattern of increase in weight may vary from organ to organ. Hematopoiesis begins in the liver during the late embryonic period, making the liver a functional organ relatively early in development.[85] Accordingly, it expands rapidly to make up approximately 10% of total body weight by the beginning of fetal life.[38] Thereafter, its growth rate follows

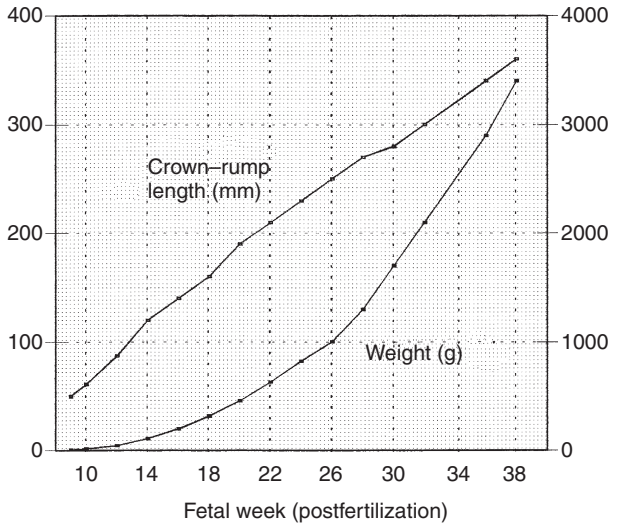

Figure 4-16 Weight and crown–rump length during human development. *(Data from Moore KL, Persaud TVN: The Developing Human: Clinically Oriented Embryology, 6th ed, Philadelphia, 1998, WB Saunders.)*

that of the whole body, so that in proportion to body weight, liver size remains virtually constant.[88]

The same proportional growth pattern is seen in heart and kidney, but growth of the head is quite different. At the beginning of the fetal period, the head is approximately half the crown-rump length; at 12 weeks, it is approximately one-third this value. Thereafter, the rate of growth continues to slow in relation to the rest of the body.

An important point is that the establishment of the gross form of an organ does not necessarily correspond to initiation of function. The human fetal gastrointestinal tube closely resembles that of the newborn infant as early as the middle of the sixth month. By contrast, cell differentiation and the development of complex enzyme systems necessary for the digestive process continue through birth and well beyond.[89]

The early human fetus is approximately 95% water, and a progressive increase in solids occurs throughout fetal growth.[88] Most of the water (in a ratio of 4:1) is extracellular in early fetal life, but more is found within cells as the fetus matures, so that by birth the ratio is approximately 1:1.[90] Protein is accumulated most rapidly before the fetus weighs 1 kg, with the accumulation rate slowly declining thereafter. Fat deposition rate is low until the middle of gestation, when the proportion of fat (especially subcutaneous fat) to total body weight increases exponentially.[91]

5 Regulation of Embryogenesis

Matthew K. Lee, Yang Chai, David Warburton, and Harold C. Slavkin

Vertebrate body plans result from the divergent proliferation, migration, survival, and differentiation of cells derived from a single fertilized egg. This divergence is induced and sustained by regulatory signals within the embryo that modulate cell behavior. Behavioral changes accumulate over successive generations of cells, so the same stimulus may have disparate effects on cells at different developmental stages, with different lineages, or in different physical contexts. Because a cell's response to a specific stimulus is altered by its historical and physical context, regulatory processes can be used iteratively to control development. In this way, the mechanisms regulating early embryogenesis are recapitulated during the development of limbs, organs, and craniofacial structures in an essentially fractal process. This recapitulation underlies the disrupted organogenesis that accompanies somatic malformation in many human congenital syndromes. Conversely, the same mechanisms guide tissue regeneration after injury to the adult organism. The elucidation of embryonic regulatory mechanisms therefore represents an area of enormous therapeutic importance as well as a signal accomplishment of modern biology and medicine.

This chapter introduces some of the mechanisms by which key embryonic events are initiated. The regulation of initial axis determination in the oocyte, mesodermal induction in the blastula, and mesodermal patterning during gastrulation is discussed for the African frog *Xenopus laevis,* long a leading model of vertebrate embryology. Among vertebrates, the mechanisms underlying initial embryonic patterning are most completely elucidated for the frog. By comparison, the initial patterning of birds and mammals is more complex and incompletely defined.[1] Mouse and chicken development are discussed as excellent models of left-right axis determination and segmentation. For each developmental stage, a regulatory mechanism that is important in guiding embryogenesis during that period is introduced. In addition, some examples of disrupted late embryonic regulation are correlated with specific clinical syndromes to demonstrate how regulatory pathways are reiterated temporally and spatially within the embryo and fetus.

Critical events in embryogenesis are initiated by the expression of key genes. Gene transcription, in turn, is regulated by transcription factors that bind the promoter region immediately upstream of the protein coding region and by enhancers and suppressors that bind at variable distances upstream or downstream of the coding region. Transcriptional regulators typically bind many different genes, some of which also may encode transcriptional regulators. In this way, dozens of genes may be controlled by a single stimulus. The activity of a transcription factor is not dependent solely on its expression; the affinity of a transcription factor for its binding site may depend on its posttranslational modification, the presence or absence of cofactors, or the packing state of the targeted chromatin. The same variables also determine whether that factor increases or decreases the activity of a particular gene. Gene expression is thus subject to regulation by a variety of molecular mechanisms, many of which are implicated in embryonic regulation. Some of this variety is evident in the following examples.

THE SPATIAL ORIENTATION OF THE OOCYTE IS INITIATED BY EGG ROTATION

Vertebrate embryos arise from radially symmetric spheres or cups, and their development requires the establishment of spatial references. Vertebrates develop asymmetrically along three spatial axes: anterior-posterior (anteroposterior), dorsal-ventral (dorsoventral), and left-right. These axes become visible during gastrulation but are established earlier, in the blastula. In the frog *Xenopus,* oocytes are intrinsically divided into animal and vegetal hemispheres. Fertilization occurs in the animal hemisphere, where sperm entry induces formation of an aster centered on the sperm centriole as well as an array of vegetal cortical microtubules.[2] The aster induces the egg cortex to rotate through a 30-degree angle with respect to the vegetal hemisphere, thereby displacing some of the clear vegetal cortex into the animal hemisphere.[3] The intersection of vegetal cortex with animal cytoplasm is visible as a gray crescent that becomes the dorsal pole of the embryo.[4,5] Conversely, the ventral pole forms at the area of contact between animal cortex and vegetal cytoplasm.[6]

How does cortical rotation regulate gene transcription? In *Xenopus,* the convergence of vegetal cortex with animal cytoplasm results in localized activation of Wnt signaling at the gray crescent. The Wnt pathway regulates many cellular processes in both adult and developing organisms and centers on β-catenin, a membrane-bound multifunctional protein that participates in transcriptional activation.[7] In the absence of Wnt signaling, β-catenin is continuously produced and destroyed by ubiquitin-mediated proteolysis. Two inhibitors of this proteolysis, Dishevelled (Dsh) and GSK-binding protein (GBP), are expressed in the vegetal hemisphere and attached to kinesin light chains.[8] Kinesins are cargo-carrying molecular motors that hydrolyze ATP to move along microtubules toward the *plus* end, and the vegetal cortex microtubules that assemble after sperm entry are aligned with the plus ends directed toward the dorsal pole.[2] Kinesin activity therefore results in transportation of Dsh and GBP into the gray crescent, with attendant dorsal accumulation of β-catenin (Figure 5-1). As the oocyte undergoes successive rounds of cleavage, β-catenin becomes increasingly localized to the cytoplasm and then the nuclei of cells on the dorsal aspect,[9] where it binds and modulates the activity of transcription factors that, in turn, regulate the transcription of a large array of genes.

MESODERMAL INDUCTION IN THE BLASTULA IS REGULATED BY Nodal SIGNALING

In the preceding example, β-catenin signaling is dependent on extrinsic factors: the maternally derived β-catenin protein and a microtubule-dependent mechanical contraction that is initiated by sperm aster. Once the oocyte begins to cleave, embryonic regulation is increasingly dominated by intercellular communications.

This is apparent during the differentiation of the oocyte into endoderm, mesoderm, and ectoderm. Whereas cells from the vegetal pole form endodermal derivatives and cells from the animal pole form ectodermal derivatives, the mesoderm arises from the ectoderm in response to signals from the endoderm. The mesoderm, in turn, is divided into dorsal and ventral regions that give

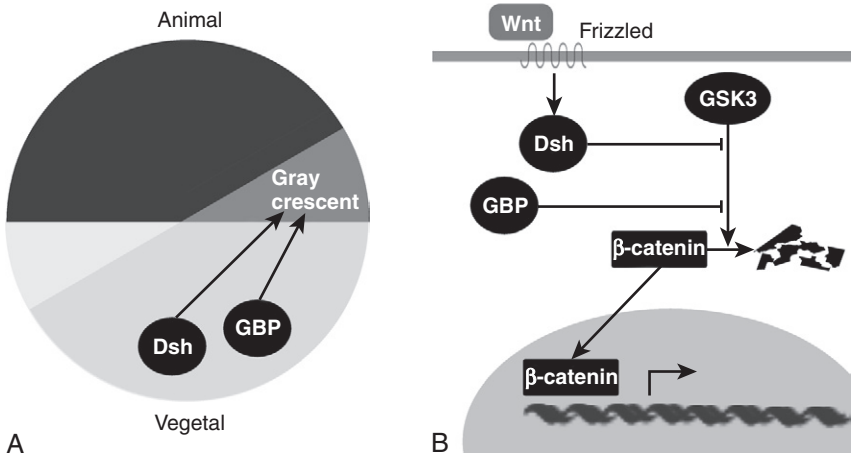

Figure 5-1 Cortical rotation in the *Xenopus* oocyte up-regulates β-catenin. A, Disheveled (Dsh) and GSK3-binding protein (GBP) are distributed in the vegetal hemisphere before fertilization. Fertilization induces cortical rotation and microtubule formation; Dsh and GBP are transported along these microtubules to the intersection of vegetal cortex and animal cytoplasm (the gray crescent). **B,** Dsh and GBP are components of the canonical Wnt signaling pathway. Wnt ligands are glycoproteins expressed on cell surfaces. In the absence of Wnt ligand, GSK3 phosphorylates β-catenin, leading to its ubiquitination and destruction. Wnt binding to its receptor Frizzled activates Dsh and thereby inhibits GSK3. In the oocyte, sequestration of Dsh and GBP inhibits GSK activity, thereby allowing β-catenin to accumulate and regulate gene transcription in the gray crescent.

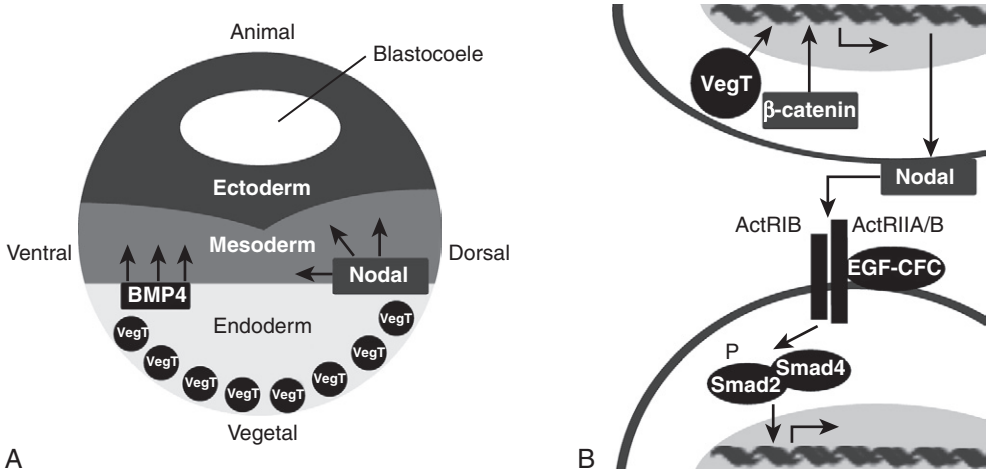

Figure 5-2 Vegetal cells secrete Nodal to induce mesoderm formation in the *Xenopus* blastula. A, Maternally derived VegT is sequestered in the vegetal cytoplasm and functions as a transcription factor that interacts with β-catenin to induce Nodal expression at the prospective dorsal pole. **B,** Secreted Nodal binds and activates cognate cell surface receptor complexes composed of TGF-β family type I and type II receptors, the activin receptors (ActRIB and ActRIIA or ActRIIB, respectively). This activation requires a cofactor of the EGF-CFC family (see text). The activated receptor complex phosphorylates the intracellular signaling proteins Smad2 and Smad4, which associate, translocate to the nucleus, and regulate gene expression. BMP-4, another TGF-β family peptide, has a similar inductive function at the ventral pole. *BMP-4,* Bone morphogenetic protein-4; *TGF-β,* transforming growth factor-β.

rise to distinct tissues. In *Xenopus,* dorsal mesodermal induction is initiated by expression of the transcription factor VegT from maternally derived mRNA sequestered in the vegetal cortex[10] (Figure 5-2); for example, the notochord comprises dorsal mesoderm, whereas the hematopoietic precursors are derived from ventral mesoderm. VegT initiates endodermal differentiation[11] and interacts with β-catenin at the gray crescent to induce the expression of Nodal, a member of the transforming growth factor-β (TGF-β) peptide family that also includes activin and the bone morphogenetic proteins (BMPs). Like other TGF-β family proteins, Nodal is secreted as an inactive precursor that is processed into a mature active dimer by an extracellular enzyme.[12] Nodal then diffuses through the intercellular space, its concentration falling and hence its stimulatory effects decreasing with increasing diffusion distance. Thus far only one Nodal protein has been characterized in mice; five Nodal-related proteins are recognized to participate in *Xenopus* mesodermal induction.[13] In the *Xenopus* blastula, Nodal is most highly expressed in the dorsal endoderm adjacent to the gray crescent[14] in a region known as the Nieuwkoop center that will confer important organizing functions during gastrulation.

When a Nodal peptide encounters a target cell, its presence is detected by cell surface receptors. Like other TGF-β family receptor complexes, the Nodal receptor complex is composed of type I and type II receptors. Both receptors are transmembrane proteins with extracellular ligand-binding domains and intracellular serine-threonine kinase domains. The activin type IB receptor (ActRIB) protein functions as the Nodal type I receptor, and either the activin type IIA or type IIB receptor (ActRIIA or ActRIIB) can

serve as the Nodal type II receptor. Upon ligand binding, the type II receptors bind, phosphorylate, and activate the type I receptors, which in turn bind, phosphorylate, and activate cytoplasmic signaling proteins. The association of Nodal with its receptor complex also requires a novel secreted coreceptor that demonstrates homology to epidermal growth factor (EGF)[15]; this family of EGF-CFC proteins includes FRL-1 in *Xenopus,* Cripto and Cryptic in mammals, and One-eyed pinhead in zebrafish (in the designation *EGF-CFC,* CFC = Cripto–FRL-1–Cryptic).

The primary substrates of ActRIB are the transcriptional regulators Smad2 and, possibly, Smad3. Of the eight mammalian Smad proteins (named for their similarity to proteins encoded by *Drosophila* Sma and *Caenorhabditis elegans* MAD ["mothers against decapentaplegic"] genes), five are TGF-β receptor family substrates.[16] One of the three remaining Smads, Smad4, is a cofactor for all receptor-activated Smads; the other two, Smad6 and Smad7, inhibit Smad signaling by functioning as false receptor substrates. Inactive receptor-activated Smads are sequestered in the cytoplasm in close proximity to the receptor by anchor proteins such as SARA ("Smad anchor for receptor activation").[17] Upon phosphorylation, Smad2 detaches from SARA to associate with Smad4 and a cofactor that confers specificity to the complex. In Nodal signaling, Smad 2 forms a complex with Smad4 and the forkhead family transcription factor FoxH1 (previously termed FAST-1).[18] The complex is transported into the nucleus, where it binds and activates the promoter for Mix2, a homeodomain transcription factor (these are discussed later). Similarly, Smad 3 partners with FoxO1, FoxO2, and FoxO3 to up-regulate the cyclin-dependent kinase inhibitor p21Cip1.[19] Modulated expression of these proteins initiates or terminates their associated cellular activities.

Among the proteins induced by FoxH1 is Nodal itself.[20] Nodal autoinduction represents positive feedback regulation that may allow its expression to spread out of the endoderm and into the marginal zone. FoxH1 also induces the expression of the secreted Nodal inhibitors Cerberus and Lefty2; this induction represents negative feedback regulation. Nodal can therefore both inhibit and sustain its own activity, and the balance between these conflicting influences determines its expression and localization.

Nodal is necessary for anterior mesoderm specification, but Nodal-deficient animals develop ventral mesoderm. The two regions have divergent differentiation potentials: Dorsal mesoderm will give rise to the head structures, whereas ventral mesoderm will differentiate into hematopoietic and renal derivatives.[14] Ventral mesoderm is induced by endodermally produced BMP-4, another member of the TGF-β family. BMP-4 signaling is transduced by the BMP type II receptor (BMPR-II) in concert with ActR-IA, BMP-RIA, or BMP-RIB type I receptors, and intracellular BMP-4 signaling is mediated by Smad1, Smad5, and Smad8.[16] BMP-4 is produced in a ventral organizing center located opposite the gray crescent. Although both BMP-4 and Nodal induce mesoderm, they appear to have antagonistic effects on mesoderm dorsalization[21] and can combine into mutually inhibitory heterodimers.[22] The overall effect of the two organizing centers is to establish a dorsal-ventral Nodal activity gradient in the endoderm that induces and patterns the mesoderm.[20]

DURING GASTRULATION, THE EMBRYO IS PATTERNED BY Nodal ANTAGONISTS

A number of generalizations about intercellular regulation are apparent from the *Nodal* signaling example. First, intercellular signaling processes can be regulated at many points. Nodal activity may be modulated by altering its transcription, translation, secretion, activation, diffusion, and degradation; its receptors, coreceptors, and cytoplasmic mediators are subject to similar control. Second, multiple factors may have similar activities. As noted, mesoderm is induced by both BMP-4 and Nodal. Moreover, receptors may bind multiple ligands with variable affinity. ActRIB also is activated by alternative TGF-β peptides such as Vg1, Derriére, and Activin,[23] and the biologic activity of Nodal may be at least partially replicated by these proteins. Conversely, Nodal also binds promiscuously with another receptor, activin-like kinase 7.[24] Moreover, the intracellular pathways of different receptors may regulate one another.[25] Finally, multiple receptors often activate the same intracellular proteins. Smad2 is activated by numerous TGF-β type I receptors, and both the activin type IB and activin-like kinase 7 receptors interact with a variety of TGF-β type II receptors to activate Smad2.[26]

Posttranscriptional regulation of Nodal signaling is an important mechanism in embryonic patterning. During *Xenopus* gastrulation, the newly formed mesoderm curls into the blastopore and expands along the inner surface of the ectoderm (Figure 5-3). This process, known as involution, places the dorsal mesoderm of the future head at a point on the embryo that is roughly opposite to the initial location of the gray crescent. This reorganization is critically regulated by a specific area of the dorsal mesodermal lip characterized by Hans Spemann and Hilde Mangold in 1923,[27] who found that implantation of the anterior dorsal lip from one newt embryo into the ventral mesoderm of another induced the formation of a complete second body axis, including a second head. Because the major portion of this material was derived from recipient tissue, it was apparent that the anterior lip, named the "organizer" by Spemann, induced ventral tissue to undergo dorsal differentiation, including the induction of neural, heart, kidney, and somite tissues, as well as head formation. The Spemann organizer is established in the dorsal mesoderm directly adjacent to the Nieuwkoop center as a result of stimulation by β-catenin– and Nodal-related signals.[13,28]

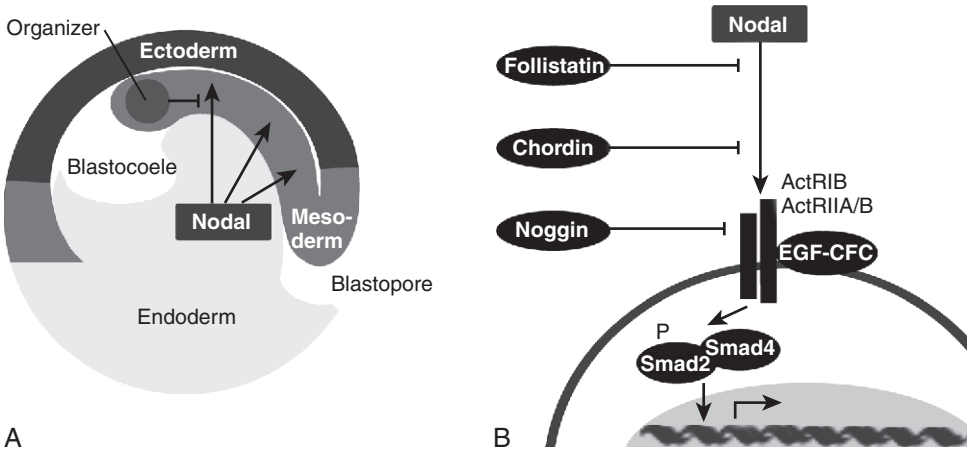

Figure 5-3 Nodal antagonists pattern the gastrulating mesoderm. A, During *Xenopus* gastrulation, the mesoderm involutes by expanding and migrating into the blastocoel through the blastopore. The leading edge contains Spemann's organizer, which is responsible for imparting dorsal characteristics to adjoining tissues. **B,** The dorsalizing activity is conferred by the secreted proteins follistatin and Chordin, which bind and neutralize Nodal, and Noggin, which binds and inactivates the Nodal receptor.

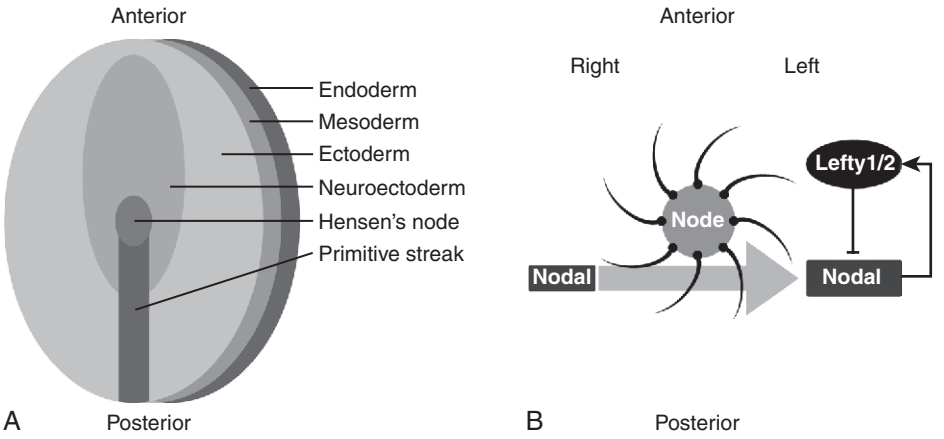

Figure 5-4 Left-right asymmetry in the mouse is established by ciliary distribution of Nodal. A, Hensen's node becomes visible in late gastrulation at the anterior margin of the primitive streak. **B,** The ventral surface is covered with cilia that propel the extraembryonic fluid in a clockwise motion, establishing a higher Nodal concentration on the left side. This asymmetry is reinforced by the induced expression of Nodal inhibitors including Lefty1 and Lefty2.

Spemann's organizer alters the fate of nearby cells by secreting proteins that diffuse into neighboring tissues to interrupt Nodal and BMP signaling. Noggin, chordin, follistatin, and Cerberus all are antagonists of BMP signaling that are secreted by Spemann's organizer, and their depletion results in failed dorsalization.[29,30] Noggin binds BMP receptors and prevents their activation,[31] whereas chordin and follistatin bind and neutralize BMPs.[32,33] Cerberus binds and neutralizes both BMPs and Nodal.[30] These interactions suggest that Nodal and BMP-4 prevent dorsalization, and that antagonists secreted by Spemann's organizer permit cells to dorsalize.

VERTEBRATE LEFT-RIGHT ASYMMETRY IS ESTABLISHED DURING LATE GASTRULATION

The early development of birds and mammals is more complicated and less well characterized than that of *Xenopus.* This is due in part to the presence of extraembryonic tissues that assume some of the organizing functions intrinsic to the *Xenopus* oocyte, thereby adding considerable complexity to the system.[34] For example, cortical rotation does not occur in chicken eggs and in mouse embryos. In these species, dorsoventral axis specification is not completely understood but is apparently mediated by gravitational influences and extraembryonic oocyte derivatives, respectively.[35,36] Mouse and chick embryos are more planar, with no blastopore; the analogous structure is the primitive streak, with Hensen's node at its anterior end. During gastrulation, tissue accumulates anterior to the node, and the node (or streak) regresses or moves to a posterior position. Somites form in the wake of node regression. Moreover, dorsoventral axis determination is not apparent in the mouse until gestation is one-third completed. Nonetheless, Nodal signaling patterns mice and birds as it does *Xenopus.*

In the frog *Xenopus,* left-right axis determination is concomitant with dorsal-ventral specification.[37] In mammals, however, establishment of left-right asymmetry occurs much later, during the one-somite stage.[38] In mice, left-right asymmetry centers on the ventral node, a transient structure located on the ventral aspect of Hensen's node. The ventral surface of the node is a pitlike structure lined with specialized cilia that are driven by kinesin motor proteins. The combination of the orientation of these cilia and their clockwise unidirectional rotation results in a corresponding leftward fluid movement called nodal flow that represents the initial break in symmetry[39] (Figure 5-4). Artificial reversal of this flow reverses the orientation of the internal organs.[38] This fluid flow appears to establish a concentration gradient of secreted factors including Nodal (initially characterized in this context[39]) or, alternatively, to induce asymmetric signaling by sensory cilia.[40] In either case, asymmetric Nodal expression is established and sustained in the left lateral plate mesoderm, and its asymmetric expression is augmented by similarly asymmetric expression of the Nodal inhibitors Lefty1 and Lefty2.[37]

The mechanism underlying left-right axis determination serves to illustrate how defective early embryogenic regulation can have subsequent pathologic consequences. One example of a disorder resulting from such regulatory disturbance is Kartagener syndrome, a human congenital syndrome in which half of the affected patients exhibit *situs inversus,* a mirror-image reversal of the internal organs.[41] The underlying dysfunction is impaired ciliary motility, which precludes establishment of the nodal flow. The lack of nodal flow results in random Nodal localization and correspondingly random organ lateralization. The same motor proteins are used in the adult, in whom ciliary akinesis manifests as immotile sperm and impaired pulmonary clearance leading to recurrent pneumonias.

NEURULATION IS INITIATED BY RECEPTOR TYROSINE KINASE SIGNALING

Neurulation follows gastrulation and represents the second major embryonic inductive event, after mesoderm induction. Once again, tissue induction is coordinately regulated by secreted agonists and antagonists. In *Xenopus,* the prospective neural plate forms in the ectoderm overlying the paraxial mesoderm, whereas in mice and chicks, the neural plate arises in the ectodermal tissue straddling the primitive streak. The newly differentiated neuroectoderm will receive anterior-posterior guidance from the Spemann organizer and adjacent tissues to give rise to the somites, notochord, and nervous tissue.[42]

Although incompletely defined, neurulation apparently is initiated by fibroblast growth factor-8 (FGF-8), which is secreted by the mesoderm to induce the differentiation of ectodermal cells[43] (Figure 5-5). FGF-8 is a member of a peptide family comprising at least 24 different FGF peptides that signal through four closely related receptor tyrosine kinases. Related receptors transduce signaling by peptides such as epidermal growth factor, platelet-derived growth factor, and nerve growth factor (peptide growth factors are named upon initial characterization, and subsequent work often reveals additional functions that are not reflected in the nomenclature).

FGF receptors are transmembrane proteins that dimerize (i.e., associate to form pairs of identical subunits) in the presence of FGF ligand. As with TGF-β receptors, FGF receptor dimerization brings the cytoplasmic tyrosine kinase domains of the two receptors into close proximity and facilitates their mutual phosphorylation and activation. Activated FGF receptors directly phosphorylate cytosolic phospholipase C gamma (PLC-γ), FGF receptor substrate 2 (FRS-2), and Grb2.[44] FRS2 and Grb2 are nonenzymatic adapter proteins that associate with each other and with the guanosine triphosphate (GTP) exchange protein Sos upon phosphorylation.

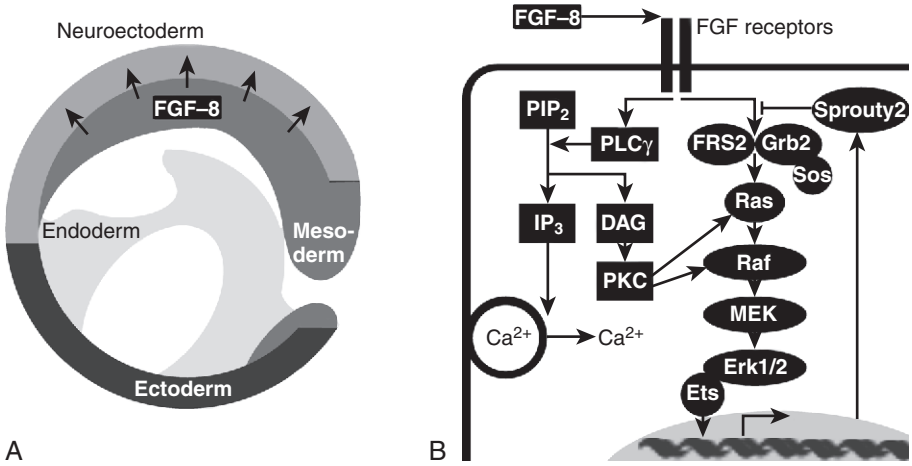

Figure 5-5 Neurulation in *Xenopus* is initiated by receptor tyrosine kinase signaling. A, FGF-8 is secreted by the involuted mesoderm to induce neuroectoderm differentiation. **B,** FGFs bind and activates dimeric transmembrane receptor tyrosine kinases that phosphorylate cytosolic FGF receptor substrate (FRS) 2, and Grb2. Activated FRS2 and Grb2 associate with Sos to activate Ras and, subsequently, Raf, MEK, and the MAP kinases Erk1 and Erk2. Erk MAP kinases phosphorylate Ets family transcription factors that regulate numerous genes. FGF-mediated Erk activation is subject to inhibitory feedback by Sprouty2, which prevents FRS2 from associating with Grb2. FGF receptors also phosphorylate phospholipase C γ (PLC-γ), which hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) into inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG). IP_3 induces calcium release from the endoplasmic reticulum into the cytosol, whereas DAG activates protein kinase C and the Erk MAP kinase pathway. *FGF,* Fibroblast growth factor; *MAP,* mitogen-activated protein; *MEK,* mitogen-activated protein kinase kinase.

The resulting heterotrimer activates the GTP-binding protein Ras, leading to sequential activation of Raf, MEK, and the mitogen-activation protein (MAP) kinases Erk1 and Erk2.[45] Erk1 and Erk2 phosphorylate Ets family transcription factors; on phosphorylation, these factors enter the nucleus and associate with serum response elements and other cofactors to bind specific sites in the promoters of numerous genes. Each step in this pathway represents a node at which the FGF-8 signal may be amplified, attenuated, or conditioned by other signaling pathways. The FGF pathway, like Nodal signaling, also incorporates a negative feedback mechanism; Sprouty2 is a cytosolic protein that, on phosphorylation by FGF receptors, inhibits the association of FRS2 with Grb2, thereby interrupting FGF-8–mediated Erk activation.[46]

FGF receptors also phosphorylate PLC-γ, an enzyme that hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2) into inositol 1,4,5-triphosphate (IP_3) and diacylglycerol. IP_3 binds to cognate receptors embedded in the membrane of the endoplasmic reticulum, thereby releasing calcium from the endoplasmic reticulum into the cytosol.[47] Intracellular calcium signaling regulates cellular activities as diverse as muscle contraction, nuclear breakdown, and egg fertilization. Diacylglycerol activates protein kinase C, which activates the Erk MAP kinase pathway through Ras or Raf.[48] The FGF-8 signaling pathway, with its extracellular ligand, transmembrane receptor, and intracellular mediators, is roughly analogous to the Nodal signaling pathway, albeit with additional intracellular signaling branches.

SEGMENTATION IS CONTROLLED BY SIGNALING GRADIENTS AND CYCLING GENES

Vertebrates, like arthropods, are segmental organisms. Segmentation becomes visible after gastrulation, when paired somites condense from the paraxial mesoderm on both sides of the midline. Somites give rise to the axial musculature, ribs, and vertebrae. Segmental boundaries also define the migration patterns for neural crest derivatives including epithelial and neural precursors. Somite size, number, and position are closely regulated, and irregularities in somite formation result in corresponding somatic malformations.[49]

In the chick embryo, somitogenesis progresses concomitantly with the regression of Hensen's node. New somites appear at regular 90-minute intervals, beginning at the anterior end and proceeding posteriorly. The leading model of somite formation was proposed by Cooke and Zeeman in 1976[50] and postulates two sets of regulatory signals: (1) a maturation wavefront that sweeps through the embryo from anterior to posterior and (2) a clock signal expressed synchronously throughout the presomitic mesoderm with a 90-minute periodicity[51] (Figure 5-6). Signaling processes initiated by the advancing maturation wavefront interact with those of the segmentation clock to establish the anterior and posterior margins of each somite.[52]

The segmentation clock is incompletely characterized, but its existence is supported by several sets of cyclically expressed genes. The most completely defined pathway centers on Notch, a single-pass transmembrane receptor whose extracellular domain contains 36 tandem repetitions of a motif that resembles epidermal growth factor.[53] Its ligands include Serrate and Jagged, proteins that are expressed on the surface of adjoining cells. On binding ligand, Notch is cleaved by proteases embedded in the membrane of the target cell.[53,54] The cleaved cytoplasmic fragment translocates to the nucleus, where it associates with the DNA binding proteins C promoter-binding factor 1 (CBF1) and recombination signal-binding protein 1 for J-kappa (RBPJK), thereby converting them from transcriptional repressors to transcriptional activators. Notch activation is antagonized by the glycosyl transferase Lunatic fringe (Lfng).[55] Lfng is a short-lived protein whose expression is up-regulated by Notch signaling. Inhibitory feedback conferred by Lfng results in cyclic Notch activation and expression of Notch-regulated transcription factors, notably members of the HES ("hairy and enhancer of split") family that share a common basic helix-loop-helix DNA binding motif.[56] At least some of the Hes factors also are unstable, and their degradation is necessary for the cyclic expression of Notch.[57]

A second set of molecular oscillators acts through the *Wnt* pathway. *Wnt* genes encode a large family of secreted lipid-modified proteins with important functions in many developmental contexts.[58,59] *Wnt* signals are transduced by Frizzled, a receptor with seven transmembrane domains that otherwise has little

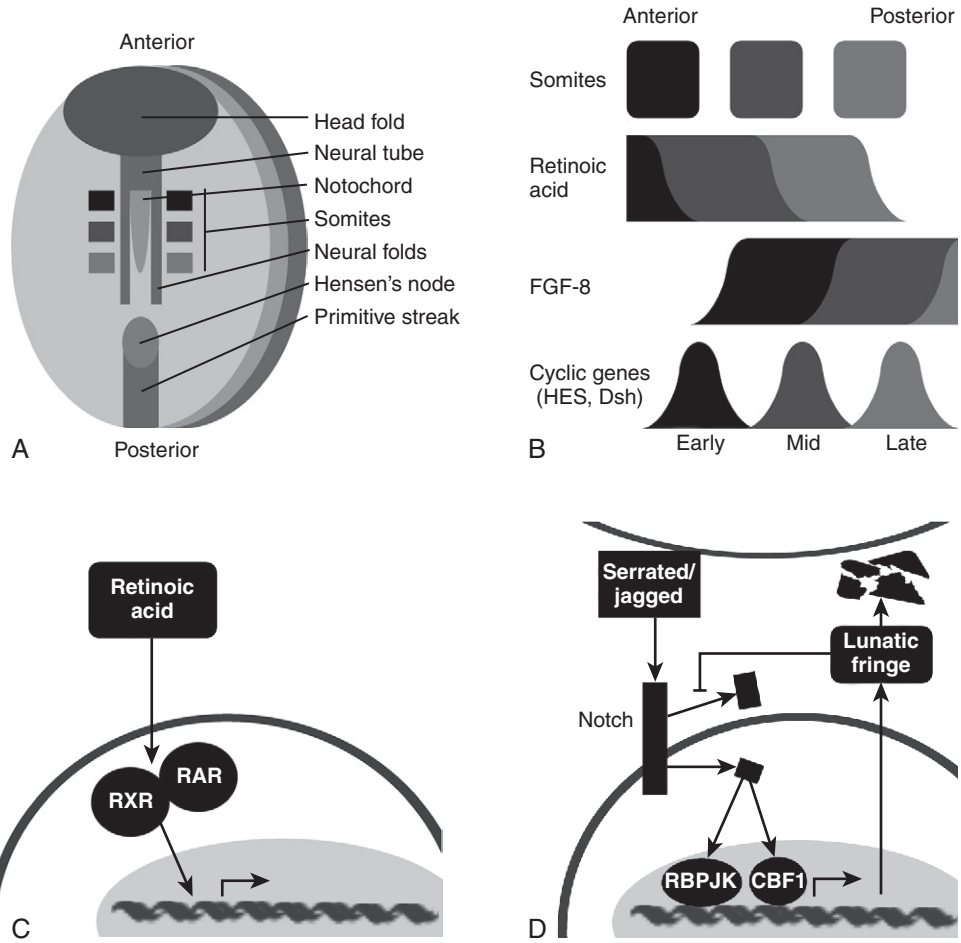

Figure 5-6 Somitogenesis is regulated by a maturation wavefront and a mesodermal clock signal. A, In chicks, somites arise from paraxial mesoderm at 90 minute intervals in the wake of node regression. **B,** The boundaries of each somite are established by one or more oscillating genes interacting with a maturational wavefront that is the product of countervailing retinoic acid and FGF-8 concentration gradients. As new somites are formed, this wavefront sweeps posteriorly. **C,** Retinoic acid, unlike Nodal or FGF, enters the cytoplasm of targeted cells, where it binds homodimers or heterodimers of retinoic acid receptors (RAR) or retinoid X receptors (RXR). **D,** The resulting complex enters the nucleus to bind specific genes. Cyclic genes include components of the Notch pathway, which is initiated by Serrate and Jagged expressed on adjoining cells. Upon binding ligand, Notch is cleaved, and the cytoplasmic fragment translocates to the nucleus to bind the centromere binding proteins CBF1 and RBPJK and to activate gene transcription. One of the induced proteins, the glycosyl transferase Lunatic fringe, inhibits Notch cleavage. Lunatic fringe also is short-lived, and the resulting oscillating feedback loop results in cyclic Notch activation. *FGF,* Fibroblast growth factor.

homology with the seven-transmembrane GTP-protein–coupled receptors that constitute the largest and most diverse class of signaling receptors in metazoans.[60] Frizzled signaling results in activation of the cytoplasmic intermediate Dsh. Dsh, as noted previously, antagonizes the ubiquitin-mediated breakdown of β-catenin. β-Catenin then accumulates in the nucleus, where it regulates gene transcription. One of the targeted genes encodes axin2, an inhibitor of *Wnt* signaling whose expression oscillates in parallel with segmentation.[61] *Wnt* cycles out of phase with Notch cycling, and the coordination between the two signaling loops is not well understood. Nonetheless, the cycling of both gene expression loops is apparently important for coordinated somite development.

The maturation wavefront appears to be defined by opposing gradients of FGF-8 and retinoic acid. FGF-8 is secreted from the posterior presomitic mesoderm,[62] whereas retinoic acid is produced in the segmented anterior mesoderm and diffuses in a posterior direction to form a gradient that antagonizes FGF signaling.[63] Unlike with Nodal and FGF-8, retinoic acid signaling is not mediated by a membrane-bound receptor. Retinoic acid is a vitamin A derivative and belongs to the steroid/thyroid hormone receptor superfamily that includes sex hormones and growth hormone. These molecules penetrate the plasma membrane and enter the cytoplasm, where they bind specific nuclear receptors composed of homo- or heterodimers of two cytosolic proteins, the retinoic acid receptors and the retinoid X receptors. The resulting complexes enter the nucleus, where they bind specific promoter response elements, thereby regulating gene transcription.

The antagonism between FGF and retinoic acid signals establishes the maturation wavefront, which moves posteriorly at a steady rate as new somites are added. The position of the wavefront at each cycle of the segmentation clock defines the border of each segment. Clock signals and wavefront signals interact to transiently express the transcription factor Mesp2 in a one-somite-wide band,[64] and presumably Mesp2 or factors coregulated with Mesp2 stabilize the boundaries and initiate the differentiation of the new somite. The mechanism by which these signals interact is incompletely defined but has been modeled mathematically.[65]

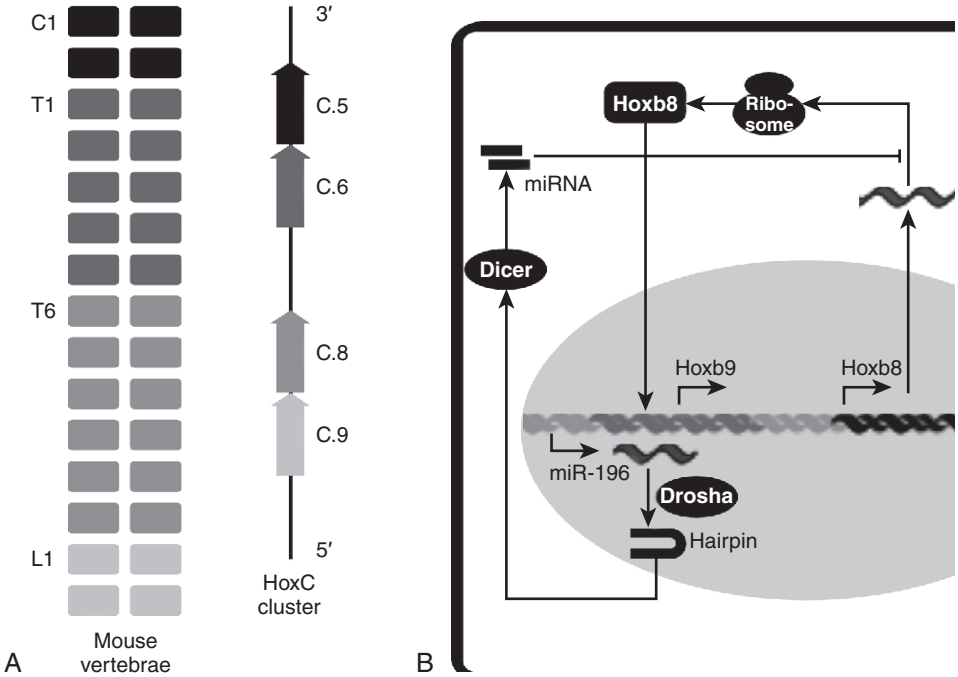

Figure 5-7 Homeobox (Hox) genes confer positional identity to differentiating segments. Hox genes are organized in four clusters, and the genes within each cluster are arranged in the same order as they are expressed. **A,** In this example, the arrangement of genes within the *Hoxc* cluster correlates with their expression within a portion of the mouse vertebral column. The *arrows* indicate the direction of transcription. **B,** One model of *Hox* expression, wherein one Hox protein, Hoxb8, facilitates the expression of the next, Hoxb9. Also shown is the regulatory function of the miR-196 miRNA sequence embedded within the *Hoxb* cluster. These sequences are processed by Drosha and Dicer into miRNAs that enable RNA-induced silencing complexes to target and inactivate Hoxb8. *miRNAs,* Micro-RNAs.

SEGMENT POSITIONAL IDENTITY IS CONFERRED BY HOMEOBOX GENES

Metazoan body plans are dependent on the divergent morphogenesis of individual segments. This, in turn, presupposes that each segment has a positional identity that determines how it develops. The mechanism by which this identity is conferred was first elucidated in the fruit fly *Drosophila melanogaster,* wherein single mutations resulted in duplication of entire body segments. The genes that controlled these so-called homeotic mutations were recognized as master switches that controlled the function of numerous genes within each segment. Sequencing revealed that the genes responsible for homeotic mutations were positioned one after another on the same chromosome, oriented in the same 5′ to 3′ transcriptional direction, and positioned in the same order as for the body domains regulated by them.[66] Each gene contained a highly conserved sequence of 180 bases, the homeobox, that encoded a 60–amino acid motif called the homeodomain. The homeodomain is a helix-turn-helix DNA-binding motif, indicating a role in transcriptional regulation. The genes themselves are called homeobox *(Hox)* genes.[67]

The mouse and human *Hox* gene complexes comprise 38 genes organized in four chromosomal complexes of approximately 120 kb.[68] As in fruit flies, the physical order of the *Hox* genes within these clusters corresponds to their expression from anterior to posterior (Figure 5-7). *Hox* expression boundaries, however, correspond to anatomic regions and not to individual somites[69]; multiple somites may be regulated by a single set of *Hox* genes to assume a similar phenotype. This coregulation underlies the similarity, for example, between the 7 human cervical vertebrae, relative to the 12 thoracic vertebrae. Moreover, differences in the size and placement of homologous structures (such as the number of cervical vertebrae in mice, humans, and chickens) correspond to differences in the distribution of the analogous *Hox* gene products.

The regulation of *Hox* expression is incompletely understood, but several mutually compatible mechanisms are supported by the evidence.[70] First, the colinear placement of *Hox* genes within each cluster suggests that transcription of one gene facilitates the transcription of the next. This may involve transcription factors encoded by the preceding *Hox* gene[71] or mechanical unpacking of the chromatin that permits transcription factors to associate with the gene.[72] Second, *Hox* expression may be regulated by the Notch segmentation clock, thereby synchronizing *Hox* genes within each somite.[73] Finally, anterioposterior gradients of FGF, retinoic acid, or other factors may confer positional regulation of *Hox* domains.[74]

The morphological development of a somite or anteroposterior region is determined by the combination of *Hox* genes, or *Hox* code, expressed within those tissues.[75] *Hox* genes regulate arrays of genes by binding *Hox*-responsive enhancers within DNA regulatory regions. Individual Hox proteins can modulate as many as 68 distinct genes,[76] some of which also are transcription factors.

In addition to transcriptional regulation, *Hox* clusters also regulate gene expression through RNA interference,[77] a mechanism in which specific mRNA strands in the cytoplasm are degraded. This degradation reduces the translation and, hence, expression of the encoded proteins. *Hox* clusters encode precursor microRNA (miRNA) transcripts that contain complementary inverted repeat sequences; the internal allowergetically favorable for the transcripts to fold back on themselves to form hairpin structures that are cleaved within the nucleus by the double-stranded RNA (dsRNA) endonuclease Drosha.[78] The cleavage products are exported to the cytoplasm where they are processed by the dsRNA endonuclease Dicer into 21-base duplexes that are then incorporated into RNA-induced silencing complexes (RISCs) whose specificity is defined by the now single-stranded miRNA. The RISC targets and cleaves mRNA strands that contain sequences complementary to the miRNA, resulting in the post-transcriptional down-regulation of the targeted gene product.

Sequence analyses predict that many *Hox* gene products are targets of the miRNA sequences encoded within *Hox* clusters.[79] One, Hoxb8, has been experimentally silenced by an miRNA (miR-196) encoded by the mouse *Hoxb* cluster.[80] Like the *Hox* genes, the miRNAs encoded by the *Hox* cluster appear to have a regional distribution that may have developmental implications.[81] Although the functional significance of Hox regulation by miRNA is unclear, accumulating evidence suggests that such regulation is widespread and highly conserved throughout metazoans.[82]

NEUROECTODERMAL REGULATION PATTERNS CRANIOFACIAL STRUCTURES

After neurulation, differentiation of the craniofacial structures begins with invagination of the neural plate to form the neural folds. The subsequent approximation and closure of these folds results in formation of the neural tube.[83] Cells dissociate from the neural folds and undergo epithelial-to-mesenchymal transformation to become the neural crest cells that migrate throughout the embryo along defined routes. The developmental contributions of neural crest cells correlate with their original position, and this identity is conferred by ectodermally secreted Wnt proteins,[84] BMP-4, and the BMP antagonists chordin and Noggin secreted by the anterior mesoderm.[85] BMP-4 and its antagonists establish an activity gradient that determines the fate of neuroectodermal derivatives, with the level required for neural crest induction greater than that required for neural plate induction and lower than that required for ectoderm specification.[86] This gradient is associated with regional expression of specific transcriptional regulators[83,87,88]: The zinc-finger transcription factors of the *Zic* family are expressed throughout the neural plate and crest; the homeobox transcriptional repressors Msx1 and Msx2 are expressed in the neural plate border; the paired-box transcriptional activators Pax3 and Pax7 are expressed at the neural plate border; and the transcriptional activators Sox9 and Sox10 localize to premigratory and migratory neural crest, respectively.

After closure, the anterior neural tube differentiates into forebrain, midbrain, and hindbrain components. The hindbrain is of particular clinical interest because hindbrain derivatives are major contributors to facial formation, and craniofacial anomalies comprise one third of all human congenital defects.[89] During early vertebrate hindbrain development, seven transient transverse bulges become apparent. These divide the hindbrain into eight developmental domains called *rhombomeres.* In contrast with somites, whose numbers vary considerably across species, the number of rhombomeres is quite stable across vertebrate classes.[90] As with the somites, the divergent differentiation of these rhombomeres is regulated by *Hox* genes whose expression, in turn, is controlled by FGF-8 and retinoic acid.[91,92] Rhombomeres give rise to cranial neural crest cells that migrate out of the neuroectoderm, proliferate, coalesce into the first three branchial arches, and ultimately coalesce into the craniofacial structures[93] (Figure 5-8). Subtle differences in rhombomere regulation are reflected in variations in cell migration and proliferation that contribute to each person's unique facial structure, whereas more disruptive mutations result in overtly dysmorphic features that often are pathognomonic for those mutations. The developmental contribution of each rhombomere is regulated by *Hox* gene expression. For example, rhombomeres 3 and 5 express Msx2, and cranial neural crest cells that express this factor undergo apoptosis when stimulated with BMP-4.[94] Similarly, Sox9 expression regulates BMP-4–mediated chondrogenesis.[95] The profile of Hox genes expressed within each rhombomere therefore guides the behavior of its derivatives.

DISRUPTED CRANIOFACIAL DEVELOPMENT IS ASSOCIATED WITH VISCERAL MALFORMATIONS

As noted previously, embryonic regulatory mechanisms also are used to control somatic and visceral development as well as tissue regeneration after injury. For example, FGF signaling regulates both limb formation and lung morphogenesis.[96-98] Disruption of FGF signaling reduces lung branching,[99] whereas abrogation of its feedback inhibitor Sprouty[100,101] has the opposite effect. Similarly, components in the FGF pathway are regulated in response to lung injury.[102,103]

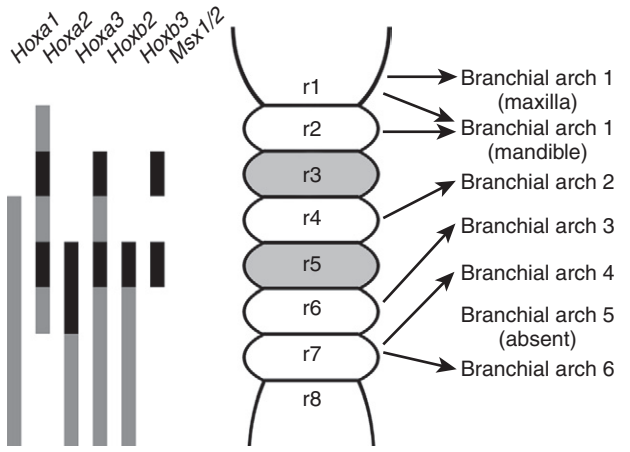

Figure 5-8 The expression of *Hox* genes within each rhombomere determines the developmental contribution of its derivatives. The distribution of selected *Hox* genes is shown, together with the branchial arches derived from the migrating neural crest cells of each rhombomere. Many neural crest cells from r3 and r5 *(shaded)* undergo apoptosis, a process that appears to be initiated by bone morphogenetic protein-4 (BMP-4) stimulation.

Because craniofacial structures are derived from cranial neural crest cells, disruptions in rhombomere regulation are associated with characteristic craniofacial anomalies. Many of the same pathways are reiterated later in fetal development, so these craniofacial malformations often are associated with additional somatic or visceral anomalies. Mutations in human Pax3 (which, as noted previously, appears to define the neural plate border) are associated with type I and type III Waardenburg syndrome, characterized by congenital deafness and partial albinism with or without limb anomalies.[104] Mutations in Sox10 are associated with type IV Waardenburg syndrome, characterized by deafness, partial albinism, and aganglionic megacolon.[105] Additional examples are listed in Table 5-1.

SUMMARY

Embryonic development is regulated by intercellular communications that are mediated by secreted molecules. These factors are expressed in organizing centers and diffuse outward to establish concentration gradients that induce tissue differentiation and confer positional and behavioral identity. Signaling factors may interact cooperatively or antagonistically with other secreted proteins to transmit signals that are transduced into targeted cells by families of related receptors with overlapping functions and specificities. Receptor families prominent in early embryogenesis include TGF-β receptors (Nodal and BMP), receptor tyrosine kinases (FGF), Notch receptors (Serrate and Jagged), Frizzled receptors (Wnt), and nuclear receptors (retinoic acid). These receptors initiate chains of intracellular kinase reactions that regulate and are regulated by other signaling pathways. Consequently, cell behaviors are specified by combinations of signals that interact in both the intracellular and extracellular domains. These pathways modulate the activity of DNA-binding proteins that alter gene transcription. Certain transcription factors (notably the Hox proteins) serve as master switches that regulate batteries of genes. These genes also may encode transcriptional regulators or micro-RNAs, so that dozens of proteins are modulated by a single stimulus, thereby initiating complex cell behaviors in a coordinated fashion. Most signaling pathways incorporate positive feedback loops that maintain and propogate pathway activity, and negative feedback loops that stabilize

TABLE 5-1

Gene Product Mutations With Associated Craniofacial and Visceral Malformations

Mutated Regulatory Mediator	Associated Syndrome/ Disorder	Craniofacial Manifestations	Somatic/Visceral Manifestations
FGF receptor-1	Pfeiffer syndrome	Microcephaly, sensorineural deafness	Broad, short thumbs and great toes; webbed hands/feet
FGF receptor-2	Crouzon syndrome	Craniosynostosis, maxillary hypoplasia, hypertelorism	Cervical fusion (18%), acanthosis nigra (5%)
FGF receptor-3	Costello syndrome	Macrocephaly, coarse facies, brain atrophy, macroglossia	Cardiomyopathy, cryptorchidism, hyperkeratosis
FGF receptor-3	Thanatophoric dwarfism	Macrocephaly, frontal bossing	Short limbs, pulmonary hypoplasia
Ubiquitin ligase E3A	Angelman syndrome	Microcephaly, developmental delay, seizures, ataxia	Fair skin and hair
Msx1	Witkop syndrome	Hypodontia	Hypoplastic nails
Pax3	Waardenburg syndrome types I and III	Hearing loss, hypopigmented hair patch and eye(s)	Limb anomalies, aganglionic megacolon
Sox9	Campomelic dysplasia	Cleft palate, macrocephaly, micrognathia, retroglossia	Skeletal anomalies, cardiac and renal malformations, sex reversal
Sox10	Waardenburg syndrome type IV	Hearing loss, hypopigmented hair patch and eye(s), central demyelinating leukodystrophy	Limb anomalies, aganglionic megacolon, peripheral demyelinating neuropathy
Noggin	Facioaudiosymphalangism syndrome	Broad hemicylindrical nose, conductive hearing loss	Joint dysplasia and synostosis

FGF, Fibroblast growth factor.

and limit signaling. Short-lived components within these feedback loops induce oscillating signals that are exploited to form repeated structures. Most signaling mechanisms are reiterated in different contexts to regulate development, homeostasis, and regeneration and are therefore relevant to the induction and amelioration of pathologic processes.

The Extracellular Matrix in Development

As a single fertilized egg develops into a fully patterned embryo, individual cells divide, migrate, change their shape, and respond to environmental cues. Throughout these processes, cells remain in constant contact with extracellular matrix (ECM), a three-dimensional latticework of glycoproteins that directs morphogenesis. The ECM surrounding individual cells provides a specialized microenvironment that regulates behavior through interacting with cell surface receptors. In this regard, integrins have emerged as the predominant cell surface receptors. The ECM and integrins regulate extracellular and intracellular signals emanating from extrinsic factors, including growth factors, hormones, and biomechanical forces. The ECM acts as a reservoir for growth factors, collaborating with integrins and ECM-degrading proteinases to present these factors to cells within developing tissues. In addition, proteolysis of the ECM generates neoepitopes that confer functions on cells and tissues distinct from those specified by their nonproteolyzed counterparts. In this chapter, as background for explicating these and other points, a review of the complex structure of the ECM, and of how integrins convey signals from the ECM to the cell interior, is presented first. To illustrate these processes in more detail, how ECM regulates angiogenesis, a key process during embryonic development, also is described.

MULTIFUNCTIONAL NATURE OF THE EXTRACELLULAR MATRIX

Normal development requires precise temporal and spatial coordination of cellular proliferation, differentiation, migration, and apoptosis. Deciding which of these programs a cell will ultimately elect is determined, to a large extent, by the ECM. Promotion or suppression of cellular proliferation by the ECM, for example, results in either stimulation or inhibition of genes involved in the regulation of the cell cycle.[1-4] To counteract runaway cellular proliferation and to sculpt or refine developing tissue structures, select cells also must be eliminated from developing tissues. To this end, loss of cell contact with the ECM leads to apoptosis during development.[5,6] Tissue-specific ECM components also regulate the transcription of genes associated with specialized differentiated functions, including alkaline phosphatase expression in osteoblasts,[7] albumin production in hepatocytes,[8] and intermediate filament protein expression in keratinocytes.[9] These observations are supported by the identification of ECM-responsive transcription factors and *cis* elements within gene promoter elements.[10,11] The mechanical properties of ECM also have been shown to regulate mesenchymal stem cell differentiation into various cell lineages.[12] Throughout development, cells move from their point of origin to other positions within the embryo, and the ECM provides the template on which migration occurs. Moreover, stem cell maintenance, self-renewal, and cell fate determination depend on the ECM.[13-16] To decipher how the ECM confers so many different functions, an appreciation of its complex structure, reviewed next, is essential.

EXTRACELLULAR MATRIX IS STRUCTURALLY DIVERSE

The ECM is an oligomeric, three-dimensional network composed of four major protein components: the collagens, structural glycoproteins (e.g., fibronectin, laminin, tenascin-C), proteoglycans (e.g., heparan sulfate proteoglycans, syndecans), and elastic fibers (e.g., elastin, microfibrillar proteins). Not every ECM network contains all of these proteins, however, nor does the composition of the ECM remain constant within any particular tissue. Rather, the distribution and organization of the ECM are both dynamic and tissue-specific. For example, mesenchymal cells are surrounded by an interstitial stromal ECM, which includes type I collagen, type II collagen, fibronectin, and proteoglycans. The basement membrane represents another specialized ECM that is composed predominantly of laminin, type IV collagen, heparan sulfate proteoglycan, and entactin. Some basement membranes exist as an amorphous sheetlike structure connected to an underlying collagenous stroma by anchoring fibrils composed of type VII collagen. Alternatively, basement membrane material may separate distinct cell layers, as is the case in the kidney glomerulus, where the basement membrane separating epithelial and endothelial cells also functions as a filter. ECM concentrates specific receptors and channels during neuronal synapse formation and maturation.[17] Cells within certain tissues (e.g., skin, arteries) need to be especially resilient to the effects of certain environmental factors such as mechanical force. In this respect, ECM reinforced with elastin fibers provides structural stability.

Within these different extracellular matrices, additional structural and functional diversity is generated through the use of alternative gene promoters and RNA splicing, and by posttranslational modifications, including glycosylation and sulfation of newly synthesized ECM proteins. Once secreted into the extracellular space, ECM proteins require integration into a functional network. Identifying binding partners for a specific ECM protein is therefore a prerequisite to ascertaining its biochemical and cell-signaling properties. For example, the ECM glycoprotein tenascin-C can interact in a tissue-specific manner with fibronectin, perlecan, neurocan, heparin, phosphacan, syndecan, glypican, and periostin.[18,19] Accordingly, understanding the biology of a single ECM component requires an appreciation of the structure and functions of numerous other affiliated proteins. In view of the number of steps involved in coordinating ECM expression, secretion, and assembly, deciphering how individual ECM proteins contribute to structural morphogenesis during development represents a formidable task.

GENETIC APPROACHES TO DISSECTING EXTRACELLULAR MATRIX FUNCTIONS

Both mapping and identifying gene mutations that lead to heritable connective tissue disorders and the generation of animal models in which ECM genes have been mutated or ablated have been successfully used to ascertain the functions of individual ECM proteins within specific tissues. Many of the diseases resulting from ECM gene mutations result from defective structural integrity of specific tissues. Mutations in collagen type VII, collagen type XVII and laminin 332 genes can cause the skin-blistering disease epidermolysis bullosa.[20,21] Mutations in type I collagen genes cause osteogenesis imperfecta,[22] and mutations in both collagen I and tenascin-X genes can cause Ehlers-Danlos syndrome.[23] In addition to gene defects that alter mechanical properties of the ECM, mutations in the fibrillin-1 gene that cause

Marfan syndrome appear to increase TGF-β signaling, leading to the cellular disease phenotype.[24]

Although mutations in ECM genes can produce heritable disorders, animal studies suggest that many structural ECM glycoproteins are essential for embryonic or fetal development. As a result, mutations in these genes often cause lethality early in development, complicating the study of gene function in vivo. Inactivation of the fibronectin gene in mice results in embryonic death due to mesodermal, neural tube, and vascular developmental defects.[25] In addition, fibronectin also has been shown to be required for normal gastrulation.[26] More targeted studies have provided data on the role of fibronectin in several developmental processes. Injection of inhibitory peptides or antibodies into postgastrulation embryos prevents fibronectin-cellular interactions and disrupts neural crest migration.[27] In contrast with fibronectin, knockout of the tenascin-C gene in mice results in viable and fertile adults,[28] suggesting that other ECM proteins may be able to compensate for tenascin-C deficiency. Consistent with this notion, experiments using isolated adult hypertensive pulmonary arteries, in which tenascin-C expression has been suppressed, indicate that osteopontin substitutes for tenascin-C in promoting smooth muscle cell proliferation.[29]

Mutations in ECM component genes may also cause adult onset phenotypes. Some of these phenotypes may result from abnormalities not grossly visible at birth, and many of these animals have not been analyzed in sufficient detail to rule out developmental defects. For example, tenascin-C gene–knockout mice suffer from several neurologic defects, including hyperactivity, poor sensorimotor coordination, clinging, and freezing behavior, as well as poor performance in passive avoidance tests.[30] Other defects in tenascin-C gene–knockout animals have subsequently been detected, including reduced corneal wound healing and hematopoiesis.[31,32] Tenascin-C gene–knockout mice also exhibit less severe inflammation in an arthritis model, suggesting that ECM components participate in the inflammatory response.[33]

Reverse genetics also has been useful in revealing unexpected functions for other ECM genes. For instance, ablation of the elastin gene was predicted to cause structural defects in the three-dimensional structure of blood vessels. Elastin-null animals, however, die within days of birth as a result of obstructive arterial disease characterized by proliferation of subendothelial smooth muscle.[34] Thus, elastin exerts an unexpected growth inhibitory role during normal vascular morphogenesis. Adult elastin–haploinsufficient mice are hypertensive, also as a result of abnormal vascular development and remodeling.[35] Results from ECM-mutant animals therefore demonstrate the important roles ECM components play both in development and in response to stressful challenge or injury.

INTEGRINS AS EXTRACELLULAR MATRIX RECEPTORS

Studying ECM receptors provides another approach to understanding how the ECM controls development and tissue homeostasis. Cell adhesion or release from the ECM is mediated by cell surface proteoglycans and integrins. The most-studied class of ECM receptors, integrins are noncovalently linked, heterodimeric, transmembrane proteins composed of one α- and one β-subunit.[36,37] At the structural level, the α- and β-subunits are distinct, with separate proteins functions. The large extracellular domains of integrins interact with ECM ligands in the extracellular space, whereas their small intracellular domains associate with the actin cytoskeleton by means of adapter signaling proteins, including vinculin, talin, and α-actinin.[38] The α6β4 integrin is an exception to this rule: It possesses an unusually long cytoplasmic domain that interacts with intermediate filaments within hemidesmosomes, rather than with actin microfilaments. The cytoplasmic domains of integrins interact with multiple signaling molecules, included focal adhesion kinase (FAK), integrin-linked kinase (ILK), kindlins, filamins, and migflilin.[39-41] Thus integrins connect the extracellular environment to a cell's internal signaling pathways.

To date, 18 α- and 8 β-subunits have been identified, and these assemble into 24 distinct αβ integrins that recognize different ECM ligands. For example, certain integrins recognize specific ECM proteins, including fibronectin, vitronectin, and tenascin-C, which contain a small tripeptide sequence designated RGD (Arg-Gly-Asp). By contrast, β4 integrins interacting with α3-, α6-, and α7-subunits recognize laminins, whereas integrins composed of the β1-integrin subunit and the α1, α2, α10, or α11 subunit bind collagen. This apparent redundancy in ligand binding specificity suggests that integrins might have overlapping functions. Gene knockout experiments in mice, however, have shown that individual integrin subunits possess unique functions.[36,37,42] For example, although the α3β1 and α7β1 integrins both recognize laminins, knockout of the α3 receptor subunit leads to kidney defects and reduced lung branching morphogenesis, whereas α7-null animals develop muscular dystrophy. The integrins α5β1 and α8β1 both bind RGD peptides including fibronectin, but whereas deletion of the α5 subunit is associated with embryonal lethality, deletion of the α8 subunit causes renal dysplasia and abnormal lung morphogenesis.[43,44] The αvβ3 and αvβ8 integrins also interact with RGD-containing ECM proteins. Ablation of the β3-subunit causes defects in platelet aggregation and osteoclast function, resulting in hemorrhage and osteosclerosis,[45,46] whereas β8-null–mice die during embryogenesis because of abnormal placental and neurovascular development.[47] Keratinocytes use both α3β1 and α6β4 integrins to adhere to laminin. Mice lacking the integrin α3β1 exhibit a poorly organized basement membrane[48] but maintain keratinocyte adherence through integrin α6β4. Further studies suggest that the α3β1 laminin receptor can organize the basement membrane, whereas integrin α6β4 functions primarily to stabilize adhesion through hemidesmosomes.[49] Overall, these studies indicate that each member of the integrin family has evolved to subserve specialized and distinct functions throughout development. Determining how integrins transmit signals to the cell interior is clearly fundamental to understanding how this specificity is attained.

Signaling Through Integrins

Binding ECM ligands promotes integrin clustering and formation of cytoplasmic protein complexes that are nucleated by integrin cytoplasmic domains. These complexes are composed of cytoskeletal proteins and numerous intracellular signaling proteins at the inner surface of the plasma membrane.[50] These complexes congregate within specialized signaling centers termed *focal adhesions.* Different types of focal adhesions form depending on whether cells are cultured on two-dimensional surfaces or within three-dimensional matrices.[51] In this chapter, all of these structures are collectively referred to as focal adhesions.

On binding to ECM, signals initiating from the cytoplasmic tails of integrin receptors rapidly initiate recruitment of proteins to focal adhesions. Focal adhesion kinase, a 120-kDa nonreceptor tyrosine kinase, is a key regulator of signaling events downstream of focal adhesion formation. On initial formation of the focal adhesion, FAK, paxillin, talin, and Arp 2/3 mediate connection of ECM and integrins with the intracellular actin cytoskeleton. FAK activation then recruits an additional wave of signaling molecules to focal adhesions, which leads to dynamic changes in membrane dynamics, directional cell migration, and focal adhesion turnover.[52]

Many observations strongly suggest that activation of FAK by integrins plays a central role in initiating cell proliferation. For example, mutation of tyrosine residues critical for FAK activation prevents integrin-mediated proliferation.[53] Additionally, oncogenic

transformation of cells activates FAK, abolishing the requirement for anchorage-dependent growth.[54] Consistent with this, introduction of constitutively active FAK mutant leads to cell transformation, anchorage-independent cell division, and the suppression of apoptosis.[55] FAK deficiency in mice causes embryonic lethality, with delayed embryonic cell migration, impaired organogenesis, and vascular defects. This phenotype also is reminiscent of fibronectin- and α5-integrin–deficient mice, supporting the notion that ECM, integrins, and FAK are intimately linked. Unexpectedly, fibroblasts isolated from FAK-null mice are able to assemble focal adhesions and display increased adherence to the ECM substrates in tissue culture. This finding may explain why FAK-deficient cells exhibit reduced migration in vivo. Of interest, a truncated form of FAK is expressed in the brain, a highly differentiated, largely nonproliferative tissue.[56] Future studies aimed at determining the nature of the signaling molecules that lie downstream from FAK may reveal how this major integrin-responsive kinase specifies so many functions in different tissues.

Inside cells, ILK and a group of integrin tail-binding proteins called kindlins regulate how signals from the ECM affect cell behavior. ILK binds the cytoplasmic tail of β-integrin subunits and regulates actin dynamics through interaction with the actin regulatory proteins α- and β-parvin. Mutations in ILK that disrupt α-parvin binding prevent normal cell migration and cause renal agenesis in mice.[57] The three kindlin proteins—kindlin-1, -2, and -3—have different expression patterns but are required for normal cell-matrix adhesion. Kindlin-2 is most widely expressed, and loss of kindlin-2 expression disrupts adhesion of endoderm and epiblast cells to their basement membranes, leading to early embryonic death.[58]

Cross-Talk Between Integrins and Growth Factors

Various extracellular growth factors regulate cell migration and dynamics by means of integrin-mediated signaling. Growth factor stimulation can activate FAK, indicating that integrin and growth factor signaling pathways intersect at focal adhesions.[59] Consistent with this notion, integrin clustering promotes recruitment and activation of growth-factor receptors within focal adhesion complexes. For example, treatment of endothelial cells with beads coated either with RGD tripeptide or with fibronectin leads to coaggregation of β1-integrins and FAK, as well as with high-affinity fibroblast growth factor (FGF) receptors within newly formed focal adhesions.[60] Parallel studies using similar approaches have extended these findings to show that integrin activation also can lead to recruitment of a more extensive repertoire of growth factor receptors, including those for epidermal growth factor (EGF) and platelet-derived growth factor (PDGF).[61]

It is not fully understood how integrin ligation leads to the recruitment of receptor tyrosine kinases to the focal adhesion site. However, the fact that high-affinity EGF receptors can directly bind actin, which in turn enhances EGF-dependent autophosphorylation and activation of downstream substrates, indicates a critical role for the F-actin cytoskeleton in coordinating signaling between integrins and growth factors.[62-64] Not surprisingly, pharmacologic disruption of the actin cytoskeleton not only prevents focal adhesion formation but also leads to reduced growth factor receptor activation.[65,66] Thus the actin cytoskeleton and associated proteins may act as a solid-state scaffold that spatially and biochemically coordinates cross-talk between integrins and growth factor receptor tyrosine kinases.

Integrins also can facilitate extracellular binding of growth factors to their receptors.[67] Transforming growth factor-β (TGF-β) is synthesized as a prepropeptide and cleaved by furin proteases before secretion. Once released in the extracellular environment, TGF-β remains associated with its propeptide—latency-associated peptide (LAP)—in a large latent complex (LLC) within the ECM. LAP binds fibrillin and fibronectin, and TGF-β as part of the LLC is inactive. ECM degradation can facilitate TGF-β receptor binding if components of the LLC-fibronectin-fibrillin complex are broken down.[68] In the absence of ECM degradation, the cell surface integrins αvβ6 and αvβ8 can bind LAP, present the active TGF-β peptide to its receptor, and promote downstream signaling. Integrin-mediated TGF-β activation increases in the presence of mechanical strain between ECM and adjacent cells, providing a potential mechanosensory signaling mechanism within developing tissues.[69]

EXTRACELLULAR MATRIX AND ANGIOGENESIS

The studies described already fully support the idea that signals generated by the ECM control many aspects of cell behavior. Instead of describing all of the developmental events in which ECM plays a role, this chapter focuses on angiogenesis, the growth of new capillaries from preexisting blood vessels. Angiogenesis also has been studied extensively in a variety of pathologic conditions, including neovascularization of solid tumors and the growth of new vessels into the retina, as occurs in diabetic retinopathy. Although developmental angiogenesis and pathologic angiogenesis differ somewhat, changes in endothelial cell adhesion to the ECM are critical in both instances. For example, in response to angiogenic factors, endothelia degrade their underlying basement membrane and invade the adjacent perivascular ECM. Proteolysis of the ECM also allows soluble serum proteins, including vitronectin, fibronectin, and fibrinogen, to extravasate into the extracellular space, thereby providing additional ECM components for endothelial cell migration. Next, endothelial cells begin to proliferate and to align themselves into angiogenic sprouts, columns of endothelial cells that orient toward sources of growth factor expression within tissues. Forming a new sprouting stalk of endothelia requires precise coordination of both cell-cell and cell-ECM adhesion. Finally, to form a patent vessel, lumina form within the column of sprouting endothelial cells and connect with existing vessels to establish blood flow and circulation. Endothelia in these new vessels then recruit pericytes and establish a new basement membrane. Interaction with pericytes and ECM further instructs endothelia within newly formed vessels to exit the cell cycle and become quiescent.

Integrins and Angiogenesis

Although vascular endothelia express a variety of integrins, including α6β1, α1β1, α2β1, α3β1, and α6β4, a great deal of attention has been focused on the αv-subunit–containing receptors. Treatment of endothelial cells with angiogenic factors, including vascular endothelial growth factor (VEGF), stimulates the expression of these integrins.[70] Furthermore, VEGF has been shown to promote EC adhesion to the ECM through αvβ3 and αvβ5 integrins, demonstrating that VEGF controls integrin activity.[71] In addition, immunoprecipitation experiments have shown that VEGF receptors (e.g., VEGF-R2) associate with αvβ3 integrins.[72] At a functional level, blockade of the αvβ3 integrins prevents angiogenesis induced by VEGF, whereas inactivating the αvβ5 integrin inhibits the angiogenic effects of FGF-2.[73] These latter studies not only demonstrate that soluble angiogenic factors and endothelial integrins communicate with one another but also suggest that different soluble angiogenic factors control different aspects of angiogenesis. In another example of differential mechanisms regarding angiogenesis, inhibition of protein kinase C (PKC)[73] disrupts VEGF-induced angiogenesis, yet PKC inhibition has no effect on FGF-2–dependent stimulation of endothelial cells.

A proangiogenic role for the αvβ3 integrin also is suggested by a number of other studies. For instance, the αvβ3 integrin localizes to newly formed embryonic blood vessels, suggesting an important role in vivo.[74] This notion is upheld by the finding that blocking the αvβ3 integrin receptor prevents angiogenesis

in various tissue types including the chick chorioallantoic membrane, mouse retina, quail embryo, and rabbit cornea.[74-76] Endothelial survival requires adhesion to the ECM,[77] and the αvβ3 integrin receptor has been shown to regulate this process.[78,79] Of interest, blocking αvβ3 integrins in vivo selectively induces apoptosis in newly formed vessels, but this treatment has no effect on preexisting vessels. In terms of the actual mechanism involved in promoting EC survival, ligation of endothelial αvβ3 integrins suppresses the activity or expression of the cell death mediators p53 and p21 WAF1/CIP1.[80]

Endothelial cell motility also requires the αvβ3 integrin receptor. To migrate, endothelial cells must reorganize their cytoskeleton in a manner that allows for the generation of intracellular forces that exert traction on the underlying ECM. Activation of the αvβ3 integrin receptor is required for sustained activation of the mitogen-activated protein kinases ERK1 and ERK2,[81] which in turn leads to phosphorylation of myosin light chains, components of the cell motility machinery required for endothelial cell motility.[82]

Null mutations of αv integrin subunits also have provided insights about how these receptors function during developmental angiogenesis. Contrary to expectations, vascular development in the αv-null mouse proceeds in a normal manner, and approximately 20% of the animals are born live.[83] After birth, however, these animals succumb to severe intracerebral and intestinal hemorrhages. These studies either reflect redundant and degenerate roles for αv integrins or indicate that αv integrins are more essential for vascular integrity than for blood vessel formation.

Matrix Metalloproteinases and Angiogenesis

Movement of angiogenic endothelial cells through the basement membrane and the perivascular tissue microenvironment requires catabolism of the ECM. The finding that matrix metalloproteinase-2 (MMP-2)-deficient mice show reduced rates of angiogenesis supports this idea.[84] Once again, the αvβ3 integrin appears to be involved, because interaction of this receptor with MMP-2 leads to MMP-2 activation on the surface of invasive endothelial cells.[85] Furthermore, treatment of angiogenic endothelia with a peptide that prevents binding of MMP-2 to αvβ3 integrins not only blocks collagenolytic activity but also inhibits angiogenesis.[86]

During angiogenesis, MMP-mediated degradation of ECM reveals neoepitopes that provoke alternative forms of endothelial cell behavior. For example, proteolytic cleavage of type IV collagen by MMP-9 results in the exposure of a functionally important proangiogenic αvβ3 integrin-binding site that usually is hidden within the native collagen structure.[87] This mechanism may allow endothelial cells to modify and respond to microenvironmental cues rapidly without de novo gene expression.

Experiments involving tissues isolated from MMP-deficient mice have provided additional clues as to how MMPs promote angiogenesis. Ablation of the gene encoding membrane-type matrix metalloproteinase-1 (MT1-MMP), an enzyme required for MMP-2 activation, leads to defective angiogenesis within remodeling cartilage and an impairment of skeletal development.[88] Similarly, homozygous mice with a null mutation in MMP-9 exhibit an abnormal pattern of skeletal growth plate vascularization and ossification.[89] In each case, tissues explanted from these null mice show delayed release of angiogenic factors, including FGF-2 and VEGF, reinforcing the idea that the MMP-cleavage of the endothelial ECM promotes the bioavailability of angiogenic growth factors.

Biomechanical Force and Angiogenesis

Cells within developing embryos are exposed to mechanical forces that maintain and modify their biologic behavior. In continuous contact with blood flow, endothelial cells are not exempt from this situation. For example, stretching endothelia increases β3 integrin mRNA levels, as well as reorganization of β1, α5, and α2 integrins.[90,91] Studies in vascular smooth muscle cells demonstrate that biomechanical-dependent cellular proliferation requires β3 and αvβ5 integrins.[92] The idea that integrins detect biomechanical signals is further supported by the recent finding that FAK is involved in mechanosensing during cell migration.[93] Biomechanical force also modulates the expression and activities of ECM components and proteases including tenascin-C and MMP-2, positive regulators of angiogenesis.[94] Collectively, these studies indicate that not only do biomechanical signals influence the ECM and its receptors, but also downstream signals generated by mechanical force modulate cell adhesion components. Additional studies are clearly needed to determine how local force differentials modulate endothelial cell behavior during angiogenesis within the developing embryo.

Extracellular Matrix–Dependent Changes in Cell Shape and Angiogenesis

A frequently overlooked function of the ECM is its ability to maintain or modify cell morphology within developing, remodeling, and differentiated tissues. Moreover, the way in which cell shape imposes itself on signaling pathways generated by the ECM and integrins is not well understood. Nevertheless, a seminal study by Folkman and Moscona in 1978[95] showed that aortic endothelial cell proliferation is tightly coupled to cell shape. In essence, the greater the extent of endothelial cell spreading, the greater the extent of proliferation. Subsequently, a role for cell shape affecting integrin-dependent signaling pathways has been demonstrated in angiogenic endothelia. The proliferation and subsequent survival of endothelial cells require interactions between ECM and αvβ3 integrin. Blocking integrin ECM binding reduces endothelial proliferation and increases apoptosis.[75] If cell spreading is prevented, however, occupation and ligation of αvβ3 integrins using antiintegrin antibodies fail to support endothelial proliferation and survival.[96] Endothelial cell rounding may therefore lead to apoptosis as a consequence of decreased integrin ligation, with correspondingly less signaling through integrins, FAK, and other downstream components. In a study using endothelia cultured in a defined concentration and area of different ECM ligands, however, cell spreading alone was conducive to proliferation, whereas cellular rounding was associated with apoptosis.[97] Thus endothelial cell shape, specified by the ECM, appears to profoundly modulate signals generated by identical ECM-integrin interactions.

To elucidate further how ECM- or integrin-dependent endothelial cell shape changes operate to control angiogenesis, it will be necessary to identify additional proteins that are able to coordinate both intracellular signaling pathways and cell morphology. To this end, the discovery that the Rho family of small GTPases (e.g., RhoA, Rac1, Cdc42) are able to relay integrin-derived signals, as well as organizing the cytoskeleton,[98,99] suggested that these proteins are well poised to integrate endothelial cell shape and function. In fact, subsequent studies showed that VEGF-dependent endothelial motility is critically dependent on Rac1,[100] and that Rac1 integrates signaling through the actin and microtubule cytoskeleton to promote capillary tube assembly in a tissue culture model of angiogenesis.[101]

CONCLUSION

Clearly, cell-ECM interactions play a fundamental role in development, yet many questions remain. The phenotypic analysis of mice bearing mutations in ECM genes and receptors is providing new insights into ECM function. A basic understanding of how different combinations of ECM proteins generate tissue-specific forms of cell behavior will be critical to translate current

molecular and cellular knowledge into improved approaches for tissue engineering and regeneration. Regardless of the outcomes of such experiments, the emergence of rapid screening techniques for the detection of ECM gene mutations, the development of diagnostic DNA and protein microarrays, and whole-genome sequencing will no doubt aid in determining whether the results gleaned from experimental systems are relevant to defects in human embryogenesis and development.

7 Stem Cell Biology

Evan Y. Snyder and Stephen Yip

CONCEPTS AND NOMENCLATURE

Stem cells have entered the consciousness of both the medical community and the lay public because their tremendous regenerative capabilities may hold great therapeutic potential.[1,2] It probably is most instructive, however, to view these cells in their original natural context: playing fundamental roles in development as the building blocks of organogenesis and the mediators of organ homeostasis.[3] Their therapeutic potential rests essentially on the ability to harness these fundamental developmental actions for therapeutic ends—"translational developmental biology," so to speak. Restoration of organ integrity and function through the replacement of damaged or defective cells is an extremely powerful concept, if such replacement can realized. It represents a paradigm shift in medical science; indeed, the stem cell concept helped give birth to the emerging field of *regenerative medicine*. Of interest, it may prove that the perinatal period—during which developmental processes are at their crescendo—is when stem cell–based approaches may find their most successful applications. To the extent that their utility can be applied to "postdevelopmental" organ dysfunction probably

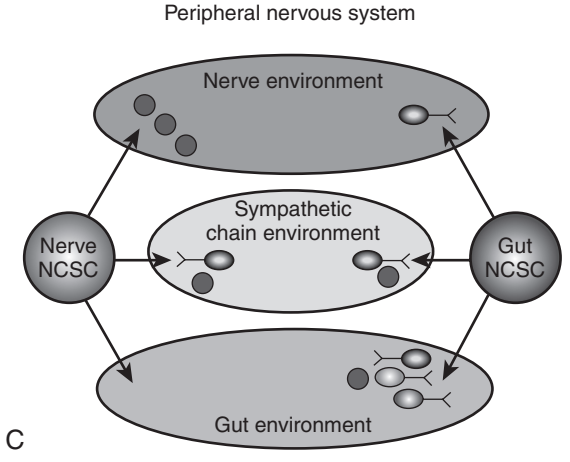

Figure 7-1 Determination of stem cell fate is governed by both internal (intracellular) and external (microenvironment or niche) signals. However, inherent difference in the relative susceptibility to these signals exists in different tissues, and this is often essential and unique to the tissue in question. **A,** Development of the hematopoietic system is reliant on signals from the microenvironment. **B** and **C,** However, progenitor cells in the developing central nervous system and the peripheral nervous system appear to rely on differential intrinsic responsiveness to external soluble factors and developmental cues. This strategy allows the nervous system to acquire distinct regional identities, as is crucial for proper development and functioning of the organism. *BMPs,* bone morphogenetic proteins; *FP,* floor plate; *HSC,* hematopoietic stem cell; *NCSC,* neural crest stem cells; *RP,* roof plate; *Shh,* Sonic hedgehog protein; *VZ,* ventricular zone. *(From Joseph NM, Morrison SJ: Toward an understanding of the physiological function of mammalian stem cells,* Dev Cell *9:173-183, 2005.)*

will depend on how well the developmental microenvironment is mimicked either naturally by the insult itself or artificially by the clinician. A partial glimpse at the potential of stem cell biology in this regard is offered by the current success of hematopoietic stem cell–mediated reconstitution of an ablated bone marrow in the context of bone marrow transplantation (BMT) for selected diseases.[4] Nevertheless, apart from the therapeutic potential of stem cells, every perinatologist—the clinical counterpart of the developmental biologist—should be familiar with basic stem cell concepts.

A stem cell is the most primitive cell of a given organ or tissue that is able to differentiate into all of the more mature and specialized daughter cells of that tissue (a property called multipotency) and to give rise to some daughter cells with exactly that same potential (a property called self-renewal). Stem cells seem to undergo *symmetric* cell division—splitting into two identical daughter cells that are themselves stem cells—when the stem cell pool must be expanded rapidly, as during the first stages of organogenesis or in the first response to extrinsic stimuli such as stress. They undergo *asymmetric* cell division—giving rise to

a more specialized daughter cell and only one new stem cell—when the stem cell pool simply needs to be maintained at a constant size. Very often, this cell division can be quite slow, because the stem cell largely exists in a quiescent state.[5] In some organ systems, it is hypothesized that when tissue turnover is required to be at its zenith, the stem cell gives rise to an even more rapidly dividing "transient amplifying cell." Stem cells have the ability to undergo both symmetric and asymmetric divisions, and normal development of the organism requires a balanced switching between the two.[6] Teleologically, this balance is significant for the persistence of stem cell pools into adulthood and for maintaining homeostasis throughout life. In fact, experiments have demonstrated that aberrant skewing toward symmetric division may be associated with malignant transformation in vivo.[7] Taking advantage of this biologic attribute, however, should permit indefinite expansion of stem cells in vitro once they have been isolated from a tissue and placed in culture.

In vivo, the microenvironment surrounding the stem cell, including the extracellular matrix and the supporting stromal cells, in conjunction with intrinsic stem cell developmental programs, appears to control the various stem cell decision pathways that ultimately lead to the creation of a given organ.[8,9] The concept of the stem cell niche was first explored in hematopoiesis but has now been extended to stem cell biology in general (Figure 7-1).[10] Cellular and extracellular constituents of the niche have come to be regarded as equal partners with stem cells themselves in the execution of proper developmental programs and in maintaining a system that can respond to dynamic needs.[11] Dysregulation of this developmental milieu may potentially lead to oncogenesis.[12] Ongoing attempts to recreate those signals on command and to master the molecular controls of the niche microenvironment are expected to provide important tools of regenerative medicine.

The coming together of two *gametes* (sperm and oocyte, respectively) yields a fertilized egg, or *zygote,* which begins to divide, yielding daughter cells that initially are *totipotent*—that is, they have the potential to give rise to the complete embryo as well as all of the extraembryonic tissues, including the trophoblast (Figure 7-2). (Each zygote is not self-renewing and therefore is not itself regarded as a "stem cell.")

The fertilized cells go through two-cell, four-cell, and then eight-cell stages, ultimately yielding a morula and then a blastocyst. The blastocyst becomes asymmetric in its appearance and function. Toward one pole of the blastocyst, a group of stem cells begin to accumulate to form the *inner cell mass* (ICM); that portion of the blastocyst is called the *fetal pole* because it is within this group of cells that the nascent embryo will begin to emerge. The ICM will then differentiate into an *epiblast,* the actual precursor of the embryo, and *extraembryonic endoderm,* a tissue that will help support the epiblast. If the ICM is extracted from the blastocyst and cultured in a dish under appropriate conditions that support their continued cell division while arresting any further differentiation, a cell population known as *embryonic stem cells* (ESCs) will result. These cells are regarded as being *pluripotent* because they have the potential to give rise to all cell types of the embryo but not to trophoblast. In vitro, much as is seen in the epiblast in vivo, ESCs, if permitted to differentiate, will begin to generate daughter cells that become partitioned to one of three fundamental germ layers: *ectodermal, mesodermal,* or *endodermal.* This occurs within 1 week and is most classically promoted experimentally by allowing the ESCs to aggregate in a floating clump of cells called an *embryoid body* (EB), so termed because it mimics—albeit in a very haphazard, random, and disorganized fashion—the emerging cell types of the embryo in vivo. A fundamental difference between an EB and an actual embryo is that a blastocyst, if implanted into a uterus (as during the process of assisted reproduction by *in vitro fertilization* [IVF]), will give rise to a complete mammalian organism after an appropriate gestational period; an EB will never do so under any circumstances. The corollary of this biologic fact is that

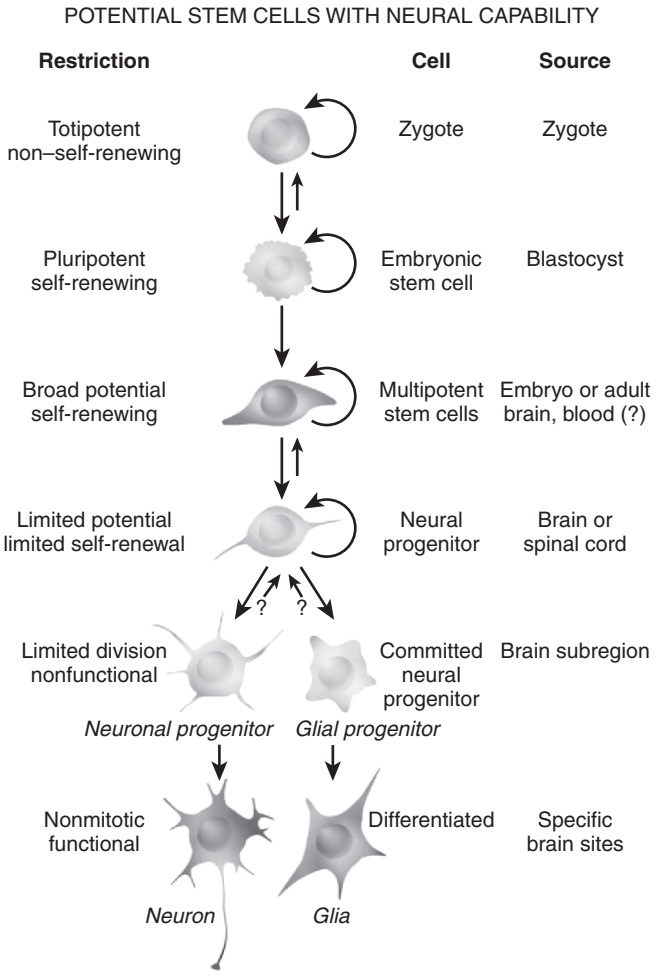

Figure 7-2 The developmental potential of mammalian stem cells into neurons. The developmental hierarchy of the stem cells is shown; pluripotentiality becomes much more restricted with maturation of the stem cell. *(From Gage FH: Mammalian neural stem cells,* Science, *287:1433, 2000.)*

even the *potential* for continued development beyond the blastocyst stage requires the environment of an intact female reproductive system. ESCs do not have the potential in vitro to give rise to an organism. Furthermore, other than for purposes of fertility treatment, it is considered unethical to implant any experimentally manipulated zygote.

The *ectoderm* ultimately gives rise to cells of the skin and the nervous system. The ectoderm differentiates into the *neuroectoderm,* which begins to roll up into a tube (called the *neural tube*) that will become the central nervous system (CNS). As the neural tube begins to close, a population of cells on the superior surface of the tube begins to migrate. These cells are collectively called the *neural crest* and will give rise to peripheral, autonomic, and enteric nervous systems as well as a host of other tissues (including the facial bones, the great arteries of the heart, the thymus, and melanocytes). The *mesoderm* gives rise to muscle, bone marrow, blood vessels, and the urogenital system, as well as the connective tissues of the body. The *endoderm* gives rise to the epithelial lining of the gastrointestinal tract, parenchymal pancreas, thyroid, parathyroid, and liver. Although ESCs in reality are derived only in artificial tissue culture, they are placed conceptually at the apex of the stem cell hierarchy because of their pluripotency (Figure 7-3). As discussed later, once a cell has been assigned to a given germ layer and even more narrowly to a given tissue or organ lineage, its potency becomes somewhat restricted,

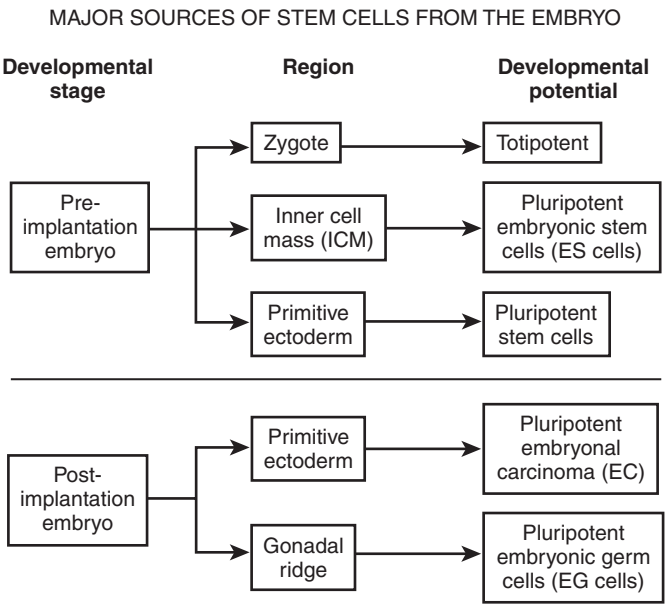

Figure 7-3 Examples of tissue-derived stem cells from different stages of development. Stem cells can be obtained from many different tissues, but their abundance and developmental potential follow a strict hierarchy in which embryo-derived stem cells have the highest pluripotentiality.

a state reflected by the term *multipotency.* It is at this stage that such cells are called *somatic stem cells* or *tissue-resident stem cells* or *tissue-derived stem cells,* distinct from *embryonic stem cells.* (The term "adult stem cells" often applied erroneously to such cells and should be avoided because of the confusion it creates.) As development proceeds, a subset of these multipotent stem cells become even more restricted in their natural fate, a condition reflected by use of the term *oligopotent* (if a few cell type options remain, often used synonymously with *progenitor cell*) or *unipotent* (if only one cell type can emerge, sometimes inferred by use of the term *precursor*).

One of the most vexing and controversial aspects of stem cell biology is the question of where pluripotent stem cells (PSCs) may reside in the body. Clearly, they can be isolated from the ICM of the blastocyst (discussed later), giving rise to cells of the three primary germ layers but not trophoblasts. ICM-derived cells remain the prototype for pluripotence. Indeed, pluripotent cells also can be derived from some neoplastic states, such as teratocarcinomas and teratomas. It was the study of such tumors in the 1970s that ultimately guided developmental biologists to search for ESCs in the normal ICM. Stem cell researchers noted more than 50 years ago that teratocarcinomas contained differentiated cells belonging to all three primary germ layers as well as a population of pluripotent cells that, when transplanted to a receptive host, would form a second tumor. In addition, teratocarcinomas also could proliferate in vitro as undifferentiated embryonal carcinoma (EC) cell lines in the presence of a feeder cell layer.[13] Subsequently, it was noted that similar tumors could be generated by implanting cells from the ICM into immune sanctuary sites, such as the testis or inside the kidney capsule. Later, cells from the postimplantation embryonic gonadal ridge were found to have a similar capacity. To this day, the ability to form a teratoma remains part of the operative definition of a pluripotent cell. EC cell lines appear to straddle the line between normal embryonic development and oncogenesis. Blelloch and colleagues have performed nuclear transplantations of nuclei from EC cell lines into normal blastocysts and further examined the genetic profiles of the former, thus establishing genetic lesions with potential for tumor development.[14]

Whether vestiges of ICM-like or gonadal ridge–like cells can still be isolated from more mature "postembryonic" or even adult tissues remains extremely controversial. Also uncertain is whether exceedingly small populations of pluripotent cells can be found in the bone marrow mesenchyme, in the umbilical cord blood, or in the amniotic fluid and placenta. A fascinating observation has recently expanded the potential source of pluripotent cells—the well-supported notion that seemingly lineage-committed cells can be artificially "dedifferentiated" or reprogrammed back to a pluripotent state through the transduction of a panel of oncogenic-type genes. These experiments are briefly discussed further on.

It does seem likely that *multipotent* stem cells persist throughout life in many organs. As noted earlier, these are stem cells that have "learned their address" and have been allocated to residence within a given tissue. They begin to appear in embryonic and fetal organs, are present throughout gestation and birth, and, in most organs, persist to some extent into adolescence and adulthood (although their number and degree of responsiveness in later life in some tissues remains controversial—such as heart, pancreas, and CNS). Such multipotent stem cells, when present, are restricted to developmental pathways characteristic of their particular organ of residence and certainly to their fundamental germ layer of derivation. Although for a brief period the stem cell field entertained the possibility that multipotent stem cells could "transdifferentiate" into cells of another organ system, the data suggesting that possibility were found to be the misinterpretation of an experimental artifact and the notion has fallen into disfavor in most circles. In essence, a multipotent stem cell of ectodermal origin can give rise to daughter cells that belong only to this germ layer; neural stem cells (NSCs) give rise only to neural tissue; hematopoietic stem cells give rise only to blood-derived cells. Blood will not give rise to brain, and brain will not give rise to blood. Nevertheless, within a given organ, the degree of plasticity and the scope of fate options remain broad. Committed progenitor cells, such as the colony-forming unit granulocyte-macrophage (CFU-GM), are more restricted in their developmental potential. These cells are limited in their ability for self-renewal and are programmed to give rise to a very limited repertoire of specialized cells within a germ layer.

To summarize, stem cells can be divided into *ICM-derived pluripotent cells* and *somatic, tissue-derived,* or *tissue-resident multipotent stem cells.* The latter designation can be further modified by specifying the particular tissue and the particular age or developmental stage from which the stem cell was observed or isolated, (e.g., a fetal NSC, an adult NSC, or a newborn hematopoietic stem cell).

These concepts are discussed in greater detail in the following sections.

EMBRYO-DERIVED STEM CELLS

Embryonic Development

A 3- to-5-day-old preimplantation human embryo known as the *blastocyst* contains the ICM and the trophectoderm.[15] The trophectoderm lacks stem cells but contains *trophoblastic precursor cells* that later become the fetal part of the placenta. During the preimplantation stage, the outer trophectodermal epithelium pumps fluid to form the blastocoel, a hollow cystic structure that gives the blastocyst its name.[16] The ICM, located at one end of the blastocoel, consists of approximately 30 pluripotent cells that can give rise to all tissue types of the fetus (Figure 7-4). (By convention, before 8 weeks gestation, the developing human is called an *embryo*; after 8 weeks gestation, it begins to be called a *fetus*.) Implantation of the embryo (embryonic days 5.5 to 7 in a mouse and days 7 to 12 in humans) is associated with further cellular differentiation and the impending disappearance of the pluripotent state. This is followed by the establishment of

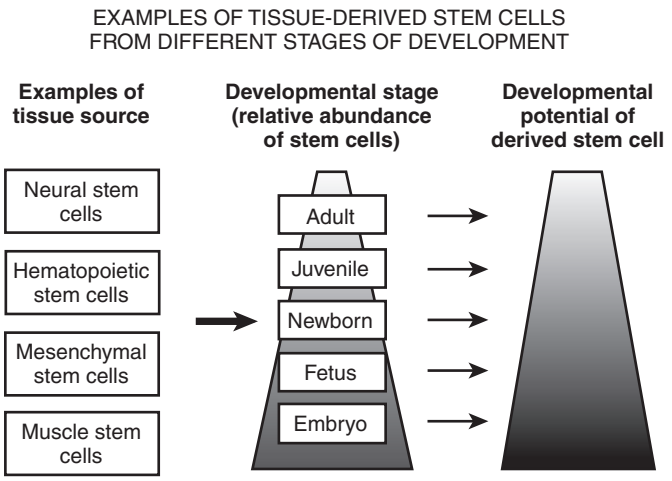

Figure 7-4 Major sources of stem cells from the embryo. Embryo-derived stem cells can be classified as being from the preimplantation or postimplantation stages. They can be further subcategorized according to region of origin, which ultimately will affect their developmental potential.

the primitive endoderm that contains precursors to cells of the embryonic yolk sac, a nutritive organ for the developing embryo.

ESCs are derived from the in vitro expansion of ICM cells from the preimplantation blastocyst stage, classically accomplished by plating the cells on specialized feeder cell layers, often mouse or human embryonic fibroblasts. (Much research is ongoing to determine whether ESCs can be derived under entirely defined conditions, including without need of a feeder layer.) Immunosurgery is sometimes used to isolate cells from the ICM and to deplete it of contaminating trophoblasts. Alternatively, the ICM can be mechanically dissected from the blastocyst. If the ICM cells begin to divide and maintain their undifferentiated state (marked by the presence of a panel of proteins—Oct4, Nanog, SSEA-4, Tra-1-80), for at least 12 passages, they are termed ESCs. The final proof that they have become an ESC line, however, depends on their ability to differentiate into all three germ layers. This capacity is routinely tested in two ways: First, the cells should yield teratomas when implanted into immunoincompetent mice (teratomas, by definition, contain representatives of all three germ layers); second, they should be able to yield cell types of these same germ layers when aggregated as the aforementioned EBs.[17] Indeed, the ability to form teratomas is part of the definition of an ESC. ESCs from primates (both monkey and human) are much harder to grow and to keep in an undifferentiated, proliferative state than are ESCs from mice.

Once established, ESCs should be capable of being maintained and expanded in an undifferentiated state in the laboratory indefinitely as stable cell lines. At this point, the goal next becomes to differentiate the ESCs in a more controlled, lineage-specific manner. Typically this process involves removing the ESCs from a feeder layer if present and often omitting mitogens (such as basic fibroblast growth factor) from the medium while adding such inducing molecules as retinoic acid or Sonic hedgehog. Novel protocols are constantly being devised for efficiently directing ESCs toward becoming different cell types. A review of these specific "recipes" is beyond the scope of this discussion; the reader is directed to such source material as *Current Protocols in Stem Cell Biology*.

Although ESC research initially was built on years of empirical observations and trial and error, its future will clearly depend on the rigorous dissection of the complex molecular mechanisms involved in maintenance of pluripotency and controlled cellular development.[18,19]

Embryonic Germ Cells

Another source of embryo-derived pluripotent stem cells is the gonadal and germinal ridge from the 7- to-10-day-old embryo. These primordial germ cells (PGCs) can be expanded in vitro to generate embryonic germ cell (EGC) lines. Transplantation of mouse PGCs (which persist through midgestation) into permissive recipients can give rise to teratocarcinomas, as noted previously. Shamblott and associates isolated human PGCs and characterized the subsequently derived EGC line.[20] They harvested and isolated gonadal ridges and mesenteries from 5– to 9–postfertilization week embryos. Extensive characterization of the resultant EGCs demonstrated that they satisfied all of the criteria previously established for hESC lines. Specifically, they could be maintained as unspecialized cells in vitro in cocultures with mouse feeder layers and, when induced to differentiate, were able to generate daughter cells belonging to all three germ layers. The EGCs have normal karyotypes and demonstrate immunohistochemical profiles similar to those of ICM-derived stem cells. The differentiated progeny of EGC lines express the broad range of developmental markers associated with neuronal, vascular, hematopoietic, muscle, and endodermal lineages.[21] As with ESCs, differentiated EGCs are characterized by a heterogeneity of lineages; differentiated cells from multiple lineages coexist, persist, and even reemerge after application of ostensibly lineage-specific instructive protocols. Obtaining pure homogeneous populations of a single cell type from pluripotent cells remains a challenge to the field. Figure 7-2 illustrates the source of pluripotent ESCs and EGCs from the preimplantation embryonic ICM and the postimplantation embryonic gonadal ridges, respectively. Both cell populations retain pluripotency and many other stem cell characteristics. Cells from the reproductive system are apparently unique in that they maintain pluripotent capacity longer than would normally be expected in any other tissue. For example, developmental pluripotency has been observed in cells isolated from neonatal mouse testis and in adult murine spermatogonial cells.[22,23] Of interest, however, the ability to demonstrate therapeutic efficacy and safety using EGCs has been less forthcoming than those for ESCs. It is unclear whether this disparity reflects a fundamental difference between ESCs and EGCs or merely the greater number of investigators focusing their efforts on working out the technical hurdles of ESC use.

Embryonic Stem Cells of Mouse Origin

Murine-derived ESCs (mESCs) originally were isolated in 1981 by Evans and Kaufman.[24] Since that time, many research teams have refined the isolation and culture techniques. Stable mESC lines were generated by the successive replating and numeric expansion of the undifferentiated subpopulation of a previous mESC culture, essentially selecting for the most proliferative cells. The use of a suitable feeder cell layer initially was indispensable to the maintenance of an undifferentiated state. It was subsequently learned that (LIF) could be used in place of the feeder cell layer for mESCs; this cytokine appears to be important in maintaining the viability of PSCs in the preimplantation mouse embryo.[16,25] LIF also has pleiotrophic actions on the organism, including effects on hematopoiesis, osteogenesis, lipid transport in adipocytes, neurogenesis, and neuronal survival.[26] The feeder cell layer appears to provide a mixture of secreted soluble cytokines, membrane-associated factors, and factors associated with the extracellular matrix. These factors, in turn, maintain the growth of the mESC lines in an undifferentiated state. Attempts have been made to analyze systemically the biochemical composition of these factors.[27]

Mouse ESC lines not only have been the object of study in themselves but have also made possible a valuable biologic tool,

the *transgenic mouse*. Specific genes of interest can be "knocked out" or "knocked in" within mESCs, which then can be placed into the ICM of a blastocyst-stage mouse. The altered mESCs now contribute to all organs of the developing mouse at its earliest stages of embryogenesis including the germ cells, allowing the traits to enter the germline. A strain of mice ultimately develops with altered expression of the gene of interest—either overexpressed or suppressed. Such transgenic mouse technology has revolutionized studying the molecular basis of both development and disease and was recognized by the 2007 Nobel Prize for Physiology and Medicine.

To take full advantage of ESCs, the mechanisms underlying cellular differentiation and lineage development must be understood. To date, the greatest advances in this regard have come from the use of mESCs, although similar protocols for hESCs are rapidly being devised; for some cell types, extrapolation from mESCs to hESCs is possible; for other cell types, the fundamental differences between mESCs and hESCs demand different strategies. Various methods have been devised to control the fate of differentiating mESCs. Obviously, it is important to avoid transplantation of pluripotential ESCs that could potentially form tumors (e.g., teratomas or teratocarcinomas) or give rise to cell types inappropriate to a given organ. Restricting the potential of these very pluripotent cells also has been a challenge. Often the strategy entails recapitulating in vitro the step-by-step molecular process by which a given cell type is generated during normal development in vivo. For example, motor neurons have been generated from mESCs by first neuralizing the cells with retinoic acid and then applying a ventralizing morphogen such as Sonic hedgehog. It is thought that, in directing an ESC toward becoming a mature cell type, the cell passes—fleetingly—through a stage of being a tissue-derived stem cell. For example, when an ESC is directed to become a neuron, it might first pass through a stage of becoming an NSC, a cell equivalent to those populating the neuroectoderm and lining the neural tube. It was this type of reasoning that helped facilitate the selective expansion of apparently multipotent neuroepithelial stem or progenitor cells from mESCs through the use of bFGF.[28] Such NSCs were then used to generate postmitotic functional neurons and glial cells. In one set of experiments, oligodendroglial and astrocyte precursors generated in this manner from mESCs were capable of myelinating host neurons in a dysmyelinated rodent.[29,30] Similarly, mESC-derived dopaminergic neurons have been able to reverse some deficits in rodent models of Parkinson disease. Long-term engraftment of lymphoid-myeloid precursors from genetically modified mESCs has been achievable.[31] mESCs also have been induced to differentiate into adipocytes, islet cells, hepatocytes, and osteoblasts.[32]

Embryonic Stem Cells of Human Origin

The isolation, growth, and characterization of human ESCs (hESCs) were reported in 1998.[33] The lag time between the routine generation and use of murine ESCs (mESCs) in the early 1980s and the success in creating primate ESCs nearly 20 years later suggests the difficulty in simply extrapolating from rodent to human and reflects the unanticipated fundamental biologic differences between the two types of ESCs in terms of growth requirements, culture conditions, and signaling pathways involved in pluripotency and differentiation. Some differences may be attributable to the fact that hESCs appear to represent a somewhat later stage in development than that characteristic of mESCs. Whereas mESCs reflect the ICM stage of murine embryonic development, hESCs, although generated from the ICM, appear to be more representative of the epiblast stage in human development.

Even the appearance of hESCs and mESCs differ: hESCs grow as flat colonies, whereas mESCs grow in round, amorphous masses. Although some of the same molecules characterize the undifferentiated pluripotent state in both species of ESCs, such as the transcription factors Oct-4 (which blocks trophectoderm formation) and Nanog (which blocks primitive endoderm differentiation), other markers differ. For example, although both species of ESCs express stage-specific embryonic antigens (SSEAs) on their cell surfaces, mESCs express SSEA-3 and hESCs express SSEA-4; indeed, SSEA-3 in hESCs is associated with the differentiated state, not the undifferentiated. In addition, mESCs grow more rapidly and robustly in vitro. hESCs are more difficult to manipulate and, to date, grow less reliably without a mouse embryonic fibroblast (MEF) feeder layer. Whereas mESCs are dependent on leukemia inhibitory factor (LIF) for feeder-free growth, hESCs have no such LIF dependence, suggesting that different signal transduction pathways are operative. Because hESCs may incorporate and express on their cell surface certain glycoproteins taken up from the feeder cells, there is the theoretical concern that immunocompatibility following transplantation of such cells into a human host might be compromised. Advances in the understanding of hESC biology have begun to suggest better conditions for the in vitro propagation of hESCs, including eliminating the need for murine feeder cells.[34-36]

Despite their differences, it is the similarities between murine and human ESCs that is most compelling and has stimulated the imagination of the regenerative medicine community. hESCs, like their murine counterparts, have the ability for indefinite self-renewal yet can differentiate into cells representing all three germ layers.[37] Indeed, a similar antigen expression profile has been demonstrated between hESCs and preimplantation human embryos.[38] Of course, the ultimate test of pluripotence as applied to murine ESCS—the ability to generate a totally chimeric mouse[39]—cannot be used for assessing hESCs, for obvious ethical reasons. Surrogate tests, however, can be used and typically consist of determination of the ability of the cells to form teratomas in immunoincompetent mice and the ability to yield multiple differentiated cell types after EB formation.

Significant cross-pollination of knowledge and technical expertise occurs between the fields of hESC research and the rapidly evolving area of assisted reproductive research, especially IVF.[16] The rapid development of preimplantation genetic diagnosis (PGD) at the eight-cell blastomere stage is an example of the union between scientific and technical advances.[40] PGD represents a significant advance in the prenatal diagnosis of genetic diseases.[41] Often, PGD indicates that a blastocyst generated by IVF in the context of assisted reproduction bears a lethal or devastating disease, rendering it morally unacceptable to implant the blastocyst. The defective blastocysts, however, can be used to generate hESC lines that then might faithfully model cellular aspects of that human disease. Such cellular models are particularly useful for conditions in which no good representative and predictive animal model exists. the resultant "disease lines" can then be used to test pharmaceuticals, to identify novel drug targets, to gain mechanistic insights at the cellular and molecular levels, and to identify better prognostic or diagnostic markers. This use of hESCs is potentially quite powerful and offers prospects for therapeutic applications apart from direct cell-mediated repair. In a similar vein, hESCs may serve as an in vitro model or surrogate for dissecting the earliest stages of human embryogenesis that, for obvious ethical reasons, cannot be directly observed in situ.

The ability to manipulate hESCs genetically (particularly developmentally important genes), although initially quite difficult, is becoming somewhat easier, thereby enhancing the value of hESCs as models of human embryogenesis and disease. Initial manipulations were through homologous recombination,[42] a technically challenging technique. More recently, lentiviral vector–mediated manipulation has proved effective for inserting reporter genes to act as biosensors (particularly when under the control of developmental stage–specific promoters), overexpressing genes, or

suppressing the expression of genes (e.g., through RNA interference). If a therapeutic gene is placed into hESCs and the hESCs are subsequently differentiated toward engraftable somatic cells, genetic defects in a host also may be correctable by this means,[543] much as has been achieved using somatic stem cell transplantation.[44,45,46,47]

Progress is being made in devising culture conditions that may potentially permit hESCs to be directed toward particular lineages in vitro. In some instances these recipes have successfully borrowed from the murine literature (e.g., generating spinal motor neurons). In other instances the strategy must differ from that in mouse ESCs (e.g., creating pancreatic beta cells). Mesenchymal precursors have been derived from hESCs with the capacity to differentiate into skeletal muscle cells, fat, cartilage, and bone.[48] Neuroectoderm, vascular endothelium, and beating cardiomyocytes emerge seemingly spontaneously and constitutively, although not as pure populations in large numbers with high or predictable efficiency. Some hESC-derived cell types have been shown to integrate successfully into rodent organs after transplantation—for example, hESC-derived neural progenitor cells implanted into the cerebral ventricles of developing brain[44,49,50]—and have even proved to be therapeutic in murine models of lethal human disease.[44] A fascinating observation is that human stem cells are capable of developing and differentiating in a murine environment, clearly responding to highly conserved even if xenogeneic signals. The hESC-derived cells can migrate extensively along established host migratory pathways, integrate into host NSC pools, contribute to adult neurogenesis in the olfactory bulb, and yield cells of all three fundamental neural lineages—neurons, astrocytes, and oligodendrocytes—as well as participate in repair.[44,50] The creation of such chimeric animals has generated considerable scientific interest but also controversy related to the admixture of human brain cells with those of a nonhuman nervous system.[51] Nevertheless, such models are required preclinically to establish proof-of-concept of repair, and to establish protocols for cell preparation and administration that achieve efficacy while ensuring safety. Supporters of this line of research are confident that hESCs, because they are "naturally immortalized" and can therefore provide an inexhaustible supply of undifferentiated cells in vitro for subsequent differentiation along numerous lineages, hold enormous therapeutic potential if the biology can be "tamed"[52] (Figure 7-5).

One of the technical challenges that must be surmounted is the anticipated immunogenicity of allogeneic hESCs when implanted into an unmatched immunocompetent host.[53,54] The degree to which such immunoincompatibility presents a de facto problem remains an area of both active investigation and debate. Some investigators have found that hESCs actually exhibit a degree of immune-"tolerizing" in mixed cultures with alloreactive human T cells.[55] In a similar vein, other reports have shown that cells from a murine ESC line are capable of reconstituting normal hematopoiesis and functional adaptive T and B cell immunity in an allogeneic graft recipient without a graft-versus-host response.[56] Nevertheless, it remains prudent to assume that overcoming immunologic barriers will still require careful consideration and could present a formidable scientific and technical hurdle to the successful clinical application of ESCs.

Another potential technical and biologic obstacle is the difficulty of achieving pure populations of single hESC-derived cell lineage. Even when various combinations of cytokines have been found to force the differentiation of hESCs toward a particular lineage, cell type heterogeneity spontaneously reemerges.[57,58] Such heterogeneity may be a fundamental property of a stem cell that cannot (and should not) be suppressed. Repair of a particular organ system may actually require the replacement of multiple collaborating cell types. On the other hand, the emergence of cell types inappropriate to a given organ is a risk and may prove dangerous. For a given disease process, only rarely has it been possible to achieve a full understanding of the array of cell types that may actually need to be replaced and in what ratio, and with what timing, and anatomic relationships. An additional conundrum lies in the recognition that treating an hESC such that its progeny are so fully mature and committed that alternate cell types are not possible also compromises the ability of that cell to integrate into a host system after transplantation. Incomplete restriction of the potential of an hESC, however, leaves open the possibility of tumor formation or the emergence of undesired cell types in the host after engraftment.

SOMATIC STEM CELLS (TISSUE-RESIDENT OR TISSUE-DERIVED STEM CELLS)

Somatic stem cells, also called tissue-derived or tissue-resident stem cells, possess the ability for (1) self-renewal and (2) differentiation into most of the specialized cells of the tissue, organ, or germ layer of their origin. Because they cannot give rise to all cell types of the organism (a property for which the term *pluripotence* is reserved), these cells are designated as *multipotent*. In the lay literature, somatic stem cells often are erroneously named "adult stem cells" to distinguish them from pluripotent cells obtained from blastocysts (i.e., hESCs), a politically controversial source; however, that misnomer is never used by true stem cell biologists unless they have obtained the cells from a fully adult organ or tissue. Typically, the most useful and robust "adult" stem cells are obtained from fetal sources.

Indeed, somatic stem cells are found in abundance during fetal development, and their number is thought to decrease as the organism ages (see Figure 7-3). The first solid-organ somatic stem cell to be described, isolated, engrafted, and exploited for therapeutic purposes and developmental insights was the NSC.[47,59,60] In fact, recognition of the existence of the NSC suggested a greater degree of inherent plasticity within the CNS than had been classically taught. The isolation and expansion of human NSCs (hNSCs)—including those with the ability to be engrafted, to respond to developmental cues, to replace missing neural cell types, and to transport in foreign genes—were first reported in 1998.[61] These hNSCs were obtained from a germinal zone (the ventricular zone) in the human fetal telencephalon. These somatic stem cells, at least those in the human, are less robust in their proliferative potential than their embryonic counterparts; in other words, whereas hESCs are "naturally immortalized," such somatic stem cells as hNSCs typically require tonic exposure to a mitogen or augmentation with manipulation of cell cycle regulatory or "stemness" genes (Figure 7-6).

NSCs (or, at least, neural progenitor cells) have been isolated from the adult human brain, but they are much less robust than their fetal and neonatal counterparts in vitro.[62] The adult cells senesce sooner than neonatal cells, an observation investigators have attributed in part to shorter telomere lengths in the older cell resulting from differences in telomerase activity. The biology and molecular pathways underlying the behavior of adult NSCs or neural progenitor cells continue to be an active area of investigation.[63-65]

The discovery of somatic stem cells in the brain helped stimulate the search for similar stem cells in other solid organs,[66,67] including heart, muscle, pancreas, and liver. When such cells have been found, those obtained from embryo and fetal organs appear to retain stem cell characteristics with greater vigor than that typical of cells derived from the same tissues at adulthood, much as observed in the brain.

Probably the prototypically ideal somatic stem cell derived from an adult tissue is the *hematopoietic stem cell*. A single hematopoietic stem cell is able to give rise to the entire spectrum of blood cells during development and to reconstitute the entire hematopoietic system of a lethally irradiated adult animal

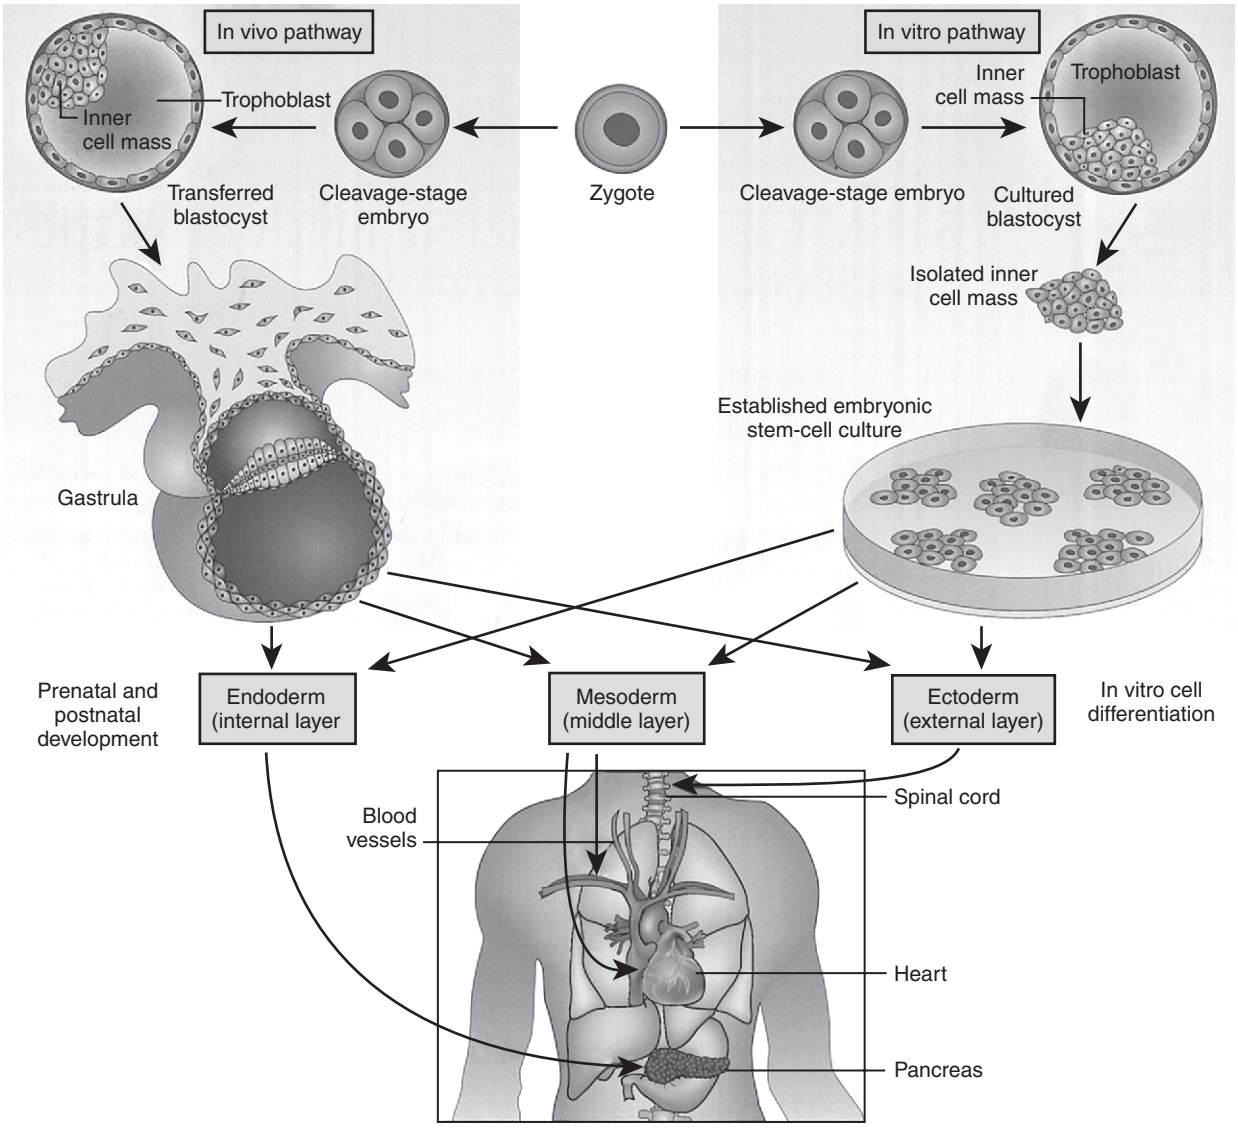

Figure 7-5 Alternative fates for an in vitro fertilized zygote: Intrauterine (in vivo) versus in vitro development. Either of two developmental pathways is possible for an embryo generated by in vitro fertilization: When an embryo is transferred to the uterus at the cleavage or blastocyst stage, its development can result in the birth of a child. When an embryo is cultured exclusively in vitro, it can result in the derivation of stem cells. These two divergent pathways may ultimately converge in the use of stem cells and their derivatives for cell-based transplantation therapies. In vitro fertilization was used first as a treatment for infertility, wherein the resulting embryos are transplanted to the uterus at the early cleavage or blastocyst stage. This in vivo pathway can result (in approximately one third of cases) in the implantation of the embryo into the wall of the uterus, where it undergoes gastrulation and subsequent prenatal development. Recent successes in the derivation of human embryonic stem cells (hESCs) have opened up a second, in vitro pathway for the development of human zygotes. Isolation and culture of the inner cell mass can result (in up to 50% of cases) in the prolonged growth of cells that have the capacity to differentiate into all three cell types of the body—endoderm, mesoderm, and ectoderm. Human ESCs have been shown to be capable of differentiating in vitro into insulin-producing cells, heart cells, blood vessel cells, and nerve cells, as have their mouse counterparts. Therefore hESCs are a promising source of tissue for transplantation for the treatment of, for example, diabetes, lung disease, cardiovascular disease, anemia and other diseases of the blood, and diseases or injuries of the central nervous system. *(From Bradley JA, Bolton EM, Pedersen RA: Stem cell medicine encounters the immune system,* Nat Rev Immunol *2:859-871, 2002.)*

or human.[68] Indeed, these capacities have come to be regarded as part of the operational definition of a somatic *stem* (as opposed to a *progenitor*) cell for any organ. For obvious reasons, most somatic stem cells cannot be tested for the important and defining attribute of reconstitution—for example, it is not possible to ablate the nervous system in the same way as for the hematopoietic system. Substantial lesions can be experimentally created in the nervous system, however. In such cases, NSCs have been found to reconstitute the missing parenchyma with a broad range of missing cell types.[45,69,70] As mentioned previously, the fate and potential of these somatic stem cells are restricted to those lineages that constitute the tissue or germ layer from which the cells were isolated. Surprisingly, the precise role for these tissue-resident stem cells in some solid organs is not yet entirely certain. For example, the existence of NSCs has been proved beyond any doubt, yet their purpose is still a matter of speculation. It

is presumed that these reservoirs of immature cells that persist into adulthood are designed to maintain a given organ's homeostasis by buffering the forces that cause cell death and dysfunction (toxins, senescence, infection, trauma) throughout the life of the organism by providing a small ready supply of "replacement" cells. If this is so, it is postulated (indeed, hoped) that their role can be exploited for even more extensive repair on demand. A growing appreciation is emerging that these pools of immature cells also restore a perturbed system to equipoise not solely by replacing missing cells, but also by providing molecular support for extant host cells (e.g., protecting and nourishing those cells and their connections or detoxifying the microenvironment).[71-73]

As noted previously, the possibility that a somatic stem cell from one organ or germ layer could "transdifferentiate" into cell types of another—as with NSCs yielding blood cells or blood-forming stem cells yielding neural or other solid organ cells—was a hotly debated topic.[74-79] More recent studies, however, have shown these initial conclusions to be due to an experimental artifact: the misinterpretation of the fusion of a donor stem cell with a preexisting host cell of another lineage.[78-84] For example, a transplanted blood cell, including its nuclear contents (often bearing a reporter transgene), would merge with a large host neuron (e.g., a Purkinje neuron), giving the misimpression that the neuron was of donor origin. Therefore, the notion of transdifferentiation has fallen into disrepute. Interesting developments in this field now revolve around whether fusion itself may play an adaptive biologic or reparative role. It appears that fusion between hematopoietic stem cells and nonhematopoietic cells is enhanced in the presence of injurious inflammation; under such conditions, the nuclear program of the host cell comes to supersede that of the donor hematopoietic cell while possibly coopting some of its genetic machinery.[85-87] This revisionist view of the process of cell fusion, which heretofore has simply been regarded as an experimental inconvenience, is now fueling new investigations into this area.[87]

In view of the recent reports[88-94] (discussed further on) that mature somatic cells may be dedifferentiated or reprogrammed experimentally in vitro to display pluripotence (through a combination of defined "stem"-ness and oncogenic genes), the possibility remains that an aberrant form of reprogramming may occur in vivo to account for the reports of transdifferentiation or lineage reassignment of somatic stem cells.[84] Such rare occurrences would need to be viewed as similar to (or at least as the first step in) metaplasia and neoplastic transformation.[95] Much more work is required in this regard.[96]

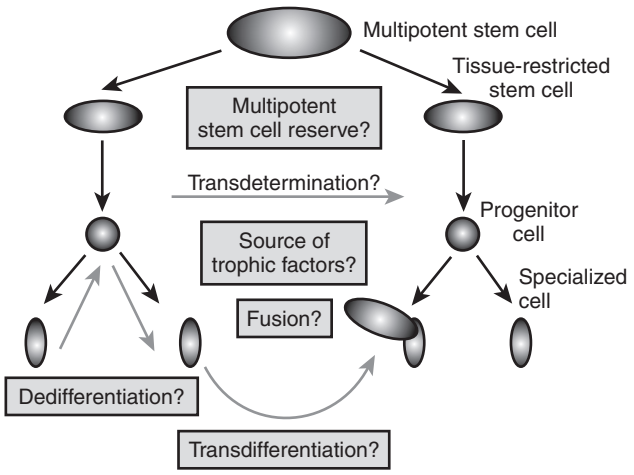

Figure 7-6 The six potential mechanisms in which adult stem cells can function in tissue repair: transdifferentiation, dedifferentiation, transdetermination, cell fusion, secretion of trophic factors, and the participation of true adult pluripotent stem cells in renewal and regeneration. *(From Rice CM, Scolding NJ: Adult stem cells—reprogramming neurological repair?* Lancet *364:193-199, 2004.)*

The allure of finding adult somatic stem cells that could change their lineage assignments in vivo—particularly cells that could be taken from the actual transplant recipient—was rooted in two concerns in the stem cell field that still prevail (the same concerns that have fueled a search for pluripotent cells in repositories other than the blastocyst): (1) avoiding the ethical minefield of obtaining pluripotent stem cells from preimplantation embryos and (2) obviating the potential for immunorejection of allogeneic grafts, which otherwise might require long-term immunosuppressive therapy or even such morally and technically thorny procedures as nuclear transfer (NT)—in lay parlance, "therapeutic cloning" (discussed later on). Of interest, in more recent reports, reprogramming the epigenome in vitro[88-94] (discussed later) appears to be a strategy with much more scientific credibility for approaching these dual problems.

An additional lesson to be learned from some of the misleading reports in the somatic stem cell field is that the expression of immunocytochemically detectable markers associated with a particular cell lineage is *not* sufficient to impute functional equivalence with that cell type. Additional evidence indicates that ostensibly cell type–specific markers can actually be expressed much more promiscuously than had been assumed, particularly when they are being assayed in systems in which their specificity was never tested. For example, a cell cannot be assumed to have become a neuron simply because it expresses a few neuron-associated markers; a cell is a neuron only if it has the functional properties of a neuron, which include electrical excitability and the ability to form synapses and spike action potentials.[82-84] Similarly, a cardiomyocyte must contract rhythmically, and a pancreatic beta cell must produce insulin in a glucose-regulated manner.

Germline Stem Cells

Spermatogenesis occurs throughout life in the mammalian male, yet oogenesis ceases before birth in most mammalian females.[97] In fact, isolation of spermatogonial stem cells from the adult murine testis[23] that may retain pluripotency has been reported. Such cells might be adult remnants of embryonic germ cells. Obviously, the possibility of harvesting cells with ESC-like properties from the adult human testis using minimally invasive techniques offers intriguing clinical opportunities.

The evidence for germline stem cells in adult murine ovaries remains more controversial.[98] Even more provocative are reports of a pool of cells within the bone marrow and in the peripheral circulation that may continually seed postnatal ovaries and contribute to ongoing oogenesis.[99] If such reports are accurate, the ability to isolate and expand bone marrow–derived germline stem cells may potentially be an important adjunct for infertility treatment. Unfortunately, other subsequent studies appear to disprove the existence of such bone marrow–derived stem cells.[100]

SOMATIC CELL NUCLEAR TRANSFER

Somatic cell nuclear transfer (SCNT), or "therapeutic cloning," is a potentially powerful technique that allows for the generation of autologous ESCs from adult somatic cells.[43] In SCNT, the nucleus from a mature somatic cell, such as a skin fibroblast, is transferred into an enucleated oocyte which is then stimulated to divide. The oocyte cytoplasm reprograms the nucleus of the somatic cell to begin reexpressing genes that mediate pluripotence and self-renewal. Furthermore, as this oocyte with this foreign nucleus begins to divide, it begins to develop along the normal pathways consistent with any preimplantation embryo,

including proceeding to the blastocyst stage from which ESCs may be derived from the ICM[43,101] (Figure 7-7). Because these ESCs possess the nuclear content of the donor skin cells—presumably obtained from the patient to undergo transplantation—the risk of immunorejection of the grafted ESCs is obviated.

It is important to differentiate the "therapeutic cloning" of SCNT from "reproductive cloning," which aims to implant the blastocyst into a womb and generate a complete organism that is genetically identical to the organism that donated the nucleus. In SCNT, only cell populations that are patient-specific are intended for diagnostic and therapeutic goals. It is illegal in virtually all countries to implant a human egg so manipulated. Although SCNT is routinely used for cloning farm animals, it remains a technical challenge using human eggs—particularly the steps of achieving an ICM and generating hESCs from it. SCNT using human material is extremely inefficient. Even in mice, the frequency of developmental abnormalities in subsequent clones can be high.[102] Despite initial misleading reports.[103-105] the generation of hESCs after SCNT remains unachieved. The hESCs that were reported were not clones of the nucleus donor but rather hESCs derived from parthenogenesis.[106] The recent report describing the derivation of ESCs from cloned primate embryos[107] suggests that success using human material, as technically daunting as it appears, may be on the not-too-distant horizon.

Of interest, recently published more tractable alternative techniques for reprogramming the nuclei of somatic cells using defined genes, rather than the undefined contents of the cytosol of an unfertilized oocyte, may sideline continued efforts to achieve human SCNT.

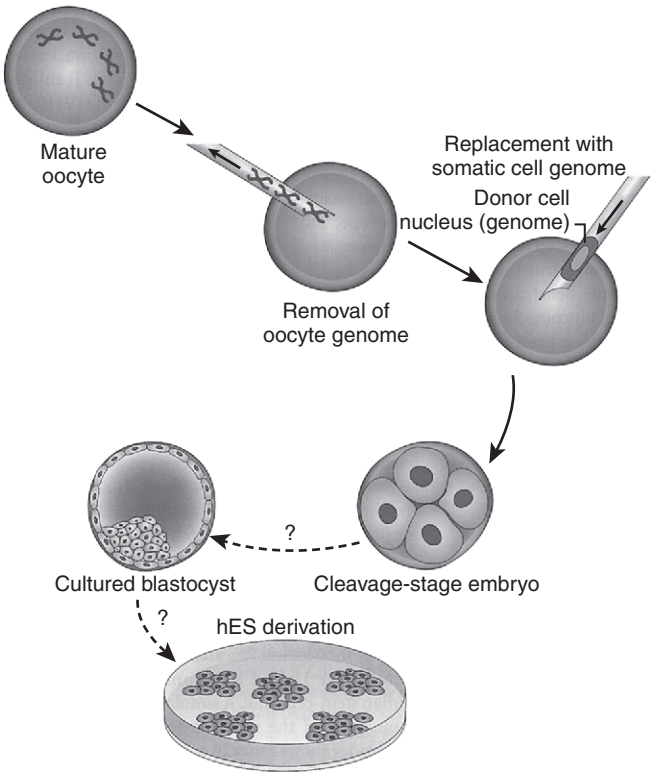

Figure 7-7 Genomic replacement (somatic cell nuclear transfer) as a way of matching stem cell–derived tissues with their intended recipient. Replacing the genetic material (genome) of an oocyte with that of a somatic cell generates a near-perfect match between the resulting donor cells and the graft recipient (donor of the somatic cell genome). For this purpose, the oocyte genome is removed and replaced with the nucleus of a cell from any one of several possible somatic (body) tissues of the graft recipient, using a micropipette. The oocyte cytoplasm enables the donor genome from a somatic cell to support embryonic development by a poorly understood process known as reprogramming. The resulting embryo is cultured to the blastocyst stage, from which embryonic stem cells are derived. Of note, owing to minor histocompatibility antigens encoded by the DNA of egg-derived mitochondria, grafts derived from stem cells grown from such embryos might not be strictly identical to the graft recipient. *hESC,* Human embryonic stem cell. *(From Bradley JA, Bolton EM, Pedersen RA: Stem cell medicine encounters the immune system,* Nat Rev Immunol *2:859-871, 2002.)*

NUCLEAR FUSION AND REPROGRAMMING ("INDUCED PLURIPOTENT STEM CELLS")

Although SCNT may be the best-studied modality for reprogramming the nucleus of an adult somatic cell to a embryonic pluripotent state, a number of other techniques for nuclear reprogramming are being actively investigated, many less technically challenging.[108-110]

Fusion of a somatic cell with an ESC generates a tetraploid hybrid that has the molecular characteristics and biologic behavior of a stem cell.[111] Soluble factors from the ESCs have the aforementioned ability to reprogram the nucleus of the somatic cell (i.e., to induce its reversion to a pluripotent embryonic state). The identity of these factors is being investigated. The transcription factor NANOG probably plays a prominent role in mediating this action.[112] A systems-based analysis of differential gene and proteomic expression and epigenetic (e.g., methylation) status is likely to be helpful in identifying other factors important in such nuclear reprogramming (Figure 7-8).[113-116]

As noted earlier, although undefined factors from an unfertilized oocyte cytosol or from the cytoplasm of an hESC appear to provide the benchmark for nuclear reprogramming, the recent identification of a set of four genes and their gene products that may do so as effectively has captured the imagination of the stem cell field and is likely to define research efforts for the next few years.

From a list of 24 genes found to be highly differentially expressed between differentiated and undifferentiated hESCs, an

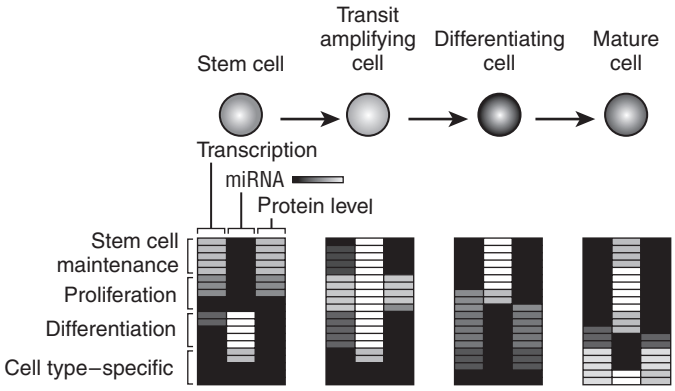

Figure 7-8 Epigenetic control mechanism, in this case microRNA (miRNA)–mediated suppression, acts in conjunction with differential transcription of genes to fine tune the expression of proteins responsible for maintenance of pluripotency, cell proliferation, and differentiation. Expression of selected genes is activated or suppressed by mechanisms such as promoter methylation and miRNA; the pattern of expression of these genes is implicit in the determination of cell fate. *(From Cheng LC, Tavazoie M, Doetsch F: Stem cells: From epigenetics to microRNAs,* Neuron *46:363-367, 2005.)*

empiric trial-and-error unbiased approach identified a combination of four from that list were sufficient to "turn back the clock" on first murine and then human somatic cells (adult, neonatal, and fetal skin fibroblasts; gastric epithelium; hepatocytes).[88-92] The four genes are *Oct3/4, Sox2, c-Myc,* and *Klf4*, introduced into fibroblasts using retroviral or lentiviral vector–mediated gene transfer under ESC culture conditions. Because the somatic cells not only expressed genes associated with pluripotence but could also form teratomas and EBs and self-renew, they were called *induced pluripotent somatic cells* (iPSCs or iPCs). When compared with ESCs, iPSCs appear to evince a similar developmental potential, gene expression pattern, and epigenetic profile.[89] Other "rejuvenating" cocktails are being devised independently by various investigators—for example, *Oct3/4, Sox2, NANOG,* and *LIN28*.[91] Of note, certain factors appear to remain common across reports and are therefore likely to be necessary; others may have actions that are redundant with those of other genes. In some cocktails, genes associated with neoplastic transformation, such as c-Myc, play a prominent role. Efforts to eliminate that gene, as well as others that may potentially have undesirable consequences, are ongoing and seem promising,[91,92] although Myc may add a degree of efficiency not seen in its absence. (The continuum between "normal" reprogramming and oncogenesis is highlighted by these types of studies.) Of interest, it appears that long-term expression of these factors is not required, which suggests that transient, non–virus-mediated provision of the proteins to the somatic cells may be sufficient to trigger resetting of the genome and epigenome. Subsequently, improvements in our understanding of the molecular basis of reprogramming has led to much more efficient techniques and some which do not rely on viral vectors.[117-120] In addition, several recent studies have highlighted the tremendous potentials of iPSCs as faithful disease models for unprecedented appreciation of pathophysiology and ideal test platforms for molecular correction of the underlying genetic defects.[121-125] Significant progress has been made since the initial descrition of reprogramming technique by Yamanaka and Blau,[120] as demonstrated by recent reports of iPSC generation from terminally differentiated T cells from the peripheral circulation.[125,126] These findings open up tremendous possibilities with such a ready source as peripheral blood for iPSC production. Another recent report demonstrated direct reprogramming of fibroblasts into functional cardiomyocytes, thereby showing practical and functionally directed instead of ontogenically directed reprogramming is possible.[126] Along with the promising potentials of reprogramming also comes new questions and cautions highlighted by reports showing prolonged epigenetic memory and influence of cell type of origin on the functional properties of the iPSCs.[127-128] In summary, much progress has been made in understanding the molecular mechanisms and technical advances in iPSC production yet many unanswered questions remain. Nevertheless, the tremendous stride of scientific and technical advances in this field bode well for its clinical translation.

These technologic advances not only will provide intriguing insights into development but also hold significant implications for the generation of patient-specific pluripotent cells for the study of the underlying mechanisms of different diseases, as well as for individualized therapeutics. Murine iPSCs already have been shown to be efficacious in treating a mouse model of sickle cell anemia[93] and a rat model of Parkinson disease.[94] Among the challenges for the iPSC strategy are making the reprogramming process more efficient and eliminating the neoplastic risk (tumors are prevalent in some animals receiving iPSC transplants).

CANCER STEM CELLS

Cancer stem cells are the malignant equivalent of normal somatic stem cells. They have the ability to maintain quiescence yet undergo symmetric division for self- renewal to sustain the growth and propagation of a tumor, as well as asymmetric division to repopulate the heterogeneous tumor cell population within the neoplasm.[129-133] The cancer stem cell, however, is autonomous and not governed by the intrinsic regulatory controls of normal stem cells, nor is it responsive to the controlled growth signals emanating from the local microenvironment. To date, cancer stem cells have been isolated principally from preexisting solid tumors (e.g., brain tumors) and appear to be responsible for maintenance of the malignancy and therefore tumor relapse.[131,132] It remains uncertain whether similar cells also are the originators of the tumor in the premalignant state, although the notion of a "normal stem cell gone bad" is appealing. The premorbid state of solid organ tumors is being investigated to address this possibility. In some leukemias, an aberration of a hematopoietic progenitor seems a likely initiator.[133]

Although the cancer stem cell—certainly in the morbid state and perhaps even in the premalignant state—would be a very desirable therapeutic target, its scarcity, growth characteristics, and ambiguous identifying characteristics make it elusive. A key achievement will be identification of a molecular marker that distinguishes, with sensitivity and specificity, cancer stem cells from normal somatic stem cells.[131]

POTENTIAL CLINICAL UTILITY OF STEM CELLS

Replacement Cell and Gene Therapies: Neural Stem or Progenitor Cells as a Prototype

NSCs, by definition, have the potential to undergo self-renewal (by both symmetric and asymmetric division) and to generate intermediate and mature cells of all glial and neuronal lineages throughout the neuraxis and at all stages of life.[60,134-136] NSCs can populate a region during its initial development or repopulate it after injury or disease. Although NSCs can migrate extensively within the CNS, they have a particular predilection for areas of pathology.[137] When the NSC engages the area of injury or developmental niche, it will respond specifically to local microenvironmental cues and alter its fate accordingly.[58,60]

More often than not, pathologic processes in CNS disease are widespread—for example, as seen in inherited and adult-onset neurodegenerative conditions, diffuse axonal injury after trauma and ischemia, inflammatory conditions, and brain neoplasms. These disorders present a clinical challenge because of their diffuse nature as well as the intermingling of diseased cells with normal brain cytoarchitecture. Targeting such a wide and complex terrain typically has been the province of pharmaceutical rather than transplantation-based therapies. Unfortunately, restorative and regenerative actions are beyond the capabilities of known pharmacologic agents. The properties of the NSC, however, make it uniquely suited to such interventions.[60,138] Transplanted NSCs have the capacity to migrate to developmental or diseased "post-developmental" niches in the mammalian (including primate) CNS and then integrate in an appropriate fashion.*

As proof of concept, unmodified and engineered NSCs have been implanted into several disease models. For example, when implanted into a globally dysmyelinated mouse brain, NSCs of both mouse and human origin will yield myelinating cells[30,142]; indeed, the implanted NSCs shift their fate to yield a greater proportion of myelinating oligodendrocytes than NSCs would in a wild type environment. Implanted mouse or human NSCs can similarly distribute missing gene products throughout the brain; for example, they can effect histologic and functional changes in the mucopolysaccharidosis type VII (MPS VII) and Sandhoff mouse models of defective lysosomal processing and storage[44,47]

*References 46, 60, 69, 134, 139-141.

performing the equivalent of a "bone marrow transplant to the brain." In an adult rodent neocortex with selective regions of neuronal apoptosis and in the substantia nigra of parkinsonian monkey, a multipotent NSC will shift its developmental fate only within those narrow neuron-deficient regions to yield pyramidal neurons or dopaminergic neurons, respectively, outside the normal temporal window of that cell type's birth.[60,73]

Many other examples of repopulation by multipotential NSCs of a diseased, traumatically injured, or developmentally deranged CNS have been reported.[71,143,144] In addition to their use for cell replacement, NSCs can be engineered to deliver therapeutic genes and viral vectors throughout the CNS.[45,72,145] Because NSCs have a strong tropism for sites of pathology, they can be quite effective in that role. For example, this ability has made them a potentially valuable adjunct in the treatment of aggressive disseminating gliomas if armed with oncolytic gene products.[145,146] The NSCs can track down even distantly invading glioma cells and deliver therapeutic genes directly to these widely dispersed and infiltrating neoplastic cells. Indeed, it was the pathotropism of exogenous NSCs[69,145] (including for brain tumors) that prompted some investigators to look for similar attributes in endogenous neural progenitors; such "glioma-tropic" behavior in pools of endogenous cells was detected,[147] helping to vouchsafe the representative nature of the implanted NSCs and their value for revealing fundamental NSC properties.

Apropos to a major problem in perinatology and neonatology, both exogenous and endogenous NSCs appear to be useful in attempting to reconstitute cerebral tissue compromised by hypoxic-ischemic insult.[69,70,134]

Finally, it has been recognized that NSCs—even when they do not differentiate into replacement cells—appear to have, even in their undifferentiated state, an intrinsic ability to rescue or protect degenerating host neurons as a result of complex host–stem cell cross-talk and reciprocal interactions.* This so-called chaperone effect has become a powerful force within the stem cell field and probably is the most tractable near-term application for stem cells against a variety of neural disorders, with extrapolation to stem cells and diseases of other organ systems (including heart, pancreas, lung, and bone).

In short, NSCs (a prototype for the somatic stem cell) possess biologic attributes that allow their use in the treatment of various diseases by a variety of mechanisms, all of which are components of fundamental stem cell biology.[148] It bears emphasizing that, to realize the therapeutic potential of pluripotent stem cells such as the ESC, they need to be directed to become somatic-like stem cells; then they too will evince the beneficial properties described here. Some of the potential uses for hESCs in cardiac cell replacement therapy have been reviewed elsewhere.[149]

SUMMARY AND FUTURE DIRECTIONS

Stem cells have the capability to undergo extensive self-renewal and to differentiate into committed progenitor cells and mature specialized cells of multiple organ systems. Stem cells can be isolated from the mammalian embryo and populations expanded in vitro. These ESCs are quite proliferative and have the capability to yield cells of all tissues of the organism. ESCs then give rise to somatic (tissue-derived or tissue-resident) stem cells, which also can be used as a source for lineage-specific cell replacement therapy. It remains to be determined how the degree of plasticity of these types of stem cells changes as the organism ages: Do vestigial embryo–like or tissue-resident stem cells persist throughout life in various reservoirs throughout the organism? Can they be isolated and used with equal efficiency, efficacy, and safety at all stages? Are the barriers between cell lineages rigid and inviolate? Many of these questions are beginning to be answered. Recent advances in understanding the biology of stem cells as well as the molecular controls of cellular pluripotency have significantly extended current understanding of the fundamental biology, with obvious practical implications. For the present, the most useful solid organ stem cells have been those derived from the ICM of the blastocyst and from embryonic and fetal tissues. Stem cells, endowed with their special biologic characteristics, also provide an invaluable tool for the study of developmental cell biology, as well as serving as cellular models of disease (for the elucidation of new pathophysiologic mechanisms and the identification of novel drug targets and diagnostic or prognostic markers). Indeed, any therapeutic use of stem cells should be viewed as "translational developmental biology."[150]

8 Homeobox Genes

Heber C. Nielsen and MaryAnn V. Volpe

In 1894 Bateson coined the term "homeosis" to describe inherited mutations in *Drosophila melanogaster* in which significant alterations of morphogenesis were observed.[1] Evidence that these alterations were the result of single-gene mutations led to the definition of homeotic genes—genes that control the formation of the body plan. With the development of gene cloning, these genes were among the first to be defined and sequenced. Early studies showed that homeotic genes are transcription factors, many of which contain within the gene a conserved 180–base pair sequence. This internal 180–base pair sequence codes for a 60–amino acid DNA binding region within the resulting protein. The protein binds to DNA, allowing the transcription factor to regulate the expression of other genes. This specific conserved region is known as the *homeobox.* Genes containing the homeobox are therefore called homeobox genes (reviewed by Gehring[2]). Generally, homeobox genes are expressed in cells of mesodermal origin, but expression of certain homeobox genes in cells of epithelial origin also has been reported.[3-5]

The discovery that the homeobox is found in many genes throughout the vertebrate kingdom created intense interest in the role of homeobox genes as master control genes of many aspects of embryonic development. A large number of *Drosophila* homeobox genes have mammalian counterparts that frequently are closely conserved in their gene or protein sequence relative to the *Drosophila* "parent" gene. Generally the homeobox portion of the gene is either 100% or very close to 100% conserved in the DNA or the amino acid sequence. Additional mammalian genes containing a strongly conserved homeobox sequence but with no counterpart in *Drosophila* also have been discovered. Well over 100 homeobox genes have been identified in humans; this number has been estimated to represent only half of all such genes within the human genome.[6] Thus homeobox genes may account for some 0.5% of the approximately 30,000 genes in the human genome. In this era of the Human Genome Project, studies using gene array technology are now uncovering evidence for a wider role for homeobox genes in development than has been previously appreciated.[3,7-9] Studies provide evidence of more complex combinatorial expression patterns within the establishment and maintenance of mature cell phenotypes, and that alterations in these combinatorial patterns may underlie the development of diseases.[9-11]

Homeobox genes function as regulators active in the development of embryonic cell fate and organ morphogenesis of all vertebrate species. Most studies of mammalian homeobox genes have been done in mice because of the ability to manipulate and study the mouse genome; however, available evidence indicates conservation of function across diverse species. Homeobox genes can be classified into two large groups: the *clustered* group, called *Hox* genes, located in specific regions on certain chromosomes and the *diverse* group of homeobox genes that are dispersed throughout the genome but are similar to the clustered group in genomic organization and conserved sequences. Some homeobox genes in the diverse group also exist in clusters, such as the so-called *Para-Hox* cluster that contains *Gsh1, Pdx1,* and *Cdx2.* Others can be grouped into families on the basis of sequence similarities outside of the homeobox, such as the *Nkx* family of genes, or their similarity to other *Drosophila* homeobox genes, such as the *Pax* family. Because of the large number of homeobox and homeobox-like genes and the affected developmental processes, this chapter focuses on the role of *Hox* genes and other specific homeobox genes in relation to development of foregut organs and limb, renal, and vascular development.

The unique and interesting genomic and genetic characteristics of the *Hox* genes have received particular attention from developmental biologists. In *Drosophila* the eight *Hox* genes are organized in a specific cluster termed the HOM-C complex, where they are arranged according to their spatial and temporal expression patterns during larval development (Figure 8-1). In the HOM-C complex, the *Hox* genes are organized on the *Drosophila* chromosome from 3′ to 5′ corresponding to their anterior (rostral) to posterior (caudal) larval expression pattern (spatial colinearity) and the timing in larval development when expression begins (temporal colinearity) (reviewed by Coletta and associates[12]). Although identical to each other within the homeobox region, the *Hox* genes also possess sequence similarities outside of the homeobox region that are important for Hox gene interactions with other transcriptional regulatory proteins. The degree of similarity is related to the proximity of genes within the cluster. Hox genes are expressed with a definitive anterior boundary. The level of this boundary is progressively more caudal for each successive gene in the cluster going in the 5′ direction.[13,14] *Hox* genes act to define specific body segments of the developing *Drosophila* larvae by the process of posteriorization, in which the most 5′ gene expressed in a given body region actively identifies that region as more posterior than the region just rostral to it. This *posterior dominance* explains why, in the presence of overlapping expression, one gene is instructive in determining body segment identity.[15] Within a given area, however, overlap in expression of the primary proximal gene with more distal genes is fairly common. Such overlap allows the potential for modification of tissue-specific or organ-specific action of the primary proximal gene through *Hox* gene interactions. In fact, two different studies—of a mouse model of the VATER Association and of humans with Currarino syndrome (which involves anomalies of the sacral and anorectal structures)—have shown that combinations of homeobox genes are important for normal structural development.[16,17]

Mutations causing ectopic expression of individual *Hox* genes result in altered body segmental identity (homeotic transformation), producing seemingly bizarre deformities in *Drosophila.* Such mutations "posteriorize" an anterior segment through ectopic expression of a posterior gene in an anterior position.[6] Classic examples of posterior homeotic transformation are represented by the Antennapedia and Ultrabithorax mutations. In the Antennapedia mutant, the *Antennapedia* gene is misexpressed in a more rostral position, causing identification of part of the head structure as mesothorax, such that the fly grows a leg instead of an antenna from the head. In the Ultrabithorax mutant, ectopic expression of the *Ultrabithorax* gene in the second thoracic segment redefines this segment as a duplication of the third thoracic segment, and the fly grows a second pair of halteres, instead of the wings that would normally develop from this body area. It is important to recognize that *Hox* genes and the other homeobox genes do not actually code for specific body structures. Antennapedia, for example, does not code for a leg. Rather, these genes

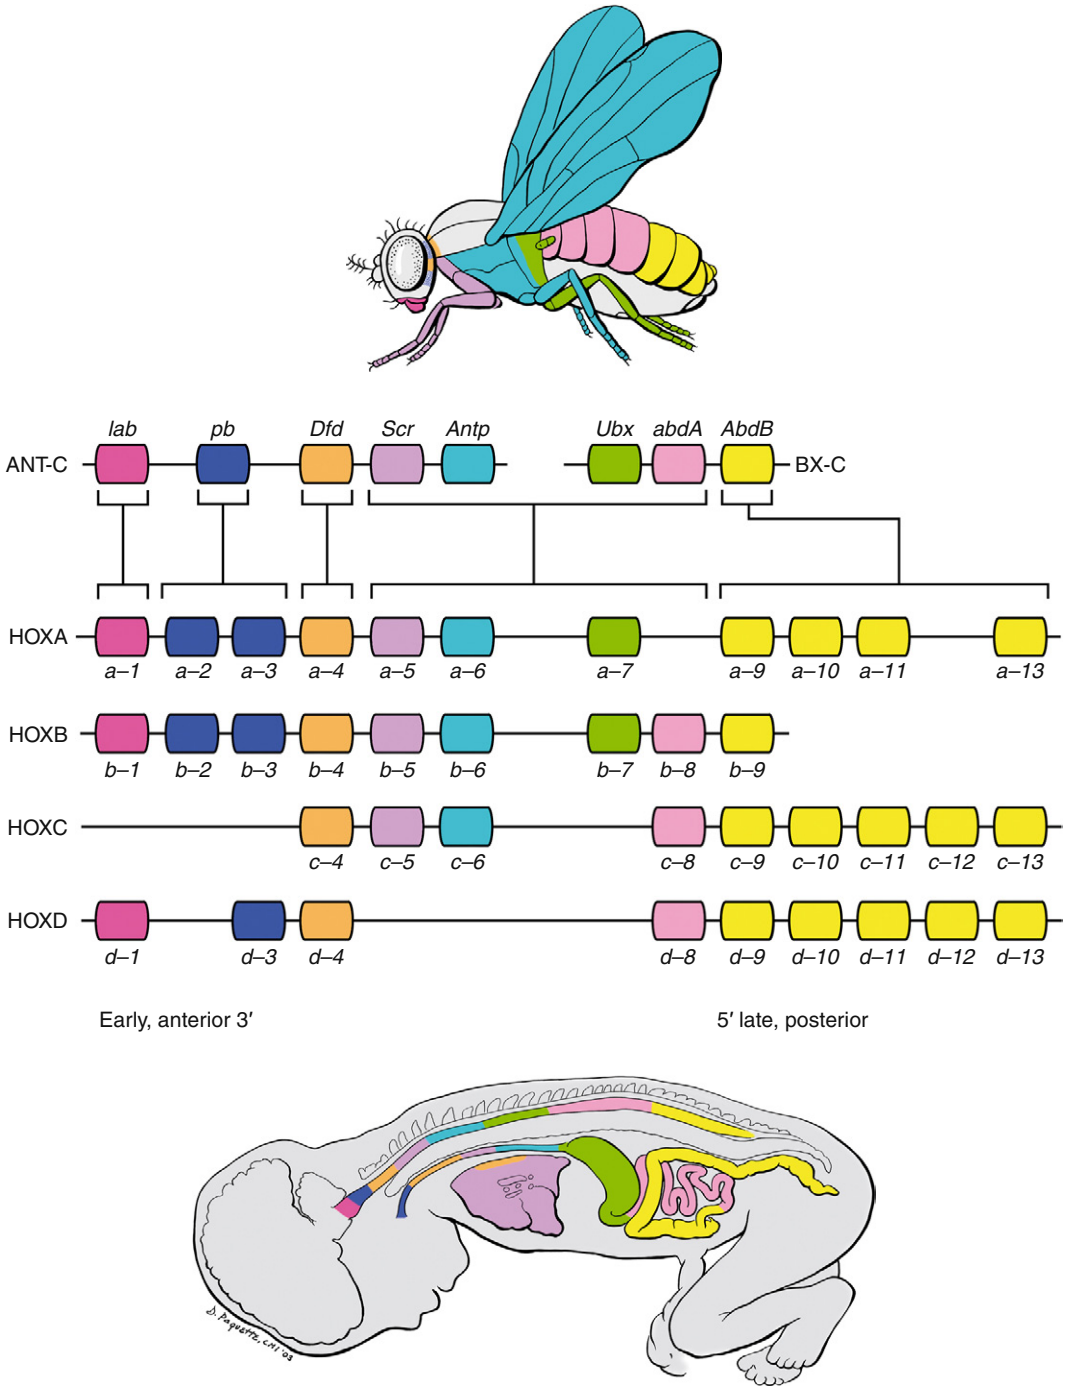

Figure 8-1 Relationship of the *Drosophila* HOM-C homeobox gene cluster and the mammalian *Hox* complex. Genes are depicted in their 3' to 5' organization on the *Drosophila* and each of the mammalian chromosomes. *Missing boxes* on the mammalian chart reflect that the specific gene is not present within that cluster. *Specific patterns* denote the mammalian genes paralogous to their *Drosophila* counterparts. Patterns also illustrate in the adult fly the body regions affected by expression of that specific *Hox* gene during embryonic development. In general, these regions correspond to the most anterior area of expression of that gene in the embryo. Loss-of-function mutations alter embryonic morphogenesis, resulting in defects of that particular body region. An exception is the pattern of the *pb* gene, which is *stippled* to indicate that although this is the most anterior region of expression in the embryo, no apparent phenotype for this region when the gene is mutated. Patterns in the human infant similarly indicate the anterior region in which that group of paralogous genes is expressed during embryonic development. For simplicity, only the nervous system, lungs, and intestinal tract are represented. These are not the only systems in which Hox genes are important. Data for the human infant are derived mostly from studies of mouse embryogenesis. *(Figure drawn after data and charts in Roberts DJ, Johnson RL, Burke AC, et al: Sonic hedgehog is an endodermal signal inducing BMP-4 and Hox genes during induction and regionalization of the chick hindgut,* Development *121:3163-1374, 1995; and in Coletta et al, 1994[12]; McGinnis and Krumlauf, 1992[68]; Mavilio, 1993[32]; Mark et al, 1997[6]; and Bogue et al, 1996.[41] © 2003 by Darisse Paquette, CMI, and Heber C. Nielsen, MD.)*

act as master control genes, giving specific embryonic cells positional and spatial cues that define their regional identity and fate and regulating the expression of genes that do code for the development of structures specific to the region defined by that homeobox gene.

In mammals, the *Drosophila* HOM-C gene cluster was duplicated onto four separate chromosomes and is called the HOM-C cluster. Although the genes are located on separate chromosomes, the unique organization and expression patterns, including spatial and temporal co-linearity, are completely retained (see Figure 8-1). Just as in *Drosophila,* the order of 3′ to 5′ chromosomal organization corresponds precisely with the anterior limit of gene expression within the embryo somite stage and ultimate organ structural development.The more 3′ the chromosomal location, the more rostral is the anterior limit of gene expression.[18] The mammalian *Hox* genes retain identity (homology) of the homeobox region at the amino acid level and near or complete identity at the DNA level. Chromosomal order within the mammalian clusters is identical to that of the *Drosophila* complex, allowing the classification of genes within the HOX-C complex as homologues of their *Drosophila* counterpart. Counterpart genes in each of the four complexes—for example, *Hoxa4, Hoxb4, Hoxc4,* and *Hoxd4*—are termed paralogous genes, or paralogs. Of great interest is that the HOX-C complex genes also retain characteristics of expression and apparent function of their *Drosophila* homologues.Thus body segments that are likely to be controlled by mammalian *Hox* genes are similar to the segments controlled by their corresponding *Drosophila* counterpart.[12]

Homeobox genes, in particular the Hox group, appear to exhibit three phases of expression during mammalian development.[19] First is expression in the very early embryo at gastrulation, which is likely to induce initial patterning.The second phase is during organ morphogenesis, with organ-specific expression that helps establish both organ structure and development of specific cell types. The third phase may begin in late fetal development or later in postnatal life. Expression generally is limited to specific cell types within an organ, such as the insulin-producing beta cell of the pancreatic islets. Evidence is increasing, however, that the specific cell type within an organ expressing a particular *Hox* gene may change over time during development. The cellular expression appears necessary to maintain a differentiated functional phenotype of the particular cell. During these phases of expression, *Hox* genes appear to have two distinct functions. One involves *homeosis,* whereby *Hox* genes impose a certain fate on groups of cells in one body region, a function active predominantly during initial patterning of the embryo but maintained throughout life.The ability of progenitor cells to "remember" or maintain homeobox gene activity appears to be unique to homeobox genes and allows these genes to provide segment identity to an organism's body plan.The other function, probably active during organogenesis and in postnatal life, is to serve as "realizator" genes or controlling genes that affect other realizator genes. Realizator genes directly influence a cell's specific identity and activity through processes of cell adhesion, cell division, survival, and apoptosis—events that control tissue and organ shape.[20,21] Homeobox genes regulate the process of transdifferentiation of specific precursor cells to a different cell type, an important event in morphogenesis.[22] In many instances the homeobox genes are subsequently down-regulated with further maturation, posing a significant biologic question: How are homeobox genes down-regulated in a development-specific fashion? A study of *Hoxb5* in liver development showed one mechanism, that of progressive gene-specific and tissue-specific methylation with advancing development.[23] More information is needed on this issue to elucidate further the mechanistic controls of organ and cellular identity and function.

Various knockout and transgenic mice models have been created to identify the developmental function of many HOM-C and other homeobox genes. Compared with the dramatic homeotic alterations caused by mutations in *Drosophila,* the results in mammals often have been surprisingly much more modest, especially in view of the significant developmental role these genes are believed to play. Knockout models of individual *Hox* genes frequently exhibit changes in vertebral body identity (for example, transformation of a cervical vertebra into a thoracic vertebra), changes in rib number or identity, and shoulder girdle alterations.[13] The reason for such comparatively restricted homeotic changes is unclear but may relate to the fact that the *Hox* genes are reproduced four times in mammals. This redundancy may allow paralogs or homologues of the targeted gene to replace some of the missing function, allowing a more normal morphogenesis.[24] This explanation is consistent with the proposed role of the HOM-C genes. In other words, nature has provided multiple backup strategies to allow normal development. Indeed, studies in which multiple *Hox* genes have been targeted show more significant homeotic changes in the developing mouse.[25-28] Thus the rule of posterior dominance used in *Drosophila* to determine which *Hox* gene is instructive within a particular segment becomes more complex in mammals. In addition to posterior dominance, it is likely that combinatorial and gradient rules influence gene dominance, a feature called *quantitative colinearity.*[25] Gene ablation studies in mice show that the phenotypic severity of loss of one *Hox* gene is amplified in combined ablation models that feature defects in two or more *Hox* genes.[27,28] Overall, these studies suggest that *Hox* genes help set up morphogen gradients in the developing organism and in developing organs to influence which combination of genes are active for development of body segments and organ regions.[20,29,30]

Of interest to those caring for the human fetus and newborn is the fact that many homeobox genes, and *Hox* genes in particular, are stimulated by retinoic acid.[31,32] Retinoic acid stimulation of *Hox* gene expression preserves temporal colinearity (the more 5′ *Hox* genes require progressively longer exposure times for stimulation) but spatial colinearity can be violated. Retinoic acid may induce *Hox* gene expression in body regions and cell types where they are not normally expressed. An in vitro example of this phenomenon in lung tissue is described further on. Alternatively, lack of appropriate retinoic acid concentrations at critical times in the developing fetus and newborn also can cause developmental defects.This is shown by an example in rats where vitamin A deficiency during the first 10 days of a 21-day gestation leads to inappropriate expression of certain *Hox* genes in more posterior regions of the embryo, where their expression normally would be repressed. In the example given, this *anterior transformation* led to anterior homeotic transformations of the vertebrae in the cervical to lumbosacral regions.[33] With current interest in the potential use of retinoic acid to assist maturation or effect repair from injury in the premature human infant, it is clear that careful and thorough examination of developmental effects must be made before such treatment should be clinically tested. Many of the teratogenic effects of retinoic acid are postulated to be mediated by induced *Hox* expression.

Much of the work on HOM-C genes has focused on development of the nervous system, because this organ system requires spatial identification, patterning, and determination of cell identity and fate that are unique to different somite regions.The anterior-posterior expression gradients of each of the four HOM-C gene clusters are relatively easily demonstrated within the developing neural system, and the importance of these genes for normal nervous system morphogenesis and development is becoming well established.[34,35] The development of other embryonic structures, however, also requires spatial identification, patterning, and determination of cell identity, for example limb morphogenesis and the development of the embryonic foregut into different structures including the lung, stomach, intestinal tract, liver, and

pancreas. In these systems the unique expression features of the HOM-C gene clusters are similarly evident.

The focus of this chapter is on the role of HOM-C and other homeobox genes in determination and morphogenesis of the foregut-derived organs, and in formation of the limbs, kidney, and cardiovascular system. This emphasis does not mean that more is known about these developing systems, or that development of these systems is more heavily dependent on homeobox genes. Rather, these systems are of particular interest to neonatologists because many neonatal diseases involve foregut-derived organs, as well as limb, kidney, and cardiovascular system. An understanding of how these developing systems are controlled may provide insights into development of new therapeutic strategies. In addition, more general information is presented on human diseases either caused by or associated with misexpression of homeobox genes.

HOMEOBOX GENES AND FOREGUT AND HINDGUT DEVELOPMENT

Lung

The embryonic lung develops as an evaginating diverticulum from the embryonic foregut. The diverticulum then becomes bilobate to form the early right and left lungs. Branching morphogenesis, driven by a number of growth factor signals and regulatory molecules, establishes the respiratory tree. The initial branching of the right and left lung primordia involves fibroblast growth factor family members (FGFs). The development of continued branching involves a complex interaction of FGFs and morphogenetic proteins such as Sonic hedgehog and bone morphogenetic protein-4 (BMP4)[36] (reviewed by Warburton and co-workers[37]). The complex pulmonary structure is populated by more than 40 different cell types arising from foregut, endoderm, and surrounding mesoderm. This complexity of structure and cell determination and differentiation clearly requires master control genes to establish positional identity and cell fate. Thus homeobox genes are prime candidates for significant roles in many aspects of lung formation, including a role in modulating the effects of other regulatory pathways, including but not limited to members of the FGF and BMP families, in the developing lung.

Early surveys of individual Hox gene expression in mouse embryos using in situ hybridization revealed expression of a few genes in the mesenchyme of developing lung, especially of *Hoxa5* and *Hoxb5,* homologues of the *Drosophila Scr* ("sex combs reduced") gene.[38,39] Among other functions in the *Drosophila* larva, *Scr* identifies the pharyngeal and upper respiratory region. Several groups of investigators interested in lung morphogenesis are focusing on these Scr paralogs and their close neighbors within the HOM-C complex in lung development. Bogue and co-workers surveyed *Hox* genes expressed in developing mouse lung using polymerase chain reaction (PCR) with degenerate primers.[40] They found 15 *Hox* genes, with *Hoxa5* and *Hoxb5* most prominently expressed. Many of these genes were stimulated by retinoic acid treatment in vivo. In another study using in situ hybridization, Bogue and associates evaluated the temporal and spatial expression of *Hoxb* cluster genes along the foregut just proximal and distal to the developing lung primordium, as well as within the developing lung itself.[41] *Hoxb3* and *Hoxb4* showed anterior expression boundaries in the foregut proximal to the position of the budding lung diverticulum, and *Hoxb5,* just at the position, in agreement with the general principles of proximal-distal patterning and overlapping expression of *Hox* genes. Within the lung, anterior-posterior expression gradients also were observed, with *Hoxb3* and *Hoxb4* expressed in mesenchyme underlying tracheal, proximal, and distal airway structures, but Hoxb5 only in mesenchyme of distal airway structures and in the pleura. Curiously, Hoxb2 also was expressed in distal lung mesenchyme, so in this respect spatial colinearity was not completely conserved.

Hoxb5

Earlier studies by Wall and associates showed that the fetal organ with highest *Hoxb5* protein expression was the spinal cord, followed closely by the lung.[42] Volpe and colleagues identified the developmental expression of *Hoxb5* protein in embryonic mouse lung.[43] Expression increases during branching morphogenesis, becoming maximal at day 15 (female lung) and day 16 (male lung), declining afterward to become very low at term and only minimally detectable in adult lung. The importance of the observed male-versus-female difference in timing of peak expression is unclear. Structurally, Hoxb5 protein was located diffusely in mesoderm during branching morphogenesis, then became localized to mesenchyme underlying conducting airways, especially at apparent developing branch points. Of interest, at late gestation Hoxb5 protein was also seen in occasional columnar epithelial cells. These findings in mouse lung development have been confirmed in human lung development with maximal expression in the pseudoglandular phase of lung morphogenesis; waning expression and localization to mesenchyme under conducting airways and at branch points in the canalicular stage; further decreasing to occasional mesenchymal cells in the saccular and alveolar stages; and no apparent expression in the adult lung.[44] The function of *Hoxb5* was studied in vitro using embryonic lung cultures. Overexpression of Hoxb5 protein (using retinoic acid stimulation) and knockout of *Hoxb5* (using antisense oligonucleotides or siRNA molecules) each altered the development of branching morphogenesis. Knockout in the early or mid-pseudoglandular period during active airway branching morphogenesis produced reduced proximal branching, and overexpression resulted in elongated proximal airways and reduced ability to form distal branches.[45] Additional studies in mouse lung organotypic cultures showed that growth factors and hormones that prematurely induce the differentiation of distal airway epithelium also significantly reduce expression of Hoxb5 protein in distal lung mesenchyme.[46,47] Dihydrotestosterone, which stimulates branching morphogenesis and delays lung maturation in male fetuses,[48,49] also up-regulates Hoxb5.[50] Some of these effects of Hoxb5 may be caused by Hoxb5 regulation of cell adhesion molecules and spatial expression pattern of FGF-10. Additionally, in those experiments Hoxb5 down-regulation affected expression of Hoxb4 and Hoxb6, suggesting that Hoxb5 may contribute to the lung phenotype for *Hoxb5* by cross-regulation of other *Hox* genes.

Results from the overexpression studies suggested a relationship of *Hoxb5* to congenital lung malformations. Studies of bronchopulmonary sequestrations and congenital cystic adenomatoid malformations show significantly increased Hoxb5 expression underlying the abnormal airways, which persisted in tissue removed at surgery during infancy.[44,45] It remains to be determined whether this abnormal persistence of high Hoxb5 protein expression is causal to the development of these lung malformations or whether some other signal initiated the formative process and Hoxb5 expression participated in determining the structural development of the already initiated malformation.

In a mouse model of pulmonary hypoplasia with congenital diaphragmatic hernia (CDH) that mimics human pulmonary hypoplasia with CDH, the Hoxb5 protein expression pattern at term resembles that at an earlier developmental stage, suggesting that modified Hoxb5 expression also may contribute to abnormal lung development in this condition.[51] In animal models of CDH in which in utero tracheal occlusion was used to accelerate lung development, Hoxb5 protein levels are prematurely down-regulated, suggesting that duration and timing of tracheal occlusion are important to modulate lung growth versus lung maturation.[52]

Hoxb2, Hoxb3, Hoxb4, and Hoxb6

Although *Hoxb2, Hoxb3,* and *Hoxb4* genes are expressed at critical time points in lung development and in specific spatial distributions, gene knockout studies involving abnormal expression

of one or more of these *Hox* genes have either not described or not evaluated lung structural or functional changes.[40,53-55] Lung abnormalities in these experimental studies remain unknown, partly because of embryonic death before birth to onset of lung development and the lack of research studies conducted to date on the mutant mice. Mice expressing mutant alleles of *Hoxb4* have severe abnormalities in closure of ventral body wall, including the sternum, that lead to a 50% rate of embryonic lethality on or before day 14.5 of gestation. Of mice that survive until birth, greater than 90% die in perinatal period apparently secondary to defects in chest cavity structure. In the *Hoxb2* mutants the abnormalities are similar to but less severe than those seen in the *Hoxb4* mutants. Genetic analyses suggest that the abnormalities seen in these mice are due to abnormal expression of both Hoxb2 and Hoxb4. *Hoxb2* mutants have decreased Hoxb3 and Hoxb4 expression, whereas *Hoxb4* mutants have decreased to absent Hoxb2 expression in neural crest cells migrating to thoracic region but unchanged Hoxb3 expression. The chest and body wall defects seen in the *Hoxb2* and *Hoxb4* mutants resemble the human condition termed the pentalogy of Cantrell. Genetic defects have been suggested but not confirmed in pentalogy of Cantrell. If two genes are involved, however, genetic diagnoses in human infants may be difficult to identify.

Recent studies show decreased Hoxb6 expression in a mouse model of pulmonary hypoplasia with CDH. In this study, Hoxb4 and Hoxa5 expression were increased at the same time that Hoxb6 was decreased, suggesting that altered relationships of the levels of these Hox proteins (and potentially others) in pulmonary hypoplasia could lead to altered transcriptional regulation of downstream genes specific for lung morphogenesis.[4]

Hoxa5

Studies of *Hoxa5* in lung development have concentrated on gene expression, although some data on protein expression are available. Like its homologue *Hoxb5,* for messenger RNA (mRNA) *Hoxa5* is diffusely and strongly expressed in developing lung mesenchyme during the embryonic to pseudoglandular stages of lung morphogenesis. Some studies described a decrease in late gestation, whereas others reported that both mRNA and protein levels remain high throughout gestation.[38,40,56] In vitro block of Hoxa5 expression using antisense oligonucleotide technology causes abnormal branching morphogenesis of the embryonic lung, resulting in foreshortened and aberrant branches.[57] A transgenic knockout of the *Hoxa5* gene results in the most significant in vivo pulmonary phenotype of any *Hox* gene knockout. The newborn pups homozygous for the *Hoxa5* deletion died an early neonatal death of respiratory failure.[58] The lung is present but structurally abnormal in these animals. Abnormalities observed include upper airway obstruction associated with cricoid cartilage abnormalities and abnormal tracheal rings, altered bronchial epithelium, and decreased production of surfactant proteins, particularly surfactant protein B. It is unclear whether the lethal respiratory failure is due to upper airway obstruction, malformed lung airway or saccular formation, or abnormal type II cell surfactant production, or possibly is secondary to alterations in rib cage or skeletal muscle that make respirations ineffective. Originally these effects on epithelial gene expression and lung function were interpreted as evidence of altered mesenchymal-epithelial cell interactions secondary to absent Hoxa5 in pulmonary mesenchyme. However, subsequent studies showing expression of *Hoxa5* mRNA and protein in bronchiolar and alveolar epithelial cells on or after day 16 of gestation in the mouse and in the adult human support a more direct role for Hoxa5 on lung epithelial cell function.[34] Studies in cell culture confirm the ability of retinoic acid to strongly stimulate Hoxa5 expression in fetal lung fibroblasts.[57] Of potential concern, this study also found that retinoic acid strongly stimulated Hoxa5 expression in the type II cell-like MLE-12 cell line, in which Hoxa5 expression normally is not apparent. This finding suggests the possibility that high doses of retinoic acid may have an undesirable effect on developing pulmonary epithelium by induction of *Hox* genes at inappropriate sites or developmental time points. More recent studies show that other *Hox* genes are expressed in developing pulmonary epithelium and pulmonary vascular cells, supporting the possibility that retinoic acid may induce both beneficial and unwanted effects on developing lung.

A study of *Hox* gene expression in developing human lung and in adults with emphysema and pulmonary hypertension showed *Hoxa5* mRNA expression in epithelial cells and possibly type 2 cells at the pseudoglandular and canalicular stages of development. Expression was increased in adult lungs with pulmonary hypertension and decreased in emphysema. The decreased expression of *Hoxa5* in alveolar epithelial cells in adults with emphysema is consistent with findings in surviving *Hoxa5*-knockout mice, which have abnormal alveolar septal development and lung morphology resembling that seen in emphysema. These mice also have ventilatory abnormalities consistent with the altered morphology.[59] This finding is supported by recent work showing that *Hoxa5* protein expression changes from mesenchymal to epithelial cells in the mid-pseudoglandular period and by studies of mRNA expression in human lungs.[43] Furthermore, as noted earlier, Hoxa5 expression is increased in a mouse model of pulmonary hypoplasia and CDH, especially in alveolar septal tips, suggesting an attempt to compensate for abnormal alveolar development in pulmonary hypoplasia.

Nkx2.1

This divergent homeobox gene clearly has importance in both lung branching morphogenesis and determination of cell differentiation. Blockade of Nkx2.1 significantly inhibits lung branching morphogenesis, both in vitro and in vivo (especially of distal branching).[5,60] In addition, Nkx2.1 is an important transcription factor regulating the differentiation and function of pulmonary epithelium. It specifically activates transcription of the surfactant protein C and surfactant protein B genes in type 2 cells and the Clara cell secretory protein gene in Clara cells. It appears also to control the determination of these cell types (reviewed by Warburton and associates[61]). An interesting case report described an infant with unexplained respiratory distress, hypothyroidism (Nkx2.1 also is involved in thyroid morphogenesis), and a haplotypic deletion of chromosomal region 14q13-21, which included the *Nkx2.1* gene.[62] The infant's problems may have been due to loss of *Nkx2.1,* but because the deletion included many more genes, such a conclusion remains speculative.

Iroquois (Irx) Genes

This strongly conserved group of divergent homeobox genes appears important in pattern specification and organ-specific development in both *Drosophila* and in mammals. In mammals, six Iroquois genes are known. During development, Irx1 through *Irx5* are expressed in multiple sites, but *Irx6* is highly restricted with weak expression. *Irx1, Irx2, Irx3,* and *Irx5,* but not *Irx4*, are found in the branching lung epithelium. In vitro knockout of each lung-expressed *Irx* gene decreased branching morphogenesis. This was associated with a loss of distal epithelial phenotype markers (surfactant protein C mRNA) and an increase in proximal epithelial markers (Clara cell secretory protein mRNA, class IV beta-tubulin mRNA), indicative of a role for *Irx* genes in the proximal-distal determination of epithelial fate.[63] *Irx5* is an immediate downstream target of Hoxb4, demonstrating the interactive hierarchy of homeobox gene functions.[64]

Liver

Much as in the lung, the hepatocytes in the embryonic liver develop from the endoderm of the foregut, invading the surrounding mesenchyme to form the developing liver structure.

The process of hepatocyte determination is driven by FGFs produced by the closely appositioned embryonic heart.[65] The target genes for these FGFs are not known but may include specific homeobox genes. Homeobox genes are important in the morphogenesis of the liver. In particular, the divergent homeobox gene *Hex* is necessary for liver formation. Hex protein normally is expressed in the third pharyngeal pouch and subsequently in developing forebrain, thymus, thyroid, lung, pancreas, and liver, and in adult thyroid, lung, and liver.[66-68] Hex promotes endoderm development into the primordial liver bud after the initial identification by FGFs of these cells for a liver fate.[69] A murine knockout of the *Hex* gene results in embryonic lethality around embryonic day 12.5.[70] Examination of *Hex*-knockout embryos shows the absence of hepatocytes and the absence of liver formation but the presence of the liver capsule. The lack of commitment of foregut endoderm to hepatocyte endoderm indicates that Hex is necessary for this commitment process and suggests that *Hex* is a target, either directly or through a pathway, of the cardiac FGFs that initiate liver formation.

In addition to *Hex,* other homeobox genes contribute to the cellular expansion and specification of cell fate. *Lhx2* is important for proper liver cellular organization, expansion and differentiation, but not for early cell fate.[71,72] *Prox1* specifies the differentiation of hepatoblasts into hepatocytes.[73] Prox1 also regulates bile synthesis and gluconeogenesis in adult liver, making it a good example of a homeobox gene that acts both in cell development and later in maintenance of differentiated phenotype.[74] Conversely, overexpression of Hoxb7 is a clinical marker for, and may be a pathogenic cause of, bile duct carcinoma in humans.[75]

Although specific roles of *Hox* genes from the HOM-C cluster remain to be demonstrated, evidence suggests they are involved and important in regulation of hepatocyte maturation and function. For example, overexpression of *Hoxa5* in transgenic mice (using regulatory elements from *Hoxb2,* a more proximal gene) caused significant growth repression in the first few postnatal weeks, resulting in a proportionate dwarf-like phenotype.[76] This growth disturbance was associated with a profound increase in liver expression of the insulin-like growth factor binding protein-1 (IGFBP-1) and with marked decreases in both liver expression of insulin-like growth factor 1 (IGF-1) mRNA and circulating levels of IGF-1. Additional studies in cultured cells showed that Hoxa5 interacts with other transcription proteins to strongly enhance IGFBP-1 gene expression. This example demonstrates how Hox proteins may act cooperatively in the developed animal to maintain cell differentiation in a tissue-specific manner.

Because the liver is a hematopoetic organ during in utero development, studies of homeobox genes in developing hepatic cells also demonstrate that specific homeobox genes have important roles for establishing lineage fates in hepatic hematopoetic multipotent stem cells and T cell progenitors.[9,77]

Pancreas

A number of homeobox genes are known to be critical in pancreas morphogenesis and cellular differentiation and function (reviewed by Ashizawa and colleagues[78] and Jensen[79]). In addition, combinations of tissue-specific and spatially restricted homeobox genes are active in both pancreatic development and in maintaining the identity of differentiated cells.[7,11,80] The current interest in developing transplant and gene therapies to treat diabetes has produced a recent explosion in the understanding of homeobox genes in pancreas development, regulation of cell fate, and maintenance of cell identity.

The pancreas develops from ventral and dorsal buds that evaginate from the distal foregut endoderm. During differentiation of the foregut endoderm in the normal embryo the ventral pancreas bud and the liver bud arise from adjacent non-overlapping regions of the ventral foregut endoderm.[65] It is the proximity to the embryonic heart that drives the foregut endoderm towards the liver primordium through action of FGFs produced by cardiac mesoderm. If removed from the presence of the heart, this region of the foregut endoderm will default to expression of Pdx1 and engender pancreatic tissue.[81] Initiation of pancreatic bud identity in the foregut involves the control of at least two homeobox genes, *Hex* and an Mnx-class homeobox gene, *Hb9.*[82,83] The further development of pancreatic tissue from the dorsal and ventral buds is directed primarily by the divergent homeobox gene *Pdx1,* a member of the Para-Hox cluster. The expression of *Pdx1* requires the action of at least two other homeobox genes, *Pax4* and *Nkx2.2.*[84] Although it was originally thought that *Pdx1* was only necessary for ventral and dorsal bud growth, recent studies make it clear that *Pdx1* is necessary for bud formation, growth and morphogenesis, and cell differentiation. Using a transgenic approach in which the *Pdx1* gene was placed under the control of a gene promoter that can be turned off by administration of doxycycline, Holland and co-workers interrupted Pdx1 expression at various stages of pancreatic development, as well as in the adult after normal pancreatic development and function was established.[81] Interruption of Pdx1 expression at developmental intervals blocked the processes of bud formation, organ growth and morphogenesis, and the identification, differentiation, and function of the islets including the endocrine and exocrine cell lineages within the islets.

Pdx1 regulates several genes involved in islet cell identity and function including insulin, glucose transporter 2, glucokinase, islet amyloid polypeptide, and somatostatin expression (reviewed by Hui and Perfetti[85]). Pdx1 is in turn regulated by glucose. In type 2 diabetes, characterized by insulin resistance and increased glucose concentrations, Pdx1 expression is elevated.[86] By contrast, loss of persistent Pdx1 expression is associated with the development of type 1 diabetes, decreased insulin production, and decreased numbers of pancreatic islet beta cells.[87] Work directed at finding transplant[88,89] or stem cell approaches to treat type 1 diabetes by restoring islet beta cells demonstrates the importance of induction of Pdx1 to generate the beta cell phenotype.[90-92]

Pdx1 gene abnormalities have been described in several human diseases. The extremely rare condition of congenital agenesis of the pancreas was found to be associated with a homozygous mutation in *Pdx1* that produced a truncated, non-functional protein product.[93] Family members heterozygous for this mutation manifested an autosomal dominant form of maturity-onset diabetes of the young (MODY type 4). Other studies have documented different mutations in *Pdx1* in families manifesting MODY type 4.[94] In all cases, the mutations alter the ability of Pdx1 to regulate the maintenance of beta cell identity and function.

Other divergent homeobox genes also exhibit functional regulation of pancreatic islet cell function. *Nkx2.2,* a member of the *Nkx* homeobox family, is expressed in three of the types of islet cells—namely, alpha, beta, and PP (pancreatic polypeptide–producing) cells—but not in delta cells. Mice in which the *Nkx2.2* gene has been knocked out lack beta cells and have marked reductions in the glucagon-producing alpha and PP cells.[95] In addition, there are many islet cells that do not produce any of the four pancreatic endocrine hormones. In other studies, deletion or disruption of the homeobox genes *Pax4* and *Pax6* shows that these genes are vital for islet endocrine cell differentiation—specifically, insulin- and glucagon-producing cells, respectively.[96,97]

Intestinal Tract

A number of *Hox* and divergent homeobox genes are expressed to influence intestinal development (reviewed by Morell[98]). As in the CNS, the development of stomach, small intestine, and large intestine exhibits a detailed representation of the spatial and temporal colinearity of expression of genes in the HOM-C complex.

Several studies have documented groups of *Hox* gene expression in the developing gut.[99,100] Expression is seen early in development of the foregut and hindgut structures and is confined primarily to the mesoderm. The developing esophagus, stomach, and cloacal region all exhibit evidence of endodermal cell Hox expression. Functions of *Hox* genes in intestinal development are less clear. Some evidence suggests that they interact with other homeobox genes in providing positional information to direct development of region-specific gut endoderm and structural morphogenesis. The temporal expression of the *Hox* genes also reflects the three waves of expression, with peaks in early embryonic mesoderm as the gut tube forms, in midgestation as determination of stomach, duodenum, small intestine, and large intestine is accomplished, and late gestation/early postnatal life as villous structures develop and are propagated. Although the specific functions of the *Hox* genes in intestinal development are not understood, several clues have been obtained from gene knockout and transgenic overexpression mouse models. Inactivation of *Hoxc4* caused disruption of esophageal muscle development and blockage of the esophageal lumen, suggestive but not identical to esophageal atresia of the human.[101] Overexpression of *Hoxa4* created an extended region of high *Hoxa4* expression into the large bowel and resulted in mice with megacolon suggestive of that found in Hirschprung disease.[102] Anterior overexpression of *Hoxc8* created the development of multiple hamartomas within the gastric mucosa.[103] The epithelium of these hamartomas resembled that seen in colonic mucosa, suggesting that anterior expression of this posterior *Hox* gene caused development of posterior mucosal characteristics. Studies have suggested that D cluster *Hox* genes are important in the development of intestinal sphincters. A multiple transgenic mouse, in which the D cluster of Hox genes from *Hoxd4* to *Hoxd13* was deleted, exhibited abnormalities of both pyloric and anal sphincter development.[104] Subsequent studies showed that deletions of either *Hoxd12* or *Hoxd13* caused anal sphincter abnormalities and rectal prolapse.[105]

Divergent homeobox genes also are critical for intestinal development. These include the members of the Para-Hox cluster *Cdx2* and *Pdx1*, as well as *Nkx2.3*. *Cdx2* is a mammalian homologue of the *Drosophila* homeobox gene *caudal*, which acts to posteriorize the rostral *Drosophila* larva. Cdx2 protein is expressed in the early embryo in the trophoblast cells; homozygous mutant embryos lacking Cdx2 fail to implant and so do not survive.[106] After day 12 of mouse development expression of Cdx2 is confined to gut epithelium where it appears responsible for posterior axial specification of the developing epithelium. Expression begins just anterior to the developing liver bud and extends posterior to the distal colon. In adult animals, high-level expression present in the proximal colon decreases with either rostral progression into the ileum and jejunum or caudal progression into the terminal colon.[107,108] Studies of *Hox* genes in context with *Cdx2* suggest that Cdx proteins may participate in establishing Hox expression boundaries in the developing gut.[109,110] Cdx2 induces several extracellular matrix proteins consistent with a proposed role of inducing enterocyte maturation on the intestinal villus.[110] Cdx2 also acts as a tumor suppressor in the adult colon.[111]

Although homozygous deletion of *Cdx2* causes lethality at implantation, it has been possible to use gene deletion to demonstrate the role of *Cdx2* in gut development in vivo. Transgenic mice that are heterozygous for the *Cdx2* deletion develop multiple polyp-like intestinal lesions that are most evident in the cecum, where Cdx2 is prominently expressed. The polyps extend proximally and distally with decreasing frequency and are found only within the normal expression domain of the *Cdx2* gene.[112] Histologically these lesions consist of normal gastric mucosa. Examined both proximally and distally from the cecum, the lesions demonstrate an orderly progression of cell type from stratified squamous epithelium (typical of the fore stomach) through the mucous glands of the cardia, the gastric glands of the corpus, to mucous cells with the appearance antral cells. Between polyp lesions is an intercalation of villi and Paneth cells, structures that lack Cdx2 expression. As Beck and colleagues have pointed out,[112] this is a remarkable presentation of an anterior homeotic shift, the only example of homeosis that to date has been demonstrated for the intestine, and also is the first report of intercalary regeneration in mammals. Another example of an anterior homeotic shift may occur in Barrett's esophagus, in which ectopic Cdx2 expression is found in the esophageal lesions.[113] Thus, Cdx2 works within the developing gut similar to the function of its *Drosophila* homologue to create a posterior phenotype that replaces a more proximal default program.

Patients with Hirschprung disease–associated enterocolitis were found to have significantly reduced expression of both Cdx2 and Cdx1 in the enterocolitis lesions. In contrast, other intestinal colitis diseases such as necrotizing enterocolitis did not display such a reduction, nor did Hirschprung disease intestine without enterocolitis.[114] Another possible clinical correlate is that of intestinal-type gastric cancer, which often is preceded in humans by metaplasia of gastric-type mucosa in the intestinal tract. The anterior homeosis observed in the heterozygous *Cdx2*-knockout mice resembles that in these types of lesions. Studies in humans suggest that reduced Cdx2 expression may be an antecedent cause of this form of intestinal cancer.[108]

The important role of the Para-Hox gene *Pdx1* in pancreatic development has already been discussed. *Pdx1* is expressed in distal foregut, where it not only defines pancreatic endoderm but also affects duodenal development. In Pdx1-deletion animals the rostral duodenum does not form villi or Brunner's glands and remains lined by a cuboidal epithelium.[115] These abnormalities are very closely restricted to the specific domain of Pdx1 expression in the distal foregut.

Members of the *Nkx* group of homeobox genes are expressed in intestinal mesoderm, where they appear to act on the overlying epithelium to direct its differentiation. For example, inactivation of *Nkx2.3,* which is expressed in gut mesoderm, causes abnormalities of adult intestinal epithelium.[116] These abnormalities include delayed villus development, increased growth of crypt cells, and hyperproliferation of epithelium, primarily in the jejunum. These findings support the general hypothesis that one important function of mesodermally expressed homeobox genes in general is to provide positional cues for overlying epithelium that defines their function and structural organization.

In addition, the divergent homeobox genes *Cdx1* and *Cdx4*, relatives of *Cdx2* but not members of the Para-Hox cluster, are expressed in developing gut endoderm and mesoderm, respectively.[117] It is not known if they are critical for development. Deletion of the divergent homeobox gene *Ncx/Hox11L.1* in mice causes a syndrome of mega ileocecal colon with intestinal dysmotility.[118]

HOMEOBOX GENES AND LIMB DEVELOPMENT

The mammalian limb provides scientists and clinicians with an outward example of embryonic structural patterning that requires a multitude of positional signals in the developing embryo to create the asymmetric and unique definition of structure along the anterior to posterior and dorsal to ventral axes. Multiple cellular processes are programmed in time and place, including a balance between rapid cell growth, cell proliferation, and apoptosis and the development of cell and structural differentiation. The easy visibility of structural changes in the limb and presence of human limb malformations in approximately 0.1% of newborns also has made limb development one of the most-studied processes for *Hox* gene involvement in both embryogenesis and malformations.

For orientation of events potentially controlled by Hox genes in limb development it is important to define the proximal to distal structures and certain regions of the developing limb. The limb has four segments that define the initial structural patterning events: the root or zonoskeleton, the proximal segment or stylopodium (one bone: either humerus or femur), the middle segment or zeugopodium (two bones: radius plus ulna or tibia plus fibula), and the distal segment or autopodium (several bones of the hands or feet with definite structural polarity). Additionally, the developing limb buds have zones that are partially defined by their location and the different influences they exert on patterning. The *apical ectodermal ridge* (AER) is located at the tip of the growing limb bud. It contains many members of the FGF family and maintains proliferation of the rapidly growing *zone of progression*, the region of mesenchymal cells that eventually become committed to the different regions of the final limb. The zone of progression determines the outward growth of limb along the proximal to distal axis. Another developmental zone is the *zone of polarizing activity* (ZPA), a region that contains posteriorizing signals and is located on the posterior edge of the outward growing limb bud. This region determines the anterior-to-posterior axis of the limb and is named for its ability to induce the formation of posterior structures when transplanted to the anterior edge of developing limbs, creating a mirror image limb.[28,119,120]

Over the past decade molecular biologists have began to unravel the molecules responsible for polarizing the developing limbs into three axes: anterior-posterior, proximal-distal, and ventral-dorsal. These molecules in general involve transcriptional regulators and signaling proteins, with the transcriptional regulators defining clear domains in the developing limb before visual evidence exists of structural definition. Much evidence now exists both from experimental studies and analysis of anomalies seen in humans that genes from the HOM-C cluster are a major group of transcriptional regulators necessary for defining regional and structural identity during limb morphogenesis. *Hox* genes subdivide the limb along two axes: the proximal-to-distal axis and the anterior-to-posterior axis. They activate downstream targets according to their position within these axes in agreement with the 3′-to-5′ proximal-distal principle of activity described at the beginning of this chapter. In addition, the principles of temporal and spatial colinearity of Hox gene expression described earlier also are maintained within the developing limb bud along the anterior-posterior and proximal-distal axes.

Many gene ablation studies have shown that mice lacking a certain *Hox* gene display a phenotype in which a specific skeletal element is missing from the region that would normally express the ablated gene. The phenotypic severity is amplified by combined ablation of two or more *Hox* genes.[27,28] Limb development also provides an example of the importance of quantitative or dose dependent regulation by *Hox* genes in addition to contributions from a Hox code in development.[121] For example, the size and number of digits depends on quantitative levels of genes from the 5′ paralog groups 11, 12, and 13 in the HOM-C complex. Limb development also shows how combinations of *Hox* genes help define a particular proximal-to-distal limb segment. For example genes from paralog groups 9 and 10 define the upper arm or the stylopodium, groups 10, 11, and 12 define the lower arm or zeugopodium, and groups 11, 12, and 13 define the digits or autopodium.[28] Restricted expression of groups of *Hox* genes from the different clusters also helps specify the anterior-posterior nature of the limb, with Hoxc4 and Hoxc5 specifying the forelimbs, Hoxc9, Hoxc10, and Hoxc11 defining the hind limb, and Hoxc6 and Hoxc8 being expressed in both fore and hind limbs. There are also specific functions within regions. For example, Hoxb5 is expressed early in the formation of the upper limb buds and is important to proper positioning of the upper limb bud along the anterior to posterior vertebral axis. Mice lacking *Hoxb5* have shoulder girdle deformities resembling Sprengel anomaly in humans where the forelimb arises more anteriorly leading to asymmetric abnormalities of shoulder position in reference to vertebral column.[122] Hoxb8 is also expressed very early in upper limb development and is necessary for inductive activity of the ZPA. Finally, non-clustered divergent homeobox genes such as *Lmx1* and *Engrailed1* are implicated in dorsal/ventral axis determination in limb development.[28,119]

Of the many *Hox* genes expressed during limb development, several are involved in limb anomalies in humans. Most notable are anomalies seen with mutations in *Hoxd13, Hoxa13,* or *Hoxa11,* which are required for normal development of the autopod. In humans with the autosomal dominant condition of synpolydactyly, mutations of the 5′ region of *Hoxd13* have been found.[123] Frameshift mutations of *Hoxd13* in humans are associated with a particular foot phenotype.[124] The autosomal dominant human hand-foot-genital syndrome has mutations in *Hoxa13*.[125] Similar anomalies are seen in mice homozygous for *Hoxa13* mutations. *Hoxa11* mutations have been found in persons with radioulnar synostosis.[126]

HOMEOBOX GENES AND KIDNEY DEVELOPMENT

Mammalian kidney development passes through three stages, the pronephros, mesonephros and metanephros, important to developmental morphogenesis and evolutionary comparisons. Given that the kidney is derived from intermediate mesoderm with a specific anterior to posterior definition and involves timely organized mesodermal-epithelial interactions for proper cellular determination, it is understandable that this process is regulated by homeobox genes. As indicated by studies in homeobox gene mouse mutants, homeobox genes help control downstream expression of other key transcriptional regulators and growth factor pathways in kidney development, including Gata 6, transforming growth factor-β_2 (TGF-β_2), and others.[8] Homeobox genes from the HOM-C clusters and the divergent *Hox* genes are both involved. Colinearity of *Hox* expression is preserved in kidney development with HOM-C genes 5′ in the clusters expressed in the nephrogenic regions and expression of 3′ genes restricted to the ureteric bud, which is formed from anterior intermediate mesoderm and pronephric duct.[127] A few *Hox* genes, including *Hoxb7, Hoxa11,* and *Hoxd11,* are necessary for kidney development.[128] Hoxb7 is expressed in the urogenital system in the mesonephros, ureter, and collecting system. Overexpression of *Hoxb7* in mice causes renal duplications.[127,129] Hoxa11 and Hoxd11 appear to act collectively in kidney organogenesis. In mice, knockout of just one of these *Hox* genes does not perturb kidney development, but double mutant mice have one hypoplastic kidney consistent with branching morphogenesis abnormalities or no kidneys.[130] These mice also lack a radius and ulna, underscoring the importance of *Hoxd11* for development of diverse structures. Additionally, *Hoxb13* gene misexpression causes renal agenesis, but whether other *Hox* genes of group 11 also are abnormally expressed in these mouse mutants is unknown.[131]

Early expression of several divergent *Hox* genes is found in intermediate mesoderm, including the *Lim1* and *Pax2* genes, suggesting they may be important in early patterning of the kidney, possibly at earlier stages than those for *Hoxa11* or *Hoxd11. Lim1*-knockout mice fail to develop kidneys as a result of failure of nephric duct formation.[132] Studies also show a sequential need for Lim1 for formation of the ureteric buds and patterning of the renal vesicles for nephron formation. This sequential function arises from action of Lim1 in distinct tissue compartments of the developing metanephros. Emx2, encoded by another divergent homeobox gene, probably is important later in kidney development during metanephros development after ureteric

bud formation. In *Emx2*-knockout mice, a ureteric bud develops but no tubular differentiation occurs.[133]

HOMEOBOX GENES AND CARDIOVASCULAR DEVELOPMENT

Homeobox genes from the clustered and nonclustered groups are implicated in cardiac morphogenesis, vasculogenesis of the great vessels, and angiogenesis and in related aspects of cellular differentiation. The clustered homeobox genes involved in these processes are derived predominantly from the *HoxA, HoxB,* and *HoxD* clusters, and the Para-Hox clusters (*Pdx* genes). Other nonclustered homeobox genes that are important to cardiovascular development include the *Nkx* family, *Prx,* and *Pitx* genes.

Hox Genes and Great Vessel Development

Morphogenetic events during the formation of the major chambers of the heart occur simultaneously with the formation of the great vessels from the pharyngeal arches and their corresponding pharyngeal arch arteries. Events in great vessel morphogenesis influence cardiac development including formation of the outflow tracts of the developing heart.

Each pharyngeal arch has a unique combination of expression of genes in the HOM-C cluster. The expression patterns of *Hox* genes in pharyngeal arches 2 through 5 is established by neural crest cells that migrate from rhombomeres expressing specific combinations of *Hox* genes. These neural crest cells also migrate to the aortic arches and ultimately contribute to the formation of the aorticopulmonary septum that divides the aortic and pulmonary outflow tracts and the endocardial cushions.[134-136]

Certain populations of neural crest cells express specific *Hox* gene combinations corresponding to the anterior-posterior origin of the cells, suggesting that *Hox* gene interactions with other key regulators help pattern the great vessels. For example, Wnt5a, which is expressed in similar regions to those for *Hox* genes in pharyngeal mesoderm and in pharyngeal neural crest cells, is necessary for cardiac outflow tract septation in mice.[137,138] Mutant mice lacking expression of the *Hoxa3* gene have many of the features seen in humans with DiGeorge syndrome/velocardiofacial syndrome (DGS/VCFS), with cardiac disease involving the great vessels as well as facial, thymic, and parathyroid abnormalities. These structures are derived from rhombomeres 5 to 7 and neural crest cells of pharyngeal arches 3 to 6, all of which have significant Hoxa3 expression.[134,136,139] Although gene defects have been seen mainly on human chromosome 22 in DGS/VCFS, Hox interactions with many cofactors during transcriptional regulation of downstream genes makes it likely that *Hox* gene mutations play a role in some cases of this syndrome. The molecular level at which *Hox* gene interactions with genes that are deleted from chromosome 22 in DGS/VCFS occurs remains to be determined.[135,140] A role for abnormal expression of Hoxa3 in formation of the great vessels and other features of VCFS is further supported by a case report of a child with a deletion in chromosome 7 leading to haploinsufficiency of genes from the entire *HoxA* cluster. This child exhibited abnormalities consistent with hand-foot-genital syndrome (see earlier section on limb development), which is known to be caused by mutations in *Hoxa13,* and also features of VCFS, including a striking resemblance to the defects described in the *Hoxa3*-knockout mice.[136,139,141]

Some studies suggest that loss of some other *HoxA* genes along with their paralogs in the other *Hox* clusters can lead to more severe cardiac defects resembling abnormalities seen in human infants. The contribution of collective groups of paralog genes from the *HoxA, HoxB* and *HoxC* clusters to the patterning of the pharyngeal arch arteries has been studied in chick embryos. For example, blocking expression of Hoxa3 and Hoxb3 proteins with antisense oligonucleotides in neural crest cells that contribute to the pharyngeal arches leads to regression of aortic arch 3, so that it is more similar in appearance to aortic arch 2. This homeotic transformation fits with the expression pattern of *Hox* genes in each pharyngeal arch. Blockade of pharyngeal arch neural crest expression of Hoxa5, Hoxb5 and Hoxc5 led to an additional pharyngeal arch and another aortic arch. In addition, isolated blockade of Hoxb5 resulted in an even more pronounced development of an additional aortic arch. This is particularly interesting because Hoxb5 is not expressed in neural crest cells during migration but becomes expressed in these cells when they reach the site of pharyngeal arch 6. The presence of Hoxb5 in this pharyngeal arch could thus contribute significantly to the appropriate patterning of arch derivatives from this region.[134,142, 143]

The paired related homeobox genes are also implicated in development of the great vessels. *Prx1* and *Prx2* gene products are expressed in mesoderm of developing great arteries and veins, in the endocardial cushions, and valves in the epicardium. Prx1 expression increases in the adventitia and outer media of developing great vessels. *Prx1*-knockout mice have normal intracardiac anatomy but have abnormal positioning and curvature of the aortic arch and a misdirected and elongated ductus arteriosus. Prx1 may exert its effects on great vessel development partly through regulation of tenascin-C, an extracellular matrix molecule localized to similar regions within the developing cardiovascular system.[144] Prx2 expression is intensely enriched in the ductus arteriosus beginning early in development, but *Prx2*-knockout mice do not show cardiovascular malformations. A combined role of Prx1 and Prx2 in cardiovascular development is suggested by the increased severity of anomalies in mice with combined null mutations for *Prx1* and *Prx2.* These mice have an unusually long ductus arteriosus, tortuous great vessels, and a retroesophageal right subclavian artery.[145-147]

Homeobox Genes and the Heart

The primitive heart tube in developing vertebrates forms from anterior lateral plate mesoderm. Through a complex process of heart rotation and folding during embryogenesis, the anterior regions of this heart tube ultimately form the ventricles, while the posterior portion of the heart tube form the atria. Even before formation of the heart tube, cell position in the heart-forming region of the lateral plate mesoderm helps determine specific anterior and posterior cell lineages that ultimately define which cells contribute to atria or ventricles of the developing heart. *Hox* genes from clusters A and D have distinct regional expression patterns during early heart development, suggesting that they participate in determining the anterior (ventricle) or posterior (atrial) phenotype of cells. *Hox* genes from paralog groups 1 to 5 are expressed in the heart-forming region and primitive heart tube of the developing chick heart, with both temporal and regional differences in expression. *Hoxa4, Hoxd3,* and *Hoxd4* are more highly expressed in posterior than in anterior regions of the primitive heart tube and primitive heart, followed by down-regulation during the stage of heart looping.[148] Other homeobox genes—*Nkx2.5, Iroquois,* and *Pitx2*—are expressed at similar or later times in heart formation, but the functional relationship of these Hox genes during heart development has not been studied. Some evidence exists for the ability of the clustered *Hox* genes to regulate *Nkx* and *Iroquois*[64,149] (reviewed by Epstein and Buck[135]). Certain homeobox genes are down-regulated during or after the stage of heart looping, suggesting that groups of clustered *Hox* genes are needed in early heart morphogenesis to specify or initiate expression of other factors for later stages of development.

Numerous studies have investigated the role of *Nkx2.5* in cardiac development. *Nkx2.5* is the mammalian homologue of the *Drosophila* gene *tinman*—so named because flies lacking *tinman* do not form the dorsal vessel, the structure similar to

the mammalian heart (thereby resembling the fabled Tin Man of Oz, who also lacked a heart).[135,150] Heart looping is prevented by inactivation of *Nkx2.5* in mice. Mutant mice form a primitive heart tube but then die in mid-gestation as a result of lack of heart looping. The fact that several of the clustered *Hox* genes are expressed in the primitive heart tube but are down-regulated at the heart looping stage suggests a possible hierarchy of gene interactions during heart development, with specific *Hox* genes being necessary early in heart morphogenesis and divergent homeobox genes such as Nkx2.5 being necessary later in development and possibly being activated by the earlier-expressed Hox genes.[149] At least 26 mutations have been found in the *Nkx2.5* gene in humans, some of which are in the homeodomain binding regions and others in regions of the gene that are involved in nuclear localization or interactions with other transcriptional regulators. Despite the variability in these mutations, recent studies suggest that the final common pathway for phenotypes seen with *Nkx2.5* abnormalities is influenced by to the total dose of Nkx2.5 protien available for DNA binding. Heterozygous loss-of-function mutations and hypomorphic alleles for *Nkx2.5* in humans are associated with atrial septal defects, conduction disturbances, ventricular septal defects, tetralogy of Fallot, and Ebstein's anomaly.[151-155]

The recently discovered homeodomain-only protein HOP is a downstream target of Nkx2.5 and also modulates Nkx2.5 function by inhibiting transcriptional activation of other cardiac specific genes by Nkx2.5. Homeodomain-only proteins such as HOP lack DNA binding activity but localize to the nucleus. HOP is expressed in cardiac muscle early in mouse development and in cells of pharyngeal arches that contribute to cardiac outflow tract. HOP expression continues in atrial and ventricular myocytes throughout development and in the adult. It probably contributes to control of cell proliferation, release of myocytes from cell cycle, and cardiac myocyte maturation. HOP also is expressed in other organs including lung, intestine, brain and kidney, but the regulatory interactions in these organs are less well defined to date.[156,157]

Another important aspect of cardiac morphogenesis is determination of appropriate left-right axis asymmetry. Situs anomalies occur in approximately 1 in 5000 live births, with equal incidence of situs inversus and situs ambiguus. Pitx2 (also called REIG, Otlx2, and Brx2) is a nonclustered homeodomain transcription factor originally identified as the gene responsible for Rieger syndrome, a disorder of autosomal dominant inheritance in which affected persons have haploinsufficiency of *Pitx2*.[158] Its potential role in left-right axis asymmetry is suggested by its expression pattern in left lateral plate mesoderm and the induction of its expression by other key mediators of left-right axis formation including Sonic hedgehog and Nodal. Mice with targeted mutations in *Pitx2* causing lack of Pitx2 protein on the left side of the embryo have cardiac defects including abnormal cardiac positioning, hypoplastic right ventricle, atrioventricular septal defects, and right pulmonary isomerism. Humans with *Pitx2* haploinsufficiency in Rieger syndrome, however, have not demonstrated left-right axis malformations in asymmetric organs such as the heart. The differences between human and mouse malformations with Pitx2 malformations can be explained by a gene dosage effect, because mice heterozygous for null *Pitx2* alleles have abnormalities similar to those seen in human Rieger syndrome without axis malformations.[159,160]

Vasculogenesis and Angiogenesis

Vasculogenesis, the formation of blood vessels from progenitor cells, and *angiogenesis,* the sprouting of new vessels from existing vessels, are processes that are active from the earliest stages of embryogenesis and organogenesis. Abnormal regulation of angiogenesis plays a role in many disease processes including but not limited to retinopathy of prematurity, bronchopulmonary dysplasia, and the progression and metastatic spread of cancer. Thus an understanding of how these processes are controlled in development and altered in newborn diseases is essential. The role of homeobox genes in pulmonary vasculogenesis and disease has been reviewed in detail.[161]

HoxA Cluster

Available evidence suggests that HoxA genes are involved in vasculogenesis. In addition to the abnormalities in large vessels discussed earlier, *Hoxa3*-knockout mice have enlarged pulmonary veins with an abnormal outer layer of cardiac cells, suggesting that Hoxa3 limits cardiac cell migration during pulmonary vein development.[139,161,162] Hoxa5 is abnormally increased in alveolar epithelial cells of humans with pulmonary hypertension, but whether this increase is causal or represents a downstream response is unknown.[3] Other *HoxA* genes are expressed in human fetal and adult vascular smooth muscle, including *Hoxa2, Hoxa4,* and *Hoxa11;* however, their role in vasculogenesis has not yet been investigated.

HoxB Cluster

Studies to date show that *HoxB* genes are the predominant Hox cluster expressed in endothelial cells. Belotti and co-workers evaluated the expression patterns of genes from the *HoxB* cluster in human umbilical vein endothelial cells (HUVECs).[163] These investigators showed that mRNA from all *HoxB* genes except *Hoxb1* are expressed in HUVECs, with low levels of *Hoxb7* and *Hoxb9;* high levels of *Hoxb2, Hoxb3,* and *Hoxb4;* and intermediate levels of *Hoxb5, Hoxb6,* and *Hoxb8.* Tissue plasminogen activator (TPA), which induces endothelial cells to change phenotype to angioblasts that create new vessel formation, increased the expression of all of these *HoxB* genes. This finding suggests that the pattern of *HoxB* expression in endothelial cells may specify this cell lineage and that *HoxB* genes may play a role in sprouting of new blood vessels in the process of angiogenesis.[163] Additionally, studies in tumor cell lines showed that Hoxb7 can increase levels of vascular endothelial growth factor (VEGF) isoforms, basic FGF, and matrix metalloproteinase-9 (MMP-9) proteins. An increase in Hoxb7 expression in tumor blood vessels suggests that this *Hox* gene could be involved in promoting vasculogenesis in the developing fetus.[164,165] Hoxb3, which is expressed in fetal lung, promotes capillary morphogenesis in cultured fetal lung cell lines by controlling ephrin A1 and by activation of the ephrin receptor EphA2.[166,167] Consistent with angiogenic and hematopoetic progenitor cells arising from the same stem cell population, erythroid progenitor cells also express *Hox* cluster genes, primarily *Hoxb2* through *Hoxb9*. Increased Hoxb4 and decreased Hoxb6 act to push embryonic stem cells or erythroid/myeloid stem cells toward an erythroid phenotype, suggesting that the combination of Hox proteins within cells helps determine their ultimate phenotype (reviewed by van Oostveen and colleagues[168]).

Divergent Hox Genes

Gax, a divergent homeobox gene, is expressed in mesoderm and muscular cell precursors in developing and adult mice. Its expression is restricted to the cardiovascular system and kidney. Gax inhibits vascular smooth muscle cell migration through changes in integrin expression, suggesting involvement in regulating the angiogenic balance. Gax also is expressed in endothelial cells, where it inhibits cell proliferation and in vitro VEGF-induced endothelial tube formation.[169,170]

In addition to the probable role of Prx1 in heart and great vessel development, Prx1 also probably is involved in pulmonary vasculogenesis. Prx1 is expressed in mesenchymal cells clusters during early lung development. It induces the expression of genes involved in the formation of adherens junctions, likely helping to stabilize cell-cell contacts in these clusters of mesenchymal cells.

Prx1 induces an endothelial cell phenotype in fetal lung mesenchymal cell lines, indicating that Prx1 is involved in mesenchymal to endothelial cell transformation.[22] Of note, not all cells expressing Prx1 differentiate into blood vessels. Thus the ultimate formation of blood vessels from aggregates of Prx1-expressing cells is likely to involve other factors including homeobox proteins that act in concert with Prx1. More recently Prx1 was found to directly regulate tenascin-C, an extracellular matrix (ECM) molecule that is an important component of the ECM around developing vessels.[171] *Prx1*-null mice have decreased amounts of tenascin-C and other markers of endothelial cells, Flk-1 and vascular endothelial cell adhesion molecule-1 (VCAM-1), further suggesting a role for *Prx1* in endothelial cell differentiation.[22] These mice also have hypoplastic lungs, supporting the hypothesis that lung vascular development plays a significant role in patterning alveolar development.[172]

Hex, whose importance for liver development is discussed earlier in this chapter, also may be involved in initiating processes of vasculogenesis and hematopoiesis. In the embryo, Hex is expressed in many multipotent progenitor cells. Expression appears first in primitive endoderm of the blastocyst and later in foregut endoderm and mesoderm. In mesoderm, Hex is transiently expressed in nascent blood islands of the yolk sac.[40,161,173] Hex expression in the distal mesenchyme of the developing lung colocalizes with Flk-, the receptor for VEGF, suggesting that Hex is an early marker of endothelial cells in the developing lung, where it may commit these cells to the vasculogenesis process initiated in the regions around developing airways. Unlike loss of Flk-1 expression, however, disruption of Hex expression does not appear to affect vasculogenesis and hematopoiesis.[161]

Hox GENES AND HEMATOPOIESIS

Blood cells of all lineages are derived from pluripotent stem cells in the process of hematopoiesis. In the developing embryo, hematopoietic stem cells arise from two main sites: (1) ventral mesoderm cells, which migrate to the yolk sac and differentiate primarily into erythroid cells and sometimes monocytes and megakaryocytes to contribute to embryonic hematopoiesis, and (2) cells in the dorsal mesentery or aorta gonad mesonephros region, which initiate definite hematopoiesis beginning in fetal liver and spleen and eventually populating the bone marrow.[168]

Studies addressing *Hox* genes in hematopoiesis have been done both in vivo and in vitro, but much work remains to be done on this topic, especially regarding the initiation of these processes in the developing human embryo and fetus.[168,174] Several *Hox* genes from the *HoxA, HoxB,* and *HoxC* but not *HoxD* clusters are expressed in hematopoietic stem cells during development, in the adult, and in certain disease states. In fact, some of the best studied diseases associated with aberrant *Hox* gene expression are the cancers of the blood cell lineages.

The number and expression level of *Hox* genes from each cluster are greatest for *HoxA.* Moreover, a change in colinear expression of *Hox* genes occurs with cell maturation. *Hox* genes located more 3′ within the clusters are down-regulated as cells mature, and higher levels of more 5′ genes are seen. It appears that certain *Hox* genes help determine specific lineage commitment, with some *Hox* genes expressed in all cell lineages but others showing a lineage-restricted expression pattern. For example, *Hoxc8, Hoxa7,* and *Hoxb7* are expressed in all hematopoietic lineages, but *Hoxc4* determines the lymphoid cell line, *Hoxa9* and *Hoxa10* determine the myelomonocytic lineage, and *Hoxb4* along with *Hoxb2* and *Hoxb12* determines the erythroid cell lineage. The combination of genes expressed depends on the cell type and on the stage of development or differentiation. Furthermore, down-regulation or up-regulation of particular *Hox* genes will produce transformation of a cell's phenotype to that of a different lineage.

Unlike congenital anomalies that are associated with Hox gene mutations, blood diseases associated with *Hox* gene abnormalities are due to translocations that lead to abnormal expression levels of a particular Hox protein. Experimental studies with decreased or over-expressed *Hox* genes are beginning to reveal significant roles for specific *Hox* genes in normal hematopoiesis. For example, *Hoxa9*-knockout mice have altered differentiation of myeloid and megakaryocytic cells and abnormal early T cell development with decreased circulating numbers of granulocytes and lymphocytes.[175] The T cells in these mice have decreased cell surface receptors including E-cadherin. Conversely, activation of *Hoxa7* or *Hoxa9* in mice leads to myeloid leukemia.[176] Similar results are seen in mice with bone marrow cell overexpression of *Hoxa9, Hoxa10, Hoxb3,* or *Hoxb8.* These findings in mice correlate with a poor prognosis in patients with acute myeloid leukemia whose cells express Hoxa9.[136,177] Some of the oncogenic potential of overexpressed Hoxa9 may relate to cooperative interactions with PBX and Meis family transcription factors (reviewed by Goodman[136]).

Hoxa10 expression is similar but not identical to Hoxa9 in hematopoietic cells and is further restricted to myeloid cells. Overexpression of Hoxa10 in mouse bone marrow leads to increased numbers of stem cells and myeloid progenitors. These mice are easily susceptible to the development of a myeloproliferative disorder resembling acute myeloblastic leukemia.[168,178]

B and T cell development may be partially determined by transcriptional regulation by Hoxa3, Hoxb3, and Hoxd3. Mice in which Hoxa3, Hoxb3, and Hoxd3 expression all are ablated have abnormal thymus, parathyroid, and thyroid glands. The *Hoxa3*-knockout mouse has decreased *Pax1* gene expression, and *Pax1*-knockout mice also are athymic, suggesting that Hoxa3 regulates Pax1 expression and subsequent thymus development. This correlation may contribute to the phenotype in the combined *Hoxa3-, Hoxb3-,* and *Hoxd3*-knockout mice.[168,179] *HoxC* genes also are expressed in the lymphoid cell line, where they appear to be particularly important for regulation of these cells.[180]

The fact that erythroid cells express almost exclusively *HoxB* cluster genes, whereas other hematopoietic cells express *Hox* genes from the *HoxA* and *HoxC* clusters, suggests that *HoxB* genes are important for regulation of erythroid cell fate and cellular differentiation. *Hoxb4* appears to be important for maintaining a source of hematopoietic progenitor cells. In fact, unlike the overexpression of other *Hox* genes, which is associated with abnormal lymphoproliferative disorders, overexpression of *Hoxb4* in adult bone marrow enhances repopulation of bone marrow with hematopoietic cells without inducing leukemia. Additionally, the level of *Hoxb4* expression appears to have an impact on myeloid growth and differentiation while suppressing erythroid differentiation.[181-183]

HoxC genes are important for appropriate commitment of the lymphoid cell line. Studies on hematopoietic and leukemic cell lines show distinct changes in the expression levels of Hoxc4, Hoxc5, and Hoxc6 proteins, depending on level of cellular differentiation of lymphoid cells or on the neoplastic or lymphoblastic potential.[180] With progressive maturation of lymphoid cells, Hoxc4 and Hoxc6 levels are increased, but Hoxc5 levels are greater in lymphoma cell lines and in certain types of non-Hodgkin lymphoma.

Studies in hematopoietic cells and certain related cancers have contributed to understanding the downstream pathways that are regulated by *Hox* genes in general. Hox proteins regulate expression of several categories of genes, including those that code for other transcription factors (including other *Hox* genes), cell adhesion molecules, and growth factors (reviewed by van Oostveen and colleagues[168]). Among the cell adhesion molecules regulated by *Hox* genes are integrins, cadherin, and neural adhesion molecule (N-CAM) and extracellular matrix molecules such as tenascin-C and connectin. Changes in expression of some of these groups of molecules can have profound effects on cellular migration, cell

death, and cellular proliferation, as well as on cell differentiation. Changes in cell adhesion to surrounding stroma are imperative for appropriate migration of differentiating cells within the bone marrow, and shedding of certain cell adhesion molecules is necessary for release of cells from bone marrow into bloodstream. Certain *Hox* genes become down-regulated as blood cells mature and are released from bone marrow, whereas others become up-regulated, possibly reflecting changes in cell adhesion molecules leading to migration and homing of blood cells to new locations within the body. Additionally, auto- and cross-regulation clearly occurs in and between the *Hox* clusters, affecting downstream regulation by Hox proteins. Other transcriptional regulators regulated by Hox proteins include members of the homeobox families of *Pax* and *NKx* genes, and the forkhead family of winged helix transcription factors. Growth factors including members of the TGF-β and epidermal growth factor (EGF) families also have been shown to be regulated by Hox proteins.[20,134,136,184]

HUMAN DISEASES ASSOCIATED WITH HOMEOBOX GENE ANOMALIES

In the preceding sections, several human conditions associated with homeobox gene anomalies have already been mentioned. Table 8-1[185-194] summarizes human conditions in which homeobox gene anomalies are known. These represent three categories of findings. In the first category are conditions in which a genome mutation in a homeobox gene has been documented in humans and appears to be responsible for the disease. Many of these are specific syndromes presenting at or shortly after birth; others are diseases that arise in childhood or adulthood. The second category consists of diseases in which a homeobox gene appears to be normal but is misexpressed—either overexpressed or underexpressed. In these disorders it is not clear whether the abnormal expression is the main cause of the disease or whether another insult is the proximate cause leading to abnormal expression of homeobox gene(s). In the latter case, abnormal homeobox expression would help establish the phenotype of the disease. Finally, interest in homeobox gene mutations in cancer has been engendered by their role in determining cell fate. The third category comprises specific cancers in which a mutation of a homeobox gene has been identified. In these diseases, as well as some others in the table, other causes of the disease separate from homeobox gene abnormalities are likely.

SUMMARY

Several classes of genes are responsible for the development and differentiation of the embryo into the complex adult organ system. A major class of such genes is the group of homeobox genes, which control axial patterning and rostral-caudal definition, as

TABLE 8-1

Homeobox Genes and Human Diseases

Disease	Gene(s)	Relevant Study(ies)
Diseases Caused by or Associated With Homeobox Gene Mutations		
Birth Defects		
Hand-foot-genital syndrome (autosomal dominant)	*HOXA13*	Mortlock and Innis, 1997[125]
Synpolydactyly (autosomal dominant)	*HOXD13*	Muragaki et al, 1996[123]
Radioulnar synostosis	*HOXA11*	Thompson and Nguyen, 2000[126]
Schizencephaly	*EMX2*	Brunelli et al, 1996[185]
Aniridia, Peter's anomaly, anophthalmia; isolated foveal dysplasia	*PAX6*	*Respectively*: Glaser et al, 1994[186]; Azuma et al, 1996[187]
Waardenburg syndrome (type I, type III)	*PAX3*	Morell et al, 1997[98]; reviewed by Stuart et al, 1993[188]
Hypodontia	*MSX1*	Reviewed by Thesleff and Nieminen, 1996[189]
Craniosynostosis (Boston type)	*MSX2*	Reviewed by Richman, 1995[190]
Rieger syndrome	*RIEG*	Semina et al, 1996[158]
Combined pituitary hormone deficiency	*PIT1*	Reviewed by Rhodes et al, 1994[191]
Deafness with fixation of the stapes	*POU3F4*	Kok et al, 1995[192]
Congenital absence of pancreas	*PDX1*	Stoffers et al, 1997[93]
Hirschsprung disease; congenital central hypoventilation, neuroblastoma	*PHOX2B*	Gaultier et al, 2005[193]
Cardiac septal defects; hypoplastic left heart syndrome; tetralogy; Ebstein's anomaly; conduction defects	*NKX2.5*	*Respectively*: Kasahara and Benson, 2004[152]; Mittmann, 2004[153]; Konig et al, 2006[154]; Elliott et al, 2003[155]
DiGeorge/velocardiofacial syndrome	*HOXA3*	Reviewed by Goodman, 2003[136]
Currarino syndrome	*HLXB9*	Riebel et al, 2004[16]
Other Diseases		
Maturity-onset diabetes of the young type 4	*PDX1*	Stoffers et al, 1997[93]
Acute myelogenous leukemia	*HOXA9*	Reviewed by Lawrence et al, 1996[174]
Pre-B cell acute lymphocytic leukemia	*PBX1*	Reviewed by Nakamura et al, 1996[176]
T cell acute lymphocytic leukemia	*HOX11*	Reviewed by Nakamura et al, 1996[176]
Rhabdomyosarcoma	*PAX3, PAX7*	Reviewed by Sorensen and Triche, 1996[194]
Diseases Associated With Homeobox Gene Misexpression		
Congenital cystic adenomatoid malformation of the lung	*HOXB5*	Volpe et al, 2003[44]
Bronchopulmonary sequestration	*HOXB5*	Volpe et al, 2003[44]; Volpe et al, 2000[45]
Type 2 diabetes	*PDX1*	Del Guerra et al, 2005[86]
Hirschprung disease–associated enterocolitis	*CDX1, CDX2*	Lui et al, 2001[114]
Gastric intestinal metaplasia	*CDX2*	Silberg et al, 2002[108]
Bile duct carcinoma	*HOXB7*	Feldmann et al, 2006[75]

well as influencing the patterning of specific organs and the differentiation and function of specialized cells. Although it is yet too early to predict treatments of diseases based on homeobox gene functions, it is reasonable to hope that understanding the varied and complex function of these genes will provide unique insights that will translate into novel approaches to a variety of human disease conditions.

Apoptotic Cell Death

Cell death can proceed by different routes, either apoptotic or necrotic, which have been classified on the basis of biochemical and morphologic criteria. *Apoptosis* has come to be used synonymously with the phrase *programmed cell death* (PCD), because it is a cell-intrinsic mechanism for suicide that is regulated by a variety of cellular signaling pathways. Apoptosis is an energy-requiring process associated with nuclear condensation and fragmentation, cleavage of chromosomal DNA into internucleosomal fragments, and packaging of the deceased cell into apoptotic bodies without breakdown of the plasma membrane. Apoptotic bodies are recognized and removed by phagocytic cells, so inflammation is notably absent around the dying cell. Apoptotic cell death plays a crucial role in the development of the mammalian nervous system and also is a prominent feature of injury or disease of the brain.

In contrast with apoptosis, *necrosis* is a passive form of cell death and often is the result of a severe or overwhelming insult that damages cellular organelles such as mitochondria. It is characterized by cellular swelling, disruption of membrane integrity, and leaking of cytoplasmic contents into the extracellular space, thereby activating an inflammatory response. As such, massive necrosis is a severe threat to tissue. More recently, the idea that cells can commit suicide by mechanisms other than apoptosis has been gaining momentum. Alternative, nonapoptotic forms of PCD have been described and classified as autophagic cell death. *Autophagy,* meaning "eating of oneself," has been shown in many different organisms. In this process, cells switch to a catabolic metabolic program in which cellular constituents are degraded for energy production as a survival mechanism during periods of nutrient stress.[1] In addition, autophagy plays a degradative role by providing a mechanism for the turnover of both damaged organelles and long-lived proteins. Autophagy may contribute to the pathogenesis of some neurodegenerative disorders, including Huntington disease and Alzheimer disease, by altering the processing of mutant forms of the huntington protein and amyloid precursor protein.[2] In the context of neurodegeneration, autophagy has been shown to contribute to cell death following cerebral hypoxia-ischemia in neonatal and adult mice.[3]

APOPTOSIS

Apoptosis is an active process leading to the ordered dismantling of cellular components such as proteins and DNA. Specialized cysteinyl aspartate–specific proteases termed caspases have been shown to be key components of the apoptotic pathway.[4] Synthesized in the cytoplasm as inactive proenzymes, caspases are activated during apoptosis cleaving key cellular proteins, including DNA repair enzymes, regulators of the cell cycle and structural components, resulting in disassembly of the cell. Studies in the nematode *Caenorhabditis elegans* identified a number of genes involved in apoptosis, including Ced-3, which now has been shown to be a member of the caspase family. Some caspases (e.g., caspase-8 and caspase-9) act either as upstream initiators in the apoptotic pathway by processing and activating other caspases (such as caspase-3), which then in turn act as downstream executioners, cleaving cellular proteins.

At least two pathways to apoptosis exist[5] (Figure 9-1). Initiator caspases most commonly are activated by an extrinsic death receptor pathway or by the intrinsic mitochondrial pathway. In the *extrinsic pathway,* ligand binding to death receptors such as Fas or tumor necrosis factor (TNF) receptor in the cell membrane leads to receptor oligomerization. The activated trimeric death receptors undergo specific conformational changes on the cytoplasmic face of the plasma membrane, allowing the subsequent recruitment of adaptor molecules and, ultimately, an initiator caspase. These sequential protein-protein interactions lead to the formation of a death-inducing signaling complex (DISC) and caspase activation.[6] By contrast, in the *intrinsic pathway* of apoptosis initiated by stress or damage to mitochondria, cytochrome *c* is released from the mitochondrial intermembrane space into the cytosol after membrane depolarization and forms a complex (termed the apoptosome) with apoptotic protease-activating factor-1 (Apaf-1) (the equivalent of Ced-4 in *C. elegans*), adenosine triphosphate (ATP), and procaspase-9, which activates caspase-9 activation. Apoptosis thus proceeds by an ordered cascade of protolysis whereby initiator caspases (i.e., active caspase-8 and possibly caspase-10 from the DISC or caspase-9 from the mitochondrial pathway) cleave and activate the executioner caspases (such as caspase-3, -6, and -7). These act as downstream executioners by processing cellular proteins in order to facilitate disassembly of the cell. In some instances, executioner caspases can inactivate proteins that would disrupt apoptosis. For example, the DNA repair enzyme, poly(ADP ribose) polymerase (PARP), which catalyzes attachment of ADP ribose units from nicotinamide adenine dinucleotide (NAD) to nuclear proteins, is inactivated by caspase-3–mediated cleavage, resulting in an increase in the ATP available for energy-demanding apoptosis. In other instances, active downstream caspases can trigger enzyme activation. Thus caspase-3 cleaves the inhibitor of the caspase-activated DNase (ICAD), thereby destroying its ability to bind and repress the apoptotic endonuclease CAD. The end result of ICAD cleavage is CAD activation, with consequent initiation of DNA

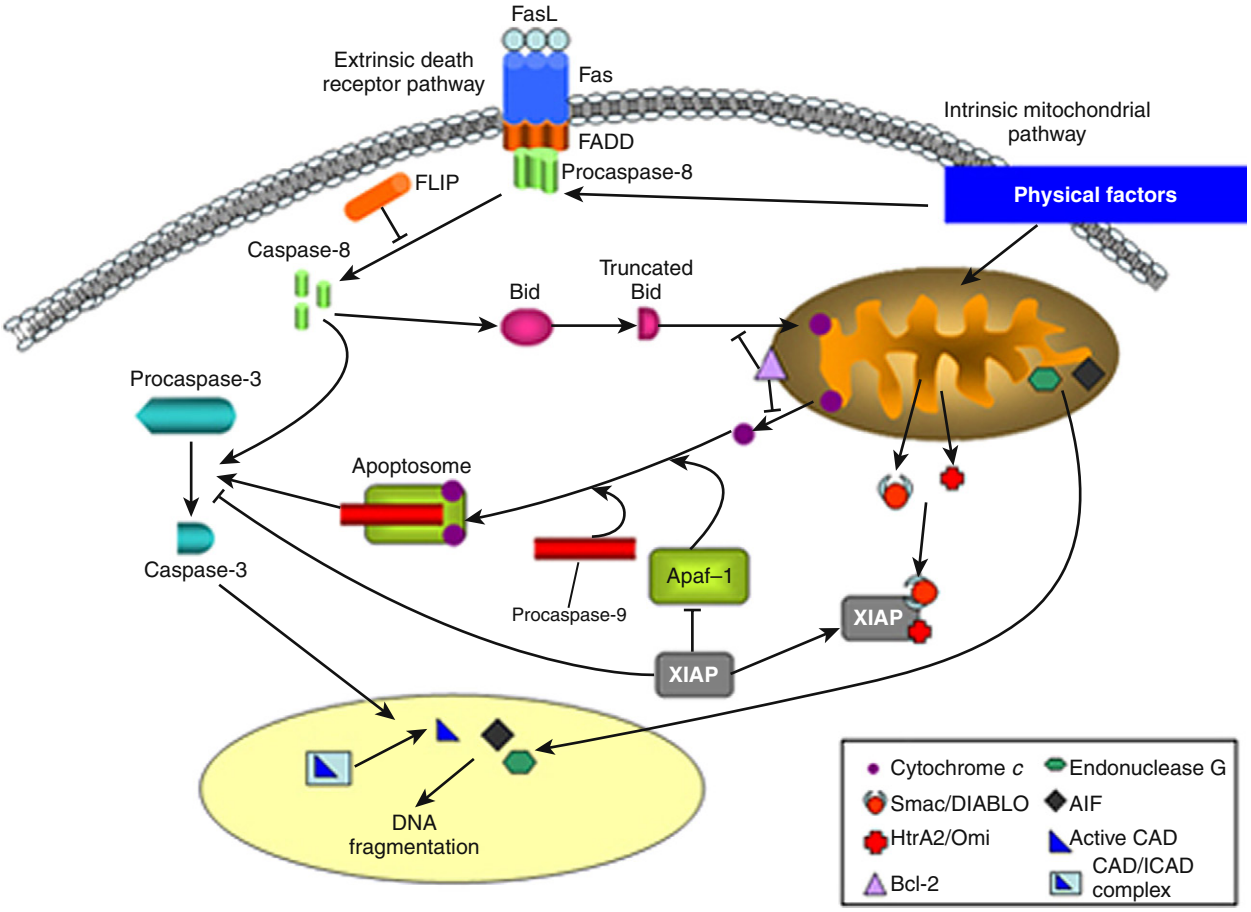

Figure 9-1 Schematic diagram of mitochondrial proteins involved in apoptosis. Stress signals such as DNA damage and accumulation of calcium ions (Ca^{2+}) and production of reactive oxygen species (ROS) in the mitochondria trigger the release of apoptogenic proteins including cytochrome *c (purple circle),* apoptosis-inducing factor (AIF) *(black triangle),* endonuclease G *(green hexagon),* and HtrA2/Omi *(red cross).* Release of at least some of these factors is inhibited by antiapoptotic Bcl-2 proteins. Once in the cytosol, cytochrome *c* can form a complex with Apaf-1 and caspase-9. The serine protease Omi/HtrA2 can sequester the X-linked inhibitor of apoptosis protein (XIAP), leading to enhanced caspase-9 activity. Both cytochrome *c* and Omi/HtrA2 in the cytosol enhance the activation of caspase-9, which in turn proteolytically activates caspase-3. Active caspase-3 then triggers apoptotic execution by activating downstream caspases and endonucleases. AIF translocation from mitochondria to nuclei in response to death stimuli triggers cellular changes, such as phosphatidyl serine exposure and chromatin condensation, that are independent of Apaf-1 and caspase-9. Endonuclease G is a mitochondrion-specific nuclease that translocates to the nucleus during apoptosis, where it cleaves chromatin-associated DNA into nucleosomal fragments independently of caspases. *CAD,* Caspase-activated DNase; *FLIP,* FLICE-inhibitory protein; *FADD,* Fas-associated protein with death domain; *FasL,* Fas ligand; *ICAD,* inhibitor of the caspase-activated DNase.

fragmentation, a key feature of apoptosis.[7] In the final stages, cell fragments are "shrink-wrapped" in the contracting plasma membrane and bud off as apoptotic bodies, which subsequently undergo phagocytosis.

Several regulators of apoptosis have now been identified as normal resident proteins in healthy cells. Bcl-2 originally was identified in follicular lymphoma as an antiapoptotic protein, supporting the concept that it is the combination of impaired apoptosis and increased proliferation in the same cell that ultimately leads to tumor formation. All members of the Bcl-2 family share at least one conserved region, termed the Bcl-2 homology (BH) domain. Other members of the Bcl-2 family that possess only the BH3 domain have now been shown to be proapoptotic (e.g., Egl-1, Bax). Some BH3-only proteins (e.g., Bid) are thought to act by binding to and preventing the action of antiapoptotic Bcl-2 family members, whereas others (possibly Bax) may integrate into the outer mitochondrial membrane and increase its permeability to proapoptotic messengers such as cytochrome *c*.[8]

Antiapoptotic family members also associate with the mitochondrial membrane as well as the endoplasmic reticulum and nuclear membranes. It is speculated that they act by maintaining membrane integrity and possibly preventing cytochrome *c* release from mitochondria. Inhibitors of apoptosis (IAP) family members act as endogenous caspase inhibitors.[9] They contain between one and three BIR (baculovirus IAP repeat) motifs that interact with capases, blocking their catalytic sites. Some IAPs also possess C-terminal RING domains that enable polyubiquitination of proteins and thus their destruction in the proteasome.[10] A number of other proteins have now been identified that are released from mitochondria after membrane depolarization and that activate apoptosis.[11] Among these, Smac/DIABLO and HtrA2/Omi each bind to and inhibit IAPs, thereby removing the block on caspase activation. Htr2A/Omi also is thought to activate caspase-independent cell death through its serine protease activity. It was recently reported, however, that the phenotype of mice lacking expression of HtrA2/Omi showed no evidence of reduced rates of cell death but in fact showed

a loss of a population of neurons in the striatum, resulting in a neurodegenerative disorder with a parkinsonian phenotype that led to death of the affected mouse approximately 30 days after birth.[12]

Early reports suggested that caspase-12, which localizes to the endoplasmic reticulum (ER) and is activated after ER stress including release of intracellular calcium stores, was the initiator caspase in ER st ress–induced apoptosis.[13] Recent reports have disproved this claim, however, and a sufficient body of evidence has accumulated to suggest an important role for caspase-12 in inflammation. Of interest, only 20% of people worldwide express the full length of caspase-12 protein; such persons have an increased risk for the development of sepsis.[14]

APOPTOSIS IN NEURAL DEVELOPMENT

The occurrence of PCD early in the development of the nervous system has been observed in a spectrum of organisms ranging from *C. elegans* to mice. A common feature of such PCD is that it takes place early during embryogenesis within the proliferative or newly postmitotic undifferentiated populations of cells in the nervous system and often is among the earliest cell death to be observed during development. It is now established that early neural PCD is essential for the normal development of the nervous system, and that the requirement for such early death is separate from that of the neurotrophic death occurring later. Although the triggers of early PCD are largely unknown, it is evident that much of developmental PCD occurs by apoptosis. Studies in mice have shown that the earliest PCD affecting the presumptive neural tissue is within the anterior distal epiblast, which is destined to become the neural plate during gastrulation at E6.5.[15] Apoptotic cells also are found in other regions including the hindbrain neural folds between embryonic days 8 and 9 (E8 and E9). Later, between E12 and E16, PCD occurs within the ventricular and intermediate zones of the cerebral cortex, which are composed of proliferating neural precursors and newly postmitotic neuroblasts.[16,17] Mutant mice defective in regulators of apoptosis (such as caspases) exhibit morphologic deformities in the central nervous system (CNS). Several mutants affected in the execution or regulation of apoptosis and abnormal closure of the neural tube show expansion of neural tissues before terminal neuronal differentiation, resulting in defects such as exencephaly and spina bifida.

A general principle of development in multicellular organisms is that excess numbers of cells are made, and then those surplus to requirement are selected to undergo PCD by apoptosis during the maturation of functional organs.[18] In the developing nervous system, neuronal and glial cell populations are shaped by apoptosis, which serves to adjust cell numbers, refine connections, and ultimately sculpt the sophisticated cytoarchitecture of the nervous system that supports its complex functionality. It is estimated that up to 50% of neuronal and glial cell types are lost during development as a result of limiting trophic support from target tissues that they innervate.[19] This is described by the *neurotrophic theory,* which suggests that it is the loss of trophic factor stimulation that initiates cell death. In other words, neurons that make connections with their target receive trophic support, which is required for active maintenance of the cells in a viable state, whereas neurons that do not make these connections die by apoptosis. Although this concept arose from studies of the nervous system, it is now recognized to be relevant to all tissues, including the innate immune system.

Finally, regardless of how a cell dies, the maintenance of normal tissue requires that cell to be removed; this removal is achieved by phagocytosis. In addition, neighboring cells become semiprofessional phagocytes to perform this function; however, the efficient recognition and ingestion of apoptotic cells, cell fragments, and necrotic cells in the brain are carried out by the microglial cells, the resident macrophages.

MODES OF CELL DEATH IN CEREBRAL INJURY

Accumulating evidence suggests that apoptosis can contribute to the pathogenesis of a number of human diseases, including cancer, viral infections, autoimmune diseases, neurodegenerative disorders, and AIDS. Although trophic factor withdrawal has a prominent role during nervous system development, it is not thought to be the primary pathogenic mechanism for cerebral injury or in neurodegenerative diseases, in which toxic insults are more likely to trigger the apoptotic pathway.

As mentioned previously, necrosis is triggered by stress or injury that damages cellular organelles, resulting in the loss of plasma membrane integrity, release of cytoplasmic contents, and inflammation. By contrast, cells dying by apoptosis do not lose membrane integrity, and the organelles remain largely intact. The apoptotic bodies formed are removed from the tissue by phagocytes. Because the apoptotic response to damage largely circumvents an inflammatory response, this mode of cell death would be particularly beneficial after injury to the brain, which has only a limited capacity for repair and regeneration. The initiation of inflammation is an important distinction between necrosis and apoptosis. In fact, evidence suggests that ingestion of apoptotic bodies can suppress an inflammatory response.[20]

Another key distinction between apoptosis and necrosis is the availability of intracellular energy. Apoptosis as a biochemically and genetically PCD requires time, energy, and, in some cases, new gene transcription and translation. As discussed later, however, the distinction between apoptosis and necrosis in vivo is not always clear-cut, and in many instances, these two modes of cell death can be regarded as a continuum of a single cell fate after injury.

APOPTOSIS AND NECROSIS SECONDARY TO HYPOXIA-ISCHEMIA

Although the precise mechanisms of brain damage in newborn infants secondary to birth asphyxia are multifactorial, an increasing body of evidence has accumulated showing that after cerebral hypoxia-ischemia, neuronal cell damage occurs not only through necrotic but also through apoptotic pathways. Necrosis can occur during hypoxia-ischemia or immediately after resuscitation, when blood flow is very low and when an acute deficit in substrate delivery results in a rapid reduction in cerebral energy production, membrane pump failure, and severe ionic imbalances with cell swelling and necrotic cell death.[21] These acute early changes may be particularly associated with an increase in excitotoxic amino acid levels and free radical production, the damaging effects of which can be blocked by specific receptor antagonists and scavengers.[22]

Apoptotic cells also are seen after hypoxic-ischemic injury in both the immature[23,24] and adult brain.[25,26] Administration of the antiapoptotic growth factor insulin-like growth factor-1 (IGF-1) after the primary insult ameliorates delayed injury; glutamate receptor blockade is only partially protective.[27,28] Apoptosis has been shown to be involved in human perinatal brain injury. In infants who die after intrauterine injury, either with or without evidence of hypoxia-ischemia, a significant number of cells in the brain show the morphologic characteristics of apoptosis.[29,30]

RELATIONSHIP BETWEEN APOPTOTIC AND NECROTIC DEATH IN CEREBRAL INJURY

It might be convenient to consider immediate cell death after hypoxic-ischemic injury as necrotic and delayed cell death as apoptotic. Published data do not entirely support such a simplifying concept, however. In experimental hypoxia-ischemia, apoptosis and necrosis can occur in adjacent populations of neurons and glial cells in the cingulate sulcus, whereas quantitative analysis of cell death show that the numbers of both apoptotic and

necrotic cells are linearly related to the severity of ATP depletion during hypoxia-ischemia.[31] Human infants who have suffered secondary energy failure have a preponderance of necrotic cells, whereas those dying in utero show a higher proportion of apoptotic cells.[29]

These complexities may arise in part from the fact that some necrotic cells represent the secondary degradation of apoptotic cells. In this context, primary cell necrosis can be regarded as an acute response to severe injury and is the common pattern of change in cerebral infarcts. Secondary cell necrosis can occur in cells triggered to begin apoptosis but unable to complete the program.[32] Cell necrosis thus should be distinguished from tissue necrosis, in which a large number of cells undergo necrosis together, which may be primary, secondary, or both.

Oxygen-glucose deprivation may induce apoptosis initially and then secondary necrosis in cerebellar granule cells.[33] Similarly, primary apoptosis precedes secondary necrosis after the injection of excitatory amino acid receptor agonists into the adult rat brain,[34] and in rat dorsal root ganglion cell cultures treated with oxidized low-density lipoprotein.[35] Studies with cultured neurons subjected to oxygen deprivation have confirmed that necrosis and apoptosis can occur in a single cell population.[36] In one such study, the administration of Trolox (6-hydroxy-2,5,7, 8-tetramethylchroman-2-carboxylic acid), which interferes with lipid peroxidation, prevented necrosis but allowed neurons to undergo apoptosis.[37] In a separate study, the induction of apoptosis in target cells by cytotoxic T lymphocytes was blocked by inhibitors of transcription or translation; instead, the target cells underwent necrosis.[38] Thus it may be possible to switch the fate of damaged cells between necrosis to apoptosis.

MOLECULAR EVIDENCE OF APOPTOSIS AFTER BRAIN INJURY

Although it is suggested that apoptosis occurring as a result of hypoxia-ischemia is morphologically different from developmental apoptosis, in that many hybrid necrotic-apoptotic phenotypes are seen, most biochemical studies agree that apoptotic processes are involved in hypoxia-ischemia. Indeed, key elements of apoptosis, such as caspase-3, Apaf-1, Bcl-2, and Bax, are up-regulated in the immature brain.[39] A number of molecular signals associated with apoptotic death are induced by impaired oxidative phosphorylation and oxidative injury.[40]

Caspases and Poly(ADP Ribose) Polymerase Cleavage

The nuclear enzyme PARP provides one of the most apparent links among oxidative stress, impaired energy metabolism, and cell damage. Free radicals such as NO and peroxynitrite can damage DNA, leading to activation of PARP, which catalyzes attachment of ADP ribose units from NAD to nuclear proteins. Excessive activation of PARP, however, can deplete NAD^+ and ATP (which is consumed in NAD regeneration), leading to an increase in the ratio of reduced (hydrogenated) NAD (NADH0 to NAD^+ and eventually cell death by energy depletion.[41] PARP is induced by hypoxia-ischemia, and genetic disruption of PARP provides profound protection against both glutamate-mediated excitotoxic insults in vitro and major decreases in infarct volume after reversible middle cerebral artery occlusion.[42] These results provide compelling evidence for primary involvement of PARP activation in neuronal damage. Genetic deletion of PARP or PARP inhibition by 3-aminobenzamide reduced infarct size after transient cerebral ischemia[43] but did not reduce the density of apoptotic cells.[44] The susceptibility of primary neurons toward apoptosis is unaffected in $PARP^{-/-}$ mice, suggesting that PARP activation is not necessary for apoptosis.[45,46] In cerebral ischemia, then, PARP may contribute to cell death by NAD^+ depletion and primary energy failure without direct involvement in apoptotic responses. However, PARP also is involved in apoptosis in another way: Specific proteolytic cleavage of PARP by caspase-3 is a mechanism to maintain the ATP needed for successful completion of the apoptotic program.[47] Both caspase activity[48] and PARP cleavage[49] have been shown to increase immediately after ischemic injury in vivo, followed several hours later by appearance of morphologic features of apoptosis.

Caspase inhibition can reduce neuronal loss from oxygen-glucose deprivation of cortical neurons[50] and hypoxic-ischemic injury in vivo.[51,52] Some results, however, suggest that although caspase inhibition may prevent the cellular manifestations of apoptosis, it does not prevent cell death.[53] For example, it was demonstrated that other caspase-independent mechanisms can contribute to neuronal cell death such as a translocation of apoptosis-inducing factor (AIF) from mitochondria to the nucleus.[54] The precise roles of PARP cleavage and caspase activity in cell death after hypoxia-ischemia need to be defined further.

Gene Expression and Activation

Apoptotic death often is preceded by the induction and activation of a considerable variety of genes, including immediate early genes,[55,56] zinc finger genes, heat-shock proteins (HSPs), and nuclear factor-kappaB (NF-κB).[57] A number of these genes have been shown to possess either proapoptotic or antiapoptotic functions. For example, NF-κB[58] and HSPs[59] are thought to be protective against oxidative stress, whereas c-Jun, which is phosphorylated by stress-activated protein kinases (SAPKs), is strongly implicated in triggering neuronal apoptosis.[55]

In vivo studies of ischemic injury have shown that several SAPKs are activated by injury. A sufficient body of evidence has shown that Jun N-terminal kinase (JNK) plays a critical role neuronal cell death.[60,61] Studies using in vivo models of JNK-knockout animals or pharmacologic inhibition of JNK signaling have shown significant neuroprotection against hypoxic-ischemic stroke in neonatal and adult brain.[61,62] Moreover, the inhibition of excitotoxic pathways that involve glutamate receptor and JNK signaling also has been shown to be protective against kainite-induced neuronal toxicity.[63] It seems that different JNK isoforms have preferential function in neuronal cell death, because targeted disruption of the *jnk3* gene, but not *jnk1* or *jnk2,* protected mice from excitotoxic injury.[64] By contrast, disruption of *jnk1* or *jnk2* genes is associated with embryonic lethality, whereas *jnk3*-null mice are normal.[65,66] Furthermore, both neonatal[61] and adult[60] mice with deletions for *Jnk3* are protected against experimental hypoxia-ischemia, suggesting a critical role for *jnk3* in neuronal cell death.

Unlike with JNK, the involvement of p38 in neuronal cell death has been controversial. Although early activation of p38 has been shown to protect cells from apoptotic death induced by TNF treatment,[67] studies of CD40 and B cell receptor signaling have shown that p38 activation does not precede apoptosis triggered by the engagement of these receptors.[68] Conversely, the p38 inhibitor SB203580 is able to prevent glutamate-induced apoptosis in cerebellar granule neurons.[69] In addition, in vivo studies have shown that inhibition of p38 provides neuroprotection in cerebral ischemia, and that mitogen kinase-2 (MK-2)-null mice (MK-2 being directly regulated by p38) are partially protected from ischemic brain injury.[70,71]

The third subclass of MAPK, known as extracellular regulated kinases (ERKs), also is activated in response to neurotoxic stress factors. Although it has been documented that inhibition of ERK signaling can significantly protect against ischemic brain injury,[72] recent studies have demonstrated the important role of ERK in traumatic brain injury.[73] Taken together, the data show that all three subclasses of MAPK are selectively activated in a brain injury, depending on the nature of the neurotoxic stimuli.

Death Receptor Activation

The activation of SAPKs as one of the earliest signals downstream of death receptor activation provides evidence that intercellular signaling may be involved in triggering cell death during tissue injury. Receptors for proapoptotic signals including TNF and interleukin-1β (IL-1β) are expressed acutely in the injured brain and may contribute to the progression of neuronal damage following hypoxia-ischemia.[74]

One of the most extensively studied cytokine-responsive receptors is the Fas receptor. It was first described to play a role in death of immune cells but has now been found to function in other tissues, including the brain, and provides an example of the ontologic importance of the apoptotic mechanism in homeostasis and development. Fas is expressed in developing brain tissues, where it may be involved in signaling development. Moreover, a role in cell death following hypoxia-ischemia is suggested, because lack of functional Fas death receptor is neuroprotective in adult models of hypoxia-ischemia.[75,76] Fas expression also is up-regulated after hypoxia-ischemia in the neonatal brain where it functions as a death receptor.[77,78]Asphyxiated infants with pontosubicular neuronal necrosis secondary to severe perinatal asphyxia show marked increase in the expression of Fas receptor protein in degenerating neurons.[79] Fas expression is paralleled by the expression of several factors of the extrinsic apopotic pathway, including FLIP (FLICE-inhibitory protein), FADD (Fas-associated protein with death domain), and caspase-8 and -3, and by the translocation of cytochrome oxidase from the mitochondria.[80] In addition to the stimulation of the extrinsic death receptor pathway, abundant evidence shows that the intrinsic or mitochondrial cascade is activated after Fas death receptor signaling and functions to amplify Fas-mediated death.[81]

Other death receptors are present in the developing brain and have the potential to respond to their ligand with cell death signaling. For example,TNF receptor–null mice are more susceptible to hypoxic-ischemic injury,[82] whereas intracerebroventricular injection of recombinant IL-6 significantly reduces ischemic brain damage, suggesting that the large increases in TNF and IL-6 secondary to cerebral ischemia are endogenous neuroprotective responses.[83] Mice lacking the survival factor NF-κB are more susceptible to TNF-induced damage.[84] The marked disparity in up-regulation of the Fas receptor and that of other TNF-related receptors suggests fundamental differences in the role of these closely related receptors in brain development and in response to injury in the newborn period.

FACTORS DETERMINING THE CHOICE BETWEEN APOPTOSIS AND NECROSIS

A number of different factors influence whether a cell will undergo apoptosis or necrosis, including developmental stage, cell type, severity of injury, and availability of ATP.

Developmental Age, Differentiation, and Cell Type

The stage of cell development may be a particular determinant of apoptosis versus necrosis. For example, cerebellar Purkinje cells differentiate early in brain development. In the porcine model of hypoxic-ischemic injury, these cells are very sensitive indicators of the degree of injury but undergo only necrosis, never apoptosis. By contrast, cerebellar granule cells, that continue to divide and migrate after birth, undergo apoptosis on a large scale after hypoxic-ischemic injury.[85] Similarly, after excitotoxic injury to the newborn rat striatum, neuronal death occurs by apoptosis, whereas in the adult, the same insult produces rapid cytoplasmic disintegration, consistent with necrosis.[86]The mode of cell death also may depend on the degree of differentiation of the cell. Dividing progenitor cells are particularly sensitive to apoptotic stimuli, because the cell cycle machinery is intimately linked to apoptosis.[87] A number of separate studies also have indicated that specific cell types may be particularly sensitised to either necrosis or apoptosis.[88,89]

Severity of Injury

The same cell type can be triggered to undergo apoptosis after mild injury but necrosis if the damage is severe.[90]This dual possibility has been demonstrated in neuronal cells in a number of in vitro studies.[91,92] It is not clear precisely how the severity of injury dictates apoptosis or necrosis. One possibility is that the degree of damage to cell organelles influences the mode of cell death. Mitochondria are particularly sensitive to hypoxic injury and play a central role in both apoptosis and necrosis. For example, inhibitors of complex I trigger apoptosis at low concentrations and necrosis at high concentrations in neuronal cell lines in culture.[91] Indeed, it has been suggested that the severity of mitochondrial damage is the most important deciding factor between these two modes of cell death.[93] In this scenario, a small increase in mitochondrial membrane permeability can result in the controlled release of apoptogenic factors through the outer membrane, while severe mitochondrial damage releases a flood of Ca^{2+} and reactive oxygen species into the cytosol, leading to the disruption of plasma membrane integrity and cell necrosis. The importance of oxidative damage in this process is underlined by the finding that complex I inhibitor–dependent apoptosis is decreased by pretreatment with free radical scavengers,[94] although it remains to be determined whether free radical accumulation results directly from the block in the mitochondrial respiratory chain or indirectly from the apoptotic process itself.

Availability of Adenosine Triphosphate

As already mentioned, apoptosis requires energy, whereas complete ATP depletion causes necrosis.Thus ATP availability is likely to be a significant determinant of apoptotic versus necrotic death. If cells sustain a lethal insult, they will be able to execute the apoptotic program if ATP levels are sufficient, whereas in situations of limited ATP availability, the same degree of cellular injury can result only in necrosis. Consistent with this possibility, glutamate excitotoxicity has been shown to induce either necrosis or apoptosis, depending on mitochondrial function. During and shortly after exposure to glutamate, neurons that died by necrosis had reduced mitochondrial membrane potential ($\Delta\psi m$) and swollen nuclei. By contrast, neurons that recovered $\Delta\psi m$ and ATP levels subsequently underwent apoptosis.[95] Consumption of ATP by cell repair enzymes also may thus influence the mode of cell death. Inhibition of PARP prevents necrosis and triggers apoptosis in cells exposed to hydrogen peroxide.[96] Perhaps the most direct demonstration of the importance of ATP is in cultured mouse proximal tubular cells, where ATP depletion itself caused apoptosis or necrosis depending on the levels: Cells subjected to antimycin to deplete ATP to below 15% of levels in control cells died of necrosis, whereas cells with ATP levels between 25% and 70% of those in control cells all died by apoptosis.[97] Extending these observations, it also is possible to alter the mode of cell death by manipulating cellular ATP levels.[98,99]

Preserving ATP levels can thus reduce the proportion of necrotic cells after hypoxic-ischemic injury and increase the relative amount of apoptosis. Choi and colleagues demonstrated that primary cell necrosis secondary to severe ischemia is reduced by the addition of the *N*-methyl-D-aspartate antagonist MK-801. In their study, residual neurons underwent a form of cell death with the hallmarks of apoptosis.[100] On the other hand, protection from apoptosis can condemn cells to a necrotic death.Thus cells treated with agents that reduce $\Delta\psi m$ alone underwent apoptosis,

whereas those kept in identical conditions in the presence of the caspase inhibitor Z-VADfmk died from necrosis.[101]

Oxidative Stress

The newborn infant, especially the premature neonate, is thought to be particularly vulnerable to tissue damage from oxidative stress because of reduced total antioxidant capacity, and several studies have looked at the possibility of reducing morbidity in this age group by ameliorating the effects of oxidative stress.[102] Oxidative stress is considered to be a major mediator of apoptosis in several cellular systems, including neurons. Stimuli that cause oxidative stress, including culture in high oxygen,[103] exposure to β-amyloid,[104] and transient hypoxia-ischemia,[24,105,106] all trigger apoptosis. Both H_2O_2 and nitric oxide species (NO) can induce apoptosis when applied exogenously and are produced in toxic concentrations by cells that are undergoing apoptosis precipitated by other physiologic stimuli.

Oxidative signals for apoptosis can originate both extracellularly and intracellularly and also can be generated by reduced concentrations of antioxidants. Indeed, a number of cerebroprotective strategies are directed at specifically reducing oxidative stress.[107,108] A neuroprotective role for antioxidants has been documented using in vivo models of hypoxic-ischemic brain injury.[109,110] Cyclosporine, an inhibitor of prooxidant-induced Ca^{2+} release from mitochondria, has demonstrated a role for mitochondrial alterations in apoptotic processes. Cyclosporine can protect against loss of cell viability induced by prooxidants or by NO, can favorably alter mitochondrial function after ischemia,[111] and protects neuronal cells against apoptosis induced by Fe^{2+}, β-amyloid peptide, or NO-generating compounds.[112]

THE ROLE OF MITOCHONDRIA IN APOPTOSIS AND NECROSIS

Mitochondria as primary generators of cell energy are vital for cell homeostasis and viability. Disruptions or alterations in mitochondrial function can lead to cell death. Main events that may play a critical role in mitochondrial dysfunction, as discussed next, include ATP deprivation, elevation of intracellular calcium concentration and ROS production, and mitochondrial permeability transition and cell death, among others.

Adenosine Triphosphate Deprivation

One of the most important events is mitochondrial failure and falling ATP levels that can cause necrosis; direct inhibition of mitochondrial metabolism also can trigger apoptosis.[91,113] ATP is, however, required for apoptotic signaling, such as caspase activation and up-regulation of apoptotic genes. ATP regeneration during reperfusion of the ischemic brain is likely to promote neuronal apoptosis. Bioenergetic defecits also can result from failure in the electron transport chain, a compromised mitochondrial potential and reduced ATP levels. Such defects characterize many neurodegenerative diseases.[114]

Elevation of Intracellular Calcium Concentration and Reactive Oxygen Species Production

Ischemic injury causes a calcium influx into cells (through glutamate receptors), which then mediate excitotoxic cell death. Mitochondria become overloaded with calcium, leading to generation of reactive oxygen species (ROS), ATP synthesis reduction, depolarization of mitochondrial potential, and increased permeability of mitochondrial membrane. High concentrations of calcium also can contribute to uncontrolled activation of calcium-dependent proteases, calpains, and endonucleases, causing degradation of cellular proteins and DNA and cell death. Generation of ROS is an important event in cell signal transduction maintenance. However, a disruption of the respiratory chains results in elevated levels of ROS, causing a lipid and protein peroxidation that disrupts mitochondrial and other cellular membranes. Precise mechanisms are beginning to be elucidated, and much current interest is focused on the mitochondrial membrane permeability transition.

The Mitochondrial Permeability Transition Pore

One of the possible effects of free radical damage on mitochondria was first put forward in a hypothesis by Sulachev[115] and confirmed later by direct experimentation. The hypothesis suggested that the mitochondrial megachannel or permeability transition pore is involved in preventing ROS accumulation. High concentrations of ROS in the mitochondria would trigger opening of the pore, allowing release of free radicals into the cytosol. The resulting decrease in mitochondrial ROS would subsequently allow pore closure. Conversely, persistent free radical accumulation in mitochondria would prevent pore closure, leading eventually to the release of the apoptosis-inducing proteins. In this way, cells producing excess amounts of free radicals would be eliminated by apoptosis. In favor of this hypothesis, it is clear that the mitochondrial permeability transition pore is activated by ROS.[116]

The opening of the megachannel also can be triggered independently of ROS, although the result in all cases is a sudden increase in the permeability of the inner mitochondrial membrane to small molecules.[117] Although transient opening of the permeability transition pore may be involved in calcium homeostasis or free radical release, sustained permeability transition causes uncoupling of the respiratory chain enzymes, failure of ATP generation, and the release of specific apoptosis-initiating proteins such as cytochrome *c* into the cytosol (see further on). Although the exact composition of the permeability transition pore is not known, experiments using specific inhibitors of mitochondrial protein function have identified key components. For example, bongkrekic acid, a ligand of the mitochondrial adenine nucleotide translocator (ANT), abolishes mitochondrial permeability transition and inhibits p53-dependent thymocyte apoptosis induced by DNA damage.[118] Similarly, the protective effects of cyclosporine implicate cyclophilin D as a key component of the permeability transition pore. Other members include cytosolic hexokinase, porin (the voltage-dependent anion channel), creatine kinase, and proapoptotic members of the Bcl-2 family of proteins.[119] Although the regulation of Bax and Bak by antiapoptotic members of the Bcl-2 family is well known, more recent evidence suggests that additional proteins participate in the process, as both inhibitors and activators. Moreover, the rearrangements in mitochondrial lipids during apoptosis play a role in the permeabilization process that probably is more important than was first envisioned.[120]

Bcl-2 Family Members and Mitochondria

Bcl-2 is a mitochondrial membrane protein that blocks the apoptotic death of many cell types.[121] The precise mechanism of Bcl-2 protection still remains unclear; however, some evidence indicates that Bcl-2 regulates an antioxidant pathway at sites of free radical generation.[122] Moreover, the proapoptotic proteins Bax and truncated Bid interact with ANT and VDAC (voltage-dependent anion-selective channel protein) to cause alterations in mitochondrial permeability transition.[123] In addition, proapoptotic Bax and Bak may form channels that permit release of proapoptotic proteins from mitochondria.[124] However, new data indicating that Bcl-2 family members prevent the mitochondrial permeability transition[125] suggest that the inhibition of free radical generation may be a secondary effect.

Consistent with this role, cytochrome *c* release can be initiated by the proapoptotic protein Bax.[126] Furthermore, Bcl-xL

can physically interact with another mitochondria-derived protein Apaf-1, to inhibit its association (and subsequent activation) of caspase-9.[127] On the other hand, in some cell types, Bcl-2 cannot prevent or delay the decrease of the cellular ATP level subsequent to metabolic inhibition, suggesting that it blocks apoptosis at a point downstream of the collapse of cellular energy homeostasis.[128]

Although the precise mechanism of Bcl-2 protection is a matter of some debate, it has been shown to protect neurons from apoptosis secondary to cerebral ischemia. Overexpression of the human Bcl-2 protein under the control of neuron-specific promoters can reduce neuronal loss after permanent middle cerebral artery occlusion.[129] In addition, mice with deletions for the genes for proapoptotic Bcl-2 proteins Bim and Bad have been shown to be protected from neonatal hypoxic-ischemic brain injury.[130]

Mitochondrial Permeability Transition and Cell Death

In intact cells, an early consequence of mitochondrial permeability transition is a reduction in mitochondrial membrane potential, and at later time points a disruption of outer membrane integrity leads to the release of proteins that are involved in apoptotic execution.[131] Support for this proposal comes from the finding that supernatants from mitochondria undergoing the permeability transition can cause apoptotic changes in isolated nuclei.[132]

Much of the information regarding the identity of mitochondrial factors involved in apoptosis has been obtained from cell-free systems established to reproduce the apoptotic program in vitro.[133] In one such model, apoptosis could be initiated by addition of deoxyadenosine triphosphate (dATP) but also required cytochrome *c*. Intact cells undergoing apoptosis showed a translocation of cytochrome *c* (which normally functions as an electron carrier in the respiratory chain) from mitochondria to the cytosol,[134] which in turn results in the activation of specific caspases involved in apoptotic execution. Among these, caspase-3 is thought to be pivotal to apoptotic execution, because cells that lack detectable levels of this enzyme fail to undergo cytochrome *c*–dependent apoptosis.[135] Although caspase inhibitors substantially reduce mitochondrial membrane potential and cell death, they do not prevent the passage of cytochrome *c* from mitochondria to the cytosol, which must occur upstream of caspase activation.

Along with cytochrome *c* and dATP, Apaf-1 has been identified as an important protein that participates in the activation of caspase-3.[136] Apaf-1 shares significant homology with *C. elegans* Ced-4, a protein that is required for apoptosis in the nematode. A third protein factor, Apaf-3, also is required for caspase-3 activation in vitro. Apaf-3 was identified as a member of the caspase family, caspase-9.[137] Genetic studies suggest that caspase-9 is the most upstream member of the apoptotic protease cascade, and the formation of an Apaf-1/caspase-9 complex activates caspase-3 in a cytochrome *c*– and dATP-dependent manner.

The effects of cytochrome *c* translocation to the cytosol are paradoxical. Although ATP is required for apoptotic execution, the mitochondrial cytochrome *c* deficit eventually will result in shutdown of the respiratory chain, and consequently, ATP synthesis will cease. Thus Fas-driven apoptosis in Jurkat cells results in the inactivation of cytochrome *c* with cessation of oxygen consumption.[138] The converse is not always true, however: Other reports have confirmed that apoptosis can proceed in the absence of cytosolic translocation of cytochrome *c*.[139,140]

Nevertheless, cytochrome *c* release is an important link between mitochondria and apoptosis, in at least some systems. Consistent with this concept of the mitochondria as a controller of apoptosis, mitochondrial changes precede the activation of cytosolic enzymes involved in apoptotic execution, and inhibitors of the permeability transition pore can prevent apoptosis.[141]

Opening of the mitochondrial pore permits a free diffusion of proapoptotic molecules that are involved in both caspase-dependent and caspase-independent cell death. Although the involvement of AIF in apoptosis is still somewhat controversial, it has been shown that AIF is a major contributor to neuronal loss after neonatal cerebral hypoxia-ischemia.[142] Apoptosis is regulated on multiple levels by several mechanisms involving a number of proteins including X-linked inhibitor of apoptosis protein (XIAP), c-IAP1, c-IAP2, Smac/DIABLO, HtrA/Omi, and XIAP-associated factor-1 (XAF1). A recent report has demonstrated that the increased Smac/DIABLO levels are associated with the alteration of XIAP levels after forebrain ischemia in adults.[143] Nevertheless, the expression and function of these regulatory proteins in neonatal brain injury are not well understood.

FUTURE DIRECTIONS

It is now widely accepted that both apoptotic and necrotic cell death are important components of neuronal loss following injury to the developing brain. The distinction between apoptosis and necrosis in tissue injury is not always clear-cut, however. The mode of cell death is determined by a number of cellular factors, including developmental status, the severity of injury, and mitochondrial function. The complexity of the events involved in oxidative damage to the brain underlines the need for therapeutic approaches that will combat multiple mechanisms of damage and interrupt both apoptotic and necrotic processes. It is likely that antiapoptotic approaches will yield the most clinical benefit, because necrotic cell death is more likely to occur as an early consequence of brain injury. In this regard, it is perhaps encouraging that so many players in the apoptotic signaling pathway have been implicated in neural cell loss after hypoxic-ischemic injury, because researchers are now presented with a plethora of therapeutic targets. Over the next few years it will be important to determine which of these will be most effective in reducing apoptotic cell death resulting from neonatal brain injury.

10 Angiogenesis

Jann Rhodes, Timothy Robert Hume Regnault, and Russell V. Anthony

Development of any tissue or organ requires the formation of a vascular network within the tissue, so vascular network formation within any tissue or organ can be viewed as a developmental requisite. Formation of tissue vasculature requires two distinct but related processes: vasculogenesis and angiogenesis. *Vasculogenesis* involves the formation of vessel tubes from the association of endothelial cell (EC) precursors or angioblasts, occurs solely in the embryo, and generally involves tissue of endodermal origin, including the heart tube and dorsal aorta, lung, pancreas, and spleen.[1] *Angiogenesis* is defined as the formation of new blood vessels from existing vessels,[2,3] is not limited to embryonic development, and is induced by inflammation, immune reactions, neoplasia, and wound healing.[4,5] Although these two processes are distinct, both are critical to embryonic development and the successful outcome of pregnancy, and they rely on many of the same molecular regulators.

A multitude of activators and inhibitors are involved in the regulation of vasculogenesis and angiogenesis.[6] During vasculogenesis, these factors induce differentiation of angioblasts to ECs, within embryonic and extraembryonic mesoderm, to form the initial vascular network[7] (Figure 10-1). The addition of new vessel segments to this vascular mesh, that is, angiogenesis, is required for the formation of a functional vascular system.[8] Formation of new capillaries, by both sprouting and nonsprouting (intussusception) angiogenesis, coupled with the remodeling and pruning of existing vessels,[8] provides for the extension and modification of the primitive vascular network (see Figure 10-1). At the same time, recruitment of perivascular cells (pericytes and smooth muscle cells) and deposition of the basement membrane provide stability and maturation of the developing vascular system (see Figure 10-1).

Although angiogenesis and the factors regulating it are important in postnatal tissues, the focus of this chapter is on the fetus and placenta and on the principal regulators of endothelium growth and morphogenesis.

EMBRYONIC/FETAL ANGIOGENESIS

The fetal circulatory system, consisting of the heart, blood components, and intraembryonic and extraembryonic vascular networks, develops out of necessity as the exponential growth of the embryo quickly outstrips the capacity of simple diffusion to meet the ever-increasing metabolic demands of the growing fetus. Definitive studies regarding the initiation of vasculogenesis and the development of extra- and intraembryonic vascular networks in the human fetus are essentially prohibitive, because yolk sac vasculogenesis begins at 16 days after conception and a

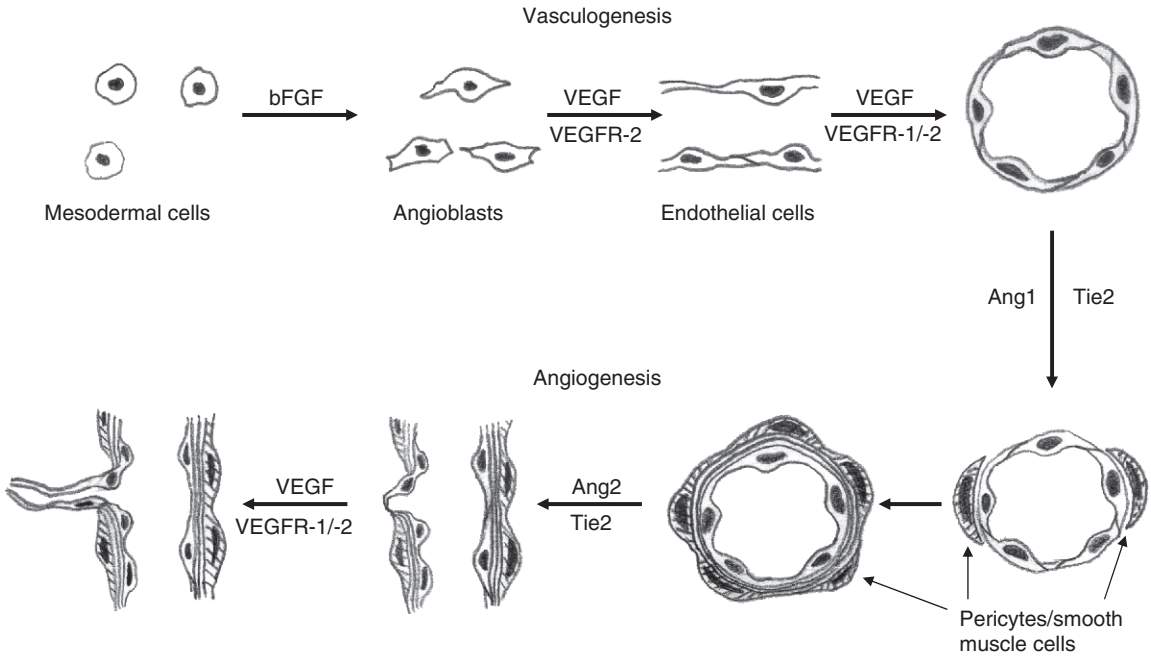

Figure 10-1 Schematic of blood vessel formation (vasculogenesis) and remodeling (angiogenesis). Embryonic mesodermal cells are stimulated by basic fibroblast growth factor (bFGF) to form angioblasts, which, under the influence of vascular endothelial growth factor (VEGF), form endothelial cells and vascular tubes. VEGF acts first through the VEGFR-2 receptor and then through VEGFR-1 and VEGFR-2. Angiopoietin-1 (Ang1), acting through Tie2, attracts pericytes around the primitive vessel, thereby stabilizing the vessel. The combined effects of VEGF and angiopoietin-2 (Ang2) provide for disruption of the vessel wall and for new vessel outgrowth or angiogenesis.

functional circulatory system between the two regions is present by day 21.[9] Therefore current understanding of human embryonic or fetal vasculogenesis and angiogenesis is derived from the conservative extrapolation and synthesis of in vitro observations, from clonogenic assays, embryonic stem cells, and embryonic explant cultures, as well as in vivo data derived from chimeric, transgenic, and knockin avian and mouse models.

De novo vasculogenesis is independently initiated in the extraembryonic (yolk sac and allantois) and intraembryonic (embryo proper) regions of the fetus.[10] Extraembryonic vasculogenesis precedes intraembryonic vasculogenesis as epiblasts, destined to become extraembryonic mesodermal progenitor cells, migrate to and localize at the proximal portion of the embryo and subsequently make ingress at the posterior region of the early primitive streak.[11] These early mesodermal cells migrate to and coalesce in the yolk sac, subsequently differentiating into either endothelial or primitive erythroid cells, and assemble into morphologically distinct structures called *blood islands.* Within the blood islands, the nascent ECs (i.e., angioblasts) surround the large, nucleated, primitive erythroblasts.[12] It has long been hypothesized that the concomitant appearance and close apposition of ECs and erythroid cells in the yolk sac are the result of the differentiation of these two cell lineages from a common progenitor, the hemangioblast. In vitro evidence demonstrates that the yolk sac blood islands are composed of cell populations that include individual enthothelial and hematopoietic progenitors, as well as bipotential progenitor cells from which both lineages may arise.[13-18] Definitive in vivo verification, however, is lacking. Support for the premise that blood islands are composed primarily of mixed progenitor cells (i.e., angioblasts, erythroblasts, and rare hemangioblasts) is provided by evidence that the extraembryonic vascular plexus is devoid of erythroid cells,[19] that differentiation of angioblasts directly from mesoderm cells occurs before the emergence of hemangioblasts,[18] that mapping studies indicate that the delineation of endothelial and hematopoietic lineages occurs during gastrulation,[20] and that multiprogenitor blood islands are present in tetrachimeric mice.[21]

Nascent yolk sac ECs assemble into strands around the erythroblasts, which remain in contact with the ECs and then coalesce with neighboring blood island ECs to form tubes and subsequently, a capillary plexus.[12] Inherent in this process is the delineation of the capillary bed into arterial and venous segments,[22-24] which then undergo rapid remodeling by sprouting angiogenesis and intussusception.[25,26] In the human, primitive, nucleated erythrocytes appear in the embryo proper concomitant with the onset of cardiac activity, thus establishing a functional vascular connection between the yolk sac and primitive heart by the end of the third week of gestation.[27] Yolk sac erythroblasts constitute a transient cell population which stop circulating from the yolk sac to the embryo by day 60 of human gestation[27] and gradually are replaced beginning at day 23 as hematopoietic cells emerge from the ventral floor of the dorsal aorta (hemogenic endothelium), the liver, and the bone marrow.[13,27-29] Unlike with the yolk sac, convincing evidence demonstrates that hematopoietic progenitors with the capacity to differentiate into multiple blood cell lineages, arise from ECs that make up the ventral aspect of the dorsal aorta.[30]

As the yolk sac regresses, the allantois emerges from the hindgut. The vascularization of the allantois, culminating in the formation and integration of the umbilical vessels into a functional placenta, is imperative for the survival of the fetus. The formation of the umbilicus proceeds by de novo vasculogenesis,[31] and much as with localization of the mesodermal cells to the yolk sac, the endothelial progenitors of the allantoic vessels cluster at the proximal segment of the embryo and exit the posterior primitive streak during the mid-streak stage to form the allantoic bud.[20,32] Once through the primitive streak, the mesodermal cells that make up the outer layer of the allantoic bud differentiate into mesothelial and chorioadhesive cells, proliferate, and subsequently fuse with the chorion. Next, the mesodermal cells in the core of the allantoic bud differentiate into angioblasts, followed by their assembly into nascent allantoic vessels—a process initiated at the distal (i.e., placental) end of the allantois and proceeding toward the developing embryo.[31,33] Much as in vasculogenesis in the yolk sac and in the embryo proper, the cells of the fledgling allantois, chorion, and placenta also can differentate into definitive hematopoietic cells.[34,35]

Development, integration, expansion and remodeling of intraembryonic vessels into a functional arterial-venous circulatory loop emanating from the heart and perfusing all tissues of the fetus, is a precisely coordinated, complex process incorporating both angiogenic and vasculogenic mechanisms.[10,25,26,36,37] Concurrent with the formation of the primary capillary plexus of the yolk sac, the heart, dorsal aorta, cardinal vein, and a sparse number of capillaries form within the embryo via de novo vasculogenesis.[10,38] Fate mapping indicates that unlike the epiblast progenitors of the yolk sac and allantois, the epiblast progenitors of the intraembryonic vasculature are medially localized and ingress at the anterior segment of the primitive streak during the mid-streak stage.[39] The newly formed mesodermal cells then migrate laterally to form the somatopleural or dorsal portion of the lateral plate mesoderm and the splanchnopleural or ventral layer of the lateral plate mesoderm.[40] Angioblasts, arising from the differentiating mesodermal somites, are dispersed and vascularize the body wall (i.e., limb buds), neural tube, and kidney.[41] By contrast, angioblasts arising from the differentiation of splanchnopleural mesoderm vascularize visceral tissues such as the lung, gut, pancreas, spleen, and liver.[29,42] Of interest, the aorta is composed primarily of ECs of somite origin, whereas the hemogenic wall of the aorta is composed primarily of ECs of splanchnopleural origin.[43,44] As the formation of hematopoietic cells from the ventral wall of the aorta ceases, the hemogenic endothelium is replaced by migrating somite ECs.[45]

PLACENTAL ANGIOGENESIS

Vasculogenesis and angiogenesis within the placenta probably are as important as embryonic angiogenesis for successful pregnancy outcome. Placental development begins early on and continues throughout gestation, as increased blood flow to the placenta is necessary to support the needs of the growing fetus. Beginning at the time of implantation, lacunae develop within the syncytiotrophoblast, coalescing to form the intervillous space, which will eventually fill with maternal blood. During this time frame, days 8 to 13 post coitus, the lacunae are separated by trabeculae composed of syncytiotrophoblasts. On approximately day 13 post coitus, maternal blood cells can be observed in the lacunae, and concomitantly the trabeculae are invaded by proliferating cytotrophoblasts, giving rise to the primary villi. Primary villi are quickly transformed into secondary villi as a result of mesenchyme cell invasion from the primary chorionic plate. Between days 18 and 20 post coitus, the first fetal capillaries are present within the mesenchyme, marking the development of the first tertiary villi.[46]

Early growth of the capillaries forms a primitive capillary network, and by 6 weeks post coitus, the basal lamina begins to form around the capillaries.[47] This primitive network is constantly being modified; the larger villi develop endothelial tubes serving as precursors of arterioles and venules. These tubes become surrounded by cells expressing α and γ smooth muscle actins, vimentin, and desmin.[48] Tertiary villi are transformed into immature intermediate villi, and after 15 weeks, the immature intermediate villi are transformed into stem villi. As the loose stroma becomes fibrotic and condensed, the peripheral capillary network condenses while the central capillaries differentiate into arterioles and venules.[49] The villous tree expands from its peripheral ends and gives rise to new villous outgrowth with new capillary networks.[47]

Increasing blood flow and pressure within the primitive vessels aid in stimulating further vessel development.[47] The first half

of gestation is characterized by branching angiogenesis, whereas from 26 weeks until full-term birth, angiogenesis within the placenta is predominantly nonbranching. Mature intermediate villi are produced in conjunction with increasing endothelial proliferation,[47] to form the main unit for nutrient exchange within the placenta. When the length of the intermediate villi vessels begins to exceed the length of the villi, formation of terminal villi occurs. Within the terminal villi, placental vessels lie very close to the intervillous space, such that placental and maternal blood supplies are separated by only a thin layer of syncytiotrophoblast. This arrangement provides a thin diffusion barrier, aiding in the transport of nutrients to the fetus.

ANGIOGENIC GROWTH FACTORS AND RECEPTORS

Angiogenesis is regulated through a complex balance between angiogenic and angiostatic substances exerting their influence at numerous levels. Promoters of angiogenesis include but are not limited to acidic and basic fibroblast growth factors, angiopoietin-1 and -2 (Ang1 and Ang2), placental growth factor, platelet-derived growth factor, transforming growth factor-α, tumor necrosis factor-α, and vascular endothelial growth factor (VEGF). Inhibitors of angiogenesis include but are not limited to angiostatin, endostatin, interferons, and platelet factor-4. For the purposes of this chapter, the focus of the following discussion is on the VEGF family and their receptors.

VASCULAR ENDOTHELIAL GROWTH FACTOR FAMILY

VEGF is a disulfide-linked homodimeric glycoprotein with a molecular weight of 40,000- to 45,000 that acts on ECs as a chemoattractant, mitogen, and morphogen.[50] VEGF is not a single protein, however, and comprises an entire family of gene products, including VEGF-A,[51] VEGF-B,[52] VEGF-C,[53] VEGF-D,[54] and VEGF-E.[55] As a result of differential splicing of the primary VEGF-A gene transcript, five isoforms of human VEGF-A are produced: $VEGF_{121}$, $VEGF_{145}$, $VEGF_{165}$, $VEGF_{189}$, and $VEGF_{206}$. The larger isoforms, $VEGF_{165}$, $VEGF_{189}$, and $VEGF_{206}$, contain heparin-binding domains,[56] and although $VEGF_{121}$ and $VEGF_{165}$ are readily diffusible and are the predominant secreted isoforms, $VEGF_{189}$ and $VEGF_{206}$ remain membrane-associated[57] but retain their biologic activity. $VEGF_{145}$ appears to be specific to human endometrium.[58] An additional member of this gene family is placental-growth factor (PlGF), and through alternative splicing, three isoforms are generated: $PlGF_{149}$ (PlGF-1), $PlGF_{170}$ (PlGF-2), and $PlGF_{219}$ (PlGF-3).[59]

Adding to the functional complexity of this family are the ligand-receptor interactions that have been identified. Receptors for this growth factor family include three kinase domain receptors: fms-like tyrosine kinase 1 (Flt-1 or VEGFR-1),[60] kinase insert domain–containing receptor (KDR) (Flk-1 or VEGFR-2)[60] and fms-like tyrosine kinase 4 (Flt-4 or VEGFR-3).[53] The receptor VEGFR-1 binds homodimers of VEGF-A, VEGF-B, PlGF, or VEGF/PlGF heterodimers,[60] whereas VEGFR-2 appears to be specific for homodimers of VEGF. The third receptor, VEGFR-3, acts as the receptor for VEGF-C and VEGF-D, but it does not interact with VEGF-A.[61] Beyond the three classic receptors for the VEGF family, some tissues produce a soluble form of VEGFR-1, which could act as a functional antagonist.[62] Furthermore, the neuropilins (NP-1 and NP-2), previously described as receptors for semaphorins,[63] exist in human umbilical vein ECs and act as receptors for VEGF-A and PlGF.[64] NP-1 also acts as a receptor for VEGF-B[65] and VEGF-E.[66] The neuropilins could add another layer of regulation to the actions of VEGF and PlGF, because NP-1 and NP-2 act as receptors for $VEGF_{165}$ and PlGF-2, but only NP-2 acts as a receptor for $VEGF_{145}$.[64, 67] NP-1 not only binds $VEGF_{165}$ but also complexes with VEGFR-1,[68] a finding that led to the suggestion that VEGFR-1 acts as a negative regulator of angiogenesis by competing for NP-1.

Regulation

Various cytokines and hormones have been shown to stimulate production of VEGF, but the primary regulator of this family of angiogenic growth factors may well be oxygen tension. Low oxygen tension results in the up-regulation of VEGF-A, the down-regulation of PlGF,[69] and the up-regulation of VEGFR-1 and VEGFR-2.[70] Although this regulation has not been entirely characterized for all four of these proteins, hypoxic regulation of VEGF-A expression is mediated at both transcriptional and posttranscriptional levels. In the presence of low oxygen tension, VEGF-A mRNA is stabilized by the interaction of heterogenous nuclear ribonucleoprotein L with the 3′-untranslated region of VEGF-A mRNA,[71] thereby increasing the mRNA half-life.

At the transcriptional level, low oxygen tension allows hypoxia-inducible factor-1 (HIF-1), a basic helix-loop-helix transcription factor, to interact with a hypoxia response element (HRE) in hypoxia-induced genes such as the VEGF-A gene, thereby stimulating transcription.[72] HIF-1 is a heterodimeric protein composed of HIF-1α *(HF1A)* or HIF-2α *(EPAS1)* combined with HIF-1β *(ARNT).* The HIF-1β subunit is constitutively expressed, whereas HIF-1α and HIF-2α are regulated by oxygen tension. Under low oxygen tension, HIF-1 is stabilized, allowing it to interact with HREs in the promoters of responsive genes. Under normal oxygen tension, however, conserved proline residues in HIF-1α and HIF-2α are hydroxylated.[73] Prolyl hydroxylation allows targeting of HIF-1α and HIF-2α by the von Hippel-Landau tumor suppressor gene product (pVHL).[74] The HIF-1α and HIF-2α chains are captured by a pVHL-ubiquitin E3 ligase complex, are ubiquitylated, and are destroyed by cellular proteasomes.[75]

The importance of this regulatory system is borne out by targeted mutations in mice, in which inactivation of both alleles of *EPAS1, ARNT,* or *VHL* is associated with embryonic death,[76-80] with defects in cardiac function, angiogenesis, vascular remodeling, and placental vascularization. Additional regulation of HIF-1 activity, however, also may result from increases in HIF-1α or HIF-2α mRNA concentrations, from translocation of HIF-1 to the nucleus, and from recruitment of transactivators.[75]

Disruption of the genes encoding HIF-1α, HIF-2α, HIF-1β, or VHL resulted in phenotypes that infer the necessity of these genes in vasculogenesis, as well as in angiogenesis. Because these genes or their respective gene products are involved in regulating VEGF-A and its receptors, similar phenotypes could be predicted with disruption of the genes encoding VEGF-A, VEGFR-1, or VEGFR-2. Indeed, disruption of a single VEGF-A allele impairs early-stage vascular development, resulting in embryonic death around day 10.[81,82] Included in the processes impaired by VEGF-A deficiency are vasculogenesis, large vessel formation, capillary sprouting, and remodeling of the yolk sac vascular network. The severity of this phenotype[81,82] indicates that VEGF-A acts in a dose-dependent manner to maintain angioblast differentiation and survival. When expression of the primary receptors for VEGF-A was disrupted,[83,84] mice lacking functional VEGFR-2[83] exhibited the more severe phenotype. VEGFR-2–deficient mice exhibited a complete failure of vasculogenesis, EC differentiation, and hematopoiesis,[83] whereas disruption of VEGR-1[84] resulted in enlarged blood vessels as well as embryonic death. Disruption of the PlGF gene[85] resulted in normal development, potentially discrediting a critical role of PlGF in embryonic angiogenesis.

Mode of Action

Biologic activity of VEGF-A is mediated by binding VEGFR-1 or VEGFR-2, ligand-mediated dimerization of the receptor, and initiation of signals leading to EC migration and growth. VEGFR-2 is viewed as the predominant receptor in regards to aniogenic signaling and is associated with endothelial mitogenesis, migration,

cytoskeletal organization, vessel permeability, and cell survival. Within the intracellular domain, seven putative phosphorylation sites exist, with Tyr1175 being the major site of activity.[86] Phosphorylation results in phospholipase Cγ-1, protein kinase C, and mitogen-activated protein (MAP) kinase activation.[87,88] The latter pathway acts on MAP kinases such as ERK-1 and ERK-2 and stimulates mitogenesis.[89,90] The available evidence on the ability of VEGFR-2 to stimulate phosphotidylinositol-3-kinase activity is conflicting,[88,91] but c-Src and nitric oxide appear to play a role in VEGF signaling.[92] Src activation has been shown to play a role in stress-activated protein kinase-2–mediated cell migration,[93] and VEGF-stimulated endothelial nitric oxide synthase activity is abolished by the VEGFR-2 antagonist SU1498.[90] Finally, activation of VEGFR-2 induces the activation of Rho-dependent kinase (ROCK), and ROCK directly phosphorylates focal adhesion kinase, promoting cell migration.[94]

The intracellular domain of VEGFR-1 contains several tyrosine residues that can be autophosphorylated, although it generally is felt that these provide weak signals for cell growth and survival in postnatal life.[87] As with VEGFR-2, the major portion of VEGFR-2 activity occurs after phosphorylation of Tyr1169. This leads to MAP kinase and phospholipase Cγ-1 activation and EC proliferation.[95] The exact role VEGFR-1 plays in this pathway remains uncertain[89,96]; however, this and other work indicate that the pattern of VEGFR-1 autophosphorylation differs depending on whether VEGF-A or PlGF is the ligand. In contrast with VEGFR-2, the extracellular domain on VEGFR-1 can be secreted as a binding protein, as a result of alternative mRNA splicing.[97] The soluble form of VEGFR-1 is deficient in signaling and appears to act as a binding protein for VEGF,[87,98] the existence of which has been associated with preeclampsia.[99,100] The third receptor, VEGFR-3, contains five internal phosphorylation sites and is a primary modulator of lymphatic endothelial proliferation and survival.[87,101] VEGFR-3 activity is mediated through activation of protein kinase C–dependent MAP kinase, and also through the activation of phosphatidyl inositol-3-kinase and AKT (protein kinase B).[94]

Angiopoietins and Their Receptor

Ang1 and Ang2, although not part of the VEGF family, act to potentiate the actions of VEGF-A; Ang2 expression is induced by hypoxia and VEGF-A.[102] Ang1 acts synergistically with VEGF-A to stimulate angiogenesis,[103] whereas Ang2 is an antagonist to Ang1 and, in the absence of VEGF, is thought to destabilize or regress blood vessels.[104] It is believed that Ang1 is important in angiogenesis (rather than vasculogenesis[105]), during the remodeling of the vasculature into a hierarchical network of mature vessels composed of endothelial and adventitial cells, by recruiting and sustaining perivascular cells.[106] Both Ang1 and Ang2 interact with the receptor Tie2, with equal affinity[104]; whereas Ang1 induces maturation and stabilization of developing neovasculature,[107] Ang2 causes destabilization required for additional sprout formation[104] and branching angiogenesis. Ang1 and Ang2 are true antagonists, competing with equal affinity for Tie2,[104] and Ang1 is thought to be the natural agonist for Tie2. This concept is supported by the similar phenotypes exhibited by targeted inactivation of either the Ang1[107] or Tie2[108] genes, both resulting in defective vascular development and subsequent embryonic death. By contrast, transgenic mice overexpressing Ang1 appeared to be generally healthy; however, their skin exhibited greater numbers of large blood vessels.[107] Further studies with mice overexpressing Ang1 showed a greater incidence of leakage-resistant blood vessels in these animals.[109] Transgenic mice overexpressing Ang2[104] die during embryogenesis, with defects similar to those in mice harboring inactivated Ang1 and Tie2 genes[107,108]—a finding further supporting the concept that Ang2 is a natural antagonist to Ang1.

SUMMARY

In the overview of angiogenesis within the fetus and placenta presented in this chapter, the focus of the discussion was on a few of the many factors that may affect fetal and placental vascular development. Later chapters deal with angiogenesis within specific organs. Although the discussion was limited to the VEGF family and the angiopoietins, their receptors, and some of the regulatory mechanisms, it should still be obvious that the regulation of vasculogenesis and angiogenesis is extremely complex. Studies in mice harboring functionally disrupted genes encoding these growth factors, receptors, or regulators have provided invaluable insight into the absolute necessity for some of the vascular growth factors and their receptors in embryonic development and have underlined the importance of vasculogenesis and angiogenesis in embryonic development and survival. Finally, not only are VEGF-A and the angiopoietins important in vascular development of the embryo and placenta, but they also are produced and act on non-ECs within the placenta. Associated with these activities are alterations in vascular growth factor expression in placenta compromised by preeclampsia and intrauterine growth restriction, again highlighting the importance of these factors for successful pregnancy outcome. Although angiogenesis during fetal and placental development is a complex topic and is difficult to examine experimentally, it holds great potential as an area for development of therapies aimed at improving pregnancy outcome.

SECTION II

Placenta and Intrauterine Environment

11

Hans-Georg Frank

Placental Development

EARLY DEVELOPMENT

As fetal membranes and uterine mucosa come into close contact, this contact zone defines the new organ placenta. Structurally, the constituting layers can just be apposed to each other or even be fused with each other; their functional connection always serves the purpose of maternofetal exchange of nutrients, gases, and waste substances. According to this definition, placental development starts at the time of implantation around 6 to 7 days after conception, as soon as the blastocyst starts invasion of the endometrium. At this stage, the blastocyst consists of an outer vesicular cellular cover, called the *trophoblast,* and of an inner cell mass, called the *embryoblast* (Figure 11-1, *A*). The placenta and the membranes are derived mainly from the trophoblast, whereas the embryoblast develops into the umbilical cord and the fetus and adds the mesenchyme to the placenta.[1]

Implantation and Lacunar Period

Before adhesion to the uterine mucosa, the blastocystic wall consists of a single layer of trophoblast cells (termed the cytotrophoblast). Those parts of the trophoblast that adhere to the mucosa and later invade it show an increased proliferation, resulting in a trophoblastic wall that is mostly double-layered. At the same time, the outer of the two layers shows disintegration of the lateral intercellular membranes. Thus it is transformed into a superficial layer of syncytiotrophoblast[2] (see Figure 11-1, *A*). Continuous proliferation of the inner cellular trophoblastic layer, together with subsequent syncytial fusion of some of the daughter cells with the covering syncytium, is responsible for an enormous increase in volume of syncytiotrophoblastic mass (prelacunar period) (see Figure 11-1, *B*). Those parts of the blastocystic wall that are not yet implanted consist of only a single layer of cytotrophoblast.[3]

At day 8 after conception, a system of confluent vacuoles appears in the syncytiotrophoblast at the implantation pole.[2] Their appearance marks the beginning of the lacunar period, which lasts from day 8 to day 13 after conception. These lacunae are formed only in the more central parts of the syncytiotrophoblast. The surrounding and separating lamellae and pillars of syncytiotrophoblast are called *trabeculae* (see Figure 11-1, *C*). This system of trabeculae and lacunae is covered by two uninterrupted syncytial layers: The basal layer, facing the endometrium, is called the *trophoblastic shell;* the superficial layer, facing the blastocystic cavity, is called the *primary chorionic plate.*

Starting at the primary chorionic plate at day 12 after conception, the cytotrophoblast invades the syncytial trabeculae and finally reaches the trophoblastic shell (see Figure 11-1, *D*). Trophoblastic proliferation inside the trabeculae is responsible for considerable longitudinal growth and for branching of the trabeculae. The branches that end blindly and protrude into the lacunae are the primary villi (see Figure 11-1, *D*). The trabeculae, from which they are derived, are called the *anchoring villi* because they connect the villous system with the trophoblastic shell. With the appearance of the first primary villi, the still-expanding lacunar system is called the *intervillous space.*

In parallel with these events, the trophoblast of the trophoblastic shell erodes maternal endometrial vessels as early as at day 12 after conception. Maternal blood leaving the eroded vessels enters the lacunar system through holes in the shell, thereby establishing a primitive maternal placental circulation (see Figure 11-1, *D*).

Meanwhile, the blastocyst is completely embedded in the endometrium and surrounded by endometrial stroma from all sides. The parts of the blastocyst surface that are implanted later pass through the same developmental steps as for the implantation pole. All data given in the following description are valid only for development at the implantation pole.

Villous Development

At day 14 after conception, mesenchymal cells from the embryonic disk spread along the inner trophoblastic surface of the blastocystic cavity, and there they transform into a loose network of branching cells, the extraembryonic mesenchyme.[1,4] From this date onward, the primary chorionic plate consists of three layers: the mesenchyme (the future connective tissue); a middle, discontinuous layer of cytotrophoblast; and a layer of syncytiotrophoblast facing the intervillous space (see Figure 11-1, *E*). Between days 15 and 20 after conception, cells of the extraembryonic mesenchyme invade the primary villi, transforming them into secondary villi. This mesenchyme never reaches the trophoblastic shell, so the segments of the anchoring villi that connect them to the trophoblastic shell remain merely trophoblastic. These trophoblastic segments are called the *cell columns* and consist of a voluminous cytotrophoblastic core and a thin, incomplete syncytial cover (see Figure 11-1, *E*). Their large share of cytotrophoblast is the main source for longitudinal growth of the anchoring villi. Some of the cytotrophoblast cells achieve an invasive phenotype and then migrate across the trophoblastic shell to invade deeply into the endometrium, forming an admixture with maternal tissue components—the so-called junctional zone (see later section, "Trophoblast Invasion").

Within a few hours of the mesenchymal invasion of the villi, some of the mesenchymal cells are transformed into macrophages that start secreting angiogenetic growth factors (see further on). Other mesenchymal cells differentiate into angiogenetic and hematopoietic precursor cells, the hemangioblastic cell cords. Around day 20 after conception, the first fetal capillaries are derived from the latter (see Figure 11-1, *F*).[5] The fetally vascularized villi are henceforth named the *tertiary villi.* Hematopoietic stem cells are derived from the same hemangiogenetic cell cords.

At the same time, the fetally vascularized allantois reaches the chorionic plate.[6] Allantoic vessels extend into the chorionic plate and even into the larger villi. There they fuse with the spreading

intravillous capillary bed. A complete fetoplacental circulation is established around the end of the fifth week after conception.[6] In newly formed villous capillaries, hematopoiesis can be observed even after this date.

Development of the Maternofetal Barrier

As soon as an intraplacental fetal circulation is established in the tertiary villi, fetal blood in the villi and maternal blood in the intervillous space come into close contact with each other (Figure 11-2). They are always separated by the placental barrier, which is made up of the following layers: (1) a continuous layer of syncytiotrophoblast, covering the villi and thus lining the intervillous space; (2) an initially complete (in the first trimester) but later discontinuous (in the second and third trimesters) layer of cytotrophoblast; (3) a trophoblastic basal lamina; (4) connective tissue derived from the extraembryonic mesoderm; and (5) fetal endothelium, which is surrounded by an endothelial basal lamina only in the last trimester (Figure 11-3). Throughout the following months of pregnancy, this barrier undergoes quantitative rather than qualitative changes; the thickness of the syncytiotrophoblast layer decreases is from more than 15 μm to a mean of 4.1 μm[6] (Table 11-1). Owing to the rapid expansion of the villous surfaces, the cytotrophoblast is relatively rarified and, at term, can be found on only 20% of the villous surface. The mean villous diameter decreases because the newly formed generations of villi generally are smaller than those of the previous generation. Accordingly, with advanced maturation, the intravillous position of the fetal capillaries is nearer to the villous surface. All of these factors result in a reduction of the mean maternofetal diffusion distance from between 50 and 100 μm in the second month down to between 4 and 5 μm at term gestation.[6]

PLACENTAL VILLI

The basic morphology of the placental villi can be seen in Figures 11-2 and 11-3. The villous core consists of fixed connective tissue cells, connective tissue fibers, macrophages (Hofbauer cells), some occasional mast cells, and fetal vessels. The stromal core is surrounded by the trophoblastic basal lamina, on which can be found variable numbers of cytotrophoblast cells (Langhans cells) and an outer, complete layer of syncytiotrophoblast.

Fetal Endothelium

Maternofetal exchange across the placental villi is focused on those villi (terminal villi and mature intermediate villi, see below) that are richly supplied with fetal capillaries. The capillaries are lined by a continuous endothelium without pores or fenestrations[6]; it acts as a passive filter, limiting macromolecular transfer across the vessel wall to a certain molecular size (below 20,000 Da).[7] In addition, permeability seems to be influenced by molecular charge.[8,9] The cells that surround the walls of the larger vessels (i.e., the pericytes and smooth muscle cells) are active in vasoregulation. Because nerves have never been observed in the placenta, vasoregulation must be accomplished by humoral means or local mechanisms, or both.[10]

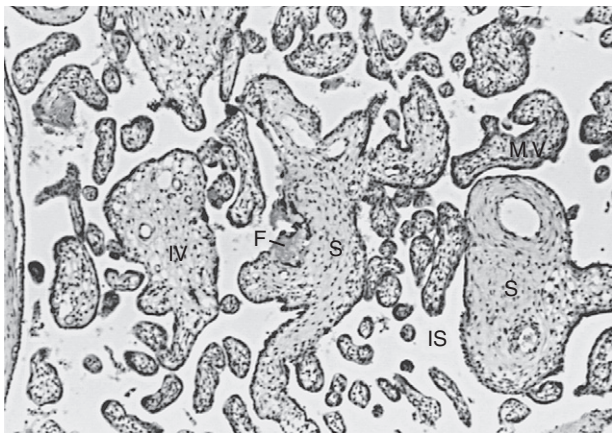

Figure 11-2 Paraffin section of placental villi, week 28 after last menstruation (×70). The assortment of villi of varied caliber is typical for the last trimester. Larger villi as stem villi *(S),* immature intermediate villi *(IV),* and mature intermediate villi *(MV)* are easily recognizable. The group of smaller villi in between, too small for identification in this figure, is composed of terminal villi, mesenchymal villi, and villous sprouts. *F,* Fibrinoid (attached to the villous surface, resulting from trophoblastic degeneration); *IS,* intervillous space.

Villous Stroma

The connective tissue cells of the vessel adventitia shade into the components of the surrounding villous stroma without any sharp demarcation line. Depending on villous type and age, mesenchymal cells, fibroblasts, or myofibroblasts will be the prevailing cell type.[11] These cells produce connective tissue fibers, which increase the mechanical stability of the villous core. In addition, macrophages (Hofbauer cells) can be observed in variable numbers. In addition to their phagocytotic activity, these are active paracrine cells that produce growth factors that regulate growth and differentiation of all villous components.[6]

Trophoblast

The trophoblastic cover of the villi is the main site for maternofetal transfer and for secretory functions. Most of these actions take place in the syncytiotrophoblast. The villous cytotrophoblast (Langhans cell) serves as a kind of stem cell, proliferating, differentiating, and afterward fusing with the syncytiotrophoblast.[12] Quantitative assessments of trophoblast proliferation and syncytial fusion have shown that it exceeds the needs for growth of syncytiotrophoblast by a factor of 5 to 6.[13] Throughout the last month of pregnancy, approximately 3.6 g of cytotrophoblast fuse syncytially per day. In this stage of pregnancy, however, the syncytiotrophoblast grows only by approximately 0.6 g per day. The daily excess production of 3 g syncytiotrophoblast is shed into the maternal circulation as syncytial knots that contain mainly aged syncytial nuclei and organelles. The reasons for this enormous turnover of trophoblast are not yet fully understood. Probably they are closely related to the apoptotic events underlying the process of syncytial fusion.[13-18]

TABLE 11-1

Summary of Mean Data on Placental Development*

Pregnancy week (postconception)	1, 2	3-6	7-10	11-14	15-18	19-22	23-26	27-30	31-34	35-38
Pregnancy month (postmenstruation)	1	2	3	4	5	6	7	8	9	10
Diameter of chorionic sac (mm)		8, 11, 17, 25	32, 40, 47, 55	62, 75, /, /						
Placental diameter (mm)				70	95	120	145	170	195	220
Placental weight (g) postpartum without clamping of cord		6	26	65	115	185	250	315	390	470
Placental wall thickness (mm) postpartum (mm)				12	15	18	20	22	24	25
Placental thickness, including uterine wall, measured by ultrasound in vivo (mm)					28	34	38	43	45	45
Length of the umbilical cord (mm)				180	300	350	400	450	490	520
Fetal weight (g) per g of placental weight		0.18	0.65	0.92	2.17	3.03	4.00	4.92	5.90	7.23
Villous volume (g) per placenta		5	18	28	63	102	135	191	234	273

All data from reference 6.
/, No data available for that week.

For syncytial fusion of cells, at least two contemporaneous signals are needed:

- To provide tissue specificity of fusion, the plasmalemmal exposition of fusogenic proteins is required; in the case of trophoblast the retroviral envelope protein HERV-W, also called syncytin-1,[19] was identified as one such fusogenic protein. It is expressed in syncytiotrophoblast.[20] Its receptor is the neutral amino acid transporter RDR that is expressed in villous cytotrophoblast.[21,22] Of interest, evidence for regulation of the expression of ligand and receptor is lacking; rather, both molecules seem to be constitutively expressed. It is, however, known, that trophoblast fusion is strictly regulated and depends on two prerequisites: (1) The cytotrophoblast must have reached a certain level of differentiation that makes it ready for fusion, and (2) the neighboring syncytiotrophoblast must show advanced stages of apoptosis, necessitating the incorporation of fresh cytotrophoblast for its survival.[6] These facts underline the need for an additional, immediate fusion signal.
- To act as such an acute fusion signal, phosphatidylserine flips from the inner to the outer plasmalemmal leaflet.[13,22] The outward flip of phosphatidylserine is provided by intracytotrophoblastic activation of initiator caspases that inactivate flippases and activate floppases.[14,23] The initiator caspases are intracellular proteases belonging to the molecular machinery of the early, still-reversible stages of the apoptosis cascade. Further progression of the apoptosis cascade in the freshly formed syncytiotrophoblast is blocked by the mitochondrial proteins Mcl-1 (myeloid cell leukemia-1) and Bcl-2, both of which inhibit cleavage and thus activation of execution caspases by the active initiator caspases. Both inhibitory proteins are transferred in large quantities from the cytotrophoblast into syncytiotrophoblast by the same fusion event.[13,24]

All cells entering the apoptosis cascade irreversibly leave the cell cycle, with consequent down-regulation of transcription to very low levels. Both kinds of apoptotic events have been demonstrated for syncytiotrophoblast. The nuclei of the latter do not incorporate ^{3}H-thymidine[25] and take up only very low quantities of ^{3}H-uridine.[13,26] Consequently, the syncytiotrophoblast depends on continuous incorporation of cytotrophoblast both for its growth and to ensure a continuous supply of mRNA for all translation processes. To enable functional mRNA transfer by a process of intercellular fusion, an unusual stability of mRNA

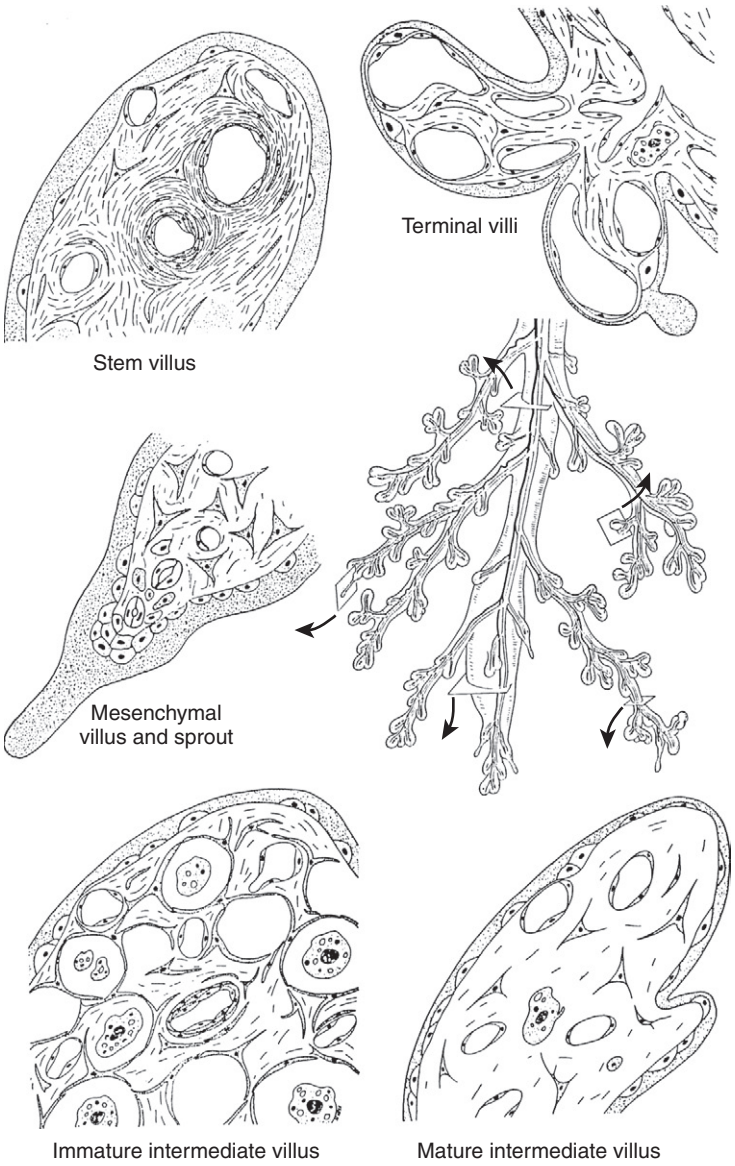

Figure 11-3 A peripheral part of the mature placental villous tree and typical cross-sections of the various villous types. *(Modified from Kaufmann P: Influence of ischemia and artificial perfusion on placental ultrastructure and morphometry,* Contrib Gynecol Obstet *13:517, S Karger AG, 1985, Basel.)*

levels is required. Such stability may be ensured by high placental concentrations of the RNAse inhibitor RNAsin.[27] Moreover, syncytial incorporation by fusion results in a kind of transplantation of fresh organelles and enzyme systems into the syncytium to replace the aged ones (Figure 11-4).

Removal of aged syncytiotrophoblast also involves apoptosis.[28] The nuclei incorporated by syncytial fusion into the syncytiotrophoblast become aggregated (see Figure 11-4). Parallel to this event, the apoptosis cascade is restarted and now passes through all execution stages until apoptotic death occurs, including activation of execution caspases, local degradation of the cytoskeleton, formation of membrane-protecting protein scaffolds by activation of transglutaminase II, activation of endonucleases with subsequent DNA degradation, and nuclear collapse.[13] The final stage of this cascade is the formation of the syncytial knots. Each of these knots is composed of 10 to 50 aggregated apoptotic nuclei, surrounded by some cytoplasm and an intact plasmalemma. The knots are then pinched off and shed into the maternal circulation (see Figure 11-4). At term, approximately 3 g of this kind of apoptotic trophoblast enters the maternal blood, from where these nuclei are removed by phagocytosis in the maternal lung. The mean survival time of a nucleus after syncytial fusion until shedding has been calculated to be approximately 3 to 4 weeks.[13]

Apoptosis is an energy-consuming process. In vitro and clinical studies[6,29-31] suggest that insufficiency of energy supply to the placenta results in abortion of the trophoblastic apoptosis cascade, to the benefit of necrotic trophoblast shedding. Necrotic trophoblast shedding products such as fetal DNA, fetal globular actin, and others have been shown to activate maternal macrophages and to damage maternal endothelium. These events are thought to be involved in the pathogenesis of preeclampsia.

As a consequence of the various stages of trophoblast turnover as described, the syncytiotrophoblast is composed of mosaic-like patches with variable ultrastructure, enzyme patterns, and functional specialization (see Figure 11-4)[6]:

1. The freshly fused, thick syncytial segments with predominant rough endoplasmic reticulum specialize in the secretion of proteohormones and placental proteins as well as in maternofetal protein transfer, including catabolism and resynthesis.
2. After degradation of ribosomes, the structurally similar segments, with predominant smooth endoplasmic reticulum, are involved in the metabolism of steroid hormones.
3. The epithelial plates or vasculosyncytial membranes are thin syncytial lamellae (1 to 2 μm thick) resulting from nuclear movement and removal. These are the main sites of diffusional transfer of gases and water and the carrier transfer of glucose.
4. True syncytial knots are a late to final stage of syncytial apoptosis, directly preceding shedding of the apoptotic material. Of note, however, not all syncytial protrusions in a histologic section of a mature placenta containing nuclear aggregates represent such true syncytial knots. Rather, many of these structures noted on histologic examination are tangential sections of the villous surfaces and are thus an unavoidable consequence of histologic sectioning.[32-34] Such artifical "trophoblast protrusions" are not only misleading mimics of apoptotic syncytial knots. In a similar way they are able to mimic trophoblastic

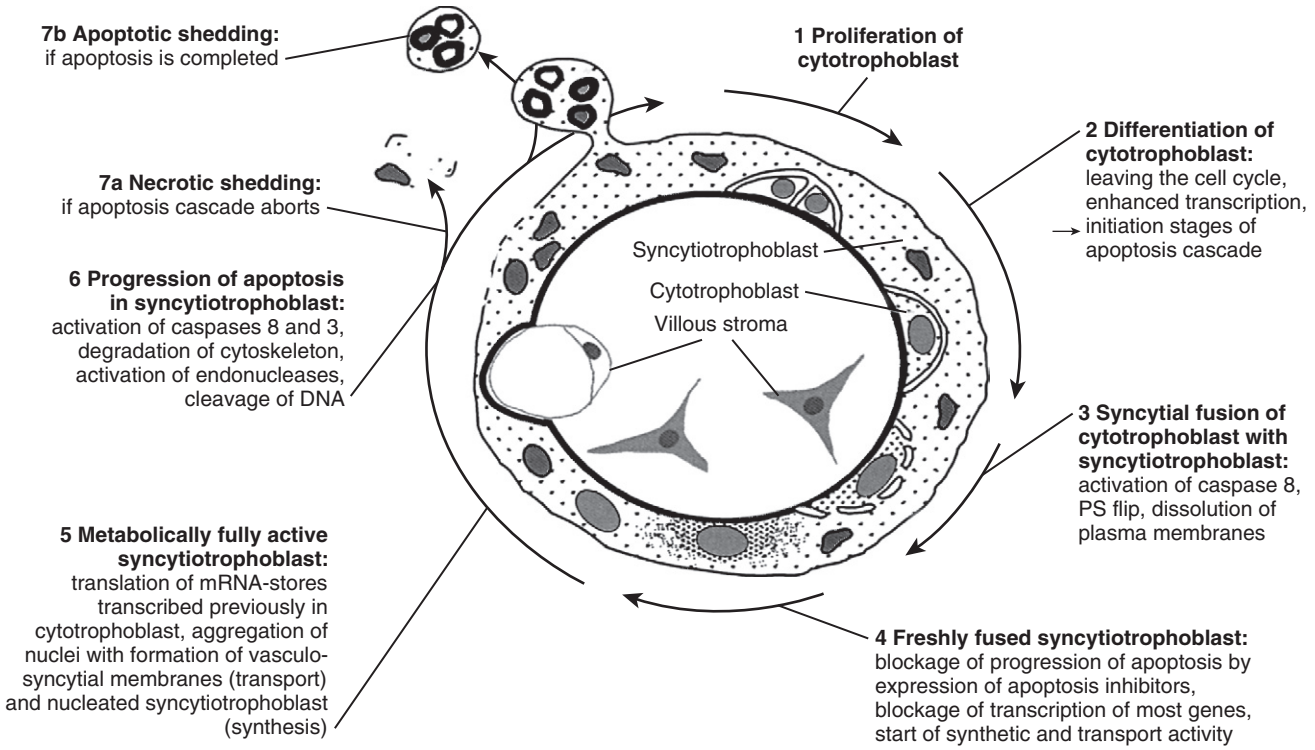

Figure 11-4 Villous trophoblast turnover. *Clockwise:* Proliferation *(1)* takes place exclusively in the cytotrophoblast cells, which act as stem cells. After differentiation of cytotrophoblast *(2),* syncytial fusion *(3)* is triggered by molecular mechanisms of early stages of the apoptosis cascade. On syncytial integration of the former cytotrophoblast into the syncytiotrophoblast, progression of the apoptosis cascade is blocked *(4).* As is typical for early apoptotic tissues, transcription is down-regulated to low levels. Therefore survival of syncytiotrophoblast depends on translation of mRNA, which is transferred into the syncytium by continuous syncytial fusion of differentiating cytotrophoblast *(5).* After more than 3 weeks of aging and restart of apoptosis *(6),* the accumulating apoptotic syncytial nuclei are shed into the maternal circulation. When the apoptosis cascade cannot be completed (e.g., in severe hypoxia), shedding is completed by necrosis *(7a/7b).* The complete cycle takes approximately 4 weeks.

(proliferative) sprouts in the early placenta. As a rule, true knots or sprouts are rare and section artifacts occur frequently.[33]

Integrity of the Maternofetal Barrier

The syncytiotrophoblast is a continuous, generally uninterrupted syncytial layer that extends over the surfaces of all villous trees; as such, it completely lines the intervillous space. In this context, therefore, use of plural terms such as *syncytial cells* or *syncytiotrophoblasts* is inappropriate. Because of the syncytial nature of this layer, it generally is believed that every substance passes from the maternal to the fetal circulation under the control of the trophoblast. Despite this view, physiologic evidence supports the existence of two different routes of transfer across the placental barrier, a transcellular and a paracellular route.[35] The transcellular route involves transfer across the plasma membranes and the cytosol of the syncytiotrophoblast. The paracellular route is thought to be an extracellular, water-filled pathway. Two different structural correlates for the latter route have been described:

- Integrity and completeness of the syncytiotrophoblastic barrier are not absolute. Gaps in the syncytiotrophoblast caused by degeneration or by mechanical forces are filled by fibrin as a result of blood clotting. Approximately 7% of the villous surfaces in normal term human placentas show corresponding fibrin spots as replacement of the syncytiotrophoblast.[36,37] Such areas may serve as relevant paratrophoblastic routes for maternofetal macromolecule transfer, thereby bypassing the syncytiotrophoblast; in vitro, maternally injected horseradish peroxidase (molecular weight, 48,000; molecular radius, 3.0 nm) was shown to pass through the fibrin spots into the fetal villous stroma.[36]
- Transtrophoblastic channels provide a paracellular transfer route for smaller molecules.[38-42] These channels, with a diameter of approximately 20 nm, pass through the syncytiotrophoblast as winding and branching, membrane-lined tubules from the apical to basal surface. Morphologic evidence for a basoapical membrane flux along these channels suggests that they are likely to be routes for membrane recycling from the basal to the apical syncytiotrophoblastic plasmalemma.[41] Functionally the transtrophoblastic channels are possible sites of transfer for water-soluble, lipid-insoluble molecules with an effective molecular diameter of less than 1.5 nm.[35,43,44] Moreover, they have been shown to be the sites of fetomaternal fluid shift, which is mediated by hydrostatic and colloid osmotic forces. In the guinea pig and in the isolated human placenta, an elevation of the fetal venous pressure of 5 to 17 mm Hg was sufficient to shift 30% to 50% of the fetal arterial perfusion volumes into the maternal circulation. Under the conditions of fetomaternal fluid shift, the channels dilate to several micrometers in diameter.[38,42] Pressure-dependent dilation and closure of the channels may act as important factors in fetal osmoregulation and water balance. Excessive fetal hydration results in an increase in fetal venous pressure and a decrease in osmotic pressure. Both factors have been experimentally proved to dilate initially narrow channels,[38,42] thereby allowing fetomaternal fluid shift and equilibration of the surplus water.

Villous Types

Human placental villi can be classified according to their position within the villous tree, the type of fetal vessels they contain, and their connective tissue structure.[45-48] Figure 11-3 illustrates a peripheral part of the villous tree containing all villous types described so far. The centrally positioned *stem villi* are characterized by centrally located arteries and veins or larger arterioles and venules surrounded by a stroma that is rich in connective tissue fibers.[49] Fetal capillaries are poorly developed. Most of the stromal cells are highly differentiated myofibroblasts that are oriented in parallel to the longitudinal villous axis.[50-52] They may be involved in longitudinal contraction of the stem villi (anchoring villi), thus regulating the width of the intervillous space and maternal blood flow impedance.[11] Such a fetal contractile system regulating the intervillous circulation is needed because the uteroplacental arteries are set free from vasomotor influences of the mother by physiologic changes in their walls[53] (see later). Approximately one third of the total villous volume of the mature placenta consists of this villous type.

The stem villi ramify into bundles of slender, slightly curved villi (see Figure 11-3) called the *mature intermediate villi.* Most of their vessels are fetal capillaries, in between which are small arterioles and venules.[54,55] The vessels are embedded in a loose connective tissue, with scant fibers and cells. These villi are the main sites of growth and differentiation of terminal villi.[48,49] Highly active enzyme patterns indicate their metabolic and endocrine activities. Approximately 25% of the villous branches are of this type.

The *terminal villi* are the final branches of the mature intermediate villi, with a morphologic resemblance to a cluster of grapes. Their bulbous peripheral parts are characterized by numerous dilated capillaries, so-called sinusoids, some of them with diameters up to 40 μm[54,55] (Figure 11-5; see also Figure 11-3). The extremely high degree of fetal vascularization and

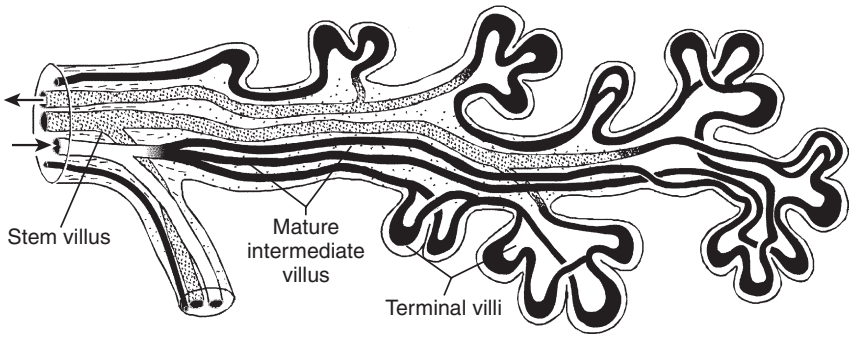

Figure 11-5 Arrangement of fetal vessels in a group of terminal villi *(no shading)* derived from one mature intermediate villus *(point-shaded).* Note the highly complex loop formation of the terminal fetal capillaries *(black).* Branching usually is followed shortly by refusioning of the two capillary branches. The branching pattern avoids basal shortcuts in such a way that each erythrocyte has to pass the terminal capillaries of several terminal villi in full length. Local dilatations of the capillaries in the terminal villi, so-called sinusoids, reduce blood flow resistance. Arterioles are *unshaded.* Venules are *dotted. (Modified from Benirschke K, Kaufmann P:* Pathology of the Human Placenta, *New York, 2006, Springer.)*

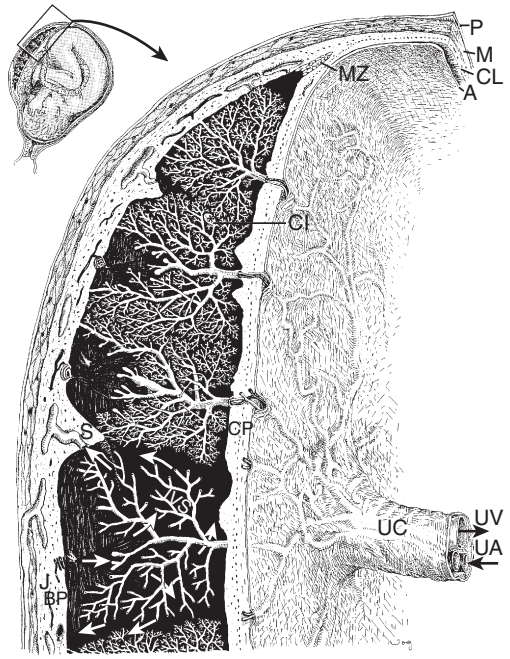

Figure 11-6 Survey diagram of the nearly mature human placenta in situ. Loose centers of the villous trees arranged around the maternal arterial inflow area are a frequent feature. These placentome centers usually exhibit immature patterns of villous branching and differentiation. *A,* Amnion; *BP,* basal plate; *CI,* cell island connected to the villous tree; *CL,* chorion laeve; *CP,* chorionic plate; *IVS,* intervillous space; *J,* junctional zone; *M,* myometrium; *MZ,* marginal zone between placenta and fetal membranes, with obliterated intervillous space and ghost villi; *P,* perimetrium; *S,* placental septum; *UA,* umbilical artery; *UC,* umbilical cord; *UV,* umbilical vein.

the minimal maternofetal diffusion distance (less than 4 μm) point to this villous type as the most likely place for diffusional exchange. The terminal villus volume amounts to 30% to 40% of the villous tree.

In some of these villous trees, stem villi are continuous with thicker bulbous villi; these are termed *immature intermediate villi*[47,48] (Figure 11-6; see also Figure 11-3). The typical structural features of immature intermediate villi include arterioles and venules, accompanied by numerous superficially located slender capillaries, and a voluminous, reticularly structured connective tissue that is rich in Hofbauer cells and poor in fibers. These villi can be found in the mature placenta only in small, restricted groups located in the centers of the villous trees[56] (see Figure 11-6). In immature placentas, they constitute the prevailing villous type. The main roles of immature intermediate villi are to act as precursors of stem villi (into which they are transformed continuously) and to provide a surface for sprouting of new villous side branches.[47,48]

The rarest and most inconspicuous villous type in the mature placenta is that of the *mesenchymal villi.* These villi represent a transient stage of villous development, derived from villous sprouts (see Figure 11-3). They differentiate via immature intermediate villi into stem villi or into mature intermediate villi. Because new sprouts are formed at the surfaces of mesenchymal and immature intermediate villi, they normally are found grouped in locally restricted sites. Structurally the mesenchymal villi can be identified by their slender shape, numerous Langhans cells, and poorly developed fetal capillaries. Some of the last-mentioned do not show lumina and are still developing and unperfused.[47,48]

Fetoplacental Angioarchitecture

Fetal arteries and veins are restricted to the stem villi, whereas arterioles and venules are mainly located in the smaller stem villi as well as in mature and immature intermediate villi.[48,54,55] All of the larger fetal vessels are accompanied by a system of long, slender capillaries, the so-called paravascular net.

In the mature intermediate villi, the arterioles and venules turn into long, coiled terminal capillary loops (see Figure 11-5).[55] At sites of maximum coiling, the capillaries stretch the surface of the mature intermediate villi, producing bulges—the terminal villi. Within the terminal villi, capillaries may dilate considerably, forming sinusoids (see Figures 11-3 and 11-5).[54] One capillary loop may supply several terminal villi in series,[54] dilating and narrowing several times for each single terminal villus. The probable function of the sinusoids is to reduce blood flow resistance and thereby guarantee an even blood supply to the long terminal capillary loops (mean length, 4000 μm) as well as to the shorter paravascular capillaries (mean length, 1000 μm).

Fetoplacental Vasculogenesis and Angiogenesis

Development of the fetoplacental vascular system entails two biologic steps, namely, *vasculogenesis*, which involves de novo formation of blood vessels from mesodermally derived precursor cells, and *angiogenesis*, which describes branching of new vessels from preexisting vessels.[57] Fetoplacental vasculogenesis starts at days 20 to 21 after conception by formation of hemangioblastic cords that shortly after develop into blind ending primitive capillaries containing blood precursor cells.[5,58] In the following phase of branching angiogenesis (day 32 to week 25 after conception), the primitive capillaries develop into a richly branched villous capillary bed that becomes connected to the allantoic vascular system of fetus and umbilical cord around the end of the fifth week after conception.[5,6] This highly branched early villous capillary bed has a low fetoplacental blood flow impedance.[58] This period is characterized by high placental levels of vascular endothelial growth factor (VEGF) but moderate placental growth factor (PlGF) expression.[57] During week 15, large centrally located villi show regression of peripheral capillary nets. In parallel, some remaining central capillaries acquire a tunica media and transform into arteries and veins.[6] Starting at approximately week 25, in the newly formed peripheral villi, angiogenesis switches from branching to nonbranching; this period is accompanied by a steep drop in VEGF and a slower decline in PlGF expression.[57,58] As a consequence of this switch, long, poorly branched capillary loops are formed in the periphery of the fetoplacental vascular trees. These loops increase fetoplacental impedance, but blood flow still increases as a result of rising fetal blood pressure. Both the biphasic changes in VEGF and PlGF levels and the resulting biphasic development of the villous vascular system are possibly due to a rise in intraplacental oxygen tension: Values are low in early pregnancy but steeply increase in the second trimester.[6,57] Abnormal placental oxygenation, resulting in abnormal levels of angiogenic growth factors, abnormal villous capillarization, and abnormal fetoplacental arterial impedance, are thought to be important factors in the pathogenesis of intrauterine growth restriction.[6,58,59]

Cotyledons and Villous Trees

The basal surface of the term placenta is characterized by 10 to 40 slightly protruding areas called *maternal cotyledons, lobes,* or *lobules*[57] (Figure 11-7, *B*). They are minimally separated from each other by the so-called placental septa[56] (see Figure 11-6). From the chorionic plate at term, 60 to 70 villous stems (trunci chorii) arise. Each of these trunks branches into a villous tree.[61] Each maternal cotyledon is occupied by at least one villous tree

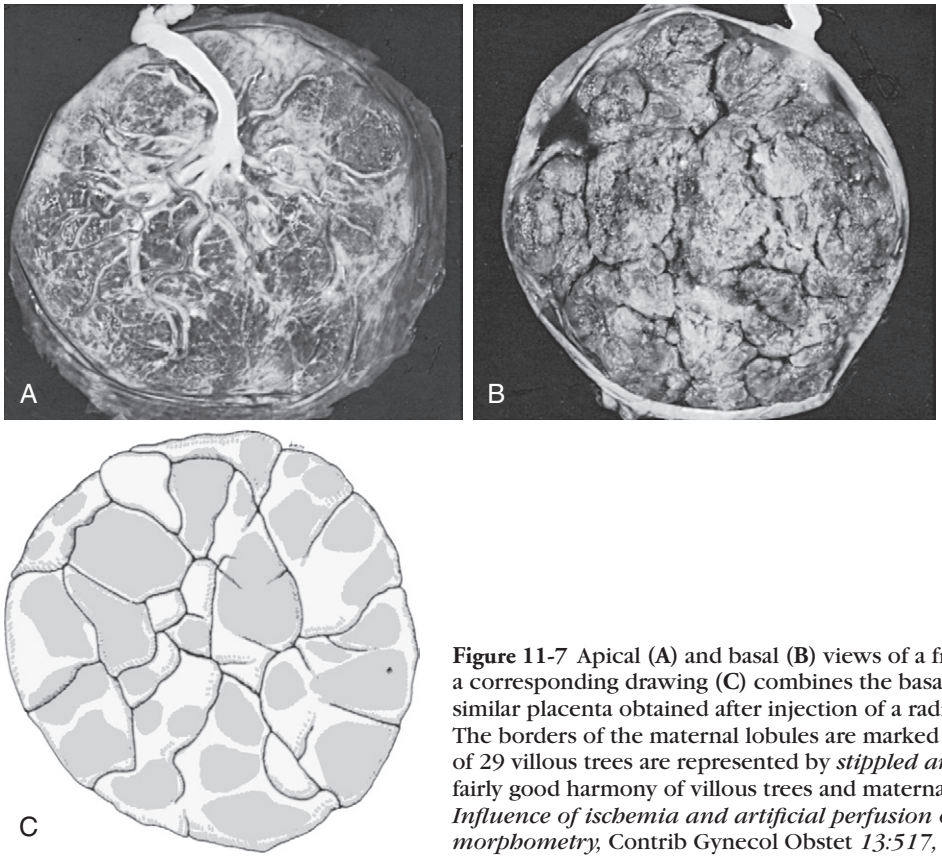

Figure 11-7 Apical **(A)** and basal **(B)** views of a freshly delivered mature human placenta; a corresponding drawing **(C)** combines the basal view with an x-ray photograph of a similar placenta obtained after injection of a radiopaque medium into the fetal vessels. The borders of the maternal lobules are marked by *lines.* The radiographic projections of 29 villous trees are represented by *stippled areas.* This combination demonstrates a fairly good harmony of villous trees and maternal lobes. *(Modified from Kaufmann P: Influence of ischemia and artificial perfusion on placental ultrastructure and morphometry,* Contrib Gynecol Obstet *13:517, Basel, 1985, Karger, AG.)*

(see Figures 11-6 and 11-7). As shown in Figure 11-7, *C*, the superficial cotyledonary borderlines are adjacent, to a large extent, to those of a corresponding group of villous trees.[56]

The human placenta belongs to the villous, hemochorial type of placentation: After leaving the spiral arteries, the maternal blood circulates through the diffuse intervillous space, flowing directly around the villous surfaces without any maternal vessel wall (see Figure 11-6). According to Schuhmann,[61] the arterial inlets normally are situated close to the centers of the villous trees. The venous openings in the basal plate are arranged around the periphery of the villous trees.

The fetomaternal circulatory unit, called the *placentone,* consists of a villous tree and the corresponding part of the intervillous space, which is centrifugally perfused with maternal blood[61] (see Figure 11-6). As depicted in Figure 11-7, *C,* every maternal lobe or cotyledon possesses at least one placentome. Owing to the insufficiency of placental septa (see further on), a majority of the maternal circulatory units belonging to the 40 to 60 placentomes overlap considerably.

The centers of typical placentomes exhibit loosely arranged villi, predominantly of the immature intermediate and mesenchymal types,[56,62] providing a large intervillous space for maternal arterial inflow. Occasionally the loose villous arrangement results in a central cavity (see Figure 11-6),[61] which may rapidly collapse after the placenta is delivered because it is a pressure-dependent in vivo structure. In the periphery of the placentomes, most villi are mature intermediate and terminal in type. They are separated by narrow intervillous clefts. Here, the maternal blood comes into intimate contact with the villous surface. Near the chorionic plate and at the border of neighboring placentomes, the villous arrangement becomes looser again, thus providing space for the venous backflow toward the venous openings in the basal plate.

The radioangiographic studies of Borell and co-workers[63] in the human placenta and of Ramsey and associates[65] in the rhesus monkey placenta support this placentome concept. Both studies have revealed a rapid filling of the centers of the maternal circulatory units, called *jet* or *spurt,* and subsequently a slow, centrifugal spreading of the blood toward the subchorial, lateral, and basal outflow area of the placentomes. In many places, the placentomes were seen to overlap so much that the typical differences between inflow and outflow areas vanished.[56]

As evident from the description of villous types, the immature centers of the placentomes act as growth zones where new formation and differentiation of villi take place. By contrast, the placentomes' periphery represents the metabolically active area and the fetomaternal exchange zone. The placentome centers are the remainders of completely immature villous trees from earlier stages of pregnancy. In normal pregnancy, they can be observed in at least some placentomes until term. They may disappear completely only in rare cases of preterm hypermaturity of the placenta.[6]

The heterogeneity of the villous trees poses problems for the histopathologic evaluation: Neighboring zones of the villous trees differ not only by the presence of different types of villi but also by different degrees of villous maturation. As a consequence, one histologic section never is representative for all parts of a villous tree or for all villous trees of a placenta.[65] This problem is greater still when small tissue samples are used, as for semithin histologic analysis and for electron microscopy. Neither technique allows a reliable diagnosis of the degree of maturation. The same holds true for histologic evaluation of samples obtained by chorionic villus sampling.

With regard to their structural arrangement and effectiveness, the fetomaternal blood flow interrelations are described as a multivillous flow system.[66] This designation implies that the fetal flow in hairpin-like capillary loops is crossed at various angles by the intervillous maternal bloodstream. Vessel arrangement and effectiveness, as defined physiologically,[66] ensure that the human

placenta does not exhibit a countercurrent flow system, as was proposed in earlier studies. The effectiveness of the system is further reduced by the fact that considerable amounts of maternal venous blood are recirculated by the arterial jet before leaving the intervillous space.

Intervillous Space

The usual appearance of the intervillous space of the delivered placenta is that of a system of narrow capillary-like clefts.[3,67] Boyd and Hamilton[3] questioned these interpretations. According to their findings on in vivo radioangiography, the rapid filling of the intervillous space is not compatible with a cleft system of capillary dimensions. The apparent width of the intervillous space (blood volume divided by one half of the villous surface area) ranges interindividually from 16.4 to 32 μm (assuming a postpartal intervillous blood volume of 23.3% to 37.9% and a villous surface area of 11.0 to 13.3 m^2).[6,28,68] In this context, an important consideration is the presence of a relatively large subchorial lake, as well as wide spaces in the arterial inflow area (central cavity). Thus the real "intervillous" volume in the exchange area is likely to be less and the intervillous clefts are likely to be narrower. With the addition of the considerable loss of maternal blood during labor,[69] however, these calculations may yield an approximation reflecting reality.

TROPHOBLAST INVASION

Trophoblast invasion is a peculiarity of all species showing interstitial implantation. This phenomenon is required for

- Anchorage of the placenta in the uterine wall
- Adaptation of the uteroplacental circulation to meet the embryonic/fetal requirements

Interstitial Trophoblast Invasion

Trophoblast invasion starts from the trophoblastic shell that is the base of the lacunar system at day 8 after conception (see Figure 11-1, *C* and *D*). In the beginning, it is a purely syncytiotrophoblastic layer. From day 13 after conception onward, cytotrophoblast enter the trophoblastic trabeculae and villi. Many of these cells remain in the villi, where they constitute the proliferating basis for later development and expansion of the villous trees. Others, which will become the extravillous trophoblast, reach and focally penetrate the trophoblastic shell (see Figure 11-1, *E*), from where they start invading endometrium and myometrium. The resulting mixture of maternal and fetal tissues stretches from the intervillous space down to the superficial third of the myometrium. It is described as the *junctional zone* (see Figure 11-1, *F*). Its superficial part, adhering to the placenta after placental separation, is the *basal plate*. Those parts that remain in the uterus after delivery are called the *placental bed* and consist mainly of intact and necrotic endometrial tissue, with intermingled trophoblastic cells.

With expansion of the placenta, within in few days the trophoblastic shell is disrupted into multiple clusters of proliferating extravillous trophoblast. Each of these clusters, a *trophoblastic cell column,* is located at the base of an *anchoring villus,* a stem villus that connects the villous trees to the basal plate.[70-72]

Trophoblast invasion is a truly invasive process during which the trophoblast cells penetrate their host tissue using a combination of migratory and proteolytic activities. The latter among others are based on the secretion of various matrix metalloproteinases[73] and serine proteases,[74] as well as urokinase and tissue-type plasminogen activators.[75] Unlike tumor invasion, however, trophoblast invasion in the placental bed stops within few days after delivery of the placenta. This raises the question as to the control of the process. Figure 11-8 summarizes the major differences between tumor and trophoblast invasion, accounting for local and time limitation of trophoblast invasiveness:

- Although tumor cells *proliferate* and invade at the same time, extravillous trophoblast cells achieve an invasive phenotype only after leaving the cell cycle. They proliferate only for as long as they are resting on the basal lamina of the anchoring villus. This separation of proliferation and invasiveness limits invasive depth to the life span of each single extravillous trophoblast cell.[76]
- Another regulatory factor may be provided by *integrin-matrix interactions.* Shortly after leaving the cell cycle, a majority of trophoblast cells start secreting ample extracellular matrix containing, among others, laminins, collagen type IV, heparan sulfate, vitronectin, cellular and oncofetal fibronectins, and fibrillin.[77-81] Of interest, extravillous trophoblast cells in late pregnancy with low invasiveness show a polygonal shape and express only those integrins that are receptors for the respective extracellular membrane (ECM) molecules (α6β4, α5β1, α1β1, and αVss integrins).[84] By contrast, in early pregnancy associated with highly invasive trophoblast, a majority of cells show a spindle-shaped body and a mismatch of integrins and surrounding ECM.[82]
- It is well known that normal extravillous trophoblast cells in vitro exhibit little invasiveness. This observation has elicited the question of whether cytokines up-regulate and control invasiveness in vivo. According to recent in vitro data, insulin-like growth factor-I (IGF-I), secreted by placental villous mesenchyme, is a very likely candidate stimulator of trophoblast invasiveness. This paracrine signal presumably is self-limiting because its concentration decreases with increasing invasive depth.[83]
- Another probable mechanism limiting trophoblast invasion is *syncytial fusion* (reviewed by Kaufmann and Castellucci[76]). The depth of the invasive zone close to the endometrial-myometrial border usually is marked by a layer of trophoblastic multinucleate giant cells that are derived from syncytial fusion and show no signs of further invasiveness.
- Finally, *apoptosis* of invasive extravillous trophoblast is induced by maternal macrophages by either of two mechanisms: (1) secretion of tumor necrosis factor-α (TNF-α) (the trophoblast cells express the respective TNF receptor I) and (2) tryptophan depletion (the maternal macrophages secrete tryptophan-catabolizing indoleamine 2,3-dioxygenase [IDO]) (see Figure 11-8).[84]
- The interaction between *maternal lymphocytes* and invasive trophoblast is still being investigated (as reviewed by Loke and King[85]). The relatively low number of T cells in conjunction with the absence of B cells at the site of implantation makes a classic allorecognition reaction of the trophoblast seem unlikely. This view is in agreement with the observation that the invasive trophoblast cells do not express classic polymorphic major histocompatibility complex (MHC) I but rather express an unusual combination of human leukocyte antigen (HLA)-C, HLA-E, and HLA-G. The absence of classic semiallogeneic MHC-I (HLA-A) molecules prevents attack by T lymphocytes, whereas the presence of the nonpolymorphic HLA-G precludes aggression by the uterine natural killer (NK) cells (large granular lymphocytes) (see Figure 11-8).
- Uterine NK cells are particularly numerous in the decidua basalis at the implantation site, where they come into close contact with invading trophoblast cells. Even if they do not interact with trophoblast invasion by direct killing activity, they may control the process by secretion of transforming growth factor-β (TGF-β), the receptor of which is expressed by trophoblast cells.[85] TGF-β has been implicated as an immunosuppressive factor in decidua by modulating the response of maternal leukocytes to trophoblast (reviewed by Loke and

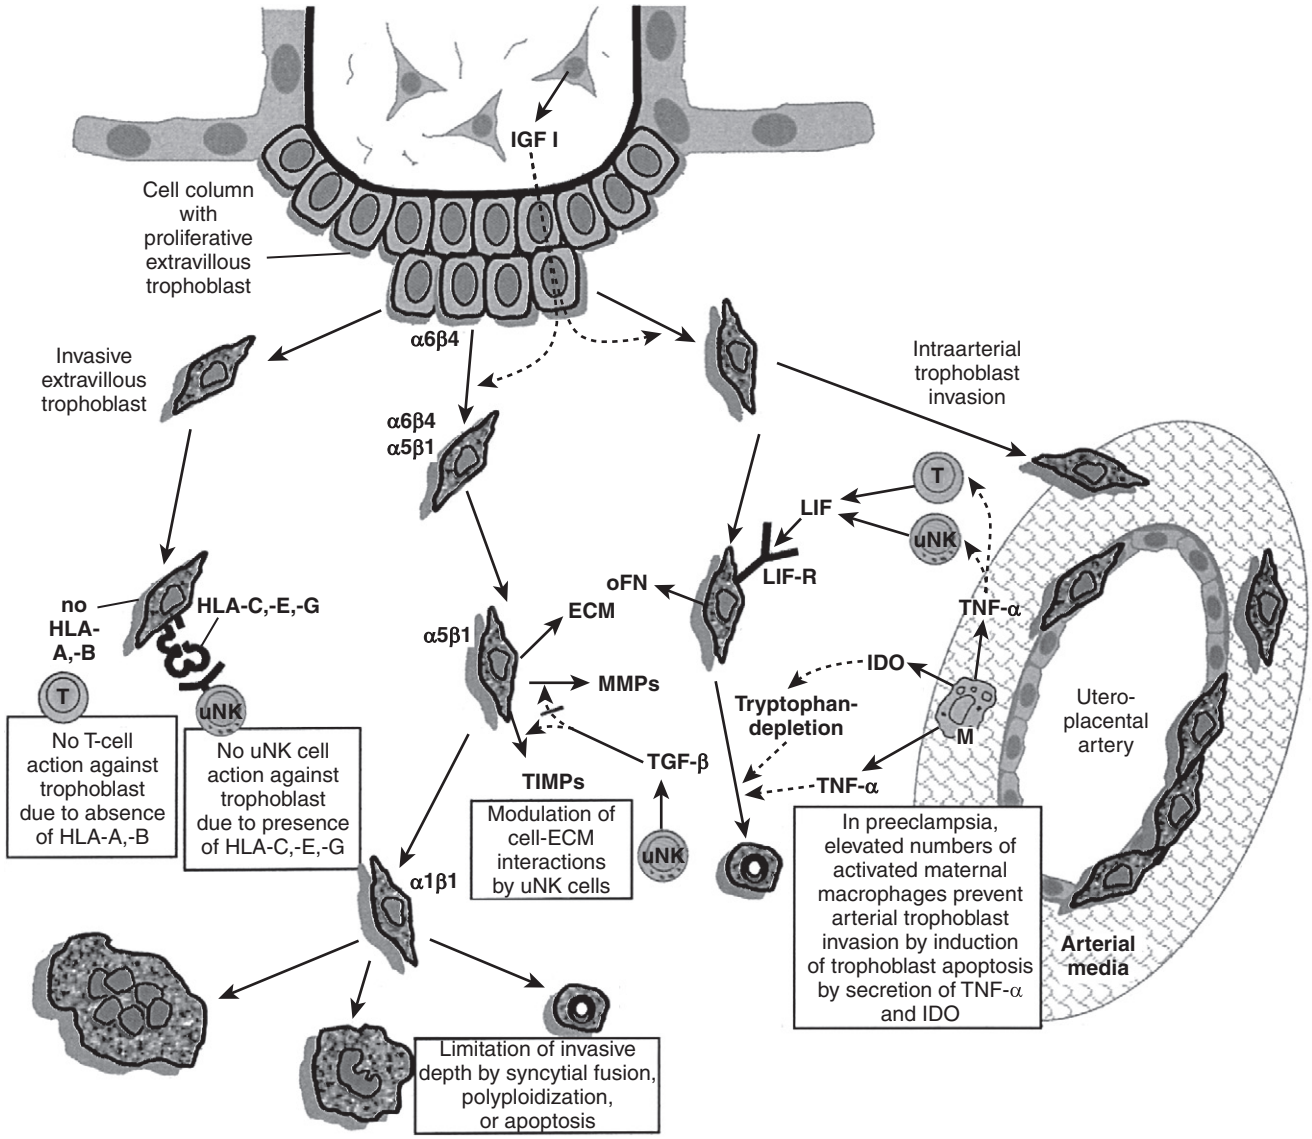

Figure 11-8 Maternofetal interactions among invasive extravillous trophoblast, maternal T cells *(T),* maternal uterine natural killer cells *(uNK),* and maternal macrophages *(M).* *Left invasion route:* Interaction between trophoblastic HLA exposition and maternal lymphocytes. *Central invasion route:* Gradual modification of integrin expression as well as modulation of ECM secretion. *Bottom:* Modes of limitation of invasive depth. *Right invasion route:* Some paracrine interactions between trophoblast and maternal immune cells; also shown: intraarterial trophoblast invasion and its inhibition by macrophages. See text for details. *ECM,* Extracellular matrix; *LIF/LIF-R,* leukemia inhibitory factor/leukemia inhibitory factor receptor; *HLA,* human leukocyte antigen; *IDO,* indoleamine 2,3-dioxygenase; *IGF-I,* insulin-like growth factor-I; *MMPs,* matrix metalloproteinases; *oFN,* oncofetal fibronectin; *TIMPs,* tissue inhibitors of metalloproteinases; *TNF,* tumor necrosis factor.

King[85]). This cytokine also restricts trophoblast invasion by down-regulation of collagenase secretion and induction of tissue inhibitors of metalloproteinases (TIMPs).[85] The inhibitory effect of TGF-β on trophoblast invasion is mediated by endoglin, a member of the TGF-β receptor complex. Moreover, TGF-β has been reported to enhance the secretion of fibronectins by trophoblast in vitro (reviewed by Benirschke and colleagues[6]). All of these observations suggest that TGF-β is a modulator of trophoblast invasion (see Figure 11-8).

Arterial Trophoblast Invasion

After erosion of the first endometrial capillaries at day 12 after conception, larger endometrial arteries (spiral arteries) and veins also erode and become connected with the intervillous space. General agreement exists that the number of corresponding maternal vessels that supply the placenta, although originally high, is considerably reduced by obliteration toward term gestation.[3] The final number of spiral arteries present in the term placenta is between 50 and 100.[3,86] The number of venous openings varies, ranging from 50 to 200.[3,86]

Pregnancy-induced changes in the uteroplacental vessels start in the second month of pregnancy. These affect primarily the uteroplacental arteries and only to a lesser extent the respective veins.[87-89] These changes obviously are induced by invasive extravillous trophoblast approaching the vessel walls. They start with funnel-like dilatation of the arteries (up to a diameter of 2000 μm), followed by dedifferentiation of the media smooth muscle cells, loss of all elastic elements, infiltration of the media with invasive extravillous trophoblast, and replacement of arterial

endothelium by so-called intraarterial trophoblast cells.[53,76,89-94] Earlier interpretations that these media changes are degenerative in nature[94] are no longer accepted[90-92]; rather, it was shown that the dedifferentiated arterial walls redifferentiate into intact media layers within a few days after delivery, with loss of extravillous trophoblast cells.[89]

The trophoblast cells infiltrating the arterial walls and replacing the arterial endothelium locally form huge intraarterial plugs, which were believed to inhibit uteroplacental blood flow. Whether plugging in the first trimester can completely block intervillous blood flow remains subject to further discussion.[6]

Moll and colleagues[53] and Brosens and co-workers[94] have pointed out that because of the degree of physiologic changes in uteroplacental arteries, these vessels must be set free from the vasomotor influences of the mother. This functional separation ensures unrestricted maternal blood supply to the placenta, regardless of maternal attempts to regulate the blood flow distribution within her own body; the mother cannot reduce the nutrient supply to the placenta without decreasing the nutrient supply to her own tissues.

Reduced physiologic vessel alterations, including reduced arterial dilatation and reduced intraarterial trophoblast invasion, are regularly observed in pregnancies complicated by preeclampsia, hypertension of pregnancy, and fetal intrauterine growth restriction.[86,95] By general agreement, failure of adaptation of the uteroplacental arteries to pregnancy conditions and thus preeclampsia and IUGR are thought to be closely related to impaired trophoblast invasion. However, several different hypotheses concerning the nature of this impairment have been proposed: The classic view is that of a general defect of trophoblast invasion,[96,97] possibly resulting from impaired integrin expression.[81] The inability of invasive trophoblast cells to express endothelial adhesion receptors, such as vascular endothelial cadherin (VE-cadherin), platelet endothelial adhesion molecule-1, vascular endothelial adhesion molecule-1, α4 integrins, and αvβ3 integrin, has been suggested as another possible mechanism.[98,99] Furthermore, recent data have shown that interstitial trophoblast invasion may be normal, whereas only the invasion of vessel walls is inhibited by activated maternal macrophages that secrete TNF-α and IDO, both inducing apoptosis in those trophoblast cells approaching the arterial walls[84,100] (see Figure 11-8).

PLACENTAL SEPTA AND CELL ISLANDS

Placental septa and cell islands are oddly shaped conglomerations of fibrinoid, intermingled with groups of trophoblastic and decidual cells. These structures are not vascularized. If they are connected to the basal plate, they are called *septa.* These septa are columnar or sail-like structures rather than real septa.[101] They cannot divide the intervillous space into separate maternally perfused chambers (see Figure 11-6). They are interpreted as dislocations of basal plate tissue into the intervillous space, caused by lateral movement and folding of the uterine wall and basal plate over each other. Parts of such septa detached from the basal plate and then attached to neighboring villi are called *cell islands.*

Similar islands, without decidual contribution, may be formed from villous tips that have not been opened up by connective tissue and fetal vessels during transition from primary to tertiary villi. In such cases, the cytotrophoblastic core proliferates and subsequently becomes largely transformed into fibrinoid. These cell islands are growth zones for the attached villous stems comparable to cell columns.[102,103]

CHORIONIC PLATE AND UMBILICAL CORD

At day 14 after conception, the primary chorionic plate consists of three layers: extraembryonic mesenchyme, cytotrophoblast, and syncytiotrophoblast (see Figure 11-1, *E* and *F*). These layers separate the intervillous space from the blastocystic cavity. Between 8 and 10 weeks after conception, the amniotic sac has expanded to such a degree that the amniotic mesenchyme comes into close contact with the mesenchymal surface of the chorionic plate and the chorion laeve (smooth chorion). As soon as amniotic and chorionic plate mesenchyme fuse with each other, the definitive chorionic plate is formed (see Figure 11-6).[104,105]

As part of the same process, the expanding amniotic sac surrounds the connective stalk and the allantois and joins them to form the umbilical cord. The allantoic vessels—two arteries and one vein—grow in thickness and length and convert into the umbilical vessels. The allantoic epithelium gradually disappears; small vesicular remnants of the allantois, however, may persist until term. The allantoic mesenchyme differentiates into a complex system of myofibroblasts that likely help regulating turgor of the cord and avoid bending of the latter with fatal consequences for the fetus.[106,107] Fusion of the umbilical vessels with the intravillous vessel system establishes a complete fetoplacental circulation at the end of the fifth week after conception. The cord is characterized by a spiral twisting, the number of spiral turns increasing as pregnancy progresses, up to a maximum of 380 turns. In most cases, the twist is leftward, or counterclockwise. The twists have been interpreted to originate with rotary movements of the fetus resulting from asymmetric uterine contractions.[6,108]

FETAL MEMBRANES

All developmental steps described so far are valid only for the implantation pole, which describes the part of the blastocystic circumference that is attached to the endometrium and implanted first. The other parts of the blastocystic circumference, implanted a few days later, undergo a corresponding although delayed development that is quickly followed by regressive changes. Collectively, these parts are called the *capsular chorion frondosum.* The first regressive changes can be observed as early as in the fourth week. The newly formed villi degenerate, and the surrounding intervillous space is obliterated. As a consequence of obliteration of the intervillous space, the chorionic plate, villous remnants, and the basal plate fuse, forming a multilayered compact lamella, the smooth chorion (chorion laeve). Formation of the smooth chorion starts opposite to the implantation pole at the so-called antiimplantation pole. From there it spreads over approximately 70% of the surface of the chorionic sac until the fourth month of gestation, when this process stops.[3,6] Between weeks 7 and 10 of pregnancy, the expanding amniotic sac comes into contact with the smooth chorion. In most places, the mesenchymal layers of both membranes fuse.

With complete implantation, the decidua recloses over the blastocyst, bulging into the uterine lumen, and is called the *capsular decidua.* With the increasing diameter of the chorionic sac, the capsular decidua locally touches the parietal decidua of the opposing uterine wall. Between weeks 15 and 20 after conception, both decidual layers fuse with each other, thereby obstructing the uterine cavity. From this point onward, the smooth chorion has contact over nearly its entire surface with the decidual surface of the uterine wall and may function as a paraplacental exchange organ. Owing to the absence of fetal vascularization in the smooth chorion and the amnion, all paraplacental material exchanged between fetal membranes and fetus has to pass through the amniotic fluid.

At term, the fetal membranes are structured as follows[6,109] (see Figure 11-6). The mean thickness of the membranes, after separation from the uterine wall during labor, is approximately 200 to 300 μm. The innermost layer, the *amniotic epithelium,* encloses the amniotic fluid. Amniotic epithelium may be involved in the production of the latter and even partially responsible for its resorption. Moreover, it seems to be involved in pH regulation

of the amniotic fluid.[110] Together with the *lamina propria,* it measures 30 to 60 μm in thickness.[111]

The next layer consists of *chorionic connective tissue,* which is directly adherent to a *cytotrophoblastic layer* of variable thickness.[112,113] Connective tissue and cytotrophoblast have a combined thickness of 80 to 120 μm. Near the placental margin, the thickness increases because persisting ghost villi, embedded in fibrinoid, split the cytotrophoblast into two layers. At the placental margin, these two layers completely disjoin by interposition of the intervillous space, and they become the chorionic and the basal plates (see Figure 11-6). Attached to the outer surface of the cytotrophoblast is a *decidual layer* approximately 50 μm thick. The latter finding indicates that the separation of membranes does not take place along the maternofetal interface but instead occurs at a somewhat deeper level.

Apart from recognition of the amniotic involvement in the production, resorption, and acid-base balance of the amniotic fluid,[110,113] definite and detailed knowledge about exchange and metabolic functions of the smooth chorion is lacking.

12 Regulation of the Placental Circulation

Charles R. Rosenfeld

Pregnancy is associated with several alterations to the maternal cardiovascular system; however, it is the development of the low-resistance, high-flow placental vascular bed that characterizes this physiologic state. Moreover, this vascular bed is unique in that it is composed of maternal and fetal components separated by several cell layers that differ in structure and function among the mammalian species studied.[1] Although these two vascular beds are intimately associated with each other in all species, clearly they function independently of each other.[2-4] An understanding of the mechanisms that control their vascular tone and the magnitude of blood flow is important in that alterations in either the maternal or the fetal aspect of placental blood flow may potentially modify the delivery of oxygen or nutrients, or both, to the fetus, as well as affecting the removal of carbon dioxide and other fetal metabolic wastes.[5] Thus the integrity of the maternal uteroplacental and fetal umbilicoplacental vascular beds is essential to fetal growth and development, minute-to-minute fetal well-being, and possibly alterations in fetal programming and the subsequent occurrence of adult-onset cardiovascular disease.[6,7]

In view of the importance of the placental vascular beds to fetal well-being and survival of the species, research in this area has been intense since the time of Barcroft's research.[8] Because detailed studies in humans remain problematic and are generally descriptive, current understanding reflects in large part experimental findings in various animal models and, in particular, the pregnant ewe. Thus conclusions about the relative importance of the mechanisms responsible for the control of blood flow to these vascular beds in the human continue to require careful interpretation. Nonetheless, recent knowledge obtained from these models has been replicated in humans, providing an excellent basis for characterizing this important aspect of pregnancy and enabling improved interpretation of clinical data obtained in Doppler flow velocity studies in women.[9]

DEVELOPMENT OF THE UTEROPLACENTAL AND UMBILICOPLACENTAL VASCULAR BEDS

Although the placenta is of fetal origin and comprises solely fetal cells, its blood supply is derived from the maternal uterine and fetal umbilical vascular beds, the former serving as the source of placental and fetal oxygen and nutrients. Notably, both vascular beds undergo substantial independent modifications throughout pregnancy. For example, the maternal uterine vasculature undergoes remodeling.[10] and the fetal vasculature exhibits vasculogenesis, angiogenesis, and branching morphogenesis.[11] These changes are essential, occur in parallel, and contribute to the increasing requirements for oxygen and nutrient delivery necessary for the logarithmic fetal growth in the last third of pregnancy and the endocrine functions of the placenta. Understanding these independent yet parallel modifications will facilitate our knowledge of fetal growth and possibly the origins of some pregnancy-related diseases, for example, preeclampsia.

In women, the uteroplacental vascular bed is composed of cotyledons, lobes, or placentomes similar to those seen in many species.[1] In contrast with their counterparts in the sheep or cow, these structures adhere to each other, rather than existing as separate entities. Nonetheless, they can be identified as individual structures when viewed from the basal or maternal side of the placenta after its delivery. These placentomes receive their maternal arterial blood by way of the spiral arteries, and alterations in the tone of these or more proximal uterine arteries may be responsible for modifying the magnitude and distribution of maternal uteroplacental blood flow.[10,12] As in pregnant sheep, a fixed number of placentomes are ultimately available during normal human pregnancy. Therefore the increase in uteroplacental blood flow that occurs during pregnancy is initially due to the development of the placenta (i.e., implantation and growth) and vasodilation of the spiral arteries, allowing an increase in perfusion of the intravillous space.[13]

When maternal uteroplacental blood flow is examined throughout ovine gestation,[14] a complex scenario is observed.[12,13] Total uterine blood flow (Figure 12-1) increases approximately 40-fold during the course of a normal singleton pregnancy, and levels are even higher in multiple gestations. This increase in uteroplacental blood flow is coincident with a doubling of maternal cardiac output and an increase in the proportion of cardiac output directed to the uterus, increasing from less than 1% of cardiac output in nonpregnant sheep to 16% to 25% at term.[15] The pattern of this increase in total uterine blood flow (mL/minute) occurs in three phases (see Figure 12-1, *B*). The first is associated with relatively low absolute blood flows, which on the basis of uterine plus conceptus wet weight is actually high, achieving values of 0.8 mL/minute per gram, compared with 0.3 mL/minute per gram for the nonpregnant uterus (see Figure 12-1, *C*). This increase in uterine blood flow is thought to reflect vasodilation secondary to the increased production of maternal ovarian and possibly fetal hormones (e.g., estrogen, progesterone), which may be required for survival of the conceptus before implantation and the initial phase of implantation and placentation.[16,17] In primates and women, this occurs in the first days or weeks of pregnancy. The second phase is associated with the development of the placentomes and, in the primate, with the development of the intravillous spaces or the maternal placental vascular bed. At this time, the maternal placental vascular bed achieves its maximum size. If this does not occur, placentation may be restricted, resulting in a small placenta and a fetus characterized by proportionate growth restriction. In the ewe, total uterine blood flow plateaus at this time, averaging approximately 500 mL/minute; however, blood flow expressed on a weight basis at the same point in gestation, which takes into account metabolically active tissues, has fallen 50% to 0.3 to 0.4 mL/minute per gram, reflecting the ever-increasing weight of the fetus and placenta (see Figure 12-1, *C*). The final phase in the "growth" of uterine blood flow is exponential and associated with a threefold increase in fetal weight that occurs in the last third of pregnancy or after 110 days in sheep (75% of gestation) and beyond 30 weeks in humans (75%).[14] Because neither the total number of spiral arteries nor that of placentomes changes, this increase in uterine blood flow must be due to vasodilation.[13,14,17]

In more recent studies, this final vasodilation has been shown to involve increased activation of large-conductance

calcium-sensitive potassium channels (BK_{Ca}) in the uterine vascular smooth muscle and membrane hyperpolarization[18,19]; Although, the initiating events are unclear recent evidence suggests signaling involves nitric oxide synthase (NOS), nitric oxide (NO), cyclic guanosine monophosphate (cGMP), and cGMP-dependent protein kinase.[20] Moreover, similar mechanisms may also exist in women.[21] Of importance, the rise in blood flow in milliliters per minute is proportionate to and parallels the rise in wet weight of the uterus and its metabolically active tissues, which includes the growing fetus, membranes, and placenta. Thus blood flow per gram of wet weight remains low (0.2 to 0.3 mL/minute per gram) during the remainder of pregnancy. In the fetus with late-onset growth restriction (i.e., after 70% of gestation), blood flow per gram of fetoplacental mass is lower and nutrient and oxygen delivery is decreased. Fetal growth is attenuated until adaptation has occurred and this ratio is reestablished, at which time a new growth curve is established that lies below the curve for normally growing fetuses.

Although total uterine blood flow increases dramatically during pregnancy, this increase reflects changes in three separate vascular beds: the placentomes, endometrium, and myometrium. The change in distribution of blood flow to these tissues cannot be determined in women but has been studied in sheep and other species.[11,22] This limitation is an important issue because measurement of changes in total uterine blood flow in women will not reflect the issue of primary importance—that is, placental perfusion. As illustrated in Figure 12-2, blood flow to these three tissues is evenly distributed in the nonpregnant uterus, each receiving approximately one third. As pregnancy progresses, a gradual redistribution of uterine blood flow occurs, so that at term the placentomes (cotyledons) receive nearly 90% of total uterine blood flow. Thus, in the last third of pregnancy, the placentomes account for most of the observed increase in uterine blood flow.

Because the placentome is the site of nutrient and gas exchange, fetal well-being is determined by changes in placental growth and perfusion. Placental weight is relatively unchanged after the middle third of ovine gestation, yet maternal placental blood flow continues to increase (Figure 12-3). This discordance in placental growth and blood flow occurs earlier in pregnancy in women and other primates compared to sheep. The pattern of change in absolute blood flow (see Figure 12-3, *B*) resembles that seen for total uterine blood flow (see Figure 12-1, *B*). Because placental blood flow accounts for more than 65% of total uterine blood flow in the last third of pregnancy (see Figure 12-2), it is not surprising that the "patterns" are similar. The principal difference between the two patterns is obvious when blood flow per gram of metabolically active tissue is examined (see Figure 12-3, *C*). In contrast with the high value for total uterine blood flow early in pregnancy followed by a fall and leveling off, placental blood flow falls in midpregnancy and then increases until term. Thus placental blood flow rises from 0.5 to 1.0 mL/minute per gram to nearly 4 mL/minute per gram—a value five times greater than that observed for the total uterus. This increase in placental blood flow must reflect vasodilation, because no change occurs in either maternal arterial blood pressure (i.e., perfusion pressure) or in the number of maternal placental arteries.[11,13] The rise in maternal placental blood flow parallels a more general process of functional maturation of the placenta, which involves the simultaneous increase in fetoplacental perfusion[23] and permeability[24]; these physiologic changes are necessary to provide nutrients

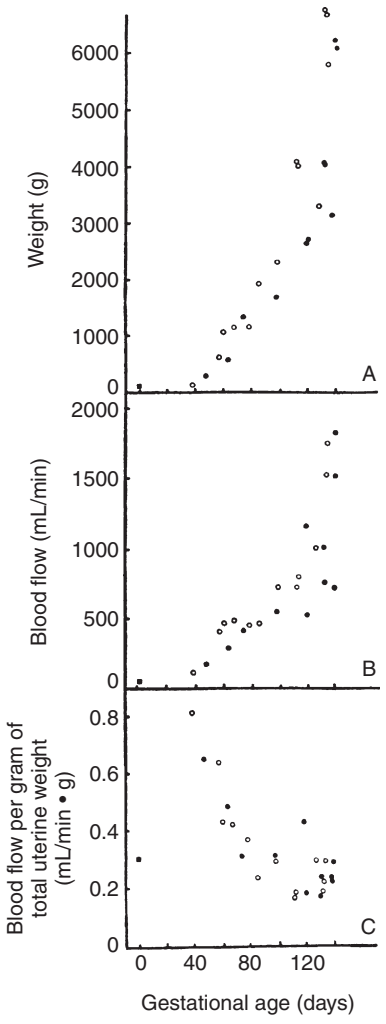

Figure 12-1 Changes in uterine weight **(A),** blood flow **(B),** and blood flow per gram of total uterine weight **(C)** during ovine pregnancy. Total weight is the sum of all metabolically active tissues. *Square,* nonpregnant; *open circle,* singleton pregnancy; *closed circle,* twin pregnancy. *(From Rosenfeld CR, Morriss FH Jr, Makowski EL, et al: Circulatory changes in the reproductive tissues of ewes during pregnancy,* Gynecol Invest *5:252, 1974.)*

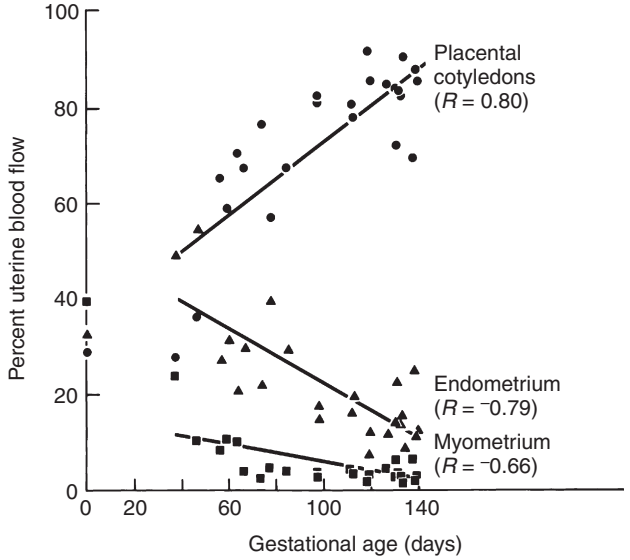

Figure 12-2 The distribution of uterine blood flow during ovine pregnancy (term = 145 days). Blood flow was determined using the microsphere technique. and oxygen for the rapidly growing fetus. Of note, the volume of placental blood flow exceeds that required for normal fetal growth,[4,5] thereby providing a "margin" of safety that protects the fetus from episodic decreases in uteroplacental blood flow associated with transient increases in maternal plasma levels of vasoconstrictors (e.g., angiotensin II [ANG II]) or occurring at the time of parturition, when increases in myometrial tone may alter placental perfusion.[13]

Although much has been learned about the functional and anatomic aspects of the maternal uteroplacental circulation, few investigators have tried to describe in detail the pattern of change in umbilicoplacental blood flow over the entire course of pregnancy.This limited effort reflects the difficulty in performing such studies even in an animal model. Nonetheless, many similarities exist between species. For example, a villous stem originating from the fetal side of the placenta contains a distal branch of the umbilical artery and vein.As pregnancy progresses, a villous tree (in the human) or vascular bed originating from this villous stem undergoes angiogenesis and branching morphogenesis throughout pregnancy, providing an ever-increasing fetal placental vascular bed with an enormous surface area for nutrient and gas exchange. Although the sheep has no villous tree, continued growth of the fetal placental vascular bed occurs as in the human.[1,11] In both species, therefore the size of the fetal placental vascular bed and the magnitude of umbilicoplacental blood flow increase, the latter increasing exponentially in the last third of normal pregnancy.[23] In contrast with the rise in uteroplacental blood flow, which reflects vasodilation, the rise in umbilicoplacental blood flow is due primarily to vascular growth and, to a lesser extent, vasodilation. Thus umbilicoplacental blood flow remains approximately 200 mL/minute per kg of fetal weight throughout gestation in most species. Conditions that attenuate the growth of the fetal placental vascular bed in the last trimester (e.g., pregnancy-induced hypertension) or increase fetal placental resistance may result in fetal growth restriction.Although this correlation is not well studied, Doppler technology has shown increases in umbilical artery resistance associated with decreased fetal growth.[22]

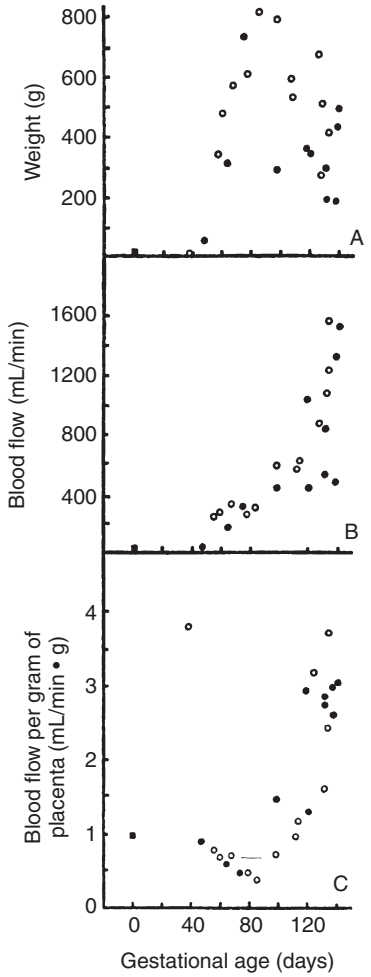

Figure 12-3 Changes in placental weight **(A),** blood flow **(B),** and blood flow per gram of placenta **(C)**. Observations on the nonpregnant animals represent the caruncles or future sites of implantation. Placental weight and blood flow in the twin gestations are the sum of the two placentas. Symbols are as noted in Figure 12-1. *(From Rosenfeld CR, Morriss FH Jr, Makowski EL, et al: Circulatory changes in the reproductive tissues of ewes during pregnancy,* Gynecol Invest *5:252, 1974.)*

VASOCONSTRICTORS

Studies of the factors controlling blood flow through the uteroplacental and umbilicoplacental vascular beds have centered on the effects of endogenous vasoconstrictors, including ANG II, catecholamines, and arginine vasopressin (AVP), a hypothalamic-pituitary peptide secreted during episodes of so-called fetal stress.This section reviews how these agents may affect placental perfusion and fetal well-being.

Normotensive pregnant women develop attenuated pressor responses to systemic infusions of ANG II early in the midtrimester, and this refractoriness is no longer evident in women in whom hypertension develops.[26,27] Pregnant sheep and several other species also exhibit refractoriness to this vasoconstrictor during pregnancy.[28,29] In pregnant women and sheep, the uteroplacental vascular bed is more refractory to Ang II than the systemic vasculature as a whole.[29-31] As in the peripheral vasculature, this uterine refractoriness also is absent in pregnant women in whom hypertension develops, possibly resulting in placental hypoperfusion.[31] This difference in sensitivity is evident when the dose-response curves depicting the relative changes in uterine and systemic vascular resistance are compared. As illustrated in Figure 12-4, at doses resulting in physiologic blood levels (less than 1.0 μg/minute), infusions of ANG II result in greater relative increases in systemic than in uterine vascular resistance. The rise in perfusion pressure also exceeds that of uterine vascular resistance; therefore uteroplacental blood flow increases throughout this dosage range.These observations suggest that the uteroplacental vascular bed is in a sense partially pressure-passive and, importantly, is protected from the vasoconstrictor effects of ANG II.[29] This protective mechanism is important because plasma ANG II levels rise in normal pregnancy and may intermittently increase further when pregnant women experience episodes of orthostatic hypotension. Notably, maternal placental blood flow is minimally affected, and the reproductive tissues as a group are more refractory than nonreproductive tissues.[32] The similarity in these responses to Ang II in women and sheep further validates the animal model as do the studies of BK_{Ca} function.[19-21]

This refractoriness of the uteroplacental circulation to Ang II may reflect several mechanisms. In earlier studies, uterine arteries from pregnant ewes demonstrated a three-fold rise in the basal synthesis of prostacyclin (i.e., prostaglandin I_2 [PGI_2]), a potent vasodilator and ANG II antagonist, and a further 1.5-fold increase in endothelium-derived PGI_2 synthesis when exposed to ANG II in vivo or in vitro by activating type 1 ANG II receptors.[29,33-35] Uterine arteries from normotensive pregnant women appear to respond similarly, whereas arteries from women with hypertensive disease appear to be unable to enhance PGI_2 synthesis in the presence of Ang II.[36] Because inhibition of cyclooxygenase activity

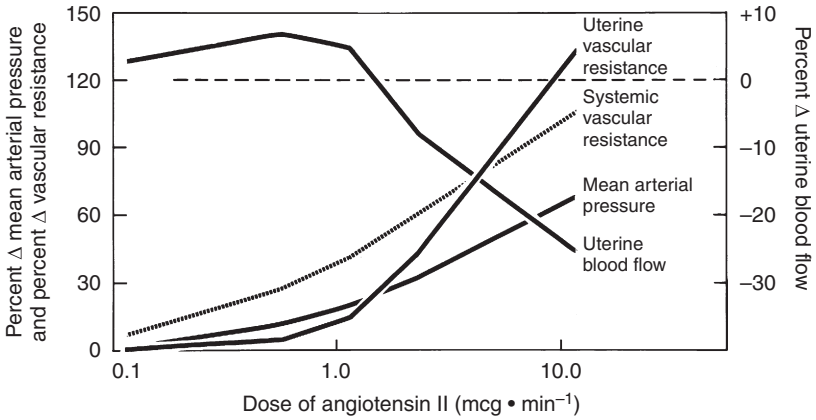

Figure 12-4 The relative changes in uterine blood flow, mean arterial pressure, systemic vascular resistance, and uterine vascular resistance during the systemic infusion of angiotensin II in pregnant sheep. *(From Rosenfeld CR: Consideration of the uteroplacental circulation in intrauterine growth,* Semin Perinatol *8:42, 1984.)*

in the uterine vascular bed of pregnant ewes decreased basal PGI_2 synthesis and enhanced constrictor responses to systemic ANG II infusions, it was believed this mechanism accounted for the attenuated uterine vasoconstrictor responses to ANG II.[35] This differential sensitivity to ANG II was not associated with down-regulation of ANG II receptors in uterine vascular smooth muscle. Of interest, however, it was observed that type 2 ANG II receptors, which do not mediate vasoconstriction, are predominant in uterine arteries from women and sheep.[29,34,37] Furthermore, uterine intraarterial infusions of ANG II did not increase vascular resistance except at doses that initiated pressor responses before uterine responses, the pattern seen with systemic infusions.[38] It now appears that the attenuated uteroplacental responses to ANG II reflect primarily type 2 receptor expression in the uterine vascular smooth muscle. Moreover, ANG II may exert its effect on uterine blood flow by activating local, systemic, or central adrenergic mechanisms and by the release of an α-agonist, which is antagonized by local PGI_2 synthesis.[29,38,39] In addition, the type 2 receptor may directly attenuate type 1 receptor signaling and activation.[40] Uteroplacental synthesis of endothelium-derived NO, which increases in pregnancy and increases further with ANG II, provides another route for attenuating responses to ANG II.[29,41] Thus several local mechanisms may contribute to the maintenance of uteroplacental blood flow while permitting adjustments in the peripheral vascular beds during increases in plasma levels of endogenous ANG II in pregnant women. Modification of these agonist-antagonist interactions may occur in hypertensive pregnancies, resulting in uteroplacental hypoperfusion and eventually fetal growth restriction.

The pressor responses to infused catecholamines, epinephrine, and norepinephrine, also are attenuated during normal pregnancy[42] and are increased in hypertensive pregnant women.[26] The uteroplacental vascular responses to α-agonists, in contrast with such responses to ANG II, exceed those seen in the systemic vasculature[42]; that is, increases in uterine vascular resistance exceed simultaneous increases in systemic vascular resistance and perfusion pressure at all doses of infused α-agonists (Figure 12-5). These changes result in a fall in uterine blood flow at doses of α-agonists that minimally alter maternal blood pressure (see Figure 12-6) and are paralleled by decreases in placental blood flow. Thus the maternal uteroplacental vascular bed is less protected from endogenous α-agonists than from ANG II. These differences are physiologically relevant. For example, it would be senseless to put the fetus at risk for placental hypoperfusion and decreased uterine oxygen delivery each time the pregnant woman rises from the supine position to standing and increases her plasma levels of Ang II. By contrast, in circumstances in which the mother's survival is at risk (e.g., from hemorrhage) and adrenal production and secretion of catecholamines are increased, it is physiologically sound to divert a significant proportion of the

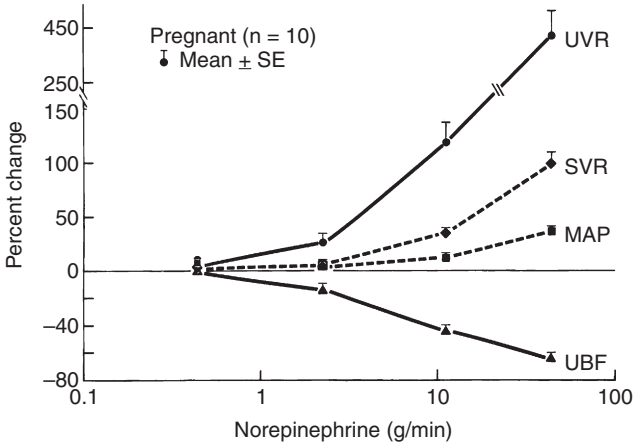

Figure 12-5 The relative changes in uterine blood flow *(UBF),* mean arterial pressure *(MAP),* systemic vascular resistance *(SVR),* and uterine vascular resistance *(UVR)* during the systemic infusion of norepinephrine in pregnant sheep. *(From Magness RR, Rosenfeld CR: Systemic and uterine responses to α-adrenergic stimulation in pregnant and nonpregnant ewes,* Am J Obstet Gynecol *155:897, 1986.)*

excessive volume of uteroplacental blood flow to tissues more relevant to maternal survival. During labor, however, circulating catecholamine levels are elevated, and this enhanced responsiveness of the placental arteries to catecholamines can potentially endanger the growth-restricted fetus or a normally grown fetus with a borderline "margin of safety" by decreasing uterine oxygen delivery to dangerous levels, resulting in fetal heart rate decelerations. This phenomenon has been noted in Doppler ultrasound studies.[9] In studies of human uterine arteries[21] and preliminary studies in intact pregnant sheep, the BK_{Ca} channel that modulates basal uterine blood flow also modifies uterine responses to α-agonists. Thus abnormalities of BK_{Ca} function or expression may contribute to abnormal placental perfusion and increased sensitivity to α-agonists as seen in hypertensive women.[43,44]

ANG II is a potent vasoconstrictor in the umbilicoplacental circulation.[45,46] It was previously thought that the fetus was more refractory than the pregnant mother to the effects of Ang II, resulting in the greater circulating levels in the fetus.[47] Of note, however, fetal clearance of ANG II is 10-fold greater than that in the mother, 95% of fetal clearance occurs across the placental vascular bed, and the umbilicoplacental vasculature is more sensitive to the vasoconstricting effects of this peptide than the uteroplacental circulation at similar plasma levels of ANG II

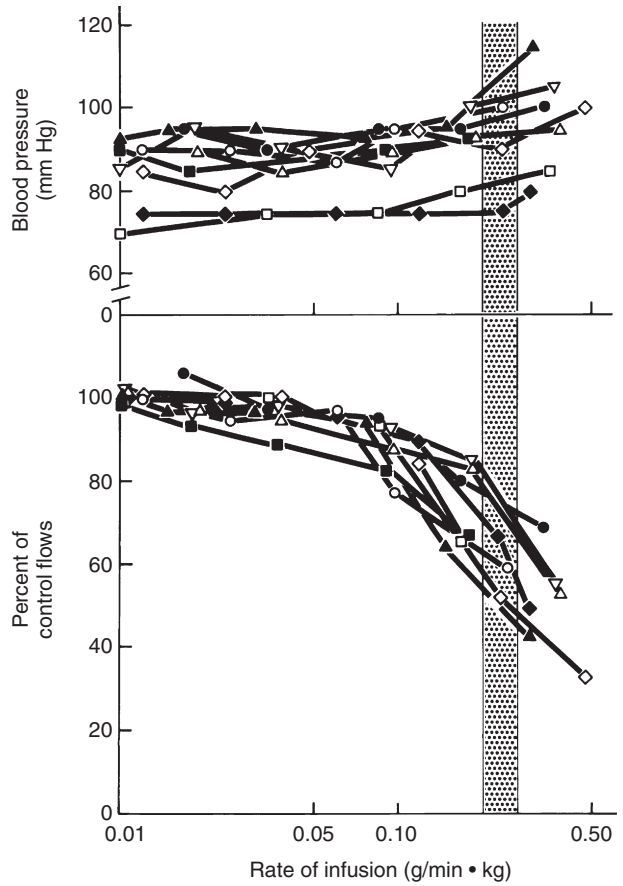

Figure 12-6 Responses of uterine blood flow and mean arterial pressure to increasing doses of norepinephrine. Uterine blood flow is represented as percentage of control flows. Different symbols represent responses of separate animals. *(From Rosenfeld CR, West J: Circulatory response to systemic infusion of norepinephrine in the pregnant ewe,* Am J Obstet Gynecol *127:376, 1977.)*

(Figure 12-7).[47] This difference between the umbilicoplacental and uteroplacental responses is explained by the predominance of type 1 ANG II receptors in the former and type 2 receptors in the latter in humans and sheep.[34,37,48-51] Furthermore, the umbilical artery smooth muscle demonstrates precocious functional maturation compared with fetal systemic arteries,[52] which express primarily the type 2 receptor.[48] By contrast, catecholamines minimally alter umbilicoplacental blood flow except at nonphysiologic doses,[53,54] and these decreases in placental perfusion may reflect a fall in fetal cardiac output, rather than increases in placental vascular resistance. Thus fetal responses to catecholamines are associated with the maintenance of umbilicoplacental perfusion as well as cerebral and myocardial blood flow. In fetal sheep, ANG II–induced modifications in arterial pressure are due primarily to increases in umbilicoplacental resistance mediated by type 1 receptors.[48,55,56]

AVP is a hypothalamic-pituitary hormone that exhibits increased secretion during episodes of intrauterine hypoxia and asphyxia.[57,58] As with adrenal catecholamines, which mediate the primary fetal responses to intrauterine "stress," umbilicoplacental perfusion is not affected substantially by AVP.[57] Thus the maternal and the fetal placental vascular beds respond differently to endogenous vasoconstrictors, probably reflecting important mechanisms necessary to ensure adequate fetal oxygen delivery and the survival of the fetus or the mother.

PROSTAGLANDINS

Interest has been considerable in the role of prostanoids in the regulation of uteroplacental and umbilicoplacental blood flows. This interest stems from observations of increased circulating levels of prostanoids, especially vasodilating prostanoids, in normotensive pregnant women and animals.[59,60] In addition, systemic and local infusion of cyclooxygenase inhibitors in pregnant sheep increases systemic and uterine responses to infused ANG II.[35] Furthermore, women with pregnancy-induced hypertension exhibit plasma levels of thromboxane (a potent vasoconstrictor) that exceed those of PGI_2, potentially accounting for the increased vascular reactivity seen in these women.[59] Because circulating PGI_2 and thromboxane may be of placental origin, these and other prostanoids could

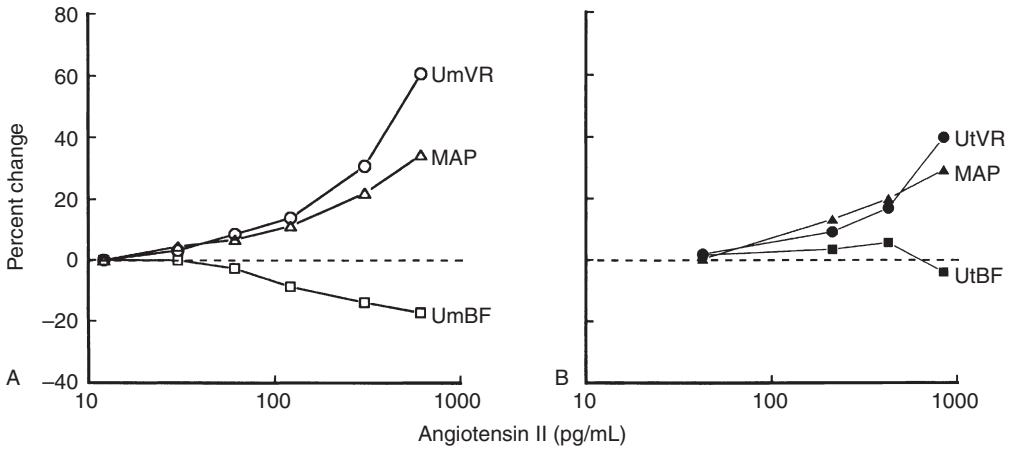

Figure 12-7 Comparison of the relative changes in blood flow, mean arterial pressure *(MAP),* and vascular resistance versus plasma levels of angiotensin II in the umbilicoplacental **(A)** and maternal uteroplacental **(B)** vascular beds during systemic infusions of angiotensin II. *UmBF,* Umbilical blood flow; *UmVR,* umbilical vascular resistence; *UtBF,* uterine blood flow, *UtVR,* uterine vascular resistence. *(From Rosenfeld CR, Gresores A, Roy TA, Magness RR: Comparison of ANG II in fetal and pregnant sheep: Metabolic clearance and vascular reactivity,* Am J Physiol *268:E237, 1995.)*

modulate the peripheral and uterine circulations in normotensive and hypertensive pregnant women. This view remains controversial, however. First, prostanoids may not be circulating hormones but rather mediate their effects through paracrine mechanisms. Thus plasma levels probably provide little physiologic information. Second, increases in vessel perfusion or shear stress increase vascular production of PGI_2.[61] The rise in placental blood flow seen in normal pregnancy, therefore, may be due to another mechanism, and the increase in prostanoid synthesis may be secondary. Third, although cyclooxygenase inhibition enhances systemic and uterine vascular responsiveness in pregnant women and sheep, this effect does not alter basal uteroplacental blood flow commensurate with the fall in plasma prostaglandin levels.[35,62] Finally, pregnancy-induced hypertension is not ameliorated or prevented by low-dose aspirin therapy.[63] This evidence suggests that prostanoids may be a class of stress hormones that antagonize the vascular responses to circulating placental vasoconstrictors, thereby protecting maternal uterine blood flow.

Similar controversy exists regarding the role of prostaglandins in the fetal compartment. PGI_2 is a potent placental vasodilator, whereas prostaglandin E_2 (PGE_2) is a vasoconstrictor (versus a vasodilator in the maternal placental circulation). The physiologic role of these two prostanoids, however, is unclear. It has been suggested that the differential effects of PGE_2 in the two placental vascular beds may act to autoregulate the two beds so that when umbilicoplacental blood flow falls, maternal placental perfusion increases to maintain fetal oxygen uptake and delivery.[64] More recently, it has been suggested that PGE_2 may potentiate the vasoconstriction seen with Ang II, whereas PGI_2 antagonizes these effects. These conclusions require further study.

NITRIC OXIDE

An endothelium-derived relaxing factor (i.e., not a prostanoid) has been identified and shown to induce vascular relaxation by activating smooth muscle guanylate cyclase and the synthesis of cGMP. This substance, NO, is the product of at least three isoforms of NOS expressed in endothelium and vascular smooth muscle. NO synthesis is increased in normotensive pregnancies and may contribute to normal cardiovascular adaptation and increased cGMP synthesis.[64] Furthermore, prolonged administration of an NOS inhibitor to the mother causes hypertension and leads to decreased cGMP levels. Marked increases in uterine venous cGMP and uterine cGMP synthesis occur in pregnant sheep, suggesting that NO may be essential to the regulation of uteroplacental blood flow.[65] Although uterine artery synthesis of NO increases in pregnancy, it is unclear what proportion of uterine cGMP synthesis is vascular versus placental or nonvascular.[64,66] Furthermore, the role of NO in the regulation of uteroplacental blood flow is unclear in view of the fact that NOS inhibition decreases uteroplacental perfusion no more than 25%.[65,67] Whereas studies of NO have focused on the role of endothelium-derived type 3 NOS, recent studies demonstrate type 1 NOS expression in uterine artery smooth muscle.[68] Its role in pregnancy is unstudied to date.

Studies of the role of NO in the regulation of umbilicoplacental blood flow are extensive, but it also is unclear to what extent NO is responsible.[64] Perfused human umbilical arteries and veins release more NO than PGI_2.[69] Inhibition of NOS increases umbilicoplacental vascular resistance in vitro and, in intact fetal sheep, results in a nearly 50% fall in umbilical blood flow.[70] Increases in NO generation also attenuate constrictor responses to several agonists. Thus NO may play an important role in both maintaining and modulating umbilicoplacental blood flow. Because inhibition of NOS does not decrease blood flow completely, NO contributes to but is not totally responsible for maintaining umbilicoplacental perfusion. Of note, potassium channels also are expressed in umbilical arteries.[71] At present, their role in umbilicoplacental blood flow is under study.

STEROID HORMONES

The placenta is a major site of synthesis of maternal and fetal steroid hormones, in particular, estrogen and progesterone. These hormones have profound vascular effects and may play important roles in promoting implantation and placentation[17] and modulating placental blood flow and other aspects of maternal cardiovascular adaptation during pregnancy. Unfortunately, few investigators have examined the role of these hormones on umbilicoplacental blood flow. In sheep, estrogen vasodilates the nonpregnant (increasing blood flow 10- to 15-fold) and pregnant uterus (increasing blood flow by 40% to 50%).[72] Furthermore, infusion of dehydroepiandrosterone (the fetal adrenal androgen precursor necessary for placental estrogen synthesis) to the fetus or the ewe increases placental estrogen production and uteroplacental blood flow.[72] No other naturally occurring substance has an effect of this magnitude on uterine or uteroplacental perfusion. Because the rise in uterine blood flow occurs in the absence of a change in perfusion pressure,[73] this phenomenon represents true vasodilation. Progesterone may antagonize and modulate these effects of estrogen. Thus the two steroids may coregulate the magnitude of maternal uteroplacental blood flow. The effects of estrogen on uterine blood flow are receptor-mediated and involve activation and transcriptional regulation of type 1 and type 3 NOS,[68,74] resulting in increased NO synthesis, increases in smooth muscle cGMP, activation of a cGMP-dependent protein kinase, and finally, phosphorylation and activation of BK_{Ca} in uterine artery smooth muscle in nonpregnant and pregnant sheep.[18,75] This potassium channel also modulates basal uteroplacental blood flow and may attenuate vasoconstrictor responses during pregnancy.[18,19] Of note, estrogen also regulates BK_{Ca} subunit expression in the uterine artery and can directly activate the channel.[76] Studies are under way to assess these effects in human uterine arteries, which may lead to the development of strategies for treating placental hypoperfusion in the future.

13 Pathophysiology of Preterm Birth

Shankari Arulkumaran and Phillip R. Bennett

EPIDEMIOLOGY

Preterm birth refers to birth before 37 weeks of gestation. It accounts for 6% to 10% of all births in Western countries and more than two thirds of all perinatal deaths. Preterm birth may result from preterm labor, spontaneous or induced, or may be by planned cesarean section for maternal or fetal complications.[1] In recent estimates, up to 30% to 40% of all cases are induced or elective, and the remaining 60% to 70% occur spontaneously.[2] Epidemiologic studies of preterm labor vary in terms of categorization, but generally, labor before 24 weeks is considered previable; before 28 weeks, extremely preterm; at 28 to 31 weeks, very preterm; and at 32 to 36 weeks, mildly preterm.[3] Gross outcomes after 34 weeks generally are considered to be as good as those after 37 weeks gestation, although the risk of minor morbidity remains.[4] It is the 3% to 7% of preterm births that occur before 34 weeks gestation that account for approximately 75% of neonatal deaths and 50% of cases of long-term neurologic impairment in children.[2]

Risk factors for preterm labor include race, age, socioeconomic status, and body mass index (BMI).[1] In the United Kingdom, the risk of preterm birth is 6% in white Europeans but 10% in Africans or Afro-Caribbeans.[5] Similarly, African American women are overrepresented in the population of women experiencing preterm birth in the United States. Lower socioeconomic status in such groups and other minority groups adds environmental causes to the plausible genetic causes of preterm birth (e.g., polymorphisms in tumor necrosis factor-α [TNF-α] a proinflammatory cytokine).[6,7] Other environmental causes include inadequate nutrition, substance abuse, and psychosocial factors.[1]

A strong association with preterm birth with a low BMI, poor weight gain, or excess weight gain and obesity was reported in eight primary studies of 122,647 women.[8] Alcohol consumption, smoking, and cocaine exposure all increase the risk of preterm birth. Dose-response effects have been described with alcohol consumption in various European studies, as well as increased risk from low to moderate and heavy smoking.[9,10] Studies from the United States confirm increased risk with cocaine exposure and other psychiatric and substance use disorders.[11,12] Maternal stress may increase susceptibility to preterm labor. Maternal stress may act by way of a neuroendocrine pathway that activates the maternal-placental-fetal endocrine systems that promote parturition by way of an immune or inflammatory pathway.[13] Elucidation of the complex interactions among maternal demographics, environmental exposures, and genetic susceptibility of mother and fetus requires a coordinated research approach that brings together the disciplines of epidemiology, laboratory-based science, and clinical trials for the best hope of significant advances in understanding preterm birth.[1]

Endocrinology and Biochemistry of Labor

Predicting, diagnosing, and managing preterm labor all remain challenging, because despite extensive research, the mechanisms that control the duration of human pregnancy and that signal the onset of labor have not yet been fully determined. Throughout pregnancy, the uterine cervix needs to remain firm and closed while the body of the uterus grows by hypertrophy and hyperplasia yet remaining quiescent.[5] During pregnancy, "propregnancy" factors such as progesterone and prostacyclin (i.e., prostaglandin I_2 [PGI_2]) inhibit myometrial contractility. Parturition involves a synchronization of changes in the structure of the cervix, myometrial activity manifesting as painful uterine contractions, and ruptured fetal membranes leading to cervical dilation and effacement. At the end of the pregnancy, "prolabor" factors begin to mediate remodeling of the cervix, and the uterus is stimulated to begin coordinated contractions.[14] It has been suggested that labor results from the activation of a so-called cassette of contraction-associated proteins (CAPs), which include gap junction proteins, oxytocin and prostanoid receptors, enzymes for prostaglandin synthesis, and cell signaling proteins. The term *labor-associated proteins* may be more appropriate, because these also are responsible for activating fetal membrane prostaglandin and cytokine production, as well as for cervical remodeling and ripening.[15]

Inflammation

Inflammation is now considered to be integral to the pathophysiologic processes underlying preterm labor. Microarray and suppression-subtractive hybridization studies have demonstrated an up-regulation of a vast number of proinflammatory genes in fetal membranes, myometrium, and the cervix with the onset of labor.[16] Such up-regulation is demonstrated by an influx of inflammatory cells into the uterus and increased expression of proinflammatory cytokines.[17] The transcription factor nuclear factor kappa B (NF-κB), which is activated within the uterus at the time of labor, regulates a number of inflammatory factors, including the interleukins IL-6 and IL-8 and cyclooxygenase-2 (COX-2), which leads to prostaglandin synthesis.[18] At term, this inflammatory-type response may be triggered by the maturing fetal lung, which produces increased surfactant lipid and protein (i.e., surfactant protein A [SP-A]). This response is associated with the activation of macrophages in the amniotic fluid and an increased inflammatory response in the uterus.[19]

Corticotropin-Releasing Hormone

Corticotropin-releasing hormone (CRH) is a peptide produced by the hypothalamus in response to stress. CRH also is expressed abundantly in the placenta, and in maternal serum, CRH has been shown to rise in the second half of pregnancy, peak during labor, and rapidly decline post partum. In patients who have gone on to deliver prematurely, elevated levels of CRH in the maternal circulation have been identified as early as 18 weeks of gestation.[20] The curve depicting the CRH increase is shifted to the left in women who subsequently deliver preterm and to the right in women who deliver post dates. This finding suggests that CRH production is linked to a placental "clock" that determines the length of gestation.[21] Presumably, then, maternal plasma CRH concentrations could help identify women at high risk for preterm delivery, and CRH antagonists may be useful in preventing preterm labor.[22]

Progesterone

Progesterone is thought to act during pregnancy to inhibit labor-associated gene expression and inhibit contractions. Unlike those in mammalian counterparts, levels of human circulating progesterone and progesterone receptors (PRs) in the myometrium do not fall with the onset of labor. In clinical practice, however, the administration of a PR antagonist RU486 can be used to ripen the cervix and induce labor. In the absence of a demonstrable fall in progesterone concentrations, a functional progesterone withdrawal may precede the onset of labor. This diminished activity could be due to alterations in the different PR levels or isoforms[23]—specifically, a reduction in myometrial responsiveness to progesterone by an increased expression of PR-A relative to PR-B.[24] It also may be due to the interaction between NF-κB and PR or changes in PR coactivator and corepressor expression.

Nuclear Factor-κB

NF-κB is a cytokine-inducible transcription factor, activated in response to infection and proinflammatory cytokines, that regulates many proinflammatory and labor-associated genes.[25] In most cells, NF-κB exists in an inactive form in the cytoplasm, bound to an inhibitory protein, such as IκBα.

Three distinct NF-κB signaling pathways have been identified to date.[14] Labor is associated with an increase in the baseline level of NF-κB DNA binding and transcriptional activity in the human amnion, and because NF-κB down-regulates progesterone receptor function, it seems to be related to a "functional progesterone withdrawal" in the human myometrium.[26]

Prostaglandins and Cyclooxygenases

Prostaglandins are derived from arachidonic acid (AA) by means of a pathway that starts with the mobilization of AA from membrane phospholipids by phospholipase enzymes. The next step is a reaction catalyzed by the cyclooxygenase (COX) enzyme, whereby free AA is converted to the prostaglandin intermediate PGH_2. Finally, PGH_2 is converted to PGE_2, $PGF_{2\alpha}$, PGD_2, prostacyclin, and thromboxane by specific synthase enzymes. Sufficient AA is present in the amniotic fluid and intrauterine tissues for prostaglandin synthesis to occur before the onset of labor. It is the COX enzyme, however, that mediates the committing and rate-limiting step of prostaglandin synthesis.[27,28]

The three known isoforms of the COX enzyme are COX-1, COX-2, and COX-3. COX-1 is constitutively expressed in various tissue types, and its expression generally is not regulated. COX-2, however, is up-regulated only after stimulation by cytokines, growth factors, and phorbol esters. Similarly, in intrauterine tissues at term (before and during labor), COX-2 messenger RNA (mRNA) and protein levels have been shown to increase. Thus the current evidence more strongly supports the involvement of COX-2, rather than COX-1, in the onset of labor.[29]

Interleukin-8

IL-8 is a chemokine that is produced by human endometrium, choriodecidua, and myometrium. IL-8 plays an important role in cervical ripening, probably aids in the formation of the lower segment of the uterus in late pregnancy, and mediates the influx of inflammatory mediators, specifically leukocytes, seen in the myometrium during labor.[27]

Oxytocin

Oxytocin (OT) is a nonapeptide, produced by the posterior pituitary, that is known to have a potent contractile activity in the pregnant uterus. It does not seem to be essential for normal parturition, however, because no increase in circulating oxytocin in the mother or fetus occurs with the onset of or during labor. Moreover, normal parturition has been observed in cases of clinical pituitary gland dysfunction.[30] The expression of the oxytocin receptor (OTR), however, does increase in the pregnant uterus. An up-regulation by two orders of magnitude has been demonstrated, leading to a strong increase in sensitivity to OT.[31] Comparable increases in OTR mRNA concentrations in the myometrium are associated with this up-regulation of OT-binding sites.[32] After delivery, myometrial OT-binding sites rapidly decrease, whereas OTR expression remains high in the mammary gland throughout lactation.[31]

In many animal models, OTR is regulated by changes in steroid hormone concentrations.[33] In humans, the lack of marked changes in estrogen concentrations or with progesterone withdrawal suggests that OTR has a more complex regulation.[34] Additional relationships in the OTR system have been demonstrated, in particular with prostaglandins. Treatment with naproxen, a prostaglandin synthesis inhibitor, resulted in a dramatic decrease in OTR in the rat uterus at term. Administration of $PGF_{2\alpha}$ restored the increase in OTR, implying the possibility of a positive feedback loop between prostaglandins and OTR.[35]

Myometrial Contractility

The basic functional unit of the myometrium is the smooth muscle cell, which is in turn arranged into bundles approximately 300 ± 100 μm in diameter. Each bundle is surrounded by connective tissue interspersed with microvasculature. The bundles are further organized into fasciculi, which are covered by a dense collagen matrix and the major vasculature of the myometrium.[36] This arrangement enables the uterus to generate an expulsive force dependent on the orientation of these fibers relative to the cervix. Uterine contractions are then initiated by the propagation of action potentials within these defined vectors of muscle bundles.[37] The intracellular basis for contraction is via the cyclic attachment and detachment of crossbridges between myosin and actin filaments, triggered by activation of the regulatory 20-kDa chain of myosin molecules. Myosin light chain is activated by phosphorylation by myosin light chain kinase, which in turn is activated by calmodulin.[38] It is through the actions of calmodulin that during an action potential, the calcium influx can be connected with a contraction—a process known as excitation-contraction coupling.[37] Once the uterus has been activated, the myometrium is susceptible to stimulation by a number of different agonists, primarily prostaglandins and oxytocin.

CAUSES OF PRETERM LABOR

Common associations with the onset of premature labor in the human are intrauterine infection, placental abruption, cervical incompetence, premature membrane rupture, multiple pregnancy, intrauterine death, fetal and uterine abnormalities, and chorioamnionitis. In many cases, however, no discernible underlying pathologic process can be identified.[37] Although current antenatal screening relies on overt clinical and environmental signs and symptoms, the clustering of instances of preterm labor within families and recurrence in susceptible women together present the case for investigating a possible underlying genetic predisposition.[39]

Infection

A strong correlation has been found between infection within the uterus and the onset of spontaneous preterm labor. Infection has the potential to activate all of the biochemical pathways, ultimately leading to cervical ripening and uterine contractions—even more so in a cervix that may be shortened or weakened.

The bacterial species identified in a majority of cases of congenital infections usually is identical to that in the maternal lower genital tract. After twin preterm delivery, chorioamnionitis is more common and severe in the presenting twin than in the second twin. These factors all suggest that ascending infection from the lower genital tract is the most common pathomechanism for chorioamnionitis.[5]

A more recent hypothesis implicates chronic periodontal disease, with the infected gum tissue acting as a reservoir for bacterial products or inflammatory mediators that play a role in the development of preterm labor.[40] Moderate to severe periodontal disease identified in the antenatal period is associated with an increased risk for preterm delivery, as is periodontal disease progression.[40] More than six causative pathogens have been identified, including *Prevotella* and *Porphyromomas* species.[41]

Chorioamnionitis

Chorioamnionitis usually starts with overgrowth of potential pathogens in the maternal lower genital tract, followed by the presence of the organisms in the uterine cavity, particularly in the decidua of the lower segment. A localized inflammatory reaction then occurs, leading to deciduitis, chorionitis, and extension through the amnion into the amniotic cavity, before eventuating in infection of the fetus itself from aspiration and swallowing of infected amniotic fluid.[42] The most common microbial isolates from the amniotic cavity of women in preterm labor are *Ureaplasma urealyticum, Fusobacterium,* and *Mycoplasma hominis.* Bacterial vaginosis and *Trichomonas vaginalis* are the two most-studied organisms associated with preterm birth.[43] Of note, screening for and diagnosis of bacterial vaginosis do not seem to mitigate the increased risk of preterm birth.[44]

Abruption

Placental abruption may lead to the onset of preterm labor through release of thrombin, which stimulates myometrial contractions by protease-activated receptors. This effect may explain the clinical impression that preterm labor associated with chorioamnionitis often is rapid, whereas that associated with placental abruption is less so, because with placental abruption, no preripening of the uterine cervix has time to occur. Generation of thrombin also may play a role in preterm labor associated with chorioamnionitis, when it is released as a consequence of decidual hemorrhage.[5]

Cervical Incompetence

The cervix maintains the fetus in situ during pregnancy and dilates during labor to allow delivery of the baby. This distal component of the uterus is composed primarily of connective tissue, of which a major portion is collagen arranged in fibers and embedded in proteoglycans. Other components include a small amount of smooth muscle (10%) and some fibroblast cells.[45] Before onset of and during early labor, the biochemical makeup of the cervix changes, so that it becomes softer (i.e., "ripens"), allowing for dilation. These biochemical changes include a decrease in collagen associated with an increase in cervical prostaglandins, proinflammatory cytokines, leukocytes, cell adhesion molecules, and nitric oxide synthase production.[46]

Classic cervical incompetence may be diagnosed in women who have an inherent weakness in the cervix or those in whom the cervix has been compromised as a result of previous medical or surgical treatments. Such treatments include mechanical cervical dilation at the time of a termination of pregnancy and surgical evacuation of products of conception. During treatment for cervical neoplasia, destruction of cervical tissue can result from laser treatment or biopsy; in the case of cervical carcinoma, the entire cervix may be removed (i.e., trachelectomy). It is now recognized that "cervical competence" represents a continuum. In a woman with a shortened or damaged cervix, bacteria may ascend into the lower segment of the uterus and stimulate an inflammatory response, which itself leads to further cervical shortening and dilation in a vicious circle, ending with additional cervical dilation and then labor. The same syndrome may be seen when the cervix is of normal length but the microbiologic burden is heavy. Variations in microbiologic burden may lead to delivery at different gestational ages in different pregnancies in the same woman.

Multiple Pregnancies

The rate of preterm labor is high in clinical conditions such as multiple pregnancies and polyhydramnios that are associated with uterine stretch. Overdistention of the uterus leads to premature up-regulation of contraction-associated proteins that mediate cervical ripening. Studies in sheep have shown that stretch increases myometrial expression of OTR and COX-2,[47] whereas in human models, stretch of myometrial and amnion epithelial cells has been shown to increase the expression of COX-2 and PGE_2 synthesis.[48] In addition, multiple pregnancies are associated with multiple placentas and a consequent earlier rise in placental CRH concentrations in the circulation and, subsequently, higher rates of preterm birth.[5]

Genetics

The most consistent risk factor identified in women who experience preterm labor is a previous pregnancy resulting in preterm birth. Most studies quote a risk of 15% to 18% with one previous preterm birth and 28% to 32% with two previous preterm deliveries.[49,50] On the basis of these data, a previous preterm birth has been suggested as evidence of a genetic basis for preterm labor. This explanation is problematic, however, because preterm labor is a complex syndrome involving various etiologic disorders and masked by multiple confounding environmental risk factors. To date, a single-gene determinant for preterm labor inherited in a conventional mendelian manner has not been identified. Instead, it is generally accepted that susceptibility to preterm labor is governed by multigene effects[39] These effects would regulate inflammatory, uteroplacental, endocrine, uterine contraction and remodeling, and metabolic pathways.[51]

Matrix metalloproteinases (MMPs) are proteolytic enzymes that cause extracellular matrix degredation and are associated with tissue destruction and remodeling. In preterm labor, activation is a cytokine-mediated inflammatory process, resulting in the rupture of fetal membranes and cervical ripening and dilation. Single-nucleotide polymorphisms (SNPs), which may regulate MMP expression and activity, have been studied. At present, a vast number of polymorphisms have been identified in these proteases and their tissue inhibitors.[39,52] In addition to SNPs, complementary analytic approaches such as microarray technology and chip arrays have been used to investigate the susceptibility to preterm labor.[53] Once these genetic polymorphisms can be clearly related to physiologic effects, recognition of individual predisposition to preterm labor may enable a more targeted approach to preventive care.

PREDICTION OF PRETERM LABOR

Because precise disease mechanisms underlying preterm birth are not well understood, clinical predictive tests and preventive treatments remain limited. Nevertheless, if women who are at high risk for spontaneous preterm birth in early pregnancy can be identified, they may be targeted for more intensive antenatal care and prophylactic interventions. Determination of a history of previous preterm birth, second-trimester loss, or induced

abortion is a noninvasive, simple, cost-effective method to identify women who may benefit from more and intensive screening. Further assessment can be accomplished using ultrasonographic cervical length measurement, cervical-vaginal fetal fibronectin screening, and the detection of uterine contractions.

Fetal Fibronectin

Fetal fibronectin is an extracellular matrix found in the deciduas basalis next to the placental intervillous space. It helps to attach the fetal membranes to the uterine decidua and, when mechanical or inflammatory changes occur, is leaked into the cervicovaginal fluid. It can be measured quantitatively in cervicovaginal secretions obtained from the posterior fornix during a speculum-assisted internal examination.

A commercial kit for use in the clinic, which gives a positive result when concentrations are greater than 50 ng/mL, is now available. At present, it is widely accepted as a good test for excluding preterm birth in those presenting with threatened preterm labor on the basis of its strong negative predictive value: 0.5% deliver within 7 to 10 days after a negative test result.[54] Of note, however, this is the test for which a positive result is associated with the greatest odds ratio for preterm delivery before 35 weeks gestation.[55]

Cervical Length Measurement

Ultrasonographic cervical length measurement is a reproducible method of assessing the cervix, with little inter- and intraobserver error.[56] A transvaginal probe is used to determine the length between the internal and the external os. The risk of preterm delivery increases exponentially with decreasing length, from less than 1% at 30 mm to 80% at 5 mm.[57] Among women with symptoms of preterm labor, it is estimated that 50% of those with a cervical length less than 15 mm deliver within 7 days.[58]

PREVENTION OF PRETERM LABOR

Cerclage

If preterm labor does occur secondary to cervical incompetence, inserting a suture around the cervix is commonly used to increase mechanical strength to the cervix, thereby preventing premature opening in a subsequent pregnancy. Two approaches to the cerclage procedure are used: abdominal and vaginal. In the *vaginal* approach, the McDonald or Shirodkar method may be employed. The McDonald approach involves a suture or tape placed around the cervix at the junction between the vagina and the cervix. In the Shirodkar suture, the supravaginal cervix is incised and the bladder is reflected upward, allowing the suture to be placed at the cervicoisthmic junction. The cervical epithelium is then repaired.[46]

The most common indication for an *abdominal* cerclage is a failed vaginal cerclage. This more extensive procedure requires a transverse incision in the lower abdomen and the peritoneum over the cervix and bladder, to be deflected down, to allow placement of a suture above the cardinal and uterosacral ligaments.[59] A cesarean section is required to deliver the baby, and the suture often is not removed, unlike with vaginal cerclage, in which removal at 37 to 38 weeks gestation is needed to enable vaginal delivery of the baby. Abdominal cervical cerclage also may be performed laparoscopically, although published data currently are limited to isolated case reports.

Although cervical cerclage is widely used in clinical practice, evidence on its efficacy is still limited—regarding whether it is beneficial once cervical shortening has occurred and the amount or degree of shortening warranting intervention.[59] An international multicenter trial conducted by the Medical Research Council and the Royal College of Obstetricians and Gynaecologists recruited 1292 women with a history of early delivery or previous cervical surgery. In this study, 25 women needed to be treated to prevent one preterm delivery, with no benefit to the neonate. In women with three or more second-trimester losses, however, placement of a cervical suture halved the incidence of preterm delivery before 33 weeks, and in such cases a cervical cerclage was recommended.[60]

Progesterone

Progesterone is a propregnancy hormone, and withdrawal in many animal models leads to onset of labor. In humans, a functional withdrawal is more likely, but supplementation of progesterone may nevertheless be beneficial in preventing preterm labor. Progesterone has a negative effect on many contraction-associated proteins and on prostaglandin activity.[61] In addition, it decreases uterine sensitivity to oxytocin.[62] Placebo-controlled studies using 100 mg of progesterone or placebo as a vaginal suppository between 24 and 34 weeks found a significant reduction in preterm delivery rates before 37 weeks and before 34 weeks in high-risk populations.[63] A study that also examined neonatal outcomes showed a reduction in the incidence of birth weight less than 2500 g, necrotizing enterocolitis, intraventricular hemorrhage, and the need for supplemental oxygen, but not perinatal death or respiratory distress syndrome.[64] Studies of the clinical use of progesterone are ongoing. On the available evidence, it is estimated that 1 in 7 high-risk women need to be treated with progesterone prophylactically to prevent one case of spontaneous preterm birth before 34 weeks gestation.[2]

Mechanisms of Transfer Across the Human Placenta

It has been known since the 18th century that the circulation of the human fetus is kept separate from that of the mother by intervening placental tissue.[1] This chapter reviews transport across the placenta, but current understanding of placental transfer is less clear and coherent than for more extensively researched transport organs, such as the intestine or the kidney. Also reviewed is the evidence linking altered placental transporter activities with anomalous fetal growth.

Placentas can be classified broadly according to morphologic structure into *hemochorial* types, found in the human, rat, rabbit, and guinea pig, in which maternal blood washes directly against fetal chorionic (trophoblastic) tissue, and *epitheliochorial* types, found in the sheep and pig, in which the maternal uterine epithelium is maintained[2] (Figure 14-1). Placentas of the dog and some other species are intermediate in structure between these two types (see Figure 13-1; a more detailed account of placental morphology is given in the textbook by Mossman[3]).

Corresponding functional differences are recognized in the mechanisms and degree of transfer of certain solutes, notably γ immunoglobulin G (IgG) (transferred by yolk sac in rabbits and by placenta in women, and untransported in sheep) and iron (transferred by red blood cells in sheep and cats, and receptor-mediated from plasma transferrin in women). Most other transport systems have been observed in a majority of species studied, but few extensive cross-species sets of data are available. An additional major interspecies difference is in the balance between diffusional and carrier-mediated transplacental transport. Hemochorial placentas are considerably more permeable than epitheliochorial placentas to lipid-insoluble molecules for which no specific transport systems exist—such molecules are presumed to leak across the placenta by diffusion through "pores."[4,5] The much more restricted leak pathway in sheep suggests that endogenous polypeptides and other lipid-insoluble molecules, in the absence of specific transport systems, cross the sheep placenta much less readily than the human placenta; the same may be predicted for hydrophilic drugs. These differences must be borne in mind in extrapolating conclusions drawn from one species to another.

Examples of the main mechanisms of transplacental transfer are presented next. A systematic listing of all transport studies has not been prepared since that of Schultz,[6] although many are considered in the more recent review by Atkinson and colleagues.[7] The focus of this chapter is predominantly on data obtained in humans and on those substances with net transfer toward the fetus. In the case of urea, carbon dioxide, and bilirubin, for example, net transfer is in the opposite direction. The methodologic approaches used in humans on which the results discussed hereafter are based are summarized in Table 14-1.[8-33] Placental nomenclature sometimes is confusing to persons from fields of study other than fetal-neonatal physiology. Accordingly, definitions of commonly used anatomic descriptions and terms are provided in Table 14-2.

SPECIFIC MECHANISMS OF TRANSFER

This section describes the mechanisms available for transfer across the placenta, summarized diagrammatically in Figures 14-2 and 14-3, and presents examples of each process.

Diffusional Transfer

Several specific transport systems are operational in the placenta, as discussed in subsequent sections, but any molecule for which a maternofetal concentration difference exists also tends to diffuse across the placenta. The net rate (J_{net}) of diffusional transfer of a given solute from maternal to fetal blood is influenced by the surface area available for transfer, the permeability of the placenta, and the maternofetal concentration difference. These relationships are defined by Fick's law[6]:

$$J_{net} = PS(\bar{c}_m - \bar{c}_f)\text{mol} \bullet \text{sec}^{-1} \bullet \text{g}^{-1} \quad (1)$$

where P is a proportionality constant (for placental permeability) ($cm^2 \bullet sec^{-1}$), S is surface area available for diffusion between

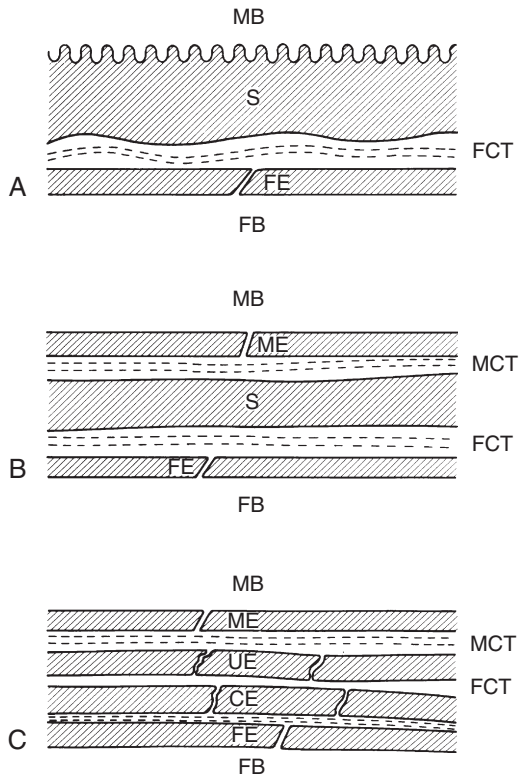

Figure 14-1 Diagrammatic representation of the three main types of placenta classified histologically. A, Hemochorial placenta, which has fetal endothelium and syncytiotrophoblast but no maternal endothelium (e.g., human). **B,** Endotheliochorial placenta, which has syncytiotrophoblast and both maternal and fetal endothelium (e.g., dog). **C,** Epitheliochorial placenta, which retains uterine epithelium in close proximity to chorionic epithelium (trophoblast) as well as both maternal and fetal endothelium (e.g., pig). *CE,* Chorionic epithelium; *FB,* fetal blood; *FCT,* fetal connective tissue; *FE,* fetal endothelium; *MB,* maternal blood; *MCT,* maternal connective tissue; *ME,* maternal endothelium; *S,* syncytiotrophoblast; *UE,* uterine epithelium.

TABLE 14-1

Some Methods of Placental Transfer Study

Method	Variable Measured	Details	Comment
Carcass analysis[8]	J_{net}*	Analysis of conceptus content at different gestational ages	Reliable only for nonmetabolized solutes, e.g., Ca^{2+}; includes all maternofetal routes; poor time resolution
Accumulation of exogenous tracer[9-12]	J_{mf}†	Fetal tracer content estimated after delivery	If fetal plasma concentrations are not low, a hybrid of J_{net} and J_{mf} is measured
Umbilical arteriovenous difference at delivery[13]	J_{mf} or J_{net}	Cord clamped at cesarean section	Non–steady-state artifact likely
Cordocentesis[14-16]	Maternofetal plasma concentration difference		Midgestation; minimal disturbance; usually only venous sample
Cotyledonary perfusion[17]	J_{mf} J_{fm}	Steady-state transfer	Perfusion may alter passive permeability, with consequent incorrect estimation of proportion of specific transport
Cotyledonary perfusion[18]	Kinetics of uptake and backflux from maternal and fetal circulations	Single pass, indicator dilution	Can demonstrate transport asymmetry; may not reflect rate-limiting element of transfer
Slices, fragments[19-21]	Kinetics of individual systems	Uptake or efflux studies	May be "housekeeping" rather than transplacental transport systems
Membrane vesicles[22-24]	Kinetics of individual systems	Microvillous (maternal facing); basal (fetal facing)	May be "housekeeping" rather than transplacental transport systems
Cultured trophoblast[25,26]	Uptake		Care needs to be taken that placental cells rather than other lineages are being studied; cells may never terminally differentiate
Receptor-binding studies[27]	Affinity/number	Many described	May have "housekeeping," endocrine, transport, or other function
Microelectrode and patch clamp studies[28-33]	Transmembrane potential difference and ion channel characteristics		Has implications for ion movements
Gene knock-out/over-expression[10]	Variety	Mainly mouse	Identify likely mechanisms/regulatory pathways

*See Equations 3 and 4 in the text.
†The permeability–surface area product PS can be derived from J for diffusional transport when microcirculation plasma water concentrations are known or inferred.[5,27]

TABLE 14-2

Some Anatomic Terms Common in Placental Transport Studies

Term	Meaning
Trophoblast	A fetally derived tissue that comprises a number of different lineages. Within the absorptive part of human placenta, these comprise syncytiotrophoblast, the syncytial layer in immediate contact with maternal blood, and, beneath it, a cytotrophoblast layer from which syncytiotrophoblast is derived. The cytotrophoblast layer is incomplete in later gestation. Other categories of trophoblast outside the exchange area include free cells in the endometrium, trophoblast invading spiral arteries, and trophoblast in nonplacental membranes. Trophoblast also may be free in the maternal circulation. The outer surface membrane of syncytiotrophoblast facing maternal blood is microvillous, and vesicular preparations made from this membrane are microvillous membrane (brush border membrane) vesicles. The fetal surface of syncytial trophoblast also is lined by a cell membrane, which can be isolated and formed into basal membrane vesicles.
Umbilical and uterine circulations	The intervillous space (maternal circulation flowing between the placental villi) is supplied by spiral branches of the (maternal) uterine artery. Circulation within the villi is supplied by the (fetal) umbilical artery and vein.
Chorion	The outermost layer of the conceptus in early gestation—hence, *chorion frondosum*, the chorionic surface that surrounds all sides of the conceptus in early gestation. As the definitive placenta develops, that part of the frondosum contributing to it becomes more villous; the remainder loses its villi to become *chorion laeve.*
Allantois	A fluid-filled compartment adjacent to the umbilical cord, connected to the fetal bladder by a tubular uracus running from the cephalic end of the bladder through the umbilicus. Of considerable size in the sheep, it is rudimentary in the human and disappears in early gestation. However, its tissue contributes to placental formation—hence the description of human placenta as chorioallantoic.
Endometrium	The lining of the uterus. In the human, it is shed at menstruation and hence is classified as deciduate. The shed tissue is the decidua.
Amnion	A fluid-filled compartment that is bounded internally by the fetal skin and externally by the amniotic membrane closely apposed to overlying chorion—hence, amniochorion. It is rupture of this membrane that allows fetal delivery through the cervix at term. The fetus drinks its contained amniotic fluid and passes lung liquid and urine into it.
Fetal membranes	These strictly comprise placenta and amniochorion, the latter being *extraplacental membranes.* In common usage, *fetal membranes* may refer to amniochorion only.
Villus	The fetal component of human placenta arborizes into a large number of small, fingerlike projections or villi; each is bathed by maternal blood flowing through the intervillous space.
Cotyledons	The human placenta is partially divided into cotyledons by incomplete septa. In some species, placental elements are quite distinct, as in the sheep, and each element is known as a cotyledon. In human placental perfusion, roughly one cotyledon is perfused. The human placenta as delivered includes some adherent maternal tissue, and the shiny fetal surface from which the umbilical cord projects is known as the chorionic plate, and the maternal tissue surface is known as the basal plate, not to be confused with thebasal vesicles (see "Trophoblast," above).
Yolk sac placenta	An important route of immunoglobulin transfer in rodents. The human yolk sac is functional only in the first trimester, and its contribution, if any, to transfer is uncertain.

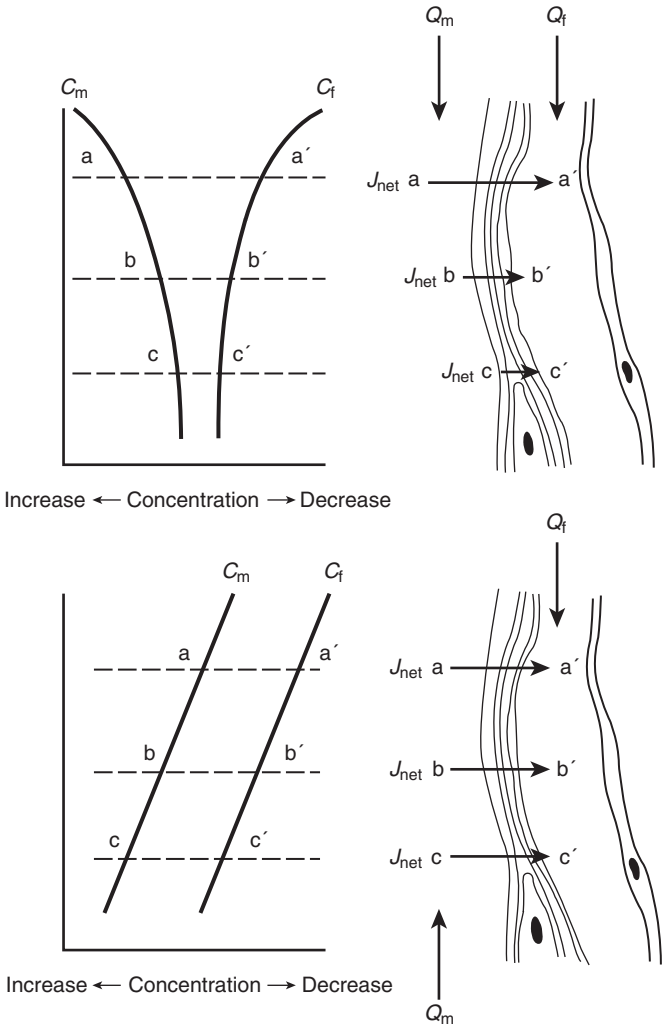

Figure 14-2 Effect of directional relationships of maternal (Q_m) and fetal (Q_f) blood flows on relative concentration differences and net fluxes of a substance crossing the placenta by diffusion under flow-limited conditions. *Top,* Concurrent maternal and fetal flows. *Left,* The maternal (C_m) and fetal (C_f) plasma concentration profiles are shown along the length of the exchange vessel that includes points a, b, and c on the maternal side of the vessel and corresponding points a′, b′, and c′ within the lumen of the fetal vessel. *Right,* This results in net fluxes (J_{net}). The net flux decreases from point a-a′ to point b-b′ to point c-c′ along the length of the exchange vessels. C_m declines along the length of the exchange vessel, and C_f increases along the length of the vessel until the concentration difference that drives net diffusion decreases to almost zero. *Bottom,* Countercurrent maternal and fetal blood flows. *Left,* C_m declines along the length of the exchange vessel, and C_f increases in the exchange vessel along its length. The maternofetal concentration difference is constant along the exchange vessel. *Right,* The net fluxes remain uniform along the length of the capillary. *Not illustrated* is the membrane-limited situation, in which the maternofetal concentration difference and the individual maternal and fetal concentration profiles remain approximately uniform along the length of the capillary; this is true regardless of the directional relationship of maternal and fetal blood flows. *(From Morriss FH, Boyd RDH, Mahendran D: Placental transport. In Knobil E, Neill JD [eds]:* The Physiology of Reproduction*, New York, 1994, Raven Press, pp 813-863.)*

the circulations within 1 g of placenta ($cm^2 \cdot g^{-1}$), and are mean plasma solute concentrations of the unbound solute in plasma in maternal and fetal blood, respectively, flowing past the exchange area.

Two pathways are available for diffusion: a *hydrophilic* route for lipid-insoluble molecules and a *lipophilic* route. Their relative importance in determining J_{net} is determined by the degree of solubility in lipid of the molecule of interest.

J_{net} may be considered as having two components:

$$J_{net} = J_{mf} - J_{fm} \tag{2}$$

where J_{mf} and J_{fm} are unidirectional transfer rates within 1 g of placenta in the maternofetal and fetomaternal directions, respectively. This general formula applies to any mechanism of transfer. For molecules crossing by diffusion only,

$$J_{net} = PS(\bar{c}_m)\text{mol} \bullet \text{sec}^{-1} \bullet \text{g}^{-1} \tag{3}$$

$$J_{net} = PS(\bar{c}_f)\text{mol} \bullet \text{sec}^{-1} \bullet \text{g}^{-1} \tag{4}$$

Hydrophilic Permeability

In the absence of specific transport mechanisms, lipid-insoluble (hydrophilic) molecules do not permeate the trophoblast cell membrane, and therefore are either excluded from the intracellular space of the placenta or cross the placental barrier by an extracellular porous route of molecular dimensions. Their transfer is slow, owing to the small surface area of this pathway, and is limited by both the size of the molecule and the membrane characteristics (permeability and pore size); thus it is said to be *membrane-limited*.[4,27,34,35] Contributions from any specific transport mechanisms for other hydrophilic solutes are additive to this baseline.

Nonphysiologic hydrophobic permeants (including mannitol, sucrose, inulin, chromium-labeled ethylenediaminetetraacetic acid, and high-dose vitamin B_{12}) have been used to assess placental permeability, because they do not possess specific transporters (or because, as in the case of vitamin B_{12}, the transport systems were saturated during studies). Table 14-3 lists the permeabilities, reported as permeability–surface area products (PSs), for some such hydrophilic molecules, across the term human placenta in vivo and, for comparison, across the term rat placenta, in various studies.[9,12,36-38] As is evident in the table, the permeability of hydrophilic substances is proportional to the diffusion coefficient in water (although the values obtained in different laboratories differ).

Such a relationship is most easily explained by diffusion through paracellular channels or pores sufficiently wide to allow free diffusion of low-molecular-weight substances (smaller than proteins). The epitheliochorial sheep placenta has reduced permeability to larger hydrophilic molecules,[39] possibly because the channels have a radius some 10 to 20 times smaller in sheep than in human and other hemochorial placentas.[5]

The morphologic nature of the paracellular channels or pores in the syncytiotrophoblast of hemochorial placentas is uncertain, but two possible pathways (not mutually exclusive) have been identified. Using electron-dense tracers, Kaufmann[40,41] and Kertschanska[42] and their colleagues visualized transtrophoblastic channels lined with tracer after imposing a hydrostatic pressure gradient across perfused guinea pig and human placenta. These workers hypothesized that under normal conditions of hydrostatic pressure, the channels are too narrow to be resolved by electron microscopy. They failed, however, to show channels that are simultaneously open to both the maternal and the fetal sides of the syncytiotrophoblast; the absence of such channels may not surprising in view of the small number of channels overall required to explain the permeability data.[43] A paracellular pathway in the human placenta also may be

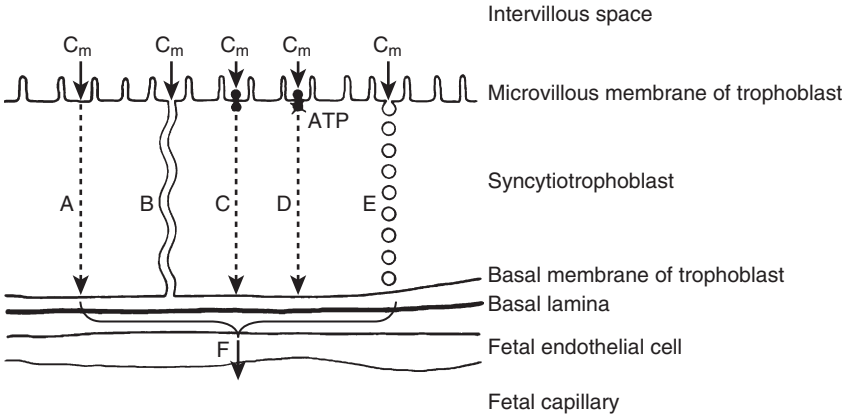

Figure 14-3 Transfer mechanisms within the placental tissue. *A,* Simple diffusion of relatively lipophilic substances (e.g., oxygen, anesthetic gases). *B,* Restricted diffusion of hydrophilic substances through hypothesized water-filled transmembrane channels of submicroscopic dimensions (e.g., mannitol). *C,* Facilitated diffusion (e.g., D-glucose). *D,* Active transport (e.g., amino acids). *E,* Receptor-mediated endocytosis (e.g., IgG—fluid-phase endocytosis). *F,* Exit mechanisms into fetal circulation. *Not indicated* are solvent drag, larger trophoblastic leaks, and the complicating factor of placental metabolism. *ATP,* Adenosine triphosphate; C_m, maternal plasma concentration; *IgG,* immunoglobulin G. *(From Morriss FH, Boyd RDH, Mahendran D: Placental transport. In Knobil E, Neill JD [eds]:* The Physiology of Reproduction*, New York, Raven Press, 1994, pp 813-863.)*

TABLE 14-3

Permeability of the Human and Rat Placenta Near Term

Substance	Diffusion Coefficient in Water at 37° C[36] ($cm^2 \cdot sec^{-1}$)	PERMEABILITY–SURFACE AREA PRODUCT* ($\mu L \cdot sec^{-1} \cdot g^{-1}$)	
		Human	*Rat*[36]
Sodium	17.0×10^{-6}	0.56[37]	0.32
Mannitol	9.9×10^{-6}	0.19[9]	0.07
Sucrose	7.5×10^{-6}		0.07
Chromium-labeled ethylenediaminetetraacetic acid	7.0×10^{-6}	0.11[9]	0.05
Cyanocobalamin	4.8×10^{-6} [12]	0.24[12]	
Inulin	2.6×10^{-6}	0.02[9] 0.15[38]	0.02

Data from cited references.

*For a discussion of the relationship of permeability surface with clearance, see Sibley CP, Boyd RDH: Control of transfer across the mature placenta. In Clarke JR (ed): Oxford Reviews of Reproductive Biology. Oxford, Oxford University Press, 1988, pp 382-435.

provided by areas of denudation of the syncytiotrophoblast.[44-47] These are normal features of the human placenta at all stages of gestation, and they are either open or filled with fibrin-containing fibrinoid deposits.[45]

Sodium

The relatively high permeability of hemochorial placentas toward hydrophilic solutes suggests that sodium transfer across the human placenta occurs primarily by membrane-limited diffusion.[4] However, the PS for sodium across human placenta is unexpectedly higher than for extracellular tracers (see Table 13-3). Several possible explanations have been proposed:

1. Placental structure may include a population of extracellular channels small enough to exclude mannitol (the smallest extracellular tracer so far studied in humans) but large enough to let through some excess sodium (indicating heterogeneity of pore size).[48]
2. Paracellular diffusion of sodium may be accelerated by a transplacental potential difference between the fetal capillary and the intervillous space (with the fetal side negative). Some evidence suggests a potential difference in certain species, but other data are contradictory.[35,48-50] An in vitro study using microelectrodes measured a transtrophoblast potential difference in mature intermediate villi of human placenta ranging from 2.5 to 10 mV, fetal side negative.[51] This finding is supported by some measurements in vivo.[52]
3. Maternofetal sodium transport may be partly transcellular, effected by the various sodium-linked transport systems demonstrable in trophoblast membrane vesicle preparations. This transport mechanism is of interest because it suggests potential endocrine control of active sodium transport to the fetus and thus of fetal hydration (see the later discussion of water transfer). In the rat, in which the sodium PS–diffusion coefficient ratio is similarly higher than that for extracellular tracers (see Table 13-3), good evidence supports active transport, involving sodium–amino acid cotransport and sodium-potassium–adenosine triphosphatase (Na^+,K^+-ATPase).[53] Other evidence points to a similar system in the pig,[54] but as yet such a mechanism has not been proved to operate in humans, even though sodium–amino acid cotransport and Na^+,K^+-ATPase activity have been convincingly demonstrated.[55,56]

Other Ions

Although the paracellular route appears to be large enough in the human to permit some diffusional permeability for all the unbound inorganic ions of plasma, the proportion of their movement that is transcellular generally is unknown. For calcium, in vitro data suggest that the paracellular route contributes approximately 50% of total maternofetal transfer,[57] with the remainder due to active transcellular transfer (see Chapter 33). Chloride, phosphate, and sulfate are maintained at higher concentrations in fetal than in maternal plasma,[58] and therefore transcellular active transport is likely to be involved in the translocation of these ions; the components of such routes certainly exist.[28,59-62]

Lipophilic Permeability

Lipid-soluble substances diffuse through the entire trophoblast cell surface. Because of the large surface area involved, P in Equation 1 is large, and the transport rate depends predominantly on which, in turn, depend on the geometric relationships of the maternal and fetal bloodstreams and their flow rates. Therefore

relatively lipophilic molecules, such as respiratory or anesthetic gases, are said to demonstrate *flow limitation* in their permeability pattern.[5,34,35] The hypothetical effect of two different geometric patterns of flow, concurrent and countercurrent, on the profile of c_m and c_f (and thus on) is illustrated in Figure 14-2.

The human placenta probably belongs to an anatomically intermediate type of exchanger[5] in that, on the fetal side, there are hairpin-like capillary loops, with opposite flow directions in each limb.[41] The maternal circulation in the intervillous space exhibits a *multivillous pool* geometry and lies at approximately 90 degrees to the fetal circulation. This arrangement is intermediate in transfer efficiency.[5]

Oxygen

It seems probable that oxygen transfer across the human placenta is flow-limited as it is in sheep[63] and rabbits.[64] For gases such as oxygen, the terms are replaced in the Fick equation by the equivalent partial pressures, and the driving force for net oxygen diffusion is the partial pressure difference between maternal intervillous space and fetal capillary. Values for partial oxygen pressure (Po_2) in blood taken from large vessels in sheep, monkeys, and humans and from the intervillous space in humans are shown in Table 14-4.

In an ideal concurrent blood flow system, the umbilical venous Po_2 should be identical to the uterine venous Po_2. In sheep and monkey, however, these two values are not identical[65] because of shunting (some maternal and fetal blood does not pass close to the site of exchange) or uneven perfusion (maternal-fetal blood flow ratios that are different between different segments of the placenta). In addition, the placenta and membranes can consume considerable amounts of oxygen from the uterine circulation. In the human, the situation is somewhat uncertain. The Po_2 of placental intervillous space samples is slightly higher than that in umbilical samples (see Table 14-4). Because the intervillous space samples are likely to be a mixture of arterial and venous blood, resulting in overestimation of the true venous Po_2, the human placenta does not fit the concurrent system model and is most consistent with the proposed multivillous pool arrangement.

It is well known that in most species, fetal hemoglobin has a higher affinity for oxygen than maternal hemoglobin (the oxyhemoglobin dissociation curve is shifted to the left).[5] In sheep direct experimental evidence demonstrates that the left shift is important, because replacement of fetal blood with maternal blood results in a halving of the umbilical venous oxygen saturation and a drop in net transplacental flux of oxygen to the fetus.[66] Similarly, fetal acidosis develops in human fetuses transfused with adult blood for Rhesus hemolytic disease.[67] Because of the left shift in the fetal oxygen-hemoglobin dissociation curve, fetal tissue Po_2 is lower than it would be if adult blood at the same Po_2 flowed through it at the same rate.

TABLE 14-4

Oxygen Tension of Maternal and Fetal Blood in Sheep, Monkey, and Human

	Po_2 (mm Hg)		
Sample	***Sheep****	***Monkey****	***Human**†*

*Data from Meschia G: Placental respiratory gas exchange and fetal oxygenation. In Creasy RK, Resnik R (eds): *Maternal Fetal Medicine: Principles and Practice*, Philadephia, 1984, WB Saunders, pp 274-285.

†Data from Soothill PW, Nicolaides KH, Rodeck CH, Gamsu H: Blood gases and acid-base status of the human second-trimester fetus, *Obstet Gynecol* 68:173-176, 1986; and Nicolaides KH, Soothill PW, Rodeck CH, Campbell S: Ultrasound-guided sampling of umbilical cord and placental blood to assess fetal wellbeing, *Lancet* 1:1065-1067, 1986. Umbilical blood was obtained by percutaneous blood sampling.

Endocytosis and Exocytosis

Endocytosis is an invagination of the cell surface to form an intracellular membrane-bound vesicle containing extracellular fluid[68]; *exocytosis* may be considered the opposite process, that is, fusion of a plasma membrane-bound vesicle to the cell surface, followed by release of its contents. Endocytosis is classically divided into two types: *phagocytosis,* the process by which large particles are ingested; and *pinocytosis,* the process by which small solutes and water are absorbed. Iron transport may use the former process in the sheep,[69] but in the human the latter process is relevant to placental transport. Low-density lipoprotein, the transferrin-iron complex, and IgG all probably gain entry to the human placental syncytiotrophoblast by endocytosis.[70-72] Only IgG seems to be transported intact across the cell and exocytosed. Transfer of iron to the fetus may involve an exocytotic process as well, but not until after some intracellular processing has occurred that results in the return of transferrin to the maternal plasma.[72] The latter also is probably true for the transfer of retinol across the subhuman primate placenta.[73]

Asymmetric transport by endocytosis and exocytosis has three recognized phases, as described next.

Pinocytosis

The pinocytosis phase of the transport process may be fluid phase (nonselective),[68,74,75] adsorptive with nonspecific solute binding (e.g., that between cationized proteins and anionic sites in the plasma membrane of human and guinea pig placenta),[76,77] or mediated by a specific receptor. In receptor-mediated transport, the specific receptors always become associated with specialized regions of the plasma membrane called *coated pits,* which on electron microscopy can be seen to be covered with a "coat" of the protein clathrin.[78,79] Invaginated coated pits with their associated receptors and receptor-ligand complexes form coated vesicles within the cell.

Transsyncytial Movement of Vesicles

The mechanism by which transsyncytial movement of vesicles occurs remains obscure. In other tissues, many vesicles fuse with lysosomes, and for some macromolecules, such as low-density lipoproteins in fibroblasts, this is the last step of the process.[78] For directed transplacental transport of intact IgG to occur, however, either some vesicles must avoid lysosomal fusion or the transported molecule must be protected from digestion. Transsyncytial movement of vesicles may occur by diffusion down a concentration gradient from the site of endocytosis to the other side. Alternatively, as in secretory cells, microtubules and other components of the cytoskeletal system may direct vesicle shuttling.[80-82] In this regard, certainly a well-developed cytoskeletal system is known to be present in human placental syncytium.[83]

Exocytosis

In the process of exocytosis, vesicles fuse with the plasma membrane at the opposite pole of the syncytium followed by release of the contents by fission. It is unknown how exocytosis occurs in the placenta. Generally, endocytosis cannot occur without exocytosis, as areas of plasma membrane that are continuously lost from a cell surface must be continuously replaced to maintain the polarity of the epithelium.[68,75] It is unclear how this process takes place in an asymmetric syncytial transporting epithelium such as human placenta.

Although investigations of the role of endocytosis and exocytosis in the placental transfer of proteins and other macromolecules generally have focused on the syncytiotrophoblast, the fetal capillary endothelium also provides a considerable barrier to the exchange of such molecules.[84,85] Endocytosis and exocytosis also could be important mechanisms in this layer,[86] but this area of investigation requires a considerable amount of additional work.

Immunoglobulin G Transfer

The selective transfer of IgG across the placenta confers passive immunity to the fetus. In other species, particularly rabbits, guinea pigs, and rodents, this function is served by the yolk sac placenta, rather than by the chorioallantoic placenta.[74,87] The mechanism of selective IgG transfer across the yolk sac placenta has been studied in depth. The pioneer of these studies, Brambell,[88] suggested that uptake of IgG is by a nonselective process but subsequent binding to receptors selectively prevents its degradation in phagolysosomes, allowing release of the intact molecule on the fetal side. The identification of specific Fc receptors by placental cells,[74] however, suggests that IgG transfer is accomplished through receptor-mediated endocytosis (reviewed by Wild[87]). This proposed mechanism is supported by the fact that maternofetal immunoglobulin transfer is highly selective (IgG, but not IgA or IgM, crosses the placenta, and transfer of IgG1 is greater than that of other IgG subclasses). FcRn (neonatal FcR) and FcγRIII are expressed by the syncytiotrophoblast[86] and function to transport IgG through the cytoplasm in microvesicles, avoiding fusion with lysosomes. Interference with this pathway by inactivating mutations of FcRn reduces IgG transfer to the fetus.[89] Transfer across the fetal capillary endothelium is less well understood; FcγRII is expressed by endothelial cells; however, it is not clear whether this functions to block immune complex transfer to the fetus or to facilitate IgG transport.[90]

Water Transfer

The human conceptus at term gestation contains 4 L of water (80% by weight of the intrauterine contents[91]). As Barcroft[92] pointed out, the net molar flux of water into the fetus is greater than that of any other substance, including oxygen. From kinetic analysis of plasma and amniotic fluid deuterium oxide concentrations, Hutchinson and colleagues[93] concluded that at 40 weeks of gestation, the unidirectional flux of water across the human placenta is approximately 60 mL/minute in both directions, some 10,000 times the net flux.[94] Unidirectional fluxes from amniotic fluid to fetal plasma and amniotic fluid to maternal plasma (and in the reverse directions) represent only approximately 5% of the transplacental fluxes.

The main reasons for asymmetric unidirectional fluxes and thus for net water flux across the placenta are likely to be hydrostatic and osmotic pressure differences between fetal and maternal placental microcirculations. For example, acutely increasing the osmotic pressure of either maternal or fetal plasma by injection of hypertonic solutions leads to net flux of water out of the fetus or mother in primates,[95] rabbits,[96] and sheep.[97-99] In less acute experiments in the guinea pig, increasing fetal plasma colloid but not crystalloid osmotic pressure increased water acquisition over 20 hours.[100] Similarly, altering the hydrostatic pressure difference changes flow across both perfused guinea pig[101] and sheep placenta.[102] Despite these observations, the size and direction of osmotic and hydrostatic pressure differences between the microcirculations in vivo are unknown.

The factors regulating water acquisition remain somewhat obscure for at least two reasons. First, the reflection coefficients across placenta for the many solutes present in plasma are unknown. Accordingly, calculation of the total effect of osmotic pressure of fetal and maternal plasma from knowledge of their individual solute concentrations,[4] or from freezing point depression or colloid osmometry data, cannot be accomplished.[103] The relatively large apparent pore radius in the hemochorial placenta led Faber and Thornburg[4] to suggest that hydrostatic pressure, together with colloid osmotic pressure, rather than small solute osmotic pressures, governs net water flux across these in contrast with epitheliochorial placentas. Second, solute concentrations in plasma of the microcirculation may be different from those in the large vessels from which samples have been collected. Similar problems apply to the measurement of hydrostatic pressure. In women, it is not even clear whether fetal plasma total osmolarity is higher than[104] or equal to[4] maternal plasma osmolarity, whereas hydrostatic pressure in the intervillous space (insofar as it can be estimated) is lower than in the umbilical vein.[91,105] Both of these latter observations, if they reflect the steady state in vivo, are, in the absence of other forces, incompatible with the net transplacental acquisition of water by the fetus.

A further area of uncertainty is the extent to which transplacental water flow is transcellular as opposed to paracellular. Both Faber and Hart,[106] using the fetal side–perfused rabbit placenta, and Meschia and colleagues,[35] using an in vivo sheep preparation, showed that the clearance of ^3H_2O was much greater than would have been predicted on the basis of molecular size alone if water had been restricted to the same paracellular route as, for example, for sodium. Illsley and Verkman[107] measured the osmotic water permeability of a microvillous membrane vesicle preparation from which the paracellular route was excluded. Although uptake was found to be low compared with other plasma membranes, these investigators calculated that it was sufficiently high to account for the entire transplacental water flux[94] without the need to invoke a paracellular route for water. Despite the many probable inaccuracies in such a calculation, it does at least appear that a proportion of transplacental water movement in the human placenta is likely to be transcellular. Such transcellular fluxes may be mediated by aquaporins, a family of membrane proteins functioning as water channels and found in the syncytiotrophoblast.[108]

One report suggests that the transfer across the rat placenta of inert hydrophilic tracers is asymmetric, with fetomaternal transfer greater than maternofetal transfer.[109] Such asymmetric transfer is impossible to explain by paracellular diffusion alone, and the study investigators suggested that it could result from bulk flow of water, creating solvent drag in the fetomaternal direction. On this basis, these workers further suggested that solute-free water is driven transcellularly across the placenta, driven by osmotic gradients set up by active transport of solute. Water and dissolved solute then return from fetus to mother by paracellular filtration across the placenta, the whole system runs to ensure that the net flux of water to the fetus is exactly correct. Reports of asymmetric transfer across the perfused human placental cotyledon,[110] together with the hydrostatic gradient as noted previously, suggest that a similar model could apply in humans. Despite this and several other attempts to model fetal water acquisition,[94,111] the nature and control of water transfer across the placenta are poorly understood at present. It also remains possible that an important fraction of net water transfer between mother and fetus occurs extraplacentally by way of the amniochorion.

TRANSPORTER PROTEIN–MEDIATED TRANSPORT

The flux of small hydrophilic solutes across the plasma membrane is mediated by transporter proteins. These include *carriers,* which translocate solute by a saturable mechanism and use energy either from prevailing electrochemical gradients (facilitated diffusion—e.g., glucose) or from the hydrolysis of ATP (active transport—e.g., amino acids, calcium), and *channels* through which ions diffuse along electrochemical gradients.[112]

The transporter protein itself may hydrolyze ATP, or it can cotransport with another solute, a diffusion gradient for which is set up by the hydrolysis of ATP by a separate transporter protein (secondary active transport). Many such transporter proteins in the microvillous (maternal-facing) and basal (fetal-facing) plasma membranes of the human syncytiotrophoblast have been characterized. These transporter proteins are important for transplacental transfer or are involved in solute supply to the trophoblast for its own metabolism. For transplacental transfer to occur by way of this transcellular route, both an entry and an exit step would be required (see Figure 13-3).

Transplacental active transport can occur by means of a pump-leak or leak-pump mechanism. In the former process, the active step, localized to the microvillous membrane, generates a higher intracellular concentration of the substance than in maternal plasma, followed by a leak across the opposite plasma membrane (as is probably the case for many amino acids). In a leak-pump system, the substance is pumped out of the trophoblast at the basal plasma membrane, thereby lowering its intracellular concentration so that a leak from maternal plasma into the syncytium occurs (as is perhaps the case for calcium). Two solutes for which transporter proteins are recognized to play an essential role in maternofetal transfer are glucose and amino acids.

Glucose Transfer

The fetus has high glucose demands, particularly in the third trimester, so a rapid, high-capacity transfer system is necessary. Glucose transfer is membrane-limited, and paracellular diffusion alone is not sufficient to meet the needs of the developing fetus.[9] Instead, glucose is primarily transferred across the placenta by facilitated diffusion, in a saturable, stereospecific and competitive manner, which is independent of energy sources.[113-118] This transfer is achieved through the activity of facilitative glucose transporter (GLUT) proteins on both the microvillous and basal plasma membranes of the syncytiotrophoblast[22,119] and is driven by a concentration gradient from maternal to fetal blood. This mechanism is highly efficient, and it has been shown, in the isolated perfused human placental cotyledon, that transplacental glucose flux is directly proportional to the maternal arterial concentration.[113]

Glucose transporter protein-1 (GLUT1) is one of a family of transporter proteins that translocate glucose by facilitated diffusion.[120] GLUT1 is abundantly expressed by the placenta and is present at three-fold higher levels on microvillous than on basal plasma membrane, thereby prioritizing transport into the syncytiotrophoblast from maternal blood.[22] This fulfills the glucose requirements of the placenta (up to 60% of the total glucose uptake is believed to be metabolized intracellularly) and establishes a steep concentration gradient from syncytiotrophoblast to fetal blood, facilitating transsyncytial transfer. Other GLUT family members also have been detected in the placenta, including GLUT3, GLUT4, and GLUT12,[121-123] although discrepancies regarding their exact messenger RNA (mRNA) and protein expression patterns are apparent in the literature (as reviewed by Atkinson and colleagues[124]).

Amino Acids

Transplacental transfer of amino acids is essential to meet the developmental and metabolic requirements of both fetus and placenta.[125] Amino acids are actively transported across the syncytiotrophoblast by a variety of transporter molecules, which are saturable, stereospecific. and energy-dependent (reviewed by Jansson and Powell[126] and by Regnault and associates[127]). The transporter systems are characterized on the basis of competitive interactions and are analogous to those described for other epithelia.[128] The expression of at least 13 amino acid transporter systems by the placenta has been described; findings of relevant studies are summarized and referenced in Table 14-5. These are members of the solute carrier family (SLC) and can be classified into monomeric transporters and heterodimeric systems, whereby a specific light chain functions in conjunction with shared heavy chains (CD98/4F2hc or rBAT) and, further, according to sodium dependence or independence. Expression patterns across gestation indicates highly specific regulation of placental amino acid transfer; however, despite differences in substrate specificity, localization (microvillous membrane or basal plasma membrane) and predominant direction of flux, the transporters have overlapping actions.

Uptake of amino acids by vesicles prepared from either the microvillous membrane or the basal plasma membrane of the syncytiotrophoblast of the human placenta has been extensively investigated.[55,149] Recently a method of quantifying uptake of ^{14}C-methyl aminoisobutyric acid (MeAIB) into intact placental villous fragments has been developed, resulting in a more physiologic system with multiple cell types and enabling longer-term in vitro treatments to investigate transporter regulation.[150]

Human umbilical venous plasma concentrations of most amino acids are significantly higher than maternal concentrations at midgestation[14,151] and at term.[152] Placental tissue concentrations of free amino acids appear to be higher than in either maternal or fetal plasma,[153,154] presumably because of a high syncytiotrophoblast concentration. This observation suggests active transport into the syncytiotrophoblast from maternal blood, followed by a passive leak down the concentration gradient to fetal plasma. However, no intrinsic reason exists to suggest that a passive leak should not also occur from syncytiotrophoblast into maternal plasma. The observed asymmetric transcellular transport (maternofetal flux) is explained by the differential expression or activity of carriers on the microvillous and basal plasma membranes of the syncytiotrophoblast.

Studies with perfused placental cotyledons have confirmed preferential maternofetal transfer of the neutral amino acids L-leucine and L-alanine in the human placenta.[155] In addition, a faster rate of maternofetal transfer has been demonstrated for AIB (a nonmetabolizable amino acid analogue), L-leucine, and the basic amino acid L-lysine.[156] The fetomaternal transfer rates of AIB, L-leucine, and L-lysine are all nearly half the maternofetal transfer rate. Transport of these amino acids in the fetomaternal direction is thought to occur by the paracellular route, because transfer rates are not different from those for the extracellular marker L-glucose. These experiments have been carried out with equal maternal and fetal perfusate amino acid concentrations, and the importance of paracellular transfer may be even greater in vivo because fetal plasma amino acid concentrations are higher than maternal levels.

The sodium-dependent uptake of many amino acids across the microvillous plasma membrane suggests that uptake from the maternal circulation is driven by a low sodium concentration within the trophoblast compared with that in the intervillous space. The sodium gradient is maintained by trophoblastic Na^+,K^+-ATPase activity, and inhibition of the sodium-potassium (Na^+-K^+) pump with ouabain inhibits AIB accumulation by the perfused cotyledon.[157] More puzzling, however, is how the accumulation of amino acids such as leucine is energized, when they appear to have only a sodium-independent pathway for uptake.[158] One possibility is that this uptake is energized by exchange transport with amino acids that are concentrated in the syncytiotrophoblast by sodium-dependent cotransport.[159] In fact, despite a high concentration of leucine in placental tissue[133] and fetal plasma,[152] ^{14}C-leucine is not concentrated by human placental slices, apparently because of a rapid efflux of leucine from the slices.[160] By contrast, ^{14}C-alanine is concentrated eightfold. It could be that the pump-leak hypothesis represents an oversimplification and is not always applicable.

Neutral amino acids are transported by sodium-dependent transporters system A and ASC, and by sodium independent

TABLE 14-5

Placental Amino Acid Transport Systems and Their Distribution in the Syncytiotrophoblast

System	Protein(s)	Gene(s)	Na^+ Dep	Substrates	Excludes	Location
Monomeric						
A[129-131]	SNAT1 SNAT2 SNAT4	SLC38a1 SLC38a2 SLC38a4	Yes	Alanine, serine, proline, glycine, MeAIB	Anionic and cationic amino acids, leucine	MVM, BM

transporter system L. System A has been widely studied in placenta, particularly in relation to fetal growth control, and exists in three isoforms—SNAT1, SNAT2, and SNAT4—expressed by both microvillous and basal plasma membranes.[119,158,161-164] ASC is present only on the basal plasma membrane and is distinguished from system A by its relative pH insensitivity, higher stereospecificity, and intolerance of *N*-methylated amino acids.[25,161] Both isoforms (LAT1 and LAT2) of system L are expressed by microvillous membrane and basal plasma membranes[158,161] but differ in their affinities for leucine and alanine. System L also is present in the basal membrane. Tryptophan, which may have an important role in immune evasion by placenta and fetus,[165] also is transported by system L.[143,158,166]

Taurine is an essential amino acid for fetal growth and is transported by a β-amino acid–specific sodium- and chloride-dependent transporter, TauT.[138,139,167] Cationic amino acids are taken up by syncytiotrophoblast membranes using the sodium-independent transporters system y^+, system b^{0+}, and system y^+L.[133,134,168] However, in the term placenta, transport of cationic amino acids across the microvillous plasma membrane is predominantly by systems y^+ and y^+L, and that across the basal membrane is predominantly by system y^+L.[134]

Only limited maternofetal transfer of the anionic amino acid glutamate across the perfused cotyledon has been described.[155] An additional finding is a negative umbilical artery–umbilical vein concentration difference, suggesting uptake from the fetal circulation into placenta.[169] The reasons for the lack of transfer of anionic amino acids are incompletely understood. A sodium-dependent, potassium-coupled, anionic amino acid transporter, system X^-_{AG}, is present in both microvillous and basal plasma membranes.[129,170] System X^-_{AG} seems to be efficient, because aspartate and glutamate are concentrated 23- and 34-fold, respectively, by human placental slices, whereas other amino acids tested are concentrated no more than 12-fold.[160]

GESTATIONAL CHANGES

A majority of early studies examining the mechanisms of solute transfer across the human placenta have focused on the organ at term. The fetus clearly has varying nutrient demands across pregnancy, however, and because fetal growth in the third trimester far exceeds that of the placenta, increased expression or activity of transporters must account for the more efficient uptake of nutrients. Recent studies on villous fragments or membrane vesicles from first-trimester placentas reveal changes in the expression or activity of many transporter systems across gestation; however, the patterns are system-specific, illustrating the tightly regulated and selective nature of placental nutrient transfer. For example, the activity of system A and system y^+ in microvillous membrane vesicles from term placentas is elevated compared with that in preparations from first-trimester placenta,[171,172] whereas system y^+L is down-regulated across gestation,[172] and system β is unchanged.[173]

These changes in activity do not necessarily represent differences in gene expression or protein synthesis, because discrepancies exist among mRNA, protein, and activity levels for most transporter systems examined. Such discrepancies may be due to post-translational modification or regulation at the level of membrane trafficking or may reflect differential expression of transporter isoforms, as illustrated by system A, in which mRNA for SNAT1 and SNAT2 remain constant over gestation, whereas SNAT4 is elevated in first-trimester placenta.[174] Of interest, the activity of the the glucose transporter and the sodium-hydrogen (Na^+-H^+) exchanger in the microvillous membrane is similar in

second-trimester and in term placentas,[22,175,176] suggesting that the first trimester is the key time of change. Furthermore, some evidence indicates differences in mRNA expression for system A isoforms between early and late first trimester, potentially corresponding to the onset of maternal blood perfusion of the placental villi.[174]

Glucose transporters also exhibit changes in expression over gestation, with recent studies demonstrating up-regulation of GLUT1 expression and activity (in basal plasma membrane only) at term, coincident with down-regulation of GLUT-3 and -4.[122] This pattern is accompanied by changes in the cellular localization of GLUT12, from syncytiotrophoblast in first trimester to vascular endothelial at term, reinforcing that GLUT1 is the predominant syncytial glucose transporter at term.[22]

Studies of the microvillous membrane of the syncytiotrophoblast suggest that the activity of the Na^+-H^+ exchanger and Ca^{2+}-ATPase is higher at term than in the first trimester[142,171,175]; however, its total electrogenic ion transport appears to be reduced with advancing gestation.[29] More detailed studies are needed to examine the transfer capacity of the placenta as a whole, to delineate temporal shifts in the expression and activity of the different transporter systems and to elucidate how the gestational changes are regulated.

TABLE 14-6

Activity of Transporters in Syncytiotrophoblast Microvillous and Basal Plasma Membranes in Intrauterine Growth Restriction

Transporter*	MVM Change	BM Change

PLACENTAL TRANSFER AND FETAL GROWTH

Net placental transfer over the course of gestation must exactly equal the solute and water composition of the baby at term. Placental transfer is thus intimately involved in determining fetal growth. Idiopathic intrauterine growth restriction (IUGR) has therefore been ascribed for many years to placental insufficiency. Because of the importance of oxygen delivery, the tendency of babies with IUGR to be hypoxic, and the flow limitation of oxygen transfer (see earlier), placental insufficiency has become almost synonymous in the literature with a reduction in uterine or fetoplacental blood flow. This concept also is consistent with the association of IUGR with preeclampsia and abnormal uterine Doppler measurements.[177] However, although placental oxygen delivery and blood flow are undoubtedly important in determining fetal growth, more recent data show that this is not the complete picture. Growth-restricted fetuses are hypoaminoacidemic and hyperlacticacidemic, and they also tend to be acidotic.[15,178-180] Placental transfer of amino acids, lactic acid, and protons is not predominantly flow-limited; therefore the barrier characteristics of the placenta in IUGR also need to be considered.

Such a focus has led to the demonstration that the activity and expression of certain transporter proteins in both the microvillous and basal plasma membranes of the syncytiotrophoblast are altered in IUGR. These data, showing that a syncytiotrophoblast transport anomaly is an important facet of the pathophysiology in IUGR resulting from placental insufficiency, are summarized and referenced in Table 14-6. Some transporter activities increase, some decrease, and some exhibit no change. This variability shows that the anomaly is complex and does not reflect a general down-regulation of metabolic activity, as might be expected.

Although no differences in glucose placental transport have been detected between normal and IUGR pregnancies, a reduction in lactate transfer has been demonstrated. Lactate is an end product of metabolism, but during pregnancy it is an important energy source for the fetus in late gestation.[189] It is supplied to the fetus by cotransport across the placenta with H^+, by the monocarboxylate transporters (MCTs).[190] Multiple MCTs are expressed by human syncytiotrophoblast price[191]; the best-characterized are MCT1 (found predominantly on the basal plasma membrane) and MCT4 (located on both basal and microvillous membranes).[192] Of interest, the reduced lactate transfer in IUGR is confined to the basal membrane, indicating that fetomaternal lactate transfer is diminished.[186] This observation is consistent with the elevated lactate levels measured in growth-restricted fetuses[193] and suggests that placental clearance of lactate is attenuated in IUGR.

The reduction in activity of the amino acid transporters is likely to be particularly important in determining fetal growth rate. Human in vivo studies with stable isotopes revealed that in normal pregnancy, the delivery of neutral amino acids is only just sufficient to meet fetal requirements,[125] and in IUGR, maternofetal ^{13}C-leucine transfer is reduced in comparison with normal findings.[194] In healthy pregnancies, the activity of the system A amino acid transporter in the microvillous plasma membrane, per milligram of membrane protein, is inversely proportional to fetal size at birth.[195] This finding may reflect a compensatory up-regulation of the transporter in the smaller placentas of small normal babies, a hypothesis that is supported by data from mice in which the placenta-specific insulin-like growth factor-II (IGF-II) gene has been knocked out.[10] In the absence of placental IGF-II, the fetus maintains a normal growth trajectory despite placental abnormalities until day 16 of embryonal life (E16) of pregnancy, as a result of an up-regulation of system A. Failure of this compensatory mechanism (by a subsequent reduction in system A activity) between E16 and term corresponds to the onset of fetal growth restriction.[196] The finding that the same transporter activity is lower than normal in the microvillous membrane vesicles of placentas of IUGR-affected babies[176,181] suggests that they are doubly disadvantaged compared with physiologically normal infants: They have a small placenta and less transporter activity per milligram of membrane protein.

The activity of other amino acid transporters (system L and system β) is reduced in membrane vesicles prepared from placentas in pregnancies complicated by IUGR,[172,185,197] together with certain ion transport systems, such as the Na^+-H^+ exchanger,[188,198] which could indirectly affect fetal development through altering trophoblast pH and electrochemical gradients necessary for optimal syncytiotrophoblast function.

Diabetes mellitus during pregnancy can result in fetal overgrowth (macrosomia), and data suggest that syncytiotrophoblast transporter activities also are affected in this condition.[199-202] Materanofetal glucose transfer is increased in women with diabetes, not solely as a result of elevated maternal glucose levels but also because of a two-fold increase in basal plasma membrane GLUT1 levels.[201] Microvillous membrane GLUT1

remains constant, further supporting basal plasma membrane transfer as the limiting step in glucose movement across the syncytiotrophoblast.

Certain amino acid transporters also are altered with macrosomia; however, significant differences have been noted in the responses of individual transporters to gestational diabetes and type 1 diabetes. System A activity is up-regulated in gestational diabetes and type 1 diabetes,[201,203] whereas system L is elevated only in the former.[204] Moreover, these changes were observed only in those placentas that were themselves overgrown, suggesting increased placental metabolic activity in addition to, or instead of, elevated maternofetal amino acid transfer.[199,204] Further evidence for highly selective and differential regulation of transporter systems comes from findings that both the Ca^{2+}-ATPase[205] and lipoprotein lipase[206] are dysregulated in type 1 diabetes but not in gestational diabetes. These observations further demonstrate the need for greater understanding of the regulation of placental transporter activity, across normal pregnancy and in patients affected by IUGR and diabetes.

REGULATION OF PLACENTAL TRANSPORTERS

Investigations into the regulation of placental transporter activity and gene expression have thus far focused mainly on the GLUTs and system A. Evidence from in vitro studies indicates that GLUT1 is regulated by substrate availability. Glucose uptake is enhanced in isolated trophoblast cells incubated in a low glucose environment, and is inhibited by hyperglycaemia.[207] These effects correlate with changes in GLUT1 mRNA expression; however, they are apparent only at extreme glucose concentrations and thus may be more relevant to pathologic states (e.g., diabetes) rather than to normal pregnancy. Longer-term nutritional manipulation also affects placental glucose transport: Undernourishing pregnant rats in late gestation results in IUGR, coincident with reduced expression of GLUT3 but not GLUT1 or GLUT4.[208]

The effects of insulin on placental glucose transport also have been investigated. Studies using term placenta, either perfused cotyledon[209] or microvillous membrane vesicles,[23] failed to show any effect of insulin on glucose uptake. However, insulin can acutely stimulate glucose uptake by first-trimester placental villous fragments,[122] suggesting differences in the regulation of glucose transport across gestation. This observation is consistent with a stimulation of glucose uptake by insulin by the early pregnant rat placenta. These acute effects may be due to changes in membrane localization of GLUTs, supported by the preferential up-regulation of basal plasma but not microvillous membrane GLUT1 protein by IGFs, hypoxia, and growth hormone (GH).[210] Longer exposure to insulin in isolated first-trimester trophoblast cells leads to a sustained elevation in glucose uptake, through the up-regulation of GLUT1 mRNA expression.[207] A similar effect was detected in response to insulin-like growth factors (IGF-I and IGF-II).[211]

Insulin also may affect glucose transport by enhancing the activity of GLUT4 and GLUT12. Both of these insulin-responsive GLUT isoforms are gestation regulated: GLUT4 is abundant in the syncytiotrophoblast in early pregnancy but absent at term,[122] whereas a shift in cellular localization of GLUT12, from syncytial to stromal-vascular, is apparent over the course of pregnancy.[123] Such shifts show remarkable similarity to the spatial and temporal expression patterns of insulin receptors in the placenta, which change from predominantly syncytial to endothelial[212,213] in the third trimester, suggesting that the syncytial uptake of glucose is more sensitive to changes in insulin levels in early pregnancy.

Similar experiments have been performed to examine the regulation of neutral amino acid uptake. System A activity is regulated by substrate availability in fibroblasts, with low concentrations of amino acid stimulating accelerated uptake of MeAIB[214,215]; a similar adaptive regulation is observed in placental cell lines.[216] Acute exposure to leptin and insulin stimulates ^{14}C-MeAIB uptake by villous fragments from term placentas[217] but has no effect on first-trimester placentas. By contrast, growth hormone appears to inhibit system A activity in first-trimester but not term villous fragments.[217,218] More chronic effects of hormones—insulin, IGF-1, and cortisol—on MeAIB uptake have been investigated in cultured trophoblasts derived from first-trimester placenta or choriocarcinoma cell lines (BeWo). In each case, system A activity was stimulated in a dose- and time-dependent manner[219,220]; as supported by some evidence, cortisol may mediate its effects through changes in ATA2 mRNA and its trafficking to the plasma membrane.[220]

The actions of these hormones on placental transport are of interest because the endocrine and metabolic environment may be altered in pregnancy complications. Dietary manipulation during pregnancy in animals is a powerful model for studying the chronic effects of hormones on nutrient transport. Pregnant rats fed a low-protein diet have low circulating levels of insulin, IGF-1, and leptin, and fetuses are growth-restricted at term.[221,222] Also of interest, changes in the expression and activity of system A appear to coincide with the onset of IUGR, with a down-regulation of SNAT2 mRNA and protein, and MeAIB uptake, from E16 only. Similarly, subjecting rats to a brief perioid of hyperglycemia in early pregnancy results in decreased system A activity at term, again through effects on the SNAT2 isoform.[223] These studies further support amino acid transport as an important mechanism for modulating fetal growth and provide in vivo models to elucidate how placental transport is regulated across gestation and in normal and abnormal pregnancies.

15 Endocrine and Paracrine Function of the Human Placenta

Theresa M. Siler-Khodr

By the early 1900s the placenta was recognized as an endocrine organ. Reports by Zondek and Aschheim[1] and Philipp[2] described placental hormone activities similar to those of both ovarian and hypophyseal hormones, and the significance of placental hormone products for the maintenance of pregnancy was recognized. Since that time the role of placental hormones, which act as endocrine, paracrine, and autocrine regulators of pregnancy, has been defined not only for hypophyseal and gonadal hormones but also for multiple hypothalamic hormones, cytokines, growth factors, other proteins, peptides, and eicosanoids. The regulation and function of each of these factors as related to the placenta are discussed in this chapter.

HYPOPHYSEAL- LIKE HORMONES

Possibly the best-known hormone of pregnancy is human chorionic gonadotropin (hCG). Its activity was first reported in the early 1900s.[1,2] Wislocki and Bennett[3] originally proposed that hCG was synthesized by the cytotrophoblast because its concentrations in pregnancy were parallel to the number and density of cytotrophoblast in the placenta. Since then, it was shown that hCG is synthesized primarily by the syncytiotrophoblastic cells[4] but is regulated by a releasing factor, gonadotropin-releasing hormone (GnRH I and GnRH II isoforms), which is produced largely in the cytotrophoblasts.[5-7] Human CG is a glycoprotein composed of α and β subunits that are translated from separate messenger RNAs (mRNAs).[8] The α subunit is produced in excess of the β subunit, and this ratio increases as gestation progresses. As a result, little free β-hCG is secreted, and the hCG in maternal circulation is mostly intact hCG or free α-hCG. Intact hCG (i.e., having both α and β subunits) is required for its known biologic activities, which are similar to those of human luteinizing hormone (hLH). In addition, the degree of glycosylation of the hCG molecule decreases as pregnancy advances and a decreased level of glycosylation in very early pregnancy has been correlated with early pregnancy loss.[9,10]

Human CG can be immunologically distinguished from hLH using antisera directed against the C-terminal amino acids of its β subunit, which are not present in hLH. Use of β-subunit hCG–specific antisera is the basis for most current pregnancy

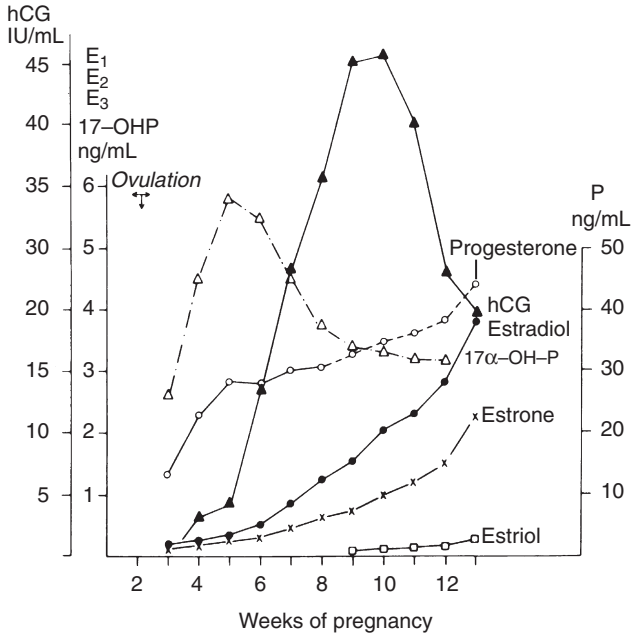

Figure 15-1 Maternal plasma levels of human chorionic gonadotropin (hCG) and steroids during human pregnancy. *E_1,* Estrone; *E_2,* estradiol; *E_3,* estriol; *17α-OH-P,* 17α-hydroxyprogesterone; *17-OHP,* 17-hydroxyprogesterone; *P,* progesterone. *(From Tulchinsky D, Hobel CJ: Plasma human chorionic gonadotropin, estrone, estradiol, estriol, progesterone, and 17 alpha-hydroxyprogesterone in human pregnancy. 3. tests. Increasing hCG secretion can be detected in the maternal circulation by 24 hours after implantation and increases with a doubling time averaging 2.11 days. It reaches peak levels of approximately 50 international units/mL at 9 to 10 weeks from the date of the last menstrual period, declining thereafter to 1 international unit/mL by midgestation[11] (Figure 15-1). In early gestation, the hCG doubling time is an effective way to predict the outcome of a pregnancy. An abnormally slow doubling time of hCG is considered to be a sign of a poor prognosis for pregnancy outcome.[12]

In early pregnancy, hCG has both endocrine and paracrine functions: (1) to stimulate formation of the corpus luteum of pregnancy, which in turn produces progesterone, and (2) to stimulate placental steroidogenesis and uterine activities allowing for implantation. In very early pregnancy hCG maintains corpus luteal progestone production. As the placenta develops, an ovarian-placental shift occurs whereby the placenta takes over the production of progesterone. This shift is completed at least 2 weeks before peak placental hCG production is attained (35 to 47 days after ovulation) (see Figure 15-1). Another hormonal function ascribed to hCG is that of a thyrotropic activity, which may affect increased thyroid function. Other data, however, suggest that a distinct thyrotropic factor is synthesized by trophoblastic tissue. In addition, hCG may have immunosuppressive functions.[11,12]

Multiple factors can influence hCG production, such as GnRH,[14] neurotransmitters,[15] cyclic adenosine monophosphate (cAMP),[16] epidermal growth factor,[17] activin,[18] cytokine,[19] prostaglandins,[20] and hCG itself.[20] Each of these is produced by the placenta as well as other trophoblastic tissues. Human CG is known to affect placental steroidogenesis by stimulating both progesterone and estrogen formation. Estrogens can inhibit GnRH stimulation of hCG,[22] thereby completing a feedback axis in the paracrine placenta. Other hormones such as inhibin[23] also have been shown to modulate this axis.

Proteins with lactogenic and growth hormone–like activity were first extracted from human placenta by Higashi in 1961.[24] Shortly thereafter, Josimovich and MacLaren[25] isolated the protein originally named human placental lactogen (hPL). This designation was later changed to *human chorionic somatomammotropin* (hCS), to reflect its growth hormone–like activity as well as its lactogenic activity. This peptide chain of 192 amino acids has considerable homology with human growth hormone and prolactin (PRL). It is synthesized by the syncytiotrophoblasts of the placenta, attaining maximal production in late gestation. At that time accounts for 10% of the total protein synthesis of the placenta. It is the product of two genes that flank the human growth hormone V (hGH) gene expressed in the human placenta.[26,27]

Placental concentration of hCS during pregnancy parallels the mass of the placenta throughout gestation. As a result, maternal circulating hCS levels increase throughout gestation and appear to reflect placental function. Human CS is secreted into the maternal circulation, where it induces metabolic changes such as mobilization of fatty acids, insulin resistance, decreased utilization of glucose, and increased availability of amino acids through decreased maternal use of protein.[28] In addition, the lactogenic activity of hCS suggests a synergistic role with that of PRL and steroids in preparation of the breast for lactation.[29] In the placenta, both hCS and hGH-V may regulate IGF-I[30] and affect fetal growth by direct action on placental nutrient transport. The absence of hCS and hGH-V expression is reported to result in severe fetal growth restriction.[28]

Factors that control the release of hCS are poorly defined. Human CS is stimulated by high-density lipoproteins, apolipoproteins,[27,30] angiotensin,[31] cyclic adenosine monophosphate (cAMP),[32] and arachidonic acid (AA) and are inhibited by the prostaglandins PGE_2 and $PGF_{2\alpha}$,[33] catecholamines, phorbol esters, and diacylglycerols.[34] In addition, dopaminergic agents have been shown to inhibit its release.[35] The releasing and inhibiting factors found in the placenta, however, have not yet been shown to affect hCS release.

PRL also is known to increase during pregnancy both in maternal blood and in amniotic fluid.[36] The PRL in maternal blood is primarily of maternal pituitary origin, whereas that in amniotic fluid PRL is synthesized by the decidua. The role of these high amniotic fluid PRL levels (up to 3 μg/mL) in pregnancy is not understood. Decidual PRL can be stimulated by α-hCG.[37]

Other pituitary-like peptides such as adrenocorticotropic hormone (ACTH), melanocyte-stimulating hormone (MSH), β-endorphins, and β-lipoproteins have been demonstrated in the human placenta by immunologic and biologic assays,[38] although chemical identity of these placental peptides has not been completely defined. Prostaglandins have been found to increase β-lipotropin and β-endorphin levels in amniotic fluid.[39] Chorionic corticotropin-releasing hormone (CRH) is produced by the placenta and stimulates the release of chorionic ACTH.[40] The physiologic role of chorionic ACTH has not been defined, but it may affect placental cortisol production or fetal adrenal function or both.

STEROIDOGENESIS AND THE MATERNAL-FETAL-PLACENTAL UNIT

Although the placenta was known to be the source of steroid hormones since the early 1900s, it was not until the late 1950s that their biosynthetic pathyways were understood. In 1959, Ryan[41] demonstrated that the placenta could convert dihydroepiandrosterone sulfate (DHEA) to estrogens; five years later, Diczfalusy[42] proposed and subsequently demonstrated the existence of a fetal-placental unit in which fetal enzymes and placental enzymes work in concert to produce estrogens. Although

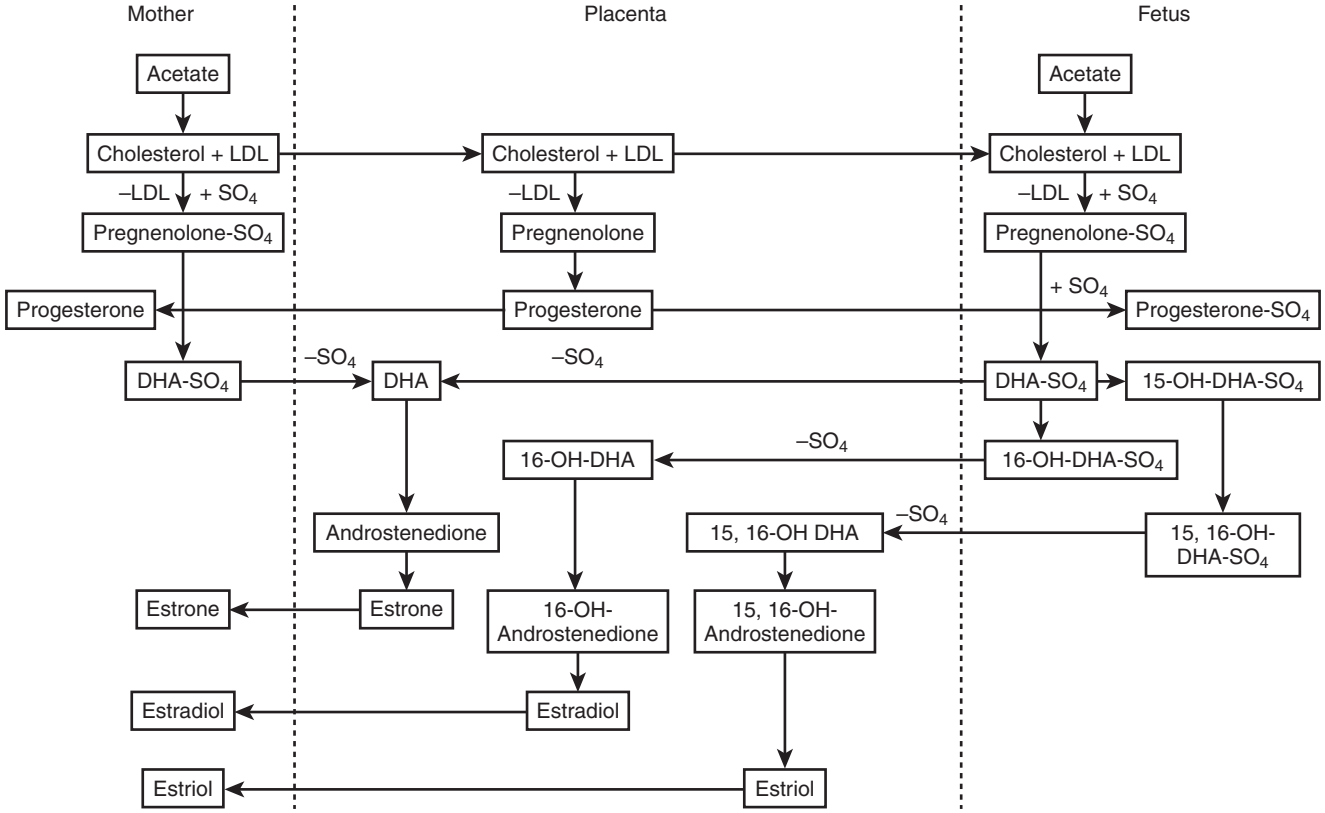

Figure 15-2 Steroidogenic pathways in the human maternal placental-fetal unit. *DHA-SO_4,* Dihydroepiandrosterone sulfate; *LDL,* low-density lipoprotein; *OH,* hydroxy.

the use of maternal cholesterol for placental progesterone synthesis was suggested by Bloch as early as 1945,[43] further studies that unquestionably confirmed these findings and established that maternal cholesterol was the principal precursor of progesterone production were not completed until 1970.[44] The fetal-placental unit was then expanded to include the mother, because maternal cholesterol is needed for placental production of progesterone and for the precursors used for fetal androgen production.[45] Fetal DHEA-SO_4, in turn, is used as a substrate for placental synthesis of estrogens. Thus the maternal-fetal-placental unit functions to produce progesterone and estrogens. These steroids are found largely in the maternal circulation during pregnancy. A comprehensive review of the literature defining their synthesis and functions is available.[45]

Figure 15-2 diagrams the tissues and enzymes that participate in the biosynthesis of progesterone and estrogens.[46] Maternal cholesterol, derived from low-density lipoprotein (LDL), is transported to the placenta and bound to specific LDL receptors on the syncytiotrophoblast, where it is incorporated by endocytosis and hydrolyzed to free cholesterol in the lysosomes.[8] In the syncytiotrophoblastic cells of the placenta, the cholesterol is converted to pregnenolone. Mitochondrial enzymes—the 20, 22-desmolase complex—catalyze this metabolic transformation. Some of the pregnenolone is sent to the fetus, but much is converted to progesterone by the 3β-hydroxysteroid dehydrogenase-Δ^5,Δ^4-isomerase complex.[10,11] Approximately 90% of this progesterone goes to the mother and 10% to the fetus. The fetus has the former enzyme activity needed for pregnenolone synthesis but is severely lacking in the latter enzymatic complex, which is needed for progesterone production. Thus the progesterone that circulates in the fetus at high levels is of placental origin and may be used as a precursor of Δ^4-3-ketosteroids. Because progesterone is not dependent on fetal enzymes, it is a poor indicator of fetal well-being and more related to placental function.

In the fetus, steroids are rapidly sulfated by an adrenal sulfatase, resulting in steroid sulfates, which are steroids biologically inactive. This sulfation step may serve as a protective mechanism to ensure that the fetus is not exposed to high levels of active steroids. Pregnenolone sulfate is rapidly converted to DHEA-SO_4 by fetal adrenal zone enzymes, 17α-hydroxylase and 20,21-desmolase.[47] DHEA-SO_4 may be hydroxylated in the fetal liver at the 16α or 15α position or at both positions. These androgens are then transferred to the placenta.

In the placenta, the SO_4 must be cleaved before the 3β-hydroxysteroid dehydrogenase–isomerase complex can convert DHEA or the hydroxylated DHEAs to androstenedione or hydroxylated androstenediones. These androgens are then aromatized to estrone (E_1), 16α-OH estrone, or 15α-OH estrone and then converted to estradiol (E_2), estriol (E_3), or estetrol (E_4) by the action of the placental 17β-hydroxylation enzyme.[15-17] Although maternal DHEA-SO_4 serves as 40% of the precursor for E_2 synthesis, the latter hormones are formed predominantly from fetal precursors because the maternal liver has limited 5α- or 16α-hydroxylation capabilities.[48] Thus E_3 and E_4 levels are good indices of fetal well-being. Most of the estrogens are then sent to the mother.

Placental steroidogenic capacity is functional early in pregnancy, but not until 35 to 47 days after ovulation can placental progesterone production alone support the maintenance of pregnancy.[49] Before that time, human pregnancy is dependent on the progesterone produced by the corpus luteum of pregnancy or provided by exogenous supplementation. At 35 to 47 days after ovulation, the ovary may be removed and the pregnancy will continue. This change in control locus from ovary to placenta is the aforementioned ovarian-placental shift.

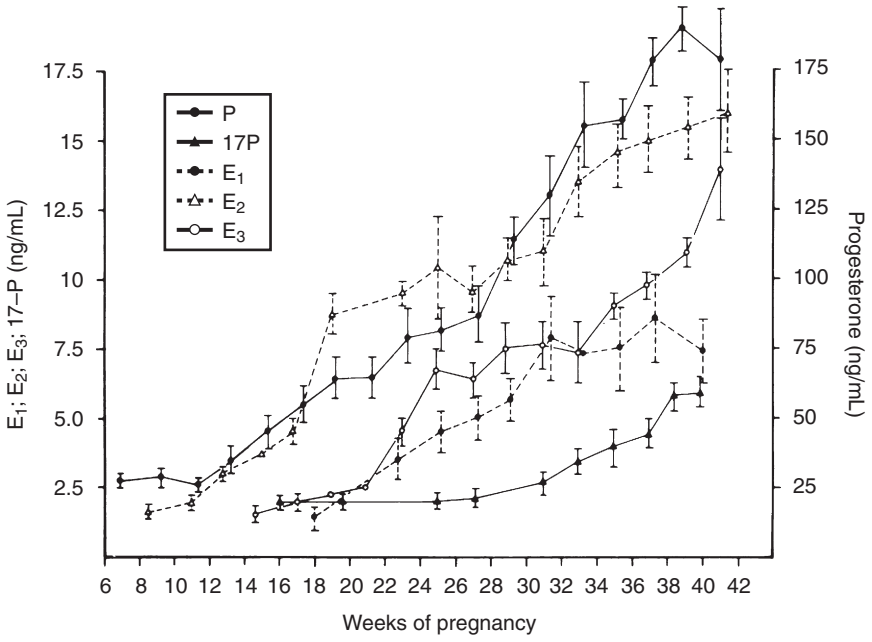

Figure 15-3 Maternal plasma levels of progesterone (P) and 17-hydroxyprogesterone (17P) and of estrone (E_1), estradiol (E_2), and estriol (E_3) during human pregnancy. *(From Tulchinsky D, Hobel CJ, Yeager E, Marshall JR: Plasma estrone, estradiol, estriol, progesterone and 17-hydroxyprogesterone in human pregnancy: I. Normal pregnancy,* Am J Obstet Gynecol *112:1095, 1972.)*

The concentration of steroid hormones in the maternal circulation increases dramatically throughout gestation[50] (Figure 15-3). Multiple functions of estrogens and progesterone in pregnancy are recognized. As discussed previously, progesterone is required for the maintenance of pregnancy by means of its suppressant effect on uterine contractions.[46,49,51] It also influences breast development while suppressing lactation by inhibiting lactose synthesis. Progesterone also affects glucose homeostasis and water metabolism. In addition, it has been shown to have immunosuppressive activity.[51] Estrogens influence uterine growth, blood flow, contractility, metabolism, and breast development.[22] Both estrogens and progesterone modulate the activity of other primary factors involved in the initiation of labor, such as prostaglandins and oxytocin. Before parturition, an increase in the estrogen to progesterone ratio (E/P) occurs within the intrauterine tissues. This altered E/P milieu may enhance and modulate prostaglandin and oxytocin production and action at the time of parturition. It is now known that placental steroid hormone production is influenced by protein trophic hormones and other factors such as hypothalamic-like releasing or inhibiting hormones, growth factors, cytokines, and prostaglandins.

Maternal circulating levels of glucocorticoids and mineralocorticoids are increased in pregnancy.[52] Although the placenta produces ACTH, its action is primarily in the placenta. However, the placenta has the ability to produce cortisol and to convert it to cortisone, as well as the reverse reaction. The activity of these enzymes differ with gestation stage and endocrine milieu.[53] A positive feed-forward axis of cortisol on placental CRH in late gestation (discussed later) may directly affect the fetal adrenal gland and can increase the production of DHEA-SO_4 (an estrogen precursor). CRH may therefore have an important role in parturition.

HYPOTHALAMIC-LIKE RELEASING AND INHIBITING ACTIVITIES

Although it was recognized since the early 1900s that the human placenta is an endocrine tissue, it was not until 1967, possibly both in protest and in prophecy, that Benirschke and Driscoll[54] stated, "Perhaps even more challenging at this time is the quest for an understanding of the regulatory phenomena which must be responsible for the predictability of levels of various hormones in the secretions of a normal pregnant woman, since it is difficult to conceive that no feedback mechanisms exist for those various rises and declines of hormone titers." In the 1970s, elucidation of such factors began.[5]

Since the mid-1970s, numerous studies have established that trophoblastic tissues contain and produce all the defined hypothalamic releasing and inhibiting activities.[5-7,14,55] These data have led to the general acceptance of the hypothesis that the classic hormones of the placenta are produced by means of a controlled paracrine-autocrine system. Human chorionic GnRH, the first-described placental hormone with hypothalamic-like activity, has been localized to the cytotrophoblast of the placenta,[5] and the synthesis of peptides having GnRH biologic and immunologic activity has been demonstrated.[6] The complementary DNA (cDNA) that encodes the GnRH I (mammalian GnRH) has been defined.[56] This same mRNA contains a 56–amino acid peptide, called gonadotropin-releasing hormone–associated peptide (GAP), that is thought to have prolactin-inhibiting factor (PIF) activity. Thus the placenta also can make PIF. Further chemical[57] and biologic data[58] suggest that another chorionic GnRH also may exist. The expression and action of a GnRH II (chicken II GnRH) by the placenta also have been demonstrated.[7]

GnRH I and GnRH II and their analogues bind to specific receptors on the syncytiotrophoblast. GnRH I stimulates cAMP[59] and hCG release without affecting hCS release.[13,14,60] The pattern and degree of hCG response are related to gestational age[13] and estrogen and progesterone levels[62,63] and can be modulated by inhibin.[24] A role for Ca^{2+} in the GnRH I stimulation of hCG has been indicated.[61] GnRH I and GnRH II also directly regulate placenta steroid release[63] and regulate prostanoid production from the term placenta.[7,64,65] In early gestation, GnRH I antagonists and GnRH I superagonists can inhibit hCG, steroid, and prostaglandin release from placental explants, and because this action can be partially reversed with exogenous GnRH I, a specific receptor-mediated action is suggested.[7,65] The release of GnRH

I by placenta is affected by cAMP, prostaglandins, epinephrine,[66] and inhibin.[24] Thus a paracrine axis for chorionic GnRH I and GnRH II–hCG–steroids–prostaglandins–inhibin–PRL has been proposed. In addition, a placental peptidase that can inactivate GnRH I and GnRH II has been isolated.[67] This peptidase may play an important role in the metabolism of GnRH and thus affect the homeostasis of this axis.

Numerous studies in which GnRH analogues or antisera have been administered to pregnant rats, monkeys, or baboons have indicated a possible function of chorionic GnRHs in the maintenance of pregnancy.[68] Administration of GnRH analogues in early pregnancy can induce pregnancy failure.[69-71] Maternal concentrations of GnRH I vary throughout pregnancy and parallel GnRH levels in the placenta and those of hCG.[14,72] Premature labor has been associated with low levels of circulating GnRH I in the first half of gestation. Thus these data support the hypothesis that chorionic GnRHs plays a significant role in the normal physiology of pregnancy.

Human placenta and membranes also produce a chorionic thyrotropin-releasing hormone (TRH). Attempts to define its chemical identity have led to conflicting findings. Shambaugh and colleagues identified chorionic TRH with bioactivity and immunoactivity coincident with TRH.[73] Maternal levels have not been studied; however, at least a part of the TRH administered to the mother can pass through the placenta and affect fetal thyroid function.[74] One study has reported that low levels of immunoreactive TRH in amniotic fluid were correlated with low Apgar scores.[75]

A chorionic somatostatin also has been localized to the cytotrophoblast of the human placenta.[76] Concentrations are highest in first-trimester placentas. Amniotic fluid has the capacity to rapidly degrade somatostatin. Somatostatin administered to the mother can cross the placenta to the fetus[77]; however, the high levels at term in the fetoplacental circulation appear to be of fetal origin.[78] Studies on somatostatin at other times of gestation have not been done. A role for somatostatin in the placental-decidual unit has been reported. Somatostatin is thought to acutely inhibit prolactin-releasing factor (PRL-RF).[79] PRL-RF is a 24,000-Da molecule that has been extracted from human placenta and is active in stimulating both the chronic and the acute release of decidual PRL. No effect of either somatostatin or PRL-RF on hCS release has been found. A chorionic growth hormone–releasing factor (GRF) has been identified in both the rat and porcine placenta, yet its chemical nature or activity remains to be determined.[80,81]

Chorionic CRH is another hormone with hypothalamic-like activity identified in the placenta.[82,83] It has been localized to both the syncytiotrophoblastic and cytotrophoblastic cells of the placenta and also is found in the cytotrophoblasts of the chorion.[84] Its chemical nature appears to be essentially identical to that of hypothalamic CRH, having a placental mRNA that hybridizes with the hypothalamic cDNA. Other studies, however, also have found some larger-molecular-weight chorionic CRHs that await further definition. Human chorionic CRH is transferred to both the maternal and the fetal circulations.[40,84,85] Concentrations in the maternal circulation are greater than those in the fetus and increase throughout pregnancy. A rapid increase is seen at term gestation, and the higher levels are maintained during labor (Figure 15-4). In pregnancies complicated by hypertension, the maternal circulating levels of CRH are already elevated by 28 weeks of pregnancy.[86] Chorionic CRH has been shown to be biologically active in stimulating the release of ACTH and β-endorphin.[40,84,87] Thus it is speculated that chorionic CRH may control placental, fetal, or maternal ACTH and endorphin levels. In late gestation, dexamethasone induces a paradoxical stimulation of mRNA for chorionic CRH.[88]

The increasing CRH released into the maternal circulation has been noted to correlate with the length of gestation and is sometimes referred to as a *placental clock*.[89] Ongoing studies suggest that CRH level may serve as a parameter that can predict preterm delivery.[89,90] Other studies have demonstrated that CRH can directly stimulate DHEAS production by the fetal adrenal.[91] Because DHEAS is the precursor for estrogen, this may be one mechanism by which a favorable endocrine milieu for parturition is effected. CRH is also thought to regulate the immune tolerance at implantation.[92]

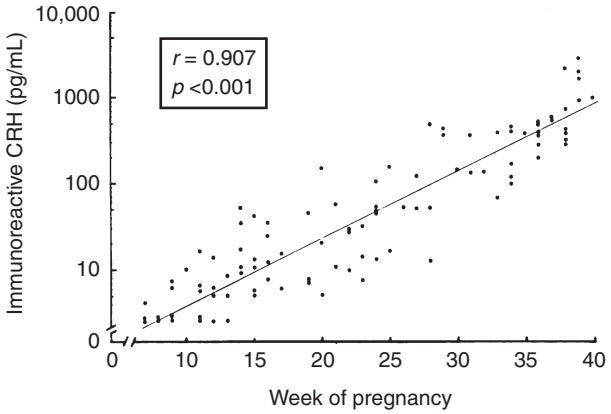

Figure 15-4 Maternal plasma levels of corticotropin-releasing hormone (CRH) during human pregnancy. *(From Sasaki A, Shinkawa O, Margioris AN, et al: Immunoreactive corticotropin-releasing hormone in human plasma during pregnancy, labor, and delivery,* J Clin Endocrinol Metab *64:224, 1987.)*

Another hypothalamic hormone thought to play a role in parturition is oxytocin. A review of this topic has been presented by Soloff.[93] A placental oxytocinase, cystine aminopeptidase, has been described and may play an important role in the regulation of oxytocin levels. Oxytocin has been shown to increase both prostaglandin[94] and ACTH[87] release from intrauterine tissues.

OTHER CHORIONIC CYTOKINES, GROWTH FACTORS, AND PEPTIDES

Cytokines, such as interferons, tumor necrosis factor-α (TNF-α), leukemia inhibitory factor (LIF), and interleukins,[95-99] also are produced by the placenta, and their receptors are expressed in the uteroplacental tissues. The cells of the placenta that express cytokines include the trophoblast, macrophage, and endothelial cells.[99-102] Cytokine expression varies with the stage of gestation but is now known to play an important role in implantation and immunosuppression during pregnancy,[103,104] as well as in regulation of trophoblastic and vascular functions in the placenta during gestation[105] and in the initiation and progrss of parturition.[100-102,106] Cytokines affect these activities by regulation of other cytokines, growth factors, hormones, and prostanoid production.[107-109]

At the time of implantation, the shift of the cytokine helper T cell ratio T_H1/T_H2 toward T_H2 is postulated to be of primary importance in suppressing the immune response at the uteroplacental interface.[106] The role of cytokines in parturition has been likened to an inflammatory response. Cytokine production is thought to be involved in preterm labor in pregnancies associated with intrauterine infection, as well as in preterm labor of other causes[101]; prostanoid production is increased, possibly through cytokine increases.

Another cytokine produced by the placenta is leptin.[110,111] It is proposed to play a role in the cytotrophoblast invasion at the time of implantation and to participate in regulating fetal growth and placental function.[112,113] Its increased production in preeclampsia and gestational diabetes has led to the hypothesis that this cytokine may play a role in these diseases of pregnancy.

Another class of hormones identified in the placenta and chorionic membranes is that of growth factors. The early blastocyst expresses platelet-derived growth factor A (PDGF-A), transforming growth factor (TGF)-α, and TGF-β.[114] These factors are thought to be involved in signaling implantation. At this early stage, other growth factors such as epidermal growth factor (EGF), basic fibroblast growth factor (bFGF), nerve growth factor (NGF-β), and granulocyte colony-stimulating factor (G-CSF) are not detected in early gestation[17] but are expressed by the placenta at later gestation stages.[115] Receptors for EGFs, as well as many other growth factor receptors, have been identified in the placenta and membranes.[116] Most of the EGF receptors in the placenta are localized to the syncytiotrophoblast and correlate with induction of differentiation function of trophoblast rather than proliferation.[117-119] The finding that EGF stimulates hCG secretion supports this hypothesis.[17] EGF also stimulates prostaglandin synthesis.[119] Another growth factor, hepatocyte growth factor or scatter factor, appears to be essential for placental development.[120,121]

The production of insulin-like growth factors I and II (IGF-I and IGF-II) from human placental tissues also has been demonstrated.[122] Within the placenta, IGF-I has been localized predominantly to the syncytiotrophoblast of the fetal villi.[123] IGF-binding proteins (IGFBPs), which are carrier proteins protecting IGF from degradation while blocking its bioactivity, also have been localized to these cells.[122,123] In addition to placental IGFBP, IGFBP-1 is produced by the decidua in large amounts. Receptors that bind IGFs have been identified in the human placenta; IGF-I receptor is the most dominant.[122-124] Placental growth hormone concentrations correlate with IGF-I levels throughout pregnancy.[30] IGFs potentiate the action of EGF[125] and stimulate decidual PRL production.[126] The production of progesterone is enhanced, whereas that of estrogen is inhibited.[127] Placental transport of glucose and amino acids also is enhanced by IGFs, and IGFs also regulate both fetal and placental growth.[128-130] In addition, production of placental thromboxane, a potent vasoconstrictor, is specifically inhibited by IGF-I.[131] Thus the production of placental IGF-I and its binding proteins is thought to be of major importance for normal intrauterine fetal growth.[129]

Relaxin also is synthesized by the membranes, decidua, and placenta.[132] Receptors for relaxin are present in the syncytiotrophoblast of the placenta.[133] A biologic action for relaxin on the collagenase activity of the chorionic-amnionic membranes has been demonstrated. Relaxin also stimulates prostaglandin release and increases collagenase, the enzyme that degrades collagen. Thus an important role for relaxin in human parturition is likely.

Inhibin also is synthesized by the cytotrophoblast of the placenta.[134,135] Its release by the placenta can be stimulated by 8-Br-cAMP as well as α-hCG. Inhibin has been shown to inhibit GnRH stimulation of hCG and chorionic GnRH production.[135] Antiserum to inhibin increases hCG release, and this effect can be partially reversed by GnRH I antagonist. Activin potentiates the GnRH-stimulated hCG release.[23] Thus activin and inhibin are actively involved in the GnRH-hCG-steroid-prostaglandin axis.

Vasoactive peptides, such as vascular endothelial growth factor, endothelin, angiotensin, and arginine vasopressin and their receptors, also are expressed by the human placenta. The peptides endothelin and endothelin 3 are produced by the placenta, and both are active and potent vasocontrictors in the fetal-placental circulation.[136-139] Endothelins also inhibit decidual prolactin release.[139] The angiotensin-renin system has been described in the placenta and is thought to be a factor in the regulation of vascular tone in the placental bed mediated by angiotensin II production and action.[140] Other peptide hormones effecting vascular tone, such as atrial natriuretic peptide (ANP) and its receptors, have been demonstrated in the placenta.[141] ANP is a vasodilator hormone that is thought to be produced by the cytotrophoblast because secretion decreases as these cells differentiate in vitro to syncytiotrophoblast. ANP inhibits the vasoconstrictive action of endothelin and angiotensin and induces vasodilatation in the uterus and the placenta.

Neuropeptides such as enkephalins[142] and dynorphin[143] have been found in the placenta. Receptors for opiate-like substances are present on the syncytial membrane of the placenta. The stimulation of these receptors has been shown to modulate acetylcholine[144] and hCG release.[145,146] Adrenergic agonists and antagonists affect placental hCG and PRL release,[147] whereas dopaminergic receptor stimulation has been shown to lower hCS[35] and increase hCG release.[35] A parathyroid hormone–related protein has been extracted from placental tissues[148] and localized to the cytotrophoblastic cells.[149] Parathyroid hormone–related protein has been shown to have potent vasodilator activity in the fetal-placental circulation.[150]

EICOSANOIDS

An important role for eicosanoids, such as thromboxanes, prostacyclins, and leukotrienes, during pregnancy is well recognized. In general, prostanoids and eicosanoids are thought of as products of the decidua and chorionic membranes, which are active in their production. Prostanoids and leukotrienes, however, also are produced in large quantities by the placenta.[151] In the placenta, the chorionic membranes, and decidua, AA must be mobilized (i.e., deesterified from lipoproteins) before it can be used for production of eicosanoids and prostanoids.[152] Mobilization of AA is induced through two enzymatic pathways. In the first pathway, the hydrolysis of AA from phosphatidylethanolamine is catalyzed by phospholipase A_2. The other pathway releases AA from phosphatidylinositol by the enzymatic activities of phospholipase C, monoacylglycerol lipase, and diacylglycerol lipase. AA is converted to prostaglandin G_2 (PGG_2) by cyclooxygenase and then by the enzyme prostaglandin hydroperoxidase to PGH_2. PGH_2 is the common precursor for the prostaglandins PGD_2, PGE_2, and $PGF_{2\alpha}$, which are formed by the enzymatic action of specific endoperoxides isomerases D and E, and reductase F. The levels of PGD_2, $PGF_{2\alpha}$, and PGE_2 can be measured directly. Thromboxanes and prostacyclin (i.e., prostaglandin I_2 [PGI_2]) are synthesized from PGH_2 by thromboxane and prostacyclin synthetases. Owing to the rapid nonenzymatic conversion of thromboxane A_2 (TxA_2) to TxB_2, TxB_2 levels are used as a measure of TxA_2 synthesis. Similarly, prostacyclin is enzymatically metabolized rapidly to 6-keto-$PGF_{1\alpha}$, which is measured directly.

The level of some prostanoids in term amnion, chorion, decidua, and placenta has been determined.[58,151] Human term placentas convert AA primarily to thromboxane, prostacyclins, PGE_2, $PGF_{2\alpha}$, and PGD_2. Production of $PGF_{2\alpha}$ is approximately half that of PGE_2; and prostacyclin production is one fifth.[153] Prostaglandins, thromboxanes, and prostacyclin have been implicated as important hormones during pregnancy, at the time of implantation, in the regulation of fetal growth and in the initiation and progress of labor. Their role in implantation has been demonstrated by the inhibitory effect of indomethacin (a cyclooxygenase inhibitor) on implantation. Other studies suggest that production of prostaglandins, thromboxane, and, particularly, prostacyclin may enable the trophoblast to invade and colonize the maternal spiral blood vessels of the myometrium.[154] Prostacyclin is known to be a potent vasodilator and inhibitor of platelet aggregation.

After implantation, during the period of fetal growth and development, prostaglandins, thromboxane, and prostacyclin play an important role as vasoregulators of the fetal-placental unit.[155] PGE_2 is known to be a vasodilator of uterine blood flow while constricting the umbilical circulation. $PGF_{2\alpha}$ vasoconstricts both the maternal and the umbilical circulations. In pregnancies associated with hypertension, increased production of thromboxane and reduced prostacyclin have been demonstrated.[156] Amniotic, chorionic, decidual, and placental tissue levels of PGE_2 and $PGF_{2\alpha}$ also are decreased in pregnancies complicated by hypertension.

Similarly, prostacyclin levels in the amnion are diminished in hypertensive pregnancies. Thromboxane production was not found to be increased in pregnancies associated with normotensive intrauterine growth restriction and in some cases was reduced.[157]

Other pregnancy-related functions of prostaglandins are the ability to affect protein synthesis in the placenta and modulation of the production of certain other hormones.[158-160] One study found that $PGF_{2\alpha}$ suppresses hCS production. Other studies in vitro have shown a direct stimulatory action of AA but not $PGF_{2\alpha}$ or PGE_2 on hCS. The ability of $PGF_{2\alpha}$ to stimulate hCG release in pregnant women has been reported. In addition, both PGE_2 and prostacyclin have been shown to increase cAMP levels.

An important function of prostaglandins, thromboxanes, and prostacyclin in pregnancy is their role in the initiation and progress of labor. Prostaglandins of the E and F series are elevated 6- to 12-fold in the amniotic fluid of women in labor.[156,161] Metabolites of thromboxane and prostacyclins (i.e., TxB_2, 6-keto-$PGF_{1\alpha}$) also are increased in amniotic fluid (two- to four-fold). It has been shown that infusion of PGE_2 and $PGF_{2\alpha}$ can be used to induce labor. These prostaglandins in larger doses also are effective in inducing midtrimester abortions. Intraamniotic administration of AA, the precursor of prostanoids, has resulted in the initiation of labor and delivery.[162] Chronic ingestion of aspirin, a cyclooxygenase inhibitor (of production of prostanoids from AA), can override this action of AA.[163]

As discussed previously, factors that are known to stimulate prostanoid production include CRH, cytokines, and growth factors. Both CRH and cytokines are thought to play a primary role in parturition, and increased prostanoid production is proposed to be one of the mechanisms of their action. In addition, it has been demonstrated that glucocorticoids, progesterone, and estrogens have an effect on prostaglandin production.[164] Studies have shown that GnRH can affect prostaglandin release from the placenta.[58,59,65] Placental prostaglandin release is highest when chorionic GnRH is highest; however, the response of prostaglandins to GnRH varies throughout gestation, as does the basal release of prostaglandins.[88] Of interest, basal prostaglandin release can be inhibited by a GnRH antagonist.[65]

As noted earlier, EGF can promote prostaglandin release from amniotic membranes. Another factor known to stimulate prostanoid release is platelet-activating factor (PAF).[165] The mechanism of action of PAF may involve mobilization of Ca^{2+}. PAF is present in amniotic fluid during active labor but not when labor is not occurring. Thus a role for PAF in the regulation of prostaglandins at parturition has been hypothesized.[166] A role for PAF at the time of implantation also has been suggested.[167]

ENZYMES THAT REGULATE PLACENTAL ENDOCRINE AND PARACRINE ACTIVITIES

Placenta enymatic activities also regulate autocrine, paracrine, and endocrine activities of the placenta by affecting their metabolism and thus their concentrations. In a number of cases these enzymes have been well demonstrated. In the case of GnRH, a highly active post–proline peptidase is known to regulate its concentration.[67] The placenta, having both endocrine and enzymatic activity, produces large quantities of this enzyme, providing a means for compartmentalization and localization of this specific activity. A role for protease in the degradation of angiotensin II during pregnancy has been described.[168] In the case of cortisol, a dual oxidative and reductive enzymatic activity regulates the balance between cortisol and cortisone.[53] In the placenta, oxidation of cortisol to cortisone predominates, whereas in the decidua, the reverse reaction dominates. Furthermore, differential regulation of these enzymatic systems throughout pregnancy has been demonstrated.[53] For prostaglandins, regulation of expression of the prostaglandin dehydrogenase has been proposed to participate in the initiation of labor.[169,170] In addition, oxytocinase and aminopeptidase may be involved in the regulation of parturition.[171,172]

INTEGRATION OF THE PLACENTA WITH THE INTRAUTERINE TISSUES

The human placenta has multiple physiologic functions that can be appreciated from the long list of regulatory factors it produces that act on the various cell types. Of note, however, the placenta does not act in isolation. It functions are integrated with those of other intrauterine tissues, such as the maternal uterus, chorion, amnion, decidua, and amniotic fluid and the fetus. These other intrauterine tissues produce or extract some of the same hormones and carrier proteins that regulate placental hormone activity. Metabolic signals and precursors as well as hormones are carried by maternal and fetal blood or transported from cell to cell from the uterus, decidua, chorion, amnion, and amniotic fluid to and from the placenta. Integration of the intrauterine tissues provides for the normal physiology of pregnancy, allowing for its maintenance and timely parturition. In addition, recent studies have demonstrated that fetal experience in utero results in the programming of adult functions and beyond—that is, in utero experience can affect epigenetic phenomena in generations to come.[173,174] Thus aberrations within these intrauterine autocrine, paracrine, and endocrine systems may be responsible for many of the disorders that occur during pregnancy and in adult life. Understanding of this system is rapidly developing and promises to lead to an enhanced ability to regulate these systems and thus to better maintain pregnancy, control the timing of parturition, and ensure the well-being of offspring in future years and generations.

Fetal and Maternal Responses to Intrauterine Infection

In the last 20 years, infection has emerged as a significant cause of preterm parturition.[1-8] It is the only pathologic process for which a firm causal link with prematurity has been established and a defined molecular pathophysiology is known.[9] Moreover, fetal infection and inflammation have been implicated in the genesis of fetal and neonatal injury,[10,11] leading to cerebral palsy[12-16] and chronic lung disease.[17-20] This chapter reviews the evidence showing the association of infection with spontaneous preterm birth, the role of cytokines and other inflammatory mediators in the host response to intrauterine infection, and finally, the fetal and maternal inflammatory response to intrauterine infection.

Systemic maternal infection (e.g., pneumonia, pyelonephritis, malaria, typhoid fever) has been associated with preterm labor and delivery.[21-31] Yet many of these conditions are rare in developed countries; thus the attributable risk of systemic maternal infection for prematurity is considered to be low. In addition, periodontal diasease was proposed as a risk factor to preterm labor.[32-34] Evidence suggests that some microorganisms isolated in amniotic fluid may have an oral origin,[32] and preterm neonates have evidence of a humoral immune response to microorganisms normally present in the oral cavity.[33,34] However, after adjustment for other factors, periodontal disease associated with

preterm birth was not related to abnormal intrauterine bacterial colonization or histologic chorioamnionitis.[35]

Intrauterine infection and inflammation frequently are associated with preterm labor and delivery. It has been estimated that at least 40% of preterm births occur to mothers with evidence of intrauterine infection or inflammation, which is largely subclinical in nature.[36-38] Moreover, the lower the gestational age at delivery, the greater the frequency of intrauterine infection,[39] and thus the higher the burden of disease attributable to intrauterine infection and inflammation. Discussed next are the pathways of intrauterine infection, its frequency and microbiology, and the rate of fetal infection.

PATHWAYS OF ASCENDING INTRAUTERINE INFECTION

Microorganisms may gain access to the amniotic cavity through several pathways: ascending from the vagina and cervix; hematogenous dissemination through the placenta (transplacental infection); retrograde seeding from the peritoneal cavity through the fallopian tubes; and accidental introduction at the time of invasive procedures, such as amniocentesis, percutaneous fetal blood sampling, chorionic villus sampling, or shunting.[40-44] The most common pathway of intrauterine infection is the ascending route.[3,40,43,44] Supporting evidence includes the following: (1) Histologic chorioamnionitis is more common and severe at the site of membrane rupture than in other locations, such as the placental chorionic plate or umbilical cord[45]; (2) in virtually all cases of congenital pneumonia, inflammation of the chorioamniotic membranes is present[40-42]; (3) bacteria identified in cases of congenital infections are similar to those found in the lower genital tract[43]; and (4) in twin gestations, histologic chorioamnionitis is more common in the firstborn and has not been demonstrated in the second twin alone. Moreover, when intraamniotic infection is detected, the presenting sac is nearly always involved.[46] Indeed, the membranes of the first twin are generally apposed to the cervix, which is taken as evidence in favor of an ascending infection.[43]

STAGES OF ASCENDING INTRAUTERINE INFECTION

Ascending intrauterine infection is believed to occur in four stages[3] (Figure 16-1). Stage 1 corresponds to a change in the vaginal/cervical microbial flora or the presence of pathologic organisms (e.g., *Neisseria gonorrhoeae*) in the cervix. Some forms of bacterial vaginosis may be an early manifestation of this initial stage. In stage 2, the microorganisms gain access to the intrauterine cavity, reside in the decidua, and a localized inflammatory reaction leads to deciduitis. Microorganisms may then be located in the chorioamniotic membranes. In stage 3, the pathogens may invade the fetal vessels (choriovasculitis) or proceed through the amnion (amnionitis) into the amniotic cavity, leading to microbial invasion of the amniotic cavity. Rupture of the membranes is not a prerequisite for intraamniotic infection because microorganisms are capable of crossing intact membranes.[47] Finally, in stage 4, bacteria may gain access to the fetus by different ports of entry. Aspiration of the infected fluid by the fetus may lead to congenital pneumonia. Otitis, conjunctivitis, and omphalitis may occur by direct spreading of microorganisms from infected amniotic fluid. Seeding from any of these sites to the fetal circulation may result in fetal bacteremia and sepsis.

MICROBIOLOGY OF INTRAAMNIOTIC INFECTION

The most common microbial isolates from the amniotic cavity of women with preterm labor and intact membranes are *Ureaplasma urealyticum, Fusobacterium* spp., and *Mycoplasma hominis.*[3,37,48-50] Other microorganisms that have been found in the amniotic fluid include *Streptococcus agalactiae, Peptostreptococcus* spp., *Staphylococcus aureus, Gardnerella vaginalis, Streptococcus viridans,* and *Bacteroides* spp. Occasionally, *Lactobacillus* spp., *Escherichia coli, Enterococcus faecalis, Neisseria gonorrhoeae,* and *Peptococcus* spp. have been encountered. *Haemophilus influenzae, Capnocytophaga* spp., *Stomatococcus* spp., and *Clostridium* spp. are rarely identified.[51,52] In 50% of patients with microbial invasion, more than one microorganism is isolated from the amniotic cavity. The inoculum size varies considerably, and in 71% of cases, more than 10^5 colony-forming units per milliliter are found.[45]

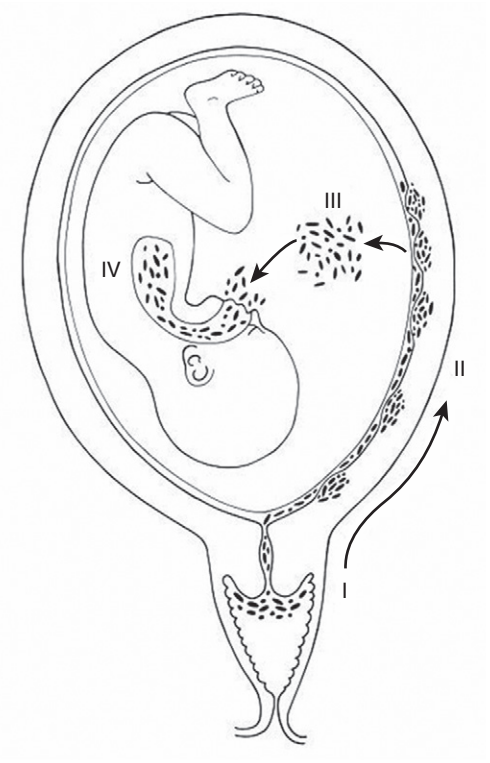

Figure 16-1 The most common pathway of intrauterine infection is the ascending route. *(Reproduced with permission from Romero R, Mazor M. Infection and preterm labor.* Clin Obstet Gynecol *31:553, 1988.)*

The role of *Chlamydia trachomatis* as an intrauterine pathogen has not been clearly defined. This microorganism is an important cause of cervicitis and has been isolated from amniotic fluid.[53,54] Ville and colleagues[55] tested 89 patients with preterm prelabor rupture of membranes (PROM) for the presence of *C. trachomatis* DNA in the uterine cervix (collected by cervical swabs) and amniotic fluid (collected by transabdominal amniocentesis). Cervical samples tested positive for *C. trachomatis* DNA in 23% (20 of 89) of the cases, whereas amniotic fluid samples were positive in 30% (6 of 23). The presence of *C. trachomatis* DNA was not associated with a shorter amniorrexis-to-delivery interval or with an increase in perinatal morbidity or mortality. Thus, *C. trachomatis* DNA is present in the amniotic fluid of symptomatic and asymptomatic patients; however, the clinical implication of its presence is not yet clear.

Viral genome has been recovered from the amniotic fluid of both high- and low-risk pregnancies (Table 16-1).[56-61] In high-risk pregnancies, especially those complicated by nonimmune hydrops, viral genome may be recovered in a substantial proportion of cases.[57,61,62] In contrast, the prevalence of viral genome in the amniotic fluid of asymptomatic pregnancies may range from 0% to 15%, with no apparent change in perinatal outcome.[56-58] Adenovirus is the most common viral DNA isolate, in either symptomatic or asymptomatic pregnancies, followed by cytomegalovirus (CMV) and enterovirus.[56-61] The pathways by which

	High-risk	303*	124 (41)	Adenovirus (74), CMV (30), enterovirus (22), HSV (9), parvovirus (8), EBV (4), RSV (2)	Nonimmune hydrops, ventriculomegaly, growth restriction, stuck-twin syndrome, hepatic calcifications, ascites, myocarditis, pericardial effusion, hydramnios
Baschat et al. (2000)	Low-risk	240	20 (8.9)	Adenovirus was more commonly isolated from complicated pregnancies (16/240 versus 23/138, $p < .005$) Among all pregnancies: adenovirus (39), enterovirus (5), CMV (3), RSV (1), EBV (1), parvovirus (1)	
	Fetal complications‡	138	27 (19.6)		CNS malformations (7), SGA (4), multiple malformations (4)
Reddy et al. (2002)	High-risk	138	25 (18)	Tested for CMV, parvovirus, adenovirus, enterovirus, HSV, EBV, RSV (not discriminated)	Increased incidence of preterm labor and delivery, PPROM, IUFD, SGA
Baschat et al. (2003)	Low-risk	686	44 (69)	Adenovirus (37), CMV (5), EBV (2), enterovirus (2), RSV (1)	—

*371 specimen samples: amniotic fluid ($n = 253$); fetal blood at cordocentesis ($n = 42$), cord blood at the time of delivery ($n = 18$), fetal ascites ($n = 8$), pleural effusion ($n = 10$), and other tissue samples ($n = 40$).

†Pregnancies lost within 30 days of genetic amniocentesis.

‡Fetal anomalies, SGA, proven maternal infection; samples obtained from amniotic fluid, fetal blood or pleural fluid.

CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *HSV,* herpes simplex virus; *IUFD,* intrauterine fetal demise; *PPROM,* preterm premature rupture of the membranes; *RSV,* respiratory syncitial virus; *SGA,* small for gestational age.

viruses gain access to the amniotic cavity in asymptomatic low-risk pregnancies have not been clearly elucidated.

Congenital infection by CMV, rubella virus, parvovirus, and herpes simplex virus has been extensively described; however other viruses are emerging as potential fetal pathogens, including adenovirus, coxsackievirus, human papilloma virus, influenza virus, lymphocytic choriomeningitis virus, and respiratory syncytial virus. In addition to the well-known teratogenic effects, viral infections during pregnancy have been proposed as being involved in the pathogenesis of placental implantation[63-65] and neuropsychiatric disorders.[66] Reddy and collegues[61] studied the association of positive viral genome in the amniotic fluid and abnormal sonographic findings at the time of amniocentesis that was performed for clinical indications.The presence of viral DNA was studied by polymerase chain reaction (PCR) assay for CMV, parvovirus B19, adenovirus, enterovirus, herpes simplex virus, Epstein-Barr virus, and respiratory syncytial virus in 423 pregnancies with a normal fetal karyotype. Amniotic fluid positive for vital PCR was found in 13.5% (57 of 423). Among patients with abnormal sonographic findings, a higher rate of positive viral PCR in the amniotic fluid was reported in patients with structural malformations (20.3%), fetal growth restriction (29.6%), hydrops (50%), and other abnormalities (36%) than those with normal findings on ultrasound examination (8.4%).[61]

FREQUENCY OF INTRAAMNIOTIC INFECTION IN PRETERM GESTATION

Microbial Invasion of the Amniotic Cavity and Preterm Delivery

Preterm labor and preterm PROM account for approximately two thirds (one third each) of preterm deliveries, and the remaining third are the result of indicated delivery because of maternal or fetal indications (i.e., preeclampsia, growth restriction).[67-70] Microbiologic studies suggest that intrauterine infection is the underlying cause for 25% to 40% of preterm births[8]; however, this is probably an underestimation because some pathogens are difficult to identify by conventional cultivation techniques.[71,72] Indeed, using molecular microbiologic techniques, additional bacterial recombinant DNAs have been identified in culture-negative amniotic fluid from women in preterm labor.[51,73,74] In addition, microbial colonization of the chorioamnion was shown to be twice that of the amniotic cavity; thus rates of intrauterine infection based on amniotic fluid cultures further underestimate its true incidence.[75] A review of the evidence supporting the association between intrauterine infection and spontaneous preterm labor (with or without intact membranes) follows.

Microbial Invasion of the Amniotic Cavity in Patients With Preterm Labor and Intact Membranes

Patients with preterm labor and intact membranes have a mean rate of positive amniotic fluid cultures for microorganisms, of approximately 12.8% (379 of 2963), based upon the review of 33 studies.[36,37] Women with positive amniotic fluid cultures generally do not have clinical evidence of infection at presentation. However, they are more likely to develop clinical chorioamnionitis (37.5% [60 of 160] versus 9% [27 of 301]), to be refractory to tocolysis (85.3% [110 of 129] versus 16.3% [8 of 49]), and to rupture their membranes spontaneously (40% [6 of 15] versus 3.8% [2 of 52]) than patients with negative amniotic fluid cultures. Moreover, the earlier the gestational age at preterm birth, the more likely that microbial invasion of the amniotic cavity is present,[39] and at 21 to 24 weeks gestation, most spontaneous births are associated with histologic chorioamnionitis, compared with approximately 10% at 35 to 36 weeks.[39] Several investigators

have demonstrated that the rate of neonatal complications is higher in neonates born to women with microbial invasion of the amniotic cavity than in those without infection.[76]

Microbial Invasion of the Amniotic Cavity in Patients With Preterm PROM

In patients with preterm PROM, the rate of positive amniotic fluid cultures for microorganisms at admission is approximately 32.4% (473 of 1462)[37]; however, clinical chorioamnionitis is present in only 29.7% (49 of 165) of cases with proven microbial invasion.[9,37] The rate of microbial invasion in preterm PROM reported by these studies is probably an underestimation of the true prevalence of intrauterine infection. Indeed, available evidence indicates that the incidence of intraamniotic infection is higher among women with preterm PROM and a severely reduced volume of amniotic fluid than among those without oligohydramnios.[77,78] Because women with oligohydramnios are less likely to undergo an amniocentesis, the bias in these studies is to underestimate the prevalence of infection. In addition, women with preterm PROM admitted in labor generally do not undergo amniocentesis. These patients have a higher rate of microbial invasion of the amniotic cavity than those admitted without labor (39% [24 of 61] versus 25% [41 of 160]; $p < .05$).[79] Furthermore, of patients who are not in labor at admission, 75% have a positive amniotic fluid culture at the time of the onset of labor.[79] Therefore studies restricted to women not in labor provide a lower rate of microbial invasion of the amniotic cavity than those that include patients in labor.

Microbial Invasion of the Amniotic Cavity in Patients Presenting with Acute Cervical Incompetence or a Sonographic Short Cervix

Women presenting with a dilated cervix, intact membranes, and few, if any, contractions before 24 weeks gestation are considered to have clinical cervical incompetence. Of these patients, 51.1% have a positive amniotic fluid culture for microorganisms.[80] A sonographic short cervix in the midtrimester, defined as a cervical length of 25 mm or less, is a powerful predictor of spontaneous preterm delivery.[81,82] Recently subclinical microbial invasion of the amniotic cavity was detected in 9% (5 of 57) of asymptomatic patients with a sonographic cervical length of less than 25 mm.[83] Thus intraamniotic infection is frequently associated with an acute cervical incompetence.[84] Whether intraamniotic infection is a cause or a consequence of cervical dilatation or a short cervix has not been determined. It is possible that shortening of the cervical canal or a silent cervical dilatation with protrusion of the membranes into the vagina may lead to a secondary intrauterine infection. The outcome for patients with microbial invasion of the amniotic cavity is uniformly poor because they develop subsequent complications such as rupture of membranes, clinical chorioamnionitis, or pregnancy loss.

Microbial Invasion of the Amniotic Cavity in Patients with Twin Gestations and Preterm Labor

Microbial invasion of the amniotic cavity occurs in 11.9% of twin gestations.[46] This finding is in contrast to the 21.6% of abnormal amniotic fluid cultures observed in singleton gestations with preterm labor and delivery.[45] These data suggest that intraamniotic infection is a possible cause of preterm labor and delivery in twin gestations, but they do not support the hypothesis that intraamniotic infection is responsible for the high rate of preterm delivery observed in these patients.[85,86] Moreover, when intraamniotic infection is detected, the presenting sac is nearly always involved.[46]

Chorioamniotic Infection, Histologic Chorioamnionitis, and Preterm Birth

Inflammation of the placenta and chorioamniotic membranes is a nonspecific host-response to a variety of stimuli, including infection. Traditionally, acute inflammation of the chorioamniotic membranes has been believed to be an indicator of amniotic fluid infection,[40-44,87-89] a view based upon indirect evidence. Several studies have demonstrated an association between acute inflammatory lesions of the placenta and the recovery of microorganisms from the subchorionic plate[90,91] and the chorioamniotic space.[87] Bacteria have been recovered from the subchorionic plate of 72% of placentas with histologic evidence of chorioamnionitis.[49,87,90] Furthermore, a strong correlation is seen between positive amniotic fluid cultures for microorganisms and histologic chorioamnionitis.[88,89] Moreover, Cassell and associates[75,92] have reported an association between positive microbial cultures from material obtained from the chorioamniotic interface and histologic chorioamnionitis. The presence of inflammation in the umbilical cord (funisitis) represents evidence of a fetal inflammatory response.[93,94] In contrast, histologic chorioamnionitis reflects a maternal inflammatory response.

Several studies have examined the prevalence of inflammation in placentas from women delivering preterm infants. Collectively, the evidence shows an association between preterm birth and the occurrence of acute chorioamnionitis, and that the lower the gestational age at birth, the higher the frequency of histologic chorioamnionitis and funisitis.[49]

Fetal Infection

The most advanced and serious stage of ascending intrauterine infection is fetal infection (stage IV). The overall mortality rate of neonates with congenital neonatal sepsis ranges from 25% to 90%.[95-102] The wide array of results may reflect the effect of gestational age on the likelihood of survival. One study, which focused on infants born before 33 weeks gestation, found that the mortality rate was 33% for those infected and 17% for noninfected fetuses.[100] Carroll and colleagues[103] have reported that fetal bacteremia is found in 33% of fetuses with positive amniotic fluid culture and in 4% of those with negative amniotic fluid culture. Furthermore, Goldenberg and colleagues[104] reported for the Alabama Preterm Birth Study that 23% of neonates born at 23 to 32 weeks gestation have positive umbilical blood cultures for *U. urealyticum* and *M. hominis.* Newborns with positive blood cultures had a higher frequency of a neonatal systemic inflammatory response syndrome, higher umbilical cord serum concentrations of interleukin (IL)-6, and more frequent histologic evidence of placental inflammation than those with negative cultures.[104] Therefore subclinical fetal infection is far more common than traditionally recognized.

INTRAUTERINE INFECTION AND INFLAMMATION AS A CHRONIC PROCESS

Although intrauterine infection has been traditionally considered an acute complication of pregnancy, accumulating evidence suggests that this may be a chronic condition. The evidence in support of this view is derived from studies of the microbiologic state of the amniotic fluid and the concentration of inflammatory mediators at the time of genetic amniocentesis.

Microbial Invasion of the Amniotic Cavity at the Time of Genetic Amniocentesis

Compelling evidence from studies of the microbiologic state of the amniotic cavity, using traditional cultivation techniques at the time of genetic amniocentesis, suggests that intraamniotic

infection may be chronic in nature. Cassell and associates[92] reported the recovery of genital mycoplasmas from 6.6% (4 of 61) of amniotic fluid samples collected by amniocentesis between 16 and 21 weeks. Two patients had positive cultures for *M. hominis* and two for *U. urealyticum.* The patients with *M. hominis* were delivered at 34 and 40 weeks without neonatal complications, whereas those with *U. urealyticum* had premature delivery, neonatal sepsis, and neonatal death at 24 and 29 weeks. Subsequently, Gray and colleagues[105] reported a prevalence of positive cultures for *U. urealyticum* of 0.4% (9 of 2461) in amniotic fluid samples obtained during second-trimester genetic amniocentesis. After excluding one patient who had a therapeutic abortion, all patients (8 of 8) with positive amniotic fluid cultures had either a fetal loss within 4 weeks of amniocentesis ($n = 6$) or preterm delivery ($n = 2$). Furthermore, all had histologic evidence of chorioamnionitis. A similar finding was reported by Horowitz and associates,[106] who detected *U. urealyticum* in 2.8% (6 of 214) of amniotic fluid samples obtained between 16 and 20 weeks of gestation. The rate of adverse pregnancy outcome (fetal loss, preterm delivery, and low birth weight) was significantly higher in patients with a positive amniotic fluid culture than in those with a negative one (50% versus 12%; $p = .04$). Of interest, patients with a positive amniotic fluid culture were more likely to have an obstetric history that included more than three previous spontaneous abortions than those with a negative culture (33% versus 4%; $p = .03$).[106] In a retrospective study of 2718 women undergoing genetic amniocentesis, 1.8% (49 of 2718) of samples were positive for *Ureaplasma/Mycoplasma;* 34 patients were treated with oral erythromycin.[107] Midtrimester pregnancy loss was significantly higher in the untreated than the treated group (44.4% versus 11.4%; $p = .04$). In contrast, no significant differences were observed between the untreated and the treated group in the rate of preterm delivery (20% versus 19.4%; $p = .7$) and adverse pregnancy outcome (55.6% versus 28.6%; $p = .1$).[107] These observations suggest that microbial invasion of the amniotic cavity could be subclinical in the midtrimester of pregnancy and that pregnancy loss or preterm delivery may take weeks to occur.

Chronic Intraamniotic Inflammation and Preterm Birth

IL-6 concentrations in amniotic fluid are considered to be a marker of intraamniotic inflammation frequently associated with microbiologic infection in the amniotic fluid or the chorioamnionitic space.[108-111] Romero and colleagues[112] reported the results of a case-control study in which IL-6 determinations were conducted in the stored fluid of patients who had a pregnancy loss after a midtrimester amniocentesis and a control group who delivered at term. Patients who had a pregnancy loss had a significantly higher median amniotic fluid IL-6 concentration than those with a normal outcome.[112] Similar findings were reported by Wenstrom and associates.[113] Of note, the maternal plasma concentrations of IL-6 were not associated with adverse pregnancy outcome.

The same approach was subsequently used to test the association between markers of inflammation in midtrimester amniotic fluid of asymptomatic women and preterm delivery. The concentrations of matrix metalloproteinase (MMP)-8,[114] IL-6,[115,116] IL-10,[117] C-reactive protein,[118] tumor necrosis factor-alpha (TNF-α),[119] and angiogenin[120] in amniotic fluid obtained at midtrimester amniocentesis were significantly higher in patients who subsequently delivered preterm than in those who delivered at term.

Collectively this evidence suggests that a chronic intraamniotic inflammatory process is associated with both spontaneous abortion and spontaneous preterm delivery. Whether intraamniotic inflammation can be detected noninvasively remains to be determined. Goldenberg and associates[121] have demonstrated that the maternal plasma concentration of granulocyte colony-stimulating factor at 24 and 28 weeks gestation is associated with early preterm birth. To the extent that granulocyte colony-stimulating factor may reflect an inflammatory process, this finding suggests that a chronic inflammatory process identifiable in the maternal compartment is associated with early preterm birth.

Is the Relationship Between Intrauterine Infection and Spontaneous Preterm Birth Causal?

The existence of an association does not mean that infection *causes* preterm delivery. Indeed, it has been argued that microbial invasion of the amniotic cavity is merely the consequence of labor.[122-125] Determining whether or not this relationship is causal is critical because it has major clinical and therapeutic implications. The evidence supporting a causal role for infection follows the criteria outlined by Sir Branford Hill during his presidential address before the Section of Occupational Medicine of the Royal Society of Medicine in 1965[126] and includes (1) biologic plausibility, (2) temporal relationship, (3) consistency and strength of association, (4) dose-response gradient, (5) specificity, and (6) human experimentation.

Although animal experimentation indicates that the administration of bacterial products or microorganisms to pregnant animals can lead to preterm labor and delivery,[127-138] three observations in humans also suggest that infection precedes the spontaneous onset of preterm labor and delivery: (1) subclinical microbial invasion of the amniotic cavity or intrauterine inflammation in the midtrimester of pregnancy leads either to spontaneous abortion or preterm delivery; (2) patients with preterm PROM who on admission had a positive amniotic fluid culture for mycoplasmas (*U. urealyticum* or *M. hominis*) had a significantly shorter amniocentesis-to-delivery interval than those with sterile amniotic fluid[139] (suggesting that patients with preterm PROM and microbial invasion of the amniotic cavity are more likely to initiate preterm labor than those with a negative amniotic fluid culture)[139]; and (3) colonization of the lower genitourinary tract with microorganisms is a risk factor for preterm delivery. These conditions include asymptomatic bacteriuria, bacterial vaginosis, and infection with *N. gonorrhoeae.*[140-151]

The consistency and strength of association between infection and preterm delivery has been demonstrated by the many studies in which amniotic fluid was cultured for microorganisms in patients with preterm PROM[152] and preterm labor with intact membranes.[45] Moreover, the relative risk is higher (greater than 2) for preterm delivery in patients with preterm labor and intact membranes and microbial invasion of the amniotic cavity than in those without microbial invasion of the amniotic cavity. The hazards ratio is also high for the duration of pregnancy in women with preterm PROM with intrauterine infection.

The likelihood of a causal relationship is increased if a dose-response gradient can be demonstrated. Evidence supporting such a gradient includes the following: (1) the median concentration of bacterial endotoxin is higher in patients in preterm labor than in patients not in labor[153]; (2) the microbial inoculum is significantly greater in patients with preterm PROM admitted with preterm labor than in those admitted with preterm PROM but not in labor[79]; and (3) the rate of abortion or preterm delivery after the administration of *Escherichia coli* bacterial endotoxin to pregnant mice exhibits a clear dose-response gradient.[154]

One of the criteria for causality that is not met is specificity. Although intrauterine infection appears to be sufficient to induce preterm labor and delivery, it is not specific because many patients have a preterm delivery in the absence of evidence of intrauterine infection and inflammation. However, a high degree of specificity is rare in biologic systems. Although the causal relationship between smoking and lung cancer is widely accepted,

it is also nonspecific. Lung cancer occurs in nonsmokers and, of course, smoking can cause diseases other than lung cancer, such as emphysema and chronic bronchitis. Moreover, the formulation of "the necessary and sufficient cause" can inappropriately restrict the conceptualization of causality. In the case of preterm labor, microbiologic, cytologic, biochemic, immunologic, and pathologic data indicate that preterm labor is a syndrome and that infection is only one of its possible causes.[9,155]

An important criterion for causation is whether eradication of the agent can decrease the frequency of outcome or illness. Many trials of antimicrobial treatment for the prevention of preterm birth have been conducted. Evidence shows that treatment of patients with asymptomatic bacteriuria will reduce the rate of prematurity and low birth weight[150] and that antibiotic treatment of patients with preterm PROM prolongs the latency period and reduces the rate of maternal and neonatal infection.[156-158] However, treatment of patients with preterm labor and intact membranes has not been effective in most trials.[159-162] The reasons for this are likely related to the syndromic nature of preterm labor with intact membranes, the chronic nature of the process, and the inclusion in the clinical trials of many patients who do not have intrauterine infection and thus cannot benefit from antimicrobial treatment. This applies to patients presenting with preterm labor and those with bacterial vaginosis.[163,164]

Detection of Microbial Footprints in Amniotic Fluid with Sequence-Based Techniques

Estimates of the frequency and type of microorganisms in intrauterine infections are based on standard microbiologic techniques (i.e., culture). A positive amniotic fluid culture can only be obtained if the culture conditions in the laboratory are able to support the growth of a particular microorganism. Thus, although a positive culture is indicative of microbial invasion of the amniotic cavity, a negative culture indicates that the laboratory was not able to grow bacteria from the specimen, either because bacteria was absent (a true negative result) or because the laboratory conditions did not support the growth of a specific microorganism (a false negative result). For example, surveys of terrestrial and aquatic ecosystems indicate that more than 99% of existing microorganisms cannot be cultivated in the laboratory and that their identification can be performed only with molecular methods.[165] Two strategies have been used to detect microorganisms in the amniotic fluid with PCR. The first, also known as broad-range PCR, utilizes primer pairs designed to anneal with highly conserved DNA regions of all bacteria, such as the 16S ribosomal DNA. A positive result indicates the presence of bacteria, but identification of the specific organism requires sequencing of the PCR products. Another approach to molecular diagnosis of infectious diseases is to use specific primers for a particular microorganism. For example, three studies have used primers to the conserved sequence of microorganisms,[51,73,172] and others have favored specific primers to recover bacterial DNA from the amniotic fluid.[173,174]

Blanchard and colleagues[174] were the first to report the recovery of *U. urealyticum* in amniotic fluid samples using specific primers for the urease structural genes. In their study, 293 amniotic fluid samples collected by amniocentesis at cesarean delivery were cultured for bacteria, mycoplasmas, and chlamydiae and had PCR assay performed for *U. urealyticum*. Among the ten PCR-positive amniotic fluid samples, only four were also culture-positive. Subsequently, Jalava,[73] Hitti,[51] and Markenson[172] and their colleagues applied broad-spectrum bacterial 16S recombinant DNA PCR for the detection of bacteria in the amniotic fluid. These studies indicate that PCR assay is a more sensitive method to detect the presence of microorganisms. For example, Jalava and associates[73] studied 20 amniotic fluid samples from patients with PROM and 16 control samples: PCR assay detected five microorganisms (*U. urealyticum* [n = 2], *H. influenzae* [n = 1], *Streptococcus oralis* [n = 1], and *Fusobacterium* spp. [n = 1]); however, only two were positive by routine bacterial culture. Furthermore, the two patients who developed infectious complications were correctly identified by PCR assay, and amniotic fluid glucose concentrations were lower in the PCR-positive samples than in PCR-negative patients. Hitti and associates[51] studied 69 women in preterm labor with intact membranes. PCR assay results were positive in 94% (15 of 16) of the culture-positive amniotic fluid samples and 36% of the patients with a negative culture result. Of the women with elevated IL-6 concentrations, 36% (5 of 14) had bacteria detected by PCR assay. In the study by Markenson and colleagues,[172] 55.5% of the amniotic fluid samples from women in preterm labor (with no clinical evidence of infection) were PCR-positive; microorganisms were recovered in only 9.29% of the samples ($p < .05$). Of the amniotic fluid samples with elevated IL-6 concentrations, 67% (6 of 9) were also PCR-positive.

Oyarzun and colleagues[173] described a PCR amplification technique aimed at detecting the 16 microorganisms most commonly cultured from the amniotic fluid of patients in preterm labor (*U. urealyticum, M. hominis, G. vaginalis, E. coli, Fusobacterium* spp., *Peptostreptococcus anaerobius, Bacteroides fragilis, C. trachomatis, H. influenzae, N. Gohorrhoeae* and *Streptococcus* spp., among others). In 50 patients with preterm labor and intact membranes and 23 patients not in labor, amniotic fluid samples were studied using bacterial culture and PCR assay. All control samples were both culture-negative and PCR-negative. A higher proportion of samples were positive by PCR when compared with culture (46% [23 of 50] versus 12% [6 of 50]). The sensitivity of PCR for the prediction of preterm labor before 34 weeks was better than culture (64% [7 of 11] versus 18% [4 of 11], $p < .05$). However, some patients with positive results on PCR assay delivered at term without maternal or neonatal complications.

The clinical significance of the detection of *U. urealyticum* by PCR assay with specific primers in the amniotic fluid of women in preterm PROM has been investigated.[175] In this study, patients were divided into three groups according to the results of amniotic fluid culture and PCR assay: culture-negative and PCR-negative (n = 99), culture-negative and PCR-positive (n = 18), and culture-positive regardless of PCR results (n = 37). PCR analysis was more sensitive than culture to detect *U. urealyticum* (28% versus 16%). Moreover, patients with a positive PCR assay of amniotic fluid but a negative culture had a stronger inflammatory reaction in amniotic fluid, white blood cell count, and amniotic fluid IL-6 concentration, a shorter interval to delivery, and a higher rate of histologic chorioamnionitis, funisitis, and neonatal morbid events than those with a negative amniotic fluid culture and a negative result on amniotic fluid PCR assay for *U. urealyticum*.[175] This study demonstrated that patients with preterm PROM and a positive result on PCR assay for *U. urealyticum* (but a negative culture) had a worse pregnancy outcome than those with a sterile culture and a negative PCR. Similar results have been observed in the context of preterm labor with intact membranes.[176]

Compelling evidence from studies using PCR at the time of genetic amniocentesis suggests that asymptomatic intraamniotic infection may be more frequent than previously reported using traditional microbiologic techniques. Gerber and colleagues[177] identified *U. urealyticum* using PCR in 11.4% (29 of 254) amniotic fluid samples obtained between 15 to 17 weeks gestation. Patients that were positive for *U. urealyticum* had a significantly higher rate of preterm labor in a previous pregnancy (20.7% versus 2.7%; $p = .0008$), a subsequent episode of preterm labor in the current pregnancy (58.6% versus 4.4%; $p < .0001$), preterm birth before 37 weeks gestation (24.1% versus 0.4%; $p < .0001$), and preterm PROM (20.7% versus 0.4%; $p < .001$) than those who had a negative result. Similar findings were reported by Nguyen and colleagues,[178] who identified *M. hominis* in 6.4% (29 of 456)

of amniotic fluid samples from 456 women obtained between 15 to 17 weeks gestation. The rate of preterm labor and spontaneous preterm delivery before 37 weeks gestation was higher in women with a positive result on PCR assay for *M. hominis* than in those with negative PCR (14.3% versus 3.3%; $p = .01$; 10.7% versus 1.9%; $p = .02$, respectively). Perni and colleagues[179] performed genetic amniocentesis in 179 asymptomatic women between 15 and 19 weeks gestation. *M. hominis* and *U. urealyticum* were detected by PCR assay in 6.1% (11 of 179) and 12.8% (22 of 172) of cases, respectively. Preterm PROM occurred in 2.8% (5 of 179) of women, and the same proportion of patients had a spontaneous preterm birth with intact membranes. All women with preterm PROM had a positive amniotic fluid culture for either *M. hominis* or *U. urealyticum,* whereas none with spontaneous preterm labor were positive for these microorganisms. Finally, Wenstrom and colleagues[58] compared amniotic fluid samples from a group of 62 pregnancy losses after midtrimester amniocentesis with 60 control subjects from a population of 11,971 women. PCR assay was performed for the presence of adenovirus, parvovirus, CMV, Epstein-Barr virus, herpes simplex virus, β-actin DNA, enterovirus, and influenza A virus. No difference in the prevalence of viruses in the amniotic fluid samples was observed between cases and controls (8% versus 15%; $p = .3$). Of interest, adenovirus was identified in 6% of cases and in 8% of controls ($p = .7$).

Collectively, these studies suggest that PCR assay is more sensitive than culture for the detection of microorganisms in the amniotic fluid, particularly in patients with evidence of intraamniotic inflammation. We predict that the application of sequence-based methodology for the identification of microorganisms will lead to increased recognition of the importance of infection in perinatal disease.

Are Microorganisms in the Chorioamniotic Membranes Always Indicative of Pathology?

Intrauterine infection can also be present without a positive amniotic fluid culture or a positive PCR assay result. Specifically, if the infection is localized to the decidua or the space between the amnion and chorion, microorganisms may not be detected in the amniotic cavity. Evidence shows that the rate of microbial colonization in the chorioamniotic space is higher than that observed in the amniotic cavity.[180] Patients with positive amniotic fluid cultures in the membranes but negative cultures in the amniotic fluid often have elevated amniotic fluid concentrations of inflammation indicators, such as IL-6.[180] Therefore some patients with intraamniotic inflammation but negative cultures in the amniotic fluid may have infection in the extraamniotic space. Indeed, fluorescent *in situ* hybridization with a DNA probe specific for conserved regions of bacterial DNA (the 16S ribosomal RNA) has detected bacteria in the fetal membranes of up to 70% of women undergoing elective cesarean delivery at term.[181] Organisms were also detected in fetal membranes after preterm delivery without labor.[181] Inflammatory cells were frequently found in the amnion or chorion of preterm fetal membranes but not in term tissues. These findings suggest that the presence of bacteria alone is not sufficient to cause preterm labor and delivery and that microbial colonization of the chorioamniotic membranes may not always elicit a fetal or maternal inflammatory response. However, preterm labor is more frequent when a fetal inflammatory response is elicited.[181]

MOLECULAR MECHANISMS FOR PRETERM PARTURITION IN THE SETTING OF INTRAUTERINE INFECTION

A solid body of evidence supports a role for inflammatory mediators in the mechanisms of preterm parturition associated with infection. These factors may also play a part in spontaneous labor at term, although the evidence for this is less compelling. Attention has focused on the role of proinflammatory cytokines, such as IL-1β, TNF-α, and chemokines, such as IL-8. However, other proinflammatory platelet-activating factors, prostaglandins (PGs), and antiinflammatory cytokines may also play a role.[9] The current understanding of the proposed pathophysiology of preterm parturition in the context of intrauterine infection is summarized. The interested reader is referred to the references for a comprehensive discussion.[9]

During the course of ascending intrauterine infection, microorganisms may reach the decidua, where they can stimulate a local inflammatory reaction and the production of proinflammatory cytokines and inflammatory mediators (e.g., platelet-activating factor, PGs, leukotrienes, reactive oxygen species, nitric oxide).[3,9] If this inflammatory process is not sufficient to signal the onset of labor, microorganisms can still cross intact membranes into the amniotic cavity where they can stimulate the production of inflammatory mediators by resident macrophages and other host cells. Finally, microorganisms that gain access to the fetus may elicit a systemic inflammatory response syndrome, characterized by increased cord blood concentrations of IL-6[10,11] and other cytokines,[182] as well as cellular evidence of neutrophil and monocyte activation.[183]

The Importance of Toll-Like Receptors in Preterm Parturition

The first line of defense against infection is provided by the innate immune system. One of the mechanisms by which the innate immune system recognizes microorganisms is by using pattern recognition receptors, which bind to molecular structures present on the surfaces of microorganisms[184] and are classified according to their function and subcellular localization.

Toll-like receptors (TLRs) are a group of transmembrane pattern recognition receptors,[185] and ten different TLRs have been identified in humans.[184] TLR-2 recognizes peptidoglycans, lipoproteins, and zymosan (gram-positive bacteria, mycoplasmas, and fungi); TLR-4 recognizes the presence of lipopolysaccharide, which is produced by gram-negative bacteria; and TLR-3 recognizes double-stranded RNA (viruses).[184,186,187] Ligation of TLRs results in activation of nuclear factor (NF)-κB which, in turn, leads to the production of cytokines, chemokines, and antimicrobial peptides.[184] Moreover, activation of the toll pathway also induces surface expression of costimulatory molecules, required for the induction of adaptive immune responses, such as CD80 and CD86. In combination with antigenic microbial peptides, these molecules, presented by major histocompatability complex class II proteins in dendritic cells and macrophages, can activate naïve $CD4^+$ T cells that initiate most adaptive immune responses.[184]

In pregnant women, TLR-2 and TLR-4 are expressed in the amniotic epithelium.[188] Because TLRs are crucial for the recognition of microorganisms, it could be anticipated that defective signalling through these pattern recognition "receptors" will impair bacteria-induced preterm labor. Indeed, a strain of mice that has a spontaneous mutation for TLR-4 is less likely to deliver preterm after intrauterine inoculation of heat-killed bacteria or lipopolysaccharide administration than wild-type mice.[189,190] Moreover, in humans, spontaneous labor at term or preterm with histologic chorioamnionitis, regardless of the membrane status (intact or ruptured), is associated with an increased messenger RNA and protein expression of TLR-2 and TLR-4 in the chorioamniotic membranes.[188] These observations suggest that the innate immune system plays a role in parturition.

Prostaglandins and Lipoxygenase Products

Intrauterine PGs have been considered to be the key mediators in the biochemic mechanisms regulating the onset of labor. They can induce myometrial contractility[191-194] and changes in the

extracellular matrix metabolism associated with cervical ripening,[195-199] and they are thought to participate in decidual and fetal membrane activation.[9]

Supporting the role for PGs in the initiation of human labor includes evidence that (1) administration of PGs can induce early or late termination of pregnancy (abortion or labor)[200-208]; (2) treatment with indomethacin or aspirin (PG inhibitors) can delay spontaneous onset of parturition in animals[209-211]; (3) PG concentrations in amniotic fluid abruptly increase before the onset of spontaneous labor at term,[212] and concentrations of PGs in plasma and amniotic fluid increase during labor[213-219]; and (4) intraamniotic injection of arachidonic acid can induce abortion.[220]

Infection is thought to increase PG production by amnion, chorion, or decidua through the activity of bacterial products, cytokines, growth factors, and other inflammatory mediators. Indeed, amniotic fluid concentrations of PGE2 and PGF2α, and their stable metabolites are significantly higher in women with preterm labor and microbial invasion of the amniotic cavity than in women with preterm labor alone.[218,221] Similar observations have been reported on patients in labor with high concentrations of proinflammatory mediators in the amniotic cavity (e.g., IL-1β, TNF, IL-6). Moreover, amnion obtained from patients with histologic chorioamnionitis produces higher amounts of PGs than that obtained from patients without documented chorioamnionitis. In mice, quantitative real-time reverse transcriptase (RT)-PCR measurements demonstrated that bacteria-induced preterm labor substantially increased the expression of genes involved in PG synthesis.[222]

Metabolites of arachidonic acid derived through the lipoxygenase pathway, including leukotrienes (LTs) and hydroxyeicosatetraenoic acid (HETEs), have also been implicated in the causation of spontaneous preterm and term parturition. Concentrations of 5-HETE, LTB_4, and 15-HETE are increased in the amniotic fluid of women with preterm labor and microbial invasion of the amniotic fluid cavity.[223,224] Similarly, amnion from patients with histologic chorioamnionitis release more LTB_4 in vitro than amnion from women who delivered preterm without inflammation.[225] Moreover, ovariectomy-induced preterm labor increased the expression of genes involved in lipoxin, LTs, and HETEs synthesis.[222] However, the precise role of arachidonate lipoxygenase metabolites in human parturition remains to be determined. 5-HETE and LTC_4 can stimulate uterine contractility, and LTB_4 is thought to play a role in the recruitment of neutrophils to the site of infection and the regulation of arachidonic acid metabolites of the cyclooxygenase (COX) pathway.[226,227] Additionally, LTB_4 has been shown to act as a calcium ionophore (i.e., increases phospholipase activity and enhances the rate of PG biosynthesis in human intrauterine tissues).[228]

Proinflammatory Cytokines and Preterm Labor

A substantial body of evidence supports the participation of the proinflammatory cytokines IL-1 and TNF-α in preterm parturition: (1) IL-1β and TNF-α stimulate PG production by amnion, decidua, and myometrium[229-231]; (2) human decidua can produce IL-1β and TNF-β in response to bacterial products[230,232,233]; (3) the concentrations and bioactivity of IL-1β and TNF-α in amniotic fluid are elevated in women with preterm labor and intraamniotic infection[234-237]; (4) women with preterm PROM and intraamniotic infection have higher IL-1β and TNF-α concentrations in the presence of labor[228-231]; (5) IL-1β and TNF-α can induce preterm parturition when systemically administered to pregnant animals[127;238]; (6) TNF-α is involved in the mechanism of bacterial-induced preterm parturition in animal models[239;240]; (7) pretreatment with the natural IL-1 receptor antagonist before the administration of IL-1 to pregnant animals prevents preterm parturition[241]; (8) the concentrations of IL-1β in fetal plasma is elevated in the context of preterm labor with intrauterine infection[242]; and (9) placental tissue obtained from patients in labor, particularly those with chorioamnionitis, produces greater amounts of IL-1β than that obtained from women not in labor.[243]

Considerable redundancy exists, however, in the cytokine network, and blockade of a single factor is insufficient to prevent preterm delivery in the context of infection and inflammation. Indeed, the administration of anti-TNF and the natural IL-1 receptor antagonist to pregnant animals with intrauterine infection did not prevent preterm delivery.[244] Moreover, results of knockout animal experiments suggest that infection-induced preterm labor and delivery occur in animals that lack a particular cytokine.[245]

The precise mechanisms by which IL-1 and TNF participate in the activation of the myometrium has been the subject of intensive research, and evidence shows that they involve the participation of cytosolic phospholipase A-2, COX-2,[246,247] mitogen-activated protein (MAP) kinases,[248] and NF-κB.The latter transcription factor is responsible for many of the actions of IL-1 and TNF in amnion and may affect uterine function by blocking factors that promote uterine quiescence (e.g., progesterone).[249]

Antiinflammatory Cytokines and Preterm Labor

IL-10 is thought to be a key cytokine for the maintenance of pregnancy[250] and has been implicated in the control of preterm parturition associated with inflammation.[251] Indeed, IL-10 expression is reduced in the placental tissues of pregnancies complicated by preterm labor and chorioamnionitis compared with that in placental tissue from normal controls.[251] IL-10 inhibits COX-2 messenger RNA expression in cultured placental explants from women after preterm labor and preterm birth but not in those from women in labor at term, indicating that the mechanisms involved in the regulation of the inflammatory response during term and preterm parturition may be different.[251] Further evidence for the role of IL-10 in down-regulation of the inflammatory response during preterm labor derives from a study where the administration of dexamethasone or IL-10 to pregnant rhesus monkeys, significantly reduced the IL-1B–induced uterine contractility. IL-10 treatment also attenuated the concentrations of TNF-α and white blood cells in amniotic fluid.[252] Moreover, the administration of IL-10 to animal models of infection has been associated with improved pregnancy outcome.[253,254]

Matrix-Degrading Enzymes

The causal mechanisms of preterm PROM are poorly understood. Because the tensile strength and elasticity of the chorioamniotic membranes have been attributed to extracellular matrix proteins, matrix-degrading enzymes have been implicated in preterm PROM. Compelling evidence shows that preterm PROM is associated with increased availability of MMP-1,[249] MMP-8,[255-257] MMP-9,[258-260] and neutrophil elastase,[261] but not MMP-2,[260,262] MMP-3,[263] MMP-7,[264] and MMP-13.[264a]

Vaginal bleeding may predispose to membrane rupture by causing a separation between the chorioamnion and the decidua, which weakens the fetal membranes.[265] Alternatively, during the formation of a retroplacental clot, thrombin is generated.[266] This enzyme can stimulate the production of MMP-1[267] and MMP-3[266] by decidual cells and MMP-9 by amniochorionic membranes.[268] These MMPs can degrade fibrillar collagen (type I and III) and other components of the extracellular matrix of the chorioamniotic membranes.[269] The mechanisms responsible for defective endometrial hemostasis during pregnancy have not been identified. However, in some cases, the only manifestation of intrauterine infection may be vaginal bleeding.[265] This observation would link vaginal bleeding in the first and second trimesters of pregnancy, endometrial bleeding/deficient hemostasis, and intrauterine infection. This association is important because women with preterm PROM often have clinical or subclinical abruptions,

and histologic examination of the membranes in patients with abruption indicates that acute chorioamnionitis is a frequent occurrence.[270]

Because intrauterine infection is present in 30% of patients with preterm PROM and proinflammatory cytokines can stimulate the production of MMP-1, MMP-9, and MMP-8, a genetic predisposition to overproduction of MMPs in response to microorganisms may lead to preterm PROM. Indeed, fetal carriage of a 14 CA repeat in the promoter of the gene encoding for MMP-9 is associated with preterm PROM,[271] and a polymorphism in the promoter region of the gene for MMP-1 (nt-1607) also conferred an increased risk for preterm PROM (OR 2.29; 95% CI 1.09 to 4.82).[272] Additionally, single nucleotide polymorphisms in the MMP-8 promoter in neonates of African American women modified the risk for preterm PROM.[273] The combination of three minor allele haplotypes (−799T/−381G/+17G) was associated with a significantly higher risk for preterm PROM (OR 4.63; 95% CI 2.01 to 11.94). In contrast the combination of the three major allele haplotypes (−799C/−381A/+17C) had a protective effect against preterm PROM (OR 0.52; 95% CI 0.36 to 0.75).[273]

FETAL INFLAMMATORY RESPONSE SYNDROME

What is Fetal Inflammatory Response Syndrome?

Fetal microbial invasion is the last stage of ascending intrauterine infection. Clinical and experimental evidence suggests that the fetus can be exposed to microorganisms and their products (i.e., bacterial endotoxin)[153,274] that are present in the amniotic cavity and that the fetus can respond by mounting both cellular and humoral immunoresponses.[275-277] Gomez and colleagues proposed that fetal microbial invasion can result in a systemic fetal inflammatory response syndrome (FIRS) that can progress to multiple organ dysfunction, septic shock, and death in the absence of a timely delivery.[10] FIRS represents the fetal counterpart of the systemic inflammatory response syndrome (SIRS),[10] described in adults.[278] However, FIRS is a peculiar condition because of the unique circumstances of the patient (fetus) and of its environment (uterus); thus its diagnosis, management, treatment, and consequences are sui generis.[279-281]

The term *fetal inflammatory response syndrome* was coined to define a subclinical condition originally described in fetuses of women presenting with preterm labor and intact membranes as well as preterm PROM. The operational definition was an elevation of fetal plasma IL-6 concentration greater than 11 pg/mL.[10] This cytokine was selected as the marker for the definition of FIRS[242] for the following reasons: (1) IL-6 is a major mediator of the host response to infection and tissue damage; it is capable of eliciting biochemic, physiologic, and immunologic changes in the host, including stimulation of the production of C-reactive protein by liver cells; and (2) because many of the diagnostic criteria proposed for SIRS in adults[278] cannot be applied to the human fetus because the vital signs (with the exception of heart rate) cannot be readily determined before birth or in the intrapartum period. In contrast, the proinflammatory cytokine IL-6 is easy to measure and readily detectable in peripheral blood. IL-6 is also elevated in adults with SIRS.[282]

The original work describing FIRS was conducted in samples obtained by cordocentesis (Figure 16-2).[10,11] In patients with preterm PROM, fetal plasma IL-6 concentrations greater than 11 pg/mL are associated with a shorter cordocentesis-to-delivery interval than that observed with plasma IL-6 concentrations of 11 pg/mL or less (median, 0.8 day [range, 0.1 to 5 days] versus 6 days [range, 0.2 to 33.6 days], respectively; $p < .05$).[11] One approach to determine whether fetal inflammation was present before birth is to examine the umbilical cord. Funisitis and chorionic vasculitis (inflammation of the umbilical cord or of the fetal vessels on the chorionic plate, respectively) are the histopathologic landmarks of FIRS.[94] Neonates with funisitis are at increased risk for neonatal sepsis,[93] as well as pathologic conditions with long-term consequences such as bronchopulmonary dysplasia[20] and cerebral palsy.[16] The amniotic fluid white blood cell count is another indirect marker of fetal inflammation. Indeed, neutrophils are not normally present in amniotic fluid; these cells are recruited into the amniotic compartment in the course of intrauterine infection, and their origin is predominantly fetal.[283]

		n	Procedure-to-delivery interval (median, range, days)
I	AF IL-6 ≤7.9 ng/mL FP IL-6 ≤11 pg/mL	14	5 (0.2-33.6)
II	AF IL-6 >7.9 ng/mL FP IL-6 ≤11 pg/mL	5	7 (1.5-32)
III	AF IL-6 >7.9 ng/mL FP IL-6 >11 pg/mL	6	1.2 (0.25-2)
IV	AF IL-6 ≤7.9 ng/mL FP IL-6 >11 pg/mL	5	0.75 (0.13-10)

Figure 16-2 Classification and procedure-to-delivery interval of women according to amniotic fluid (AF) and fetal plasma (FP) IL-6 concentrations. Analysis was restricted to 30 women with preterm prelabor rupture of membranes (PROM) and available AF. White in the fetal or AF compartment represents a low FP or AF IL-6 concentration, respectively, whereas black/gray in the fetal or AF compartment denotes elevated fetal plasma or AF IL-6 concentration, respectively. In the absence of a fetal systemic inflammatory response, no differences in the procedure-to-delivery interval were observed between patients with and those without inflammatory response in the amniotic fluid (median 5 days versus median 7 days, respectively; groups I and II; $p > .05$). Among patients with an elevated fetal plasma IL-6 concentration (groups III and IV), the presence or absence of an inflammatory response in the amniotic fluid did not alter the procedure-to-delivery interval *(Reproduced with permission from Romero R, Gomez R, Ghezzi F, et al. A fetal systemic inflammatory response is followed by the spontaneous onset of preterm parturition,* Am J Obstet Gynecol *179:186, 1998.)*

Fetal Target Organs in the Fetal Inflammatory Response Syndrome

After adjustment for gestational age, FIRS is associated with a higher rate of neonatal complications,[16,20] and mothers of affected fetuses frequently have subclinical microbial invasion of the amniotic cavity.[10] Evidence of multiorgan involvement is characteristic (Figure 16-3), with a higher rate of severe neonatal morbidity (respiratory distress syndrome, suspected or proven neonatal sepsis, pneumonia, bronchopulmonary dysplasia, intraventricular hemorrhage, periventricular leukomalacia, and necrotizing enterocolitis).[10,11]

Hematopoietic System

In FIRS, the fetal hematologic profile is characterized by significant changes in the granulocyte and red blood cell lineages.[284] Neutrophilia is present in two-thirds of affected fetuses; neutropenia occurs in 7%.[284] The median plasma concentration of granulocyte colony-stimulating factor is significantly higher than that in the absence of FIRS, which may contribute to the fetal neutrophilia.[182] FIRS has also been associated with changes in markers of monocyte and neutrophil activation.[183] Fetuses delivered within 72 hours of cordocentesis had a higher expression of CD11c, CD13, CD15, and CD67 than those delivered at term.

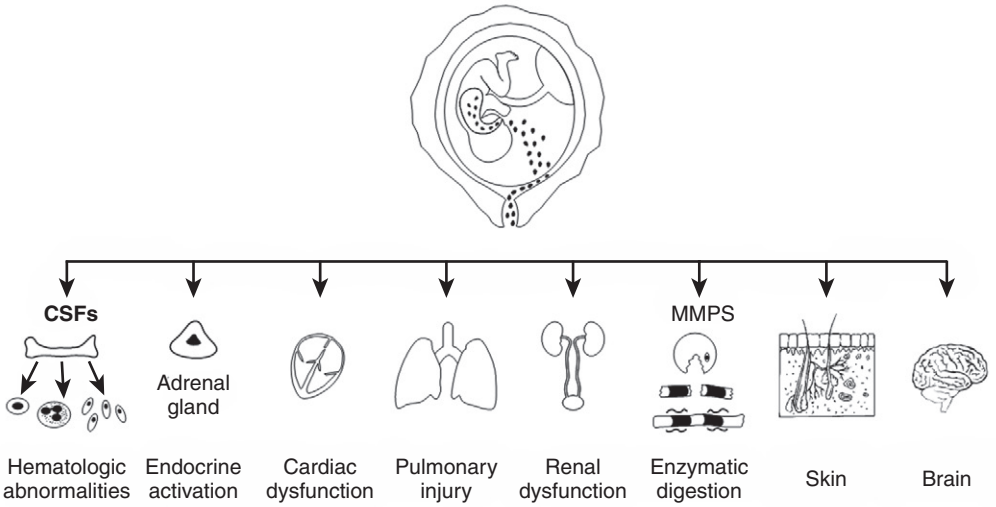

Figure 16-3 Fetal target organs during the fetal inflammatory response syndrome (FIRS). Several fetal organs, including the brain, lungs, heart, and kidneys, as well as the hematopoietic system, have been proposed to be targets during FIRS. *CSFs,* Colony-stimulating factors; *MMPs,* matrix metalloproteinases.

The median nucleated red blood cell count is higher in fetuses with FIRS than in those without FIRS.[284] It was proposed that IL-6 may have a unique, short-term role in elevating fetal nucleated red blood cell counts.[285] Collectively, these results indicate that fetuses destined to deliver prematurely have phenotypic evidence of activation of the monocyte-neutrophil system.[183]

Fetal Thymus

Considerable evidence indicates an association between thymus involution and infection in both fetuses and neonates.[286-288,288a,288b] Indeed, subclinical chorioamnionitis has been associated with the finding of a small thymus in very-low-birth-weight infants,[286] possibly because of an acute fetal[287] and neonatal[287,288] involution. In neonates, thymic involution has been reported to correlate with the duration of acute illness and with the percentage of lymphocytes in the peripheral blood smear.[288] Thymic involution has been attributed to both stress (through steroid production) and proinflammatory cytokines.[289-291] Di Naro and colleagues[292] reported that in the presence of intraamniotic infection and inflammation, fetuses from mothers with preterm labor and intact membranes had a sonographically small thymus. In another study, infants born preterm (less than 28 weeks gestation) with sonographic signs of cerebral white matter damage (white matter echolucencies in postnatal cranial ultrasound scans) were more likely to have undergone thymic involution (interval between birth and thymus involution) before the median interval for the gestational age-group.[291]

Adrenal Glands

Similar to adult patients admitted to intensive care units with burns[294] or pancreatitis,[294] fetuses with FIRS have endocrine evidence of "stress," which is expressed by an elevation of the cortisol and dehydroepiandrosterone sulfate ratio.[293] This endocrine milieu may contribute to the onset of spontaneous preterm labor. Indeed, Yoon and colleagues[293] reported that in patients with preterm PROM there is a significant association between the fetal plasma cortisol and dehydroepiandrosterone sulfate ratio and a shorter interval from cordocentesis to delivery (hazards ratio, 2.9; 95% CI, 1 to 8.4). Patients with preterm PROM who went into spontaneous labor and delivered within 7 days of cordocentesis had a significantly higher median fetal plasma concentration of cortisol than those who delivered after 7 days ($p < .0001$). Fetal plasma cortisol, but not maternal cortisol, was an independent predictor of the duration of pregnancy after adjusting for gestational age and the results of amniotic fluid cultures (hazards ratio, 2.9; 95% CI, 1.3 to 6.7). Importantly, a significant correlation was seen between fetal plasma cortisol and fetal plasma IL-6 ($r = 0.3$; $p < .05$).[293] These endocrine changes may have short and long-term implications given the observations about the effects of glucocorticoids in fetal programming of several metabolic functions.[295-299]

Fetal Skin

Fetal dermatitis can occur during FIRS. Skin samples from fetuses between 21 and 24 weeks gestation expressed both TLR-2 and TLR-4 in the fetal epidermis[300]; TLR-2 expression is dramatically increased in fetuses born from mothers with chorioamnionitis. Moreover, TLR-2 and TLR-4 were expressed in the mononuclear inflammatory infiltrate of the dermal-epidermal junction. The investigators in the study reporting these findings proposed that microorganisms are recognized by the fetal skin through "pattern-recognition receptors," and thus participates in the fetal inflammatory response to microbial products.[300]

Fetal Kidneys

Yoon and colleagues[78] reported an association between oligohydramnios and a higher rate of fetal infection and inflammation in patients with preterm PROM. In view of the antimicrobial properties of the amniotic fluid,[301,302] oligohydramnios may reduce the protective effect of this component of innate immunity. Alternatively, oligohydramnios may be the result of a redistribution of blood flow away from the kidneys occurring during the host response to microbial products.[78]

Fetal Heart

Echocardiographic studies have shown that fetuses with preterm PROM and intraamniotic infection undergo changes in cardiac function that are consistent with a high left ventricular compliance.[303] These changes may reflect a compensatory mechanism similar to that observed in adults with sepsis. In cases of overwhelming fetal sepsis, myocardial depression may lead to fetal death. In the context of FIRS, it is possible that soluble factors that are elevated in the circulation of patients with septic shock, such as bacterial products and cytokines, contribute to the myocardial depression.[304-306] Fetuses that are unable to modify their cardiac compliance to maintain ventricular stroke volume and cardiac output may suffer inadequate brain perfusion, predisposing them

to hypotension and brain ischemia *in utero*. This could create conditions predisposing to periventricular leukomalacia and brain injury.[307,308]

Fetal Lung

Amniotic fluid and its contents can be inhaled by the fetus and reach the distal parts of the airways and the alveoli. Color Doppler ultrasound studies demonstrated influx and efflux of amniotic fluid from the fetal upper respiratory tract.[309,310] Intrauterine inflammation has been associated with the development of bronchopulmonary dysplasia.[311-314]

Watterberg and colleagues[17] reported that low-birth-weight infants exposed to chorioamnionitis had higher concentrations of IL-1β in tracheal lavage samples and were more likely to develop bronchopulmonary dysplasia, but had lower incidence of respiratory distress syndrome in comparison with control infants. Ghezzi and colleagues[19] reported that IL-8 concentrations in amniotic fluid were higher in women with preterm labor (with intact membranes) and preterm PROM, delivering infants at 24 to 28 weeks gestation in whom bronchopulmonary dysplasia developed. In a subsequent study,[18] preterm neonates born at 33 weeks gestation or earlier in whom bronchopulmonary dysplasia developed had significantly higher median amniotic fluid IL-1β and IL-8 concentrations than those who did not. Similarly, Yoon and colleagues[20] reported that neonates born between 25 and 34 weeks gestation who developed bronchopulmonary dysplasia had a significantly higher median umbilical cord plasma IL-6 concentration than that of preterm infants without bronchopulmonary dysplasia, further supporting the association between FIRS and bronchopulmonary dysplasia.

Models of intrauterine inflammation, such as intraamniotic administration of endotoxin or the inoculation of bacteria, have supported the effects of microbial products and inflammation on lung development.[315-317] Bry and colleagues[318] conducted the first experimental study on the effects of antenatal inflammation on the fetal lung. Intraamniotic injection of IL-1α to pregnant rabbits induced an increase in the messenger RNA and protein expression of surfactant proteins A and B as well as surfactant lipids, resulting in an improvement of neonatal lung function. Injection of IL-1α also induced preterm delivery. These observations suggested that fetal lung inflammation accelerates fetal lung maturation in preparation for preterm birth. However, the biologic consequences include a reduction in the number of alveoli (that are increased in size), an inhibition of the microvascular development, and a thickening of the arteriolar walls, which collectively resemble the changes observed in infants with bronchopulmonary dysplasia.[319] Therefore the short-term gain in lung maturity can result in a predisposition to the development of chronic lung disease.

Fetal Brain

A link between exposure to perinatal infection and inflammation and brain injury is well recognized.[12-15,320] The first observations of this association date back to 1955 when Eastman and DeLeon[321] reported that intrapartum maternal fever conferred a seven-fold increased risk for cerebral palsy. Subsequently, Nelson and Ellenberg,[322] using data from the Collaborative Perinatal Project, showed that among low-birth-weight infants, chorioamnionitis was associated with an increased incidence of cerebral palsy from 12 to 39 per 1000 live births.

Dammann and Leviton[323] proposed that intrauterine infection leads to a fetal inflammatory response, which, in turn, contributes to adverse outcomes such as preterm labor and delivery, intraventricular hemorrhage, white matter damage, and neurodevelopment disability (mainly cerebral palsy). Several lines of evidence support this concept: (1) A fetal inflammatory response precedes spontaneous preterm delivery in the context of infection[10,11]; (2) clinical and histologic chorioamnionitis are associated with an increased risk of cerebral palsy[12-14,16,320,324-337] (this association has also been reported in near-term infants)[13,338]; (3) a large body of experimental evidence indicates that intrauterine infection results in white matter damage and neuronal lesions[339-344]; (4) white matter lesions are associated with intrauterine inflammation and infection in women with spontaneous preterm labor[331,345-347]; (5) elevated concentrations of cytokines in amniotic fluid and fetal plasma,[14,16,348-352] and fetal vasculitis (chorionic and umbilical cord vessel inflammation),[16,353-356] are associated with the development of intraventricular hemorrhage, white matter damage, and cerebral palsy.

Leviton[357] proposed that inflammatory cytokines (TNF-α) released during the course of intrauterine infection could participate in the pathogenesis of periventricular leukomalacia by four different mechanisms: (1) induction of fetal hypotension and brain ischemia[358]; (2) stimulation of production and release of tissue factor, which, in turn, can activate the hemostatic system and contribute to coagulation necrosis of white matter[359]; (3) induction of the release of platelet activating factor, which could act as a membrane detergent resulting in brain damage[360]; and (4) a cytotoxic effect of TNF-α on oligodendrocytes and myelin.[361,362] Yoon and colleagues[14] have suggested another mechanism: microbial invasion of the amniotic cavity (which occurs in approximately 25% of preterm births) results in congenital fetal infection and inflammation that stimulates fetal mononuclear cells to produce IL-1β and TNF-α. These cytokines promote the passage of microbial products and other cytokines into the brain by increasing the permeability of the blood-brain barrier.[363,364] Interferon-γ and lipopolysaccharide also increase the permeability of the blood-brain barrier. This increase in permeability is, at least in part, dependent on cyclic guanosine monophosphate and nitric oxide.[364] Microbial products activate human fetal microglial cells to produce IL-1 and TNF-α, which in turn stimulate astrocyte proliferation and production of TNF-α. TNF-α damages oligodendrocytes, which are the cells responsible for the deposition of myelin.

A strong association is recognized between prematurity and cerebral palsy.[365] Approximately one-third of the neonates who develop cerebral palsy have birth weights less than 2500 g.[366] Cerebral palsy rates are 25 to 31 times higher in newborns with a birth weight less than 1500 g compared with normal birth weight neonates.[366] Extremely premature neonates, in addition to being exposed to an exaggerated fetal systemic inflammatory response, display a limited ability to buffer the effects of the proinflammatory cytokines[15,367-373] generated by intrauterine infection and inflammation. It is important to stress that some studies did not demonstrate an association between inflammation and brain damage in the preterm infant.[374-377] Hypoxic and ischemic damage and inflammation are proposed to have a synergistic role in causing fetal brain injury.[378-380] Recently, the administration of *N*-acetylcysteine has been demonstrated to restrict brain damage in an animal model, which combined inflammation induced by lipopolysaccharide and ischemia. This has potential therapeutic effects in humans, given that *N*-acetylcysteine crosses the placenta.[381-383]

CONCLUSION

The evidence reviewed in this chapter indicates that intraamniotic infection and inflammation is causally linked to preterm parturition and the development of FIRS in a subset of patients. FIRS can affect multiple organ systems and predispose to short-term and long-term complications. Two of the long-term complications include bronchopulmonary dysplasia and cerebral palsy. Possible modulation of the maternal and fetal inflammatory response during pregnancy may have considerable importance for the understanding of the mechanisms of disease and preterm birth, and for limiting fetal injury.

Maternal Cardiovascular Disease and Fetal Growth and Development

Within the womb, fetal growth and development depend on inherited genetic programs, the nutritive support of the maternal host, and interactions between the two. The importance of the fetal environment is evident in the long-term consequences of suboptimal *in utero* conditions on the future health of the offspring.[1-3] In crafting the fetal environment, both the placenta and the mother play critical roles. The placenta must initiate maternal adaptations to support the developing pregnancy, and then must successfully distribute substrates and wastes across the uterine interface. For her part, the mother must respond successfully to placental demands for resources by undertaking dramatic cardiovascular adaptations without simultaneously jeopardizing her own health. Disturbances at any of these steps, from implantation to maternal adaptation, may have an impact on the uterine environment and trigger adaptive or pathologic alterations in fetal growth and development.

Although essentially all maternal systems undergo some degree of adaptation during pregnancy, the maternal cardiovascular system experiences the most dramatic changes, indicating its critical role in determining the adequacy of the intrauterine environment. By augmenting cardiac output and blood volume, reducing peripheral vascular resistance, and remodeling uterine vasculature, pregnancy triggers a cardiovascular response that increases blood flow to the uterus by more than 10-fold, generating a

dependable vascular supply designed to withstand moment-to-moment fluctuations in substrate supply and removal.[4-6] In most women, these fetal and placental demands for adaptation are met without compromise of the mother's well-being, and the fetus is well served by successful maternal cardiovascular adaptation. But in cases of abnormal placental development combined with latent or overt maternal cardiovascular disease, these essential physiologic demands may jeopardize maternal health, or fail to occur altogether, thereby compromising fetal growth, development and survival. In this regard, both fetal growth and maternal cardiovascular adaptation to pregnancy are intimately linked by their dependence on proper placental function.

This chapter examines the associations between maternal cardiovascular disease (CVD) and aberrant fetal growth and development. Although much has been learned about the metabolic and endocrine regulation of fetal growth, its associations with maternal cardiovascular disease are still largely descriptive. Beyond these clinical associations, this chapter addresses several unique mechanisms by which maternal cardiovascular disease alters the fetal environment and, alternatively, mechanisms by which fetal or placental maldevelopment may trigger maternal vascular disease. One key to understanding the maternal-fetal-placental relationship is an appreciation of the essential cardiovascular adaptations to normal pregnancy. This chapter therefore begins with an overview of the changes that pregnancy induces in a woman's cardiovascular physiology. Thereafter follows a summary of some common vascular diseases of pregnancy, including special mention of preeclampsia, an important condition unique to human gestation. The proposed pathophysiology of preeclampsia is considered in detail in order to highlight mechanisms by which maternal, fetal, and placental maladaptation may be related to one another. The chapter then addresses the associations of disturbed fetal growth with maternal disease and proposes potential mechanisms for this interaction. Finally, mention is given to several potential long-term consequences of cardiovascular disease in pregnancy for the offspring.

MATERNAL CARDIOVASCULAR ADAPTATIONS TO PREGNANCY

Maternal cardiovascular adaptations in pregnancy serve to augment uterine blood flow by more than 10-fold over the course of pregnancy and are essential for supporting a nutritive intrauterine environment.[6] Most of these vascular adaptations are induced early and progressively by signals from placental hormones, mechanical forces, and physiologic demands placed by other maternal organ systems. The adaptive changes of pregnancy include increases in cardiac output, stroke volume, heart rate, myocardial contractility, plasma volume, blood volume, and total body water and decreases in systemic vascular resistance and blood pressure. A summary of the major cardiovascular changes of pregnancy is presented in Table 17-1.

Cardiac Output

Cardiac output begins to rise as early as 5 weeks of gestation.[7-9] By 8 weeks, it is already elevated some 22% above nonpregnant values, increasing more slowly thereafter to a maximum of 30% to 50% by the third trimester.[7,8,10,11] The timing of these cardic output peaks in pregnancy has not been established, although a review by van Oppen and co-workers[12] of 33 cross-sectional and 19 longitudinal studies suggests a range of 25 to 30 weeks of gestation. A majority of latent maternal cardiac diseases will become clinically apparent at this same time, potentially impairing uteroplacental blood flow and fetal growth. An exaggerated increase in cardiac output is noted in pregnancies complicated by multiple gestation,[8,13] anemia,[14,15] high altitude,[16] hyperthyroidism,[17] and other coincident risk factors for cardiovascular disease. Such pregnancies are associated with increased risk for failed maternal adaptation, fetal growth restriction, and preeclampsia.

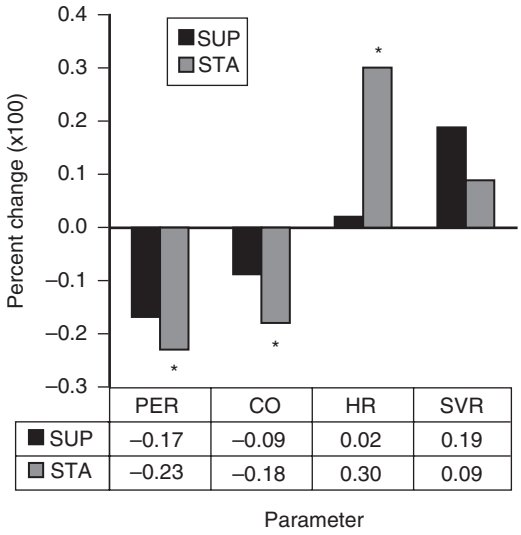
Heart Rate and Stroke Volume

Cardiac output is the product of heart rate and stroke volume, both of which increase in pregnancy. The maternal heart rate varies widely in pregnancy but generally rises 10% to 20% above normal values by 32 weeks of gestation.[8,18] The tachycardia of pregnancy (100 beats per minute or greater) usually is well tolerated but does result in an elevated myocardial oxygen demand and decreased diastolic filling time—changes that may be debilitating for women with preexistent cardiac disease. Stroke volume, which increases rapidly to its maximum of 20% to 30% above baseline by 20 weeks of gestation, accounts for much of the early gestational increase in cardiac output.[11,19,20]

Contractility and Blood Volume

The hemodynamic factors determining stroke volume include contractility, preload and afterload. An increase of maternal myocardial contractility in pregnancy is suggested by some studies, but is difficult to distinguish from concomitant alterations in preload (i.e., venous return).[20,21] It is clear, however, that venous return to the heart increases dramatically as total body water, blood volume, and possibly venous tone are augmented within the first few weeks of pregnancy.[11,22,23] Water gain is mediated by the nonosmotic release of arginine vasopressin (AVP), activation of the renin-angiotensin-aldosterone system (RAS), and resetting of the osmolar set point early in pregnancy.[24] It is proposed that rapid vasodilatation in the first weeks of pregnancy induces

relative arterial underfilling, which triggers the water- and sodium-sparing response.[25] A woman's total blood volume may increase by 30% to 50% (for an additional 1.5 to 1.6 L), depending on her response to early placental signals (the so-called hypervolemia of pregnancy).[8,26,27] Both plasma and red cell compartments contribute to the increase in total blood volume, although a more rapid and robust increase in plasma volume (40% to 60% by 28 to 32 weeks) compared with red cell volume (25% to 33% at term) results in a physiologic anemia of pregnancy.[28] As with cardiac output, multiple gestations (e.g., twins) induce an earlier and greater blood volume expansion, which may exceed 65% of normal.[29,30] In the setting of latent or overt pregestational cardiac disease, the hypervolemia of pregnancy may overwhelm right ventricular pump function and lead to heart failure as blood volume approaches its maximum values at 28 weeks. Conversely, failure to achieve this critical augmentation of blood volume and cardiac output early in pregnancy is strongly associated with pregnancy loss and the ultimate development of preeclampsia and fetal growth restriction.[31-38]



Blood Pressure and Systemic Vascular Resistance

Despite substantial increases in blood volume and cardiac output, maternal blood pressure manages to fall gradually to its nadir at 24 to 32 weeks before returning to prepregnancy values at term.[18,26] This phenomenon is due to an early and sustained fall in the systemic vascular resistance, reaching values 25% to 35% below normal by midpregnancy.[10,21,39] The exact physiology of this response is unknown but probably includes peripheral vasodilation by estrogens, progesterone, atrial natriuretic peptide (ANP), prostacyclin (i.e., prostaglandin I_2 [PGI_2]), and nitric oxide, and the arteriovenous shunt effect of the developing uteroplacental circulation.[21,22,25,40] The peripheral vasodilation is further enhanced by maternal refractoriness to arterial vasopressors, most notably angiotensin II (Ang-II) and norepinephrine. A relative loss of this refractoriness to vasopressors in early pregnancy identifies women at risk for the subsequent development of preeclampsia and fetal growth restriction.[41,42]

Regional Blood Flow and the Uteroplacental Circulation

The enhanced cardiac output of pregnancy is not evenly distributed among all organs. Disproportionate increases in blood flow benefit the uterus (and placenta), breasts, kidneys, and skin. The requirement for substantially increased uterine blood flow vis-à-vis nutritional support of the growing fetus and placenta is obvious, and its importance cannot be overstated. Moreover, it has become clear that the uteroplacental circuit is the common factor linking maternal cardiovascular function to fetal growth.

Data from studies in humans suggest that uterine blood flow must increase from a baseline of 40 mL/minute before pregnancy to greater than 500 mL/minute[4,5,43] at term. By the end of gestation, nearly 90% of flow is directed to the placenta, with approximately 10% reserved for the decidua and 5% for the myometrium.[6] Blood flow through the uterine circulation is critically dependent on maternal cardiac output, as evidence suggests that at baseline, this circuit is maximally dilated and unable to further increase its flow by autoregulation.[44] This point is well illustrated by the 20% decrease of intervillous blood flow induced by simple changes in maternal posture (such as upright standing or supine recumbency) which can reduce maternal venous return and cardiac output[45-48] (Figure 17-1). Conditions that decrease maternal cardiac output, and therefore uterine blood flow, are not well tolerated by the fetus, and lead to transient or sustained metabolic adjustments. Moreover, the uterine circulation remains sensitive to certain vasoconstrictors during pregnancy (e.g., nicotine) which may impose periodic limitations on placental perfusion and lead to disturbances of fetal growth.[49]

Anatomic Changes in Maternal Uterine Blood Flow in Pregnancy

Anatomically, blood is directed to the uterus primarily through the uterine arteries, which arise from the internal iliac arteries in the pelvis, and secondarily through the ovarian arteries, which arise from the abdominal aorta. The uterine arteries arborize in an arcuate pattern (arcuate arteries) to supply the myometrium, and then descend in a radial pattern (radial arteries) to the endometrium (decidua) before terminating as the spiral arterioles. The intervillous spaces (IVSs) of the term placenta are supplied by approximately 100 to 200 spiral arterioles and drained by 75 to 175 uterine venules[50] (Figure 17-2) (see Chapter 11 for details of placental implantation and villous structure) At the level of the spiral arterioles, pulsatile blood pressure has been largely dissipated (25 mm Hg in spiral arteries, 15 to 20 mm Hg in the intervillous space, and 5 to 10 mm Hg in the uterine veins), allowing a high volume of slow-moving maternal blood to bathe the placental villi floating in the IVS.

Of all the vascular adaptations of the uterus, none is more remarkable than the "physiologic transformation" of the spiral arterioles, which converts the highly resistive, muscular vessels of the decidua and myometrium into widely dilated, high-flow "uteroplacental arteries" that supply the intervillous spaces of the placenta[51] (Figure 17-3). The remodeling of these arterioles takes place in three phases under the primary influence of extravillous cytotrophoblast cells which migrate distally from the anchoring villi of the placenta deep into the maternal decidua and myometrium. In the initial phase (beginning at approximately 5 weeks of gestation), the terminal ends of the spiral arterioles are plugged by clumps of extravillous trophoblasts which prevent maternal perfusion of the developing lacunar spaces, thus maintaining a local hypoxic environment essential for the proliferation of placental cells.[52-54] Over the ensuing 5 weeks, a true vascular

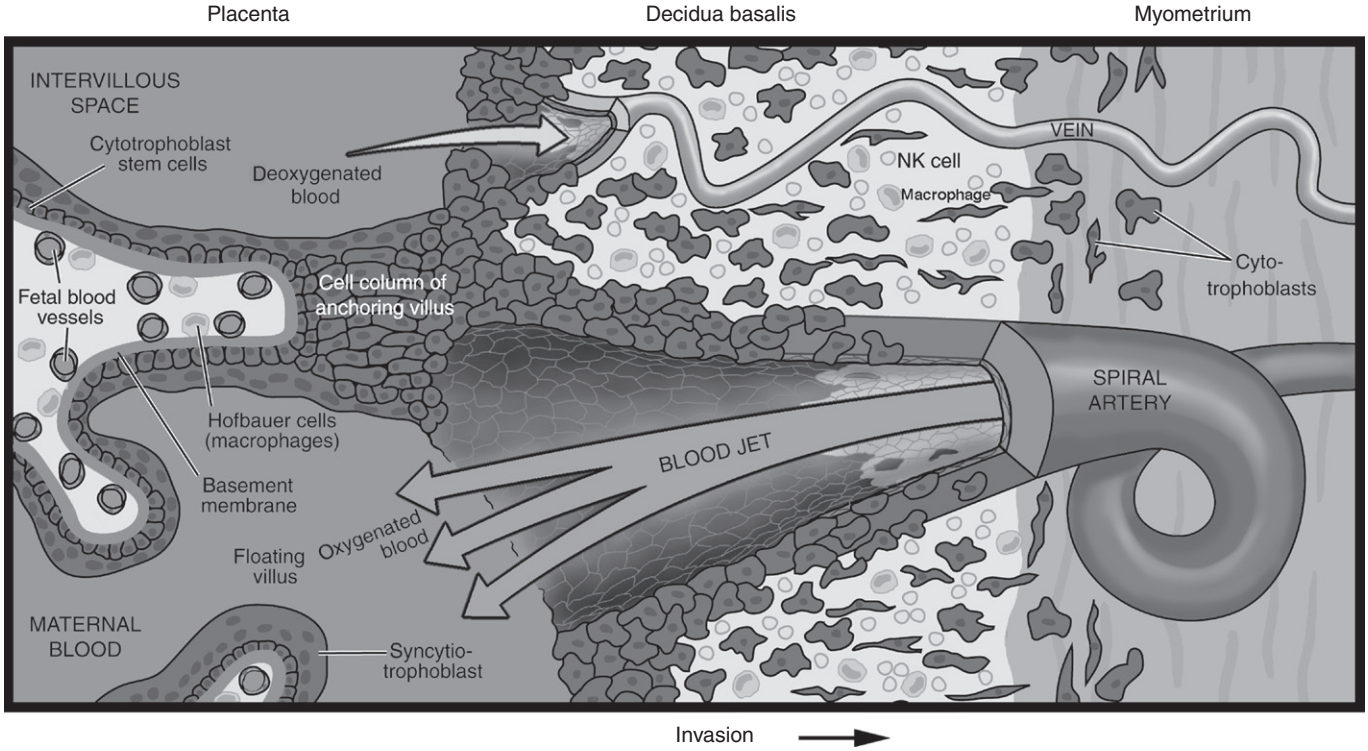

Figure 17-2 Blood supply to the intravillous space. The spiral arteries penetrate the uterine myometrium and decidua basalis beneath the placenta. Invasive trophoblast from columns of anchoring villi migrate toward these vessels and invade their lumens, replacing the normal intima and media. Blood is directed into the intravillous space, where it percolates over the floating villi and is removed by the decidual veins. *(Modified from Zhou Y, McMaster M, Woo K, et al: Vascular endothelial growth factor ligands and receptors that regulate human cytotrophoblast survival are dysregulated in severe preeclampsia and hemolysis, elevated liver enzymes, and low platelets syndrome,* Am J Pathol *160:1405-1423, 2002.)*

connection to the placenta is delayed while a gradual loss of the medial smooth muscle fibers and decidual basalis occurs in the distal portion of the spiral arterioles.[54] The second phase of remodeling at 11 to 14 weeks is characterized by the dissolution of the endovascular plugs within the spiral arterioles, the rapid increase in oxygen tension within the placenta, and the proximal infiltration and replacement of arteriolar endothelium with endovascular cytotrophoblast cells.[55-57] During this phase, the oxygen tension within the placenta increases from 20 to greater than 50 mm Hg, which triggers the conversion of placental villous trophoblast from a state of proliferation to one of differentiation and maturation.[58,59] Finally, a second "wave" of arterial transformation is proposed to occur from 14 to 17 weeks[60] as endovascular trophoblast cells complete their replacement of the maternal endothelium, eroding the elastic lamina and muscular intima of the spiral arterioles to the level of the inner third of the myometrium, to form the mature so-called uteroplacental arteries.[61] The endovascular trophoblast lining the transformed vessels embeds itself in a fibrinoid extracellular matrix composed of secreted proteins and maternal fibrin, thereby creating large, dilated conduits connecting the radial arteries of the myometrium to the IVSs. These low-resistance uteroplacental arteries are essentially unresponsive to local vasoconstrictors.[62,63]

Trophoblast cell differentiation and invasion are regulated by physicochemical signals at the decidua-placenta interface.[64-66] Low oxygen tension in the early placenta enhances the activity of hypoxia-inducible factor (HIF), which facilitates the expression of transforming growth factor-β3 (TGF-β3), a cytokine that helps maintain the proliferative, "noninvasive phenotype" of the epithelial villous cytotrophoblast.[67,68] This phenotype is characterized by the cell surface expression of E-cadherins (the epithelial class) and integrins αvβ6 and α6β4, which interact with the superficial extracellular matrix proteins of the decidua.[64] The "invasive phenotype" of the extravillous trophoblast is induced in a carefully choreographed manner by local paracrine factors, cell-to-cell contact, extracellular matrix, and oxygen tension.[66,67,69,70] The access of oxygenated blood to the villous spaces after 10 weeks of gestation and consequent increase in Pa_{O_2} down-regulates HIF activity and TGF-β3 expression, thereby enabling expression of stage-specific invasive cell surface markers—integrins αvβ3 and α1β1, vascular endothelial (VE)-cadherin, PECAM-1—on the trophoblast surface.[52,71] Additionally, it is proposed that the oxygen tension gradient at the tips of the anchoring villi regulates the stage and site-specific expression of the vascular endothelial growth factor (VEGF) family members VEGF-A to -C and of their tyrosine kinase receptors, VEGFR-1 and VEGFR-2.[72,73] During normal placentation, deeply invasive cytotrophoblasts down-regulate expression of VEGFR-2 and up-regulate expression of VEGFR-1 and secretion of VEGF-A and soluble VEGFR-1 (i.e., sFlt-1 [soluble FMS-like tyrosine kinase-1]), which has the autocrine and paracrine effects of promoting α1 integrin and promoting the invasive endovascular phenotype. Simultaneously, the invading trophoblast will begin to express matrix metalloproteinases (MMPs) to facilitate migration through the decidua and into the spiral arterioles.[74,75] On reaching their destination in the lumen of the spiral arteriole, these cells assume an endothelial cell phenotype through the expression of typical surface adhesion molecules such as vascular cell adhesion molecule-1 (VCAM-1) and platelet endothelial cell adhesion molecule-1 (PECAM-1), a process termed *pseudovasculogenesis.*[64,76,77] Disruption of this process leads to shallow implantation and absent or incomplete remodeling of the spiral arterioles. These pathologic findings,

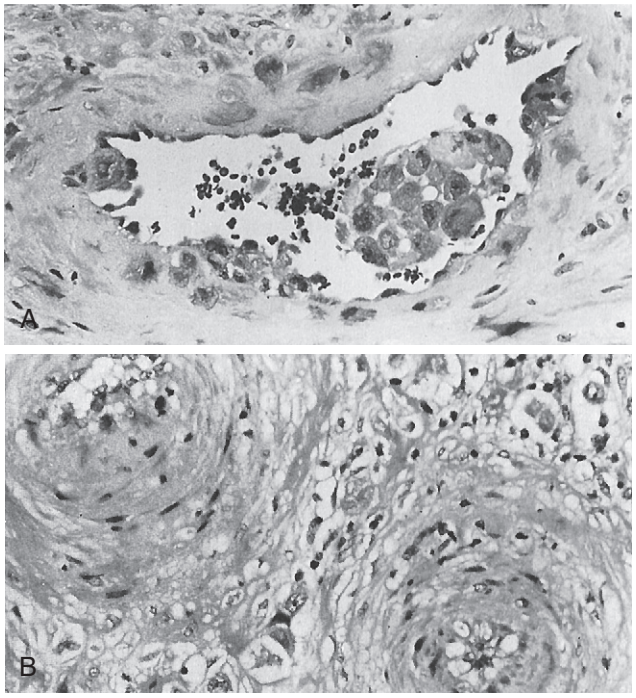

Figure 17-3 Photomicrographs of placental bed spiral arteries. **A,** Normal transformed spiral artery with irregular, dilated shape, attenuated media and intima, and intravascular trophoblasts. **B,** Untransformed basal arteries with medial hyperplasia and restricted lumen. *(Modified from Rushton DI: Placenta as a reflection of maternal disease. which may lead to vascular insufficiency and chronic hypoxia, are described in placental bed biopsy material obtained in pregnancies complicated by both preeclampsia and idiopathic intrauterine fetal growth restriction.[50,51,63,78]

Functional and Molecular Changes in Maternal Uterine Blood Flow in Pregnancy

Augmented uteroplacental blood flow in pregnancy requires more than just physiologic transformation of the spiral arterioles. Equally important is the functional transformation of the uterine arteries to a low-resistance shunt capable of accepting up to 20% of maternal cardiac output. This is accomplished via two mechanisms: (1) the growth and remodeling of uterine vessels (angiogenesis) throughout pregnancy, and (2) the development of uterine vascular refractoriness to vasoconstrictors. With these adaptations, the relative fall in uterine vascular resistance exceeds even the fall in systemic vascular resistance.[79] Data from pregnant animals demonstrate elevations of circulating metabolites for nitric oxide and prostacyclin in the uterine circulation, suggesting that an increase in the endogenous production of these endothelium-derived vasodilators may be acting on the uterine vasculature.[80-83] Similar to the maternal systemic circulation, the uterine arteries are resistant to vasoconstrictor actions of angiotensin II (Ang-II), and likewise show enhancement of the vasodilator effects of prostacyclin and nitric oxide. Consequently, it can be shown that direct uterine artery infusion of inhibitors of prostacyclin or nitric oxide synthesis (L-NAME or indomethacin) will decrease ovine uterine blood flow and enhance the local constrictor response to Ang-II).[83,84] In humans, systemic circulating prostacyclin metabolites are elevated,[85,86] whereas conflicting data suggest the same for nitric oxide metabolites (nitrite and nitrate).[40,87,88] Significant arteriovenous gradients of cyclic guanosine monophosphate (cGMP), the second messenger of nitric oxide, have been documented across the uterine circulation suggesting, at the least, a functional role for NO-mediated vasodilatation in this circuit.[88]

Adaptive Changes That Mimic Cardiovascular Disease

From the preceding discussion it is apparent that virtually all aspects of maternal cardiovascular physiology are altered during the course of a normal pregnancy, some to quite an extreme degree. These changes lead to a number of signs and symptoms that mimic cardiac disease. Dyspnea is experienced by nearly 70% of pregnant women by the third trimester, although it usually is of a mild and nondebilitating nature.[80] Other symptoms include decreased exercise tolerance, occasional orthopnea, fatigue, and syncope. Physical findings that mimic disease include tachycardia, jugular venous distention, and altered heart sounds such as systolic and diastolic murmurs or ancillary heart sounds. Edema is common to 70% of pregnancies,[90] and results from increased venous hydrostatic pressure coupled with decreased colloid oncotic pressure. It is important to recognize that these signs and symptoms are secondary to normal cardiovascular adaptations in pregnancy and do not necessarily indicate maternal disease.

CARDIOVASCULAR DISEASES IN PREGNANCY

Overview and Definitions

Cardiovascular disease in pregnancy is not rare—despite the fact that reproductive aged women are among the healthiest members of society. This speaks to the physiologic stresses placed on the cardiovascular system by fetal and placental demands for maternal adaptation. Overall, greater than 10% of pregnancies in developed countries will manifest some form of pregestational or de novo cardiovascular impairment; an even greater percentage suffer these diseases in underdeveloped regions.[91-94] In total, cardiovascular disorders in pregnancy are associated with nearly 15% of perinatal deaths and more than 15% of preterm deliveries.[93,95] These disorders are important risk factors for intrauterine growth restriction, stillbirth, and in some instances, congenital heart disease. Furthermore, growing evidence suggests a link between maternal cardiovascular disease, a suboptimal intrauterine environment, and long-term adverse health outcomes in the offspring.[96-100]

Hypertensive disorders constitute the largest class of cardiovascular disease in pregnancy, affecting 5% to 8% of gestations and having the greatest overall impact on fetal outcomes.[95,101] The hypertensive disorders of pregnancy include chronic hypertension and four unique pregnancy-associated conditions: eclampsia, preeclampsia, superimposed preeclampsia, and gestational hypertension.[27] These conditions have in common the element of hypertension—defined most recently as sustained systolic and diastolic blood pressures of 140 mm Hg or greater and higher than 90 mm Hg, respectively[27]—but they differ dramatically in their pathophysiology. *Preeclampsia* is a syndrome diagnosed clinically as *de novo* hypertension *and* proteinuria after 20 weeks of pregnancy, with associated pathologic activation and dysfunction of the maternal vascular endothelium injury leading to diverse manifestations of tissue hypoxia and end-organ injury.[102-104] *Eclampsia* is the occurrence of seizures in the setting of preeclampsia, and superimposed preeclampsia refers to preeclampsia in the setting of chronic hypertension.[27] A new diagnosis of hypertension in pregnancy without accompanying evidence of preeclampsia is termed *gestational hypertension*, which may be found to be transient or may be the first presentation of chronic hypertension (Table 17-2).

Classification of the Hypertensive Disorders of Pregnancy

Classification	Definition and Diagnostic Criteria
Preeclampsia	Hypertension with proteinuria *Hypertension*: Blood pressure >140 mm Hg systolic or >90 mm Hg diastolic after 20 weeks in a previously normotensive woman *Proteinuria*: >300 mg/L in a random specimen or >300 mg/day in a 24-hr timed collection (de novo hypertension with systemic symptoms of *preeclampsia* in the absence of proteinuria is highly suspicious)
Severe preeclampsia	Includes any of the following: *Blood pressure* >160/110 mm Hg *Proteinuria*—excretion >5 g/day, *or* 3+ or greater on dipstick testing CNS symptoms or seizures Liver injury Thrombocytopenia Pulmonary edema Renal failure/oliguria Fetal growth restriction
HELLP syndrome	Variant syndrome of preeclampsia manifesting as hemolysis, elevated liver enzymes, low platelets
Chronic hypertension	Prepregnancy hypertension >140/90 mm Hg or newly diagnosed hypertension before 20 weeks gestation that persists longer than 6 weeks after conclusion of pregnancy (new-onset chronic hypertension); may or may not include chronic proteinuria or other chronic end-organ injury
Superimposed preeclampsia	Diagnosis of preeclampsia in setting of chronic hypertension; suspected when acute worsening of hypertension is accompanied by evidence of accelerating end-organ injury (e.g., proteinuria)
Gestational hypertension	Development of hypertension without evidence or symptoms of preeclampsia; resolves shortly after conclusion of pregnancy

CNS, Central nervous system.

Preexistent acquired or congenital cardiac disease affects a much smaller percentage of pregnancies, especially in developed countries. In the United Kingdom, the incidence of congenital or acquired heart disease in pregnancy has declined from 3% to 1% and would have fallen further if it were not for the greater percentage of females with previously lethal congenital cardiac defects now surviving until the reproductive years.[91,105] Cardiac lesions may adversely affect fetal growth by (1) restricting pregnancy-associated increases in cardiac output, or (2) enabling right-to-left shunting of deoxygenated blood (cyanotic heart disease). Examples of restrictive lesions are valvular stenosis, coarctation, and cardiomyopathy. Cyanotic lesions include Eisenmenger syndrome, corrected transpositions, and uncorrected patent ductus arteriosis. Fetal growth restriction accompanies 6% of pregnancies with restrictive congenital lesions, but 25% of corrected, and 67% of uncorrected cyanotic lesions.[106,107] Owing to the multifactorial inheritance pattern of congenital heart disease, infants of women with these lesions also carry an 8% to 14% risk of having a heart defect themselves,[106,108] although the specific lesion usually is not recapitulated in the offspring. Marfan syndrome, however, is a genetic condition that can affect mother and fetus similarly. Marfan syndrome is an autosomal dominant inherited defect of the fibrillin-1 gene leading to defective collagen biosynthesis, which may manifest clinically as aortic valve insufficiency and aortic root dissection in pregnancy.[109] As a genetic model of heart disease, Marfan syndrome illustrates the potential for a maternal cardiac condition to signify a developmental risk in the offspring. Indeed, affected fetuses have been diagnosed prenatally with Marfan syndrome on the basis of the typical ultrasound findings of aortic regurgitation and heart failure.[108,110]

Preexistent maternal renovascular disease also may affect fetal growth and development. Nearly 40% of infants in a cohort of pregnancies complicated by moderate or severe renal disease were born small for gestational age (SGA); 20% of the cases also were associated with preeclampsia.[111] Autoimmune conditions such as systemic lupus erythematosus are associated with high rates of fetal growth and developmental aberrations arising through at least two mechanisms. First, maternal rheumatalogic disorders associated with vascular or renal involvement may impair normal cardiovascular adaptation and predispose to inadequate uteroplacental circulation, resulting in fetal loss, growth restriction, and preeclampsia.[112,113] Indeed, rates of fetal growth restriction approach 40% in women with active lupus erythematosus.[114] Placental examination in these cases reveals a high incidence of decidual vasculopathy and villous infarction.[115-117] The exact mechanisms of placental vasculopathy are still unclear but may involve prothrombotic (i.e., thrombophilic) actions of antiphospholipid autoantibodies such as anticardiolipin antibody or the lupus anticoagulant. These autoantibodies are proposed to promote inappropriate intravascular and intravillous thrombosis by disturbing phospholipid–annexin-V association on the surface of endovascular membranes.[118] Furthermore, evidence from murine studies suggests that antiphospholipid antibodies recognizing epitopes on the surface of trophoblast cells induce activation of the classic complement cascade, resulting in placental injury and subsequent fetal loss or growth restriction.[119-121] As a second mechanism, autoimmune disease in pregnancy has the potential to induce fetal and neonatal rheumatologic disorders through the transplacental passage of self-reactive IgG autoantibodies (e.g., anti-Ro/SSA, anti-La/SSB).[122] The neonatal lupus syndrome is a recognized complication of active maternal disease and may include several transient manifestations such as lupus dermatitis, anemia, and thrombocytopenia but also permanent congenital heart block secondary to autoimmune-mediated injury of cardiac conduction fibers.[123,124]

Preeclampsia and Eclampsia

Preeclampsia deserves special attention because of its strong association with aberrant fetal growth and development. Preeclampsia is a pregnancy-specific and uniquely human disorder, affecting from 2.6% to 7.3% of gestations, and having a predilection for first conceptions, African-American race, multiple gestations, and those pregnancies complicated by medical conditions such as chronic hypertension, diabetes, or collagen vascular disease (for which rates may approach 25%).[93,125] The exact etiologic mechanism of preeclampsia is unknown, although the multitude of documented risk factors and predispositions point to a multifactorial origin that often involves placental or vascular susceptibility (Box 17-1). More than any other cardiovascular disease of pregnancy, preeclampsia is associated with disruptions of fetal growth and development because of the common involvement of the placenta. Known as the "disease of theories," preeclampsia is perhaps best regarded as a two-stage process in which relative or absolute placental ischemia initiates—by design or accident—a maternal inflammatory response and endothelial dysfunction, whose manifestations include hypertension, proteinuria, and various derangements of end-organ performance.[103,126,127] It is not known exactly how placental dysfunction translates into endothelial dysfunction, although many proposed factors have experimental support, including, for example, oxidative stress, cytokine and immune cell activation, prostaglandin imbalance, trophoblast deportation, VEGF antagonism, and endocrine disturbances of leptin and insulin.[128-135] In this context, alterations of fetal growth in preeclampsia may arise from (1) primary or acquired placental insufficiency, (2) deficient maternal hemodynamic adaptation and uterine hypoperfusion, (3) pathologic disturbances of fetal-placental growth signaling,

or (4) shared genetic and environmental constraints. The following summary of the pathophysiology of preeclampsia illustrates mechanisms by which fetal growth and developmental are likely to be impaired.

Placental Origin

A placental origin of preeclampsia is suggested by the many marked pathologic and biochemical abnormalities identified in comparison with pregnancies without preeclampsia. The vascular lesions characteristic of severe or early preterm preeclampsia clearly lead to impairment of uteroplacental blood flow, offering an immediate explanation for the association with fetal growth disturbances.[135] Indeed, many similar lesions are apparent in placentas from nonpreeclamptic pregnancies associated with such growth restriction.[51,137] An important point, however, is that investigation of the placenta often is limited to cases of severe and early-onset disease—the variant of preeclampsia most closely associated with fetal growth restriction. Cases of mild preeclampsia at term are underrepresented in many reports and may show no histologic, biochemical, or molecular disturbances.

Failed Trophoblast Invasion

Among the pathologic hallmarks of preeclampsia, several placental findings warrant mention. These include decidual atherosis, placental infarction, and failed trophoblast invasion and transformation of the spiral arterioles. Examination of placental bed biopsy material obtained in women with preeclampsia reveals shallow decidual penetration of the interstitial trophoblast and absent or severely restricted invasion and transformation of the distal third of the spiral arterioles that feed the placenta.[63,138]

On the basis of a number of elegant histologic in situ and in vitro experiments, Zhou and associates[64,66,77] have proposed that in preeclampsia, cytotrophoblast fails to switch its cell surface adhesion molecules from the proliferating but noninvasive phenotype to the invasive phenotype and, finally, to the endovascular phenotype. Their studies demonstrate that superficially invading cytotrophoblasts in preeclamptic pregnancies continue to express markers of the early, undifferentiated trophoblast lineage including E-cadherin and αvβ6 and α6β4 integrins, and that these cells fail to express markers of the invasive or endovascular phenotype such as αvβ3, α1β1, VE-cadherin, VCAM-1, and PECAM-1.[77,139] TGF-β3, whose transcription is activated by hypoxia-inducible factor-1α (HIF-1α), is known to suppress expression of the invasive phenotype in trophoblast.[67,140] It has been proposed, although not universally accepted, that impaired oxygen sensing in the nascent placenta maintains activation of HIF-1α and, consequently, overexpression of TGF-β3, thereby preventing the cells from assuming their invasive phenotype.[68,141,142]

Another line of research has demonstrated dysregulation of the VEGF family of ligands and receptors in preeclampsia, leading to altered angiogenic control of trophoblast invasion and spiral artery remodeling.[72,73,143] Specific findings include decreased expression of VEGF-A and VEGFR-1 with increased secretion of soluble VEGFR-1 (sFlt-1). The resulting failure of trophoblast pseudovascularization and endovascular invasion allows persistence of the native muscular and intimal layer of the spiral arterioles, thereby impeding placental blood flow; this pathophysiologic mechanism is supported by numerous clinicopathologic studies[144-146] (Figure 17-4). Indeed, failure of transformation of the spiral arterioles also is noted in cases of pure intrauterine growth restriction, even without a diagnosis of preeclampsia.[138]

Infarction, Atherosis, Thrombosis

Other vasculopathic findings of the preeclamptic placenta having relevance for fetal growth include decidual atherosis, villous infarction and thrombosis (see Figure 17-4).[136] Placental vascular resistance may be markedly increased, to the point at which uterine artery blood ceases to flow, or even reverses direction, during cardiac diastole[147,148] (Figure 17-5). In vivo estimates of *intervillous* blood flow obtained by Doppler ultrasound investigations in severe preeclampsia suggest a reduction in blood flow approaching 40%.[148,149] At the subcellular level, preeclamptic placentas may demonstrate ultrastructural abnormalities including increased syncytial knotting, decreased microvillous surface area, and decreased villous arborization—all of which serve to further reduce the effective placental surface area and nutrient exchange.[150,151] Shedding of syncytiotrophoblast microvillous membranes and cell fragments is increased in preeclampsia and can be measured in the maternal circulation.[131,152] Villous thrombosis occasionally is noted in the preeclamptic placenta, especially in the setting of growth restriction or with early and severe disease.[153] Maternal thrombophilias, such as antiphospholipid antibody syndrome or factor V Leiden mutation, are associated with increased placental thrombosis, and with both preeclampsia and fetal growth restriction.[154,155] Of importance, certain of the thrombophilias have a genetic origin and may consequently be expressed in the fetus and placenta, thereby affecting fetal growth and development in a direct fashion.[156,157]

The primary cause of placental maldevelopment in preeclampsia is unknown but may include constitutional defects in the fetal trophoblast or interaction with a "hostile" maternal decidual environment.[158] Regardless of the primary etiologic process, local imbalances of growth factors, cytokines, prostanoids, and nitric oxide will arise in underperfused decidua and placenta, further contributing to vasospasm, shunting, apoptosis, and defective vascularization.[130,158] Pathologic activation of these signaling pathways in the placenta is suspected to contribute to disturbances of fetal growth and development already initiated by deficient uteroplacental blood flow. Angiogenic factors that mediate hypoxic signaling and that are dysregulated in preeclamptic placentas include platelet-derived growth factor (PDGF), VEGFs and their receptors (Flt-1 and KDR), placental growth factor (PlGF), and angiopoietin-1 and -2 (Ang-1 and Ang-2).[73,133,159-162] Altered expression of inflammatory cytokines including tumor necrosis factor-α (TNF-α) and the interleukins IL-1β and IL-6 has been demonstrated in the placenta of women with preeclampsia by some[163,164] but not all[165,166] investigators. Changes in levels of placental factors reported to be associated with preeclampsia are summarized in Table 17-3.

Vascular reactivity is abnormally regulated in the preeclamptic placenta, and abundant evidence implicates alterations in the

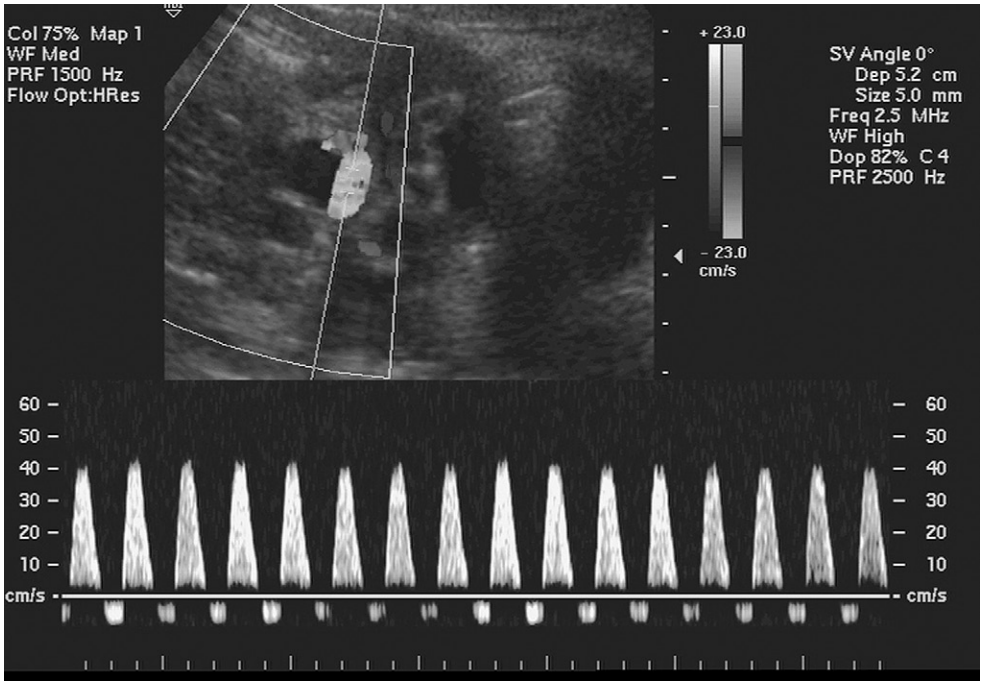

Figure 17-4 Doppler velocimetry of umbilical artery. The Doppler waveform demonstrates reversal of flow in the umbilical artery of this infant whose mother developed severe preeclampsia at 28 weeks. *(Modified from Tekay A, Campbell S: Doppler ultrasonography in obstetrics. production and response of local vasoregulators such as the renin-angiotensin system,[186,187] endothelin-1,[188-190] nitric oxide,[191-194] prostacyclin and thromboxane,[178,195,196] and peptide hormones such as adrenomedullin and atrial natriuretic peptide.[197,198] Oxidative stress, which is proposed to arise in the preeclamptic placenta secondary to hypoxia and ischemia-reperfusion injury, may have many consequences for placental, maternal, and even fetal well-being.[184] The isoprostane 8-iso-$PGF_2\alpha$, a marker of oxidative injury, is elevated in preeclamptic placentas, potentially blocking the invasive capacity of trophoblast by reducing their metalloproteinase and collagenase expression, with further exacerbation of placental insufficiency.[199] Other markers of oxidation found in the placenta include lipid peroxides, nitrotyrosine, and protein carbonyls. ROS-generating enzymes such as NADPH and xanthine oxidase are expressed at high levels in preeclamptic placentas, accompanied by down-regulation of antioxidant systems.[158] To a variable degree, disturbances of these same vasoregulatory systems may be demonstrated in the cord blood of newborn infants whose mothers have preeclampsia. For example, the concentration of soluble IL-8 and endothelin and the degree of monocyte

and neutrophil activation were elevated, while the concentration of IL-6 and the expression of cell adhesion molecules were decreased, in the cord blood of these infants versus control subjects.[200-202] Although these usually are thought of as potential mediators of maternal endothelial and inflammatory activation, studies are just now beginning to focus on the potential for placental inflammation to disrupt fetal growth and development.

Maternal Pathophysiology of Preeclampsia

As previously mentioned, the maternal syndrome of preeclampsia is characterized by endothelial dysfunction and intravascular inflammation that is thought to originate in the placenta.[102,103,127,203] Examination of maternal serum at the time of severe or early disease may reveal alterations of numerous factors and homeostatic systems potentially involved in the primary or secondary pathophysiology of this process. The metabolism of nitric oxide, prostacyclin, thromboxane, endothelin, angiotensin, ANP, and other vasoactive substances is disturbed.[204] Lipid hydroperoxides and other reactive oxygen species may be elevated, while antioxidant systems depleted.[205] Simultaneous activation of the coagulation and fibrinolytic cascades are sometimes evident. Circulating markers of endothelial, platelet, and monocyte activation may be elevated, along with inflammatory cytokines that mediate these responses.[204] The breadth and degree of activation of these systems generally are not seen in other hemodynamic disorders of pregnancy such as chronic or gestational hypertension, or congenital or acquired heart disease.

Of particular relevance to fetal growth, however, are maternal metabolic alterations which may precede or accompany preeclampsia. For years it has been known that diabetes is a significant risk factor for preeclampsia. Infants of diabetic mothers display numerous aberrations in growth and development including macrosomia, growth restriction, and congenital anomalies. More recent work confirms that insulin resistance and hyperlipidemia—two components of the heritable metabolic syndrome—also predispose affected women to preeclampsia and, as metabolic markers, tend to worsen during the disease process and for up to 3 months afterward[205,206] (Table 17-4). As part of this syndrome, preeclamptic women are found to have elevated triglycerides, free fatty acids, and small dense low-density lipoprotein (LDL), all of which are susceptible to oxidative modifications that impair vascular endothelial function.[207,209] It is not known what effect these metabolic changes would have on the developing fetus, although experimental maternal hyperinsulinemia in late pregnancy is associated with intrauterine growth restriction and altered carbohydrate metabolism in rat pups.[209,210]

Cardiovascular Disease and Fetal Growth and Development

It is now apparent that fetal growth disturbances are associated with maternal cardiovascular diseases in pregnancy. Many clinical studies have estimated the size and prevalence of this effect.[211] Clinical outcome studies categorize birth weights as SGA, defined as less than 10% of normal for gestational age; large for gestational age (LGA), defined as greater than 90% of normal for gestational age; or appropriate for gestational age (AGA). In general, cardiovascular disorders of pregnancy are associated with reduced intrauterine growth, although this is not always the case. Depending on the clinical situation, anywhere from 4% to 40% of infants will be SGA.[211] A mixture of growth disturbances that varies with gestational age and associated pregnancy complications has been described for the infants of preeclamptic women.[212,213] It is important to remember that birth weight is but one crude marker of fetal growth and development. Body composition parameters such as body mass index (BMI) (calculated as weight/height^2) or ponderal index (PI) (calculated as weight/length^3) are proposed to be more sensitive markers for overgrowth or undergrowth than is crude birth weight, although these measurements are not universally reported.[213]

TABLE 17-4

Correlates of Insulin Resistance Associated With Preeclampsia

Condition	Biomarker(s)
Gestational diabetes	Hyperglycemia
Polycystic ovary syndrome	Hyperinsulinemia
Obesity/excessive weight gain	Hyperlipidemia
	Increased TNF-α
	Elevated PAI-1
	Hyperleptinemia

PAI-1, Plasminogen activator inhibitor-1; *TNF-α,* tumor necrosis factor-α.

Growth Restriction

Because preeclampsia is a heterogeneous syndrome with multiple potential inciting factors, it is not surprising that the fetal growth effects are also heterogeneous. In a review of the epidemiologic literature, Misra[211] concluded that the best evidence suggests a consistent negative association of preeclampsia with birth weight only when the disease occurs preterm, or is of a severe nature. Data from other investigators confirmed this conclusion, reporting that the rate of SGA was 5.8% in pregnancies complicated by mild preeclampsia (not different from controls), but increased to 20.5% in pregnancies with severe preeclampsia.[214] Gestational hypertension without preeclampsia, however, does not appear to be associated with fetal growth restriction.[215] Therefore, when proteinuria is included as a covariate, the association of gestational hypertension with SGA increases two- to four-fold.[215] In a large prospective cohort study at McMaster University Medical Centre, 1948 hypertensive pregnancies were studied.[217] Compared with newborns of women with gestational hypertension only, infants of women with preeclampsia or superimposed preeclampsia were 2.2 and 2.1 times more likely to be SGA, whereas infants of women with chronic hypertension only were not at risk for being SGA. The overall likelihood of SGA in preeclamptic offspring was 25% in this study. The fact that chronic and gestational hypertensive women delivered infants without growth restriction suggests that maternal hypertension per se is not the primary determinant of fetal growth in hypertensive pregnancies. Rather, it is likely that the placental defects uniquely associated with preeclampsia determine the fetal outcome, and that low birth weight is more closely related to iatrogenic preterm delivery. Illustrating this point, a controlled retrospective study reported that 26% of infants born to mothers with preeclampsia were of "low birth weight" (<2500 g), which represented a four-fold increased risk above that in control pregnancies.[218] The adjusted odds for SGA, on the other hand, were only 2.5, suggesting that much of the excess in low birth weight was due to earlier iatrogenic delivery. A more recent study, by Xiong and co-workers,[219] that controlled for multiple demographic and obstetric factors including race, age, parity, obesity, medical history, anemia, and smoking reported an increased likelihood of being SGA for infants of preeclamptic mothers only when born before 37 weeks of gestation. Those born after 37 weeks did not manifest growth restriction, and as the pregnancy passed 40 weeks, the infants from preeclamptic mothers were actually larger than the control infants (Figure 17-6).

The fetal growth decrements attributed to preeclampsia affect body composition as well as birth weight. A large population-based study of 672,130 births in Norway demonstrated that infants born to preeclamptic mothers were lighter, shorter, and leaner than control infants (born to nonpreeclamptic mothers).[213] The fetal growth decrements were accentuated in infants born before

37 weeks but persisted even in the term neonates. As would be expected for infants of preeclamptic mothers, the rate of asymmetric SGA was twice that of symmetric SGA, although rates of symmetric SGA were still elevated two-fold over those in control subjects at both early and late gestational ages, suggesting that a significant proportion of infants began to slip from their growth potential earlier than the second trimester.

On careful evaluation, it is possible to detect abnormal maternal cardiovascular function as soon as fetal growth delay becomes evident. Vasapollo and associates used echocardiography to study 21 otherwise healthy pregnant women newly diagnosed as carrying SGA fetuses.[220] Compared with matched control subjects (with AGA fetuses), these women demonstrated higher average blood pressure and peripheral vascular resistance and lower cardiac output, stroke volume, and left ventricular mass. Similarly, a failure to increase cardiac output in the first weeks of pregnancy was prospectively associated with SGA[36] Very commonly, the failure of maternal cardiovascular adaptation also is associated with abnormal placentation. Of women with Doppler evidence of shallow placentation, 45% also had evidence of suboptimal maternal cardiovascular adaptation, and 80% of these patients ultimately developed preeclampsia or fetal growth restriction.[221] These findings lend support to Roberts' two-compartment hypothesis, which predicts the highest rates of preeclampsia in pregnancies with both an underlying maternal vascular impairment and shallow placentation.[126]

Growth Excess

Contrary to obstetric lore, not all infants born of a hypertensive pregnancy will suffer from growth restriction. Xiong and coworkers[218] examined a perinatal database from Alberta, Canada, for the years 1991 to 1996 to determine the impact of preeclampsia and gestational hypertension on birth weight. After controlling for multiple factors, these investigators found that, in addition to the expected association with SGA and low birth weight, the offspring of women with gestational hypertension and preeclampsia were more likely to be LGA than infants of nonhypertensive mothers. Even though the effect is not large (odds ratio [OR], 1.1 to 1.5), Rasmussen and Irgens were able to demonstrate that the rates of birth weight, length, and ponderal index above the 97.5th percentile are significantly higher in births with preeclampsia than in those without preeclampsia.[213] This finding has been replicated by other investigators[211,219] and lends support to the idea that near term, some infants of preeclamptic and hypertensive women may have enough placental reserve to benefit from increased cardiac output and metabolic manipulations of the mother.

Mechanisms of Growth Disturbance

Reduced Placental Perfusion

At first glance, it appears obvious that abnormalities of fetal growth and development in preeclampsia may be immediately related to decreased placental size and perfusion. Direct tracer technique measurements of blood flow suggest a two- to three-fold decrease in uteroplacental perfusion in hypertensive women from that in normotensive gravidas.[222,223] These studies, performed at the time of diagnosis, however, do not fully address the variety of growth patterns that may be associated with preeclampsia. More recent studies controlling for gestational age and birth weight, however, suggest that placental mass may be the same, or even greater, in some pregnancies complicated by preeclampsia and growth restriction.[224,225]

Substrate Delivery

Very little information exists to describe the transport of substrates across the placenta in preeclampsia. Growth-restricted fetuses without preeclampsia were noted to have lower serum alpha aminonitrogenous amino acids such as valine, leucine, isoleucine, lysine, and serine weeks before delivery,[226] and placental homogenates contained significantly more free L-arginine and phenylalanine.[227] Only tyrosine was decreased in free amino acid preparations from preeclamptic placentas.[227] More recently, Powers and co-workers[228] measured amino acid concentrations in maternal and neonatal blood from pregnancies complicated by preeclampsia. Maternal serum amino acids were elevated in the setting of preeclampsia, as were the fetal blood concentrations. Surprisingly, among the preeclamptic pregnancies, SGA fetuses had significantly higher cord amino acid concentrations than those in non-SGA fetuses (321 ± 32 μmol/dL versus 251 ± 17 μmol/dL), suggesting that in contrast with conditions in pure intrauterine growth restriction, placental transport of amino acids may be enhanced or their utilization may be reduced, or both, in preeclampsia, especially among those fetuses with growth restriction. Likewise, cord venous concentrations of total cholesterol and triglycerides and the total cholesterol to high-density lipoprotein cholesterol (HDL-C) ratio were reported to be elevated in offspring born after preeclamptic pregnancies compared with control infants, whereas only the level of triglycerides

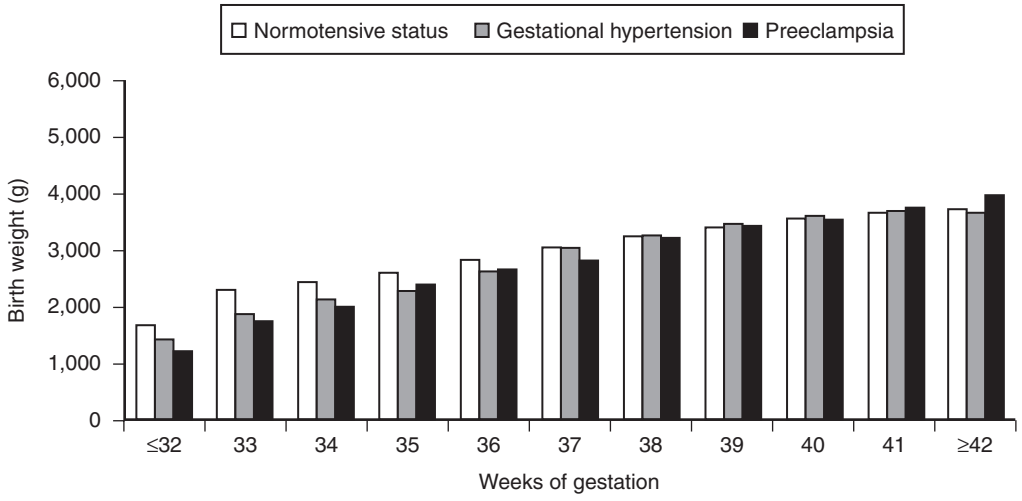

Figure 17-6 Impact of preeclampsia and gestational hypertension on birth weight (n = 87,798), Alberta, Canada, 1991 to 1996. *(From Xiong X, Demianczuk NN, Saunders LD, et al: Impact of preeclampsia and gestational hypertension on birth weight by gestational age,* Am J Epidemiol *155:203-209, 2002.)*

was elevated in SGA infants of women without preeclampsia.[229] These findings also implicate selective enhancement of transplacental substrate delivery, rather than the maternal dyslipidemia of pregnancy; no significant correlation has been made between newborn and maternal concentrations of lipids or cholesterol.

Cytokines

Transplacental transfer of cytokines has been implicated as a means of altering fetal development in settings of infection and prematurity. Low-dose endotoxin infusion into the pregnant rat has been used as a model for glomerular injury of preeclampsia.[230] The endotoxin induces a generalized Shwartzman reaction in the pregnant rat with fibrin and platelet thrombi in the kidneys, which can be reduced with prostacyclin infusion.[231] This protocol also has been suggested as a good model for preeclampsia because it results in proteinuria, thrombocytopenia, and hypertension.[232,233] Infusion of low-dose endotoxin in pregnant rats may lead to fetal death, resorption, and fetal anomalies, presumably through reduced uterine blood flow or induction of other humoral factors.[233,234] The placentas of endotoxin-treated rats display more apoptosis and higher peroxynitrite levels, suggesting an overall reduction in effective placental surface area in association with oxidative stress, which may explain some facets of growth restriction.[235] This finding also has been reported in rats infused with the nitric oxide synthase inhibitor L-NAME (nitro-L-arginine methyl ester).[235] Endotoxin may or may not cross the placenta from mother to fetus,[236,237] but a fetal inflammatory response has been documented. Fetal and placental growth restriction demonstrates a dose response to maternal endotoxin administration[233,235] but not necessarily at low doses. At sub-fetotoxic levels, an increase in central nervous system (CNS) anomalies of the offspring is seen, including periventricular leukomalacia and neuronal necrosis.[238] Expression of proinflammatory cytokines TNF-α and IL-1β is increased within a few hours of maternal lipopolysaccharide administration.[237] More subtle testing of the offspring disclosed no impairment in the maze test but revealed aberrations in male sexual behavior.[239]

Human studies of fetal cytokine concentrations in preeclampsia show conflicting results. Levels of TNF-α, IL-6, and IL-1β have been variously reported to be lower[200,240,241] or unchanged.[242,243] In the largest study reported, Odegård and colleagues[200] measured cord IL-6 in 271 preeclamptic pregnancies and 611 control pregnancies and demonstrated a significant decrease, especially in infants with concomitant growth restriction. Although human studies have suggested that inflammatory cytokines are elevated in umbilical cord blood of infants born to preeclamptic mothers, no direct association with neurodevelopmental injury has been documented.

Growth Factors

The TGF-β family of cytokines plays a role in both growth and immunology of pregnancy.[244] The three members of the family—TGF-β1 to TGF-β3—and their receptors are expressed in the placenta both early in its development and at term.[167,2456] In normal pregnancies, umbilical cord TGF-β correlates well with birth weight, presumably owing to its regulation by IGF-1, which also correlates with birth weight.[244] Ostlund and associates demonstrated that cord TGF-β1 levels were significantly lower in the cord blood from fetuses with intrauterine growth restriction with or without preeclampsia, but levels were not decreased with preeclampsia alone.[244] This finding suggests that preeclampsia does not a priori alter fetal TGB-β1 production, unless other disturbances in growth also are present.

Glucocorticoids

Glucocorticoids may be powerful effectors of fetal growth and development. High fetal concentrations of glucocorticoids are associated with low birth weight and subsequent hypertension in adulthood.[246-248] The fetus has an independent and functioning HPA axis to regulate its glucocorticoid level that becomes active at 16 weeks of gestation. The fetal HPA axis is shielded from excess maternal glucocorticoids and exogenous negative feedback by the placenta, which possesses high levels of the enzyme 11β-hydroxysteroid dehydrogenase types 1 and 2.[249,250] The type 2 isoform efficiently catalyzes the conversion of active corticosterone and cortisol to their inactive metabolite, cortisone, thus preventing high maternal glucocorticoid concentrations from overwhelming the fetal system.[251-253] Maternal cortisol levels normally are several times higher than fetal concentrations, and increase near term.[254] Placental 11β-HSD2 activity increases gradually with gestational age in parallel with placental size and maternal cortisol levels, thereby protecting the fetus from excess glucocorticoid exposure.[255] Growth-restricted newborns demonstrate lower placental 11β-HSD2 activity and mRNA expression and higher circulating cortisol–cortisone ratio, which may result from deficient placental inactivation of maternal compounds.[255-257] Among preterm newborns with growth restriction, placental 11β-HSD2 activity does not appear to increase appropriately with gestational age, and its inactivity is strongly correlated with low relative birth weight, or length and infant head circumference[257] (Figure 17-7).

Other important findings include a significant decrease in placental 11β-HSD type 2 activity and an increase in fetal cord cortisol in preeclamptic pregnancies compared with levels in normal control subjects.[258-260] McCalla and co-workers[258] demonstrated

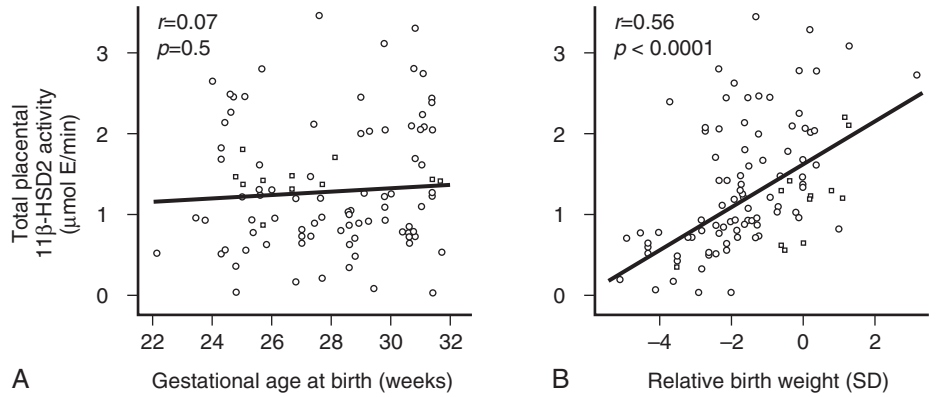

Figure 17-7 Correlation of total placental 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) activity with gestational age **(A)** and relative birth weight **(B)** in preterm SGA pregnancies. *E,* cortisone; *SGA,* small for gestational age. *(From Kajantie E, Dunkel L, Turpeinen U, et al: Placental 11beta-hydroxysteroid dehydrogenase-2 and fetal cortisol/cortisone shuttle in small preterm infants,* J Clin Endocrinol Metab *88:493-500, 2003.)*

that placental 11β-HSD2 activity was reduced approximately 25% in cases of preeclampsia. Fetal cord cortisol was more than doubled, and infants of these preeclamptic pregnancies were significantly smaller even when controlled for gestational age. Kajantie and associates also demonstrated reduced total placental 11β-HSD activity and fetal cord cortisone in preterm pregnancies with preeclampsia from levels measured in uncomplicated preterm pregnancies.[257] Other investigators have demonstrated a three-fold reduction in the level of placental 11β-HSD2 mRNA in hypertensive pregnancies compared with matched control pregnancies[259] (Figure 17-8). The infants in this study were all born near term (37.0 versus 36.9 weeks) and did not manifest fetal growth restriction (2462 versus 2702 g), suggesting that preeclampsia inhibits 11β-HSD expression independently of growth restriction. Why placental 11β-HSD2 function is decreased in preeclampsia is not known, although subsequent work suggests that hypoxia down-regulates the gene expression and enzyme activity in both early and late placenta, consistent with theories of the pathogenesis of preeclampsia.[260]

Insulin and Insulin-Like Growth Factors

The insulin-like growth factors, IGF-1 and IGF-2, are potent regulators of cell division, differentiation, and apoptosis and also influence fetal and placental growth.[261-264] Their concentrations in the fetus are strongly correlated with birth weight, and the absence of either factor in genetically deficient mice is associated with up to a 40% reduction in fetal size.[265] The actions of IGFs are mediated by IGF receptors and are stringently regulated by specific binding proteins (IGFBPs), six of which have been identified.[262,266] IGFBP-3 is the major circulating binding protein, sequestering approximately 80% of IGFs in the plasma. IGFBP-1, on the other hand, has a high affinity for IGF, and acts to modulate acute plasma changes or local concentrations of IGF-1 by reducing its bioavailability. Consistent with this role, circulating fetal IGFBP-1 concentrations are inversely related to birth weight.[261,263] IGF-2 is important for fetal embryonic development.[267] IGF-2 influences pancreatic beta cell proliferation and thus may regulate fetal growth and metabolism by enabling insulin secretion.[268,269] IGF-1, which predominates in late gestation, is produced mainly in the fetal liver under the influence of insulin and nutritional supply.[268]

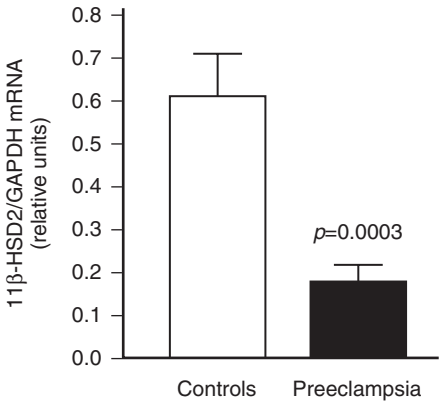

Figure 17-8 Relative expression of placental 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) messenger RNA (mRNA) in women with preeclampsia (n = 18) and in control subjects (n = 20). *GAPDH,* Glyceraldehyde 3-phosphate dehydrogenase. *(From Schoof E, Girstl M, Frobenius W, et al: Decreased gene expression of 11beta-hydroxysteroid dehydrogenase type 2 and 15-hydroxyprostaglandin dehydrogenase in human placenta of patients with preeclampsia,* J Clin Endocrinol Metab *86:1313-1317, 2001.)*

IGF signaling is important for decidual development, and appears to be critical for proper trophoblast differentiation and invasion in the first trimester, and subsequent placental growth in the second and third trimesters.[172,270,271] Cytotrophoblasts express IGF (especially IGF-2) and high levels of IGF receptors which promote invasive growth in an autocrine and paracrine fashion.[272] In a coordinated manner, maternal decidua express large quantities of IGFBP-1, which potentially acts as a counter-regulatory component but also may induce trophoblast proliferation. Indeed, overexpression of human decidual IGFBP-1 in transgenic mice leads to modest fetal growth restriction and placentomegaly with abnormal, shallow decidual invasion.[273]

Normal IGF-IGFBP relationships are disrupted in the maternal, placental, and fetal compartments in preeclampsia and may contribute to fetal growth abnormalities.[172,271,274-277] IGFBP-1 immunostaining is reportedly increased in the syncytiotrophoblast and anchoring villi of placentas from women with severe preeclampsia compared with controls.[172] Likewise, maternal plasma IGFBP-1, the main source of which is the placenta, is significantly increased in women with severe or early preeclampsia at the time of diagnosis.[172,278-280] It has been proposed that increased maternal IGFBP-1 production at the decidual interface impairs normal trophoblast invasion, predisposing the mother to the future development of preeclampsia.[172] It is not known why IGFBP-1 expression would be up-regulated in preeclamptic placentas, although hypoxia, which stimulates IGFBP-1 expression in other cell types, has been implicated.[281] By contrast, at 16 to 24 weeks of gestation, maternal plasma IGFBP-1 concentrations are significantly *decreased* in women destined to develop preeclampsia at term, suggesting that the hypoxic trigger does not develop until later in pregnancy.[277,282,283]

In contrast with IGFBP-1, maternal plasma IGF-1, which normally increases in pregnancy and is derived from hepatic synthesis, is reduced in preeclamptic women.[172,284,285] The significance of this decrease for fetal growth is uncertain, because although maternal IGF-1 concentrations correlate with fetal size at birth, fetal and maternal IGF systems appear to function independently of one another.[286] Maternal IGF-2 does not change significantly in either normal or preeclamptic placentas.

Most pertinent for fetal growth, of course, are fetal concentrations of the IGFs and their IGFBPs. In a rigorous study of more than 800 infants, Vatten and colleagues demonstrated that cord plasma IGF-1 was significantly lower in the setting of severe or early preeclampsia, independent of fetal weight.[287] Conversely, cord IGFBP-1 was elevated in neonates from a pregnancy with severe preeclampsia, replicating many other investigators' findings. After adjustment for birth weight, however, the association of IGFBP-1 with preeclampsia was lost. Thus it appears that cord IGFBP-1 is regulated primarily by fetal weight, and not by processes related to preeclampsia.

Apoptosis

Another potential link between preeclampsia and fetal growth restriction is the process of trophoblast apoptosis, which appears to be up-regulated in both conditions.[288,289] Ishihara and co-workers[289] demonstrated a significant down-regulation of the antiapoptotic protein Bcl-2 in the syncytiotrophoblast of placentas from pregnancies complicated by either SGA or preeclampsia, whereas other investigators[288] have reported increased evidence of apoptotic activity in pathologic specimens of cytotrophoblast. Fas ligand expression was found to be elevated in trophoblast and in paired maternal-cord blood samples from hypertensive pregnancies.[290,291] Isolated trophoblast from pregnancies complicated by either intrauterine growth restriction or preeclampsia demonstrates increased susceptibility to induction of apoptosis by hypoxia or TNF-α.[292,293] It is hypothesized that dysregulated trophoblast apoptosis during the process of endovascular invasion would impair placental perfusion, contributing to both SGA

and preeclampsia.[292,293] Similarly, inappropriate loss of syncytiotrophoblast from the floating villi nearer to term would reduce the effective villous surface area, thereby restricting transplacental passage of nutrients and oxygen.

Leptin

The disruption of metabolic pathways in preeclampsia may have particular relevance for alterations of fetal growth. Leptin, a 16-kDa hormone secreted by adipocytes, placenta, and select other tissues, is involved in the neuroendocrine regulation of body fat, feeding behavior, energy homeostasis, and reproduction.[294,295] Leptin levels correlate with body mass index in the nonpregnant state, and its production by adipocytes is stimulated by estrogens, progesterone, insulin, and inflammatory cytokines (e.g., TNF-α, IL-1).[294,296,297] Leptin actions include alteration in food intake, sympathetic nervous system activity, fatty acid synthesis, and triglyceride oxidation.[294] In pregnancy, leptin has dual functions in both the maternal and fetal compartments. In the mother, serum leptin levels increase two- to four-fold in normal pregnancy, presumably owing to placental production.[298-300] The increase of maternal leptin in pregnancy is related not to maternal body mass index but rather to placental size.[301,302] Leptin is actively produced in the syncytiotrophoblast and secreted into the maternal circulation. Leptin and its receptor also are expressed in the early placenta and may play a role in regulating the phenotype of invasive trophoblast.[303,304] The high levels of leptin in pregnancy reflect some degree of leptin resistance at the level of the hypothalamus and serve to augment mobilization of fatty acids in the periphery. Levels of circulating leptin are significantly higher in pregnancies complicated by preeclampsia.[305,306] The increase predates the clinical diagnosis, but levels rise still further once the diagnosis is made.[277] The source is likely to be placental, and secretion of leptin by cultured trophoblast is increased by hypoxia and cytokines, both of which are present in the preeclamptic placenta.[307-309]

It is widely suspected that leptin plays a role in the regulation of fetal growth.[310,311] In the fetus, similar to the nonpregnant adult state, leptin reflects adiposity and body composition. Cord leptin levels correlate with placental weight, birth weight, ponderal index, infant length, head circumference, gestational age, and cord insulin levels.[312-318] Cord leptin does not correlate with maternal leptin in normal pregnancies, suggesting a fetal-placental mode of regulation independent from the mother's compartment.[314,319,320] With only 1.6% of placental leptin being secreted into the fetal circulation, it is suspected that fetal adipose tissue is the major source of cord leptin.[321,322] Cord leptin levels are elevated in LGA infants and decreased in SGA infants[323-325] in proportion to body mass. Alternatively, the lower leptin concentration in SGA infants may be due to placental insufficiency or to lower levels of IGF-1 and insulin.[294,320,326]

Severe or early preeclampsia appears to disturb fetal leptin regulation and may be one mechanism of impairing fetal growth.[294] In contrast with uncomplicated pregnancy, a positive correlation between maternal and fetal leptin levels is observed in cases of preeclampsia, suggesting either enhanced placental permeability or basolateral secretion.[305] In the setting of preeclampsia, cord leptin has been reported to be increased, decreased or unchanged.[305,327-329] Odegård and associates[329] demonstrated that among hypertensive pregnancies, cord leptin was elevated at each gestational age. These workers suggest that leptinemia may be secondary to uteroplacental hypoxia or a disturbed fetal-placental interface and speculate that a resetting of leptin signaling may result in future insulin resistance and cardiovascular disease in the offspring.

Inherited Thrombophilias

Fetal growth restriction also may be linked to preeclampsia by its association with inherited and acquired thrombophilic conditions.[330,331] Multiple studies have reported an association between thrombophilic tendencies in women and adverse pregnancy outcomes, including both preeclampsia and intrauterine growth restriction,[330-335] but not all.[336,337] It is hypothesized that a maternal or fetal predisposition to clotting would lead to thromboses in the placental vasculature, thereby restricting oxygen and nutrient exchange, resulting in fetal growth impairment. Alternatively, fetal thrombophilia may lead to vascular disruption and potential developmental anomalies.[338] Histopathologic examination of placentas from preeclamptic women with thrombophilic conditions does not always disclose a greater frequency of thrombotic or inflammatory lesions,[339] thus casting doubt on the potential etiologic role of thrombophilia in the pathogenesis of preeclampsia.

Long-Chain Fatty Acid Metabolism

One particularly intriguing genetic association between maternal vascular disease and in utero growth restriction concerns a fetal inborn error of metabolism. Long-chain 3-hydroxyacyl-coenzyme A (CoA) (LCHAD) deficiency is a recessive condition resulting in the interruption of fatty acid β-oxidation and the accumulation of 3-hydroxy fatty acid metabolites.[340,341] Fetal manifestations of the disease include premature delivery, asphyxia, growth restriction, and potentially stillbirth.[342] Mothers of affected infants have an 80% likelihood of developing HELLP syndrome (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets) or acute fatty liver of pregnancy (AFLOP), two severe pregnancy complications with similarities to preeclampsia.[341] One possible explanation of this preeclampsia-like response is fetal-to-maternal transmission of accumulated oxidized 3-hydroxy fatty acids and their metabolites. As with preeclampsia, oxidative stress at the placental interface and within the maternal vasculature may lead to both fetal and maternal manifestations.

Therapeutics

In some instances, fetal growth disturbances may be associated with the treatment for cardiovascular disease, and not the disease itself. Pregnant women with vascular disease are subjected to numerous therapies, including seizure prophylaxis, antihypertesive treatment, immunosuppression, and others.

Magnesium

Magnesium sulfate is administered to nearly all preeclamptic women in the United States as a means of preventing eclamptic seizures in labor, and is commonly used as an inhibitor of preterm labor. Maternal magnesium administration has been associated with decreased rates of cerebral palsy when used in preterm pregnancies to prevent seizures or labor.[343-347] Other investigators, however, have not found a decrease in frequency of this disorder among preterm infants treated with magnesium whose mothers did not have preeclampsia.[100,348-351] Although preeclampsia and prematurity may be associated with fetal intracranial hemorrhage and subsequent neurodevelopmental delay, magnesium does not reduce the incidence of objective ultrasound evidence of CNS abnormalities.[350,351] It is, however, associated with lowered cerebral perfusion in preterm infants on the first day of life.[352,353] Although one small trial for the prevention of neurologic injury in preterm infants showed that magnesium exposure tended to *increase* the overall risk for neonatal death, a recent review of data for more than 6000 subjects concluded that administration of magnesium in doses used to prevent eclamptic seizure had no effect on pediatric mortality rates but decreased the risk for cerebral palsy by 30%.[354,355]

Antihypertensives

Substantial evidence accumulated from interventional trials in pregnancy indicates that the β-blocker atenolol increases the risk of intrauterine growth restriction, whether used to treat chronic hypertension or to prevent preeclampsia.[356] Other β-blockers, such as labetalol, do not share this effect on fetal growth.

Angiotensin-converting enzyme (ACE) inhibitors generally are not used in pregnancy because of deleterious effects on fetal and neonatal renal function and the associated potential for teratogenic effects.[357] The other commonly used antihypertensives, such as diuretics, calcium channel blockers, and direct vasodilators, have not been associated with disturbances of fetal growth or development.

Future Risks for Offspring of Preeclamptic Mothers

Neurodevelopmental Outcomes

In view of the "hostile" intrauterine environment supposed by current models of preeclampsia, offspring of mothers with preeclampsia or other hypertensive disorders of pregnancy might be expected to have increased long-term risk for neurodevelopmental disorders such as neurodevelopmental delay or impaired cognition. Few well-designed studies have been conducted to answer this question, however, and conflicting results have been obtained from retrospective cohort and case-control studies. Oftentimes, adequate controls for confounding factors such as gestational age at delivery, the presence or absence of growth restriction, and the peripartum use of medications such as glucocorticoids or magnesium sulfate seizure prophylaxis are lacking.

Cerebral Palsy

Cerebral palsy is a chronic, nonprogressive disorder of the white matter causing motor function impairment that becomes detectable within months to years after birth.[358,359] The inciting etiologic event in cerebral palsy is still elusive but traditionally has been thought to be asphyxial injury associated with labor and delivery.[358] More recent studies, however, suggest that in a majority of cases, predelivery antecedents related to early developmental anomalies or infections can be identified.[343,358] The association of cerebral palsy with preeclampsia has been studied in a number of investigations. A recent meta-analysis of 10 observational trials from 1966 to 1999 reported that the risk for cerebral palsy in low-birth-weight and growth-restricted infants was 50% lower in cases complicated by maternal preeclampsia.[359] This protective benefit appeared to persist even after controlling for the use of magnesium sulfate. Preeclampsia seemed to reduce the risk for cerebral palsy in low-birth-weight infants even when magnesium was not used.[360-362] It is unclear how preeclampsia, a disorder characterized by placental hypoxia-ischemia and inflammatory activation, could be protective against cerebral palsy. One potential explanation is that the early compensatory signals initiated by placental insufficiency (such as increased cardiac output[363] or altered uteroplacental blood flow[364]) more than make up for the reduced perfusion later on in pregnancy and prepare the infant for subsequent deprivation.[359] It is illustrative that in term preeclamptic pregnancies, the negative association with cerebral palsy and preeclampsia is *not* seen, suggesting that longer in utero exposure to placental hypoxia may eventually override initial protective effects.[365,366] Recent studies support this possibility by suggesting that most infants born to preeclamptic mothers are either AGA or LGA in comparison with gestational age–matched control infants.[212,218,219] Alternatively, it is proposed that rather than preeclampsia's conferring a protective effect, perse, there is a comparative excess of cerebral palsy in the preterm control groups who are disproportionately exposed to chorioamnionitis and other risk factors.[100,367]

Cognition

Several observational studies have noted an association between hypertension or preeclampsia in pregnancy and developmental delay.[368] These studies found a greater frequency of mild neurodevelopmental abnormalities in SGA infants born of hypertensive mothers[369,370] compared with nonhypertensive mothers. Of note, birth weight and SGA were more strongly correlated with future deficits than was hypertension per se. Some researchers have even suggested that preeclampsia may help prevent cognitive delay because germinal matrix hemorrhage is less common in very-low-birth-weight infants when preeclampsia was present.[371-373] Reduced placental blood flow by itself does not seem to increase the risk of neurodevelopmental or cognition delay, because no difference in behavior was observed between preterm preeclamptic children with and those without ultrasound evidence of placental blood flow restriction.[374] Thus other factors associated with early embryonic or fetal development are likely to influence the cognitive outcome.

Hypertension

Within multiple populations, long-term, prospective studies have identified a weak association between hypertension in pregnancy and hypertension in the offspring.[375-377] Seidman and co-workers[375] demonstrated a 2.3-fold increased risk of systolic hypertension at the age of 17 years in female (but not male) offspring born after a preeclamptic pregnancy. However, it appears that growth restriction accompanying a hypertensive pregnancy, rather than the hypertension itself, better predicts future cardiovascular risks. In a large epidemiologic survey of the Danish Perinatal Cohort Study, Klebanoff and colleagues[378] reported that pregnant women who were themselves SGA at birth had a 1.8-fold increased risk of developing hypertension in pregnancy over that in with women who were AGA at birth. Of interest, no association was found between hypertension in these womens' mothers' pregnancies and that in their own pregnancies. Prematurity by itself also predicted an increased risk of hypertension in pregnancy, although this relationship was not statistically significant.

Tenhola and co-workers[379] studied the vascular and metabolic outcomes in a group of 12-year-old children born after either a normal or a preeclamptic pregnancy. These investigators noted that the offspring of the preeclamptic women had significantly elevated systolic and diastolic blood pressure even after adjustment for current weight and height. The preeclamptic pregnancy offspring also had higher circulating epinephrine levels. The blood pressure at 12 years of age was inversely correlated with birth weight only in the children in the preeclampsia group. No difference was observed in serum lipids, insulin, blood glucose, or adrenocortical hormones, or in current weight or height. These data (and other findings[377]) suggest that preeclampsia may be related to future hypertension, but that birth weight and adolescent obesity may better predict the future risk for metabolic syndrome.

CONCLUSION AND OUTLOOK

It is apparent that cardiovascular diseases are common in pregnancy and that they are associated with considerable morbidity in both mother and fetus. The importance of cardiovascular function in pregnancy relates not only to maternal well-being but also to normal fetal growth and development. The intimate association between fetal growth and maternal cardiovascular function hinges on the adaptive and maladaptive potential of the placenta, and future investigation of the links between maternal disease and the fetal environment must focus on this interface. Increased understanding of the compensatory potential of the placenta can be expected to drive the development of therapies aimed at ameliorating diseases that remain dormant for nearly a lifetime.

18 Fetal Origins of Adult Disease

David J. P. Barker

Hitherto the search for the causes of chronic disease, and for ways to prevent them, has been guided by a "destructive" model. The principal causes to be identified were believed to act in adult life by accelerating destructive processes associated with normal aging—for example, the formation of atheroma, rise in blood pressure, and loss of glucose tolerance. This model, however, has had limited success. Obesity, cigarette smoking, and psychosocial stress have been implicated, and evidence on dietary fat has accumulated to the point at which a public health policy of reduced intake is prudent, if not proven. The effects of modifying adult lifestyle, when formally tested in randomized trials have, however, been disappointingly small.[1] The model has proved incapable of answering important questions. For example, in Western countries the steep increase in coronary heart disease has been associated with rising prosperity, so why do the poorest people in the poorest parts of these countries have the highest rates?

PROGRAMMING

The recent discovery that people who develop coronary heart disease grew differently than other people during fetal life and childhood has led to a new "developmental" model for the disease.[2-5] Like other living creatures in early life, human beings are "plastic" and able to adapt to their environment. Phenotypic plasticity is the phenomenon by which one genotype can give rise to a range of different physiologic or morphologic states in response to different environmental conditions during development.[6] Gene-environment interactions are ubiquitous in development. Their evolutionary benefit is that, in a changing environment, they enable the production of phenotypes that are better matched to their environment than would be possible if one genotype produced the same phenotype in all environments.[6]

The development of the sweat glands provides a simple example of what is often referred to as "programming."[4] All human beings have similar numbers of sweat glands at birth, but none of them function. In the first 3 years after birth, a proportion of the glands become functional, depending on the temperature to which the child is exposed. The hotter the conditions, the greater the number of sweat glands that are programmed to function. After 3 years, programming is complete and the number of sweat glands is fixed. Thereafter the child who has experienced hot conditions will be better equipped to adapt to similar conditions in later life because people with more functioning sweat glands cool down faster.

The sweat glands encapsulate the essence of programming: a critical period during which a system is plastic and sensitive to the environment, followed by loss of plasticity and development of a fixed functional capacity. It may be advantageous, in evolutionary terms, for the body to remain plastic during development. Why this plasticity is ultimately lost in most tissues and systems is a question for which only speculative answers have emerged. Some tissues, the trabeculas of bone, for example, do remain plastic throughout life. It has been suggested that plasticity during intrauterine life enables animals, and humans, to receive a "weather forecast" from their mothers that prepares them for the type of world in which they will have to live.[7] If the mother is poorly nourished, she signals to her unborn baby that the environment it is about to enter is likely to be harsh. The baby responds to these signals by adaptations, such as reduced body size and altered metabolism, which help it to survive a shortage of food after birth. In this way programming gives a species the ability to make short-term adaptations, within one generation, in addition to the long-term genetic adaptations that come from natural selection.

TABLE 18-1

Hazard Ratios (95% Confidence Intervals) for Death From Coronary Heart Disease (CHD) According to Weight at Birth and at Age 1 Year in 10,636 Men in Hertfordshire

Birth Weight (pounds)	DEATH FROM CHD	
	Before 65 Years	All Ages
At birth		
≤5.5	1.50 (0.98-2.31)	1.37 (1.00-1.86)
6.5	1.27 (0.89-1.83)	1.29 (1.01-1.66)
7.5	1.17 (0.84-1.63)	1.14 (0.91-1.44)
8.5	1.07 (0.77-1.49)	1.12 (0.89-1.40)
9.5	0.96 (0.66-1.39)	0.97 (0.75-1.25)
> 9.5	1.00	1.00
***p* for trend**	.001	.005
Age 1 year		
≤18	2.22 (1.33-3.73)	1.89 (1.34-2.66)
20	1.80 (1.11-2.93)	1.58 (1.15-2.16)
22	1.96 (1.23-3.12)	1.66 (1.23-2.25)
24	1.52 (0.95-2.45)	1.36 (1.00-1.85)
26	1.36 (0.82-2.26)	1.29 (0.93-1.78)
≥27	1.00	1.00
***p* for trend**	< .001	< .001

TABLE 18-2

Percentage of Men Aged 64 Years With Impaired Glucose Tolerance or Type 2 Diabetes According to Birth Weight

Birth Weight (pounds)	Men With 2-hr Glucose of ≥7.8 mmol/L (%)	Odds Ratio (95% Confidence Intervals)*
≤5.5	40	6.6 (1.5-28)
6.5	34	4.8 (1.3-17)
7.5	31	4.6 (1.4-16)
8.5	22	2.6 (0.8-8.9)
9.5	13	1.4 (0.3-5.6)
>9.5	14	1.0

*Adjusted for current body mass index

Overlooked until recently, a growing body of evidence has shown that systems of the body that are closely related to adult disease, such as the regulation of blood pressure, are also plastic during early development. In animals it is surprisingly easy to produce lifelong changes in the blood pressure and metabolism of a fetus by minor modifications to the diet of the mother before and during pregnancy.[8] When undernutrition during development is followed by improved nutrition, many animals stage accelerated or "compensatory" growth in weight or length. This restores the animal's body size but has long-term costs that include reduced life span.[9] This chapter sets out the evidence that chronic disease is initiated through two basic biologic phenomena: developmental plasticity and compensatory weight gain in childhood.

BIRTH WEIGHT AND CHRONIC DISEASE

Exploring the developmental origins of chronic disease has required studies of a kind that had not previously been carried out. It was necessary to identify groups of men and women now in middle or late life whose size at birth had been recorded. Their birth weights could then be related to later occurrences of chronic diseases. In Hertfordshire, United Kingdom, starting in 1911, when women had babies they were attended by a midwife, who recorded the birth weight.[2,10] A health visitor went to the babys' homes at intervals throughout infancy, and weights at 1 year were recorded. Table 18-1 lists the findings for 10,636 men born between 1911 and 1930. Hazard ratios for coronary heart disease decrease with increasing birth weight. Stronger trends with weight are seen at 1 year. Table 18-2 shows findings for a sample of men who had glucose tolerance tests.[11] The percentage with impaired glucose tolerance or type 2 diabetes decreased steeply with increasing birth weight. The association between low birth weight and coronary heart disease has now been replicated among men and women in Europe, North America, and India.[12-17] Low birth weight has been shown to predict altered glucose tolerance in studies of men and women around the world.[18-22] These associations with low birth weight and later disease depend on slow fetal growth rather than premature birth. The association between coronary heart disease and poor weight gain in infancy, first shown in Hertfordshire,[2,10] has been confirmed in the Helsinki Birth Cohort.[5]

Figure 18-1 shows the growth of men and women who either were hospitalized for management of coronary heart disease or died of it.[5] They belonged to a cohort of 8760 people who were born in Helsinki during 1934 to 1944. Growth is expressed as Z-scores. The Z-score for the cohort is set at zero, and a child maintaining a steady position as large or small in relation to other children would follow a horizontal path on the figure. Boys and girls in whom coronary heart disease developed later in life, however, were small at birth and remained small in infancy but experienced accelerated gain in weight and body mass index (weight/height^2) after the age of 2 years. Their heights, however, remained below average, which is consistent with the known association between the disease and short adult stature.[23]

Table 18-3 is based on 2997 patients treated for hypertension and 698 patients treated for type 2 diabetes in the Helsinki Birth Cohort.[24] These two disorders are associated with the same general pattern of growth as for coronary heart disease. Small size at birth is followed by accelerated weight gain in childhood. The highest risk for each disease occurs among men and women who had low birth weight but were in the highest body mass index group at 11 years. As with coronary heart disease, the risk for disease is determined not only by the absolute value of body mass index in childhood but also by the combination of body size at birth and during childhood.[25,26] It is the tempo of weight gain in childhood as well as the attained body size that determines risk.

BIOLOGIC MECHANISMS

There are a number of mechanisms by which reduced fetal and infant growth followed by accelerated weight gain in childhood may lead to later disease. Babies who are thin at birth lack muscle, a deficiency that will persist, because the critical period for muscle growth is around 30 weeks in utero, and little cell replication occurs after birth.[27] If thin babies develop a high body mass index in childhood, fat mass may be disproportionately high. This is associated with the development of insulin resistance.[28]

Small babies have reduced numbers of nephrons.[29] It has been suggested that this leads to hyperperfusion of each nephron and resulting glomerular sclerosis, further nephron death, and a cycle of increasing blood pressure and nephron death. This may be exacerbated if accelerated weight gain increases the degree of hyperperfusion. This framework fits with the hypothesis that essential hypertension is a disorder of growth with two separate mechanisms: a growth-promoting process in childhood and a self-perpetuating mechanism in adult life.[30]

One of the mechanisms linking poor weight gain in infancy with coronary heart disease is altered liver function, reflected in elevated serum concentrations of total and low density lipoprotein cholesterol and high plasma fibrinogen concentrations.[31]

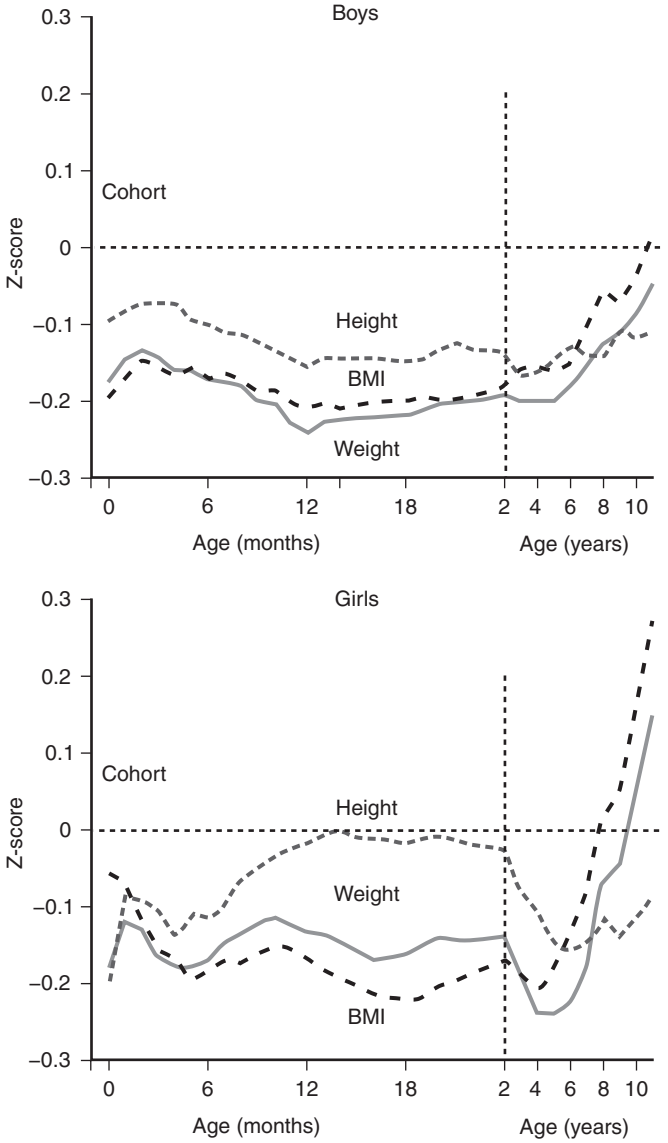

Figure 18-1 Mean Z-scores for height, weight, and body mass index in the first 11 years after birth among boys and girls in whom coronary heart disease developed in adulthood. The mean values for all boys and all girls are set at zero, with deviations from the mean expressed as standard deviations (Z-scores).

Unlike organs such as the kidney, the liver remains plastic during its development until the age of approximately 5 years. Its function may be permanently changed by influences that affect its early growth.[32-33] Liver development may play an important role in the early pathogenesis of coronary heart disease. Studies of men and women born in Sheffield, England[34] showed that a smaller abdominal circumference at birth (a measure that reflects reduced liver size) was a stronger predictor of later elevations of serum cholesterol and plasma fibrinogen than any other measure of body size at birth.

Observations on animals show that the environment during development permanently changes not only the body's structure and function but also its responses to environmental influences encountered in later life.[7] Table 18-4 shows the association of low income in adult life with coronary heart disease among men in Helsinki.[35] As expected from numerous studies in the Western world, men who had low incomes had higher rates of the disease. The association of low income and heart disease is, however, limited to men who exhibited slow fetal growth and were thin at birth, defined as a ponderal index (birth weight/length^3) of 26 kg/m^3 or less. Approximately one fourth of all boys born in Britain today are as thin as this. Men who were not thin at birth were resilient to the effects of low income on coronary heart disease.

One explanation of these findings emphasizes the psychosocial consequences of a low position in the social hierarchy, as indicated by low income, and suggests that perceptions of low social status and lack of success lead to changes in neuroendocrine pathways and hence to disease.[36] The findings in Helsinki seem consistent with this. People who are small at birth are known to have persisting alterations in responses to stress, including raised serum cortisol concentrations.[37]

Table 18-3 shows that the effect of a high body mass in childhood is conditioned by size at birth. Table 18-4 shows that the effect of low income in adult life is conditioned by size at birth. Therefore the effect of any single influence on the burden of disease cannot usefully be quantified because its effect will depend on the path of development that preceded it. The pathogenesis of coronary heart disease and other chronic diseases cannot be understood within a model in which risks associated with adverse influences at different stages of life add to each other.[38] Rather, the consequences of adverse influences depend on events at earlier critical stages of development. This embodies the concept of developmental "switches" triggered by the environment.[7] The effects of any particular birth weight on disease will depend not only on the subsequent path of development but also on the path of growth that led to the birth weight. The same weight can be attained by many different paths of fetal growth, and each is likely to be accompanied by different gene-environment interactions, although this remains to be demonstrated.[39]

THE PLACENTA'S ROLE IN PROGRAMMING

To date, most epidemiologic observations that have demonstrated the link between prenatal life and later chronic disease have used birth weight as the marker of early life in utero. A baby's birth weight reflects its success in obtaining nutrients from its mother. The source of these nutrients is not only the mother's daily diet but her nutritional stores and metabolism, which are the product of her lifetime's nutrition.[40] A baby's nutrition also depends on the placenta's ability to transport nutrients to it from the mother.[39] This ability is reflected in its size because large babies usually have large placentas.[41] New data from the Helsinki Birth Cohort allow researchers to address three questions: (1) What measures of placental size can be used as markers of its function for long-term studies linking placental size with later disease? (2) Is a large placenta always beneficial? (3) Are there sex differences in the maternal-placental phenotypes that predict chronic disease?

Measurements of Placental Size That Reflect Its Function

Low placental weight at birth has been shown to predict hypertension and coronary heart disease in later life.[25,42] Placental weight, however, does not distinguish the thickness of the placenta from its surface area. To increase the surface for nutrient and oxygen exchange, the placenta can increase the surface area of its villi, expand its invasion across the surface of the uterine lining, or invade the maternal spiral arteries more deeply. The long-term consequences may be different. Textbooks of midwifery written early in the last century describe the placental surface as being either oval or round.[43] To describe the extent to which the surface was more oval than round, in the past two so-called diameters of the surface were routinely recorded in some hospitals—a maximal diameter and a lesser one bisecting it at right angles. These measurements are available for the Helsinki Birth Cohort comprising 20,436 men and women born in the city in 1924 to 1944. The mean lengths of the two diameters were 19.5 and 16.9 cm, and the lengths were highly correlated (correlation coefficient = 0.63).[44] The diameters were used to estimate the surface area. How closely this area reflects the total surface area for maternal-fetal exchange through the gestational period is not known, but it is reasonable to suppose that they correlate. The two diameters and placental weight were combined to estimate thickness.

Placentas from pregnancies complicated by preeclampsia had a more oval surface than those from normotensive pregnancies because of a disproportionate reduction in the lesser diameter.[45] When the two diameters were analyzed together, preeclampsia was not associated with the length of the maximal diameter, but was strongly associated with a short lesser diameter. This is shown in Figure 18-2. The relation with the lesser diameter was graded: The shorter the lesser diameter, the greater the risk for, and severity of, preeclampsia. This led to the suggestion that placental growth is polarized from the time of implantation.[45] Growth along the major axis, reflected in the major diameter, may align with the rostrocaudal growth of the fetus; growth along the minor axis may be nutritionally sensitive. Because preeclampsia is only related to growth of the minor axis, tissue along this axis may be functionally different to tissue on the major axis. Alternatively growth along the minor axis may be a more sensitive marker of the impaired implantation that initiates preeclampsia.

Large Placentas

Although low placental weight at birth has been shown to predict hypertension and coronary heart disease in later life,[25] a study of men and women born in a maternity hospital in Preston, United Kingdom, showed that high placental weight in relation to birth weight is also associated with hypertension.[46] Table 18-5 shows that whereas people with both low placental weight and low birth weight had higher mean systolic blood pressures than people with low placental weight but high birth weight, the highest mean systolic pressures occurred in people who had high placental weight but low birth weight. This observation has been replicated, and high placental weight in relation to birth weight has also been shown to predict coronary heart disease.[47] These associations with large placental size suggest that cardiovascular disease can be initiated through placental expansion as well as through restricted placental growth. Observations in sheep show that in response to undernutrition a fetus is able to extend the area of the placenta by expanding the individual cotyledons.[48,49] This increases the area available for nutrient and oxygen exchange and results in a larger lamb than otherwise would have been. This is profitable for the farmer, and manipulation of placental size by changing the pasture of pregnant ewes is standard practice in sheep farming.

Placental expansion in response to undernutrition in midgestation can only occur, however, if the ewe was well nourished before conception.[49] A similar phenomenon may occur in humans. In the Helsinki Birth Cohort, the effects of the placental area on hypertension depended on the mother's socioeconomic status, a marker of her current nutrition, and on her height, which reflects her nutrition and metabolism in childhood and adolescence.[44] In people whose mothers were of low socioeconomic status or below average height, hypertension was associated with low placental weight and area. In people whose mothers were likely to have been the best nourished and who were tall and middle class, hypertension was predicted by large placental size in relation to birth weight. Figure 18-3 shows the trends in the

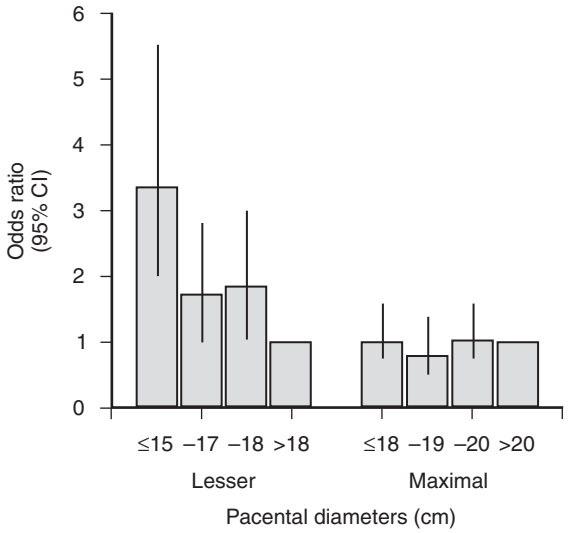

Figure 18-2 Odds ratios for preeclampsia according to the diameters of the placental surface.

6.5	149	152	151	167
7.5	139	148	146	159
>7.5	131	143	148	153

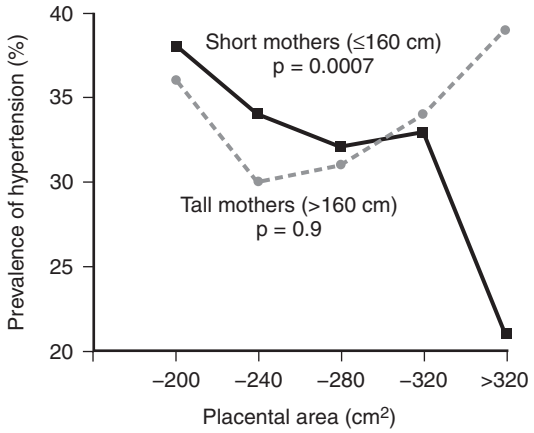

Figure 18-3 Prevalence of hypertension according to placental area in the offspring of short and tall mothers.

prevalence of hypertension with placental area in people divided according to whether their mother's height was above or below the median of 160 cm. In people whose mothers were short, the prevalence of hypertension fell progressively with increasing placental area, whereas in people with tall mothers, the association was U-shaped: If the mother was of lower social class, hypertension was associated with small placental area, but if she was middle class, it was associated with large area. Figure 18-3 illustrates the important point that the effects of placental size in programming later disease are conditioned by the mother's nutrition.

Of the two diameters of the surface, the lesser diameter was more closely associated with hypertension, suggesting that expansion of the surface along its minor axis may be a response to fetal undernutrition.[44] Compensatory placental growth may be beneficial in some circumstances, but if the compensation is inadequate and the fetus continues to be undernourished, the need to share its nutrients with an enlarged placenta may become an added metabolic burden. A long-term cost of this added burden is hypertension, possibly as a result of impaired development of low-priority organs like the kidney.[29]

Sex Differences in Placental Programming

Boys grow faster than girls from an early stage of gestation, even before implantation, and this makes them more vulnerable if nutrition is compromised.[50] In the Helsinki Birth Cohort, small differences in average body measurements at birth concealed large differences in body proportions. At any placental weight, boys tended to be longer than girls; the placentas of boys were smaller than the placentas of girls when related to the weight of the baby.[17,51] This suggests that the placentas of boys are more efficient but may have less reserve capacity, which therefore increases the babies' vulnerability to undernutrition. Boys tend to have larger head circumferences at birth but are thinner than girls.[17] These differences suggest that they may more readily trade visceral development to protect brain growth. The growth of every human fetus is constrained by the limited capacity of the mother and placenta to deliver nutrients to it.[52] The male fetus, by growing more rapidly and investing in brain growth rather than placental growth, is adopting a more dangerous strategy that puts it at greater risk for becoming undernourished.

The relation between the placental diameters and later hypertension was different in the two sexes.[51] In women, hypertension was associated with a short lesser diameter and a small placental area. These trends were stronger in women whose mothers were short but did not differ with the mother's social class. In men, hypertension was associated with a large lesser diameter in relation to birth weight. This trend was confined to men whose mothers were middle class. An interpretation of these findings is that during development in the womb girls respond more to their mother's lifetime nutrition and metabolism than to their current diets, whereas boys are more responsive to their mother's current diet. The greater effect of the Dutch famine on boys supports this,[53] as do the greater effects of experimental maternal malnutrition on male animals.[54,55] Although boys' responsiveness to their mothers' current diet enables them to capitalize on an improving food supply and promotes the agenda of rapid growth, it makes them vulnerable to food shortages. An ultimate manifestation of boys' dangerous growth strategies in the womb may be that men have higher blood pressures and shorter lives than women.

MOTHERS AND BABIES TODAY

In view of the considerable evidence showing that coronary heart disease and the related disorders stroke, hypertension, and type 2 diabetes originate through undernutrition and other adverse influences in utero, followed by accelerated weight gain in childhood, protecting the nutrition and health of young women and their babies must be part of any effective strategy for preventing chronic disease. Evidence that certain cancers are initiated in fetal life adds to the urgency of this.[56-58] The so-called fetal origins hypothesis resulted from studies of the geographic association between coronary heart disease and low income in England and Wales and the recognition that a poor intrauterine environment played a major role in this association.[59] Areas of the country with high coronary mortality rates are characterized historically by poor maternal nutrition and health, reflected in high maternal and neonatal mortality.[60] It is becoming clear that the concept of maternal nutrition must be extended beyond a mother's diet in pregnancy to include her lifetime nutrition and metabolism. The Helsinki studies allow estimation of the magnitude of the effects of early growth on later disease. If, for example, each child in the cohort had been in the highest third of birth weight and had reduced his or her standard deviation score for body mass index between age 3 and 11 (see Table 18-3), the incidence of type 2 diabetes would have been reduced by 57%.[24] Thus early development establishes a substantial part of the risk for chronic disease in later life.

Physiologic Effects of Multiple Pregnancy on Mother and Fetus

BACKGROUND INFORMATION

Multiple pregnancy, including twins and higher-order multifetal gestations, presents a challenge to obstetricians, perinatologists, and neonatologists. Besides the social, economic, and psychologic effects on individual patients and families, multiple pregnancy has a significant physiologic impact on both the mother and each individual fetus. Multiple births account for a disproportionate share of adverse obstetric and neonatal outcomes. Parturients are at increased risk for gestational hypertension, gestational diabetes, abnormal placentation, placental abruption, preterm labor, and cesarean delivery, whereas fetuses are at increased risk for genetic and anatomic anomalies, growth abnormalities, intrauterine fetal demise (IUFD), prematurity, and abnormalities specific to monochorionicity, such as the twin-to-twin transfusion syndrome (TTTS).

Maternal and neonatal outcomes may be optimized by use of management protocols based on an appreciation of the physiologic effects of multiple pregnancy on both the mother and the fetus. A multidisciplinary approach to the care of these patients has been recommended.[1] This chapter reviews important physiologic and pathophysiologic aspects of multifetal gestations.

Incidence

As of 1973, the reported incidence of twins worldwide was 1 in 80 pregnancies, whereas higher-order multiples were significantly less common.[2] In the United States, however, the incidence of multiple gestations has increased since the late 1960s because of the use of infertility treatments, such as superovulation and assisted reproductive technology (ART).[3] In the more recent past, some countries have reported a doubling of twin pregnancy rates.[4] The incidence of multiple pregnancies has been increasing at a greater rate than that for singleton pregnancies. In the United States, between 1973 and 1990, twin births increased by 65% and higher-order births increased by 221%, whereas singleton births increased by only 32%.[3]

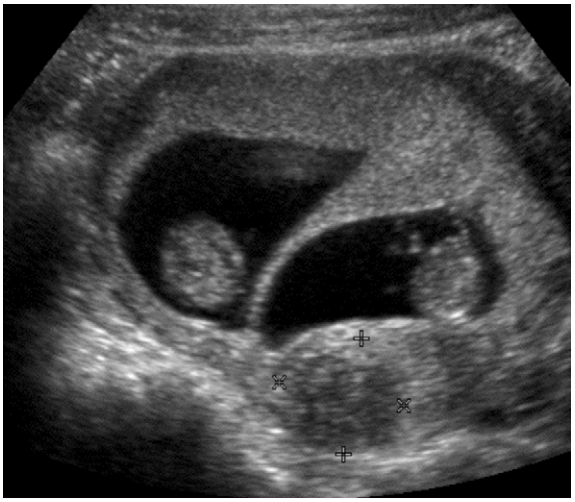

Figure 19-1 First-trimester twin peak sign in a dichorionic twin pregnancy.

Zygosity and Chorionicity

Zygosity refers to the genetic make-up of a pregnancy. Multiple gestations can be monozygotic or dizygotic. *Monozygotic* twins result from the division of a zygote arising from the fertilization of one ovum by one sperm. *Dizygotic* twins result from the fertilization of separate ova by separate sperm. Approximately two thirds of twins are dizygotic, with "identical twins" accounting for the remaining third.[5]

Chorionicity refers to the membrane composition of the pregnancy—the chorion and amnion. It is determined by the mechanism of fertilization and by the occurrence and timing of embryo division. All dizygotic twins have separate dichorionic diamniotic placentas; that is, each fetus has its own separate placenta and amniotic sac. The reason is that dizygotic twins result from the fertilization of two separate ova by two separate sperm. Monozygous gestations can be dichorionic diamniotic, monochorionic diamniotic, or monochorionic monoamniotic, depending on the timing of division. If the zygote splits during the first 3 days after fertilization (at the morula stage), a *dichorionic diamniotic* placenta results. Approximately one third of monozygotic twins have this type of placenta.[5] If the zygote splits between days 3 and 8 (at the developmental stage), the pregnancy will be *monochorionic diamniotic,* accounting for approximately two thirds of monozygous twins.[5] These twins share one placenta but coexist in separate amniotic sacs. A *monochorionic monoamniotic* pregnancy results if the zygote splits after the amnion has formed (the embryonic disk stage) at approximately 9 to 12 days; the twins share the same placenta and amniotic sac. This type accounts for approximately 3% of all monozygotic twins.[5] If the yolk sac has already formed and division occurs, the monozygotic pair will be conjoined. Conjoined twins are rare, occurring in 1 in 50,000 births.[6] With zygote division after day 17, a singleton gestation will result.[7] Higher-order multiples may be composed of any combination of monozygotic and dizygotic fetuses.[8]

The precise mechanisms causing spontaneous monozygotic and dizygotic twins are not well understood. Dizygotic twins and high-order multiples probably derive from multiple ovulations resulting from simultaneous growth of multiple follicles.[9] Factors well known to be associated with an increased incidence of dizygotic twins include advanced maternal age, family history of such twinning, multiparity, and certain ethnicities.[10-12] Dizygotic twinning may be related to higher baseline levels of gonadotropins in certain women. Fertility treatment also is associated with increased rates of dizygotic twins. Under all of these conditions, the ovary is exposed to high levels of gonadotropic hormones, resulting in multiple ovulation.[9]

Monozygotic twinning, however, is less understood than dizygotic twinning. Before the use of ART, the frequency of monozygotic twins was constant throughout the world. The incidence was approximately 4 per 1000 births.[2] With infertility treatment, however, the incidence of monozygotic twin gestations may be increasing.[13] The mechanism is unknown, but twinning may be secondary to trauma during the procedure or associated with increased levels of gonadotropins.[14,15]

Determination of Chorionicity

The determination of chorionicity is important in the management of multiple gestations because monochorionic twins are at increased risk for adverse outcomes.[16] Prenatally, ultrasound imaging is the best diagnostic method. Chorionicity is most accurately determined in the first trimester (from 6 to 10 weeks) by counting the number of gestational sacs. The presence of two separate gestational sacs, each with its own heartbeat, suggests a dichorionic diamniotic pregnancy, whereas one gestational sac with two separate heartbeats suggests a monochorionic pregnancy.[17] The amnion can be visualized by transvaginal ultrasound imaging at approximately 7 to 8 weeks of gestation. Before this time, amnionicity may be difficult to determine. When two separate amniotic sacs, each with a single heartbeat, are visualized, the pregnancy is diamniotic. Conversely, when one amniotic sac with two heartbeats is visualized, the pregnancy is monoamniotic.[18] In addition, determination of the number of yolk sacs can be used as an indirect method to indicate the number of amniotic sacs and consequently the amnionicity.[19] At early gestational ages, chorionicity and amnionicity should be confirmed by another ultrasound scan in 2 to 3 weeks, because misdiagnosis is a possibility[20] (Figures 19-1 to 19-3).

After the first trimester, determination of chorionicity and amnionicity becomes less accurate. As a result, different techniques are needed to determine amnionicity and chorionicity in multiple gestations in the second and third trimesters. These methods include assessing fetal gender, evaluating the placenta, and examining the intertwin membrane.

If the fetuses are of different genders, the pregnancy is almost certainly dichorionic. If the gender is unknown, however, or is the same for all fetuses, chorionicity is still unknown. When placentas are clearly separate, the pregnancy is likely to be dichorionic. If

the placentas are adjacent or fused, however, no diagnostic information is gained.

Valuable information may be obtained by assessing the dividing membrane. In dichorionic pregnancies, the membrane contains four layers: two amnions and two chorions. In monochorionic diamniotic pregnancies, the membrane is composed of two layers: two amnions. In dichorionic placentas, a *twin peak sign* has been described in all three trimesters.[21] Placental tissue forms a triangular projection from the chorionic plate into a cleft between the membrane layers. By contrast, a T-shaped junction is present in monochorionic placentas.[22]

Membrane thickness also can be evaluated to help with the diagnosis of chorionicity.[23, 24] Because a dichorionic membrane is composed of four layers, it should appear thicker than a monochorionic membrane. Winn and associates[25] designated a 2-mm thickness as indicative of a thickened, dichorionic membrane. In 32 pregnancies, these workers found a 95% positive predictive rate for dichorionic pregnancies and an 82% predictive rate for monochorionic pregnancies.[25] Other studies have evaluated both membrane thickness and the number of membrane layers.[26] Examining membranes by ultrasound imaging in the second and third trimesters may be difficult and less accurate. Monochorionic membranes may appear thicker, depending on the ultrasound technique used, and dichorionic membranes can thin out as the pregnancy progresses.[20]

If a dividing membrane is not noted, careful evaluation must be performed to determine amnionicity. The differential diagnosis includes a monochorionic monoamniotic pregnancy versus a monochorionic diamniotic pregnancy, in which one twin has oligohydramnios, with an adherent membrane giving the illusion of monoamnionicity. Rare cases have been reported in which monochorionic diamniotic membranes rupture.[27] Nonetheless, in most cases, the pregnancy is a normal monochorionic diamniotic pregnancy, and the intertwin membrane is difficult to visualize.

Although early determination of chorionicity is a primary objective in the management of multifetal pregnancies, extenuating circumstances, such as late diagnosis of a multiple gestation or lack of conclusive findings on early ultrasound studies, may make this goal unattainable. The optimal management of certain obstetric situations, such as discordant anomalies, requires knowledge of chorionicity. DNA zygosity studies on amniocytes have been used successfully in complex cases requiring definitive diagnosis of chorionicity.[28]

MATERNAL PHYSIOLOGY AND MULTIPLE PREGNANCY

The maternal physiologic adaptation to singleton pregnancy is exaggerated in multiple gestations and involves every organ system. Although most current teachings on maternal physiology in multiple gestations derive from actual studies in the pregnant patient, some concepts have been extrapolated from knowledge regarding maternal physiology in singleton pregnancies.[29]

Uterine Changes

In both singleton and multiple pregnancies, uterine growth and change begin soon after conception. By 18 weeks, the intrauterine volume of a twin pregnancy is approximately twice that of a singleton pregnancy.[30] This difference in intrauterine volume

between singleton and multiple gestations continues until term. As should be appreciated, higher-order multiples have even greater intrauterine volumes.[31]

In singleton pregnancies at term, blood flow to the uterus is approximately 500 to 700 mL/minute. The increased blood flow is directly related to the increasing uterine size and results from a combination of the increased cardiac output of pregnancy and uterine demand. In multiple pregnancies, the increase in uterine blood flow is thought to be even greater.[31] A portion of the increased blood flow may be secondary to the decreased uterine and placental vascular resistance associated with multiple gestations. Doppler studies have indicated that the resistance in the uterine arteries is lower in twins than in singletons.[32]

Uterine activity appears to be increased in multiple pregnancies. After 23 weeks, women with twins report more contractions than those experienced by women with singleton pregnancies.[33] Uterine distention is one of many factors that may contribute to the onset of parturition.[34]

Cardiovascular Adaptation

The cardiovascular changes in multiple gestations are similar to those in singletons but are expressed to a greater degree.[35] The maternal heart size in twin pregnancies is the same as in singleton pregnancies. The cardiac output is increased, however, to compensate for increased uterine blood flow. As a result, contractility and heart rate also are increased.[35] An even greater drop in diastolic blood pressure in the second trimester and a greater rise during the third trimester have been documented in women pregnant with twins independent of age, race, or body habitus.[36] Blood pressure is dependent on maternal position, and postural changes can lead to hypotension. Because patients pregnant with twins have a greater decrease in mean arterial pressure, they seem to have be at greater risk for postural hypotension.[31]

Intravascular Volume

Pregnancy is known to be a hypervolemic state, and the increase in plasma volume at term averages approximately 45% to 50% in singletons.[37] Development of hypervolemia is thought to be a protective mechanism against excessive blood loss.[37] Plasma volume is increased even further in a multiple pregnancy.[38] Depending on the number of fetuses, plasma volume can increase by 50% to 100%.[39] As a result of this increased volume, total concentrations of serum proteins and electrolytes are reduced when compared with those in singleton pregnancies. Total intravascular protein mass is unchanged, however, as are serum sodium, potassium, and chloride concentrations and osmolality.[40]

These physiologic changes are of particular importance in addressing preterm labor and preeclampsia. Because of the slight drop in colloid oncotic pressure associated with β-mimetic medications, women with multiple gestations are at increased risk for volume overload and pulmonary edema when they are given this type of tocolysis.[37,41] Likewise, magnesium sulfate has been associated with fluid overload.[42] Other tocolytic agents (especially when used simultaneously) and antenatal steroids also have been associated with an increased risk for development of pulmonary edema.[43]

Although most young healthy women adapt to the cardiac and volume changes associated with multiple pregnancy, those with underlying medical problems and older women may be at increased risk for adverse outcomes such as myocardial infarction, particularly when they are treated for preterm labor and for preeclampsia.[35] For example, a woman with a multiple gestation and an underlying heart condition may be at increased risk for myocardial infarction because of the increased volume status combined with use of β-mimetic tocolytics or magnesium sulfate therapy.[31]

Pulmonary Adaptation

The changes in pulmonary function are similar in singleton and in multiple gestations. Such changes bring about a state of compensated respiratory alkalosis. The diaphragm level rises approximately 4 cm during a singleton pregnancy, the subcostal angle widens, and the thoracic circumference increases. Consequently, the residual volume decreases, and tidal volume increases. No increase in respiratory rate is noted, although the mother may have a sensation of tachypnea from increased respiratory effort.[44] In multiple gestations, the level of the diaphragm rises higher than in singleton gestations, a change that further reduces residual volume and functional residual capacity while increasing tidal volume.[40] Because of increased tidal volume and oxygen consumption, it is likely that women with multiple gestations have higher pH than women with singleton gestations.[39]

Hematologic Adaptation

Pregnancy is associated with dilutional anemia. Although placental production of chorionic somatomammotropin, progesterone, and prolactin stimulates erythropoiesis, only a small increase in red blood cell mass is seen.[37] The increased plasma volume of pregnancy, combined with the smaller increase in red blood cell production, results in maternal dilutional anemia despite adequate iron stores.[45] Anemia (characterized as a hemoglobin concentration lower than 10 g/dL or a hematocrit less than 30%) occurs 2.4 times more frequently in mothers of twins than in mothers of singletons.[46] Malone and partners[47] prospectively studied 55 women with triplet pregnancies at a tertiary care center and found a 27% incidence of anemia in these patients. Multiple gestations have been shown to increase erythropoietin production, perhaps as a physiologic mechanism to improve the anemia associated with pregnancy.[48]

Certain components of the coagulation system are elevated in pregnancy. Factor VII, VIII, IX, and X levels increase in pregnancy, whereas plasma fibrinolytic activity decreases. These alterations result in a hypercoagulable state until after the postpartum period. The changes are similar in both women with singleton pregnancies and women with multiple gestations.[44] Levels of plasminogen, fibrin split products, antithrombin III, and α_2-macroglobulin also are similar in both types of pregnancies.[49] Women with twin gestations, however, generally demonstrate a greater increase in plasma fibrinogen than that typical for women with singleton pregnancies.[31]

Women with multiple gestations are at increased risk for postpartum hemorrhage, which is defined as blood loss greater than 500 mL during the first 24 postpartum hours.[50] The risk for such hemorrhage is increased after vaginal and cesarean deliveries. The average blood loss at a twin delivery is approximately 1000 mL.[38] Uterine atony, secondary to overdistention of the uterus, is thought to be the main contributory pathophysiologic change.[8] In addition, women with multiple gestations also are at increased risk for placental abruption, which may result in increased blood loss at delivery.[46]

Endocrine Adaptation

Serum levels of progesterone, estradiol, estriol, human placental lactogen, human chorionic gonadotropin (hCG), α-fetoprotein, cortisol, aldosterone, and free thyroxine are increased in women with multiple gestations compared with levels in singleton pregnancies.[39] To date, it is not known whether carbohydrate metabolism is affected by multiple pregnancy.[46] It seems intuitive that women with multiple gestations would be at increased risk for gestational diabetes because of increased placental lactogen production; however, published studies have yielded conflicting findings. Spellacy and associates[46] evaluated 1253 women with twins

and did not find an increased risk for gestational diabetes. More recently, Malone and co-workers[47] found a 7% incidence of gestational diabetes in women pregnant with triplets compared with the 2% incidence in singleton pregnancies. These investigators suggested that the increased risk for gestational diabetes could be secondary to maternal age–related changes (many patients were older gravidas, with a mean age of 32 ± 2.9 years), the weight gain associated with multiple gestations, or the increased serum levels of human placental lactogen.[47]

Renal Adaptation

The normal increase in glomerular filtration rate and size of the renal collecting system is more marked in women with multiple gestations.[39] It is well known that kidney size is increased during pregnancy. Higher levels of progesterone or compression at the pelvic brim, secondary to overdistention of the uterus, may lead to increased stasis and an increased incidence of urinary tract infections.[44]

Gastrointestinal Adaptation

The enlarging uterus displaces the stomach and intestines during both singleton and multifetal pregnancies. Increased progesterone levels decrease gastrointestinal tract motility and tone while delaying gastric emptying time. As a result, pregnant women commonly suffer from constipation. The esophageal sphincter has decreased tone, resulting in acid reflux. Hemorrhoids also are common, being secondary to the venous compression and pressure from the enlarged uterus.[44] In addition, nausea and vomiting complicate almost 50% of multiple gestations, probably the result of the higher levels of β-hCG and steroid hormones.[51]

Patients with multiples are at increased risk for acute fatty liver of pregnancy, a rare condition of unknown origin resulting in elevated values on liver function tests, nausea, and vomiting.[52] If undiagnosed, this condition is associated with poor outcomes including coma, liver failure, disseminated intravascular coagulopathy, renal failure, metabolic acidosis, and fetal death. Even if it is diagnosed early, maternal mortality rates are increased (8% to 10%).[53] Treatment includes supportive care and delivery.[39]

The incidence of acute fatty liver is 1 per 13,000 in the general obstetric population.[54] Four series of cases have shown a 16.7% occurrence in twins.[31] Meanwhile, in the series of 55 triplet pregnancies evaluated by Malone and co-workers,[47] the disease was present in 7% of patients. An association between this disease and an autosomal recessive order of mitochondrial fatty acid oxidation in the children of affected women has been postulated.[55-58] When patients with multiple gestations demonstrate elevated values on liver function testing in combination with vague complaints of nausea and vomiting, a high level of clinical suspicion is waranted in order to diagnose this potentially catastrophic disease.[52]

Nutrition

Weight gain is a physiologic response to pregnancy. The average woman carrying twins gains between 40 and 45 pounds.[59] Few studies have examined weight gain in triplet and higher-order multiples.[3] The pattern of weight and the amount of weight gain appear to be different in twin pregnancies from those in singleton pregnancies. For example, weight gain occurs faster and earlier in women with multiple gestations.[3] Weight gain and pattern of gain seem to affect pregnancy outcomes.[60] Poor weight gain in early pregnancy (less than 0.85 lb/week) has been associated with poor intrauterine growth.[3] By contrast, large weight gains have been associated with greater birth weights.[3] Nutritional counseling may lead to improved weight gain in women pregnant with twins.[60] Whether better weight gain translates into better perinatal outcomes is yet to be determined.

It is recommended that women with multifetal pregnancies increase their daily caloric intake approximately 300 kcal more than that of women with singleton pregnancies.[61] Iron and folic acid supplementation also is recommended.[62]

Gestational Hypertension and Preeclampsia

The risk for developing pregnancy-induced hypertension or preeclampsia is between 10% and 20% in twin pregnancies and between 25% and 60% in triplet pregnancies, and it may be as high as 90% in quadruplet pregnancies.[39] The cause of these increased rates is unknown, but the disorder may be secondary to high levels of circulating β-hCG.[63] The rates of preeclampsia seem to be the same for monozygous and for dizygous twins.[64] Eclampsia frequency also seems to be increased in multiple pregnancies.[63] In addition, when preeclampsia occurs in higher-order multiple gestations, it seems to occur earlier and is more severe, and the clinical presentation often is atypical.[63] Because of the increased risk for preeclampsia, women with multiple gestations require frequent monitoring for early signs and symptoms.[50]

FETAL PHYSIOLOGY AND MULTIPLE PREGNANCIES

Multiple gestations contribute disproportionately to overall perinatal morbidity and mortality. These pregnancies carry an increased risk for both preterm birth and low birth weight.

Perinatal outcome is influenced by chorionicity, because dichorionic pregnancies have substantially better outcomes than those documented for monochorionic ones.[39] The effect of zygosity on outcomes, however, is less clear.[66]

The offspring of multiple births constitute less than 3% of the U.S. population but are highly represented among infants of low birth weight (less than 2500 g) or very low birth weight (less than 1500 g).[3] Ninety percent of triplets and 50% of twins are of low birth weight, compared with 6% of singletons. Preterm birth (before 37 weeks of gestation) occurs in 88% of triplets and in 48% of twins, compared with 11% of singletons. Birth before 32 weeks of gestation occurs in 31% of triplets, 11% of twins, and less than 2% of singletons.[3] More important, the incidence of extreme prematurity in multiple gestations is significant. For triplets, the risk for delivery before 28 weeks may be as high as 14%.[67]

Various interventions have been attempted to decrease the rates of preterm delivery in women with multiple gestations, such as home uterine monitoring, voluntary bed rest, prophylactic tocolytics, and elective cerclage.[1,68-70] Nevertheless, no intervention has proved to be successful.[1] Predictors for preterm delivery have been identified. At 24 weeks, a cervical length of 25 mm or less is a predictor of spontaneous preterm delivery before 32 weeks. Likewise, a positive fetal fibronectin study at 28 weeks also is indicative of spontaneous preterm birth (at less than 32 weeks).[71] If delivery between 24 and 34 weeks is anticipated, maternal corticosteroids are recommended (Figure 19-4).

Fetal Growth in Multiple Pregnancy

Normal Growth

As suggested earlier, multiple gestations are associated with increased risk for low birth weight.[72] Part of this increased risk results from preterm labor and delivery, and a portion of this risk is secondary to complications inherent to multiple gestations. Serial ultrasound imaging is the best method for evaluating fetal growth in a multiple pregnancy, and the biometric parameters used to assess singletons are accurate in multiples.[39] Although individual growth curves for twins and triplets have been described, singleton weight standards generally are used for assessing weight in twins and higher-order multiple births.[39,73]

In twins, each fetus grows at the same rate as for singletons up to approximately 32 weeks of gestation. After this gestational age,

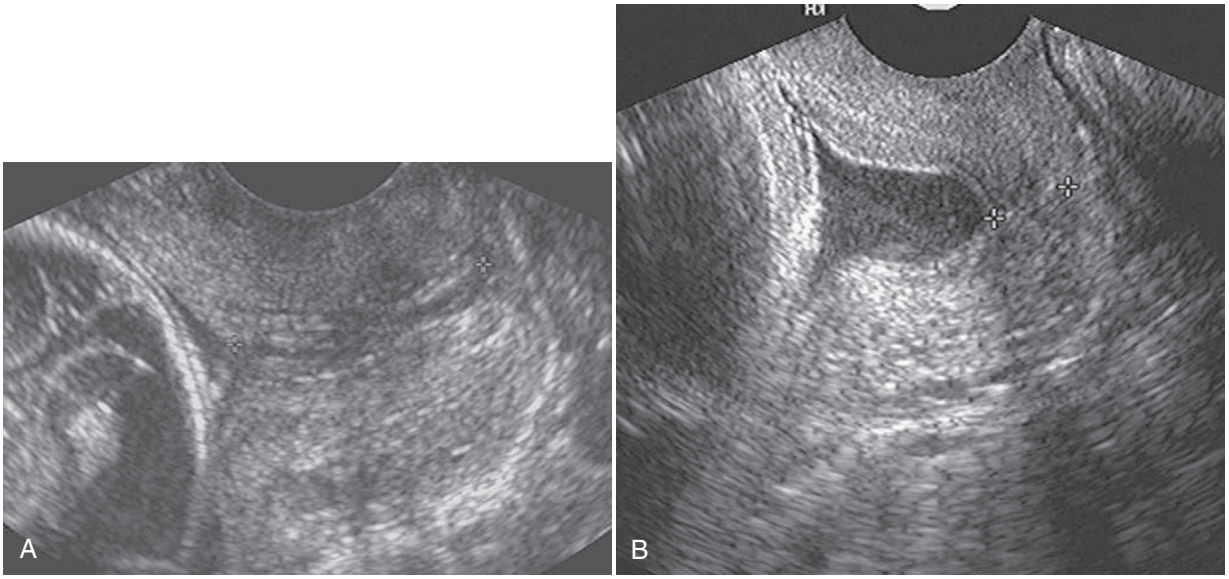

Figure 19-4 A, Normal cervix. **B,** Shortened cervix.

twins do not gain weight as rapidly as singletons.[74] As a result, multiple gestations are at increased risk for poorer growth compared with age-matched singletons. After approximately 32 weeks, the combined weight gain in twins is the same as in a singleton at the same gestational age.[75] Nonetheless, values for head circumference and body length generally are similar. Ultrasound imaging has demonstrated that twin femur length growth patterns are similar to those of singletons throughout gestation, but a reduction in abdominal circumference occurs at approximately 32 weeks.[76-79] In higher-order multiple pregnancies, this weight difference seems to become evident at even earlier gestational ages.[80]

Discordant Growth

Multiple gestations exhibit a significant increase in fetal growth abnormalities directly proportional to the number of fetuses.[81] *Growth discordancy* is the difference in sonographic estimated fetal weight expressed as a percentage in relation to the larger twin.[81] Various definitions of fetal growth discordancy have been proposed, with specific weight differences ranging between 15% and 40%.[81] However, adverse outcomes generally are related to discrepancies of 25% and greater. Discordancy has been associated with a 6.5-fold increased risk for fetal death and a 2.5-fold increased risk for perinatal death.[82] The more severe the discordance, the greater the likelihood of fetal compromise such as perinatal asphyxia.[81]

Growth discordancy has different implications depending on chorionicity.[83] Dizygotic twins are distinct individuals that exhibit genetically different growth patterns. It is not surprising, therefore, that these twins may have divergent birth weights. Nonetheless, several pathologic conditions result in discordant weight gain in these fetuses, including in utero crowding, unequal sharing of the placenta, and the combination of a normal fetus with an anomalous fetus. Situations unique to monochorionic twinning, such as TTTS, also can result in growth discordancy.[81]

Two of the most frequent findings in severely discordant twins include small placental weight and umbilical cord abnormalities.[84] For example, velamentous cord insertion—umbilical cord inserting directly into the membranes—occurs 9 to 10 times more frequently in twin gestations than in singletons and 25 to 50 times more frequently in triplets than in singletons.[85] A 13-fold increase in birth weight discordancy has been noted in monoamniotic twins with a velamentous umbilical cord insertion[83] (Figure 19-5).

In addition to growth discordancy, multiple gestations are associated with increased risk for intrauterine growth restriction. Uteroplacental insufficiency is thought to be the main cause of growth restriction in multiple gestations. Concordant growth in twins does not rule out intrauterine growth restriction, because in certain situations, both twins may exhibit growth restriction.[80] Management of both growth discordancy and intrauterine growth restriction includes intensive antepartum surveillance with delivery at term, provided that results of fetal testing are reassuring. Antenatal corticosteroids should be administered to the mother if delivery is anticipated between 24 and 34 weeks, to decrease complications of prematurity.

Multifetal Reduction

The purpose of first trimester multifetal reduction is to improve outcomes by decreasing maternal complications secondary to multiple gestations and by decreasing adverse fetal outcomes associated with preterm delivery.[39] Intracardiac injection with potassium chloride is performed between 10 and 13 weeks of gestation in dichorionic pregnancies.[86] This procedure is contraindicated in monochorionic pregnancies because vascular communications between the fetuses can result in long-term adverse sequelae for the surviving fetus.[87] Adverse outcomes, such as pregnancy loss, are thought to be decreased with provider experience.[88] In addition, it is controversial whether or not the procedure is associated with adverse outcomes, such as intrauterine growth restriction.[89]

Stone and colleagues[90] reported on a series of 1000 cases of multifetal reduction. In each case, multifetal reduction was performed transabdominally at 10 to 13 weeks of gestation. This series demonstrated a loss rate of 6.2%. Although the loss rate was highest among patients who originally were carrying six or more fetuses, the rate did not differ for starting numbers of three, four, or five fetuses. Birth weights demonstrated a linear decline with increasing starting and finishing numbers of fetuses. Gestational ages at delivery for finishing numbers of one, two, and three fetuses were similar to those for spontaneous singletons, twins, and triplets. The same group demonstrated improved outcomes when twin pregnancies were reduced to singleton pregnancies.

Stone and colleagues[91] compared 101 women with twin pregnancies reduced to singleton pregnancies with 365 patients with triplet reduced to twin pregnancies. These investigators found

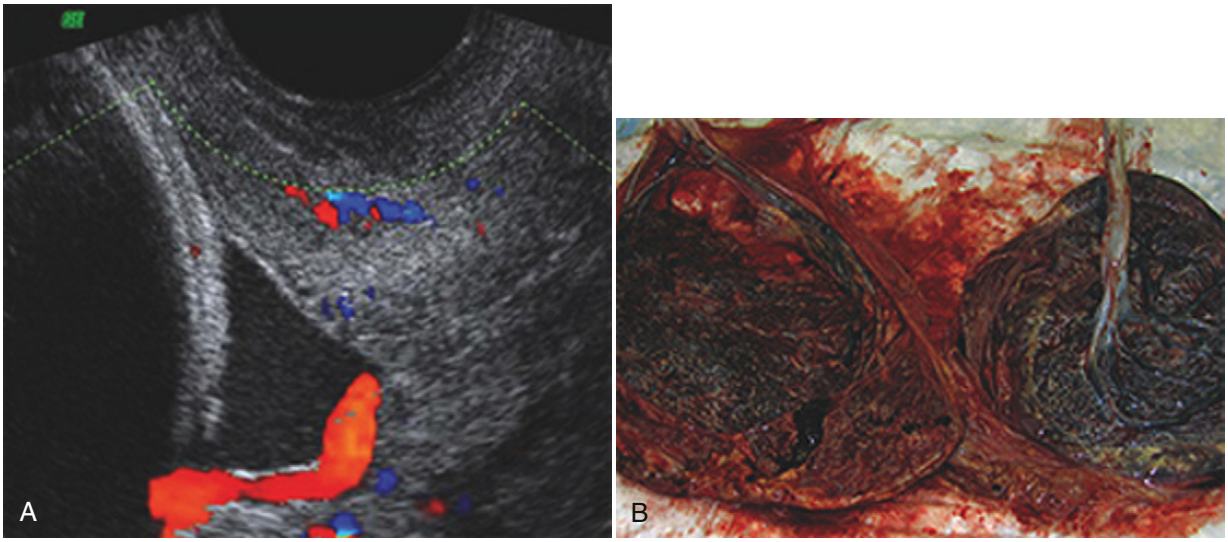

Figure 19-5 Increased risk for placental abnormalities associated with multiple pregnancies. A, Velamentous cord insertion with vasa previa as demonstrated by color Doppler ultrasound imaging at 26 weeks. **B,** Twin placenta at 34 weeks with velamentous cord insertion and vasa previa. *(Courtesy Carnegie Hill Imaging for Women, New York.)*

a threefold decrease in the spontaneous loss rate in the group reduced to singleton pregnancies compared with the group reduced to twin pregnancies. Reduction to singleton pregnancy also was associated with statistically significant increased birth weight and gestational age at delivery. In addition, cesarean delivery rates were decreased in the patients undergoing reduction to singleton pregnancies.

Multifetal pregnancy reduction is an ethical dilemma.[92] The starting number of fetuses needed to justify the procedure is controversial. Various studies have yielded conflicting findings regarding whether multifetal reduction from triplets to twins results in improved perinatal outcomes over those achieved with expectant management.[93-95] Triplet and higher-order multiple pregnancies have been associated with increased costs derived from antepartum hospital stays, missed work hours, and neonatal intensive care in the postpartum period. Multifetal pregnancy reduction has the potential to reduce such costs.[96] Nonetheless, some women will experience grief after their decision to reduce.[97]

Fetal Lung Maturity in Multiple Gestation

At this point, consensus is lacking on whether pulmonary maturation differs between singleton and multiple pregnancies. In one study of singleton and twin pregnancies, after 31 weeks of gestation, twins exhibited higher values on the TDx-FLM ("twin diagnosis"–fetal lung maturity) fluorescence polarization assay (Abbott Laboratories, Abbott Park, Illinois) than those measured for singletons.[98] The reason for the apparent acceleration of changes in pulmonary maturity indices in twin gestations is unknown. Likewise, it is not known whether this difference may reflect an increased risk for respiratory distress syndrome associated with multiple pregnancies. If age-specific risks of developing respiratory distress syndrome are similar for twins and for singletons, new guidelines will be needed to avoid false-positive prediction of adequate lung maturity in twins.[98]

For assessing lung maturity in multiple gestations, a debate is ongoing regarding whether all amniotic sacs or just one sac should be tapped. Some evidence indicates that in certain situations, one fetus may attain pulmonary maturity before the others.[80] Two series found lecithin-sphingomyelin ratios to be similar in 34 sets of twins.[99,100] In another study in 8 sets of twins (6 of 8 twins were delivered vaginally), a significant difference was noted in phospholipid profiles for tracheal aspirates obtained in the postpartum period.[101] Other studies have shown a significant discrepancy between lecithin-sphingomyelin ratios in the presenting fetus of a multiple pregnancy and the other fetuses irrespective of delivery mode.[102,103]

Fetal Pathophysiology and Multiple Pregnancy

Pathophysiology Specific to Multifetal Gestations

Certain pathophysiologic situations are unique to multiple pregnancies. These include early vanishing twin, fetus papyraceus, monochorionic monoamniotic twins, conjoined twins, TTTS, and twin reversed arterial perfusion (TRAP).

Vanishing Twin

The incidence of early pregnancy loss in multiple gestations is higher than was initially thought.[44] The routine use of ultrasound monitoring has shown that early fetal wastage is common in multiple gestations. In patients with twin gestations scanned in the first trimester, rates of demise range from 13% to 78%.[104] This early disappearance of a twin has been termed the *vanishing twin phenomenon.* Explanations include physiologic resorption, misinterpretation of artifact, and sonographic error.[44] Although this phenomenon may be associated with first-trimester bleeding and spotting, it has not been associated with adverse pregnancy outcomes.[80]

Fetus Papyraceus

Fetus papyraceus, also known as fetus compressus, results when one twin dies at approximately 15 to 20 weeks. The dead fetus loses all water content and becomes compressed with continued development of the surviving twin. Such pregnancies rarely enter birth statistics. Thus, along with the vanishing twin phenomenon, fetus papyraceus may contribute to underestimation of the incidence of twinning.[7]

Monoamniotic Twins

Monoamniotic twins are a rare form of monozygous twins in which both fetuses occupy the same sac. The diagnosis is made by ultrasound imaging. No amniotic membrane is visualized in a same-sex twin pregnancy with one placental mass

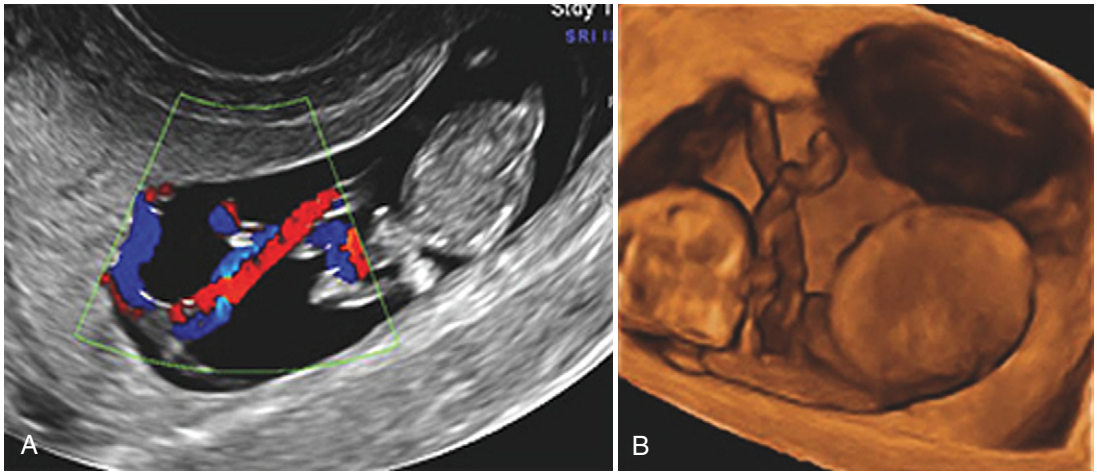

Figure 19-6 **A,** Two-dimensional ultrasound imaging with color Doppler demonstrating cord entanglement in a monoamniotic twin pair at 10 weeks. **B,** Three-dimensional image from the same patient. *(Courtesy Carnegie Hill Imaging for Women, New York.)*

(see Figure 19-8). Unexplained rupture of a dividing membrane also has been observed. However, these pregnancies should be managed as for true monoamniotic twins, because they have been found to have similar outcomes.[27] The diagnosis of monoamniotic twins has been confirmed by observing cord entanglement[105] (Figures 19-6 and 19-7).

Monoamniotic twins are associated with a high perinatal mortality rate. Past studies indicated fetal mortality rates ranging from 30% to 68%.[106-108] Monoamniotic pregnancies are associated with preterm delivery, growth restriction, vascular anastomosis, congenital anomalies, cord entanglement, and cord accidents.[109] The management of these pregnancies has been controversial, particularly regarding the optimal timing of delivery and protocol for antenatal surveillance.[108,110,111] Delivery generally is performed by cesarean section. Although vaginal delivery is not contraindicated, it should be undertaken with caution.[112] Inadvertent severing of the second twin's umbilical cord at delivery of the presenting twin has been reported.[113]

Data suggest better outcomes with intensive surveillance. In a study by House and colleagues,[114] 22 patients were managed at a tertiary care center over a 10-year period. Management included close fetal surveillance with daily testing starting at 24 to 26 weeks of gestation. Antenatal corticosteroids were routinely used, and elective delivery was performed at 34 to 35 weeks, provided that the results of testing were reassuring. No fetal deaths occurred in this group of patients. Nevertheless, monoamniotic twins were more likely to be born prematurely and had more respiratory problems compared with monochorionic diamniotic and dichorionic diamniotic pregnancies.

Conjoined Twins

Conjoined twins are an extremely rare form of monoamniotic twins, occurring in 1 in 50,000 pregnancies.[6] The diagnosis is made ultrasonographically. If the diagnosis is suspected early in the first trimester, a follow-up scan is needed for confirmation, because an incorrect diagnosis is possible at early gestational ages.[115]

Conjoined twins may be joined at various anatomic locations. Five distinct types have been recognized.[39] The first type is thoracopagus, accounting for 75% of conjoined twins. The fetuses face each other and usually have a common sternum, diaphragm, upper abdominal wall, liver, pericardium, and gastrointestinal tract.[116] The second type is omphalopagus, also known as xiphopagus, which is a rare form of thoracophagus, in which the abdominal wall is connected and the fetuses have a common liver. The third type, pygopagus, accounts for 20% of the cases

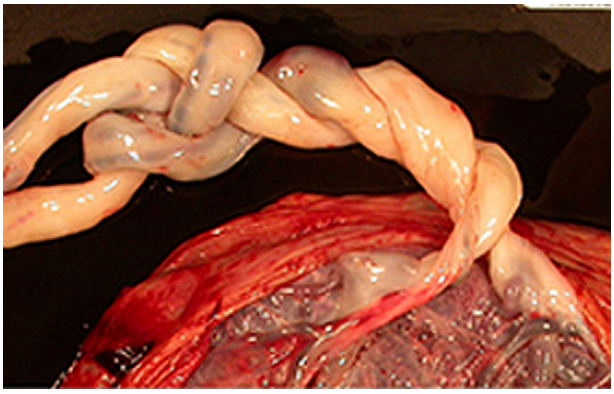

Figure 19-7 Entangled cords in a monoamniotic twin pregnancy at delivery. *(Courtesy Carnegie Hill Imaging for Women, New York.)*

of conjoined twins. The fetuses face away from one another and share a sacrum, bladder, and rectum.[116] In the fourth type, ischiopagus, the twins share a bony pelvis. This type accounts for 5% of the cases.[116] Finally, the fifth type, craniopagus (cephalopagus), is classified by partial or complete fusion of the skull, meninges, and vascular structures and accounts for 1% to 2% of the cases.[115]

If conjoined twins are diagnosed early, parents should be counseled about the option for termination of the pregnancy. Depending on the type of conjoined twin and the gestational age, this procedure can be performed by dilatation and curettage, dilatation and evacuation, induction, or hysterotomy.[115] If expectant management is desired, care should be transferred to a referral center. Generally, delivery should be performed by cesarean section as near to term as possible, with a multidisciplinary team approach.[115] Vaginal delivery is possible in selected cases of extreme prematurity or if survival is improbable. Successful separation of the twins depends on the degree of organ and vascular sharing between the two fetuses.[117]

Twin-to-Twin Transfusion Syndrome

TTTS is a complication of monochorionic pregnancies characterized by an imbalance in the blood flow across a shared placenta of two fetuses. The net effect of this imbalance in fetal support is marked developmental discrepancy, with a large, hyperperfused recipient twin and a small, hypoperfused and anemic donor twin. If the condition goes untreated, the prognosis is poor, with a 60%

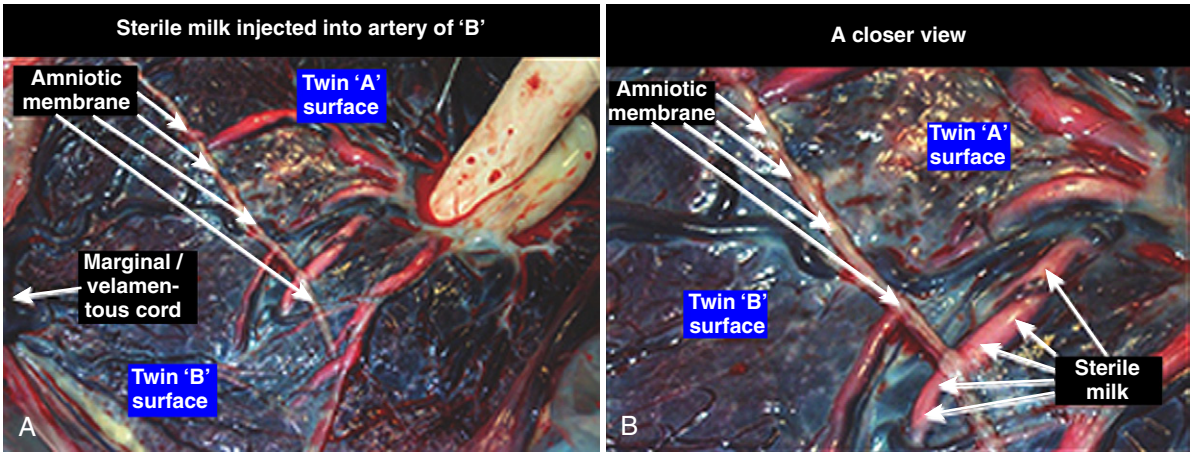

Figure 19-8 **A** and **B,** Placental anastomoses in twin-to-twin transfusion syndrome (TTTS). *(Courtesy Carnegie Hill Imaging for Women, New York.)*

to 100% mortality rate for both twins.[118-120] When one twin dies in utero, the surviving twin is at risk for severe neurologic damage. The true incidence of TTTS is unknown, because many of these pregnancies result in early loss.[116]

Although all monochorionic twins share a portion of their vasculature, TTTS will develop in only 5% to 15%.[2] TTTS also has been described in dichorionic pregnancies in a few case reports.[121,122] Although the exact origin of the condition is not known, Bajoria and colleagues[123] proposed the following mechanism. In monochorionic placentas, three types of vascular communications are possible: arteriovenous communications, arterioarterial communications, and venovenous communications. One cotyledon near the dividing membrane may receive arterial blood supply from one fetus yet may drain directly by a vein to the other side. The arteriovenous shunt is usually deep in the placenta and is unidirectional. Superficial arterioarterial and venovenous connections are crucial for maintaining the bidirectional flow.[115] According to the theory proposed by Bajoria's group,[123] TTTS results from absence of the superficial anastomoses that maintain balanced blood flow (Figure 19-8).

Diagnosis of TTTS is made by ultrasound imaging. The four requirements for the diagnosis of TTTS are (1) the presence of a single placenta, (2) same-gender fetuses, (3) weight discordance of greater than 20%, and (4) significant amniotic fluid discordance, often with a "stuck twin."[115] The recipient twin may exhibit signs of heart failure and hydrops. On echocardiography, the recipient twin may have decreased ventricular function, tricuspid regurgitation, and cardiomegaly.[124] Doppler studies may show abnormalities in both twins. A staging system has evolved for the purpose of describing this disease progression: In stage I, the bladder of the donor twin is still visible; in stage II, the donor twin bladder is no longer visible; stage III is characterized by abnormalities on Doppler studies; stage IV, by presence of hydrops; and stage V, by IUFD[125] (Figure 19-9).

Weight and hematologic discordances are no longer considered diagnostic of TTTS.[116] Likewise, a stuck twin is not pathognomonic for TTTS because it has been observed in cases of structural fetal anomalies, congenital infection, chromosomal abnormalities, and premature rupture of membranes.[116] The differential diagnosis for TTTS includes abnormal cord insertion or uteroplacental insufficiency with poor fetal growth and decreased urine output in one twin and fetal anomalies, such as bladder obstruction and aneuploidy.[115]

Because of the poor outcomes associated with this disorder, expectant management is rarely employed. Successful medical management with use of digoxin has been described.[126] Use of indomethacin is no longer recommended after reports of associated fetal demise.[127,128]

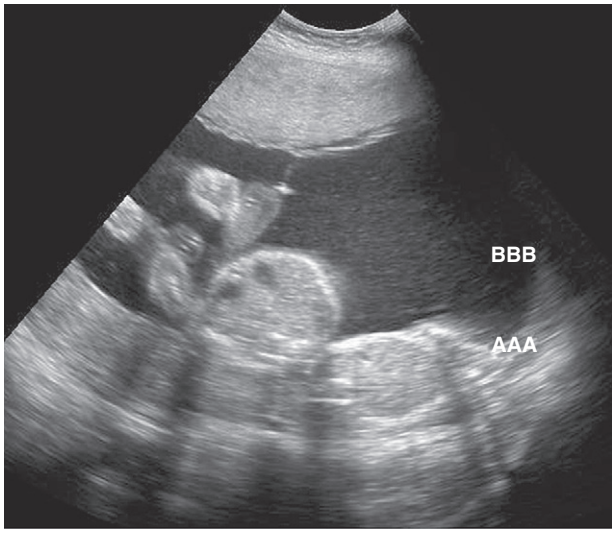

Figure 19-9 "Stuck twin" in multiple gestation complicated by twin-to-twin transfusion syndrome (TTTS). The two fetuses are labeled *AAA* and *BBB*. *(Courtesy Carnegie Hill Imaging for Women, New York.)*

One management option for TTTS is serial reduction amniocentesis.[129-136] Under ultrasound guidance, an 18-gauge spinal needle is placed into the sac with polyhydramnios. Fluid is removed until the amniotic fluid level returns to normal (provided that the patient can tolerate the procedure). This procedure is repeated as often as necessary to maintain a normal amniotic fluid volume. The mechanism by which this procedure restores the amniotic fluid balance is unknown. It is possible that removing fluid from the sac with polyhydramnios results in decreased pressure on the sac with oligohydramnios, which may result in increased perfusion to the stuck twin, with consequent improved amniotic fluid volume for that twin.[115]

Amniotic septostomy is another management option.[137] In this procedure, a 20-gauge spinal needle is inserted through the dividing membrane under ultrasound guidance. The amniotic fluid equilibrates across the two sacs. As in serial amnioreduction, it is uncertain how this technique improves outcomes.[115]

According to one proposed mechanism, the donor swallows a large fluid volume, resulting in restoration of circulating blood volume and better perfusion. Studies regarding the effectiveness of this treatment technique have been conflicting. In one report of 12 cases, pregnancy was prolonged by 8 weeks, with an 83% survival rate.[138] In a second study comprising 3 cases, all of the pregnancies were lost in 5 days as a result of preterm premature rupture of membranes.[139]

Serial reduction amniocentesis and amniotic septostomy do not affect the placental anastomoses. As a result, neither of these techniques is thought to prevent the neurologic complications associated with this disease entity.[115] Laser ablation of placental anastomoses is a treatment that may correct TTTS and reduce the neurologic complications associated with these pregnancies.[126,132,140-143] In this procedure, a fetoscope is placed in the sac with polyhydramnios under ultrasound guidance, and the anatomy of the placental vessels is studied. An arteriovenous shunt is diagnosed by identifying an artery supplying a cotyledon without a vein returning on the same side of the dividing membrane. A vein may be seen on the other side of the dividing membrane draining the cotyledon of the second fetus. A 0.4-mm neodymium:yttrium-aluminum-garnet laser fiber is then placed in the fetoscope and used to ablate these vessels. A reduction amniocentesis is simultaneously performed. A multicenter trial is currently in progress.

Until this trial is completed, antenatal management includes obtaining serial ultrasound scans with assessment of cardiac function, amniotic fluid, and weight discordancy. Treatment should be tailored to each clinical situation; however, reduction amniocentesis may be performed as the first therapeutic intervention. For patients with severe and early-onset TTTS, referral to a center performing laser therapy may be warranted. Antenatal corticosteroids should be administered to the mother if delivery is anticipated between 24 and 34 weeks. If either fetus shows compromise between 32 to 34 weeks, immediate delivery should be considered.[115]

Twin Reversed Arterial Perfusion Syndrome

TRAP, also known as acardia, is defined by the absence of a normally functioning heart in one fetus of a multiple pregnancy. The incidence is estimated to be 1% of monozygotic twin pregnancies.[109] The true incidence is unknown, because many cases of TRAP may result in early pregnancy loss.[116] The normal fetus perfuses the acardiac twin by an umbilical artery–to–umbilical artery anastomosis at the placental surface. Reversal of blood flow in the umbilical artery of the recipient twin is characteristic, and deoxygenated blood is brought from the pump twin to the acardiac twin. As a result, the gestation includes a normal twin and an amorphous twin. A range of anomalies can be seen in the acardiac twin, including anencephaly, absent limbs, intestinal atresia, abdominal wall defects, and absent organs.[144] As a consequence of the increased cardiac workload, heart failure can develop in the normal twin.[39]

Ultrasound imaging is used for diagnosis, and the differential diagnosis of acardia includes IUFD and anencephaly in one twin.[116] The cause is thought to be the development of arterial-to-arterial vascular anastomoses between the umbilical arteries of twins in early embryogenesis.[116] Seventy-four percent of affected gestations are monochorionic diamniotic, and 24% are monochorionic monoamniotic. The pump twin generally is morphologically normal, but approximately 9% of these twins are found to have trisomy. Thirty-three percent of acardiac twins have an abnormal karyotype, including monosomy, trisomy, deletions, mosaicism, and polyploidy.[145]

The goal of management is to optimize the outcome for the normal twin. Poor prognosis has been associated with polyhydramnios and congestive heart failure in the pump twin. Prognosis for the pump twin depends on the ratio of the weight of the perfused twin to the weight of the pump twin. Standard biometric measurements cannot be used to measure the acardiac twin. As a result, a second-order regression equation has been devised[146]:

$$\text{Weight in grams} = (-1.66 \times \text{length}) + (1.21 \times \text{length}^2)$$

When the twin weight ratio is greater than 0.70, the risk for congestive heart failure is 30% for the pump twin.[39]

In the absence of indicators of poor prognosis (congestive heart failure, polyhydramnios, and a twin weight ratio greater than 0.70), expectant management with serial ultrasound imaging is suggested.[109] Antenatal corticosteroids for the mother are advised if delivery is anticipated between 24 and 34 weeks, and tocolysis is suggested to stop preterm labor.[116] Medical management with indomethacin and digoxin has been used.[147,148] More invasive management has included hysterotomy of the acardiac twin followed by interval delivery of the pump twin.[149,150]

Percutaneous interruption of the circulation in the acardiac twin also has been described. Procedures have included insertion of a thrombogenic coil into the recipient twin's umbilical cord, endoscopic ligation of the cord, injection of silk soaked in alcohol into the cord, injection of absolute alcohol into the cord, and radiofrequency cord ablation.[151-160] These methods usually are reserved for when cardiac failure has already developed in the pump twin before a viable age has been attained.[39]

Pathophysiology With Special Considerations in Multiple Pregnancy

Intrauterine Fetal Demise of One Twin

Early loss of one fetus during the first trimester is common and appears to have no adverse impact on the surviving fetus or fetuses. IUFD of one fetus in the second or third trimester is less common, occurring in 2.6% of twin pregnancies and in 4.3% of triplet pregnancies.[161] This phenomenon can result in morbidity for the surviving cotwin resulting from preterm delivery.[109] The mean gestational age at delivery is 30.6 weeks for monochorionic pregnancies and 32.9 weeks for dichorionic pregnancies.[109,162]

Neurologic morbidity may be increased in monochorionic twins after IUFD of one twin.[109] Studies report a 12% to 20% risk for multicystic encephalomalacia in the twin survivor of a monochorionic pregnancy.[109,163] The proposed mechanism is a hypotensive event at the time of death resulting in acute blood loss into the dying twin, rather than thromboembolic arterial occlusion.[164-167] Neurologic morbidity has been reported after demise of the twin as early as the end of the first trimester.[109]

Management of IUFD in one twin depends on the gestational age and the chorionicity of the pregnancy. In a monochorionic pregnancy, the risk of neurologic handicap may be present from the moment of the twin's demise. As a result, immediate delivery after the demise of one twin may not prevent an adverse outcome in the surviving twin. Management recommendations include close fetal surveillance and delivery at 37 weeks (or when lung maturity has been established). Of note, multicystic encephalomalacia may not be evident on ultrasound imaging or from fetal heart rate tracing.[39] Antenatal corticosteroids should be given to the mother if delivery is expected to occur between 24 and 34 weeks. For maternal or fetal indications, delivery should occur before 37 weeks.[39]

A theoretical risk for maternal coagulopathy arises when IUFD occurs in one twin and delivery of the surviving twin is delayed.[168] In two series of twin gestations complicated by a single intrauterine demise, coagulopathy did not develop in any of the mothers; only two patients demonstrated transient biochemical evidence of coagulopathy.[162,169]

Congenital Anomalies

Congenital anomalies appear to be more common in multiple than in singleton gestations.[170] Discordancy of structural anomalies can occur in both monochorionic and dichorionic pregnancies.[39]

When a multiple gestation is complicated by a fetal anomaly in one fetus, the pregnant patient has three options: (1) expectant management and, depending on the gestational age at diagnosis, either (2) termination of the entire pregnancy or (3) selective termination of the anomalous fetus.[171] Counseling must take into account the preferences of the patient and her family, as well as the chorionicity of the pregnancy, the severity of the anomaly, and the effect the anomaly will have on the normal cotwin.[172]

If a patient elects expectant management, the patient and the family should be counseled about possible outcomes. Malone and colleagues[171] studied 14 twin pregnancies complicated by an anomalous fetus over a 5-year period at one tertiary care center and compared their findings with data on 78 normal twin pregnancies from the same center during a 2-year period. The obstetric management approach was essentially the same for all patients. Gestational age at delivery and birth weight were significantly lower in the study group. The mean gestational age at delivery for the study group was 33.6 weeks, whereas it was 35.6 weeks for the control subjects. The risk for delivering at 36 weeks or less was 78.6% for the anomalous twin group, compared with 59% for the normal twin group. Likewise, the mean birth weight for the study group was 1864 g, versus 2318 g. The lower birth weights were the result of the higher incidence of prematurity in the study group. The study infants also appeared to be at increased risk for cesarean delivery. No difference in perinatal mortality between the two groups was noted.[171] Thus it is important to counsel patients that conservative management can result in an adverse outcome for the healthy twin.[172]

Some patients may opt for selective termination of the pregnancy after counseling. In dichorionic pregnancies, ultrasound-guided intracardiac injection of potassium chloride is used. Eddelman and colleagues[173] reported favorable outcomes in 200 cases, including 164 twins, 32 triplets, and 4 quadruplets. The average gestational age at time of the procedure was 19⅔ weeks, with a range of 12 to 23⅘ weeks. The reasons for selective reduction included chromosomal abnormalities, structural abnormalities, mendelian disorders, placental insufficiency, and cervical incompetence. The unintended pregnancy loss rate was 4%. The loss rate was almost five times higher in triplets than in twins. The average gestational age at delivery was 36⅕ weeks. In approximately 84% of the cases, delivery was after 32 weeks of gestation.[173] According to this study, selective termination may result in good outcomes for the surviving twin.

In monochorionic twins, selective termination is more challenging. Complete ablation of the umbilical cord of the anomalous fetus is needed to avoid neurologic morbidity in the remaining normal fetus. Techniques used have included fetoscopic cord ligation, fetoscopic laser ablation of umbilical vessels, percutaneous injection of alcohol or occlusive materials into the umbilical cord or into the umbilical vein, and radiofrequency cord ablation.[154,155,157-159,174,175]

Chromosomal Anomalies

Most known chromosomal anomalies have been reported in multiple gestations.[39] Both monozygotic and dizygotic twins can be discordant for these anomalies. In dizygotic pregnancies, the maternal age–related risk for chromosomal abnormalities for each twin may be the same as in a singleton pregnancy.[39] It has been suggested that the chance that at least one fetus will be affected by a chromosomal defect is twice as high as in a singleton. In monozygotic twins, the risk for a chromosomal abnormality is the same as for a singleton, and in most cases, both fetuses are affected. These patients are offered genetic testing if they are 35 years of age or older. As previously stated, cases of monozygotic twins discordant for abnormalities of autosomal or sex chromosomes resulting from postzygotic nondisjunction have been reported. In the most common situation, one fetus has Turner syndrome and the other fetus has either a normal male or a normal female phenotype with a mosaic karyotype.[80]

In light of the increased risk for both genetic and structural abnormalities, patients with multiple gestations should be offered both genetic screening and prenatal diagnosis. In the first trimester, ultrasound nuchal translucency can be used to help determine whether a patient's offspring is at risk for having a genetic or structural abnormality.[39] At our institution, second-trimester screening for Down syndrome and for open neural tube defects with maternal serum α-fetoprotein, hCG, and unconjugated estriol generally is not performed, because these tests are not as reliable for multiple gestations.[39] If invasive testing such as amniocentesis or chorionic villus sampling is used, all fetuses should be tested, because of the possibility of discordancy for genetic abnormalities despite monozygosity.[39]

SUMMARY

Multiple pregnancy has a physiologic impact on both the mother and the fetus. A multidisciplinary approach may be needed for the management of these patients. The mother is at increased risk for adverse outcomes such as anemia, gestational diabetes, gestational hypertension, placental abnormalities, preterm delivery, need for cesarean delivery, and postpartum hemorrhage. The fetus is at increased risk for anatomic and genetic anomalies, growth abnormalities, and prematurity and for several problems related to monochoronicity.

Fetal outcomes are dependent on gestational age at delivery and on chorionicity. Adverse outcomes are more commonly associated with monochorionicity. Ultrasound imaging is the cornerstone of management in these patients. It is critical for diagnosis of chorionicity and structural abnormalities, as well as for surveillance of fetal growth and well-being. To date, no strategies have proved useful to prevent adverse outcomes in these pregnancies. However, antenatal corticosteroids should be administered if preterm delivery is anticipated. Furthermore, patients with complex issues unique to multiple gestations should be referred to a tertiary care center with perinatologists, neonatalogists, and pediatric specialists proficient at caring for such patients.

SECTION III

Developmental Pharmacology and Pharmacokinetics

20

Sylvain Chemtob

Basic Pharmacologic Principles

PRINCIPLES OF DRUG ABSORPTION, BIOAVAILABILITY, AND DISTRIBUTION

Drug Absorption

A majority of drugs administered to the premature newborn are injected using the intravenous route and therefore are not affected by factors that govern systemic absorption. Some agents are administered intramuscularly (e.g., vitamin K), given by an enteral route (e.g., thiazides, caffeine), or applied topically (e.g., topical antiseptics and anesthetics, nitric oxide, bronchodilators). Regardless of the route of administration, drugs often must cross cell membranes to reach their sites of action. Therefore the mechanisms governing the passage of drugs across cell membranes and the physicochemical properties of molecules and membranes are important to consider in drug transfer. Among the most important physicochemical properties of the drug molecule are lipid solubility, degree of ionization (pK_a), molecular weight, and protein binding.

Although some drugs (those with molecular size smaller than 200 Da) cross the cellular lipid membranes by diffusion,[1] it is now well known that many require transporters.[2] The greater the lipid solubility and the lower the degree of ionization, the more easily a drug will transfer across the cell membrane. Furthermore, because the active molecule is believed to be the non–protein-bound portion, drugs with lower protein binding have greater access to their site of action.

Transport Mechanisms

Other than the physicochemical properties of the drug molecules, a number of physiologic transport processes influence the mechanism by which a drug traverses the cell membrane.[3] Such processes include passive diffusion, active transport, facilitated diffusion, and pinocytosis.

Passive diffusion is the principal transmembrane process for a number of small-molecule drugs. According to Fick's law of diffusion, drug molecules diffuse from a region of high concentration to a region of low concentration, at a rate given by the following equation:

$$\frac{dQ}{dt} = \frac{DAK}{h(C_1 - C_2)}$$

where dQ/dt = rate of diffusion, D = diffusion coefficient, K = partition coefficient, A = surface area of membrane, h = membrane thickness, and $C_1 - C_2$ = concentration gradient across the membrane. Because $D, A, K,$ and h are constants under usual conditions, a combined constant P, or permeability coefficient, may be defined: $P = DAK/h$. Therefore the previous equation can be simplified to

$$\frac{dQ}{dt} = P(C_1 - C_2)$$

This equation does not take into account the ionization state of the drug molecule, the effect of regional blood flow, or the influence of tissue affinity on drug partitioning. The ionization state is affected by the pH on both sides of the membrane, according to the Henderson-Hasselbalch equation:

$$pH = pK_A + \log([base]/[acid])$$

Therefore acidic compounds, such as salicylic acid, diffuse across cell membranes more readily when the environmental pH is low because they are less ionized at low pH. Regional blood flow also influences the rate of diffusion because it affects the delivery and consequently the local concentration of drug. Finally, some drugs demonstrate increased affinity for a particular tissue component, which influences the concentration of drug on either side of the membrane. For example, tetracycline forms a complex with calcium in the bones and teeth.

Active transport is a carrier-mediated transmembrane process that plays an important role in the renal, intestinal and biliary secretion and absorption of many drugs and metabolites. Active transport is characterized by a transfer of molecules against a concentration gradient. Thus energy must be consumed to achieve this process. An example of this transport system is contributed by the adenosine triphosphate (ATP)-dependent secretion of organic acids in the renal tubule, permitting secretion of indomethacin.[4] Of note, this process, in contrast with diffusion, is saturable and therefore follows Michaelis-Menten kinetics. The Michaelis-Menten equation describes the rates of irreversible enzymatic reactions by relating the rate of substrate conversion or uptake by a protein (enzyme, transporter, receptor) to the concentration of the substrate.

Facilitated diffusion also is a carrier-mediated transport system, in which, in contrast with active transport, molecules move along a concentration gradient. This system does not require energy input but also is saturable and selective. A major class of transporters involved in facilitated diffusion includes the organic cation transporters, the organic anion transporters, and the dipeptide transporters including PepT1[2,5,6]; examples of drugs transported by these transporters are corticosterone, ethacrynic acid, and captopril, respectively.

Pinocytosis, the process of engulfing large molecules such as immunoglobins, is another important physiologic transport mode.[7]

Membrane Transporters

Transporters are membrane-integrated proteins that facilitate movement of nutrients such as amino acids, di- and tripeptides, sugars, nucleosides, vitamins, and bile acids into cells. In the intestine, it has now become increasingly clear that several of these transporters play a significant role in drug absorption. Cellular import of numerous nutrients and drugs depends upon transporters which utilize voltage and ion gradients generated by primary transporters and exchangers. Sodium and protons

frequently are cotransported with the compound of interest. Because the activity of a given transporter is a function of the electrochemical gradient driving force, the efficiency of the transport is influenced by the activity of the Na^+-H^+ antiporter and of the Na^+-HCO_3^- symporter.

A number of membrane transporters play key roles in drug import. These include the H^+-dipeptide symporters, facilitative glucose transporter-related proteins, Na^+-glucose and Na^+-nucleoside cotransporters, amino acid transporters, Na^+-neurotransmitter symporters, and the organic cation and anion transporters.[2,5,6,8] The H^+-dipeptide symporters carry cephalosporins and angiotensin-converting enzyme inhibitors, the organic cation transporters antihistaminics and β-blockers, and the organic anion transporters aspirin, indomethacin, and methotrexate. These ports of entry, along with their structural polymorphisms, may pose an additional challenge to pharmacokinetics and drug delivery.

Net absorption also is affected by the activity of exporters on the brush border membrane. The multidrug resistance-associated protein (MRP) and the P-glycoprotein families are the prototypes of these transporters. These proteins are ATP-dependent transporters (part of the large family of ATP-binding cassette [ABC] transporters) that contribute significantly to extrusion of drugs such as steroids, cyclosporines, and digoxin.[9]

The distribution of drugs requires transport across compartments, which affects their concentration at the site of drug action. Along these lines, P-glycoproteins are important efflux transporters in the blood-brain barrier and consequently influence drug concentration in brain. This transporter role, however, may not be their only function: Of interest, P-glycoproteins have been found on intracellular vesicles and, more important, at the inner membrane of the nuclear envelope,[10] suggesting that P-glycoprotein expression at the nuclear envelope may play a role in subcellular distribution of various endogenous substrates and drugs.[11] This intracellular localization is particularly relevant in the context of the recently recognized expression of cognate transmembrane receptors on subcellular organelles, notably on the nuclear envelope.[12,13]

Kinetics of Absorption

Most pharmacokinetic models assume that drug absorption and elimination follow first-order kinetics (i.e., the rate of change in the concentration of a drug depends on the amount of drug present at that particular time). This process is described in the following equation:

$$\frac{dD_B}{dt} = FK_aD_{si} - K_{el}D_B$$

where dD_B/dt = rate of change of drug in the body (D_B), F = fraction absorbed (bioavailability term), K_a and K_{el} = absorption and elimination constants, and D_{si} = drug concentration at the site of absorption. This equation applies to a single-compartment pharmacokinetic model. In a single-compartment model, the drug rapidly equilibrates with tissues of the body. Accordingly, changes in the concentration of the drug in serum or plasma mirror those in the tissues. Although many drugs follow multiple-compartment kinetics, K_a may still be calculated from a one-compartment model.[14] The importance of K_a lies in the design of a multiple dosage regimen. Knowledge of K_a and K_{el} allows for the prediction of the peak and trough steady-state plasma drug concentrations ($C_{ss\ max}$ and $C_{ss\ min}$) following multiple dosing (see section on clinical pharmacokinetics and Figure 20-3):[15]

$$C_{ss\ max} = (FD_{si} / V_d) / (1 - e^{-Kel\tau})$$
$$C_{ss\ min} = C_{ss\ max} \cdot e^{-Kel\tau}$$

where τ = dosing interval. From these equations, it is evident that peak and trough concentrations depend on the absorption rate, the volume of distribution, the elimination rate constant, and the dosing interval.

Factors Affecting Absorption of Drugs

The systemic absorption of a drug from its site of administration depends on the variables discussed previously, which constitute the physicochemical properties of the agent and of the membrane. Other factors also can influence the efficiency of drug absorption, including the disintegration, dissolution, and solubility of the compound; the blood flow to the site of absorption; the surface area available for absorption; transit time of the drug through the gastrointestinal tract; export of drugs by P-glycoproteins in enterocytes; and in situ metabolism of the agent, including the first-pass effect. A *first-pass effect* is defined as the rapid uptake and metabolism of an agent into inactive compounds by the liver, immediately after enteric absorption and before it reaches the systemic circulation. Drugs that exhibit a first-pass effect include morphine, isoproterenol, propranolol, and hydralazine. Each of the factors affecting absorption, taken separately or in conjunction, may have profound effects on the efficacy and toxicity of a drug.

In evaluating absorption of drugs through the gastrointestinal tract of the newborn, the developmental stages of this organ must be taken into account.[16] Gastric acid secretion is low in premature infants.[17] The increased pH results in a reduced absorption of weak acids and bases. By contrast, lipid-soluble drugs (such as methylxanthines) are more easily absorbed in newborns than in older children.[18] Bile salt secretion also is diminished in the newborn infant,[19] which can secondarily reduce the absorption of fats and lipid-soluble vitamins, such as vitamins D and E[20,21]; on the other hand, vitamin E is adequately absorbed in premature infants,[22] probably owing to a lower intake of iron.[23]

Enzymatic development of the gastrointestinal tract also may alter drug absorption. The elevated activity of β-glucuronidase in the brush border of newborn intestine may cleave drug-glucuronide conjugates,[24] resulting in enhanced reabsorption of free unconjugated drug into the systemic circulation; as a result, the pharmacologic activity of certain agents, such as indomethacin, may be prolonged.[25] By contrast, the presence of P-glycoproteins, highly distributed in the gastrointestinal tract epithelium apical brush border as well as in the bile canalicular face of hepatocytes, can reduce drug absorption and bioavailability[26]; decreased expression of P-glycoproteins in the immature subject may contribute to variable bioavailability.[27] Although modulators of P-glycoproteins, primarily cyclosporine and verapamil, have been used with marginal effectiveness to enhance drug action, such as in cancer treatment,[28,29] these drugs exert their own toxicity; selective inhibitors of P-glycoproteins and related multidrug resistance proteins (MRPs) have yet to be developed. Another factor that influences drug absorption and access to the target organ is the presence of metabolizing enzymes in intestinal epithelium, especially the cytochrome P-450 enzymes.[30] Depending on their activity, limited or excess bioavailability may be observed.

In comparison with adults, newborn infants also exhibit qualitative and quantitative differences in the bacterial colonization of their gastrointestinal tracts. The development of the intestinal flora has clearly been shown to affect the absorption of vitamin K.[31] Thus maturation of the gastrointestinal tract also may explain some of the characteristics of intestinal absorption of drugs in the growing child.

Finally, in addition to the physiologic changes in the gastrointestinal tract that occur during development, drug absorption also can be altered by disease processes. Diseases of genetic (e.g., cystic fibrosis) and microbial or circulatory (e.g., necrotizing enterocolitis) origin may alter the intestinal mucosa, resulting in a reduced absorptive surface.

Bioavailability

Drug *bioavailability* is the fraction of the administered dose that reaches the systemic circulation. For the clinician, the most relevant consideration is the percentage of active drug that reaches the central compartment. Bioavailability does not take into account the rate at which the drug is absorbed. Bioavailability is affected by factors that influence absorption. The absolute availability of a drug may be determined by comparing the respective areas under the plasma concentration curve (AUC) after oral and intravenous administration:

$$\text{Absolute availability} = (\text{AUC}_{\text{PO}} / \text{dose}_{\text{PO}}) / (\text{AUC}_{\text{IV}} / \text{dose}_{\text{IV}})$$

This measurement may be performed so long as the volume of distribution (V_d) and the elimination rate constant (K_{el}) are independent of the route of administration.

Distribution

The *disposition* of a drug refers to its passage in the body from absorption to excretion. After absorption, a drug is distributed to various body compartments. This distribution determines its efficacy as well as its toxicity. The *distribution* of drugs is influenced by several factors, including the size of the body water and lipid compartments, regional hemodynamic features, the degree of binding of drugs to plasma and tissue proteins, at the molecular level the tissue expression of transporter proteins (importers and exporters).

The initial phase of distribution reflects regional blood flow. Organs that are well perfused, such as the brain, heart, and kidneys, are the first exposed to the drug. The second phase of distribution involves a large fraction of the body mass, including the muscle and adipose mass. Thus the various distribution compartments form the apparent volume of distribution (V_d), which is expressed by the following equation:

$$V_d = \text{total drug in the body} / [\text{drug in plasma}]$$

Assuming instant equilibration of the drug after administration, V_d can be determined by extrapolating the drug concentration to time zero (C_0) and dividing the dose of drug administered by the concentration of drug at time zero (C_0). This equation, however, can be applied only to a single-compartment model. V_d also may be calculated using the following equation, which is independent of the model used:

$$V_d = \text{Dose}/K_{el}\,[\text{AUC}]_0^{\infty}$$

Physiologic and Pathologic Factors Affecting Distribution of Drugs

The factors that influence the distribution of drugs in the body are subject to developmental changes. The amount and distribution of total body water undergo marked changes in the perinatal period.[32] Total body water and extracellular fluid volume decrease with increasing gestational age. Consequently, the volume of distribution of many drugs has been observed to increase in preterm neonates.[33] After birth, total body water decreases, and the volume of intracellular fluid increases relative to that of the extracellular fluid. In the term newborn, as in the older child,[34] the degree of insensible water loss is linked to the metabolic rate of the infant. By contrast, in the preterm newborn, no fixed relationship exists between metabolic rate and insensible water loss, and in the very-low-birth-weight infant, evaporative heat loss is substantially greater than heat produced by basal metabolic rate.[22,35]

Many disorders of the newborn as well as drugs administered to critically ill newborn infants (such as diuretics[36,37]) can affect total body water and, secondarily, the distribution of drugs. For instance, renal and hepatic dysfunction may have important consequences on both elimination and distribution of xenobiotics. Similarly, diseases that lead to increased total body water (e.g., congestive heart failure, syndrome of inappropriate secretion of antidiuretic hormone) can have profound effects on drug pharmacokinetics and pharmacodynamics. Therefore any change in either total body water content or the relationship between extracellular and intracellular fluid volume may have significant effects on the distribution of drugs within the body.

The extent and disposition of the lipid mass in the body also contribute to the distribution of drugs. The adipose tissue mass changes markedly during development. Between 28 and 40 weeks of gestation, the amount of adipose tissue (expressed as a percentage of total body mass) increases from 1% to 15%,[38] and by 1 year of age, it represents 25% of body mass.

The nervous system contains a high proportion of lipids. Normally the maximal increment in weight of the human brain occurs in the few weeks preceding term gestation; however, a substantial part of myelination (and lipid deposition) occurs postnatally.[39] The entry of drugs into the central nervous system generally is restricted. In contrast with capillaries elsewhere in the body, endothelial cells of brain capillaries exhibit a predominance of tight junctions producing nonfenestrated capillaries, which restrict the penetration of hydrophilic substances into the brain. Consequently, ionized molecules, such as quaternary amines (e.g., neostigmine), exhibit limited capacity to diffuse into the central nervous system, whereas lipid-soluble compounds, such as cefotaxime and pentobarbital, traverse the blood-brain barrier more readily.

The distribution of drugs into brain and other organs is also dependent upon specific transporters of nutrients and endogenous compounds, as described earlier. Furthermore, efflux carriers present in brain endothelium and glia, primarily P-glycoproteins, limit drug concentration in brain. This effect is well described for a number of drugs including human immunodeficiency virus (HIV) protease inhibitors, vinca alkaloids, and anthracyclines.[40] Of interest, P-glycoproteins also are present in placenta, where they function as export transporters to limit fetal exposure to potentially toxic agents.

A major determinant of drug distribution is the cardiac output and blood flow to various organs.[41] Marked changes in the neonatal circulation take place during the perinatal period.[42,43] In addition, regional blood flow also may change acutely as a result of congestive heart failure (secondary to patent ductus arteriosus or other congenital heart diseases),[41] as a result of sudden changes in acid-base balance (especially respiratory acidosis), or secondary to the limited ability of the stressed preterm neonate to autoregulate regional blood flow.[44]

The affinity of a drug for plasma proteins is another important variable affecting drug distribution. The degree of binding is inversely related to the volume of distribution, such that increased protein binding tends to maintain the drug within the vascular space. Protein binding affects renal and plasma clearance, the half-life, and the efficacy of the agent at its site of action. Table 20-1 lists percent protein-binding values for some commonly used agents in the neonate.

Several factors modify the binding of drugs to plasma proteins:

- The amount of plasma-binding proteins
- The number of binding sites
- The affinity of the drug for the protein
- Pathophysiologic conditions that alter drug-protein binding, including blood pH, free fatty acids, bilirubin, other drugs, and disease states (e.g. renal failure, liver failure)

Albumin binds principally acidic drugs, whereas basic agents are bound to lipoproteins, β-globulins, and α_1-acid glycoproteins.[45] Albumin contains a few high-affinity and several low-affinity binding sites.[46] In the preterm newborn, both albumin

BOX 20-1

Drugs That Cause Significant Displacement of Bilirubin from Albumin in Vitro

Sulfonamides
Moxalactam
Fusidic acid
Radiographic contrast media for cholangiography (sodium iodipamide, sodium ipodate, iopanoic acid, meglumine ioglycamate)
Aspirin
Apazone
Tolbutamide
Albumin preservatives (sodium caprylate and *N*-acetyl tryptophan: rapid infusions in vivo)
High concentrations of ampicillin (rapid infusions in vivo)
Long-chain free fatty acids (FFA) at high molar ratios of FFA to albumin

and α_1-acid glycoprotein concentrations and binding affinities are deficient, resulting in an increased fraction of free drug[47] and increased distribution of free drug outside the vascular compartment.[48] Numerous conditions may further reduce the binding of drugs to proteins. For example, a decrease in pH may enhance the dissociation of weak acids from their albumin-binding sites. Thus the frequent occurrence of acidosis in premature infants may significantly change the binding of drugs to plasma proteins. The elevated plasma free fatty acid content of the newborn also may alter drug binding to plasma proteins[49,50]; this effect, however, has been questioned.[51] In a similar fashion, maternal drugs that have crossed the placenta or other agents concomitantly administered to the infant also may compete for the same plasma protein–binding sites of drugs given to the newborn.

The potential interference of endogenous compounds, particularly unconjugated bilirubin, with drug-protein binding has been well addressed.[52] A displacement of bilirubin from its albumin binding site may result in free circulating unconjugated bilirubin, which can penetrate into the brain and ultimately cause injury. Of interest, however, bilirubin itself is tightly bound to albumin and may displace drugs from their protein-binding sites.[52] In addition, free bilirubin is only sparingly lipophilic. Thus the drug-induced displacement of bilirubin from albumin binding sites possibly plays a minor role in the development of bilirubin-induced encephalopathy. Nonetheless, a few drugs can alter the binding affinity of albumin for bilirubin[52] (Box 20-1).

The volume of distribution of certain compounds also is affected by their binding to proteins outside the vascular space. For instance, digoxin exhibits a higher degree of binding to myocardial and skeletal proteins in the newborn than in the adult.[53,54] This increased binding results in an increase in the volume of distribution of digoxin.

Numerous factors influence the distribution of drugs in the body. These factors are themselves affected by development and disease conditions of the newborn infant. Major changes in the distribution of fluids and fat and their proportion relative to body mass occur at the end of gestation and during the neonatal period. Perinatal and neonatal alterations in cardiac output and regional blood flow, secondary to physiologic and pathophysiologic changes, also occur. Furthermore, the degree of drug binding to plasma proteins between the newborn and adult varies for several drugs. These variables should be taken into account in deciding on the appropriate drug dosage for a newborn.

PRINCIPLES OF DRUG ELIMINATION

The relatively high lipophilicity of many drugs does not permit their rapid elimination. After filtration through the glomerulus or passage into the bile, these agents are readily absorbed by the renal tubule or gastrointestinal mucosa. Consequently, the elimination of most drugs from the body involves the process of biotransformation followed by excretion. This section reviews the different biotransformational processes that take place in the human body and the mechanisms of renal drug excretion, with particular reference to developmental aspects.

Drug Biotransformation

Drug *biotransformation* converts drug molecules into more polar derivatives that are less able to diffuse across cell membranes. As a consequence of biotransformation, these converted molecules do not reach their receptors and in addition are not reabsorbed by the renal tubule. Thus biotransformation of drugs not only facilitates their excretion from the body but also may diminish their pharmacologic activity.

The metabolism of drugs does not always produce inactive compounds. Initial biotransformation of certain agents results in the formation of active metabolites. For instance, codeine is demethylated to morphine, acetylsalicylic acid is hydrolyzed to salicylic acid, and theophylline is methylated to caffeine. Furthermore, oxidation of certain aromatic compounds produces highly reactive electrophiles (compounds that serve as electron acceptors). This latter reaction may be primary (aromatic hydrocarbons) or may be an increasingly active secondary reaction resulting from an inhibited or overwhelmed primary metabolic pathway (as, for example, with an excessive dose of the agent, such as with acetaminophen overdose). Therefore biotransformation can produce relatively innocuous metabolites or highly toxic compounds.

The mechanisms affecting the biotransformation of drugs are usually the same as those that metabolize endogenous products (e.g., hormones). Most biotransformation takes place in the liver, but some may occur at other sites, such as the kidneys, intestinal

TABLE 20-2

Biotransformation Reactions

Reaction	Examples of Drug Substrates
Phase I (Nonsynthetic Reactions)	
Oxidation	
Aromatic ring hydroxylation	Phenytoin, phenobarbital
Aliphatic hydroxylation	Ibuprofen
N-hydroxylation	Acetaminophen
N-, *O*-, *S*-dealkylation	Morphine, codeine
Deamination	Diazepam
Sulfoxidation, *N*-oxidation	Cimetidine
Reduction	
Azoreduction	Sulfonamidochrysoidine (Prontosil)
Nitroreduction	Chloramphenicol
Alcohol dehydrogenase	Ethanol
Hydrolysis	
Ester hydrolysis	Acetylsalicylic acid
Amide hydrolysis	Indomethacin
Phase I Enzymes	
CYP1A2	Caffeine, theophylline
CYP2C	Warfarin, ibuprofen, phenytoin, omeprazole, diazepam
CYP2D6	Codeine, imipramine, propranolol, timolol, tamoxifen
CYP2E1	Acetaminophen, tamoxifen, caffeine, ethanol
CYP3A	Erythromycin, midazolam, 6β-hydroxycortisol
Phase II (Synthetic Reactions: Conjugations)	
Glucuronide conjugation	Morphine, acetaminophen
Glycine conjugation	Salicylic acid
Sulfate conjugation	Acetaminophen, α-methyldopa
Glutathione conjugation	Ethacrynic acid
Methylation	Dopamine, epinephrine
Acetylation	Sulfonamides, clonazepam

Modified from Turki J, Pak J, Green SA, et al: Genetic polymorphisms of the beta 2-adrenergic receptor in nocturnal and nonnocturnal asthma. Evidence that Gly16 correlates with the nocturnal phenotype, *J Clin Invest* 95:1635, 1995.

mucosa, and lungs. Biotransformation reactions are classically divided into two phases: phase I, the nonsynthetic reactions, and phase II, the synthetic or conjugation reactions (Table 20-2). Each phase has reactions that can take place in the microsomes or outside of the microsomal system. The great majority of phase I reactions (oxidation, reduction, and hydrolysis) are catalyzed by microsomal enzymes; other than glucuronidation, phase II reactions are extramicrosomal.

Phase I Reactions (Nonsynthetic Reactions)

Microsomal

The portion of microsomes containing the enzymes that metabolize drugs are found in the smooth endoplasmic reticulum. The oxidative enzymes of this system have attracted particular attention in research. This group of enzymes has been called mixed-function oxidases or monooxygenases. They have three principal components: an electron transporter, nicotinamide adenine dinucleotide phosphate (NADPH)–cytochrome P-450 reductase (a flavoprotein), and one of the many recently discovered cytochrome P-450 isozymes, which are oxidase hemoproteins.[55] The system requires both a reducing agent, NADPH, and molecular oxygen. The end result of the reactions catalyzed by cytochrome P-450 is the incorporation of one oxygen atom into the endogenous or exogenous compound being metabolized (hence the name *monooxygenase*) and the formation of water after reduction of the second oxygen atom.

The reactions catalyzed by the microsomal monooxygenases include aromatic ring and aliphatic side chain hydroxylation, *N*-, *O*-, *S*-dealkylation, deamination, dehalogenation, sulfoxidation, *N*-oxidation, *N*-hydroxylation, nitroreduction, and azoreduction. Epoxides also are formed by monooxygenases, converting aromatic moieties of agents to arene and alkene oxides, which are in turn detoxified by epoxide hydrolases present in endoplasmic reticulum. These electrophilic compounds react avidly with proteins and nucleic acids, exerting potential mutagenic and carcinogenic effects; polychlorinated and polybrominated biphenyls exert their toxicity by way of their metabolites.[55]

Several drugs, including cimetidine, spironolactone, and propylthiouracil, can inhibit cytochrome P-450 enzyme activity. This inhibition reduces the metabolism of potential substrates and secondarily retards their elimination. By contrast, other substrates can act as inducers of the cytochrome P-450 system. Prototypes of the most extensively studied inducers of separate cytochrome P-450 isozymes are phenobarbital (CYP3A), rifampin (CYP1A, CYP2C), and the polycyclic aromatic hydrocarbon 3-methylcholanthrene (CYP1A).

Approximately 1000 cytochrome P-450s are known; only 50 or so are functionally active in humans. Seventeen families and many subfamilies have been sequenced. CYP1, CYP2, and CYP3 families are involved in a majority of all drug metabolism reactions; members of the other families are important in the synthesis and degradation of steroids, fatty acids, vitamins, and other endogenous compounds. Individual CYP isoforms tend to have substrate specificities, but overlap is common. CYP3A4 and CYP3A5 are similar isoforms, which together are involved in metabolism of approximately 50% of all drugs. CYP2C and CYP2D6 also are involved in metabolism of many drugs. CYP1A1/2, CYP2A6, CYP2B1, and CYP2E1 are not extensively involved in drug metabolism but rather are important in activation of procarcinogenic agents including aromatic amines and aromatic hydrocarbons.

The cytochrome P-450–dependent monooxygenase system develops in fetal life and progresses through a rapid and significant increase in activity during the perinatal period[56]; nonetheless, in general, its activity in the fetus and newborn remains considerably lower than that in adult liver.[30,57] The diminished enzyme activity may be clinically important because drugs that are oxygenated slowly by these enzymes (e.g., phenobarbital, phenytoin) can exhibit a prolonged half-life in the young infant[58]; this is especially the case for CYP2A, CYP2B6, CYP2C, and CYP3A4/5 (Table 20-3). However, significant differences have been found in the developmental expression of the three important gene families implicated in xenobiotic metabolism; accordingly, drugs converted by CYP2D6 and CYP3A7, such as carbamazepine, dextromethorphan, and tricyclic antidepressants, are eliminated in the newborn nearly as rapidly as in the adult.[30] Of interest, CYP2E1 is induced and metabolized by ethanol in the fetus and has been proposed to be implicated in the development of fetal alcohol syndrome.[59]

Extramicrosomal

A few of the oxidative and reductive reactions are mediated by enzymes in the mitochondria and cytosol of the liver and other tissues. These enzymes include those involved in oxidation of alcohols and aldehydes; alcohol and aldehyde dehydrogenases; and enzymes that partake in the metabolism of catecholamines, namely tyrosine hydroxylase and monoamine oxidase. Although the activity of some of these enzymes can be detected early in gestation, their full activity is reached only in early childhood.[30] Once again, however, marked ontogenic differences between

TABLE 20-4

Plasma Half-Life of Miscellaneous Drugs in Newborns and Adults

	PLASMA HALF-LIFE (hr)	
Drug	**Newborn**	**Adult**
Acetaminophen	3.5	2.2
Phenylbutazone	21-34	12-30
Indomethacin	7.5-51.0	6
Meperidine	22	3.5
Phenytoin	21	11-29
Carbamazepine	8-28	21-36
Phenobarbital	82-199	24-140
Caffeine	100	6
Theophylline	30	6
Chloramphenicol	14-24	2.5
Salicylates	4.5-11.5	2.7
Digoxin	52	31-40

Data from Hillman LS, Martin LA, Haddad JG: Absorption and maintenance dosage of 25-hydroxycholecalciferol (25-HCC) in premature infants [abstract], *Pediatr Res* 13:400, 1979; Kolterman OG, Insel J, Saekow M, Olefsky JM: Mechanisms of insulin resistance in human obesity: Evidence for receptor and postreceptor defects, *J Clin Invest* 65:1272, 1980; and Ruffolo RR Jr: Important concepts of receptor theory, *J Auton Pharmacol* 2:277, 1982.

enzymes are observed. For instance, class I alcohol dehydrogenase, the major ethanol-metabolizing enzyme, tends to be well expressed in fetal liver, whereas class III alcohol dehydrogenase is relatively deficient in the fetus.[30]

Phase II Reactions (Synthetic Reactions)

In phase II reactions, molecules that are naturally present in the body are conjugated or combined with the drug or other endogenous compounds. The drug may have first undergone a phase I reaction, or the original drug may be directly conjugated. Conjugation converts drugs into more polar compounds, which are pharmacologically less active and are more readily excreted; an exception applies to acetylation, whereby the metabolite often is less water-soluble. Although it was previously thought that conjugation reactions represented true inactivation and detoxification reactions, current evidence indicates that certain conjugation reactions may lead to the formation of reactive species responsible for hepatotoxicity (*N*-acetylation of isoniazid). The major conjugation reactions are listed in Table 20-4.

Glucuronidation

The formation of glucuronides is the principal conjugation reaction in the body. Natural substrates of this pathway include bilirubin and thyroxine. Many drugs containing hydroxyl, amino, carboxyl, thiol, and phenolic groups, however, also use the same pathway (e.g., morphine, acetaminophen, phenytoin, sulfonamides, chloramphenicol, salicylic acid, and indomethacin).

The conjugation of a compound with glucuronic acid results in the production of a strongly acidic substance that is more water-soluble at physiologic pH than the parent compound. This heightened solubility reduces its transfer across membranes, facilitates its dissociation with its receptor, and enhances its elimination in urine and bile. The fate of the glucuronidated drugs in urine or bile depends on their molecular size. Compounds of relatively low molecular weight are almost completely excreted in urine, whereas those of high molecular weight (greater than 500) are eliminated almost entirely in bile.

Glucuronides are eliminated by the kidneys predominantly through glomerular filtration; however, tubular secretion and tubular reabsorption followed by secretion represent alternative pathways. Biliary excretion of drugs conjugated to glucuronic acid occurs by simple diffusion or by active secretion. Once in the intestine, these drugs may be reabsorbed after being deconjugated (hydrolyzed) by glucuronidase, which exhibits an elevated activity in the fetus and newborn.[24]

Drugs or conditions that inhibit formation of glucuronides are likely to prolong the pharmacologic activity of these agents. Inhibition may occur at the level of synthesis of glucuronic acid (e.g., by certain steroid hormones) or at the level of uridine diphosphate (UDP)-glucuronyl transferase activity itself, which consists of 16 different isoforms in humans. In the human fetus and newborn, glucuronide conjugation reactions exhibit reduced activity, and fetal underexpression of the 2B isoform is responsible for the gray baby syndrome associated with chloramphenicol intake. Postnatal development proceeds relatively rapidly, as occurs with the metabolism of bilirubin.[60,61]

Other Synthetic Conjugation Reactions

Other kinds of conjugation reactions that occur in the body are listed in Table 20-4. As is the case with glucuronyl transferase, the activity of the other various transferases also is lower in the fetus and newborn than in the adult.[60,61]

Overall, available data permit the following generalizations regarding drug metabolism in the fetus and newborn:

1. The rates of drug biotransformation and overall elimination are low.
2. The rate of drug elimination from the body exhibits marked interpatient variability.
3. The maturational changes in drug metabolism and disposition occurring as a function of postnatal age are extremely variable and depend on the substrate (or drug) being used.
4. Neonatal drug biotransformation and elimination are vulnerable to pathophysiologic states.
5. Neonates may exhibit activation of alternate biotransformation pathways.

Factors Affecting Biotransformation in the Liver

Several factors may alter the rate, extent, and type of biotransformation reactions in the liver. The issues of enzyme activity that may be modified by development and by endogenous or

exogenous compounds have been addressed. Environmental influences also significantly affect drug metabolism, to include the inducing or inhibitory effects of drugs per se on enzyme activities. For instance, calcium channel blockers, antifungal agents, and macrolide antibiotics are potent inhibitors of CYP3A enzymes; quinidine inhibits CYP2D6; and other compounds such as cimetidine, amiodarone, and fluoxetine reduce activity of many cytochrome P-450 enzymes. Conversely, a number of agents, including anticonvulsants and aromatic hydrocarbons, can stimulate induction of certain CYP subfamilies and isoforms.

Metabolic enzyme activity also is affected by genetic factors, which is the rule rather than the exception; however, the interplay between ontogeny and genetics remains largely unknown in drug metabolism. Approximately 70 single-nucleotide polymorphisms and other genetic variants of the CYP2D6 gene, many of which diminish enzyme activity, have been recognized; this decreased activity may be of particular importance with drugs metabolized by CYP2D6, such as β-blockers and certain opiates. In the case of CYP3A enzymes, no significant functional polymorphisms have yet been identified; hence factors regulating gene expression are more important to explain the interindividual variability (greater than 10-fold). Because genetic factors and environmental influences exert greater effects on drug metabolism than on renal excretion, drugs that are metabolized are considerably more affected by interpersonal differences than those not requiring biotransformation.

Other factors that affect biotransformation include blood flow to the liver, gender, and disease states. For certain drugs (e.g., morphine, meperidine, propranolol, verapamil), blood flow may be the limiting factor controlling drug elimination. These drugs (often termed *flow-limited* drugs) are so readily metabolized by the liver that hepatic clearance is essentially equal to liver blood flow. By contrast, the biotransformation of *capacity-limited* drugs (e.g., phenytoin, theophylline, diazepam, chloramphenicol) is determined by the liver's metabolizing capacity, rather than by hepatic blood flow.[62] The effect of gender in newborn infants remains unclear but may not be as important as in the adult.

Renal Excretion of Drugs

The renal excretion of drugs and their metabolites occurs by means of three major processes: glomerular filtration, active tubular secretion, and passive tubular reabsorption. After the entry of a drug into a renal tubule, its elimination is dependent on its lipophilicity and ionization state.

Glomerular Filtration of Drugs

The amount of drug filtered through the glomerulus depends on a molecular size less than that of albumin (molecular weight 69,000) and degree of protein binding. Hence nearly all non–protein-bound drugs are filtered. Glomerular filtration rate increases during fetal development, but in the newborn it remains far below that observed in the adult.[63-66] Furthermore, conditions that lead to decreased glomerular filtration rate, such as asphyxia, severe respiratory insufficiency, renal failure, and patent ductus arteriosus, are associated with reduced drug excretion. Certain agents (e.g., indomethacin, tolazoline) may hamper their own excretion by reducing glomerular filtration rate.[67-69]

Active Tubular Transport of Drugs

A number of transport systems found in the proximal tubule are involved in the energy-dependent secretion of organic compounds (endogenous or xenobiotic).[70] These carrier systems are relatively nonselective. One such system transports organic anions, including drug conjugates with glucuronic acid, glycine, and sulfates; examples of drugs that use this excretory system are penicillins, furosemide, and chlorothiazide. The other transport system secretes organic cations, such as histamine and choline. Multidrug resistance proteins 1, 3, 5, and 6 have been localized to the basolateral membrane, whereas multidrug resistance proteins 2 and 4 are found at the brush border membrane of tubular epithelium. Generally, these transporters operate as efflux pumps. A counteracting mechanism involves the peptide transporters PEPT1 and especially PEPT2 localized at the proximal tubular epithelium apex, which operate as influx pumps of filtered drugs. All transporters described are energy-dependent. In the case of organic cation, organic anion, and peptide transporters, cellular import requires an electrochemical gradient especially of Na^+, which is maintained largely by the Na^+,K^+-ATPase pump. By contrast, multidrug resistance proteins are directly ATP-dependent.[70] Membrane transporters, located mainly in the distal tubule, operate to actively reabsorb drugs from the tubular lumen back into the systemic circulation. Most such reabsorption occurs by nonionic diffusion. Although polymorphisms of transporters are likely to significantly affect drug disposition, knowledge regarding such polymorphisms remains limited.

Tubular secretion of organic anions and cations also is lower in newborns than in adults. This developmental characteristic explains the prolonged half-life of certain agents that use this system of elimination, as is the case with furosemide, penicillins, and glucuronidated drugs, in the newborn.

Passive Tubular Reabsorption of Drugs

In both proximal and distal tubules, nonionized forms of weak acids and bases undergo net passive reabsorption. Accordingly, this form of renal reabsorption of drugs is regulated by three factors: the concentration gradient across the tubular membrane, the ionization state of the compound in the tubular fluid (which depends on the drug's p*K*a and the tubular fluid pH), and the lipid solubility of the drug. Manipulation of these physicochemical properties can be used to enhance renal excretion. For instance, alkalinization of the urine can increase the elimination of salicylic acid up to six-fold. As inferred earlier, the term *passive diffusion* does not exclude specific transporters or exchangers involved in movement across cell membranes and into compartments.

Overall, patterns of renal excretion of drugs can be summarized as follows: (1) Renal excretion of lipid-soluble drugs depends largely on urine volume; (2) elimination of polar drugs depends on glomerular filtration rate; and (3) the renal elimination of drugs that ionize readily is principally dependent on the activity of the tubular secretory systems and the urine pH.

Effect of Disease on Drug Elimination

Most pharmacokinetic parameters are determined in healthy or moderately ill persons. In neonatal intensive care units, as in other similar environments, drugs often are administered to very sick patients. Life-threatening illnesses produce remarkable variation in pharmacokinetic behavior. Adjustment in drug dosage in the face of a changing disease is critical to avoid toxicity.[16,71] For this reason, an understanding of the pathophysiology of a disease and its pharmacologic consequences becomes of utmost importance in decisions regarding appropriate pharmacologic therapy. This section addresses the issue of disease as it applies to drug disposition in the newborn.

Cardiovascular Disease

Cardiac output is a major determinant of drug elimination. Heart failure produces a decrease in cardiac output that alters the regional distribution of blood flow. Significant decreases in cardiac output or oxygen delivery can result in adverse effects on liver function, with consequent impairment of drug clearance.[72]

Congestive heart failure also is associated with a reduction in renal blood flow and glomerular filtration rate. This compromise in renal function contributes to a decrease in drug elimination. In newborns with congestive heart failure, elevated plasma levels

of digoxin have been observed, suggesting a decreased clearance of the drug.

Renal Disease

Because the kidneys are a major route of drug elimination, alterations in their function can significantly influence drug pharmacokinetics.[64] The pharmacologic consequences of renal dysfunction depend on the fraction of drug cleared by the kidneys and on the degree of renal failure. Under these circumstances, drugs for which the kidneys represent the primary route of elimination (e.g., aminoglycosides, cephalosporins) accumulate in the body; this is especially true when renal clearance is greater than 90% of total drug clearance.

As glomerular filtration rate falls, drug elimination via glomerular filtration decreases; such is the case for digoxin, aminoglycosides, and cephalosporins. Reduction in tubular function can significantly affect the elimination of drugs that depend on tubular reabsorption or secretion, such as penicillins and furosemide. In addition, changes in plasma and urine pH alter the excretion of ionized drugs. The development of uremia may be associated with changes in cardiac output, liver function, and blood-brain barrier permeability, all of which can further disturb drug disposition.

The clinical significance of drug accumulation depends on whether the unexcreted products are pharmacologically active or toxic. Nomograms have been developed to allow modification of drug dosage in patients with renal failure. Most such nomograms, however, apply primarily to adult rather than infant patients and therefore must be used with caution.

Liver Disease

Because the liver is a major site of drug disposition, hepatic insufficiency is associated with defects in multiple liver functions, many of which have the potential to alter drug excretion. Hepatic insufficiency can affect drug elimination by (1) reducing plasma protein binding, (2) decreasing liver blood flow, and (3) disturbing intrinsic biotransformation reactions.

A decrease in plasma protein concentration influences the disposition of drugs extensively bound to proteins. Drugs with liver uptake and metabolism can be categorized into two groups: one dependent on liver blood flow (flow limited) and the other dependent on the liver's metabolic capacity (capacity limited). Drugs belonging to the first group exhibit a more uniform change in drug elimination during hepatic failure. By contrast, drugs dependent on the metabolic activity of the liver exhibit variable changes in biodisposition. This variability results from inconsistent qualitative and quantitative changes in liver enzyme activity in the presence of liver disease of variable severity.

Because of the marked variability in degree of liver dysfunction encountered clinically, it is difficult to formulate rules for dosage modification. Marked changes in pharmacokinetics (as noted with renal insufficiency) generally are not observed in liver failure.[73] Nonetheless, dosages of drugs eliminated mainly by hepatic biotransformation should be reduced in infants with severe liver disease.

The consequences of intercurrent disease on the pharmacokinetics and pharmacodynamics of drugs are irrefutably complex. An accurate prediction of drug disposition in the face of interacting intricate individual variables is virtually impossible. The relative paucity of information on pharmacokinetics of drugs in infants with cardiac, renal, and hepatic dysfunction and the often changing and transient nature of these disorders render careful clinical observations and appropriate therapeutic monitoring imperative under these circumstances.

CLINICAL PHARMACOKINETICS

The fundamental assumption of clinical pharmacokinetics is that a relationship exists between the concentration of a drug at its site of action and its serum or plasma level. Measurement of the concentration of a drug in the blood can be used to monitor the dose-response relationship and to predict its pharmacokinetics. Thus drug levels in blood permit appropriate individual dosing adjustments.

Pharmacokinetic principles can be understood only with respect to the various compartments into which a drug is distributed (Figure 20-1). A compartment is not necessarily a defined physiologic or anatomic site but is considered to consist of one or many tissues that exhibit similar affinity for a drug.

The factors that determine the movement of a drug into and out of compartments are those that affect distribution. Therefore the lipophilicity, ionization state, transporter systems (of both influx and efflux carriers), and protein binding of a drug, as well as regional blood flow, regulate the extent and rate of passage of an agent into and out of a compartment.

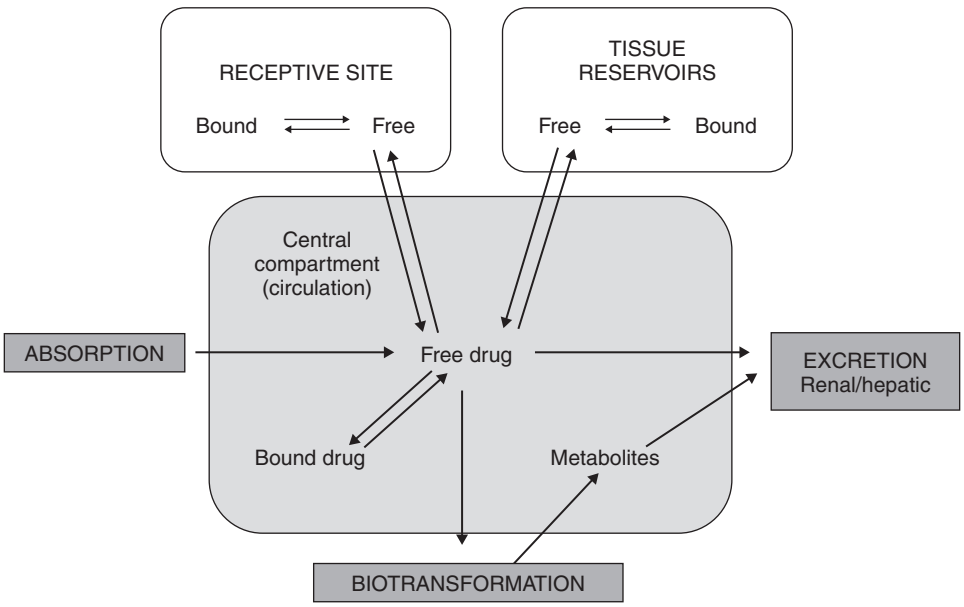

Figure 20-1 Schematic of possible drug disposition to various compartments in the body.

Single-Compartment Distribution

The simplest pharmacokinetic model is the single-compartment model. In this model, it is assumed that after administration of the drug, immediate equilibration of drug concentration is achieved in all major tissues. First-order kinetics apply with this model, meaning that the rate of change in the amount of drug in the body is a constant fraction of the amount of drug present at the time. The higher the dose, therefore, the greater the elimination rate from the compartment. The rate of disappearance of a drug concentration using first-order kinetics can be expressed as

$$\frac{dC}{dt} = -kC$$

where C = concentration of the drug, and k = first-order elimination rate constant, expressed in units of time^{-1} (e.g., h^{-1}). Integration of this equation yields the drug concentration at time t:

$$\log C = -kt/2.3 + \log C_0 \text{ or } C = C_0\, e^{-kt}$$

where C_0 = concentration at time $t = 0$. Thus the slope of the log of the concentration-time curve = $-k/2.3$.

Drug Half-Life

From the previous equation ($\log C = -kt/2.3 + \log C_0$), the first-order half-life can be obtained:

$$t_{1/2} = 0.693/k$$

Regardless of the initial concentration of drug, the time required for the concentration to decrease by half is a constant determined by k. Thus the time it takes to achieve a steady-state plasma concentration or the time it takes to eliminate the near-totality of the drug is equal to approximately five half-lives (Figure 20-2). In newborns, because the elimination rate is decreased for many drugs, the half-life often is prolonged compared with that in the adult (see Table 20-4).

To minimize the time a drug takes to achieve average steady-state plasma concentrations ($C_{ss\ av}$), a loading dose (D_L) can be given. This dose is equal to

$$D_L = C_{ss\ av} \times V_d$$

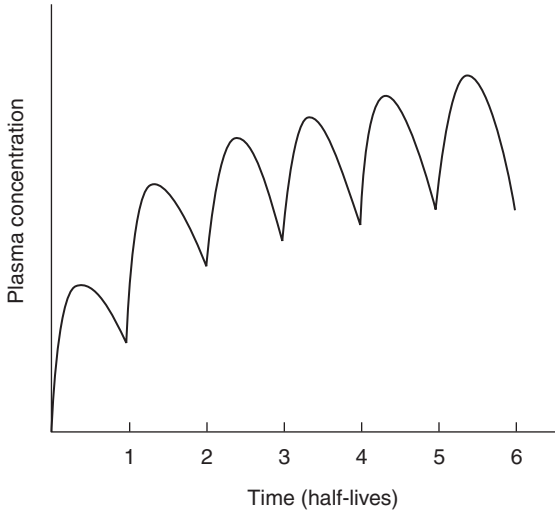

Figure 20-2 Pharmacokinetic relationships of a multiple dosing regimen. It can be readily appreciated from the graph that the time required to attain steady-state drug concentrations is equal to approximately five half-lives, when first-order rates of absorption, distribution, and elimination are in process.

Maintenance Dose

After steady-state concentration is achieved (following a loading dose), the dose necessary to maintain this concentration (maintenance dose, D_{ss}) can be calculated from the following equation:

$$D_{ss} = (0.693 \times C_{ss\ av} \times V_d \times \tau)/t_{1/2}$$

where τ = dosing interval. Thus D_{ss} also is equal to the rate of drug elimination during the dosing interval.

Optimal Dosing Schedule

Knowledge of the half-life permits the clinician to determine an optimal dosing schedule, having set the maximum and minimum effective steady-state concentrations during a multiple dosing regimen (see Figure 20-2). Using the same equation to calculate the concentration at time t ($\log C = -kt/2.3 + \log C_0$), an optimal dosing interval, τ, also can be determined. By substituting C with $C_{ss\ min}$ and C_0 with $C_{ss\ max}$, the following equation is obtained:

$$\log C_{ss\ min} - \log C_{ss\ max} = -kt/2.3$$

By further substituting k by $0.693/t_{1/2}$, the dosing interval, τ, which is the time it takes for the drug concentration to decrease from $C_{ss\ max}$ to $C_{ss\ min}$, can be determined using the following equation:

$$\tau = \log(C_{ss\ max}/C_{ss\ min}) \times 3.3 \times t_{1/2}$$

Drug Clearance

Drug clearance can be defined as the plasma volume in the vascular compartment that is cleared of drug per unit of time. Total clearance gives an indication of drug elimination from the central compartment without reference to the mechanism of this process. For drugs that are eliminated by first-order kinetics, clearance is constant.

Clearance by the kidneys is called *renal clearance,* and that by all other organs is referred to as *nonrenal clearance.* The latter most often represents clearance by the liver. Total clearance is the sum of all body clearances. The same factors that determine renal and hepatic elimination of drugs affect drug clearance.

Clearance (Cl) is mathematically defined as excretion rate/plasma concentration. Over a drug excretion time, clearance can be expressed by the following equation:

$$\text{Cl} = D_0/[\text{AUC}]_0^t$$

Rearrangement of this formula according to the equation expressing V_d (see under "Distribution" earlier) yields

$$\text{Cl} = V_d \times k$$

Multicompartment Distribution

Many drugs distribute in the body according to the kinetics of a multicompartment model. Consequently, after intravenous administration of the drug, the plasma concentration does not decline linearly as a first-order rate process but exhibits nonlinear elimination (Figure 20-3). The first part of the curve with its sharper slope, the α phase, represents the distribution of drug to highly perfused areas, including the blood. This area consists of the central compartment. With time and depending on the affinity of the drug for certain tissues, the agent distributes to the peripheral compartment or compartments. After equilibration, the tissues are saturated with the drug, and its decline in blood usually occurs by a first-order elimination process, the β phase (see Figure 20-3). Usually the half-life of drugs that distribute according to a two-compartment model is determined during the β phase.

To apply kinetic analysis of a multicompartment model, it is assumed that all rate processes for the passage of drug from one

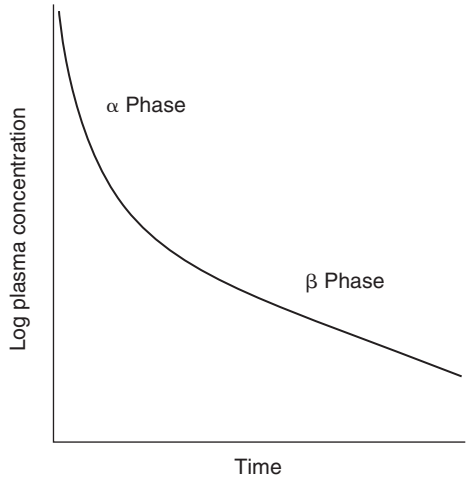

Figure 20-3 Two-compartment model for serum drug disappearance curve. The α phase represents the distribution phase, and the β phase, the elimination phase.

compartment to another exhibit first-order kinetics. Therefore, the plasma level–time curve for a drug that follows a multicompartment model is described by the summation of several first-order rate processes.

Zero-Order Kinetics

When elimination processes become saturated, disposition of certain drugs occurs according to zero-order kinetics. In contrast with a first-order process, in which the fraction of drug eliminated is constant, in zero-order kinetics, the elimination rate itself is constant. Thus the drug is eliminated at a constant rate. Consequently the zero-order half-life is not constant but is proportional to the initial amount or concentration of the drug:

$$t_{1/2} = 0.5C_0 / k_0$$

where k_0 = zero-order rate constant. Many drugs exhibit zero-order kinetics with elevated concentrations, and as these decline, first-order kinetics prevails. Examples of drugs that exhibit saturation kinetics are salicylates, phenylbutazone, phenytoin, diazepam, and chloramphenicol.

The determination of drug pharmacokinetics has not been widely accepted as an essential part of newborn intensive care. The amount of reliable pharmacokinetic data for drugs used in the ill neonate has lagged considerably behind knowledge of pathophysiology. Little doubt exists that this information as well as monitoring of serum levels can optimize drug dosage. In view of the risks of therapeutic failure and toxicity, the rationale for drug monitoring is obvious. In addition, the many complex developmental and disease-related dynamic processes that take place in the sick newborn provide sufficient justification to measure drug blood levels to obtain an indication of its kinetics.

PRINCIPLES OF PHARMACODYNAMICS: DRUG-RECEPTOR INTERACTION

Pharmacodynamics is defined as the biochemical and physiologic effects of drugs. This aspect of pharmacology is the raison d'être of pharmacotherapeutics. The mechanism of action of drugs at the receptive site has received much attention over the past 4 decades. This section reviews some of the issues regarding drug-receptor interaction; the term *receptive site* refers to the molecular entity with which the agent is presumed to interact.

Sites of Drug Action

Drugs may act outside the cell, at the cell membrane, or inside the cell. Regardless of cell localization, the drug action may be mediated by receptors or can be independent of receptors. Certain agents do not act on cellular sites but instead act on extracellular products of cells. A majority of drugs bind to specific receptor sites, whereas the action of others does not seem to be mediated by receptors. For instance, chelating agents, such as dimercaprol, penicillamine, and desferrioxamine, bind circulating metals. The action of these agents can be considered truly extracellular.

Drugs that bind to physiologic receptors and mimic the regulatory effects of the endogenous ligands are termed *agonists.* Compounds that block the effects of endogenous ligands are termed *antagonists,* which may be partial or inverse; the latter applies to drugs that stabilize the receptor in its inactive conformation. Localization of drug action refers both to drug distribution and to the specificity of the drug action. Such specificity implies the existence of receptors. Receptors consist of macromolecules that recognize and bind specific ligands and translate this binding into propagation of an intracellular message, either directly (e.g., nicotinic receptor: ion transport) or indirectly by virtue of a second messenger (e.g., protein kinase C: angiotensin II). This concept of receptor characteristics has led some investigators to suggest the existence of functional domains on the receptor molecule: a ligand-binding domain and an effector domain. Such conceptualization of the receptor is generally consistent with the mode of action of agonists and antagonists but appears to be a simplified version of complex processes (see later discussion).

Receptor Classification

Receptors traditionally have been classified pharmacologically by their response to specific antagonists. The precise classification of receptors with respect to structure-activity relationship, however, relies on multiple approaches, which include physiologic, biochemical, biophysical, and immunologic techniques. These broadened characteristics delineate more precisely the action of drugs, facilitating the development of therapeutic agents having selectivity for specific receptors. This broader scope also provides the clinician with an appropriate basis for therapeutics, by ameliorating efficacy and limiting toxicity.

Receptor Regulation

The concentration and affinity of receptors are physiologically regulated by ligand-receptor binding and activation. Receptor down-regulation is the process by which the concentration and affinity of receptors are decreased. This regulation of receptor function can be classified on the basis of the time course, short- and long-term. Short-term regulation occurs on the order of seconds to minutes, and long-term regulation takes place over hours to days. The mechanisms responsible for short-term regulation appear to involve conformational changes, transient intracellular receptor sequestration (e.g., nicotinic and α-adrenergic receptors), and phosphorylation of receptors. Protein phosphorylation is the mechanism by which most receptors are regulated, although myristoylation and palmitoylation also are involved in the regulation of expression of certain receptors. Long-term receptor down-regulation involves initial protein phosphorylation (myristoylation or palmitoylation) followed by internalization and degradation.

The term *receptor up-regulation* refers to the process of increasing receptor number. An example of up-regulation is the phenomenon of denervation supersensitivity of nicotinic receptors. The process of up-regulation is less clearly understood. Alterations in transcription of messenger RNA (mRNA), translation, or posttranslational modifications seem to contribute to receptor

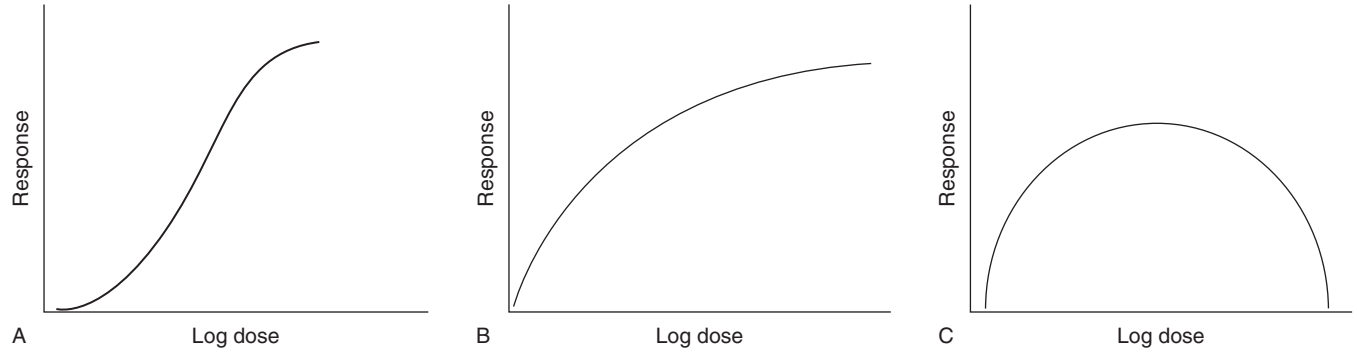

Figure 20-4 The dose-response relationship. A, "Classical" hyperbolic dose-response relationship. **B** and **C,** Examples of complex dose-response relationships: sigmoidal **(B)** and bell-shaped **(C).** The slope and shape of the curve reflect the mechanism of action of the drug. The potency is reflected by the position of the curve along the abscissa. The efficacy is reflected by the maximum position of the curve along the ordinate.

up-regulation. Thus changes in receptor number and affinity may well explain certain forms of drug tolerance, tachyphylaxis, and desensitization.

Changes in receptor binding, density, and coupling events also can occur with development. For instance, in the brain of the rat and pig, marked ontogenic changes in cholinergic muscarinic, α-adrenergic, and prostaglandin receptor density have been observed.[74-76] In addition, the pathophysiology of diseases such as testicular feminization, pseudohypoparathyroidism, myasthenia gravis, and certain forms of diabetes seems to involve receptor-associated dysfunctions.[77-79] Similarly, mutations of receptors can increase vulnerability to certain conditions or accelerate desensitization to receptor agonists, as reported for β-adrenoceptor agonists.[80] Thus developmental and pathologic considerations must be accounted for by clinicians and the investigators evaluating a response.

Relationship Between Drug Dose and Response

According to the receptor occupancy theory, response is proportional to receptor binding.[81] Thus maximal response is achieved when all receptors are bound. Although this concept has a degree of practical validity, interpretation of receptor binding often is difficult, particularly when the coupling events encompass a complex sequence of reactions. Such is the case when further receptor occupancy does not produce greater response; these observations have led to the concept of *spare receptors,* whereby a maximal response is achieved when a relatively small proportion of the receptors is occupied. Other, more complex receptor-evoked functions involve allosteric modulations and protein interactions.

The Allosteric Nature of G Protein–Coupled Receptor Signaling

The theoretical framework associated with the study of ligand-receptor interactions adheres to the law of mass action—essentially a simple reversible and saturable one-to-one interaction between ligand and receptor (Figure 20-4, *A*). This classical view has served many pharmacologists. Insights obtained from research on enzymes, ion channels, and hemoglobin, however, have led to the inference of more complex interactions between ligands and receptors. Essentially, more than one ligand may potentially interact with a receptive unit, yielding the concept of "cooperativity." This concept assumes conformational changes in the protein of interest as well as its interaction with adjacent partners, forming a dynamic oligomeric complex. Accordingly, specific molecules can be envisioned with sites distinct from the "classical" ligand-binding site, and consequently to affect this conformational state; such molecules are termed allosteric modulators. This model will yield ligand-receptor interactions of much greater complexity than those observed for the typical simple hyperbolic profiles (see Figure 20-4, *A*), and may include those for which the graphed data form a sigmoidal or bell-shaped curve (see Figure 4, *B* and *C*). (The slope and the shape of the curve reflect the mechanism of action of a drug. The potency describes the location of the curve along the *x*-axis and is influenced by the inherent affinity of the drug for its receptor and the latter's ability to couple with the postreceptor mechanisms. The efficacy is characterized by the maximum response observed regardless of dose-response profile.)

In the following discussion, G protein–coupled receptors (GPCRs), which have been the most thoroughly studied thus far, are used for the purposes of illustration. GPCRs constitute the largest superfamily of surface receptors. These receptors mediate a plethora of responses. The basic transduction unit of GPCRs is governed by reciprocal allosteric interactions occurring among three elements: (1) a seven-transmembrane domain receptor polypeptide, which binds the transmitter; (2) a trimeric (αβγ) G protein; and (3) an effector component. Binding of a transmitter leads to the exchange of GDP for GTP on the Gα chain. The activated G protein, through either its α-GTP chain or the β γ dimer, or both, in turn modulates the effector components, leading to the response. Traditionally known effectors modulated by GPCRs include enzymes such as adenylyl cyclase and phospholipases C as well as ion channels and antiporters. Recently, additional effector systems linked to the activation of receptor tyrosine kinases also were shown to be modulated by GPCR. In particular, the Erk1/Erk2/p38 MAP/JNK kinase signaling pathways were shown to be activated by stimulation of G proteins of the Gq, Gi, and Gs family by way of many distinct signaling pathways.[82-84] In addition to their G protein–mediated effects, GPCRs also have been found to interact directly and modulate the activity of an increasing list of proteins including: β-arrestins, NHERF/EBP50, JAK, endothelial nitric oxide synthase (eNOS), *N*-ethylmaleimide–sensitive factor (NSF), Rho and Arf, spinophilin, 14-3-3, Nck and Grb2, endophilins, CREB and ATFx, the gamma-aminobutyric acid isoform $GABA_A$, and the glutamate *N*-methyl-D-aspartic acid (NMDA) receptors (reviewed by Bockaert and associates[85]). In addition, contrary to traditional views, increasing evidence indicates that GPCRs exist as homo- and heterodimers (or even larger oligomeric assemblies), which may have important consequences on their signaling properties.[86,87] Although the physiologic importance of many of these interactions needs to be investigated further, the large number of proteins that appear to be involved in GPCR signaling suggests a level of allosteric complexity that was not anticipated just a few years ago.

Classically, orthosteric ligands are thought to bind to the receptor in the same space that is occupied by the endogenous ligand and to promote or stabilize specific receptor conformations. In the traditional two-state receptor activation model,[88] they were believed to control the equilibrium between an active and an inactive GPCR conformer. Increasing evidence, however, indicates that separate ligands can differentially regulate various signaling cascades engaged by a given receptor, suggesting that numerous active receptor conformations may exist and in turn result in different signaling efficacy profiles towards distinct effector systems.

One of the most striking illustrations of this phenomenon, known as *agonist trafficking,*[89] is the observation that β-adrenergic ligands that act as inverse agonists for the adenylyl cyclase pathway behave as agonists for the MAPK pathway after binding to the β_2-adrenergic receptor.[90] Similar observations also have been reported for the arginine vasopressin receptor 2,[90] the histamine receptor,[91] and the angiotensin receptor.[92] These findings led to the concept that distinct receptor conformations are responsible for the differential allosteric regulation of distinct subsets of signaling partners opening the avenue for the development of compounds that could selectively target only one of the receptor signaling modes. In this context, allosteric regulation of receptor conformation through homo- or heterodimerization, or mediated through interactions with various effectors and accessory proteins, opens many potential target sites for pharmacologic modulation. Receptors can be seen as allosteric machines for which pharmacologic potential has been only superficially explored; examples of allosteric modulators of receptors, thus far few, are oxytremorine,[93] THG113.31,[94] and SCH-202676.[95] The study and exploitation of allosteric phenomena will become of progressively greater importance in drug discovery and development, to enhance pathway selectivity and diminish adverse effects.[96]

In Vivo Efficacy

In vivo, potency also is influenced by disposition of the drug. In the clinical setting, potency per se should not be a determining factor in the selection of an agent. By contrast, maximal efficacy must be taken into consideration in choosing drugs. In all instances, toxicity of the agent must be taken into account. Under all therapeutic circumstances, the drug chosen ideally should provide the greatest margin of safety. This selectivity has been quantified as the *therapeutic index,* which usually is defined as the ratio of the median toxic dose to the median effective dose (TD_{50}/ED_{50}) and in laboratory studies as the ratio of the median lethal dose to the median effective dose (LD_{50}/ED_{50}).

CONCLUSION

Marked differences in drug disposition and action between the newborn and the adult are well recognized. As might be expected, such differences are even greater for the ill preterm neonate. These differences must be taken into consideration in decisions regarding pharmacologic therapy for newborns. Appropriate application of basic principles in pharmacology as well as adequate drug monitoring allows individualization of drug dosage and will optimize clinical outcomes in neonates by reducing adverse drug effects.[71]

21 Basic Pharmacokinetic Principles

Ralph A. Lugo and Robert M. Ward

Pharmacokinetics describes the absorption, distribution, metabolism, and excretion of drugs. The pharmacokinetic parameters of a drug are used to characterize the drug concentrations reached within the body after a dose and the changes in those concentrations over time.[1] Clinical pharmacokinetics is the discipline that applies pharmacokinetic principles to individualize dosage regimens, optimize the therapeutic effects of a medication, and minimize the chances of an adverse drug reaction. These goals are accomplished by achieving an effective concentration of unbound drug at the site of action. Clinically important sites of action include receptors, membrane transport systems, intracellular enzymes, interstitial tissues in which infections may occur, and many others. Correlations have been made between drug concentrations in the circulation and effective and toxic drug concentrations at various sites of action.[2] Depending on the strength of those correlations, ranges of effective, toxic, and ineffective circulating drug concentrations have been defined for many drugs. Pharmacokinetics serves as a guide to effective therapy, but achieving specific concentrations is not the goal of therapy. Effective therapy can be best judged by improvements in function, not just by reaching the desired peak and trough concentrations in the circulation.

Although the mathematical principles used to describe pharmacokinetics have become quite sophisticated, with advanced mathematical modeling, statistical arm theory,[3] and complex noncompartmental analysis,[4] the clinical issues in dosing are simple. Once a drug has been selected, three primary factors must be decided: what route to use for administration, how large a dose to administer, and how often to administer the dose. The size of the dose relates to its distribution within the body, and the frequency of administration relates to clearance or the rate of removal of active drug from the body. In this chapter, the factors needed to determine these parameters of drug therapy are presented mathematically and then are simplified for bedside application.

PHARMACOKINETIC MODELS

Mathematical principles may be used to describe pharmacokinetic processes to predict a drug's behavior in the body. To apply these principles using a compartmental approach requires selection of a compartmental model that best represents a drug's distribution and rate(s) of concentration change in the body.[1] Compartmental models may be classified as one-compartment, two-compartment, or multicompartment models, depending on the number of exponential equations required to describe the concentration changes. Seldom does a drug require more than three exponential equations to characterize its kinetics. Each theoretical "compartment" consists of a group of similar tissues, fluids, or organs and may be correlated with different anatomic fluids and tissues.

In a one-compartment model, all body tissues are included in the model, and an intravenously administered drug is assumed to distribute instantaneously and homogeneously throughout the compartment.[2] In general, drugs that do not distribute widely into extravascular tissues can be described by a one-compartment model, such as aminoglycosides or very large molecules. This approach simplifies the calculations necessary for therapeutic drug monitoring of these agents, because only two or three concentration determinations may be needed to characterize the pharmacokinetics for dosage adjustments adequately.

With many drugs, however, the pharmacokinetics do not fit a one-compartment model because of slow distribution from the blood into other fluids and tissues: The drug reaches the central compartment, made up of blood or plasma and highly perfused organs, such as the heart, liver, kidneys, and lungs, and diffuses out to peripheral sites such as adipose tissue, cerebral spinal fluid, and muscles.[2] The disposition of such drugs is best described using a multicompartmental approach. Examples of drugs with such behavior are vancomycin, digoxin, and lipophilic drugs (e.g., fentanyl, midazolam, propofol). For the purposes of therapeutic drug monitoring in which only two or three plasma concentrations are obtained around an administered dose, characterization of the multicompartmental pharmacokinetics is not feasible or accurate. Thus this multicompartment approach is reserved for more detailed pharmacokinetic study, when more frequent plasma sampling can be obtained.

FIRST-ORDER ELIMINATION

The change in drug amount within the body can be described with the following general equation, in which A is the amount of drug within the body, k is the rate constant of change for A within the body, and n defines the order (e.g., zero, first, second) of the process.[5]

$$\frac{dA}{dt} = -kA^n \tag{1}$$

Most drugs are eliminated by first-order exponential rates *(k)* in which a constant fraction of the drug is eliminated per unit of time. If the kinetics is characterized by first-order elimination, the rate of change of drug in the body (dA/dt) is proportional to the amount in the body. Thus, at high concentrations, a greater amount of drug is eliminated per hour than at low concentrations. This higher elimination rate results in an exponential decline in plasma concentration (Figure 21-1), which can be represented by the following equation:

$$C_t = C_0 \times e^{-kt} \tag{2}$$

where C_t is the concentration at some time t, C_0 is the initial concentration at time 0, and e^{-kt} represents the exponential decline in plasma concentration associated with first-order elimination. The plasma concentration versus time relationship may be made linear by taking the natural logarithm of each side of Equation 2:

$$\ln C_t = \ln C_0 - kt \tag{3}$$

The slope of this straight line is the elimination rate constant k (time^{-1}), which may be calculated by rearranging Equation 3:

$$k = (\ln C_1 - \ln C_2)/\Delta t \tag{4}$$

where C_1 is the higher concentration and C_2 is the lower concentration measured some time later. If the logarithm (base 10) of concentration is graphed versus time, the slope will be $k/2.303$. The half-life of a drug exhibiting first-order elimination is the time

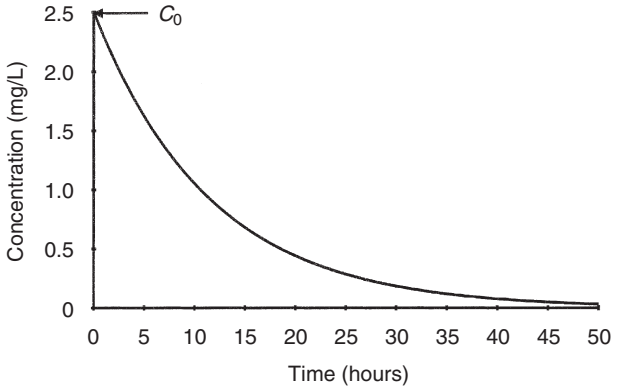

Figure 21-1 Exponential decrease in drug concentration after a rapid intravenous bolus injection graphed on linear-linear axes. The initial concentration (C_0) of 2.5 mg/L declines with a half-life of 8 hours.

necessary for the concentration in the plasma to decrease by one half. The relationship between the elimination rate constant and the half-life for a first-order process may be derived mathematically from Equation 3. For a drug whose initial concentration is 100 mg/L, the concentration at one half-life is 50 mg/L.

$$\ln 50 = \ln 100 - kt$$

$$kt = \ln (100/50)$$

which can be rearranged to

$$k = \ln 2 / t$$

where t represents one half-life; therefore

$$k = 0.693 / t_{1/2} \tag{5}$$

To illustrate the concept that the amount of drug removed per unit time decreases with declining amounts (or concentrations) of drug in the body, the amount of drug in the body at different times can be calculated with Equation 2 by substituting plasma concentration with the amount of drug in the body. For example, if a 100-mg dose of a drug with first-order elimination is administered by rapid intravenous bolus, and it has a 2-hour half-life (k = 0.693/2 h = 0.347 h^{-1}), a constant fraction of drug will be removed each hour: $e^{(0.347)(1)}$ = 29.3% of the amount of drug in the body. The amount of drug in the body each hour can be calculated to show the decreasing amount of drug removed each hour (Table 21-1).

First-Order Multicompartment Kinetics

If drug clearance from the circulation is studied thoroughly, with concentration measurements made multiple times soon after intravenous administration as well as during the terminal elimination phase, two or more exponential rates of clearance often are detected by a change in slope of a semilogarithmic graph of concentration versus time (Figure 21-2). The number and nature of the compartments for the clearance of a drug do not necessarily correspond to specific body fluids or tissues. When two first-order exponential equations are required to describe the clearance of drug from the circulation, the kinetics is designated first-order and two-compartment or biexponential.[6] Such kinetics commonly is observed for drugs that rapidly distribute from the central compartment (blood and highly perfused organs) to peripheral compartments after intravenous administration. Figure 21-2 illustrates the kinetics for such drugs. The initial rapid decrease in concentration is referred to as the α distribution phase and is primarily the result of drug distribution to tissues; however, elimination also is occurring. Accordingly, the slope of

TABLE 21-1

Amount of Drug Remaining in the Body Each Hour for a Drug Eliminated by First-Order Kinetics with a Half-Life of 2 Hours (k = 0.347 h^{-1})

Time (h)	Amount of Drug in Body (mg)	Drug Eliminated over Preceding Hour (mg)	Fraction of Drug Eliminated During Preceding Hour
0	100	0	0
1	70.7	29.3	0.293
2	50	20.7	0.293
3	35.4	14.6	0.293
4	25	10.4	0.293
5	17.7	7.3	0.293
6	12.5	5.2	0.293

this initial decrease in concentration is determined by both drug elimination and drug distribution. After the inflection point in the slope and during the terminal or β elimination phase of the curve, elimination accounts for most of the change in drug concentration and has a rate constant of β. The α distribution rate constant can be determined by subtracting the concentration during the initial period after drug administration from concentrations extrapolated to time zero from the β elimination phase (see Figure 21-2). The rate constant α is the slope of the natural logarithm of the concentration difference (Δ) versus time curve shown as the line of alternating dashes and dots in Figure 21-2. A more detailed mathematical discussion can be found elsewhere.[6,7] The equation that represents a first-order, two-compartment model is as follows:

$$C_t = Ae^{-\alpha}t + Be^{-\beta t} \tag{6}$$

where C_t is concentration at time t after the dose, A is the concentration at time 0 for the distribution rate represented by the broken line graph, α is the rate constant for the initial distribution phase, B is the concentration at time 0 for the terminal elimination phase, and β is the rate constant for terminal elimination. When concentration is graphed on semilogarithmic axes using logarithm (base 10) of concentration, the slope of the lines for α and β = α/2.303 and β/2.303, respectively.

Although many drugs demonstrate multicompartment kinetics, the intensive blood sampling required to fit data to more than one compartment usually is not clinically feasible, particularly in the newborn patient. Furthermore, the mathematical complexity of two-compartment models makes this kinetic approach clinically impracticable. To minimize cost and to simplify pharmacokinetic calculations, only two plasma concentrations—peak and trough—usually are obtained for therapeutic monitoring of commonly used drugs, such as gentamicin and vancomycin. Accordingly, a one-compartment model is assumed, and the elimination rate constant *(k)* is determined from the slope of these points plotted on a semilogarithmic scale. Because the elimination rate constant should be determined during the terminal elimination phase, it is important that blood samples for determining peak concentrations of multicompartment drugs not be drawn prematurely, that is, during the initial distribution phase. If samples are drawn too early, the high initial predistribution concentration will result in an overestimation of the slope and terminal elimination rate constant. Clinically, early sampling usually is not problematic with gentamicin because the initial distribution phase commonly occurs during the 30- to 60-minute infusion.[8] Thus a peak concentration obtained 30 to 60 minutes after the end of infusion usually reflects the terminal phase of elimination. With vancomycin, however, the half-life of the initial distribution phase is 0.05–0.45 hours.[9] Thus a peak vancomycin concentration determined using blood drawn prematurely may lead to error in estimating the pharmacokinetic parameters.

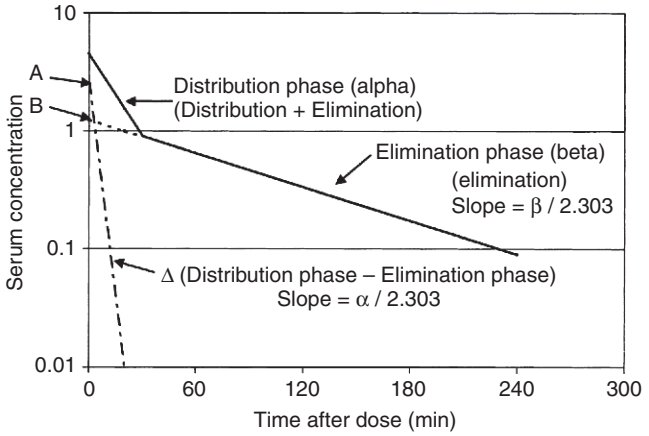

Figure 21-2 *A,* Two-compartment or biexponential kinetics graphed as a *solid line* on semilogarithmic axes with the initial rapid decrease in concentration resulting from distribution and elimination during the distribution phase (α) followed by the slower decrease in concentration during the elimination phase (β) with a slope of the elimination rate constant β/2.303. *B,* The intercept of the elimination phase extrapolated with a *dashed line* to time 0. The concentration difference (Δ) between the distribution and elimination phases is graphed with *dashes alternating with dots* with intercept A and a slope of the distribution rate constant α/2.303.

ZERO-ORDER ELIMINATION

Elimination of some drugs occurs with loss of a constant amount of drug per time, rather than a constant fraction per time as with first-order kinetics. When the rate of change in the amount or concentration of a drug is constant, these rates are described as zero-order rates, and the concentration can be calculated using the following equation:

$$C_t = C_0 - k_0 t \tag{7}$$

In this equation, C_t equals the concentration at time t, C_0 is the initial concentration, and k_0 (amount/time) is the rate constant for this process. Zero-order elimination may occur when the elimination process of a drug becomes saturated, that is, when the eliminating organ has reached the maximum capacity for drug removal. This may be referred to as *saturation kinetics.* Some drugs administered to newborns that are eliminated, at least in part, by zero-order kinetics include caffeine, chloramphenicol, diazepam, furosemide, indomethacin, and phenytoin.[10] Such elimination may occur for other drugs after excess doses or when the organ responsible for drug elimination becomes dysfunctional. With change from first-order to zero-order kinetics (dose-dependent kinetics), continuation of the same dosage usually leads to a rapid accumulation of drug, resulting in toxic drug concentrations.[10]

APPARENT VOLUME OF DISTRIBUTION

The *apparent volume of distribution* (V_d) is a mathematical term that relates the total amount of drug in the body to the drug concentration in the circulation. After a rapid intravenous bolus dose and assuming a one-compartment model, the following equation may be used to relate V_d, dose, and the change in circulating concentration.

$$\Delta \text{ Circulating drug concentration (mg/L)} = \tag{8}$$

V_d may be viewed as the volume of dilution into which the dose is added to produce the observed change in concentration. The larger the volume of distribution, the greater the dilution of a dose, and the smaller the increase in circulating concentration. Volume of distribution does not necessarily correspond to a true physiologic body fluid or tissue volume—hence the designation "apparent." For drugs that are extensively distributed to peripheral tissues, the V_d derived from changes in concentration within the circulation may be very large. For example, the V_d of digoxin in neonates and infants may reach 10 L/kg—an anatomic impossibility.[11] Large volumes of distribution indicate that tissue concentrations of drug may greatly exceed the concentration in the plasma, often because of protein binding in tissues or fat solubility. Drugs that distribute primarily into extracellular fluid (e.g., gentamicin) have small volumes of distribution (V_d of 0.25 to 0.35 L/kg in adults) that significantly increase in fluid overload states. In addition, because extracellular water makes up a larger percentage of body weight in premature and term infants, their volumes of distribution at birth will be larger for these drugs.

When administering a rapid intravenous bolus dose, Equation 8 serves as the basis for other pharmacokinetic calculations because it is easily rearranged to solve for V_d and dose. If a dose is infused over a longer period, a significant portion of the dose may be cleared from the body during the infusion, in particular for drugs with half-lives that are only three to four times longer than the infusion time. Accordingly, a more complex exponential equation that accounts for concurrent drug administration and drug elimination is required to describe the change in concentration. Such equations are needed, however, only when the drug is rapidly eliminated and the duration of infusion approaches the drug's half-life. In neonates, who often have relatively slow rates of drug elimination, only a small fraction of drug is eliminated during the time of infusion, and such adjustments often can be omitted. Accordingly, the simpler and more practical equation to estimate pharmacokinetic parameters may be used.

CLEARANCE

Clearance represents the capacity for drug removal by various organs and is defined as the volume of blood from which all drug is removed per unit of time. Both clearance and distribution volume are model-independent parameters, so plasma drug concentrations are determined by the rate at which drug is administered, its clearance, and the volume of distribution. Similarly, rate of elimination is determined from clearance (Cl) and V_d.

$$k = \text{Cl} / V_d \tag{9}$$

Drugs can be cleared through numerous pathways, although most drugs are cleared by some combination of renal clearance (Cl_R), hepatic clearance (Cl_H), and biliary clearance (Cl_B) (Figure 21-3). Thus the total systemic clearance of a drug is the sum of all the clearances by various mechanisms and can be calculated using the following equation:

$$Cl_S = Cl_R + Cl_H + Cl_B + Cl_{other} \tag{10}$$

Because it is seldom possible to calculate each organ's clearance of drug, total systemic clearance (Cl_S) is often determined by measuring the area under the plasma concentration–time curve (AUC) after a single dose:

$$Cl_S = \text{Dose} / \text{AUC} \tag{11}$$

During a continuous infusion, clearance may be determined easily by the relationship between the rate of infusion and the resultant steady-state concentration:

$$Cl_S = \text{rate of drug administration} / \text{steady-state drug concentration} \tag{12}$$

FIRST-PASS CLEARANCE

For some drugs, dramatic differences in concentrations and effects are seen for enteral versus parenteral administration, as a result of first-pass effect or presystemic drug clearance. During

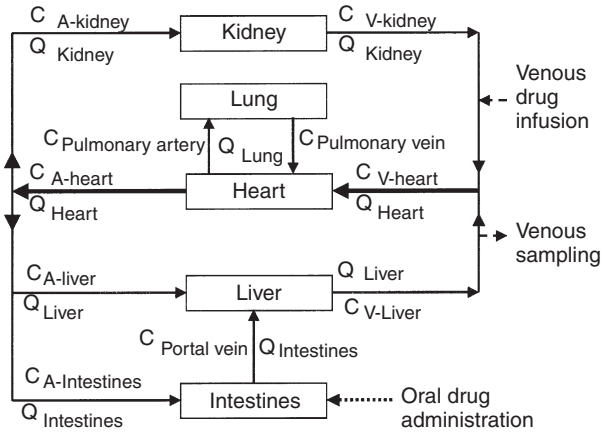

Figure 21-3 Components of drug clearance by several organs that combine to produce total body clearance in which C_A is arterial concentration, C_V is venous concentration, and Q is organ blood flow. First-pass clearance may occur during drug absorption from the intestines or during circulation of portal venous blood through the liver before it reaches the systemic circulation.

enteral absorption, drug passes through the intestinal wall, enters the portal venous circulation, and passes through the liver before reaching the systemic circulation (see Figure 21-3). Nearly complete metabolism may occur in the intestinal wall or the liver (especially for drugs metabolized by cytochrome P-450 3A4), so the amount of parent drug reaching the systemic circulation is only a small fraction of the dose administered.[12,13] The fraction *(F)* of the oral dose that reaches the systemic circulation is that which remains after hepatic or intestinal metabolism and is expressed as the extraction ratio (ER) in the following equation:

$$F = 1 - \text{ER} \tag{13}$$

F is determined from the ratio of the area under the plasma concentration curve after oral administration to that after intravenous administration. After an intravenous dose of medication, drug enters either the inferior or superior vena cava circulation, returns to the heart, and enters the systemic circulation before perfusing the liver. Drugs that undergo almost complete hepatic or intestinal metabolism before reaching the systemic circulation are described as having a high hepatic or intestinal intrinsic clearance. Drugs used in the care of newborns that exhibit moderate to significant first-pass, presystemic clearance in adults and infants include midazolam,[14] morphine,[15] and propranolol.[16]

STEADY STATE

Steady-state conditions prevail when plasma and tissue concentrations are in equilibrium and the amount of drug removed per unit time is equal to the amount administered per unit time. For drugs administered intermittently, peak and trough concentrations at steady state are unchanged after each dose. For drugs administered by continuous infusion, serum concentrations are constant. Constant serum concentrations, however, do not define steady state because distribution between tissues and the circulation may still be occurring.

The time to reach steady state is dependent only on the elimination rate constant and thus half-life. If drug is administered repeatedly at a fixed dosing interval, the time to reach greater than 90% of steady state is four or more half-lives (Table 21-2).

During long-term drug treatment, dose adjustments should be made when concentrations are close to steady state and generally not less than three half-lives after a previous dose adjustment, unless organ dysfunction is altering the half-life or volume of distribution.

TABLE 21-2

Percentage of Steady-State Concentration Reached After Drug Administration for One to Five Half-Lives

Number of Half-Lives Drug Is Administered	% of Steady-State Concentration
1	50
2	75
3	87.5
4	93.75
5	96.88

SINGLE-DOSE ADMINISTRATION BY SHORT-DURATION INFUSION

When drugs are infused over a period approaching 25% to 50% of the half-life, significant drug elimination occurs during the infusion process, and thus the standard intravenous bolus equation (e.g., Equation 8) is no longer accurate in calculating the change in concentration or the volume of distribution. A more complex mathematical model must be used to account for drug elimination during drug infusion.

To determine the concentration immediately at the end of the first infusion for a one-compartment model, Equation 14, which commonly is used to calculate concentration during a continuous infusion, may be modified:[17]

$$C_t = (R_0 / \text{Cl}) \times (1 - e^{-kt}) \tag{14}$$

where C_t is the concentration at any time (t) during the continuous infusion, R_0 is the rate of infusion, and k is the first-order elimination rate constant. During a continuous infusion, steady state (C_{ss}) is defined by the relationship between infusion rate (R_0) and clearance (Figure 21-4):

$$C_{ss} = R_0 / \text{Cl} \tag{15}$$

In Equation 14, it is intuitive to think of the factor $[(1 - e^{-kt})]$ as the percentage of steady state that is achieved at time t. Thus the concentration at any time t during the infusion process is the steady-state concentration (C_{ss}) multiplied by the percentage of steady state achieved at time t. As t becomes larger, the factor $[(1 - e^{-kt})]$ in Equation 14 approaches 1, resulting in steady-state Equation 15.

Equation 14 can be adapted easily for a single short-duration infusion. Accordingly, the duration of the infusion is represented by t, and C_t therefore represents the concentration immediately at the end of the infusion. Plasma concentrations anytime thereafter can be calculated by multiplying C_t by the decay factor ($e^{-kt'}$) for a first-order process (see Equation 2). Thus, the concentration measured at any time (t') after the completion of a single short-duration infusion can be calculated by the following equation[17]:

$$C_{t'} = R_0 / \text{Cl} \times [(1 - e^{-kt_{\text{inf}}})] \times e^{-kt'} \tag{16}$$

where C_t' is the concentration measured at some time t' after the end of infusion. The infusion time is represented by t_{inf} and often is 0.5 hour or 1 hour, and R_0 is the rate of infusion, defined by (dose/time of infusion). This single-dose equation is commonly used to calculate the measured peak and trough concentrations after administration of the first dose of an aminoglycoside or vancomycin.

Because $\text{Cl} = V_d \times k$ (derived from Equation 9), Equation 16 can be rearranged to solve for V_d after a single short-duration infusion.

$$V_d = [R_0 / (C_{t'} \times k)] \times (1 - e^{-kt_{\text{inf}}}) \times e^{-kt'} \tag{17}$$

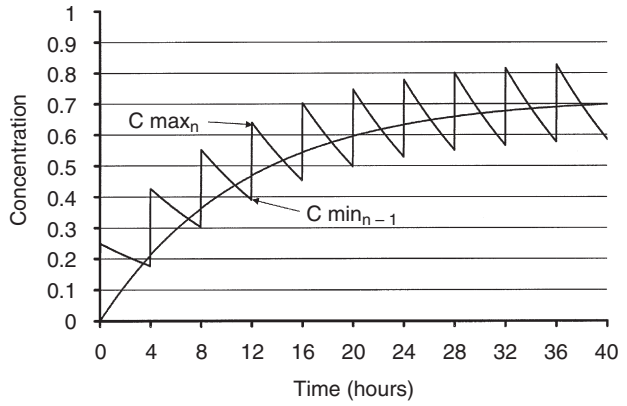

Figure 21-4 Plasma drug concentrations over time during a continuous intravenous infusion and during repeated dosing. For a continuous infusion, the rate of infusion and the clearance of the drug define the steady-state concentration, a plateau reached when the rate of elimination matches the rate of input. For multiple drug dosing using the same daily dose, the average steady-state concentration is the same as the steady-state concentration for a continuous infusion. During multiple drug dosing, the increase in concentration between the trough immediately before the nth dose, $C_{\min\,(n-1)}$, and the peak immediately after the nth dose, $C_{\max\,(n)}$, is the same increase noted after a single (i.e., first) dose of drug.

This equation represents the calculation of V_d after a single dose of drug. If pharmacokinetic parameters are calculated after multiple doses, the accumulation of drug must be taken into account.

MULTIPLE-DOSE ADMINISTRATION

In most clinical situations, pharmacokinetic parameters are calculated and dosage adjustments are made after multiple doses are administered. When multiple doses are administered at a fixed dosage interval (τ), concentrations will accumulate until steady state is achieved some five half-lives later (see Figure 21-4). The maximum concentration after the *nth* dose may be determined by adding the minimum concentration just before the nth dose (i.e., $n - 1$) and the maximum concentration achieved after the first dose is administered (see Figure 21-4). Mathematically, an *accumulation factor* may be derived that relates the maximum drug concentration after a single dose to drug concentration after n doses administered at a fixed dosage interval (τ). A full mathematical derivation is beyond the scope of this chapter and may be found elsewhere.[18] This accumulation factor *(R)* may be calculated using the following equation[17]:

$$R = (1 - e^{-nk\tau}) / (1 - e^{-k\tau}) \tag{18}$$

As n approaches ∞ (i.e., as steady state is achieved), the numerator of the accumulation factor approaches 1. Thus the steady-state accumulation factor is represented by the following equation:

$$\text{Steady-state accumulation factor} = 1 / (1 - e^{-k\tau}) \tag{19}$$

Accordingly, to calculate the maximum concentration after the nth dose of drug, the maximum concentration after a single dose ($C_{\max\,(1)}$) is multiplied by the accumulation factor:

$$C_{\max(n)} = C_{\max(1)} \times [(1 - e^{-nk\tau}) / (1 - e^{-k\tau})] \tag{20}$$

Similarly, to calculate the maximum concentration at steady state, the maximum concentration after the first dose is multiplied by the steady-state accumulation factor:

$$C_{\max\,(ss)} = C_{\max(1)} \times [1 / (1 - e^{-k\tau})] \tag{21}$$

The accumulation factor also can be used to calculate the minimum concentration after any number *(n)* of doses or at steady state by multiplying the minimum concentration after a single dose, $C_{\min\,(1)}$, by the appropriate accumulation factor.

$$C_{\min(n)} = C_{\min(1)} \times [(1 - e^{-nk\tau}) / (1 - e^{-k\tau})] \tag{22}$$

$$C_{\min(ss)} = C_{\min(1)} \times [1 / (1 - e^{-k\tau})] \tag{23}$$

From Equation 2, $C_{\min\,(1)} = C_{\max\,(1)} \times e^{-kt'}$, where $e^{-kt'}$ accounts for the first-order decline in concentration between the maximum concentration and the minimum concentration during time t'. Therefore, from Equations 22 and 23, the following equations are derived:

$$C_{\min(n)} = [C_{\max(1)} \times e^{-kt'}] \times [(1 - e^{-nkt}) / (1 - e^{-k\tau})] \tag{24}$$

$$C_{\min\,ss} = [C_{\max\,(1)} \times e^{-kt'}] \times [1 / (1 - e^{-k\tau})] \tag{25}$$

Accumulation After Multiple Intravenous Boluses

After a single, rapid intravenous bolus dose, $C_{\max\,(1)} = \text{dose}/V_d$ (derived from Equation 8); therefore the maximum concentration after the nth intravenous bolus dose—$C_{\max\,(n)}$—is determined by substituting $C_{\max\,(1)}$ into Equation 20, which is the product of the maximum concentration after a single dose (Dose/V_d) multiplied by the accumulation factor[17]:

$$C_{\max(n)} = \text{dose} / V_d \times [(1 - e^{-nk\tau}) / (1 - e^{-k\tau})] \tag{26}$$

To calculate the concentration at any time t' after administration of the nth dose, Equation 26 is multiplied by the exponential term for a first-order process:

$$C_{t'\,(n)} = \text{dose} / V_d \times [(1 - e^{-nk\tau}) / (1 - e^{-k\tau}] \times e^{-kt'} \tag{27}$$

At steady state, the accumulation factor term in the numerator ($1 - e^{-nkt}$) is equal to 1, which results in the following equation:

$$C_{t'\,ss} = \text{dose} / V_d \times [1 / (1 - e^{-k\tau})] \times e^{-kt'} \tag{28}$$

This equation may be rearranged to solve for dose and V_d so long as k and the concentration are known.

Accumulation After Multiple Administrations of Short-Duration Infusions

For a short-duration infusion, the $C_{\max\,(1)}$ after a single dose equals $R_0/Cl \times [(1 - e^{-kt_{inf}})]$, which adjusts for the amount of drug eliminated during the infusion. Thus the maximum concentration after the nth dose is the $C_{\max\,(1)}$ after a single dose multiplied by the accumulation factor; that is, $C_{\max\,(1)}$ is substituted into Equation 20[17]:

$$C_{\max\,(n)} = [R_0 / Cl] \times (1 - e^{-kt_{inf}}) \times [(1 - e^{-nk\tau}) / (1 - e^{-k\tau})] \tag{29}$$

To calculate the concentration at any time t' after completing the infusion of the nth dose, Equation 29 is multiplied by the exponential term for a first-order process:

$$C_{t'\,(n)} = [R_0 / Cl] \times (1 - e^{-k\tau_{inf}}) \times [(1 - e^{-nk\tau}) / (1 - e^{-k\tau})] \times e^{-kt'} \tag{30}$$

At steady state, the accumulation factor term in the numerator ($1 - e^{-nkt}$) is equal to 1, which results in the following equation:

$$C_{t'\,(ss)} = [R_0 / Cl] \times (1 - e^{-kt_{inf}}) \times [(1 - e^{-k\tau})] \times e^{-kt'} \tag{31}$$

In the hospital setting, pharmacokinetics often is calculated for aminoglycosides and vancomycin and usually is measured at steady state. Therefore Equation 31 represents the most important equation for the purposes of therapeutic drug monitoring. Equation 31 may be rearranged to solve for any desired parameter,

including V_d and dose. Recall that Cl = $V_d \times k$ (derived from Equation 9); thus

$$V_d = [R_0 / (C_{t'(ss)} \times k)] \times (1 - e^{-k\tau_{inf}}) \times [1 / (1 - e^{-k\tau})] \times e^{-kt'} \quad (32)$$

Similarly, because R_0 = dose/time of infusion (t_{inf}), Equation 31 can be rearranged to solve for dose:

$$\text{Dose} = [V_d \times t_{inf} \times C_{t'(ss)} \times k \times (1 - e^{-k\tau})] / [(1 - e^{-k\tau_{inf}}) \times e^{-kt'}] \quad (33)$$

where $C_{t'(ss)}$ is a steady-state concentration measured at time t' after the end of the infusion. In clinical practice, this is often the *measured peak concentration* (e.g., 1 hour after the end of infusion), a random concentration, or a *measured trough concentration.*

EXAMPLES OF MATHEMATICAL PHARMACOKINETIC DOSE ADJUSTMENTS

The foregoing equations may be used to adjust the dose and dosing intervals to attain desired peak and trough concentrations. We recommend a simple four-step approach: (1) calculate k (and half-life, $t_{1/2}$), (2) calculate V_d, (3) calculate a dosing interval and dose based on a desired peak and trough, and (4) check the peak and trough of the new dosage regimen.

Example 1

Use the four-step approach to solve the following: 100 mg of a drug is administered by rapid intravenous bolus every 8 hours. At steady state, the peak concentration measured 1 hour after the bolus is 10 mg/L, and the trough concentration measured immediately before the next dose is 2 mg/L. Calculate k, V_d, and the new dose to achieve a measured peak of 15 mg/L and a trough of 1 mg/L.

Step 1

Equations 4 and 5 are used to calculate the elimination rate constant and half-life, respectively.

$$k = [\ln(10) - \ln(2)] / 7\text{h} = 0.2299\ \text{h}^{-1}$$

Because the peak concentration was measured 1 hour after administration of the intravenous bolus, the Δt is 7 and not 8 hours.

$$t_{1/2} = 0.693 / 0.2299\text{h}^{-1} = 3.0\ \text{hours}$$

Step 2

Equation 28 may be rearranged to solve for V_d.

$$V_d = [\text{dose} / C_{t'ss}] \times [1 / (1 - e^{-k\tau})] \times e^{-k\tau'}$$

$C_{t'ss}$ is the measured peak concentration at steady state (10 mg/L), and $e^{-kt'}$ represents the decline in concentration between the end of the bolus and the measured peak, that is, 1 hour.

$$V_d = [100\text{mg} / (10\ \text{mg/L})] \times [1 / (1 - e^{-(0.2299)(8)})] \times e^{-(0.2299)(1)} = 9.45\ \text{L}$$

Step 3

Equation 4 can be rearranged to solve for Δt for a desired peak (15 mg/L) and desired trough (1 mg/L) concentration with a known k. This term is represented as the new dosing interval (τ).

$$\tau = [\ln(15) - \ln(1)] / 0.2299\text{h}^{-1} = 11.8\ \text{hours}$$

Because this desired peak concentration is measured 1 hour after the dose is administered, the dosing interval must include the additional hour. Thus the optimal τ = 12.8 hours, which can be rounded to a 12-hour dosing interval.

Equation 28 can be rearranged to solve for the new dose with a known V_d, k, and τ.

$$\text{Dose} = [C_{t'(ss)} \times V_d \times (1 - e^{-k\tau})] / e^{-kt'}$$

$C'_{t(ss)}$ is equal to the new desired measured peak concentration at steady state, that is, 15 mg/L; and $e^{-kt'}$ represents the decline in concentration between the end of the bolus and the measured peak, that is, 1 hour. Therefore

$$\text{Dose} = [15\text{mg/L} \times 9.45\ \text{L} \times (1 - e^{-(0.2299)(12)})] / e^{-(0.2299)(1)} = 167\ \text{mg every 12 hours}$$

Step 4

The new steady-state peak and trough can be measured using Equation 28.

$$C_{t'(\text{ss peak})} = 167\ \text{mg} / 9.45\ \text{L} \times [1 / (1 - e^{-(0.2299)(12)})] \times e^{-(0.2299)(1)} = 15.0\ \text{mg/L}$$

The trough is determined by changing t' from 1 to 12 hours.

$$C_{t'(\text{ss trough})} = 167\ \text{mg} / 9.45\ \text{L} \times [1 / (1 - e^{-(0.2299)(12)})] \times e^{-(0.2299)(12)} = 1.2\ \text{mg/L}$$

Example 2

In another patient, 100 mg of the same drug is infused over 60 minutes every 8 hours. The peak concentration measured 1 hour after the end of infusion is 10 mg/L, and the trough concentration measured immediately before the next dose is 2 mg/L. Calculate k, V_d, and the new dose to achieve a measured peak of 15 mg/L and a trough of 1 mg/L.

Step 1

Equations 4 and 5 are used to calculate the elimination rate constant and half-life, respectively.

$$k = [\ln(10) - \ln(2)] / 6\ \text{h} = 0.2682\text{h}^{-1}$$

$$t_{1/2} = 0.693 / 0.2682\text{h}^{-1} = 2.6\ \text{hours}$$

Step 2

Equation 32 is used to solve for V_d.

$$V_d = [R_0 / (C_{t'(ss)} \times k)] \times (1 - e^{-kt_{inf}}) \times [1 / (1 - e^{-k\tau})] \times e^{-kt'}$$

$$V_d = \frac{(100\ \text{mg} / 1\ \text{h}) \times [1 - e^{-(0.2682)}] \times e^{-(0.2682)(1)}}{[10\ \text{mg/L} \times 0.2682\ \text{h}^{-1}] \times [1 - e^{-(0.2682)(8)}]} = 7.6\ \text{L}$$

Step 3

Equation 4 can be rearranged to solve for Δt for a desired peak (15 mg/L) and desired trough (1 mg/L) concentration with a known k. This term is represented as the new dosing interval (τ).

$$\tau = [\ln(15) - \ln(1)] / 0.2682\ \text{h}^{-1} = 10.1\ \text{hours}$$

Because this desired peak concentration is measured 1 hour after a 1-hour infusion, the dosing interval must include the additional 2 hours. Thus the optimal τ = 12.1 hours, which can be rounded to a 12-hour dosing interval.

The new dose is calculated using Equation 33:

$$\text{Dose} = [V_d \times t_{inf} \times C_{t'ss} \times k \times (1 - e^{-kt})] / [(1 - e^{-kt_{inf}}) \times e^{-kt'}]$$

$$\text{Dose} = \frac{[7.6\ \text{L} \times 1\ \text{h} \times 15\ \text{mg/L} \times 0.2682\ \text{h}^{-1} \times (1 - e^{-(0.2682)(12)}]}{[(1 - e^{(0.2682)(1)}) \times e^{-(0.2682)(1)}]} = 164\ \text{mg every 12 hours}$$

Step 4

The new steady-state peak and trough can be measured by using Equation 31.

$$Ct'_{(ss)} = [R_0/\mathrm{Cl}] \times (1 - e^{-\mathrm{kt}_{\mathrm{inf}}}) \times [1/(1 - e^{-k\tau})] \times e^{-kt'}$$
$$= [(164\ \mathrm{mg}/1\ \mathrm{h})/(7.6\ \mathrm{L} \times 0.2682\ \mathrm{h}^{-1})] \times (1 - e^{-(0.2682)(1)}) \times [1/(1 - e^{-(0.2682)(12)})] \times e^{-(0.2682)(1)}$$
$$= 15.0\ \mathrm{mg/L}$$

The trough is determined by changing t' from 1 to 11 hours. This represents the Δt between the end of infusion and the measured trough.

$$C_{t'\,ss\ \mathrm{trough}} = 1.03\ \mathrm{mg/L}$$

EXAMPLES OF SIMPLIFIED BEDSIDE PHARMACOKINETIC DOSE ADJUSTMENTS

In the clinical setting, in which drugs are administered according to dosing intervals of 4, 6, 8, 12, 18, or 24 hours, approximations of pharmacokinetic values can be used to adjust dosages at the bedside using the simple equation for bolus doses (e.g., Equation 8) and calculators without linear regression or logarithmic functions. This approach only applies, however, to drugs that have half-lives that are severalfold longer than the time required for drug administration. Because drugs administered to neonates often have prolonged half-lives compared with the duration of administration, these bedside techniques are readily applicable, particularly for aminoglycosides and vancomycin. At steady state, volume of distribution can be calculated from the trough preceding a dose and the subsequent peak concentration as outlined earlier without adjusting for drug eliminated during administration. The half-life can be closely approximated by dividing the time between the peak and trough concentration (Δt) by the number of times the concentration decreased in half. When a fraction of a half-life has elapsed, the half-life can be approximated by assuming a linear process, whereas in fact it is exponential. If the exact fall in concentration is calculated, the concentration decreases during the first half of a half-life by approximately 59% of the total decrease during that half-life. This decrement introduces a small error, but it is seldom large enough to alter the outcome of the dosage adjustment, because times for drug administration are rounded off to fit fractions of the 24-hour clock.

EXAMPLE 1

Gentamicin, in a dose of 2.5 mg/kg, is infused over 30 minutes every 12 hours, resulting in a steady-state trough concentration of 1.9 mg/L and a peak of 4.5 mg/L, which was sampled 30 minutes after the end of the infusion. Recall that at steady state, the next trough (11 hours after the peak) also will be 1.9 mg/L.

Calculation of V_d

$$\Delta\ \mathrm{Concentration}(\mathrm{mg/L}) = \frac{\mathrm{Dose}\ (\mathrm{mg/kg})}{V_d(\mathrm{L/kg})}$$

$$C_{\mathrm{peak}} - C_{\mathrm{through}} = \frac{2.5\ \mathrm{mg/kg}}{V_d(\mathrm{L/kg})}$$

$$V_d(\mathrm{L/kg}) = \frac{(\mathrm{mg/kg})}{4.5 - 1.9(\mathrm{mg/L})} = 0.96\ \mathrm{L/kg}$$

Calculation of Half-Life

The half-life can be calculated from the time between the peak concentration of 4.5 mg/L and the next trough concentration of 1.9 mg/L.

$$t_{1/2}\#1: \text{Concentration decreases from 4.5 to 2.25 mg/L}$$

$$t_{1/2}\#2: \text{Concentration decreases from 2.25 to 1.12 mg/L}$$

In this example, the concentration decreases from 2.25 to 1.9 mg/L, which represents a decline of 0.35 mg/L during the second half-life, or 31% of the expected decline of 1.12 mg/L (0.35/1.12 = 31%). Thus an estimated 1.31 half-lives has elapsed.

$$t_{1/2} = 11\ \mathrm{h}/1.31\ \text{half-lives} = 8.4\ \text{hours}$$

This result is close to that obtained by the mathematically purer calculation of half-life using Equation 4:

$$t_{1/2} = 0.693/[(\ln 4.5 - \ln 1.9)/11\ \mathrm{h}] = 8.8\ \text{hours}$$

Dosage Adjustment

If the desired peak concentration is 6 mg/L for effective treatment of infection, the volume of distribution can be used to adjust the next dose after reaching the trough of 1.9 mg/L to achieve that concentration.

$$\Delta\ \mathrm{Concentration}\ (\mathrm{mg/L}) = \frac{\mathrm{Dose}\ (\mathrm{mg/kg})}{V_d(\mathrm{L/kg})}$$

$$C_{\mathrm{peak}} - C_{\mathrm{through}} = \frac{2.5\ \mathrm{mg/kg}}{V_d(\mathrm{L/kg})}$$

$$0.96\ \mathrm{L/kg} \times (6 - 1.9)\ (\mathrm{mg/L}) = \mathrm{dose}(\mathrm{mg/kg})$$
$$3.9\ \mathrm{mg/kg} = \mathrm{dose}\ (\mathrm{mg/kg})$$

If the half-life and the dosing interval remain constant, increasing the peak to 6 mg/L will raise the subsequent trough concentration to a level associated with nephrotoxicity (i.e., 2 mg/L). To maintain a trough of approximately 1.5 mg/L, the dosing interval must be increased to two half-lives or 16.8 hours (one half-life elapses as the concentration decreases from 6 to 3 mg/L, and the second as the concentration decreases from 3 to 1.5 mg/L). An additional hour must be added because the dose is infused over 30 minutes and the peak is obtained 30 minutes after the end of infusion. Thus the dosing interval of 17.8 hours is rounded to 18 hours. This regimen will maintain a trough of 1 to 2 mg/L and will achieve a peak of approximately 6 mg/L.

Physicochemical and Structural Properties Regulating Placental Drug Transfer

Evidence has accumulated that essentially all pharmacologic agents, and other exogenous substances as well, are transferred to the embryo and fetus, regardless of whether this transfer is wanted, as in intrauterine nutrition[1] or medical treatment of the fetus,[2-4] or unwanted, with possible teratogenic or toxic fetal effects.[4,5] Because of the increasing numbers of readily available over-the-counter drugs taken as self-medication by women who may be unaware of an early pregnancy or of possible adverse effects to a fetus, demands on public information are growing.[6,7] An appreciation of these considerations is important in designing meaningful toxicokinetic and drug disposition studies.[8] For such studies, it is desirable to identify parameters that determine the extent (total amount) and rate (amount per time) of placental transfer of a specific compound.

METHODOLOGIC APPROACHES

Although investigations of the pharmacokinetics of clinically indicated drugs in the maternal circulation can easily be performed, fetal sampling at earlier gestational stages is restricted to rare procedures (e.g., ultrasound-guided exchange transfusions, termination of pregnancy after maternal ingestion of the drug) and the moment of delivery, when cord blood samples can be obtained. Thus serial sampling usually is not possible, and the transplacental kinetics must be pieced together from many different subjects studied at various times.

Analysis of amniotic fluid leaking after premature rupture of membranes may allow an indirect approach to assessment of the distribution of xenobiotics from the mother to the fetus. As an alternative to fetal blood sampling, Jauniaux and Gulbis[9] introduced coelocentesis to study placental drug transfer in the first trimester, when coelomic and amniotic fluid are important compartments and the permeability of the placenta is greater than at term. Ascertaining the presence or absence of compounds or their metabolites in meconium samples gained from the newborn after birth also can be helpful to obtain qualitative data on intrauterine exposure; this approach already is used to detect maternal drug abuse in pregnancy.[10,11] These methods, however, do not allow use of kinetic models based on blood or plasma samples, which are necessary to allow extrapolating quantitative drug transfer to the fetus and subsequent risk assessment.

When more than one isolated sample is needed to establish a kinetic model (distribution between maternal and fetal circulations), the use of animal models is helpful. Their relevance with regard to human kinetics may be limited, however, because of difficulties in extrapolating the experimental results to humans.[12] Humans and guinea pigs have a hemomonochorial placenta; the rabbit has a hemodichorial placenta; and the rat has a hemotrichorial placenta.

In the rodent, the yolk sac placenta is of paramount importance during the entire period of organogenesis, as well as later in development; the hemoendothelial (hemotrichorial) placenta starts to function from the late organogenesis stage onward.[13-15] By contrast, in monkeys and humans, the yolk sac plays a much more limited and poorly understood role, and the hemomonochorial placenta starts to function at an early stage.[13-15] It is not completely understood how the species differences in placental morphology influence the transfer of exogenous compounds to the embryo and fetus.

If extrapolations from toxicologic in vitro models are planned, then the maternofetal interface must be taken into consideration.[16] The presence of membrane barriers around the developing embryo in the whole-embryo culture system could prevent the water-soluble all-*trans*-retinoyl-β-D-glucuronide from reaching the conceptus and there exerting its teratogenic potential, which, in other models without such lipophilic barrier (e.g., the limb bud organ culture), is equal to the lipid-soluble all-*trans*-retinoic acid.[17] Positron emission tomography–based study of placental transfer using radiolabeled drugs (e.g., ^{11}C-labeled heroin) may become a useful technique but probably will not be suitable for investigations in pregnant women.[18]

Human placenta obtained atraumatically at birth provides a way to investigate the human organ in in vitro perfusion studies.[19] Both maternofetal clearance and fetomaternal clearance can be standardized by comparison with antipyrine clearance. Limitations of these models include the following: The experimental period is limited to a few hours; the only available material is human placenta at term (versus that in early gestational stages, which may be more relevant with regard to toxic effects); and this type of model does not allow the observation of physiologically relevant parameters, such as blood flow (important for rapidly transferred compounds) or plasma protein binding.

PLACENTAL TRANSFER

Both rate and extent of transfer depend on the physicochemical and structural characteristics of drugs, as well as on physiologic characteristics of the maternal–placental–embryonic-fetal unit.[20-26] The concept of the placenta as lipoid membrane is useful to describe the influence of physicochemical characteristics of drugs on their placental transfer. Most drugs cross the placental membranes by diffusion, the rate of which is governed mainly by physicochemical factors according to Fick's law:[20-24,26]

$$\text{Rate of diffusion} = D \times \Delta c \times A / d \quad (1)$$

where A = area of exchange, d = membrane thickness, Δc = drug concentration gradient across the membrane (e.g., difference between maternal and fetal plasma drug concentrations), and D = diffusion constant for the drug.

From this equation, it may be predicted that a large area of placental exchange (A) consisting of membranes with limited thickness (d) favors placental transfer of drugs. A, d, and Δc can be determined in a model; D is far more difficult to predict, however, because it results from the interactions between the membrane and the molecule. The resistance within the tissue layers interposed between the maternal and fetal circulations (compartments) limits the diffusion, which is significant for hydrophilic molecules. In the human placenta, two

layers contribute to diffusional resistance: the trophoblast and the endothelium. Hydrophilic molecules either have to pass through these layers (i.e., the *membrane hypothesis*) or find their way through water-filled channels that extend through the trophoblast and communicate with the intracellular channels of the endothelial layer (i.e., the *aqueous pores hypothesis*). Such a process is known to be present, but it is not efficient in the intestinal mucosa.[27] Rapid placental transfer is therefore related to better lipid solubility and low ionization and protein binding of drugs with a molecular weight less than 500.

The permeability of lipid-soluble substances is much higher. For these substances, therefore placental flux rate is limited mainly by availability of the drug (resulting in the initial maternofetal concentration gradient, Δc) at the area of exchange, which is determined by uterine and umbilical blood flow.[28] In vivo, however, the placenta cannot be described by area and thickness. Indeed, earlier studies noted that as placental thickness and the number of placental layers decreased and the area of exchange increased during gestation, increased placental transfer occurred.[20,22-26] Thornburg and Faber[27] found that in rabbit placenta, the fetal endothelium, which is not markedly altered during pregnancy, is the layer defining the transfer rate of many drugs; area of exchange *(A)* and membrane thickness *(d)* apparently were of secondary importance. The diffusion of drugs across the hemotrichorial placenta (mouse, rat) often is faster than across hemomonochorial placenta (monkey, human) despite greater numbers of placental membranes. The sheep epitheliochorial placenta allows only small molecules to pass its "aqueous pores."

This chapter is concerned primarily with the influence of such physicochemical parameters of drugs on their placental transfer. The foregoing discussion summarizes useful concepts, but the outline of events presented in this section constitutes an oversimplification of a complex process. Thus structural characteristics of drugs must play an important role, although little is known about this important aspect.

PHARMACOKINETIC MODELS OF MATERNOFETAL DRUG EXCHANGE

The rate and the extent of drug transfer to the embryo and fetus are determined by numerous variables, listed in Table 22-1.[12] Several general types of pharmacokinetic concentration-time curves can therefore be observed in the maternofetal unit[12,29,30] (Figure 22-1). Furthermore, the rate of transfer may change during the course of treatment.[31] Model A in Figure 22-1 is applicable for a drug that crosses the placenta rapidly and distributes rapidly within a single fetal compartment, which quickly attains equilibrium with the maternal compartment. Fetal concentrations rapidly rise to reach maternal plasma levels; thereafter, the fetal and maternal curves overlap. When maternofetal exchange is rapid, two additional models are possible: After equilibrium between the maternal and fetal compartments has been attained, fetal concentrations may exceed maternal plasma levels (see curve in model C in Figure 22-1), or they may be less than corresponding maternal plasma levels (see curve in model E). As discussed later on, differential protein binding or a pH gradient in the maternofetal unit may be responsible for the relatively large (curve in model C) or small (curve in model E) extent of fetal drug exposure after equilibrium between the maternal and fetal compartments has been attained.

When the rate of placental transfer is low, model D in Figure 22-1 often is applicable in the maternofetal unit. The rise in drug concentration in the fetus is slow. However, because the transport of drug from the fetus back to the mother also is slow, fetal concentrations exceed maternal plasma levels after the crossover point of the two curves. Thus the fetus can be considered to represent a "deep" or "slow" compartment. A protein binding or pH gradient may affect the fetomaternal concentration gradient after postdistribution equilibrium in model D. In model F, the fetal concentrations never reach the corresponding maternal plasma values because the plasma protein binding or the pH gradient may favor higher maternal than fetal concentrations. Alternatively, efficient metabolism by the fetus or fetal excretion (e.g., into amniotic fluid) also may be responsible for the relatively low fetal drug levels. In model B, which is seldom observed, drug transport is slow from mother to fetus but rapid from fetus to mother. This situation implies an active or facilitated transport system, which typically is not a feature of therapeutic agents.

Such considerations in defining models may appear on first glance to be of theoretical interest only. These models are of

extreme importance, however, in interpreting results from experimental and clinical studies. When kinetic curves are inadequately defined, results may be completely misinterpreted. Owing to ethical and practical limitations, often only one or a few fetomaternal sample pairs are available for analysis in clinical studies. If these samples were taken before crossover (see model C in Figure 22-1), for example, the wrong conclusion (i.e., relatively low fetal exposure) could be reached. For an adequate description of fetal exposure, both the maternal and the fetal concentration-time curves must be defined. Although such complete data on placental transfer are rare, attempts have been made to assign the kinetics of some drugs, on a tentative basis, to the models defined in Figure 22-1; the results of various studies are compiled in Box 22-1.

The foregoing discussion makes clear why it is difficult to identify parameters that determine the placental transfer of drugs. The selection of the correct model is a prerequisite for rational interpretation of the relative importance of such parameters, such as physicochemical properties of drugs.[32] Drugs have the greatest chance of crossing the placenta if they (1) are lipid-soluble, (2) are weak acids, and (3) are of a low molecular weight (less than 500). Another important factor is protein binding.[8]

LIPID SOLUBILITY OF DRUGS

According to the basic concept of drug diffusion through a lipoid barrier, lipophilic drugs (high lipid–water partition coefficient *K*—poor water solubility) should be rapidly transferred across the placenta (panels on the *left* in Figure 22-1); the reverse should be true for hydrophilic drugs (low lipid–water partition coefficient *K*—high water solubility).[20-24,27,33] Thus substances such as thiopental, secobarbital, propofol, and antipyrine cross the placenta extremely rapidly.[20,26,34]

In the pregnant rat, the parathion metabolite *p*-nitrophenol is rapidly transferred into the fetus, where its elimination half-time is the longest of all tissues examined.[35] Bisphenol A reaches peak levels in maternal blood and fetus 20 minutes after oral administration of a single dose to the rat, with the fetal concentration attaining approximately 60% of the level detected in maternal blood.[36] Cocaine, a weak base characterized by high lipid solubility, low molecular weight (305), and low plasma protein binding (8% to 10%), quickly equilibrates between the maternal and fetal compartments, as does its metabolite cocaethylene.[37-40] More polar compounds, such as the barbiturates butethal and phenobarbital or the more hydrophilic cocaine metabolite benzoylgonine, cross the placenta more slowly. The highly lipid-soluble benzodiazepine receptor agonist abecarnil (log $P = 4.6$) reaches higher concentrations in blood of the rabbit fetus than in maternal blood, whereas its highly polar and consequently hydrophilic metabolites cannot cross the placental barrier to the same extent.[40] Although no particular influence of lipophilia or other chemostructural properties determining the extent of maternofetal transfer of a group of opioids (fentanyl > alfentanil > sufentanil) was observed, especially in the event of fluctuation in maternal flow, lipophilicity was found to be an important factor when the opioid transfer is compared with that of antipyrine.[41] Another highly lipophilic opiate, buprenorphine (with a molecular weight of 504.1 and extensive binding to α- and β-globulins but barely detectable binding to albumin), shows marked sequestration to tissues including the placenta but only a low rate of transplacental transfer (less than 10%), in spite of its high lipid solubility. These properties could explain why neonates born to mothers treated with buprenorphine during pregnancy rarely demonstrate withdrawal signs and symptoms.[42]

Comparison of the in vitro maternal-fetal gradients of antibiotics used to treat mother and fetus for perinatal infections (e.g., chorioamnionitis) or conditions associated with an increased risk for infection (e.g., prolonged rupture of membranes) revealed extremely limited placental transfer of clavulanate and ticarcillin despite low plasma protein binding (9% and 45%, respectively) and molecular weight (236 and 428) for these drugs. The equally large but more lipophilic molecule ceftizoxime (with less than 30% protein binding and a molecular weight of 406) reaches higher concentrations in the fetus than in the mother.[43,44]

Exogenous bases such as 2′,3′-dideoxyinosine and 2′,3′-dideoxycytidine and the more lipophilic antiviral drug

TCDD, 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin.

azidothymidine cross the placental barrier rapidly by simple diffusion.[45-47] The purine derivative 2′,3′-dideoxyinosine, however, crosses the placental barrier more slowly than the pyrimidines.[45,48] Again, a marked difference between their partition coefficients has been reported, with $P_{azidothymidine}$ = 0.86 to 1.26, as opposed to $P_{dideoxyinosine}$ = 0.07 to 0.32.[48] In vitro, and in women before termination of pregnancy, therapeutic maternal levels of azidothymidine resulted in fetal levels within the therapeutic range as well.[49,50] In one study, umbilical cord sample levels ranged as high as 113% to 127% of maternal levels, probably reflecting the prolonged elimination half-life in the newborn.[51] This finding raises the possibility of efficacious preventive treatment for the conceptus but also points to a high potential for adverse fetal effects. Within the human placenta, the drug is metabolized to more polar and still-undefined metabolites, which are not released into the perfusates, probably as a consequence of their reduced lipid solubility.[52] A more polar glucuronidated metabolite could cross the human perfused placenta at approximately half the rate observed for azidothymidine.[52] Tuntland and colleagues[53] proposed models that predict the extent of placental transfer of dioxynucleoside drugs. Predicted fetal-maternal steady-state plasma concentration ratios using their in vitro partition coefficient model deviated from observed values by only 3.9% ± 79% (mean % ± SD). In vivo and in vitro clearance indices were highly and significantly related to the drug octanol-water partition coefficient[53] (Figure 22-2, *A*).

Another drug in the same group of compounds is acyclovir, which is taken orally by women with recurrent genital herpes simplex infections during late pregnancy to reduce the risk of transmission of herpes simplex to the fetus. As a lipophilic compound with low plasma binding (22% to 33%), it also appears to be quickly transferred by simple diffusion.[54] The highest levels of this compound were measured in the amniotic fluid, probably secondary to unchanged renal excretion of the drug by the fetus, thus providing additional protection against ascending viral infection.[54] Placental transfer of hydrophilic substances is proportional to the coefficient of free diffusion in water, with some evidence of steric restriction of larger molecules (see Figure 22-2, *B*).[27]

The relationship between partition coefficients and placental transfer does not hold for drugs with a high or low value for the partition coefficient *K*. If *K* is large, the substance may be so tightly bound to membranes or other cell constituents (proteins, lipids) that it cannot readily cross into an aqueous phase from the lipid phase. Examples of drugs in this category are cyclosporine and chlorinated aromatics, such as 2,3,7,8,-tetrachlorodibenzo-*p*-dioxin (TCDD), which are extremely lipophilic but are transferred to the embryo and fetus in minute amounts only.[55,56] These drugs are stored in maternal liver and fat. Therefore the low fat content of the conceptus may be an additional factor limiting the placental transfer of these compounds. This concept is supported by the finding that TCDD is efficiently transferred by mother's milk, which contains a high level of fat.[57] Phylloquinone (vitamin K_1), supplemented in pregnant women whose infants are at risk for spontaneous hemorrhage, is another compound that despite its high lipophilicity is transferred through the human placenta (at

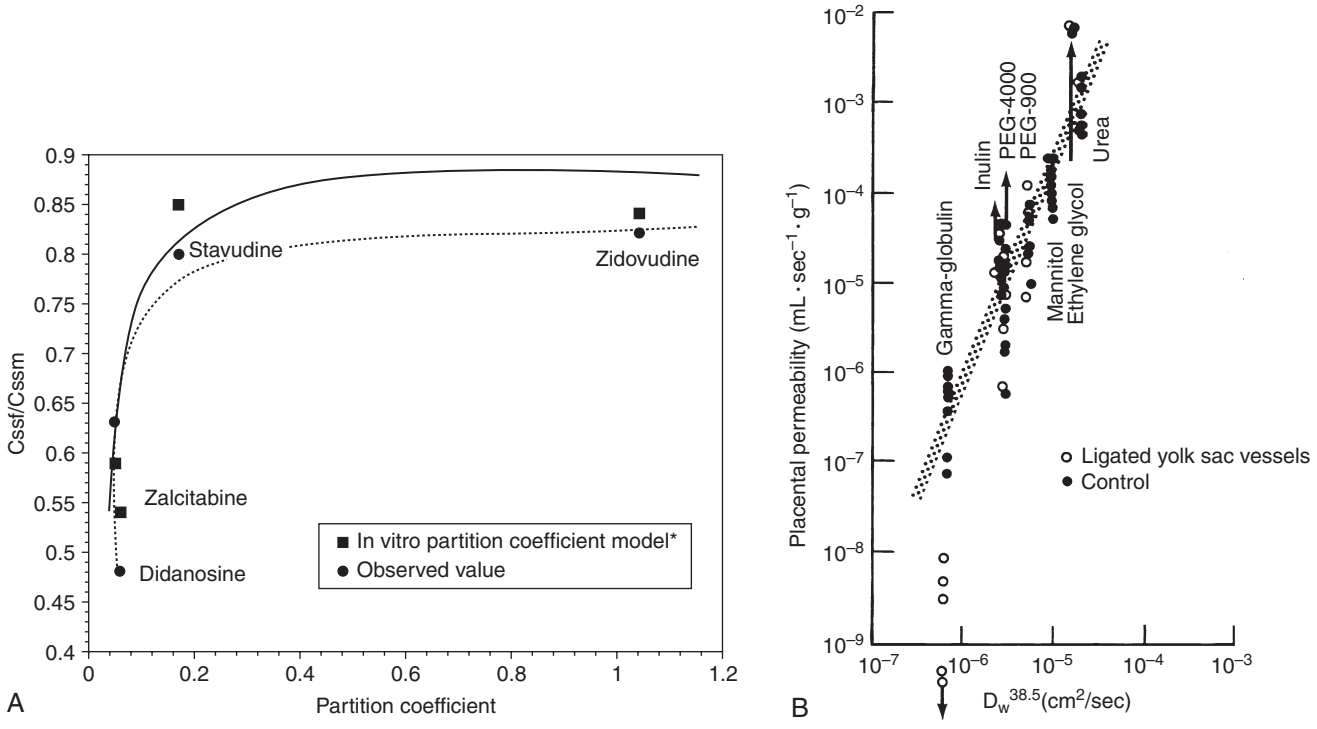

Figure 22-2 A, Comparison of an observed and in vitro partition coefficient model of predicted fetal-maternal steady-state plasma concentration ratios ($C_{ss\,f}/C_{ss\,m}$). Details regarding the model can be found in the original publication by Tuntland and associates.[53] The octanol-water partition coefficient is taken as the mean of reported values. **B,** Permeability of guinea pig placenta in fetuses with *(closed circles)* and without *(open circles)* intact vitelline circulations, as functions of coefficients of free diffusion in water at 38.5° C. The linear regression line is a least-squares fit of a logarithmically transformed datum, and the *shaded area* is the 95% confidence interval of means. γ-Globulin data are shown but were not used in computation of regression, because γ-globulin transfer is not a diffusional process in chorioallantoic placenta. *PEG,* Polyethylene glycol. *(**A,** Modified from Tuntland T, Odinecs A, Pereira CM, et al: In vitro models to predict the in vivo mechanism, rate and extent of placental transfer of dideoxynucleoside drugs against human immunodeficiency virus,* Am J Obstet Gynecol *180:198, 1999; **B,** from Thornburg KL, Faber JJ: Transfer of hydrophilic molecules by placenta and yolk sac of the guinea pig,* Am J Physiol *2:C111, 1977.)*

22 to 34 gestational weeks) only slowly and in minor quantities.[58] Data suggest, however, that if with an adequate lag period between maternal supplementation and delivery, maternofetal transport of the vitamin can be enhanced.[58]

In the perfused term rat placenta, hydrophilic *p*-aminobenzoic acid crosses to the fetal compartment more readily than does lipophilic antipyrine. The mechanism of its transplacental passage is not clear.[59]

IONIZATION OF DRUGS

Most drugs are weakly acidic or basic substances and are thus ionized at physiologic pH. Passive diffusion across lipophilic membranes depends on the degree of ionization. Only the nonionized (lipophilic) portion of the drug is assumed to pass readily through the lipoid barriers, whereas the ionized form carries a charge and is therefore polar, so it cannot pass through the membranes.

This generalization is true for quaternary ammonium compounds, such as neuromuscular blocking agents, which are fully ionized (e.g., dimethyltubocurarine, pancuronium, succinylcholine).[60-64] After maternal administration, fetal drug levels increase slowly up to levels that are only approximately 10% of corresponding maternal plasma concentrations (see model F in Figure 22-1 and Box 22-1), during both early[60] and late[61] gestation. Transfer of these compounds is confined to water-filled pores within the lipid membranes—a mechanism much less efficient than transfer across the lipid portions of the membranes.

This rule does not apply to all highly ionized substances. Weak acids, which constitute an important group of drugs, appear to be rapidly transferred across the placenta. Salicylate[65,66] and valproate (valproic acid [VPA]),[5,67-69] two drugs essentially fully ionized at physiologic pH, are rapidly transported to the conceptus. Fetal salicylate concentrations reach corresponding maternal levels approximately 1 hour after administration;[66] in mouse and rat, transplacental equilibrium of VPA between embryonic and maternal compartments was reached in less than 0.5 hour.[70-72] Similar observations have been made for the antibiotics ampicillin and methicillin.[4] It seems that the small portions of nonionized drug are responsible for the efficient transport across the membranes; the equilibrium between the ionized and the nonionized form is rapidly reestablished for further transfer of nonionized drug.

The importance of ionization is supported by studies using the perfused human placenta. One such investigation compared the maternal-fetal clearance ratios of VPA and its glucuronides—β-glucuronidase–susceptible (VPA-G) and non–β-glucuronidase–susceptible (VPA-GR, in which R denotes *resistant*). The glucuronidated acids characterized by partition coefficients of 0.0141 and 0.219 (compared with 1.6 for VPA) were expected to have negative log of dissociation constant (pK_a) values between 3 and 4, resulting in higher ionization compared with VPA. As expected, the placental transfer was found to be significantly lower for the glucuronides (13% and 17%, compared with 95% for VPA). Furthermore, although transport was positively correlated with log partition coefficient, no significant dependence on molecular weight was noted.[73] In vivo, similar observations were made concerning lower placental transfer of glucuronidated retinoids in the rabbit.[74] Barbiturates[20] and ascorbate[75] also are efficiently transferred to the fetus.

Similar reasons may underlie the efficient transfer of some basic substances, such as the tertiary phenothiazines, meperidine, nicotine,[39,76,77] and lysergic acid diethylamide (LSD).[78] As noted earlier, the nonionized portion (in rapid equilibrium with the ionized form) of a drug may cross to the conceptus. Lead and metallic mercury can be transferred from the blood of occupationally exposed mothers to the fetus.[79,80]

In late gestation, the pH of fetal blood is 0.1 to 0.15 unit lower than the pH in maternal blood.[20] This pH gradient between fetal and maternal blood influences the extent of transfer of acidic and basic drugs. As discussed earlier, only the nonionized form of a drug can readily pass the lipoid membranes. Because basic drugs are ionized at the relatively low (acidic) pH of fetal blood to a higher degree than in maternal blood, this class of drugs accumulates in fetal blood *(ion trapping)* (models C and D in Figure 22-1). The reverse is true for acidic drugs, which reach lower concentrations in fetal than in maternal blood in late gestation (models E and F in Figure 22-1). The ratio between the fetal and maternal concentrations ($C_{fetal}/C_{maternal}$) for a particular drug can be calculated using the Henderson-Hasselbalch equation from the pK_a of the drug and the fetal and maternal blood pH:

$$\frac{C_{fetal,\ free}}{C_{maternal,\ free}} = \frac{1 + 10^{(pk_a - pH,\ fetal)}}{1 + 10^{(pk_a - pH,\ maternal)}} \quad (2)$$

The pH gradient determines the concentration gradient of *free* concentrations, which are unbound to plasma proteins. The *total* concentrations (free and protein-bound) are determined by the protein-binding gradient across the placenta (see later). Basic drugs such as amide-type local anesthetic agents are ionized to a greater degree in fetal blood than in maternal blood. Therefore the free concentrations of drugs such as lidocaine, bupivacaine, 2-chlorprocaine, ropivacaine, and pethidine accumulate at considerably higher levels in fetal blood (by a factor of approximately 1.5)[81,82] (Table 22-2). An obvious influence of the fetal pH on maternofetal clearance of bupivacaine and ropivacaine has been demonstrated in vitro.[83] The total concentrations of these drugs are, however, much lower in fetal than in maternal blood because of low fetal protein binding (see later).

Low fetal-maternal total concentration ratios do not imply minor or no effects on the fetus. Both the pharmacologic effects and the toxicologic actions of a drug usually are associated with the free, but not the total, drug concentration. Indeed, fetal side effects of amide-type local anesthetic agents are related to the pH gradient across the placenta and not to the protein-binding gradient.[82] A fall in fetal pH (fetal acidosis as in fetal distress), particularly if accompanied by a rise in maternal pH (maternal alkalosis from hyperventilation), increases the fetomaternal pH gradient and increases fetal drug accumulation and the risk of fetal side effects. This correlation has been observed in experimental and clinical studies for both lidocaine[84-86] and bupivacaine.[87-89] The reverse would be expected with regard to the effects of the fetomaternal pH gradient on the extent of placental transfer of acidic drugs. In agreement with the pH partition hypothesis, the fetal free concentrations of VPA were lower than the corresponding maternal values (fetomaternal free concentration gradient was 0.82 ± 0.34 in one study).[90] Again, the concentration gradient of the total levels was quite different. Owing to decreased maternal plasma protein binding (see later), the total concentrations in fetal plasma exceeded those in maternal plasma by a factor of 1.7.[68,90]

The pH partition hypothesis is supported by data in experimental animals that indicate that the transplacental distribution of salicylate is affected by maternal acidosis. Treatment of pregnant rats with ammonium chloride decreases maternal pH and increases the fetomaternal concentration gradient.[91] Maternal acidosis during treatment with VPA can be expected during or after prolonged epileptic seizures. Acetylsalicylic acid often is taken by patients suffering from pyrexia, which under certain conditions also can be associated with acidosis. Low-dose aspirin is used to treat pregnancy-induced hypertension. Acetylsalicylic acid transfers rapidly and reaches a steady state in the perfused placental cotyledon model.[92] Maternal acidosis in the course of the illness may lead to a significant fetomaternal gradient.

Little is known of the plasma and embryonic tissue pH during early human gestational periods. The period between week 3 and weeks 6 to 8 after conception may be particularly important for the formation of major malformations, such as those found after

intake of thalidomide or retinoids. Studies during similar early periods of organogenesis in mouse, rat, and monkey have yielded surprising and potentially important results. The intracellular pH (pH_i), as determined by distribution of the weak acid dimethadione, is surprisingly high during early organogenesis.[70,93,94] Embryonic pH_i considerably exceeded corresponding maternal plasma pH at that period and decreased during later developmental periods to approach values similar to those for other tissues. By comparison, maternal muscle pH remained low (6.9 and 7.0) during all developmental periods.

An acidic drug such as VPA would be expected to be ionized to a greater degree in the relatively basic milieu of the early embryo. Based on the pK_a of VPA (4.7), the pH partition hypothesis predicts a concentration of the drug in the embryo twice as high as that in maternal plasma, and this has been confirmed experimentally[70,93] (Table 22-3). The pH_i of the embryo decreases with advancing gestation; thus, in agreement with the pH partition hypothesis, so does the embryonic-maternal concentration gradient. Salicylate, dimethadione, metabolites of halothane (trichloroacetic acid) and methoxyethanol (methoxyacetic acid), and acidic thalidomide metabolites also accumulate in the early rodent embryo (see Table 22-3).[70] It has been hypothesized that acidic metabolites formed by hydrolysis of thalidomide within the embryo may be trapped there because of their high polarity.[95-97] The pH hypothesis is just as likely to provide an explanation for the embryonic accumulation of these acidic metabolites.

Neutral drugs, such as the anticonvulsants valpromide and ethosuximide (see Table 22-3), should not be affected by transplacental pH gradient. Concentrations of these two drugs in the embryo are essentially the same as corresponding concentrations in maternal plasma.

Certain human teratogens or their metabolites are weakly acidic substances, such as VPA, trimethadione (metabolite: dimethadione), phenytoin, thalidomide (glutamic acid derivatives as metabolites), warfarin, isotretinoin, and etretinate (metabolite etretin). Basic drugs are not represented in lists of human teratogens. Perhaps the reason for the predominance of acidic drugs in the list of human teratogens stems is that these substances accumulate in the early embryo, resulting in unexpectedly high-level "exposure" relative to that incurred by the maternal organism. Some weak acids may be teratogenic because they can alter the pH_i of the embryonic cell. This concept is attractive as a general mechanism of teratogenesis because the pH controls numerous cellular functions, including proliferation and intercellular communication. Structure-activity studies are required to answer some of these questions. Certainly, the finding that some

related substances without an acid function do not accumulate in the embryo and exhibit low teratogenic potency supports the hypothesis of a special significance of the acid function in teratogenicity.

PROTEIN BINDING OF DRUGS

Protein binding of xenobiotics can occur in maternal blood plasma and other maternal tissues, in placental tissues, and in fetal blood plasma and other fetal tissues. Therefore not only may drugs from the maternal plasma cross the placenta, but also a portion that initially was bound to placental proteins, acting as a temporary sink, may diffuse to the conceptus later. In the human placenta, the transfer of some drugs, including vinblastine,[98] vincristine,[98] cyclosporine,[99] and digoxin,[98,100] appears to be regulated by an adenosine triphosphate (ATP)-dependent membrane protein, P-glycoprotein, presumably protecting the fetus from toxic substances.[98] Rifabutin, being more lipophilic than rifampin, has a greater clearance in the single-cotyledon perfusion system; however, because of its trend toward greater disposition in the placental tissue, accumulation in the fetal circulation may be proportionately less.[101] Placental binding and metabolism are not discussed in this chapter.

Plasma protein binding may affect both the rate and the extent of placental drug transfer (see Table 22-1). The plasma proteins have two functions: For the drugs bound to them they serve as *vehicles* allowing the drug to be transported, although, depending on the affinity of compound, they may impair transfer. Conversely, they offer binding sites on the other side of the placental barrier, *acceptors,* that potentially allow for additional transfer.

Maternal plasma protein binding is a limiting factor for drugs that are transferred through placental membranes relatively slowly. Only the portion of the drug unbound to proteins ("free drug") is available for placental transfer, and it takes considerable time to reach distribution equilibrium between the maternal and fetal compartments. Here the permeability across the placenta is rate-limiting, and the plasma protein-bound fraction can be regarded as a storage bin or reservoir of drug.

Many lipophilic drugs, which are highly protein-bound, actually permeate the placenta rapidly. Plasma protein binding is rapidly reversible and may even increase the amount transferred by presenting more drug to the placenta. Here, plasma protein binding plays a transport role, serving as a vehicle especially for drugs with poor water solubility, which otherwise would not reach the placenta in large amounts. Protein binding depends on the concentration of the protein (P) to which the drug is bound as well as on the binding affinity constant (K_a) and the number of binding sites available (n):

$$B/F = n \times K_a \times P \quad (3)$$

where B/F is the ratio of bound concentration to free concentration of drug.

The importance of protein binding, however, depends on the degree of binding; a clinically significant effect is expected only when it exceeds approximately 80%.[102] This may account for the failure to detect differences in transplacental transfer between methimazole (no binding to plasma proteins) and propylthiouracil (67% bound to albumin) in vitro.[103] Little information is available on the effects of maternal or fetal hypoproteinemia on placental drug transfer. In a study by Brown and colleagues,[104] fetal (umbilical cord) serum concentrations of the antibiotic cefazolin in human newborns suffering from hydrops fetalis were not different from those obtained from nonhydropic infants. Conversely, no transfer was observed in the presence of little albumin (1 mg/mL) in the perfused human placental cotyledon,[105] and indeed, low digoxin levels have been found in transplacentally treated human fetuses suffering from severe rhesus disease, resulting in hypoproteinemia.[106] In vitro, the transplacental transfer of olanzapine (plasma binding in vitro: albumin, 90%; α_1-acid glycoprotein, 77%) was largely dependent on the concentration of acceptor proteins on the opposite side of initial drug placement.[107]

Convincing evidence indicates that the binding affinity or the number of binding sites of fetal proteins is similar to that of maternal proteins (see later).[108-110] Therefore the extent of placental transfer is determined by the relative concentrations of the binding proteins in maternal and fetal blood.[111] Two major binding proteins are known: albumin and α_1-acid glycoprotein. The fetal-maternal concentration ratios of these two proteins differ greatly from each other (Table 22-4). At the end of the first trimester and the beginning of the second, fetal albumin concentrations are approximately 30% of corresponding maternal levels, increasing during gestation to reach maternal levels during the third trimester. At the time of birth, fetal albumin levels even exceed corresponding maternal values[112-115] (Figure 22-3). Fetal α_1-acid glycoprotein concentrations are low during early gestation (reaching only 10% of maternal values by the end of the first trimester and the beginning of the second trimester) and then slowly increase to reach approximately one third of corresponding maternal concentrations during late gestation (see Table 22-4).[112,114]

Therefore the development of a fetomaternal plasma protein-binding gradient (and thus the extent of the placental transfer) for a particular drug depends greatly on the nature of the binding protein. This correspondence is exemplified by a comparison of fetal and maternal protein binding of diazepam,[114] VPA,[113] and propranolol[114] (Table 22-5). The first two drugs are bound predominantly to albumin; consequently, protein binding is low in fetal plasma during early to midgestation but increases steadily to reach an extent that exceeds maternal binding at term (Figure 22-4; see also Figure 22-3). Propranolol is bound predominantly to α_1-acid glycoprotein; consequently, protein binding is low in fetal plasma during early and midgestation but does not significantly increase during later gestational periods.

Protein binding is defined either as the percentage of drug bound ($C_{bound}/C_{total} \times 100$) or as the unbound (free) fraction ($C_{unbound}/C_{total}$). The fetal-maternal concentration ratio of total drug at postdistributive equilibrium can therefore be predicted as follows:

TABLE 22-4

Human Maternal and Fetal Serum Albumin and α_1-Acid Glycoprotein Concentrations During Gestation

F, Fetal; *M,* maternal.

$$\frac{C_{fetal,\ total}}{C_{maternal,\ total}} = \frac{\text{unbound fraction (mother)}}{\text{unbound fraction (fetus)}} \quad (4)$$

If the drug is an electrolyte, the pH difference between fetal and maternal blood has to be taken into account:

$$\frac{C_{fetal,\ total}}{C_{maternal,\ total}} = \frac{1 + 10^{(pk_a,\ fetal)}}{1 + 10^{(pk_a - pH,\ maternal)}} \frac{\text{unbound fraction (mother)}}{\text{unbound fraction (fetus)}} \quad (5)$$

Such predicted fetal-maternal concentration ratios are indeed in gross agreement with those found in clinical studies for numerous drugs[111] (Table 22-6 and Figure 22-5; see also Figure 22-4).

Owing to the low fetal albumin concentrations during early pregnancy, fetal concentrations of drugs such as VPA are much lower in fetal blood than in maternal plasma during this period (see Figure 22-4).[113] The concentration pattern of albumin and free fatty acids in the maternofetal unit has important implications for the placental transfer of some drugs that are predominantly bound to albumin and the binding of which can be modified by free fatty acids. Free fatty acid concentrations in maternal plasma rise slowly during pregnancy. The free fractions of those drugs, which may be displaced from albumin-binding sites, would therefore also be expected to rise during pregnancy. Decreasing maternal albumin concentrations amplify this effect.[115-118] During birth, maternal plasma free fatty acid concentrations rise sharply to levels two to three times higher than normal concentrations; the free fractions of salicylate,[119-121] diazepam,[116-122] VPA,[69] and *N*-desmethyl diazepam[118] in maternal plasma also rise sharply to values approximately three times those observed for adult control subjects or in cord plasma samples.[115-118] Accordingly, the amount of "free" drug available for placental transfer also is increased. In the fetus, the fatty acid concentrations remain at low levels, and binding of these drugs is therefore not compromised by endogenous ligands.[123,124] Consequently, the fetus acts as a "sink" for these drugs, and fetomaternal plasma concentration gradients for VPA (see Figures 22-4 and 22-5), diazepam, *N*-desmethyl diazepam, and salicylate[125] are significantly higher than unity. Fetal and neonatal distress may be a result of this unexpectedly high total drug load and its partial displacement after birth. Such adverse effects have been observed in neonates of VPA-treated mothers,[126] as well as in neonates and older infants of mothers who received relatively high doses of diazepam *(floppy infant syndrome).*[127-130] This situation may be especially serious for the neonate because the increased free concentrations of these drugs may persist for a prolonged period as a result of the known deficiency of the neonatal drug elimination mechanisms. This effect may be pronounced in critically ill and preterm neonates.

The pattern of protein binding of warfarin[118] in fetal, maternal, and neonatal plasma mirrors that of VPA, diazepam, and salicylate. It may be that free fatty acids increase the albumin binding of warfarin by allosteric interaction. The free fractions of drugs such as phenytoin, phenobarbital, furosemide, and indomethacin

AGP, α_1-Acid glycoprotein; *ALB,* albumin.

also are increased in neonatal and infant plasma[118]; the reasons for these effects are not clear, and other endogenous displacing agents, such as bilirubin, may play a role. Lethargy has been observed, particularly in those neonates with elevated plasma free fraction values of phenobarbital.[131]

MOLECULAR WEIGHT OF DRUGS

Placental transfer cannot be predicted on the basis of protein binding, lipid solubility (partition coefficient), or ionization (dissociation constant) alone. Although warfarin has a good placental passage, the lipophilic superwarfarin brodifacoum appears not to cross the human placenta, which may result from its large molecular structure with a long polycyclic hydrocarbon side chain.[132] Most investigators agree that for drugs of molecular weight greater than 500 to 600, transfer across the human placenta is limited.[2,4] Accordingly, the high molecular weight of erythropoietin is believed to be the reason for its poor placental transfer in the placental perfusion model ex vivo.[133] When four oral hypoglycemic agents were compared with regard to maternofetal transport in the recirculating single-cotyledon human placenta model, it was found that glyburide (with a molecular weight of 494) did not cross the human placenta in significant amounts. The glyburide-antipyrine transport ratio (0.11:0.21) was much lower than the tolbutamide-antipyrine transport ratio (0.74:1.05) (Figure 22-6). The investigators found a highly significant relationship between the mean drug (tolbutamide, chlorpropamide, glipizide, and glyburide) antipyrine transport ratios obtained in their experiment and the independent variables (molecular weight, log partition coefficient, and selected dissociation constants [$R^2 = 0.91$; $p = .0001$]). This relationship was described by the following formula:

$$T^{d} / T^{a} = -4.90 + 0,5 \log (P^{d}) + 1.26\ pK_{a} - 0.0073\ MW^{d} \qquad (6)$$

where T^{d} = placental transport of the drug, T^{a} = placental transport of antipyrine, and MW^{d} = molecular weight of the drug.

Molecular weight was the most important variable in this regression ($F = 61,75$; $p < .001$) and determined the cumulative percentage of transport of the drugs tested. Neither the log partition coefficient nor the dissociation constant individually provided significant associations by simple regression with either the drug-antipyrine ratio or the cumulative percentage of transport of these drugs. Furthermore, the high plasma protein binding of glyburide (99%) could account for this finding, as discussed by Koren.[134] Diazepam has similar physicochemical properties but crosses the placental barrier rapidly.[135,136] These results are consistent with the aqueous pore hypothesis noted previously, according to which higher molecular weights and "unsuitable" molecular structures result in steric inhibition. Frequently used drugs such as the nonsteroidal antiinflammatory agent diclofenac (with a molecular weight of 318.15) readily cross the placenta in the first trimester.[137]

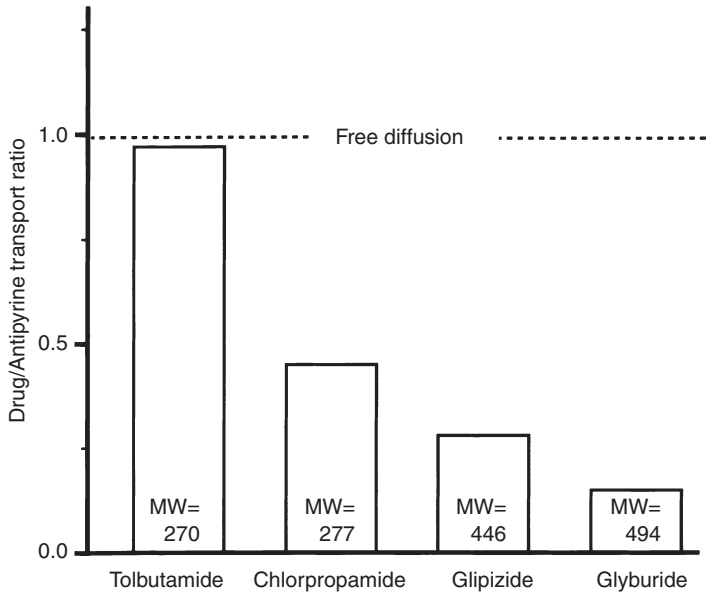

Figure 22-6 Placental transport of four oral hypoglycemic agents in comparison with the freely diffusible substance antipyrine. Values are means. *MW,* Molecular weight. *(Modified from Elliott BD, Schenker S, Langer O, et al: Comparative placental transport of oral hypoglycemic agents in humans: A model of human placental drug transfer,* Am J Obstet Gynecol *171:653, 1994.)*

In vitro heparin does not cross the human term placenta;[138] no biologic activity and very low fractions of radioactivity used for labeling were found in the fetal circulation in the human perfused placental cotyledon model for unfractionated heparin, low-molecular-weight heparin (Cy 216), and dermatan sulfate.[139] These data correspond with clinical observations in newborns whose mothers had been treated with unfractionated heparin or low-molecular-weight heparin.[140] The naturally occurring coagulation inhibitor dermatan sulfate (Desmin 370) (with a molecular weight of 370) cannot pass the ovine placenta at all. Although both molecular weight and charge density of the glycosaminoglycan may account for the placental barrier to heparin, these factors do not explain the failure of the low-molecular-weight dermatan sulfate, which is characterized not only by a smaller molecular size but also by a lower charge density, to cross the placenta.[141]

STEREOSELECTIVITY

Amino acids circulating in the maternal plasma are the primary source of material for protein synthesis by the fetus and also contribute to the fetal energy supply. Amino acids are transferred across the placenta from mother to fetus against a concentration gradient by active, stereospecific placental transport, which functions unidirectionally from the maternal to the fetal side.[142-144] The transfer of neutral branched-chain amino acids is faster than that of neutral straight chains or basic amino acids.[145,146] According to the results of in vitro studies, taurine, β-alanine, and hypotaurine share a specific putative membrane carrier. Histidine also is quickly transported, reaching a maternofetal gradient of 1:2 (1:3 to 1:4 in vivo). It has been suggested that intracellular partitioning or preferential release (transport asymmetry) at the fetal-facing surface of the syncytiotrophoblast may play a role in the placental transport of amino acids.[144] In the guinea pig, the transfer is stereoselective for L-alanine over D-alanine.[147] In the perfused human placenta, S(+)-γ-vinyl-γ-aminobutyric acid was cleared from the maternal circulation more effectively than the R(–)-enantiomer. This more complete clearance, even if it did not result in higher levels in the fetal circulation, suggests either stereoselective sodium-dependent placental uptake on the maternal side of the placenta (as it is known to exist in other tissues) or stereoselective binding to enzymes such as γ-aminobutyric acid transaminase.[148]

The chiral nonsteroidal antiinflammatory drug ketotifen is known to be transferred to the fetus with S-R plasma concentrations averaging 2.3 in premature neonates given a racemic formulation of ketoprofen as a tocolytic agent. Maternal S-R plasma concentrations are close to 1. Because the R(–)-enantiomer does not undergo substantial metabolic inversion in humans, another mechanism had to account for this finding; it appears that stereoselective protein binding results in a higher "free" S(+)-ketotifen concentration with a consequently increased transfer across the placenta (compared with R(–)-ketotifen).[149]

Placental transfer of the water-soluble antiepileptic drug vigabatrin (with a molecular weight of 129), which is unbound to plasma proteins, is low and occurs by simple diffusion. In a human case report, however, a slight difference was found between the kinetics of the entantiomers.[150] The anthelmintic drug albendazole sulfoxide has a chiral center, and the formulations used are racemic. After single-dose oral administration in the last trimester in the ewe, area-under-the-curve ratios of the (–) and (+) enantiomers were 0.36 in the dam) and 0.64 in the fetus, indicating a higher impairment for (+)-albendazole sulfoxide in its placental transfer to the fetus.[151]

The placental transport of retinol and related substances (retinoids) is highly structure-specific. Although in the mouse, rat, and rabbit, retinoids with a free carboxyl group in the 13-*cis* configuration are only poorly transferred early in pregnancy,[152-158] a significant increase in transfer has been demonstrated for later gestational periods in the mouse and in the rat.[159] The β-glucuronide conjugates also show very limited placental transfer (in mouse, rat, rabbit, and monkey).[160] The placental transfer of all-*trans*-retinoic acid (in rat) and all-*trans*-4-oxoretinoic acid (in rabbit) are efficient.[151,158,159,161] The high affinity of the retinoids with the all-*trans* configuration for certain plasma and embryonic cellular binding proteins may be the reason for the efficient transport of these compounds. Binding to plasma albumin cannot explain these differences in transport, because all retinoids with free carboxyl groups bind avidly to albumin and other plasma macromolecules. The increase in glucuronide

transfer in later gestational periods may result from the change in the rodent placental structure from a choriovitelline to a chorioallantoic placenta. In the cynomolgus monkey, a relatively efficient transport for 13-*cis*-retinoic acid has been observed after the chorioallantoic placenta has been fully established.[162] This placenta type is functional at earlier developmental stages in the monkey (and presumably in the human) than in the rodent species; this timing may explain the efficient placental transfer and high teratogenicity of 13-*cis*-retinoic acid when it is administered during early primate organogenesis. The racemic antiepileptic drug ethosuximide appears to be transferred by nonstereoselective diffusion.[163]

SELECTIVE TRANSFER MECHANISMS: ACTIVE TRANSPORT, FACILITATED DIFFUSION, AND PINOCYTOSIS

Available evidence is limited for transfer of therapeutic agents to the embryo or fetus by active transport. Such a transport mechanism would function against a concentration gradient and at the expense of metabolic energy; furthermore, it would be saturable at high substrate concentrations, and it would be competitively inhibited by similar compounds that use the same carrier. Active transport, however, is of great importance for the transfer of endogenous compounds and nutrients, such as amino acids, acetylcholine, vitamin B_{12}, vitamin H (biotin), creatine, and ions such as sodium, potassium, calcium, magnesium, and iron.[164] Folate is preferentially transferred to the fetus.[165] A folate receptor in the placenta may play a crucial role in the transfer of folate to the fetus.[166]

Even though many dideoxynucleosides are at least partially actively transported across cell membranes, this transport mechanism does not appear to be operative for antiviral drugs, such as acyclovir, azidothymidine, dideoxyinosine, and ganciclovir in the human placenta.[167-170] Some evidence, however, supports a carrier-dependent, nucleobase-type uptake in the placenta in addition to diffusional transfer of the drug.[171]

A number of studies suggest that dexamethasone is actively transported across the placenta. In experimental animals (rat, sheep), fetal levels of this steroid are much lower than corresponding maternal values, even after prolonged treatment.[143,172] This low fetal-maternal concentration ratio also has been observed after fetal administration of this glucocorticoid. In addition, sex differences mediated by differential placental transport from the mother have been documented.[173] This concentration gradient is not the result of differential protein binding or metabolism. Placental clearance of dexamethasone from the fetus to the mother is 8.5 times higher than in the reverse direction.[174] The fetomaternal concentration gradient of betamethasone also is low in the human[175]; the reasons for this effect have not been established. Pteridine also is actively transported from the sheep fetus to the mother at a rate that greatly exceeds transport in the reverse direction.[176] [1β-^{3}H]Calcitriol and its metabolites hardly cross the placenta of the rat.[177] The placenta also plays the role of a "metabolic barrier" for endogenous, but not synthetic, estrogens.[178-180] Maternal estradiol does not appear in the fetus but is present there as the less potent estrone and its sulfate conjugate. Placental metabolism may therefore protect the fetus from potent estradiol. By contrast, the synthetic estrogen diethylstilbestrol is transferred to the fetus as the potent parent compound.[178-180] The phytoestrogen daidzein is transferred across the placenta of the rat.[181]

The placental transfer of polypeptides is extremely limited, as has been demonstrated for thyroid hormones, growth hormones, corticotropin, chorionic gonadotropin, erythropoietin,[182] oxytocin,[183,184] interferon,[185] placental lactogen,[29] and protein C.[186] Maternal hormones therefore cannot necessarily influence the development of fetal organ systems when the fetus is deficient in synthesis of its own hormones. Thus fetal endocrine systems function autonomously, and the placenta protects the fetus from exposure to maternal hormones.[29]

The polypeptide atosiban, a synthetic oxytocin antagonist used as a tocolytic agent in women in preterm labor, is transferred minimally to the ovine fetus and under steady-state conditions reaches only 10% of maternal levels in the umbilical cord blood.[183,184] Insulin complexed to antibodies, however, can be transferred to the fetus.[187] This finding is of clinical significance because extremely high concentrations of animal (bovine or porcine) insulin-antibody complex levels were measured in samples of cord blood from infants with macrosomia whose mothers were treated with animal insulin. The transferred insulin must therefore have biologic activity, which may even account for harmful effects such as macrosomia, which is known to be associated with an increased risk for respiratory distress syndrome and hypoglycemia.[188] As the transport of insulin-antibody complexes suggests, proteins are transferred to the fetus to some extent.[189-191] Considerable selectivity, however, has been recognized in the placental transport of proteins. Molecular weight does not play a major role. As discussed previously, polypeptides do not enter the fetal circulation to a significant extent, whereas much larger macromolecules, such as γ-globulins (immunoglobulin G [IgG]) and polyvinylpyrrolidone, are transported. Relatively small fragments of IgG (with molecular weights of 20,000 to 50,000) are poorly transported, as compared with larger fragments (with molecular weights of 50,000 to 82,000) and intact IgG.[192] Therefore binding of IgG is high, resulting in relatively extensive transport of this protein as compared with other proteins such as albumin, transferrin, IgE, IgM, IgA, insulin, and growth hormone, all of which pass the placental membranes to a much lower extent.[190] The process by which antibodies are transported across the placenta appears to be highly selective.

Retinol (vitamin A) is transported to the embryo or fetus bound, at least in part, to retinol-binding protein.[192-194] This transport mechanism appears to be especially important during early gestation because the early embryo is not able to synthesize its own binding protein.[192] In addition, lipoproteins, as well as retinol-binding protein present in large amounts in the yolk sac, may play a role in placental transport of retinol.[193,194]

Water-soluble vitamins are present in higher concentrations in fetal blood than in maternal blood, and active transport mechanisms have been suggested for some of these substances.[195,196] The most extensive data are available for vitamin B_{12}, a polar molecule of high molecular weight (1355) that is not expected to transfer by simple diffusion. A receptor-mediated endocytosis process has been identified as a carrier mechanism for this compound.[164]

In the rabbit placenta, maternal iron is concentrated by a facilitated process as an iron-transferrin complex. This step is followed by a release of iron into the placental cells and return of the apoprotein to the maternal circulation. Thus, in the rabbit placenta, a carrier protein for iron transport may be involved in the process of facilitated diffusion.

In the term human placenta, an electroneutral anion exchange mechanism mediating the transfer of conjugated bile acids across the brush border of the syncytiotrophoblast has been identified.[197] This mechanism could be the basis for previous observations demonstrating higher serum bile acid levels in the umbilical artery (versus the umbilical vein) in human newborns at the time of delivery and suggests a transport of bile acids from the fetal to the maternal circulation.[198]

CLINICAL APPLICATIONS

In a group of drugs with similar pharmacodynamic properties, the efficiency of placental transfer can vary considerably. If no further information is available, comparison of lipid solubility,

protein binding, ionization, and molecular weight may help to select the drug with efficient placental transfer for fetal therapy, as well as the drug with limited placental transfer to prevent effects on the fetus.An example of these considerations has been published in the field of antihypertensive treatment in pregnancy.[199] Oral hypoglycemic agents and biologically active insulin-antibody complexes cross the placental barrier, whereupon they can induce harmful fetal effects such as macrosomia. Newer oral hypoglycemic agents (characterized by a higher molecular weight) cannot pass the placenta; use of such agents may therefore constitute a future alternative to the more invasive insulin therapy in some patients even in pregnancy.[135,200] This finding indicates that identification of structural properties responsible for pharmacodynamic and pharmacokinetic differences is helpful in estimating which drug will be the least hazardous for the fetus if delivery is imminent and maternal pain relief is unavoidable.

A successful reduction in placental transfer of the cytostatic cisplatin was achieved by coupling the drug to cholylglycinate (Bamet-R2)[201]; this finding suggests the possibility of treating certain maternal tumors during pregnancy with a lower risk to the fetus. Liposome encapsulation of VPA reduced placental transfer in the perfused placenta model by 30%, and microencapsulation of chloramphenicol reduced maternal transfer by 85%.[202]

To treat intrauterine infection, broad-spectrum antibiotics that cross the placenta and concentrate in the fetus (e.g., the lipophilic ceftizoxime) are desirable.[203,204] Some investigations have been performed to identify antibiotics with efficient placental transfer rates in the human perfused placenta.[205-211] If only maternal treatment is desired, antibiotics with relatively limited placental transfer, such as macrolides, are favored.[212] Another example is that of treatment for toxoplasmosis: In early pregnancy, spiramycin is preferred because it barely crosses the placenta, where it accumulates. Later, however, when treatment of the fetus is necessary, pyrimethamine is used, because this drug is efficiently transferred to the fetus.[2]

Another indication for intrauterine drug treatment is intentional or accidental drug poisoning. Once the ingested compound has been identified as one that is transferred to the fetus and the ingestion has been confirmed to involve potentially harmful quantities, it is essential that both mother and fetus be adequately treated with an available antidote. Acetaminophen and warfarin-like compounds frequently are used for intentional drug poisonings. Whether the antidotes—*N*-acetylcysteine and vitamin K, respectively—cross the placenta in sufficient degree to ensure effectiveness is still a matter of discussion.[58,132,213,214]

In the ex vivo placenta model, an inhalant (birch pollen major antigen Bet v1, a17-kDa protein) and a nutrient allergen (the cow's milk whey protein beta-lactoglobulin [BLG], with a molecular weight of 18.5 kDa) appear to be actively and selectively transferred across the human placenta.As discussed in this chapter, this phenomenon may be useful as a new preventive strategy for induction of tolerance to specific allergens in the fetus by controlled intrauterine exposure.[215] Estimations for the placental transfer of substances of abuse have been made by Little and VanBeveren using the chemical properties described in this chapter.[216]

23 Pharmacogenetics

Denis M. Grant

Pharmacogenetic disorders constitute a special subclass of genetic disorders (see Chapter 1) that happen to involve proteins functioning in drug metabolism or action.[1] Accordingly, a key distinguishing feature of pharmacogenetic defects is that they often are phenotypically innocuous in the absence of a drug challenge. Pharmacogenetic variants, then, are not life-threatening per se, obviating the need for prenatal genetic diagnosis. For the perinatal pharmacologist, however, genetically based variation in drug disposition in the fetus, the mother, and the neonate must be included among many variables, such as developmental changes in fetal and neonatal gene expression, organ maturation, placental transfer and metabolism of drugs, and a host of hormonal and environmental influences that can combine to produce specific patterns of toxicity in mother and child on exposure to xenobiotics. Therefore knowledge of potential genetic contributions to drug-induced toxicity in pregnancy and neonatal life can be important in ascertaining drug involvement in observed pathophysiologic states and to prevent their further occurrence in patients.

Recent years have witnessed both an explosion of interest in the field of pharmacogenetics and the birth of the related field of "pharmacogenomics," as a result of technological advances in genetic analysis capability and the availability of the complete sequence of the human genome. The terms *pharmacogenetics* and *pharmacogenomics* often are used interchangeably, and indeed the distinction between the two is largely related simply to differences in experimental approach.[2,3] Classic pharmacogenetics—the study of the role of inheritance in producing interindividual differences in drug response—is a "phenotype to genotype" approach that starts with a clinical observation of unexpected drug response, employs a range of biochemical and molecular genetic methods to elucidate its underlying mechanisms, and uses this information in the development of predictive tests that can be applied to the individualization of therapy. Pharmacogenomics, on the other hand, is a "genotype to phenotype" approach that takes advantage of the availability of human genome sequences and modern genomic analysis methods to discover novel disease susceptibility genes and potential drug targets using whole-genome association and linkage methods or more focused candidate gene approaches.

A number of excellent reviews have summarized current knowledge of the molecular biology of pharmacogenetic defects and understanding of their clinical consequences, practical potential, and ethical implications.[3-12] Although many of the best-studied examples are of genetic alterations that affect the biotransformation of drugs, much recent research also has begun to focus on how genetic differences in intended drug targets can directly influence drug efficacy. This chapter provides an overview and examples of some selected pharmacogenetic traits that influence the metabolism of drugs and hence their *pharmacokinetics* (Table 23-1); briefly discussed are some that alter drug targets and hence directly affect their *pharmacodynamics* (Table 23-2). Polymorphic variation in drug transporters (see Table 23-1), although also an important determinant of drug distribution and disposition at sites of action, is not considered in detail here.

PHARMACOGENETIC DEFECTS AFFECTING DRUG PHARMACOKINETICS

Variation in the function of drug-metabolizing enzymes among human populations results in variable drug and metabolite concentrations, and thus has effects that are directly attributable to altered tissue drug levels. Genetic defects in a number of drug-metabolizing enzymes have been well characterized with respect to both their molecular mechanisms and clinical correlates, although evidence is now accumulating that altered drug transporter function also may produce significant phenotypic variation in drug response. In general, the clinical consequences associated with genetically polymorphic drug-metabolizing enzymes may be classified under four main categories:

1. Functional drug overdose in persons unable to eliminate an active drug efficiently
2. Lack of therapeutic effect either in persons who metabolize an active drug too quickly or in those unable to convert a prodrug to its pharmacologically active metabolite
3. Idiosyncratic drug toxicity unrelated to the intended effect of a therapeutic agent (e.g., hypersensitivity reactions, drug-induced lupus, drug-induced birth defects), which may occur more frequently in persons of a particular metabolizer phenotype
4. Apparently spontaneous disorders for which the cause is unknown but presumably is complex and multifactorial, and which may involve drug or chemical exposures

Polymorphisms of Phase I Drug Oxidation

Considering that a majority of lipid-soluble drugs are metabolized at least to some extent through oxidation, predominantly by members of the liver microsomal monooxygenase (cytochrome P-450 [CYP]) enzyme system,[13] it is somewhat surprising that until the mid-1970s, only a few isolated reports of inherited defects of drug oxidation had been published.[14] This scarcity of research may be due largely to the known multiplicity and overlapping substrate specificity of this enzyme superfamily, implying that for many drugs, multiple biotransformation pathways exist. Thus compensatory metabolism by alternate pathways may potentially prevent the clinical manifestations that would be associated with a defect in a particular metabolic reaction. Nonetheless, in the more than 3 decades since the first discovery of a CYP oxidation polymorphism, a large number of genetic defects of drug oxidation have been characterized in considerable detail[15] (see also Table 23-1). Selected examples drawn from known polymorphisms in the CYP superfamily are presented next.

CYP2D6 Oxidation Polymorphism

CYP2D6 oxidation polymorphism, previously reviewed in detail,[16] provided the first clear demonstration of polymorphic drug oxidation involving a CYP enzyme. It also illustrates the classic experimental "phenotype to genotype" paradigm of pharmacogenetic investigation, progressing from initial clinical observation of a variable drug response to an understanding of the biochemical and molecular mechanisms that produce the

TABLE 23-1

Some Genetically Polymorphic Enzymes Associated With Variable Drug Pharmacokinetics

Enzyme	Representative Chemical Affected
Cytochrome P-450 family	
CYP1A1	Benzo[a]pyrene
CYP1A2	Caffeine
CYP1B1	17β-Estradiol
CYP2A6	Nicotine
CYP2A13	Nicotine-derived nitrosamine ketone (NNK)
CYP2B6	Bupropion
CYP2C8	Paclitaxel
CYP2C9	Warfarin
CYP2C19	Omeprazole
CYP2D6	Codeine
CYP2E1	Halothane
CYP2J2	Arachidonic acid
CYP3A4	Cyclosporine
CYP3A5	Nifedipine
CYP3A7	
CYP4B1	2-Aminofluorene
Flavin-dependent monooxygenase (FMO3)	Trimethylamine
Dihydropyrimidine dehydrogenase (DPD)	5-Fluorouracil
NAD(P)H:quinone oxidoreductase (NQO1)	Benzene
Myeloperoxidase (MPO)	Benzo[a]pyrene
Microsomal epoxide hydrolase (EPHX1)	Benzo[a]pyrene-4,5-oxide
Endothelial nitric oxide synthase (eNOS)	Nitric oxide
Butyrylcholinesterase (BCHE)	Succinylcholine
Paraoxonase (PON1)	Paraoxon
Glutathione *S*-transferases	
GSTM1	Nitrogen mustard
GSTT1	Dichloromethane
GSTM3	
GSTP1	
GSTA3	
Arylamine *N*-acetyltransferases	
NAT1	Sulfamethoxazole
NAT2	Isoniazid
Thiopurine *S*-methyltransferase

OCT2	
MRP1	

clinically distinct phenotypes. Such fundamental knowledge can now be applied back to the development and clinical use of predictive tests that may be of value to the clinician in choosing the appropriate type and dose of drug to prescribe to individual patients.

TABLE 23-2

Some Genetically Polymorphic Drug Targets Associated with Variable Pharmacodynamics

Target	Representative Drug Class/Example Drug(s)
Mu (μ) opioid receptor	Opiates, e.g., morphine-6-glucuronide
β_2-Adrenergic receptor	β-Agonists, e.g., albuterol; antagonists, e.g., metoprolol
5-Lipoxygenase (5-LO)	5-LO inhibitors, e.g., montelukast
Bradykinin B2 receptor	ACE inhibitors, e.g., enalapril
Dopamine receptors	Dopamine antagonists, e.g., clozapine
Serotonin transporter	SSRIs, e.g., fluoxetine, paroxetine
Estrogen receptor-α	Conjugated estrogens

ACE, Angiotensin-converting enzyme; *SSRIs,* selective serotonin reuptake inhibitors.

The first clinical observations leading to this discovery were provided during independent studies of the oxytocic agent sparteine[17] and the antihypertensive drug debrisoquine.[18] Wide interpatient variations in the dose of debrisoquine required to achieve a hypotensive response were shown to result from genetic differences in the extent to which the drug is hydroxylated to 4-hydroxydebrisoquine. Using a metabolic ratio of the parent drug to its hydroxylated metabolite excreted in urine after a single oral dose, a bimodal population frequency histogram was observed that divided subjects into extensive metabolizers (EMs) and poor metabolizers (PMs), with PM phenotype frequencies ranging from 3% to 10% in various white populations. At the same time, studies of variations in the response to sparteine showed that a similar percentage of German subjects were almost entirely unable to metabolize the compound to its dehydro metabolites.[17] Correlation studies subsequently established that defective metabolism of debrisoquine and sparteine is under identical genetic control. Because these initial observations, the polymorphism has been shown to control, either fully or partially, the rate of oxidation of a number of other clinically useful drugs as well[16] (Box 23-1). The fact that the debrisoquine-sparteine polymorphism is not a generalized drug oxidation defect, however, is supported by numerous reports showing unimpaired metabolism of a wide variety of other drugs whose metabolic fate depends in general on cytochrome P-450 oxidation.

The clinical consequences of the debrisoquine drug oxidation defect have been thoroughly investigated for a number of the affected drugs in Box 23-1.[16,19] One interesting example is that of codeine, which exerts its analgesic effect predominantly through its conversion to morphine—a reaction mediated by the debrisoquine-oxidizing cytochrome P-450. Thus, in PMs of debrisoquine, codeine is ineffective in the relief of pain.[20] An important point is that although the biotransformation of each of the compounds listed in Box 23-1 is measurably affected by the debrisoquine oxidase polymorphism, not all result in the occurrence of altered drug responses. For example, PMs with a genetic oxidation defect experience a greater incidence of excessive β-blockade and loss of cardioselectivity because of elevated plasma drug concentrations after administration of the β-adrenergic antagonist metoprolol[21] but not after administration of the closely related propranolol,[22] even though both are linked to the oxidation defect. The reason for this difference is that propranolol follows several additional metabolic pathways, which, along with renal elimination, can compensate for defective biotransformation by the debrisoquine oxidizing enzyme. In addition, certain drugs such as quinidine and certain neuroleptic agents are potent inhibitors of the polymorphic enzyme without necessarily being significantly metabolized by it. Coadministration of these with any of the drugs listed in Box 23-1 could then lead to potentially significant drug-drug interactions or even misclassification (phenocopying) of normal persons as genetic PMs.

BOX 23-1

Some Drugs With Oxidation Affected by the Debrisoquine Oxidation (CYP2D6) Polymorphism

Antiarrhythmics
- Encainide
- Flecainide
- *N*-propylajmaline
- Propafenone
- Sparteine
- Aprindine
- Mexiletine

β-Adrenergic Receptor Blockers
- Alprenolol
- Bufuralol
- Carvedilol
- Metoprolol
- Propranolol
- Timolol
- Bunitrolol

Neuroleptics
- Haloperidol
- Perphenazine
- Sertindole
- Thioridazine
- Zuclopenthixol
- Risperidone

Antidepressants
- Amitriptyline
- Brofaromine
- Citalopram
- Clomipramine
- Desipramine
- Fluoxetine
- Ifoxetine
- Imipramine
- Maprotiline
- Mianserin
- Nortriptyline
- Paroxetine
- Selegiline
- Tomoxetine

Other Drugs
- Cinnarizine
- Codeine
- Debrisoquine
- Dexfenfluramine
- Dextromethorphan
- Dihydrocodeine
- Guanoxon
- Hydrocodone
- Phenformin
- Indoramin
- Methoxyamphetamine
- Methoxyphenamine
- Perhexiline
- Terodiline
- Tropisetron
- Tramadol
- Orphenadrine
- Tolterodine
- Tamoxifen
- Dolasteron
- Flunarizine
- MDMA ("ecstasy")
- Mequitazine
- MPTP
- Nicergoline

MDMA, 3,4-Methylenedioxymethamphetamine; *MPTP,* 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

Much progress has been made in determining the biochemical and molecular mechanisms leading to the occurrence of the PM-of-debrisoquine phenotype in human populations. The CYP isoform that is now known to be responsible for the biotransformation of debrisoquine and other affected compounds is designated CYP2D6. Thus far a total of 104 different alleles at the gene locus (*CYP2D6*) encoding the CYP2D6 protein have been detected in human populations, many of which contain sequence alterations that contribute to the occurrence of EM and PM phenotypes.[23] Of note, the underlying basis of a clinical phenotype that generally is considered by clinicians to be rather homogeneous—the poor metabolizer of debrisoquine—is based on a large and heterogeneous set of molecular defects ranging from single-nucleotide substitutions (SNPs), insertions or deletions that change single amino acids and alter enzyme stability or kinetics, to entire gene deletions or duplications that produce either completely absent or elevated function, respectively. As a result, it also is now clear that significant phenotypic differences may exist within as well as between the so-called metabolizer phenotypes. Although such a high degree of allelic multiplicity poses practical problems in devising simple yet reliable molecular tests to predict defective drug oxidation by CYP2D6 and its severity, the rarity of many of the known variants coupled with ongoing improvements to high-throughput genotyping technology may allow for the development of relatively robust and predictive tests for large-scale population studies.[24,25]

CYP2C9 Oxidation Polymorphism

Polymorphic variants of CYP2C9[26] may also be of considerable clinical importance because of the role of this enzyme in metabolizing a number of therapeutically useful drugs, including warfarin, phenytoin, glipizide, and tolbutamide.[27,28] A total of 37 allelic variants are known to exist at the *CYP2C9* gene locus.[29]

The most common of the activity-impaired enzymes arise from the *CYP2C9*2*[30] and *CYP2C9*3*[31] variants, each possessing one SNP that alters a single amino acid and impairs enzyme function significantly. Because of the narrow therapeutic index of the anticoagulant warfarin, significant hypercoagulation-related toxicity from this drug has been observed in persons possessing CYP2C9-defective alleles,[32,33] although it is evident that other environmental factors also play significant roles in determining warfarin plasma concentrations and therapeutic efficacy.[34,35] Similar observations have been made for the anticonvulsant phenytoin, a drug with saturation kinetics and significant dose-related cognitive side effects that are amplified in PMs of CYP2C9.[36] On the other hand, the antihypertensive response to the angiotensin II type 1 receptor antagonist irbesartan is actually improved in persons possessing one defective CYP2C9 allele over that in persons with only wild-type alleles.[37]

CYP2C19 Oxidation Polymorphism

A well-studied cytochrome P-450 polymorphism affects the function of another member of the CYP2 family, CYP2C19. Originally discovered during studies with the seldom-used anticonvulsant

mephenytoin, the defect is now known to affect the function of a small number of commonly prescribed drugs, including the proton pump inhibitors omeprazole, lansoprazole, and pantoprazole and the anxiolytic diazepam.[38] A total of 25 allelic forms of the *CYP2C19* gene have been characterized to date,[39] with two defective alleles making up the bulk of those associated with PM status. The frequency of defective alleles (specifically the *CYP2C19*3* variant) is higher in Asian than in other populations,[40] resulting in an incidence of PM status approaching 20% in many Asian groups compared with approximately 3% in white populations. The efficacy of omeprazole in increasing intragastric pH and in successfully treating peptic ulcer has been shown to be significantly higher in persons possessing defective CYP2C19 alleles,[41] suggesting that dosing regimens for this drug in normal extensive metabolizers in fact may be inadequate. On the other hand, although the clearance of diazepam[42] and the bioactivation of the antimalarial proguanil[43] are altered in PMs of CYP2C19, the clinical consequences of these findings are modest at best.

Polymorphisms of Phase II Drug-Conjugating Enzymes

Arylamine N-Acetyltransferase 2 Polymorphism

The arylamine *N*-acetyltransferase 2 (NAT2) polymorphism (reviewed by Boukouvala and Fakis[44]) lends a special historical perspective to the field of pharmacogenetics. In 1953, high interindividual variation was observed in the urinary excretion of the new tuberculostatic drug isoniazid. This observation was followed by the finding that frequency histograms of plasma isoniazid concentrations after a single oral dose in a normal population were distinctly bimodal, allowing for classification of subjects as "rapid" or "slow" eliminators of the drug. It was soon established that the basis of the observed population variations was related to differences in the rate of arylamine and hydrazine *N*-acetylation taking place to a large extent in the liver.[45] The enzymatic reaction is now known to be catalyzed by a cytosolic arylamine *N*-acetyltransferase (NAT), which uses the essential cofactor acetyl coenzyme A as acetyl group donor to conjugate primary amine and hydrazine nitrogen atoms, or hydroxylamine oxygen atoms with acetate, producing amides, hydrazides, and acetoxy esters.

The clinical and toxicologic consequences of the acetylation polymorphism have been studied in considerable detail. For instance, slow acetylators are more prone to develop a drug-induced systemic lupus erythematosus–like syndrome during prolonged therapy with procainamide or hydralazine, hematologic toxicity from dapsone, or polyneuropathy after isoniazid treatment. The slow acetylator phenotype also appears to be a predisposing factor in the etiology of sulfonamide-induced idiosyncratic adverse drug reactions. In addition, epidemiologic studies suggest an increased risk for bladder cancer in slow acetylators who are exposed to carcinogenic arylamines, which are substrates for NAT, whereas rapid acetylators may be at higher risk for colon cancer. Rapid acetylators also encounter therapeutic failure more often on treatment with once-weekly isoniazid dosage regimens and require higher doses of hydralazine to control hypertension or of dapsone for dermatitis herpetiformis.

Molecular cloning experiments established that two functional human NAT enzymes exist, NAT1 and NAT2, and that genetically based variation in NAT2 is associated with the isoniazid acetylation polymorphism. Work over the past 2 decades has provided direct evidence for the existence of, at last count, 36 variant alleles at the human *NAT2* gene locus that are correlated with the acetylator phenotype.[46] Each of the quantitatively significant human allelic variants possesses a diagnostic combination of nucleotide substitutions (i.e., SNPs) at positions 191, 282, 341, 481, 590, 803, and 857 within the intronless 870–base pair *NAT2* gene coding region. At the level of protein function, the single I114T amino acid change produced by a T341C mutation common to the nine *NAT2*5* alleles drastically reduces V_{max} values for substrate acetylation without altering enzyme affinity or stability, possibly by preventing the proper folding of the nascent polypeptide into its enzymatically active conformation. On the other hand, the mutations causing R197Q (*NAT2*6*), G286E (*NAT2*7*) and R64Q (*NAT2*14*) amino acid substitutions produce proteins with significantly reduced stabilities.[47] The population frequencies of certain of the *NAT2* alleles also show marked interethnic differences.[47] For instance, *NAT2*5B* (I114T) is the most common allele in white populations but is almost entirely absent in Asians, accounting for most of the known interethnic difference in the frequency of the slow acetylator phenotype between these populations. *NAT2*7B* (G286E), on the other hand, is more prevalent in Asians than in white persons.

NAT1 function also is variable in human populations, and at least some of this variation may be genetically determined. The use of the NAT1-selective substrate *p*-aminosalicylic acid as a probe drug has allowed for the identification of probands from whom variant alleles at the *NAT1* gene locus have been isolated and characterized. [48] A total of 26 *NAT1* allelic variants are known,[49] although those recognized to significantly alter function are rare in most human populations. Association studies have attempted to correlate variation in the more common *NAT1* alleles, particularly *NAT1*10*, with susceptibility to a variety of cancers, with equivocal results; the functional consequences of these variants for enzyme activity in vivo are also still unclear.

Thiopurine S-Methyltransferase Polymorphism

Clinical relevance has been clearly demonstrated for a polymorphism that occurs in the drug methylating enzyme thiopurine *S*-methyltransferase (TPMT).[50-52] This enzyme catalyzes the detoxifying methylation of the cytotoxic agent 6-mercaptopurine, a drug commonly used in cancer chemotherapeutic regimens for the treatment of childhood acute lymphoblastic leukemia. The TPMT-catalyzed reaction competes with a reaction that produces cytotoxic thioguanine nucleotides, which constitute the pharmacologically active principle in producing leukemic cell death. Thus, in persons with impaired TPMT function, excessive production of thioguanine nucleotides leads to a higher incidence of adverse reactions to the drug, often necessitating cessation of therapy and drastic dose reduction.[53] To date, 8 variant TPMT alleles have been identified[54]; three of these, *TPMT*2, TPMT*3A,* and *TPMT*3C,* account for 95% of the cases of defective function. Although the frequency of each of the 7 known activity-impairing variants is quite low, such that persons possessing two defective copies number only approximately 1 in 300, functional impairment is observed even in heterozygotes, who make up approximately 11% of a typical white population. Because of the relatively small number of relevant mutations known to impair function, simple genetic diagnostic assays can be devised as guides to dosing regimens in initiating chemotherapy. On the other hand, TPMT expression in blood cells is an accurate reflection of tissue enzyme activity, so a direct blood enzyme assay also is feasible.[55]

PHARMACOGENETIC DEFECTS AFFECTING DRUG PHARMACODYNAMICS

Table 23-2 provides some selected instances in which genetic variation in specific drug targets may influence drug efficacy. Although a detailed discussion of these examples is beyond the scope of this review, a brief summary of one selected instance is presented next. Of note, however, because of the multifactorial nature of many drug responses and physiologic processes, the clinical significance of many of the genetic variants in drug targets observed so far has yet to be conclusively established.[56] In addition, because most drug targets, such as receptors, have important endogenous physiologic roles, the likelihood of

encountering severely function-impairing mutations arising from single-gene defects for many of these proteins is quite low.

β-Adrenergic Receptor Polymorphisms

Variations in the genes encoding β-adrenergic receptors recently have been shown to correlate with a variety of responses to β-agonists as well as to physiologic and pathologic stimuli.[57-60] For instance, recent experimental observations have suggested that allelic variants possessing an arginine at position 16 of the β_2-adrenergic receptor protein impart increased agonist-mediated vascular desensitization, whereas variants with glutamic acid at position 27 have increased agonist-mediated responsiveness.[61] Asthmatic patients who were homozygous for arginine at position 16 of the β_2-adrenergic receptor also were shown to have greater therapeutic response to albuterol for the relief of their airway constriction.[62] Polymorphisms in the β_1-adrenergic receptor have been shown to affect exercise capacity in patients with congestive heart failure[63] and resting hemodynamics in patients undergoing diagnostic testing for ischemia.[64] Finally, it has been suggested that polymorphic variants of the β_3-adrenergic receptor may be risk factors for obesity.[65]

PHARMACOGENETICS IN CONTEXT: GENE REGULATION AND DEVELOPMENT

Pharmacogenetic defects must be considered as only one part of the complex series of genetic and environmental factors that regulate the level and developmental time course of protein expression. Furthermore, many of these variables have potential relevance for the perinatal pharmacologist. For instance, with regard to drug-metabolizing enzymes, differential activation of transcription of cytochrome P-450 and other oxidative metabolism genes at varying stages of prenatal and postnatal development has been shown to produce age-specific isozyme patterns.[66] Different P-450 genes have been shown to be activated immediately after birth, in the months following birth, at the onset of puberty, or according to neonatal imprinting by sex hormone exposure, most notably in rodent species; certain isoforms also may be specifically suppressed at puberty. Significant differences exist between the forms of P-450 expressed before and after birth.[67-69] Of interest, one isoform of the CYP3A family (CYP3A7), which previously was considered to be fetus-specific, has been demonstrated to display both expressions in all fetal livers tested and polymorphic expression among adult human livers.[70] On the other hand, recent studies suggest that differences in the content and activity of cytochromes P-450 in early life are unlikely to account for the increased clearance of many drugs in children.[71]

In addition, it is known that the expression of certain classes of P-450 isozymes is induced (at the level of transcriptional activation) by specific drug or hormonal exposures.[72] For example, polycyclic aromatic hydrocarbons present in cigarette smoke may cause elevation in the liver content of CYP1A isozymes; this response has been shown to be both genetically and developmentally variable.[73] Expression of CYP1A2, which appears to be responsible for the metabolism of caffeine, theophylline, phenacetin, and a variety of aromatic amine procarcinogens, develops slowly (possibly through exposure to environmental inducing agents) over the first several months of extrauterine life,[74] and in women, its activity is drastically impaired during pregnancy.[69] It also has been suggested that a glucocorticoid-inducible P-450 isozyme may be involved in the process of oxygen contracture and subsequent closure of the ductus arteriosus at birth.[75]

The consequences of allelic variation in phase II enzymes for drug therapy also may be important for the pediatric pharmacologist, especially because both genetic and regulatory factors may govern the expression of metabolizing capacity during development.[76] For instance, longitudinal NAT2 acetylator phenotyping studies in developing infants[77] have demonstrated that all neonates are phenotypically slow acetylators, suggesting that the manifestation of the isoniazid acetylation polymorphism develops relatively slowly over the first 1 to 2 years of life. NAT1 activity has been detected in human fetal liver, adrenal glands, lung, kidney, and intestine, although at a lower level than that observed in adult tissues.[78] NAT1 also is present in the placenta[79] and in human preimplantation embryos[80]; in view of its ability to metabolize a catabolite of folic acid,[81] a role for this enzyme in neural tube development has been suggested.[82] As a consequence of the different substrate specificities and tissue-selective patterns of expression of NAT1 and NAT2, exposures to certain arylamine chemicals may be expected to result in different patterns of elimination or toxicity (or both), depending on the levels of expression of these enzymes during fetal and neonatal development. Obviously, further work is required to delineate these patterns of expression and their consequences for drug therapy and toxicity.

From the previous examples, it is apparent that when genetic factors, which may differ between mother and child, interact with such developmental and gene regulatory processes, a vast potential exists for variation in metabolizing capacities for drugs and xenobiotics. Thus clinical outcomes (adverse drug reactions, fetal toxicity) are dependent not only on the chemical agent but also on the genetic constitution of mother and child and the time point of exposure in relation to the functional integrity of the drug biotransformation systems.[83-85]

INTERACTION BETWEEN ONTOGENY AND PHARMACOGENETICS: CLINICAL PEDIATRIC PHARMACOGENETICS

The examples just cited highlight how rapidly the field of pharmacogenetics has grown in the last several years, aided greatly by advances in analytical techniques, cellular assays and most especially genomic technologies. One of the main challenges has been to provide unified approaches to both genotype and phenotype for the handling of specific drugs and other xenobiotics. Recognition of the specificity of drug metabolic pathways and the ability to determine which pathways are critical for handling a new drug before its widespread use in humans may lead to decreased population variability and risk of untoward side effects. Use of in vitro techniques employing human hepatic microsomes (with specific inhibitors of drug metabolizing enzymes) and recombinantly expressed enzymes can determine whether a new drug is likely to be metabolized polymorphically in the population and what other drugs may potentially interact with the new drug to alter its kinetics. In vivo probe compounds (such as dextromethorphan for CYP2D6 and caffeine for NAT2) can help map regulation and development of expression of metabolic pathways safely in large populations. As outlined in the previous section, one of the main challenges in pediatric developmental pharmacology is to integrate the growing body of data on specificity of metabolic pathways with their ontogeny.[66,76]

The interaction of genetics and ontogeny of drug metabolism has been the topic of several reviews.[83-86] For example, the availability of potentially toxic electrophilic metabolites to mediate toxicity often depends on the interaction of several metabolic pathways, one of which may be genetically polymorphic, whereas others are developmentally regulated. Although the genetic abnormality may potentially be critical to the ultimate toxic outcome, risk may be modulated by developmental expression of other pathways, perhaps explaining why some drug-induced toxicities (such as hepatotoxicity from valproic acid[87]) may be more prevalent among younger patients. Knowledge of specificity of metabolic pathways also can help in the design of clinical pharmacokinetic studies of new drugs. For example, if a new drug is metabolized by CYP1A2, an enzyme that appears to develop over the first postnatal year of life and then undergoes

down-regulation during puberty (at earlier Tanner stages in girls than in boys[88]), studying patients by age-groups of 6 to 12 years and 13 to 18 years (with children in various Tanner stages) may lead to increased and difficult-to-interpret variability. It may make better sense to group patients by Tanner stage, studying smaller numbers of more homogeneous patients to assess the effects of puberty on handling of the compound. A similar approach can be taken for the newborn—determining the pathways of clearance for the drug, elucidating the ontogeny of those pathways, and thereby more rationally choosing doses for clinical studies.

As with any new field during a period of rapid scientific expansion, it is difficult to predict the ultimate impact of pharmacogenetics on "real-life" pharmacotherapy. The advances of the last several years, however, suggest that the field will have a direct impact on patient care.[10,12,89-92] The field is clearly expanding beyond just drug metabolism. Molecular approaches will lead to (1) disease susceptibility markers, early preclinical "diagnosis" of disease diathesis for early therapeutic intervention; (2) syndrome diagnostic markers, to determine more specific causes of complex human symptoms and thus improve specificity of therapeutic choices; (3) pharmacogenetic markers for drug metabolism and efficacy variants; and (4) markers to individualize idiosyncratic adverse drug reaction risk, minimizing both individual and population risk of adverse drug effects. Routine availability of molecular diagnostics in the clinical laboratory will usher in a new era for clinical pharmacogenetics.

24 Drug Distribution in Fetal Life

Marianne Garland

Drug distribution and clearance determine the concentration of drug that will be attained at the site of drug action. Drug targets include cell surface receptors, intracellular receptors, enzymes, transcriptional mechanisms, ion channels, and molecular transport systems.These targets may be within the circulatory system, in well-perfused tissues, in less well-perfused tissues, or behind specialized endothelial or epithelial barriers.The fetus lies behind one of these circulatory barriers—the placenta. The placenta keeps the maternal and fetal circulations separate but brings them into close apposition for transport of nutritional needs and removal of waste products. In addition, this interface is the major route of drug delivery to and elimination from the fetus.The fetus also has specialized circulatory arrangements designed for intrauterine life that require additional considerations in the understanding of fetal drug distribution. Furthermore, developmental differences in body composition, drug metabolism, renal clearance, and specialized barriers make fetal drug distribution distinct from that in the infant, child, and adult.

Most drug action is predicted on the basis of plasma drug concentrations. It is not easy, even in experimental models, to measure tissue concentrations, particularly when extracellular versus intracellular concentration warrants consideration. Hence major emphasis is placed on the determinants of fetal plasma concentration. An appreciation of this aspect of pharmacokinetics requires an understanding of physicochemical properties of drugs, placental transfer of drugs, and fetal clearance of drugs. Many of these concepts also pertain to tissue distribution. Drug delivery to the central nervous system of the fetus is of particular interest and serves in this chapter to illustrate the concepts relevant to tissue distribution. In considering developmental

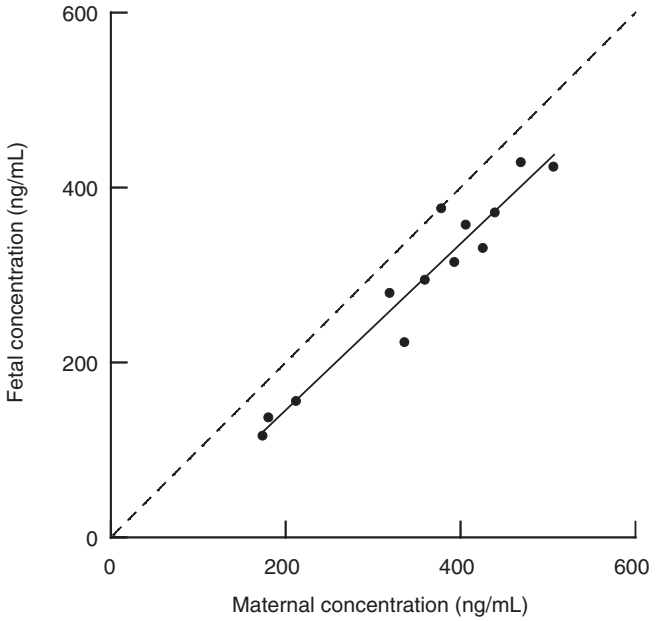

Figure 24-1 Paired fetal and maternal zidovudine concentrations in plasma samples obtained at steady state in the chronically catheterized baboon infused with 150 to 350 μg/minute of zidovudine.

issues relevant to fetal disposition of drugs, an important point is that drug targets also have complex developmental trajectories. Understanding fetal drug distribution may allow prediction of drug concentration at the site of drug action, but prediction of drug action, which is the true goal, requires understanding the interaction between the drug and its target.

DETERMINANTS OF FETAL PLASMA CONCENTRATION

The plasma concentration of the drug in the mother is the main factor determining the fetal plasma concentration. Figure 24-1 shows the concentrations of zidovudine measured in paired samples of maternal and fetal baboon plasma under steady-state conditions.[1] Doubling the maternal concentration essentially doubles the fetal concentration. Of note, the fetal concentration of zidovudine is always slightly less that that in the mother. This observation suggests that other factors also influence the fetal plasma concentration. How placental permeability, fetal drug elimination, drug ionization and protein binding, and, in non–steady-state situations, volumes of distribution affect fetal drug levels is the focus of this chapter.

Once the maternal concentration is known, fetal distribution can be divided into three segments: transfer across the placenta, modification of the fetal plasma concentration, and tissue distribution. In order to describe how differences in these various contributors affect fetal drug levels (be it plasma, extracellular, or intracellular), an integrated pharmacokinetic approach, with graphic representations, is used throughout.

MATERNAL PLASMA CONCENTRATION

The maternal plasma concentration is the driving force for drug delivery to the fetus. For many drugs, physiologic changes of pregnancy lead to altered drug absorption, distribution and clearance in the mother, and thus different plasma concentrations from those seen in the nonpregnant state.[2-9] Overall, plasma drug concentrations tend to be lower in pregnancy. There is an increase in the volume of distribution from an increased plasma volume and increased fat deposition as well as addition of the fetal compartment. Maternal renal clearance is enhanced owing to increased cardiac output and renal blood flow. Hepatic clearance also may be enhanced as a consequence of increased hepatic blood flow or hormonal stimulation of drug-metabolizing enzymes.[10,11] In some cases, however, pregnancy hormones may inhibit drug-metabolizing enzymes.[3] Unfortunately, good comparative data are available for only a small number of drugs. For fetal considerations, these numerous physiologic changes of pregnancy that alter maternal drug distribution can be bypassed by measuring the concentration of the drug in maternal plasma.

DRUG TRANSFER ACROSS THE PLACENTA

The placenta is the specialized interface between mother and fetus across which drug distribution occurs. Most drugs are believed to cross the placenta by passive diffusion; accordingly, the surface area provided by the placenta and the nature of the interface, together with drug characteristics, determine placental permeability. The role of transporters in the placenta is beginning to emerge as a contributor to fetal drug disposition. Transporter activity modifies transfer of several important drugs and is discussed further on.

Structural Development of the Placenta

The following discussion is a synopsis of placental development highlighting the aspects relevant to drug transport,[12] with a focus on the relationship among the maternal and fetal circulations, the surface area of exchange, and the nature of the diffusional barrier.

During implantation, the trophoblastic tissue invades and becomes surrounded by decidua. The placenta develops at the embryonic pole with trophoblast in contact with the rest of the decidua gradually breaking down. Spaces develop within the expanding trophoblastic tissue to form the lacunae that lie between the villous structures. The uterine spiral arteries supplying the decidua and the veins draining the decidua are invaded by trophoblast in such a manner that these maternal vessels open directly into the lacunae and maternal blood bathes the villous structures. Anchoring villi extend the full thickness of the trophoblast layer; most villi have the appearance of treelike structures (Figure 24-2, *A*). As pregnancy advances, the placental surface area increases by increasing the number of villi and the number of branches. As with most epithelial transport surfaces, the luminal plasma membrane of the villus trophoblast has microvilli that further increase surface area (see Figure 24-2, *C*). Later in gestation the diffusional capacity of the placenta increases mostly by thinning of the trophoblast layer where it overlies fetal vessels within the villi. The villus itself consists of a stromal core to support the fetal blood vessels and is surrounded by a single layer of syncytial trophoblast attached to a basement membrane (see Figure 24-2, *B*).[13] Cytotrophoblasts and some Hofbauer cells (placental tissue macrophages) lie between the two. The syncytial trophoblast is a multinucleate cellular structure formed by the fusion of trophoblastic cells to form a syncytium. Underlying cytotrophoblastic cells add to the syncytiotrophoblast by fusion and, near term, few cytotrophoblasts are present within the villus. The fetal arterioles branch into a capillary bed also surrounded by a basement membrane.[14] The capillaries are nonfenestrated and have variably spaced tight junctions between endothelial cells.[15-17] In the mature placenta, the contact zones between the syncytiotrophoblast and endothelial cells are free of nuclei and are thinner than other regions (see Figure 24-2, *B*). The layers between maternal and fetal blood over which diffusion occurs are shown in Figure 24-2, *C*. In addition to the microvillus surface, the luminal membrane of the syncytiotrophoblast (that in contact with maternal blood) contains clefts. The abluminal membrane also has infoldings. The continuous nature of the syncytiotrophoblast precludes

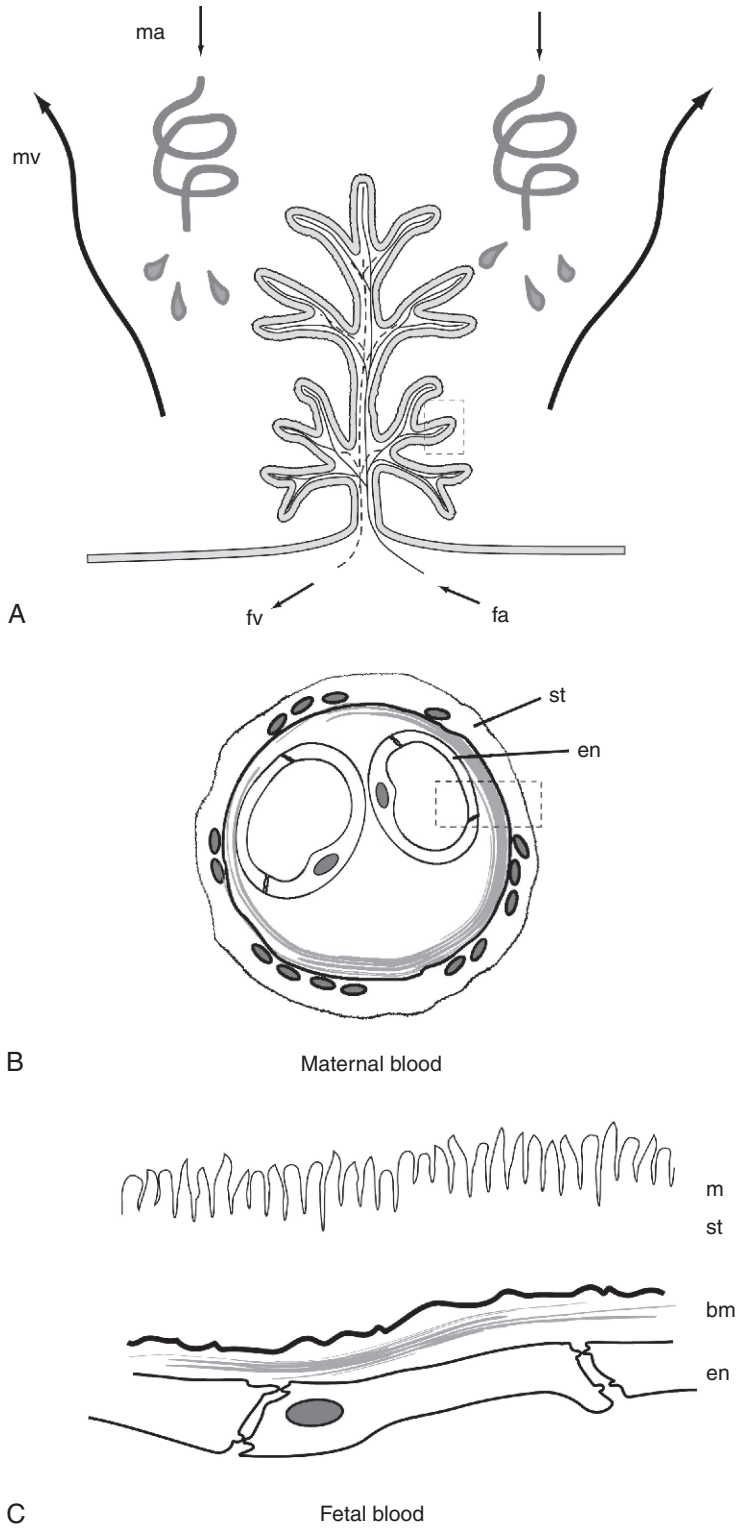

Figure 24-2 Schematic diagram of mature human placental structure. A, The placental villus supports vessels from the fetus and is in direct contact with maternal blood. **B,** The syncytial trophoblast forms a continuous cellular layer over the fetal villi. Areas in close apposition to fetal capillaries are thinner and lack nuclei. **C,** The layers that drugs must cross to transfer from one circulation to the other are depicted. Area surrounded by the *dashed line* is enlarged in the succeeding diagram; *arrows* indicate direction of blood flow. *en,* Endothelium; *fa,* fetal artery; *fv,* fetal vein; *m,* microvilli; *ma,* maternal artery; *mv,* maternal vein; *st,* syncytiotrophoblast.

intercellular spaces through which transport can occur. By contrast, the endothelium does allow some paracellular transport of low-molecular-weight hydrophilic substances. Placental capillaries are less permeable than most other capillaries present in tissues with continuous capillaries; however, they are still more permeable, by two orders of magnitude, than those present in the brain.[17]

Models of Placental Transfer of Drug

From an anatomic perspective, many placental characteristics are important in the transfer of drug to the fetus. The most striking features are the very large exchange surface and the very thin syncytial-endothelial barrier between the circulations, supporting passive transfer of substances (see Figure 24-2). Visualization of the human placental structure suggests a crosscurrent exchange interface; however, experimental data at best support a concurrent model (detailed in Chapter 14, Mechanisms of Transfer Across the Human Placenta).

The simplest and perhaps most illustrative way to view the maternal-fetal dyad with respect to drug distribution is as a two-compartment model[1,18-20] (Figure 24-3). This model differs from the standard peripheral compartment model in that the fetal compartment includes an elimination route independent of the placenta. In addition, at least in experimental models, this compartment can be sampled. Rate equations for the model describe how the amount of drug in each compartment changes with time and are determined by considering how much drug is entering and leaving each compartment. The amount of drug *(D)* that leaves in a given time period (mass/time) equals the clearance (Cl, volume/time) multiplied by the mean concentration (*c*, mass/volume) for that time period as follows (see parameter descriptions in Figure 24-3):

Rate equation for maternal compartment:

$$\frac{dD_m}{dt} = R_m - Cl_m \cdot c_m - Cl_{mf} \cdot c_m + Cl_{fm} \cdot c_f \quad (1)$$

Rate equation for fetal compartment:

$$\frac{dD_f}{dt} = Cl_{mf} \cdot c_m - Cl_{fm} \cdot c_f - Cl_f \cdot c_f \quad (2)$$

Solutions of these rate equations can be used to generate concentration-time plots for each compartment, to illustrate the effects of decreasing placental permeability after administration to the mother of a single oral bolus of drug (Figure 24-4) or when drug is administered as a continuous infusion (Figure 24-5). Both Figures 24-4, *A,* and 24-5, *A,* show the effect of decreasing placental permeability after a single oral bolus of drug (for Figure 24-4) and when drug is administered as a continuous infusion (for Figure 24-5) to the mother. The assumption is that drug crosses the placenta by passive diffusion, so the clearance will be the same in both directions. In Figures 24-4, *A,* and 24-5, *A,* no direct fetal clearance occurs—that is, fetal nonplacental clearance is set at zero. The only parameter that varies is placental clearance. (Figures 24-4, *B-D,* and 24-5, *B-D,* are discussed further on.) Placental permeability will affect peak fetal drug concentrations when administered by bolus, but total fetal drug exposure, represented by the area under the curve, is the same in each case. Under steady-state conditions (obtained with continuous intravenous infusion or repeated bolus doses), for drugs with low placental permeability, fetal levels will be as high as those achieved for highly permeable drugs if continued for an extended time.

A much-debated question is whether fetal drug concentrations can exceed those in the mother with passive placental transfer. During the elimination phase after bolus administration, fetal concentrations are higher than maternal—but the peak fetal concentration will not exceed the peak maternal concentration (see Figure 24-4). Even for rapidly transferred substances, the peak concentration will be blunted. In addition, mean steady-state concentrations will not exceed maternal concentrations; however, during the elimination phase, fetal concentrations may exceed maternal levels (see Figure 24-5). Also, total drug exposure in the fetus will not exceed that in the mother. In Figures 24-4, *A,* and 24-5, *A,* when there is no direct fetal clearance, not only is the area under the curve (measure of total drug exposure) the same in each fetus, but the area under the curve is the same in the mother as in the fetus. In the absence of direct fetal elimination, mean steady-state concentrations (or areas under the concentration time curves) in the fetus are equal to those in the mother. This is an important concept to grasp, because single maternal-fetal drug determinations after bolus drug administration have caused considerable confusion in the understanding of fetal drug distribution. In certain situations, mean active drug concentrations in the fetus exceed maternal concentrations—for example, in the presence of active transport from the maternal to fetal circulation and after prodrug administration, when drug metabolite concentrations can be higher in the fetus than in the mother. These circumstances are explored later on.

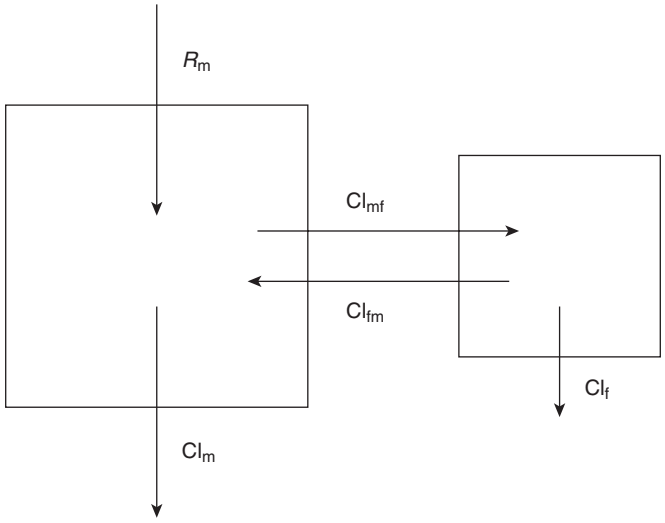

Figure 24-3 The two-compartment model representation of the maternal-fetal dyad. Drug movement into and out of each compartment is indicated by the *arrows.* Clearance parameters are used to characterize the elimination from or transfer between compartments. *Cl,* Clearance; *f,* fetal; *m,* maternal; *R,* rate of infusion of drug to maternal compartment.

Passive Transfer of Drug Across the Placenta

It is thought that most drugs cross the placenta by passive diffusion. *Passive diffusion* is the movement of substances in solution across a *semi-permeable membrane,* in this case, the placenta. This process uses the kinetic energy of the molecules, rather than any energy provided by cellular mechanisms. As molecules bounce around in solution, some will cross to the other side of the membrane. The percentage that crosses is determined by the number of molecules in solution (concentration) and the ease with which molecules cross. Subsequently, as a result of the random movements, a certain percentage of these molecules will in turn cross back to the other side, again dependent on the concentration and ease of transfer. Because the membrane is essentially the same in both directions, more molecules will cross from the side with the higher concentration, and net transfer will be to the side of lower concentration. Once equilibrium is reached, the concentrations on the two sides of the membrane will be the same, with no net transfer. Because net transfer is proportional

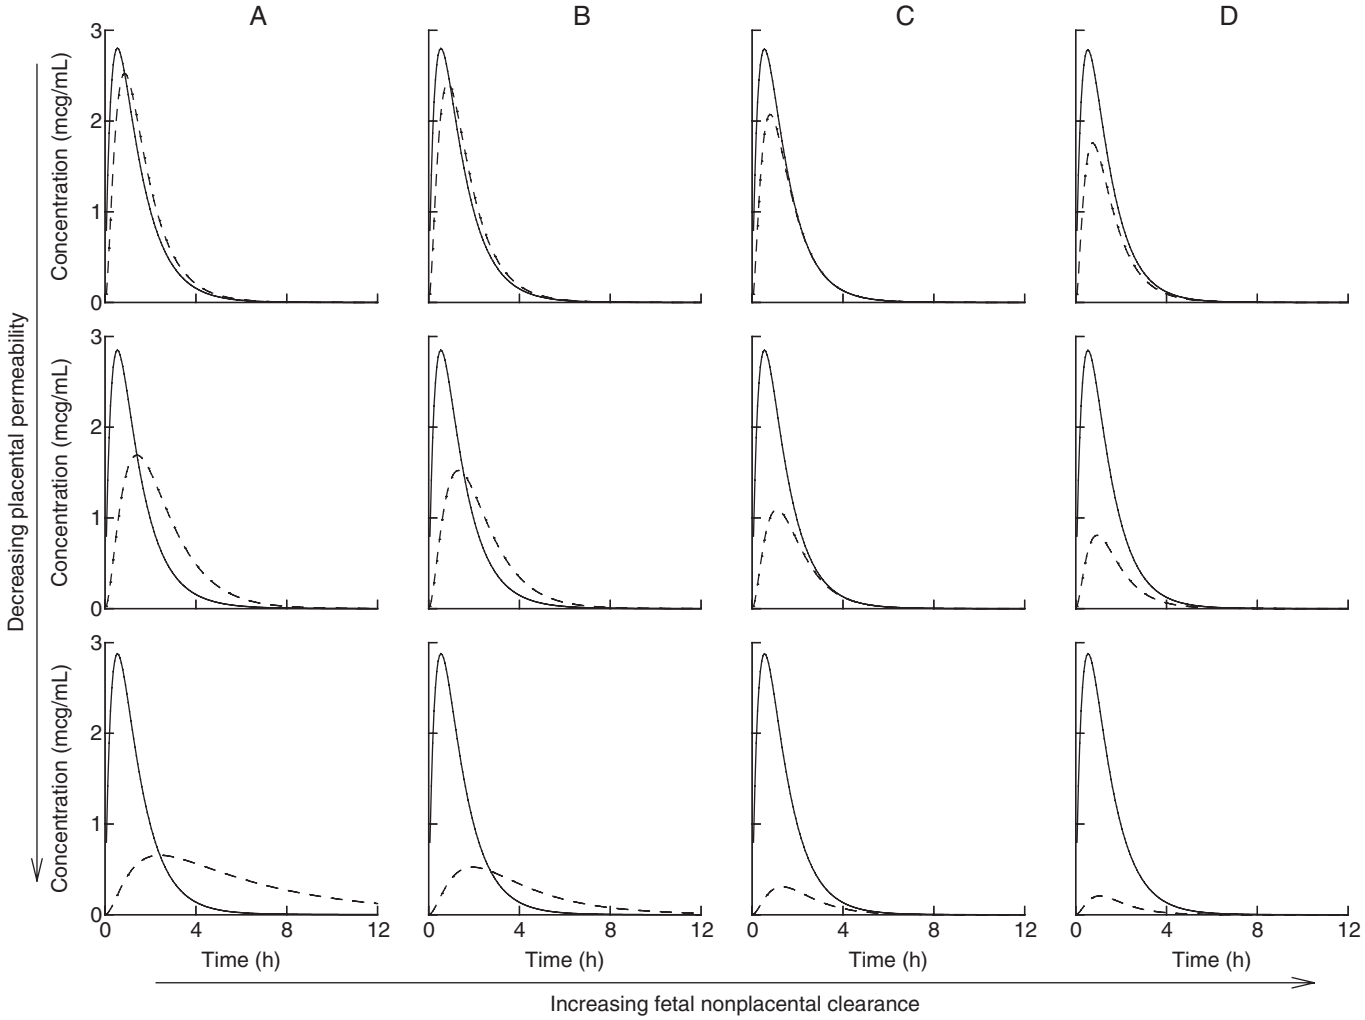

Figure 24-4 Drug concentration–time curves for the mother *(solid line)* and the fetus *(dashed line)* after an oral bolus of drug. These plots represent the solutions for the rate equations of a two-compartment model following an oral bolus of drug where placental clearance (a measure of placental permeability) and fetal nonplacental clearance (direct fetal elimination) were varied while all other system parameters remained constant. The general parameters used to make these plots are those obtained experimentally in the pregnant baboon following zidovudine administration.[1,28] The *top row* represents high placental permeability in that placental clearance is 20% of maternal clearance. In the *middle row,* placental clearance is 5% of maternal clearance (that observed experimentally). The *bottom row* represents limited placental permeability in that only 1% of drug administered to the mother will cross the placenta to the fetus. Levels of direct fetal elimination increase with progression from **A** to **D: A,** no direct fetal clearance; **B,** fetal clearance is 1% of maternal clearance (that observed experimentally); **C,** fetal clearance is 5% of maternal clearance, as would be the case when fetal metabolic activity expressed per tissue mass is similar to that in the adult; **D,** fetal clearance is 10% of maternal clearance, as would occur only when fetal enzyme activity is higher than that in the adult.

to the concentration gradient across the membrane, it is not a measure of the permeability of the placenta.

Permeability is the ease with which a molecule (or drug) crosses a membrane and is a function of the membrane itself and properties of the molecules. The *placental barrier,* as described previously, consists of a closely apposed layer of syncytiotrophoblast and fetal endothelial cells. Cell membranes consist of *lipid bilayers* and allow the passage of small, lipid-soluble molecules relatively easily. Tight junctions between endothelial cells in the placenta minimize paracellular transport. The composition of lipid membranes may alter transport characteristics. Known influences on lipid composition include diet, hormones, and pregnancy.[21,22]

Permeability can be considered per unit of placental tissue or as the placental unit as a whole. Traditional membrane studies express permeability in terms of surface area and thickness of the membrane. In the placenta, the membrane is very thin, and permeability is much more dependent on surface area. Because it is difficult to estimate placental surface area, permeability usually is expressed per unit tissue mass or in terms of the whole placenta. For comparisons in different experimental situations, placental perfusion studies often report relative permeabilities comparing test drugs with known substances, usually antipyrine.

Figures 24-4 and 24-5 show examples of passive diffusion systems. The concentration of drug in maternal plasma and the initial lack of drug in fetal plasma provide the gradient across the placenta. In the case of bolus administration (see Figure 24-4), net transfer of drug occurs from mother to fetus, and the fetal concentration increases until the concentration is equal in the maternal and fetal compartments. At this point, net transfer is zero. From this point on, the maternal concentration is less than the fetal concentration, and net transfer is from the fetus to

the mother. In the case of a constant infusion (see Figure 24-5), the fetal concentration increases owing to net transfer from mother to fetus until steady state is achieved. In Figure 24-5, *A,* with no elimination from the fetus, an equilibrium is established whereby the fetal and maternal concentrations are equal and no net transfer occurs in either direction. Drug molecules are still randomly crossing back and forth across the placenta as determined by the permeability and drug concentration, but at the same rate in both directions. When the drug infusion is stopped, the maternal concentration will fall, setting up a gradient from fetus to mother. This fundamental process provides the foundation for all distributive properties of drugs.

Rates of transfer from mother to fetus can be determined in experimental models. Using the Fick principle, measuring the change in concentration over either the uterine or umbilical circulations (at specific flow rates) will determine the amount of drug removed from maternal plasma or the amount of drug taken up by fetal plasma. These measurements can be achieved by in situ perfusion of whole placentas of small animals, controlling placental and umbilical blood flows, or in chronically instrumented sheep models using flow probes on uterine and umbilical circulations.[23] In addition, the human placenta can be perfused ex vivo.[24-26] The calculated measures of placental clearance obtained from these experimental models provide a measure of placental permeability. Of note, this measure has the same units as those for placental clearance (volume/time). This method also can determine the amount of drug eliminated by the placenta.

Another method uses mean steady-state concentrations in the mother and fetus applied to a two-compartment pharmacokinetic model (see Figure 24-3).[20] This method calculates the placental clearances in both directions across the placenta and is used in sheep and primate models.[27-30] In the absence of active transport and fetal metabolism, these placental clearances are measures of the permeability of the whole placenta. The advantage of this model is that blood flow measurements are not required. It does require drug administration to "steady state" (in both compartments) and drug determinations from both circulations. Neither of these methods can be utilized clinically, so extrapolations from animal and ex vivo placental perfusion studies are required to predict drug concentrations in the human fetus. The two-compartment model under steady-state conditions better reflects long-term drug therapy. In addition, parameters derived under steady-state conditions can be used to model single-dose situations. Most of the equations and graphs in this chapter are generated from this model and provide a framework for understanding the effects that physiologic parameters have on fetal distribution.

Molecular size and *solubility* are the drug characteristics that determine drug permeability. Lipid-soluble drugs with molecular weights of up to 600 are readily transferred across the placenta. Water-soluble drugs up to 100 daltons in size also readily cross; larger hydrophilic molecules cross according to their coefficient of diffusion in water.[24] Placental perfusion studies comparing substances of varying sizes and solubilities demonstrate relative permeability rankings that are a combination of the two factors.

Active Drug

When drugs are present in plasma, they may be bound to plasma proteins, or if they are weak acids or bases, they may exist in an ionized state. Only drug that is *unbound* and *nonionized* is available for transfer across the placenta; in this state, it often is referred to as *active* drug. The percentage of drug bound to protein is determined by the number and affinity of binding sites, whereas the percentage of drug ionized is determined by the pK_a of the drug and the pH of the plasma. In both cases, drug will either bind or dissociate—that is, it will shift between ionized and nonionized forms. On the maternal side, the active drug concentration decreases as it is transferred across the placenta to the fetus. Subsequently, drug bound to proteins will dissociate, and ionized drug will shift from an ionized to a nonionized form; newly formed active drug will then be available for further transfer. On the fetal side, active drug increases in concentration and will bind to proteins and ionize to achieve the appropriate proportions determined by the conditions. If protein-binding attributes and pH were the same in mother and fetus, total drug concentrations in the mother and the fetus would be the same at equilibrium. Because differences exist in protein binding and fetal pH is slightly less than maternal pH, the drug concentrations will be different in the fetal and the maternal compartments.

The two major proteins involved in binding drugs are albumin and α_1-acid glycoprotein, the latter particularly involved in binding basic drugs.[5,31,32] During pregnancy, maternal albumin concentrations fall, although total albumin is increased.[31,33,34] In the fetus, albumin levels increase with gestation and, toward term, exceed those in the mother.[31] α_1-Acid glycoprotein levels tend to be rather variable in both the mother and fetus, but fetal levels are almost always less than maternal levels.[31] Protein binding is expressed as percent of drug protein bound. Equation 3 and Figure 24-6 describe the relationship between protein binding in the mother (M) and fetus (F) and the effect on total drug concentration at steady state (C_{ss}).

$$C_{ssFtotal} = \frac{C_{ssMunbound} / C_{ssMtotal}}{C_{ssFunbound} / C_{ssFtotal}} C_{ssMtotal} \quad (3)$$

Binding differences less than 40% to 60% tend to be insignificant. For drugs with high protein binding, however, a major effect on the fetal-to-maternal difference in total drug may be seen. Although bound drug may seem to be of little relevance, because it is not active, it serves as a depot that may prolong fetal or newborn exposure, particularly when affinity is high or when drug clearance in the newborn is poor.

The pK_a of a drug determines the degree of *ionization* at a specific pH. Usually only 0.1 pH unit difference exists between mother and fetus, so the difference in ionization is minimal. The effect of maternal and fetal pH differences on fetal-to-maternal concentration ratios of drugs that are weak acids and bases can be calculated from the Henderson-Hasselbalch equation:

The Henderson-Hasselbach equation:

$$pH = pK_a + \log \frac{[base]}{[acid]} \quad (4)$$

For weak acids:

$$C_{ssFtotal} = \frac{1 + 10^{(pH_F - pK_a)}}{1 + 10^{(pH_M - pK_a)}} C_{ssMtotal} \quad (5)$$

For weak bases:

$$C_{ssFtotal} = \frac{1 + 10^{(pK_a - pH_F)}}{1 + 10^{(pK_a - pH_M)}} C_{ssMtotal} \quad (6)$$

Weak acids are less ionized and weak bases are more ionized at lower pH. As fetal pH decreases below maternal pH, the amount of total drug in the fetus will change (Figure 24-7); weak acids will decrease in amount, whereas weak bases will increase. While the pH differential is maintained, drug effect will not be altered, because active drug levels are not affected. In the fetus, transition back to a normal pH is likely to be gradual, and placental redistribution will occur without exposure of the fetus to excessive (for basic) or subtherapeutic (for acidic) concentrations of active drug. If at the time of delivery the fetal pH is low, total concentration of basic drugs may be higher than in the mother, and as pH corrects in the newborn and drug quickly returns to an active nonionized state, adverse drug effects may occur. For acidic drugs, drug concentrations in the newborn infant may be less that that required for therapeutic benefit after resolution of fetal acidosis.

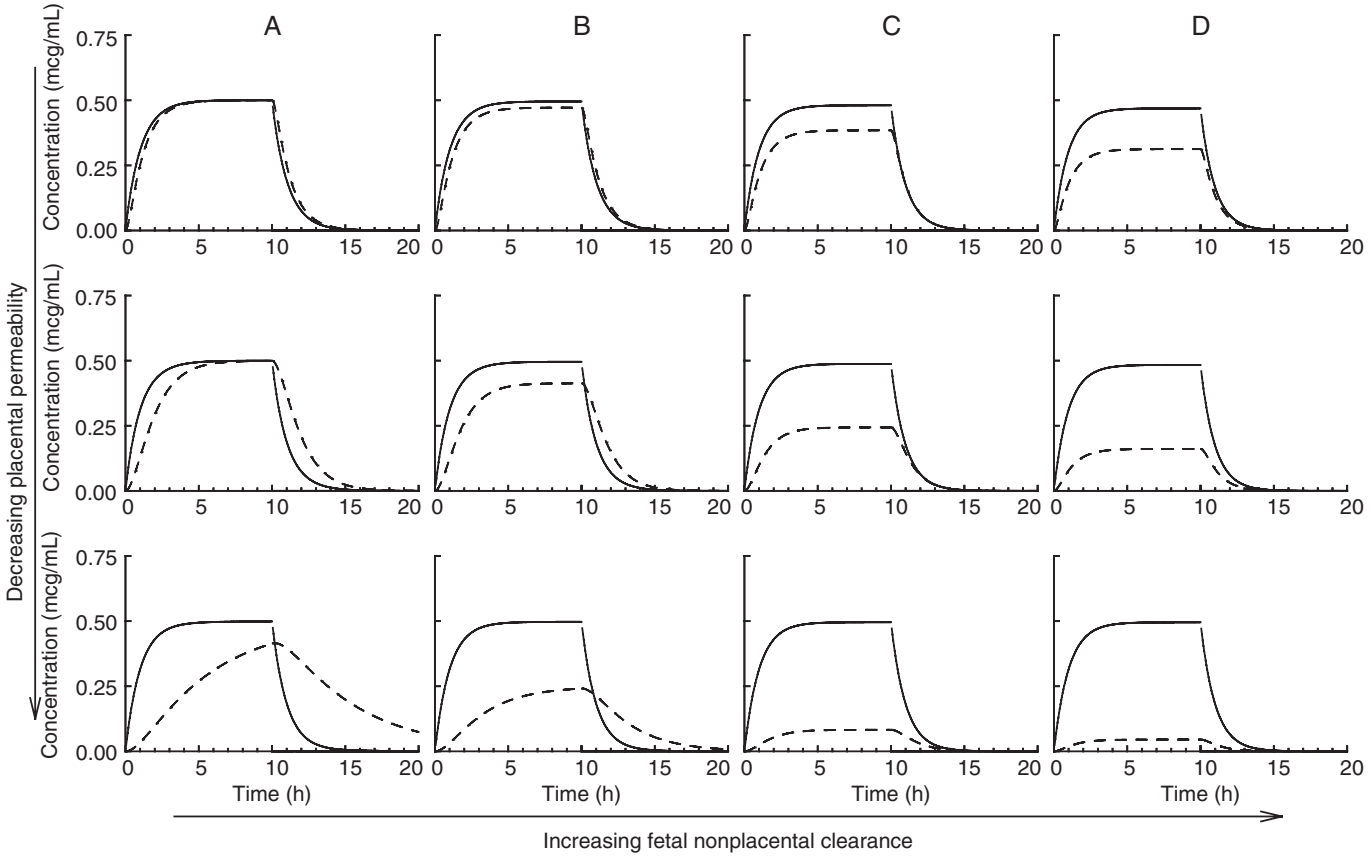

Figure 24-5 Drug concentration–time curves for the mother *(solid line)* and the fetus *(dashed line)* during and after a constant infusion of drug. These plots represent the solutions for the rate equations of a two-compartment model during and after infusion of drug wherein placental clearance (a measure of placental permeability) and fetal nonplacental clearance (direct fetal elimination) were varied while all other system parameters remained constant. Steady-state concentrations provide a good estimate of fetal exposure in relation to maternal concentrations. See Figure 24-4 for details on the specific parameter values.

Placental Blood Flow

The two sides of the placenta are perfused independently. Maternal placental blood flow is about twice that going through the umbilical circulation (Chapter 14, Mechanisms of Transfer Across the Human Placenta). Experimental situations show that decreasing blood flow, particularly in the umbilical circulation, will decrease delivery of freely diffusible drugs across the placenta (flow limited) but will have little effect on drugs that are "permeability limited." Placental circulations are fairly stable at most times in pregnancy, but will show gradual increases over gestation. Fetal compromise and uterine contractions are two clinical entities in which decreased fetal drug transfer has been demonstrated clinically. Changes in blood flow are unlikely to affect steady-state levels achieved unless the increased blood flow enhances nonplacental clearance mechanisms in the mother or the fetus.

Active Transport of Drug Across the Placenta

Cell membranes, including those of the syncytiotrophoblast and villous capilliary endothelium, contain large numbers of transport proteins that require cellular energy to function.[35,36] The specificity, orientation (into or out of the cell), and position (whether luminal or basal membrane) are important factors in determining the effect placental transporters will have on drug disposition.[37] Few drugs appear to be entirely dependent on active transport for transfer across the placenta to the fetus. Most drugs will cross to the fetus by passive diffusion. However, placental transport proteins may modify the final concentrations achieved.

The transporters involved in drug disposition belong primarily to two classes.[36] These are the ATP-dependent binding cassette proteins ("ABC transporters") and the solute-linked carrier proteins ("SLC transporters"). In the placenta, ABC transporters cause efflux of drug from the syncytiotrophoblast or fetal endothelium.[38] Energy in the form of ATP is required for activity. ABCB1 (P-glycoprotein), and ABCG2 (breast cancer–related protein [BCRP]) are located in the apical membrane directing drug toward the maternal circulation. ABCB2 (multidrug resistant protein 2 [MRP2]) and ABCC1 (multidrug resistant protein 1 [MRP1]) are on the basolateral membrane and direct drug toward the fetus.[38,39] ABCG2 also is on the fetal endothelium and can direct drug toward the fetus.[38] The SLC transporters are a more diverse group and include organic anion and cation transporters.[40-42] Those found in the placenta include OAT1 and OAT4, OCT1 to OCT3, and OCTN1 to OCTN3, with OAT4 and OCT3 localized to the basolateral membrane.These transporters use the electrochemical gradient of the cell for energy and can transfer substrates in both directions.While solute exchange is not obligatory, solute exchange can allow transfer against a concentration gradient by using the electrochemical gradient of the co-substrate.

The overall impact of transporters on drug disposition is still being delineated, though, in general, their action tends to protect the fetus from drug exposure. Studies in placental culture systems, the perfused human placenta, and mouse models wherein P-glycoprotein was inhibited show significant increases in drug levels on the fetal side.[43-45] In mice lacking ABCB1, increases in drug toxicity have been demonstrated in

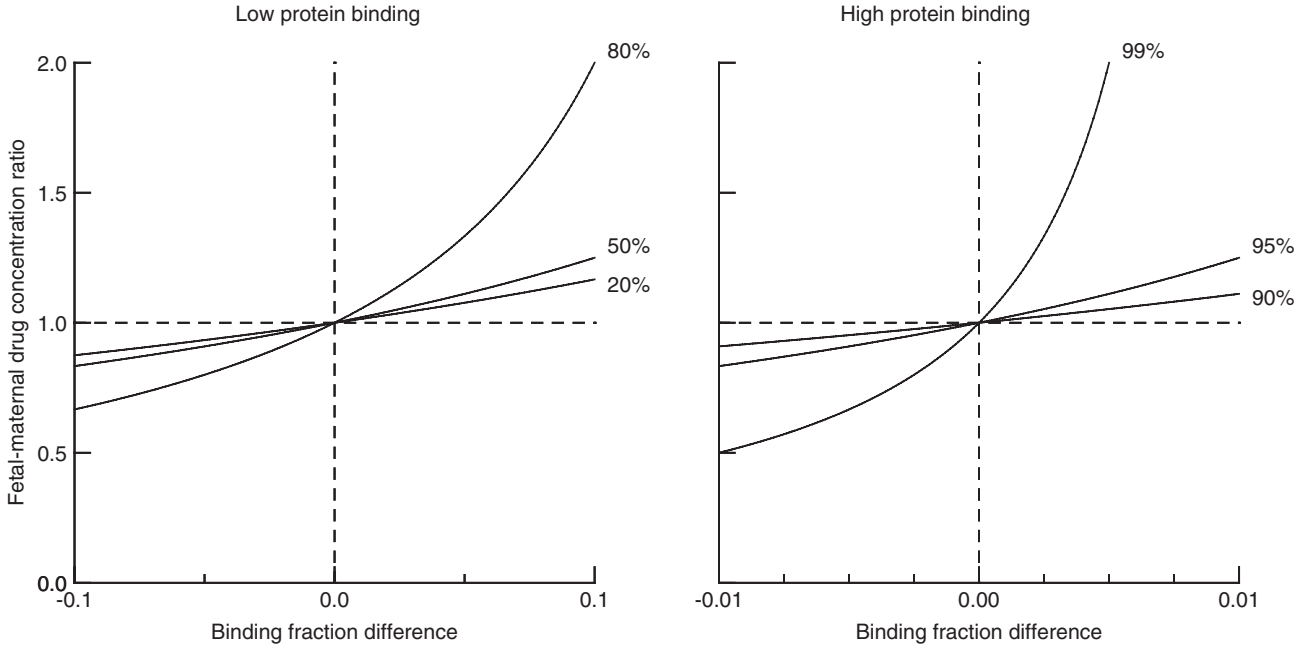

Figure 24-6 Effect of fetal-maternal differences in protein binding on steady-state fetal to maternal total drug concentration ratios. Recall that unbound drug concentrations will be the same in the fetus as in the mother. Drugs that exhibit low protein binding (up to around 50%) exhibit only small differences in the fetal-to-maternal concentration ratio, even with binding differences up to 10%. As binding increases, more marked effects are seen. For drugs that are highly protein bound, even small differences (less than 1%) can have marked effects on fetal-to-maternal total drug ratio. Graphs are plotted from Equation 3 for various levels of maternal protein binding, with fetal protein binding ± 10% of maternal for left-hand graph and ±1% of maternal for right-hand graph.

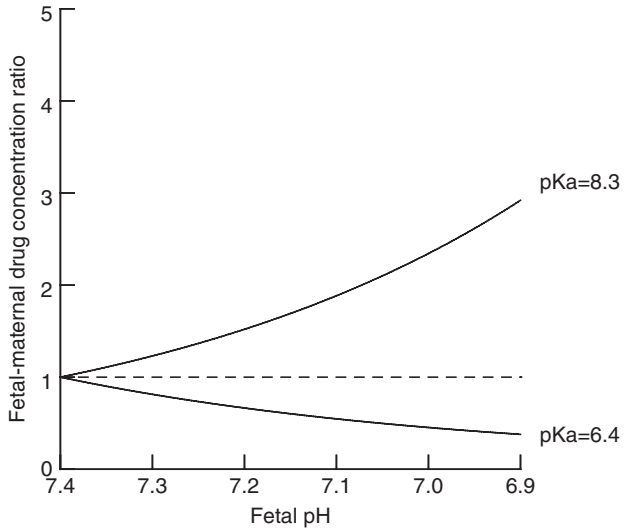

Figure 24-7 Effect of fetal-maternal pH differences on steady-state fetal-to-maternal total drug concentration ratios. Recall that nonionized active drug concentrations will be the same in the fetus as in the mother. Total concentrations of weak acids will be less in the fetus, whereas total concentrations of weak bases will be higher in the fetus. Graph is plotted from Equations 5 and 6 with maternal pH set at 7.4.

the fetus.[46] Placental ABC transporters are differentially regulated by hormone concentrations, inflammatory cytokines, and growth factors.[38] In the two compartment model, active transport will be reflected by differences in the maternal-to-fetal and fetal-to-maternal clearances. Active efflux transport from fetus to mother will effectively reduce fetal drug exposure.

Other Transport Mechanisms

Facilitated diffusion processes are known to occur in the placenta for disposition of nutrients and waste products and also have a role in drug transfer.[47] Specific macromolecules are taken up across the placenta by pinocytosis. An example is IgG, which can be administered therapeutically.[48] Aquaporins present in the placenta may provide bulk flow channels for small hydrophilic drug molecules.[49]

Placental Metabolism

The placenta is a highly metabolic organ producing and modifying many different hormones. However, the extent to which drugs are metabolized is not well delineated. Several members of the cytochrome P-450 subclasses are present and capable of metabolizing drugs at the maternal-fetal interface though expression is often less than other tissues.[50,51] Using sensitive methods, conjugation enzymes have also been detected in the placenta.[52,53] Again the extent to which they diminish fetal exposure is unclear. The placenta will act as a first pass clearance system and decrease drug concentrations reaching the fetus. However the fetus may well be exposed to metabolites of drugs that are not always harmless.[54] In the two compartment model with maternal administration, placental metabolism would have the same effect as fetal metabolism.

MODIFIERS OF FETAL PLASMA CONCENTRATION

Fetal Circulation

Streaming of oxygenated blood from the umbilical vein, through the ductus venosus and foramen ovale in the heart leads to the delivery of better oxygenated blood to the head and upper extremities. Thus the concept of having different distribution in separate regions is not new.[55] The high extraction of oxygen

from fetal blood maintains this differential across the placenta and thus, the difference in carotid arterial and descending aortic oxygen tensions is able to persist. A similar phenomenon is likely to occur with drugs that cross the placenta, although it has never been clearly documented. This difference will be most pronounced when the umbilical arteriovenous difference is greatest—most likely to occur after bolus administration or for drugs highly metabolized by the fetus.

The fetal circulation also affects drug distribution in the liver.[56] The fetal liver is the first organ encountered by fetal blood returning from the placenta. In the healthy fetus, 50% to 90% of blood flow is diverted through the ductus venosus.[57] Pathologic conditions can lead to redistribution of hepatic blood flow with enhanced hepatic metabolism of drug. Similarly, the same constraints pertaining to umbilical arteriovenous differences hold.

Fetal Drug Clearance

Thus far the discussion has been limited to systems in which the fetal nonplacental clearance is zero. As noted previously, that is not the case with zidovudine, for which the fetal steady-state levels can be less than those in the mother. However, differences cannot be attributed to differences in protein binding or pH, or to active transport.[28] Clear evidence demonstrates that the fetus can metabolize zidovudine to its glucuronide metabolite.[28] Figure 24-3 and Equation 2 include an elimination component directly from the fetus. The effect of direct fetal clearance on fetal drug concentrations is shown in Figure 24-3, *B* to *D,* with oral administration and Figure 24-4, *B* to *D,* with intravenous administration. Direct fetal clearance lowers fetal drug concentrations; this decrease is most marked when placental permeability is reduced. Of note, this effect differs from those of protein binding and ionization in that fetal clearance affects active drug concentrations and hence reduces *active* drug concentrations in the fetus.

The Two-Compartment Model at Steady State

In many of the examples given, the effect of changes in physiologic parameters is best appreciated by comparing steady-state concentrations in the mother and the fetus. A relationship between fetal and maternal plasma concentrations can be deduced from the rate equations for the two-compartment model under steady-state conditions. *Steady state* is defined as the condition in which the amount of drug in a compartment does not change with time—that is, the amount of drug being added to the system is the same as that leaving the system.

Rate equation for maternal compartment at steady state:

$$\frac{dD_m}{dt} = R_m - Cl_m \cdot C_m - Cl_{mf} \cdot C_m + Cl_{fm} \cdot C_f = 0 \qquad (7)$$

Rate equation for fetal compartment at steady state:

$$\frac{dD_f}{dt} = Cl_{mf} \cdot C_m - Cl_{fm} \cdot C_f - Cl_f \cdot C_f = 0 \qquad (8)$$

Rearranging the fetal equation gives an expression that relates fetal steady-state plasma concentration to the maternal concentration.

$$\frac{C_{ssF}}{C_{ssM}} = \frac{Cl_{mf}}{Cl_{fm} + Cl_f} \qquad (9)$$

This expression shows the interdependence of fetal clearance mechanisms and placental permeability in determining fetal drug exposure. For drugs that cross the placenta by passive diffusion, Cl_{mf} will be equal to Cl_{fm} (clearance being an attribute of the placenta and a measure of placental permeability). When fetal nonplacental clearance and placental clearance are equal, the fetal concentration is 50% of maternal concentration (see Figure 24-5, *C, middle row,* and Figure 24-5, *B, bottom row*). Furthermore, the same degree of fetal or nonplacental clearance will have a more marked decrease on fetal plasma concentration when placental clearance (or permeability) is low (see Figures 24-4 and 24-5).

Fetal Elimination Mechanisms

Drug-metabolizing enzymes are both present and active in the fetal liver, albeit at reduced levels compared with the adult liver for most enzymes.[28,50,51,58-63] As seen in the model in Figure 24-5, even small amounts of fetal clearance can have marked effects on the fetal-maternal drug ratio, depending on placental permeability. As might be expected, drug-metabolizing capacity will increase as gestation advances; however, placental permeability also increases with advancing gestation. In the sheep, fetal metabolism of acetaminophen increases concordant with growth.[61] In the baboon, fetal morphine metabolism does not appear to change over a similar period of time.[64] Another potential issue is induction of drug-metabolizing enzymes. Maternal smoking is known to induce many placental enzymes, but little is known about corresponding induction of hepatic enzymes prenatally.[54] Phenobarbital has been used successfully near term to reduce hyperbilirubinemia by induction of glucuronosyltransferase UGT1A1.

The *products of metabolism* also must be considered. These often are inactive; however, some metabolites are known mutagens, some are pharmacologically active, and others are true drugs in that a *prodrug* was administered.[65] Rate equations for metabolite formation can be written for the two-compartment model. The solution for these equations is clearly more complex, even at steady state, but fetal metabolite concentration can be expressed as a function of maternal concentration.[66] In this instance, because metabolite is being formed in the fetus and because placental clearance for metabolites often is less than for the drug, the tendency is for fetal metabolite concentrations to exceed those in the mother unless other clearance pathways exist.

In adults, the other major route of drug elimination is urinary excretion. The *fetal urinary excretion system* is unique in that fetal urine, a major component of amniotic fluid, is swallowed by the fetus, thereby providing the potential for any drug excreted in fetal urine to be absorbed back into the fetus through the fetal intestinal tract. The extent to which this occurs is not known. Clearly, not all drugs are reabsorbed in their entirety, because many can be detected in meconium. Under steady-state conditions, drug excreted into urine that is reabsorbed would not contribute to fetal nonplacental clearance; however, drug that becomes sequestered in meconium would contribute to that clearance. Recent research suggests almost complete reabsorption (personal communication).

TISSUE DISTRIBUTION

Volume of distribution is a term used to describe the volume a drug appears to occupy based on the plasma concentration and has little bearing on the physical system. Volumes of distribution vary from drug to drug based on the solubility of the drug in different tissues reflective of the tissues lipid and water content. Individual patients also differ in body composition. The fetus has a very high water content, so lipid-soluble drugs will not have a large volume of distribution. For water-soluble drugs, the volume of distribution would be expected to be higher (per tissue mass) than in the adult, particularly if the amniotic fluid compartment cannot be separated out. Fat deposition occurs during the last trimester, so during this period the capacity for transfer of lipid-soluble drugs would be greater. Drug would concentrate into fat tissues until steady state is achieved. Because the fetal volume of distribution is small compared to that of the mother, the effect of fetal changes is unlikely to be detectable in maternal plasma

concentrations. The total amount of drug delivered to the fetus, however, could be substantially higher.

Fetal Blood-Brain Barriers

The brain has evolved a complex set of protections to shield it from external influences and yet still provide passage for the essential nutrients and communication signals. The capillaries that supply the brain are continuous (nonfenestrated), have extremely tight junctions preventing paracellular transport, and are surrounded by astrocytic foot processes.[67,68] Several transporters are present in the endothelium, transporting drugs among other substances from the endothelium back to the circulation.[69-72] Pial membranes carry blood vessels across the surface of the brain. Where the pial membrane comes in contact with the ependyma of the ventricular system choroidal tissue develops.[68] The capillaries within the choroidal tissue are fenestrated; however, the overlying ependyma is highly specialized with very tight junctions; therefore transfer is essentially all transcellular. Several drug-metabolizing enzymes have been identified in choroidal ependymal tissue and are thought to protect the brain from substrates.[73-77] In addition, many transporters are present on both luminal and abluminal sides.[69-71] With respect to drugs, P-glycoprotein is on the abluminal side, removing drugs or their metabolites from the ependymal cell back to the capillary. Other transporters are present on the luminal and abluminal membranes transporting substances into and out of the ependymal cells. The remainder of the ependyma that is in contact with the ventricular system forms a loose network of cells with minimal barrier function. Thus, once in the cerebrospinal fluid, drugs have access to target neurons that lie near brain surfaces. Within the brain itself, certain cells have been identified as containing drug-metabolizing enzymes, although whether their function is protective or activational is not clear.[76,78] Transporters also are present on neuronal cells. Although not all of the details are known at this time, the distribution of drug metabolizing enzymes and specific transporters at specific sites give some hint of the complexity to unfold.[79,80]

The fetal blood-brain barrier is more robust than was once thought, although developmental changes are still likely. Much ongoing research in neonatology is directed toward neuroprotection of the fetal and neonatal brain. Hence understanding brain distribution of potential agents requires prediction of the concentration at the site of action to optimize effectiveness. Again, plasma concentration is the driving force for drug movement by passive diffusion of drugs down a concentration gradient modulated by metabolism and active transportation.

CLINICAL APPLICATIONS

Most drugs taken during pregnancy are for the mother's benefit. Use of drugs for fetal benefit is increasing, however. Various clinical scenarios are likely to be encountered, with potential ramifications for the patient and the unintentional recipient. Optimally, a drug that achieves therapeutic concentrations in the mother while minimizing fetal concentrations will be selected for maternal treatment, whereas a drug that achieves therapeutic concentrations in the fetus while minimizing maternal adverse effects will be selected for fetal treatment. An appreciation of fetal drug distribution, as summarized in Box 24-1, and drug properties will allow selection of appropriate drugs to attain these goals. It must be kept in mind that drugs are developed primarily for use in nonpregnant adults, and desired characteristics include good oral bioavailability, good tissue distribution, and long half-life—properties that generally lend themselves to placental transfer and hence fetal exposure. Furthermore, what may generally be seen as improvements in drug formulation may alter distributive characteristics unfavorably for the fetus.

BOX 24-1

Key Points in Fetal Drug Distribution

- The maternal plasma concentration is the driving force for drug delivery to the fetus.
- Drug size and solubility determine a drug's placental (and tissue) permeability.
- Protein binding and ionization of drugs can lead to prolonged exposure for the neonate after birth.
- Fetal elimination mechanisms decrease fetal plasma concentration most markedly for drugs with low permeability.
- Products of fetal metabolism (drug metabolites or active moieties of prodrugs) can reach higher levels in the fetus than those in the mother.
- Drug transporters and drug metabolizing enzymes at the tissue level are important regulators of drug concentrations at the site of action.

Developmental Pharmacology of Adrenergic Agents

For hemodynamic responses to adrenergic agents, classic pharmacodynamic theory describes differences among agents in receptor specificity, potency, and pharmacologic profile based on parameters such as the median effective dose (ED_{50}) or half-maximal concentration. These pharmacodynamic parameters, however, are derived exclusively from in vitro studies. This chapter describes clinical studies in neonates, infants, and children based on a method of analysis that permits derivation of the *threshold,* or minimum plasma drug concentration, associated with discernible effects. The threshold is derived by graphic analysis of in vivo dose-response data. Examples are provided of both animal and human data, which demonstrate agreement of experimental results with predicted responses. This approach permits more direct comparison of studies with different patient populations and studies from different investigators. Also provided in this chapter is evidence of first-order clearance kinetics of dopamine and dobutamine over the ranges of dosages used normally in neonates, infants, and older children.

In numerous instances in clinical neonatology, pharmacologic principles developed in adult humans and animals have been used to guide pharmacologic therapy in newborns. Because newborns are not just small adults, however, this approach has resulted in many untoward drug-related incidents, including the historic chloramphenicol "gray baby syndrome,"[1-3] errant aminoglycoside drug doses,[4-6] the excessive absorption of topical antiseptics,[7-11] and the benzyl alcohol "gasping syndrome."[12,13] Inotropic drugs are among several classes of drugs whose initial use in neonates and children was based on data generated in adults. Drug manufacturers generally have avoided costly clinical trials of inotropic agents in neonates and children. Industry has instead relied on the experience of clinicians who care for newborns and who base the use of such drugs in their patients on information generated in adults. Thus information on safety and efficacy in newborn and pediatric patients has been the result of practical experience generated in the clinical setting. Adverse effects of drugs that enter the clinical setting in this fashion are reported only after use has become widespread.

To compound this situation further, the plasma concentrations of all of the widely used inotropic agents were well below the level of detection of available assays at the time of the initial pharmacologic investigations. This technical problem inhibited assessment of the pharmacokinetics and pharmacodynamics of these inotropic drugs. The development and application of sensitive assays for commonly used inotropic drugs subsequently permitted evaluation of their actions in the clinical setting. We have used this approach to evaluate the pharmacokinetics and pharmacodynamics of inotropic drugs in neonates, older infants, and children. This chapter reviews the results of such studies, which provide a rational basis for the use of inotropic drugs in critically ill newborns and children.

PHARMACOLOGIC PRINCIPLES

Pharmacokinetics

Pharmacokinetics is the study of in vivo drug disposition. In most circumstances, plasma drug levels are measured, and their concentrations at different time intervals are analyzed by comparison against classic models. A derived parameter that reflects the rate of drug disposition is then calculated. The pharmacokinetic parameter most familiar to clinicians is the half-life. Figure 25-1 shows a typical graph of concentration versus time. Drug is administered as a bolus at time zero. Plasma drug concentration rises rapidly to a short-lived peak concentration. The plasma concentration rapidly decreases as the drug is equilibrating in the plasma compartment. This equilibrium period is referred to as the *distribution phase* or *α phase.*

A second, more prolonged period of decay in plasma drug concentration also is observed. In this latter period, the rate of decay of plasma drug concentration is dependent on mechanisms for elimination or clearance, such as excretion and metabolism. This is called the *elimination phase* or *β phase.* For drugs whose mechanisms of elimination have not been saturated, the β or elimination phase of the decay curve is linear when displayed on a semilogarithmic plot. Such drugs are said to have *first-order* or *linear kinetics.* First-order kinetics simply describes nonsaturability within the range of dosages that were studied. Drugs whose elimination kinetics are saturable have nonlinear exponential decay curves.

The plasma half-life, or the time required for drug concentration to decrease by 50%, is determined graphically or by computer analysis of the decay curves. For drugs with extremely rapid rates of disposition, the short half-lives are difficult to determine accurately. Small errors in the timing of samples during the elimination phase lead to large errors in half-life determination. In addition, drugs with extremely short half-lives, such as inotropic drugs with half-lives of 1 to 2 minutes, usually are administered by continuous infusion. In such circumstances, a more appropriate pharmacokinetic parameter is the *plasma clearance rate.* Clearance is calculated by the following formula:

$$\text{Plasma clearance rate (mL/kg/min)} = \frac{\text{Dose of infusate (g/kg/min)}}{\text{Steady-state concentration (g/mL)} - \text{baseline concentration (g/mL)}}$$

For drugs with first-order kinetics, a linear relationship exists between the steady-state plasma drug concentration and dose. The calculated clearance rate is independent of dose, a finding suggesting nonsaturability of elimination mechanisms over the range of dosages studied. Experimentally, this rate is determined by measurement of steady-state plasma drug concentration at several different stable infusion rates. Clearance usually is normalized to body weight, whereas half-life is independent of body mass. Although clearance rate is a more appropriate derived parameter for drugs with short half-lives, it is a concept less familiar to clinicians.

We examined elimination kinetics for the inotropic agents dopamine and dobutamine in neonates, older infants, and children in the critical care setting.[14-17] In each study, the drug was infused with a calibrated infusion pump. Samples for measurement of plasma drug concentration were collected at several infusion rates. Data were analyzed by computer-based graphic analysis. Figure 25-2 is a representative plot of data for plasma dobutamine concentration versus dose in newborns and older children. For each patient, a linear relationship between dose and plasma drug concentration was found, confirming first-order kinetics. The clearance rate of dopamine and dobutamine

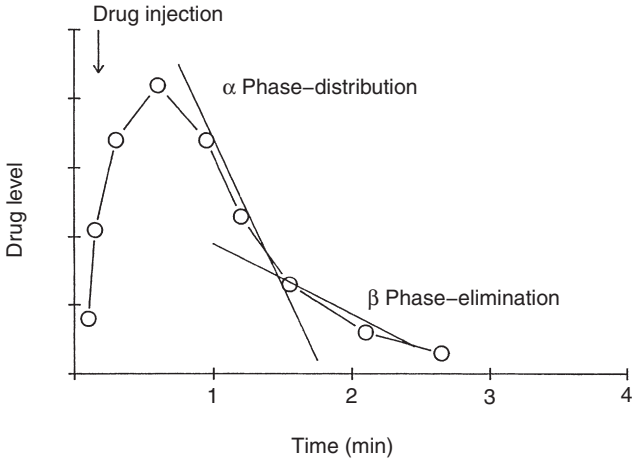

Figure 25-1 Typical concentration versus time result used to generate drug half-life.

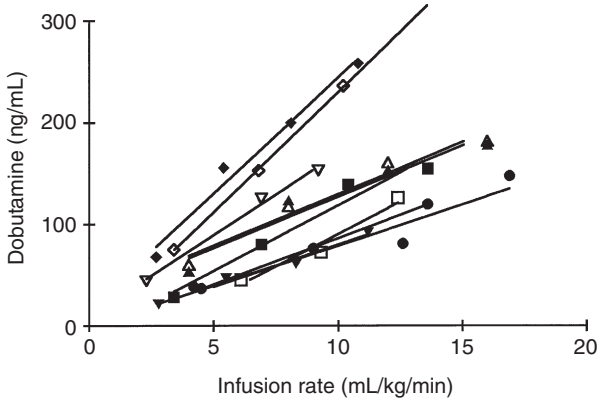

Figure 25-2 Plasma dobutamine level (ng/mL) versus infusion rate. The correlation between dobutamine level and infusion rate was significant ($r = 0.97$; $p < .001$). *(From Habib DM, Padbury JF, Anas NG, et al: Dobutamine pharmacokinetics in pediatric intensive care patients,* Crit Care Med *20:601, 1992.)*

in neonates and older children is independent of dose, a finding that further supports first-order kinetics over the range of dosages studied.[14-17] The more remarkable observation was the wide range of actual clearance rates. Although mean clearance was 75 to 90 mL/kg/minute, the range was 30 to 170 mL/kg/minute. A similar wide range of dopamine clearance levels has been observed. Figure 25-3 illustrates the mean and range of dopamine and dobutamine clearance rates in multiple studies.[14-18] Significant interpatient variation was noted for both dopamine and dobutamine plasma clearance rates in each of the clinical circumstances studied. Initially, it was not clear whether this was the result of specific illnesses in these patients or the result of other factors. Although it is important to generate the pharmacokinetic data under conditions of actual drug use in critically ill patients, physiologic derangements may have contributed to the high interpatient variations. To address this issue, we examined the clearance rate of dobutamine in a set of healthy normal patient volunteers using identical methods.[17] In each of the individual patients, a linear relationship between dose and plasma drug level was noted. The range of clearance rates, 38 to 218 mL/kg/minute, was similar to that seen in critically ill patients. This observation suggests that the high variation in clearance rate among individual patients is not caused by illness itself.

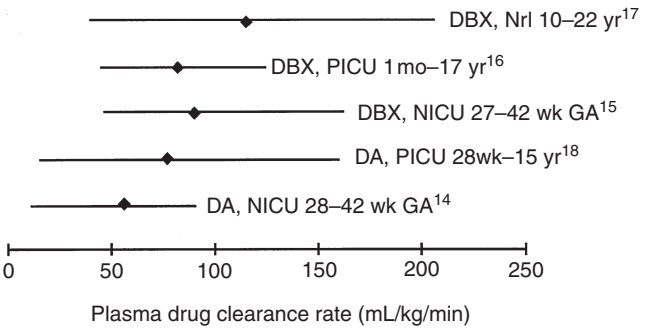

Figure 25-3 Ranges of clearance values in different studies.[14-18] Patients were in either neonatal or pediatric intensive care units (NICU or PICU) at the ages indicated. *DA,* Dopamine; *DBX,* dobutamine; *GA,* gestational age; *Nrl,* normal.

These pharmacokinetic data have significant clinical implications: The first-order clearance kinetics for these agents indicates that plasma drug level is directly and linearly related to dose. In the dosage range studied, clinicians need not be concerned that increasing dose leads to a sudden and exponential increase in plasma level, as seen with drugs with saturable kinetics such as phenytoin or aminoglycosides.

Special Pharmacokinetic Considerations in Neonates: Endotracheal Epinephrine

During cardiopulmonary resuscitation, establishment of an airway and adequate ventilation is generally the first priority. When epinephrine administration is indicated, the endotracheal route often is chosen as a matter of expediency. Animal models and case reports in neonates and children have established that endotracheal epinephrine during cardiopulmonary resuscitation can effectively restore spontaneous circulation.[18-26] In addition, endotracheal epinephrine administration to animals with normal circulatory status, hypovolemia, or asphyxia-induced bradycardia can increase heart rate, mean arterial pressure, and cardiac output.[27-29] The pharmacokinetics of endotracheal epinephrine depends on effective dispersion of the drug over the respiratory mucosa, pulmonary blood flow, and matching of ventilation (i.e., drug dispersal) to perfusion.[21,26]

During cardiopulmonary resuscitation, gross perturbations of ventilation and perfusion occur. Preexisting medical conditions, such as pulmonary edema, pneumonia, and airway disease, also affect the pharmacokinetics of endotracheally administered drugs.[30] Furthermore, epinephrine is a local vasoconstrictor and therefore inhibits its own uptake in the local pulmonary vasculature.[27,31] It should not be surprising that endotracheal administration results in lower peak plasma concentrations and a prolonged depot effect.[21-33] Administration of typical intravenous emergency epinephrine doses (0.01 mg/kg) by the endotracheal route does not significantly affect arterial epinephrine concentration during cardiopulmonary resuscitation in adults, whereas the same dose delivered intravenously increases arterial epinephrine concentration.[30] Animal models and studies in adult humans demonstrate that with use of the endotracheal route, a 5- to 10-fold increase in epinephrine doses generally is necessaryto attain hemodynamic effects comparable with those achieved using the intravenous route.[18,20-34]

The appropriate "endotracheal epinephrine" dose for neonates is not known. In comparison with intravenous doses, higher endotracheal doses of epinephrine are necessary for similar effects, yet prolonged hypertension from depot effects may be particularly dangerous to preterm infants at risk for intracranial hemorrhage. In addition, data are limited regarding metabolism of catecholamines after cardiopulmonary resuscitation in

neonates. Schwab and von Stockhausen[35] demonstrated that in premature neonates, free epinephrine was effectively inactivated by sulfoconjugation after endotracheal administration of 0.25 mg/kg during cardiopulmonary resuscitation. These investigators did not note any adverse effects, yet they documented 10-fold higher plasma epinephrine concentrations 1 and 2 hours after resuscitation.[32]

Pharmacodynamics

Classic pharmacodynamic theory suggests that the laws of mass action can describe the effects of administered agents such as adrenergic agonists. For a single ligand (e.g., exogenous agonist or endogenous catecholamine) interacting with a single class of receptors, the dose-response relationship is characterized by a sigmoidal dose-response relationship.[36] The actual data used to derive these curves usually are obtained after cumulative, stepwise-increasing doses. Boluses of the drug are most commonly infused. Larger doses are administered after return of the preparation to steady-state or baseline conditions. Concentrations ranging over 4 to 6 logarithms are needed to construct the sigmoidal dose-response curves. The data are fitted either graphically or by means of computer-based modeling programs to the expected sigmoidal response. Derived parameters such as the concentration necessary for 50% maximal effect or inhibition (ED_{50} or ID_{50}) and potency ratios are then used to define the pharmacologic profile. These parameters also are used to compare individual drugs, to compare subjects being studied under different physiologic or clinical conditions, or to compare subjects at different developmental ages. The assumptions underlying this methodology are as follows: (1) the administered agent achieves a steady-state concentration and effect at the receptor site after the bolus administration; (2) the maximum effect observed experimentally is indeed maximal, accurately measured, and physiologically meaningful; and (3) the maximum effect is relevant to the proposed clinical application of the drug or agent.

These experimental prerequisites preclude their measurement in human subjects in vivo. Maximal effects are difficult to achieve, and such doses may lead to dangerous side effects. Clinical administration of drugs rarely varies over a 4- or 5-log concentration range. Pharmacologic literature on the clinical application of newer inotropic agents reveals that the major portion of basic information used to define the pharmacologic profile, to determine their potency in comparison with other agents, and to ascertain their potential clinical relevance is derived largely from in vitro data.[37-42] It is clear that the generation of data from cumulative responses in isolated tissues is not relevant to how these drugs are used clinically. Nonetheless, a derived parameter is necessary to permit comparison of drug effects from different investigations. Ample information suggests that age, diagnosis, and intercurrent clinical problems significantly affect response,[40-43] metabolism,[14-17,44-45] or side effects[46] of inotropic agents.

Our goal in optimizing administration of inotropic agents was to develop an alternative approach to study the pharmacodynamics of inotropic drugs based on the relationship of the plasma concentration during clinical administration to the hemodynamic effects. Previous investigations comparing responses to infused catecholamines had suggested that no change occurred in a particular response until the catecholamine concentration reached or exceeded a "physiologic threshold."[47] Beyond the threshold value, a log-linear relationship holds between the plasma catecholamine concentration and the physiologic response. This concept is illustrated in Figure 25-4, in which the classic sigmoidal dose-response curve is shown and the location of the ED_{50} and the threshold on the classic dose-response curve are illustrated. The threshold model at the lower concentrations of the sigmoidal dose-response curve also is shown. A zero-order equation ($y = a$) relates the response to the log of the plasma catecholamine or drug concentration (pg/mL) below the threshold concentration. Above the threshold concentration, a linear increase occurs in response to logarithmic increases in plasma catecholamine concentrations ($y = m \log x + b$). A computerized nonlinear, least-squares regression program was developed to fit experimental data to these assumptions.[48] The *threshold* is defined as the catecholamine concentration at the intersection of these two lines. The program determines the best fit for the baseline value of the response, the threshold drug concentration at the threshold for that response, and the slope and correlation coefficient of the log-linear regression line beyond the threshold value. Goodness of fit to this model can be determined statistically.

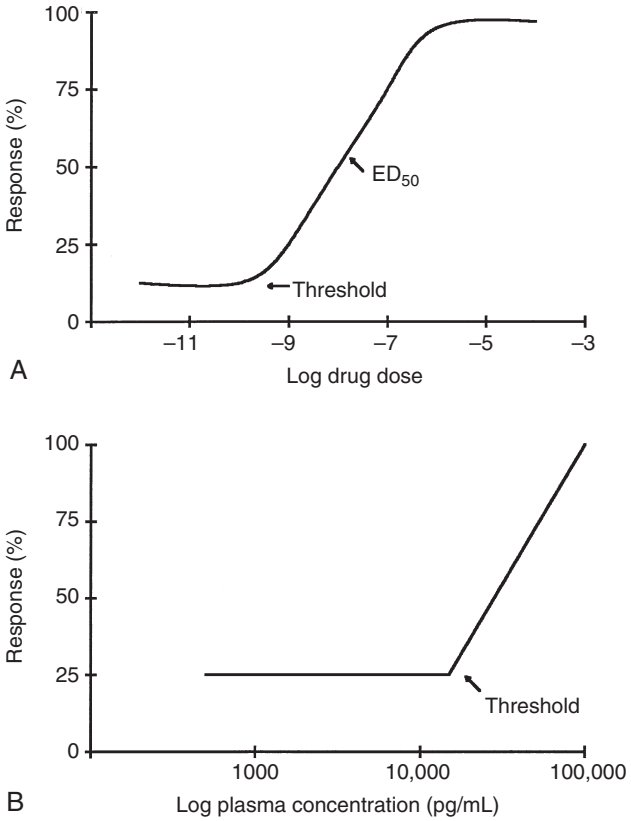

Figure 25-4 **A,** Dose-response curve showing the approximate location of the median effective dose (ED_{50}) and threshold. **B,** Log transformation of dose-response curve. The location of threshold is indicated as the intersection of the zero-order and log-linear responses.

To confirm the validity of this approach for in vivo studies, we first performed experiments in human infants and children. Preliminary studies confirmed that steady-state plasma concentrations and hemodynamic responses were achieved within 15 minutes. Thresholds for individual hemodynamic responses, including increases in blood pressure, cardiac output, and heart rate, were determined for each patient. Excellent agreement was observed between the predicted log-linear dose-response relationship and the measured data in newborns, older infants, and children. Figure 25-5 is a series of representative curves plotted from data for several children depicting the log-linear relationship of plasma dobutamine concentrations and hemodynamic parameters. Thresholds, similar to clearance rates, varied substantially between patients. Nonetheless, the data for most patients demonstrated the predicted log-linear relationship between plasma inotropic drug concentration and responses. Using the apparent threshold and plasma clearance rate for each patient, it is possible to calculate the minimum infusion rate that would

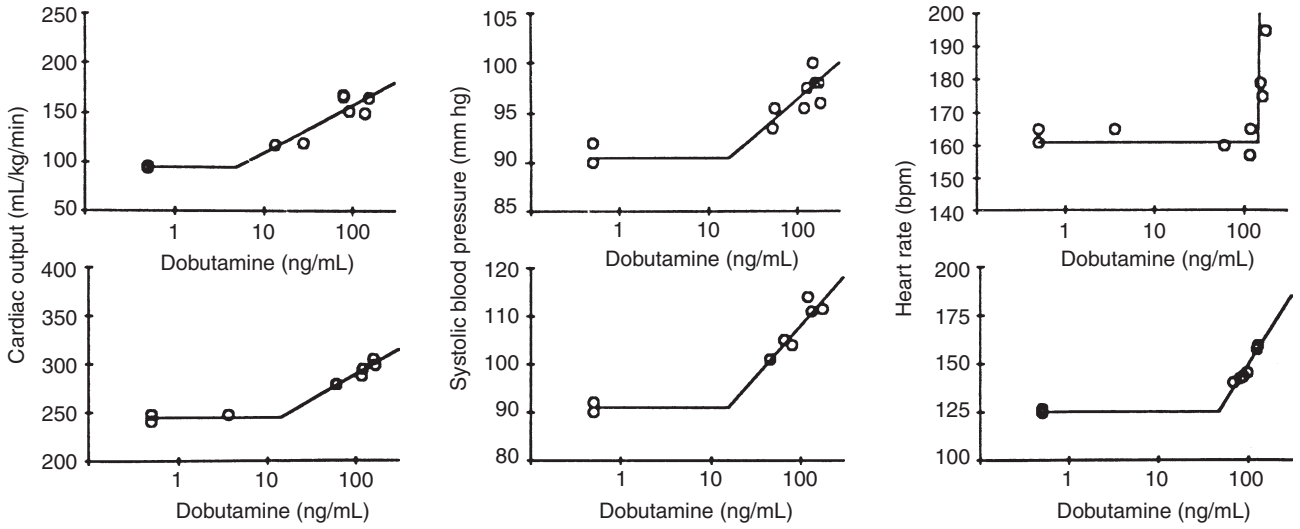

Figure 25-5 Representative dose-response curves. Plasma dobutamine levels are plotted on the logarithmic horizontal axis. Each response is plotted on a vertical linear axis. The *lines* indicate the computer-generated best fit. See Figure 25-3 for abbreviations. *NICU,* Neonatal intensive care unit; *Nrl,* normal; *PICU,* pediatric intensive care unit. *(From Habib DM, Padbury JF, Anas NG, et al: Dobutamine pharmacokinetics in pediatric intensive care patients,* Crit Care Med *20:601, 1992.)*

result in plasma drug concentrations equal to or greater than the threshold. The threshold for hemodynamic responses to dopamine occurred at plasma concentrations of dopamine achieved at an infusion rate of approximately 1.0 mcg/kg/minute and was fairly uniform among patients. For dobutamine, the plasma threshold was achieved at infusion rates of approximately 2.0 mcg/kg/minute.

These results agree with those of other studies demonstrating the effectiveness of dobutamine as an inotropic agent in the newborn,[49-51] despite contradictory reports.[43] In most of the patients we studied, dobutamine demonstrated a lower threshold for increases in cardiac output than for changes in blood pressure. This finding suggests that the hemodynamic effects of dobutamine in this age-group are the result of a direct inotropic response. Clearer evidence of a direct inotropic effect was indicated by the improvement of a load-independent index of myocardial contractility (the relationship of left ventricular end-systolic wall stress to rate-corrected velocity of fiber shortening) after dobutamine was infused. Generation of threshold data permits comparisons of different agents or among patients of different gestational ages. For example, comparison of the ratio of the cardiac output threshold to heart rate threshold (inotropic-chronotropic ratio) indicates a ratio of 2.5:1 for dopamine versus 6:1 for dobutamine in neonates.[14,23] This finding suggests a greater margin of efficacy versus adverse effects for dobutamine.

As noted during the study of the plasma clearance rate of dopamine and dobutamine, a wide interpatient variation was seen in the plasma threshold for the cardiovascular effects of both agents. The threshold for increases in systolic blood pressure in neonates in response to dopamine infusion ranged from 3 to 45 ng/mL of dopamine, which would have been achieved at infusion rates of 0.2 to 2.5 mcg/kg/minute. For dobutamine, the ranges were similarly quite wide. In infants and children, the threshold for dobutamine-mediated increase in cardiac index was observed at infusion rates of 0.2 to 9 mcg/kg/minute. The data are presented graphically in Figure 25-6. The mean and range of thresholds for each study group are shown. The interpatient variation in threshold was nearly 2 logs wide. It is possible that physiologic derangements were the source of the high interpatient variation in sensitivity to the pharmacodynamic effects of inotropic drugs. To address this issue, the clearance rate of dobutaminewas investigated in a set of healthy normal patient volunteers.[17] In these normal volunteers,

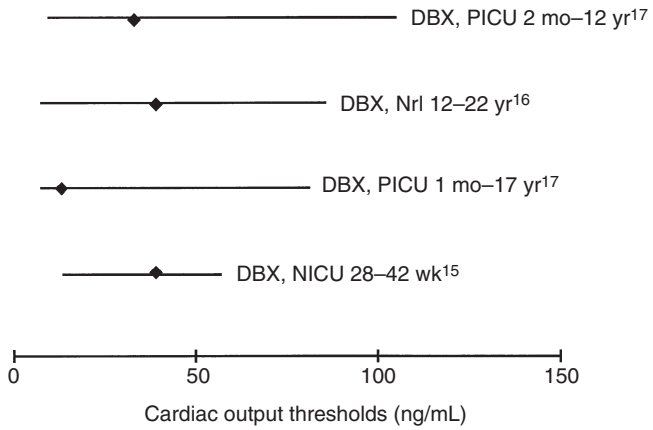

Figure 25-6 Ranges of threshold values in different studies.[15-17] Patients were in either neonatal or pediatric intensive care units (NICU or PICU) at the ages indicated. *DBX,* Dobutamine; *Nrl,* normal.

the range of thresholds for improvements in cardiac index was 4 to 20 ng/mL. The mean threshold for the entire group was achieved at dobutamine infusion rates of approximately 2 mcg/kg/minute.

The threshold approach provides several important advantages. First, it is based on actual data from clinical subjects. Pharmacologic data point to major differences in pharmacokinetics under different clinical situations, such as congestive heart failure, renal disease, or liver dysfunction.[44,45] Extrapolation of pharmacokinetic or pharmacodynamic data derived in experimental animal preparations may not be applicable to these conditions. Second, the traditional pharmacologic approach has used bolus drug injections for generation of dose-response curves. In this setting, drug doses and presumably plasma level or concentration at the receptor vary over 4 to 6 log units. Various investigators (ourselves included),[14,15,45,52] however, have shown that plasma concentrations of these agents during clinical use vary only over 1 to 2 log units. For example, plasma dobutamine concentrations in critically ill neonates averaged 23 ng/mL at the recommended

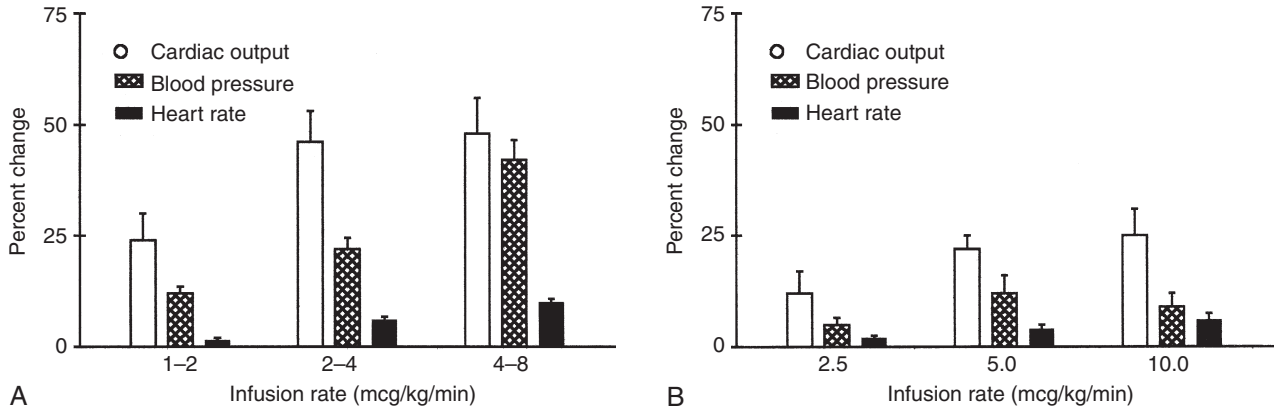

Figure 25-7 Comparison of hemodynamic responses to dopamine and dobutamine in neonates. Results are shown as a percentage of increase in cardiac output *(open bars),* blood pressure *(hatched bars),* or heart rate *(solid bars)* above pretreatment levels. *(Data from Padbury JF, Agata Y, Baylen BG, et al: Pharmacokinetics of dopamine in critically ill newborn infants,* J Pediatr *117:472, 1990; Martinez AM, Padbury JF, Thio S: Dobutamine pharmacokinetics and responses in critically ill neonates,* Pediatrics *89:47, 1992; Habib DM, Padbury JF, Anas NG, et al: Dobutamine pharmacokinetics in pediatric intensive care patients,* Crit Care Med *20:601, 1992; and Berg RA, Padbury JF, Donnerstein RL, et al: Dobutamine pharmacokinetics and pharmacodynamics in normal children and adolescents,* J Pharmacol Exp Ther *265:1232, 1993.)*

starting dose of 2.5 mcg/kg/minute and 92 ng/mL at 7.5 mcg/kg/minute. Because the ED_{50} was developed from a series of drug doses substantially beyond the range in clinical use, it may represent dose-response relationships quite different from those in the clinical arena. The threshold dose is based on steady-state, in vivo conditions and reflects the direct relationship between drug dose and effect during actual clinical conditions.

Finally, this experimental approach demonstrates the most rational use of these drugs in the clinical setting. The stepwise increase in dose with titration to the desired clinical end-point maximizes the beneficial effects of these agents while minimizing the adverse effects such as tachycardia or other arrhythmias (and also desensitization). Because a log-linear relationship exists between dose and response, a "doubling dose"–response curve, as was used in our dopamine studies (2 to 4 to 8 mcg/kg/minute), gives the best results. Likewise, weaning by successive 50% reductions in dose also is more rational than minute decreases with each change.

Special Pharmacodynamic Considerations in Neonates

Developmental changes in myocardial structure and function would be expected to modulate the responses of the newborn to catecholamines. The neonatal myocardium has a greater percentage of noncontractile tissue compared with that in adults and older children and has incomplete sympathetic innervation.[53] In addition, oxygen consumption and myocardial demands are relatively higher in the neonate. Although neonatal myocardial function is excellent at rest, myocardial reserve is limited. Contractility is near maximal at rest. Preload reserve, contractility reserve, and heart rate reserve all are limited.[53,54] It has been presumed that these issues would limit the neonatal myocardial response to catecholamines, although such limited response is not well documented. Similarly, differences in the degree of peripheral maturation and the mechanisms for vascular constriction and relaxation may affect the newborn's responses to inotropic agents.

When catecholamine infusions are used in neonates, the underlying disease states often are associated with pulmonary hypertension. Studies in infants and adults have demonstrated that higher doses of dopamine can increase pulmonary artery pressure, although these results are not consistent.[55-57] Pulmonary α-adrenergic receptors lead to pulmonary vasoconstriction, whereas dopaminergic receptors lead to pulmonary vasodilatation. In most circumstances, increased cardiac output and aortic blood pressure decrease baroreceptor-mediated sympathetic activity, thereby ameliorating pulmonary vasoconstriction. Adverse effects on pulmonary vasculature are not well documented in the neonatal population, and their occurrence has not limited the popularity of these agents in critically ill infants with clinical evidence of pulmonary hypertension.

In the neonate, cardiovascular shock generally is the result of intravascular volume depletion and myocardial dysfunction secondary to hypoxic injury. Therefore intravascular volume repletion is recommended for initial treatment of cardiovascular shock.[55] Myocardial dysfunction or vasoregulatory disturbances, however, frequently accompany shock. In this circumstance, inotropic and vasoactive therapy with catecholamines can improve myocardial function and oxygen delivery.[55-62] We compared the hemodynamic responses of newborns to either dopamine or dobutamine in the studies described earlier to generate the threshold data.[14-17] When responses are expressed as a percentage of improvement in cardiac output, blood pressure, or heart rate above initial level, as shown in Figure 25-7, dopamine has a greater effect on both cardiac output and blood pressure than that seen with "equivalent" (equimolar) doses of dobutamine. Dobutamine has a greater proportional effect on cardiac output than on blood pressure, consistent with its "selective inotropic effect" observed in many studies in adults.[63] This finding implies that in clinical disorders such as congestive cardiomyopathy, which frequently accompany perinatal asphyxia, dobutamine is a preferred inotropic agent. By contrast, cardiovascular dysfunction secondary to neonatal sepsis may be accompanied by substantial derangements in peripheral vascular function;in this setting, therefore, dopamine, with its greater effects on blood pressure and peripheral vascular contractility, is preferred.

Other investigators have suggested that dopamine may be more effective than volume expansion or dobutamine for management of hypotensive preterm infants during the first few days of life.[55,59-62] In this population, hypotension may be more frequently caused by poor peripheral vasoregulation with or without myocardial dysfunction than by volume depletion.[55,59,60] The greater chronotropic effect of dopamine can be a clinical limitation to its usefulness. Concomitant treatment with both drugs is frequent and not necessarily discouraged; however, direct pharmacodynamic evidence of differences, if any, in dose-response relationships when these drugs are given together is limited.

Neonates in congestive heart failure have high levels of endogenous catecholamines[62] and frequently require exogenous catecholamines for hemodynamic support.[64] Epinephrine infusions in isolated intact newborn piglet hearts resulted in left ventricular systolic and diastolic dysfunction, associated with irreversible ultrastructural abnormalities.[65] The clinical relevance of these worrisome in vitro findings is not clear.

SUMMARY AND CLINICAL IMPLICATIONS

The approach to pharmacokinetic and pharmacodynamic studies of inotropic agents presented in this chapter provides insights not afforded by more traditional methods. An experimental approach to the generation of a derived parameter, the threshold, is provided to describe dose-response results for in vivo data. This derived parameter permits comparison of responses among different subjects and results of different investigators. This approach avoids some of the flaws inherent in extrapolation of in vitro data to the clinical setting and allows new insights into the comparison of drug effects between different agents, in different clinical settings, and at different developmental ages. It also demonstrates the most rational approach to clinical use of these agents. Volume expansion is indicated before administration of inotropic agents. With an inadequate response in clinical (perfusion) or physiologic parameters (blood pressure, urine output, acid-base status, or cardiac output or contractility), inotropic support is indicated. The clinician should start at a low dose, near or just above the predicted threshold. The administration rate should be increased by doubling the dose every 15 to 30 minutes until the desired clinical response is observed or until undesired side effects (usually tachycardia) are observed. In a similar fashion, a rational approach to weaning by 50% reductions in dose is based on recognition of the log-linear relationship between dose and response. Therefore incremental adjustments in dose should be 25% to 50% reductions, with continued monitoring of clinical and physiologic responses. These approaches maximize beneficial responses while minimizing both adverse effects and desensitization.

Maternal Drug Abuse: Effects on the Fetus and Neonate

GENERAL PRINCIPLES

Substance abuse by pregnant women is the leading *preventable* cause of psychologic, physical, and mental problems in infants and children. Women of reproductive age, like many other demographic groups in today's society, have been steadily increasing their nonmedical consumption of drugs to the point of abuse. *Substance abuse* is defined as an excessive self-administration of licit and illicit chemicals to alter perception of the user's cognitive status.[1] The most commonly abused substances are alcohol, cocaine, marijuana, tobacco, and psychotherapeutic agents. Among the opioids, morphine, heroin, and methadone appear to be the ones most frequently used by women of child-bearing age.

Although the maternal effects of substance abuse may be tolerable and desired by the user, the effects on the fetus and neonate often are serious and manifested in neurobehavioral and physical anomalies. With the thalidomide disaster of the late 1950s and early 1960s, it became evident that the placenta is not a protective barrier against all therapeutic and abused substances. Although several compounds are human teratogens, most agents given to pregnant women do not pose significant reproductive hazards when used in recommended doses.[2] Some teratogenic drugs are continued throughout pregnancy, however, because the therapeutic benefit to the woman outweighs the risk to the unborn child.[3]

Numerous attempts have been made to describe the nature and extent of maternal drug abuse during pregnancy and its potential impact on the fetus and neonate. The National Institute on Drug Abuse's National Pregnancy and Health Survey[4] revealed that 5.5% (221,000) of the approximately 4,000,000 women who gave birth to live babies in the United States in 1992 had used some licit or illicit drug during pregnancy. The most frequently used drugs in pregnancy among these 221,000 women were: 1.1% (45,000) used cocaine (all forms), 0.1% (3600) used heroin, 2.9% (119,000) used marijuana, 0.1% (3400) used methadone, 0.1%(4,500) used methamphetamine, 0.3% (12,100) used inhalants, 0.2% (8,700) used hallucinogens, and 1.5% (61,000) reported the nonmedical use of psychotherapeutic agents at some point during their pregnancy. In addition, but not included in the aforementioned 221,000 women, 18.8% (757,000) of women reported the consumption of alcohol and 20.4% (820,000) reported that they smoked cigarettes during their pregnancy.[4] The significant impact of maternal substance abuse also is reflected in the 2002 to 2003 National Survey on Drug Use and Health, which found that of pregnant patients 15 to 44 years of age, 4.3%, 18%, and 9.8% used illicit drugs, tobacco, and alcohol, respectively. The approximate numbers of births in the United States complicated by maternal use of drugs in 2002 were 172,934 for illicit drugs, 723,911 for tobacco, and 394,129 for alcohol.[5] Hence, the impact of substance abuse during pregnancy in the United States extends far beyond only the risks to the health of the mother, affecting a large number of unborn children as well.

Maternal drug abuse during pregnancy is an indication of the seriousness of psychological dependence (addiction) on the nonmedical use of drugs because the evidence suggests a trend among mothers to decrease the rate of drug consumption from 3 months before pregnancy and throughout the gestational period, rather than to achieve complete discontinuation of drug use.[4] In addition, the tabulated figures provided by the National Pregnancy and Health Survey[4] may actually be underestimates, in view of the underreporting of live neonates born to substance-abusing women.

Physicians dealing with high-risk pregnancies attributable to maternal drug abuse must recognize that fetal and neonatal complications are confounded by polydrug use in these patients.

Studies have indicated a strong association between cigarette smoking and alcohol consumption and use of illicit drugs. For example, of those women who reported both alcohol and cigarette use during pregnancy, 20.4% also used marijuana and 9.5% used cocaine.[4] Therefore fetal and neonatal dynamic outcomes represent a composite of all of the substances used by mothers during pregnancy. In addition, maternal drug and polydrug abusers are at higher risk for sexually transmitted diseases and poor prenatal care, and they generally lack the appropriate and necessary resources to care for the neonate with complications associated with in utero drug exposure.

Significant differences in total rates of substance use were found among four sociodemographic variables related to pregnant women[4]: marital status, level of education, employment status, and method of hospital payment. The rates of illicit drug use during pregnancy of marijuana, cocaine, and cigarettes were highest for women who were unmarried, unemployed, had less than 16 years of formal education, or relied on public aid to pay for hospital expenses.[4] The highest rates of alcohol use during pregnancy were by women who were married, employed, had completed college, or had private medical insurance.[4]

It is important for emergency and obstetric medical staff to recognize that the prevalence of substance abuse differs among ethnic minorities and different age-groups, to be able to execute efficient implementation of the most appropriate management algorithms. Overall, 11.3% of African-American women, 4.4% of Caucasian women, and 4.5% of Hispanic women used illicit drugs while pregnant.[4] While African-American women had higher rates of drug use, the estimated population of Caucasian women who used illicit drugs was much larger than that of the African-American or Hispanic populations. Therefore, in terms of actual numbers of users, most women who took drugs while they were pregnant were Caucasian (113,000) followed by African-American and Hispanic women (75,000 and 28,000, respectively).[4] Alcohol and cigarettes were abused by Caucasian women more often (22.7% and 24.4%, respectively); cocaine was most often used by African-American women (4.5%).[4] Rates of marijuana use were highest (3.5%) in the youngest age-group (younger than 25 years of age), whereas cocaine use was highest (1.6%) among older women (25 years of age and older).[4]

This chapter presents an overview of current knowledge about substance abuse during pregnancy and the potential associated fetal and neonatal effects. A general course of treatment also is described for each substance of abuse. In addition, studies on how drugs of abuse eventually reach the fetus and the neonate to elicit their harmful effects are well documented and covered elsewhere in this text and other publications.[6-35]

MATERNAL DRUGS OF ABUSE DURING PREGNANCY

Alcohol

Alcohol is an anxiolytic analgesic with a depressant effect on the central nervous system (CNS). Women who drink heavily (defined as consumption of an average of at least 2 drinks per day, or 1 drink per day and occasional binges of 5 or 6 drinks in one sitting, or 45 drinks or more per month)[36] have a higher predilection for polydrug use and exhibit other confounding risk factors—including older age and parity or, conversely, an increased likelihood of being a younger, single, separated, or divorced woman—that may complicate pregnancy and may jeopardize fetal and neonatal outcome.[37,38] How much drinking during pregnancy is too much? *Risk drinking* during pregnancy, sufficient to potentially damage offspring, has been defined as an average of more than 1 drink (0.5 ounce) per day, or less in the case of binge drinking (i.e., more than 5 drinks per drinking episode).[39] Most reports of adverse prenatal alcohol exposure are related to heavier drinking. More recent research, however, has demonstrated adverse effects for children exposed prenatally to even a small amount of alcohol. Detection of maternal alcohol exposure is particularly challenging because no reliable biologic marker for such exposure has been identified.

The adverse effects of alcohol on the developing fetus make up a spectrum of structural anomalies and behavioral and neurocognitive disabilities, collectively called fetal alcohol spectrum disorders (FASDs).[40] Children with the severe form of such disorders—those with the complete phenotype—are identified as having *fetal alcohol syndrome* (FAS), representing one end of the spectrum. Heavy maternal consumption of alcohol during pregnancy generally is accepted as the factor responsible for FAS.[41] FAS is the most commonly known cause of mental retardation (surpassing Down syndrome) and is characterized by fetal and neonatal growth restriction, severe cognitive impairment resulting from abnormal neural development, microphthalmia, short palpebral fissures, midfacial hypoplasia, abnormal palmar creases, cardiac defects, and joint contractures.[42-45,45a] No single finding is considered pathognomonic, and not all features are present in every neonate who has FAS.

The association of FAS with ethanol dose is not always clear. In many cases, only a few of the typical characteristics are present. Neonates with partial-expression FAS (namely, those with only one or two of the syndrome's characteristics) exhibit *fetal alcohol effects.* This condition is observed in the infants of women who consume fewer than two drinks per day. It remains unexplained, however, why only 10% of fetuses exposed to large amounts of ethanol per day (the ethanol content of six maternal drinks per day) exhibit full-blown FAS. Possible explanations include variations in placental and fetal vasculature, different rates of organogenesis, different rates of ethanol metabolism and elimination by the fetus, and differences in fetal susceptibility to teratogenesis.[46-48] Acetaldehyde has been suggested as a possible causative factor. Some evidence points to substantially higher levels of acetaldehyde in mothers with alcoholism who give birth to children with FAS than in those mothers who have normal babies.[49] Although no definite exposure threshold has been identified, a dose-response relationship is recognized.[50] Furthermore, placental perfusion experiments have shown that the human placenta metabolizes alcohol and contributes to the acetaldehyde transferred into the fetal circulation.[51]

FAS occurs in approximately 1 to 3 infants per 1000 live births in the United States; 2.5 to 10% of women with alcoholism have a child with FAS.[52,53] It generally is accepted that FAS occurs when maternal alcohol consumption reaches six to seven drinks per day (one standard drink is the equivalent of 12 ounces of beer or a 5-ounce glass of wine, or 1.5 ounces of liquor, or approximately 15 g [0.5 ounce] of absolute alcohol). It has been shown that having two drinks per day does not increase the risk for FAS; however, having three drinks per day during pregnancy is associated with a lower intelligence quotient (IQ) at the age of 4 years in children born to women with this drinking history.[1,54]

Pharmacology of Alcohol

The level of blood alcohol (ethanol—C_2H_5OH) depends on the type of beverage (e.g., beer slows absorption) and its ethanol concentration, the gastric contents, and gastrointestinal motility.[55] From 80% to 90% of the absorption of ethanol occurs within 30 to 60 minutes of its consumption. Food may delay absorption for 4 to 6 hours.[55] Absorption occurs primarily in the small intestine, whereas 20% to 30% is rapidly absorbed through the stomach. Ethanol distributes rapidly throughout the fetal circulation because it is both water- and lipid-soluble. The ethanol molecule is mildly polar so it easily crosses cell membranes, the blood-brain barrier, and the placenta. The volume of distribution is estimated to be 0.6 L/kg in adults and 0.7 L/kg in children; this corresponds to total body water. The volume of distribution is slightly smaller in women because of their lower water and higher fat content compared with men. Because of the rapid distribution of alcohol,

early determination of the blood alcohol concentration provides a reliable estimate of ethanol consumption.

Once ethanol is absorbed into the bloodstream, it is the metabolite acetaldehyde that causes the pharmacodynamic effects in the consumer. Approximately 95% of ethanol is converted by hepatic oxidized nicotinamide adenine dinucleotide (NAD^+)-alcohol dehydrogenase to the obligate intermediate acetaldehyde, which is more toxic than alcohol. Acetaldehyde is oxidized in the liver by NAD^+-dependent aldehyde dehydrogenase to form acetate. Acetate also is oxidized once in the bloodstream. The kidneys, muscles, lungs, and intestines also contribute to ethanol metabolism. Up to 5% to 10% of ethanol is excreted unchanged in the breath, urine, and sweat. The average rate of alcohol metabolism is 10 mL/hour. Alcohol is esterified with fatty acids to produce fatty acid ethyl esters, which accumulate in neonatal meconium and may be a promising marker for use in a screening test for heavy maternal drinking during pregnancy.[56,56a]

Effects of Alcohol Consumption on the Fetus and Neonate

Early diagnosis of FAS in a neonate or infant is essential to minimize the development of subsequent secondary disabilities. FAS is diagnosed when characteristic facial dismorphology (short palpebral fissures, flat philtrum, thin upper lip), growth restriction, CNS impairment, and neurodevelopmental abnormalities are present with or without confirmation of prenatal alcohol exposure. Multiple approaches to the diagnosis of FAS have evolved, including the guidelines by the Institute of Medicine (IOM) from 1996 (revised 2005), the 4-Digit Diagnostic Code (created using data from the Washington State Fetal Alcohol Syndrome Diagnostic and Prevention Network of Clinics, revised 2004) (Table 26-1, *A*) and the Canadian Guidelines (created in 2005), which also harmonize the IOM and 4-Digit Diagnostic Code approaches (see Table 26-1, *B*).[57] FAS diagnostic variables are presented in Table 26-2. Diagnosis of FAS in a neonate or infant also can be based on the presence of at least one sign in each of the first two categories listed in Table 26-2; a neonate or infant also must have at least two of the three characteristics in category 3.[58] Although the approaches are different, the underlying fundamental criteria are similar. The 4-Digit Diagnostic Code is now being used throughout the United States and Canada (see Table 26-1A).

Other features associated with FAS may include specific minor anomalies of the face—epicanthal folds, a flat nasal bridge, a thin vermilion border of the upper lip, a hypoplastic maxilla, and a flattened midface. Strabismus, ptosis, poorly formed external ears, congenital heart defects, neural tube defects, renal abnormalities, and unusual palmar creases also have been documented. All infants with FAS have evidence of intrauterine growth restriction (IUGR): Birth weight, body length, and head circumference are reduced for gestational age.[59] Infants with FAS may not experience catch-up growth and may remain small in comparison with opioid-exposed infants born small for gestational age (SGA).[60] Mild to moderate developmental delays are commonplace, and delays in motor and language development, hyperactivity, hypotonia, hyperacusis, and tremulousness are often described by caregivers.[1]

Pregnant women who are heavy drinkers are at increased risk for spontaneous abortion.[53,61,62] In a study of 1248 women,[62] an estimated minimum harmful dose was 1 ounce of absolute alcohol (two drinks) twice per week. The investigators showed a 25% miscarriage rate in women drinking 1 ounce of absolute

TABLE 26-1A

4-Digit Diagnostic Code Criteria for Fetal Alcohol Syndrome Disorders (FASDs)

Rank	Growth Deficiency	FAS Facial Phenotype	CNS Damage or Dysfunction	Gestational Exposure to Alcohol
4	*2 Significant* Height and weight below 3rd percentile	*3 Severe* All 3 features: PFL 2 or more SDs below mean Thin lip: rank 4 or 5 Smooth philtrum: rank 4 or 5	*4 Definite* Structural or neurologic evidence	*4.1 High risk* Confirmed exposure to high levels
3	*5 Moderate* Height and weight below 10th percentile	*6 Moderate* Generally 2 of the 3 features	*7 Probable* Significant dysfunction across 3 or more domains	*8 Some risk* Confirmed exposure Level of exposure unknown or less than rank 4
2	*9 Mild* Height or weight below 10th percentile	*10 Mild* Generally 1 of the 3 features	*11 Possible* Evidence of dysfunction but less than rank 3	*12 Unknown* Exposure not confirmed present or absent
1	*13 None* Height and weight at or above 10th percentile	*14 Absent* None of the 3 features	*15 Unlikely* No structural, neurologic, or functional evidence of impairment	*16 No risk* Confirmed absence of exposure to birth

CNS, Central nervous system; *FAS,* fetal alcohol syndrome; *PFL,* palpebral fissure length.

TABLE 26-1B

Harmonization of the Institute of Medicine (IOM) Nomenclature and 4-Digit Diagnostic Code

IOM Nomenclature	Growth Deficiency	FAS Facial Phenotype	CNS Damage or Dysfunction	Gestational Exposure to Alcohol
FAS (with confirmed exposure)	2, 3, or 4	3 or 4	3 or 4	3 or 4
FAS (without confirmed exposure)	2, 3, or 4	3 or 4	3 or 4	2
Partial FAS (with confirmed exposure)	1, 2, 3, or 4	2, 3, or 4	3 or 4	3 or 4
ARND (with confirmed exposure)	1, 2, 3, or 4	1 or 2	3 or 4 (2 for <6 years)	3 or 4

ARND, Alcohol-related neurodevelopmental disorder; *CNS,* central nervous system; *FAS,* fetal alcohol syndrome.
Data from Chudley AE, Conry J, Cook JL, et al: Fetal alcohol spectrum disorder: Canadian guidelines for diagnosis. CMAJ 172(Suppl 5):S1, 2005.

TABLE 26-2
Diagnostic Variables in Fetal Alcohol Syndrome

Category	Variables
1	Prenatal or postnatal growth restriction
	Weight, length, or head circumference below 10th percentile after correction for gestational age
2	Central nervous system involvement
	Neurologic abnormalities: neonatal irritability and childhood hyperactivity
	Developmental delay
	Cognitive impairment: mild to moderate mental retardation
3	Characteristic facial dysmorphology
	Microcephaly: head circumference below third percentile
	Microphthalmia or short palpable fissures
	Poorly developed philtrum and vermilion border; flattened or absent maxilla

alcohol or more, compared with 14% in those women who drank less. This effect was independent of smoking, gestational age, or a history of spontaneous abortion. In another study[61] comprising 32,000 women, a significantly higher risk for second-trimester spontaneous abortion was noted in those consuming one or two drinks per day than in those who consumed less than one drink per day.[61] Among women reporting the consumption of more than three drinks per day, the risk was even higher. A recent population-based, case-control study suggested that drinking during pregnancy is associated with an increased risk of miscarriage, although the effects appeared to be concentrated among those who drank regularly (at least once a week to daily) and possibly among those who drank 14 units of alcohol (in this study, one alcohol unit was half a pint of beer or a small glass of wine) a week.[63]

An increased risk for abruptio placentae has been reported in heavy drinkers.[64,65] A recent study reported that alcohol consumption may be an independent risk factor for placental abruption.[66] Considerable controversy remains regarding the association among maternal alcohol consumption, duration of pregnancy, and the incidence of stillbirth.[53,67-69] The major problem in research efforts to explain poor fetal and neonatal outcomes is the inability to separate high maternal ethanol intake from other confounding variables such as cigarette smoking, polydrug use, and poor prenatal care. A study that adjusted for such confounders found that low to moderate levels of alcohol consumption during pregnancy were associated with slightly higher rates of stillbirth, but the increased rate was not statistically significant.[70] Many investigators have studied the effects of maternal ethanol use on fetal and neonatal growth, as well as on the development of fetuses exposed to ethanol in utero. An average of two drinks per day before conception correlated with a marginally lower birth weight (mean of 91 g) (in comparison with birth weights of infants of lighter drinkers), independent of smoking.[71] A study of 31,600 pregnancies[1] confirmed this observation. In addition, the risk of IUGR is increased with an alcohol consumption of one to two drinks per day.[46-48,72-75] Alcohol interference with the transplacental transfer of amino acids across the placenta may alter embryonic development by inhibiting protein synthesis and prenatal growth. The literature suggests that the level of alcohol consumed by the father also may have an effect on fetal birth weight.[76] A prospective cohort study[77] of 359 neonates that assessed the critical period of alcohol exposure during pregnancy revealed that craniofacial abnormalities are definitively related to first-trimester alcohol exposure.

A recent study from Finland suggested that prenatal alcohol exposure alters long-term brain metabolism in multiple brain areas. These changes corroborate previous findings that long- standing biochemical alterations may occur in response to prenatal exposure to alcohol.[78] A behavioral study[72] of 124 infants born to women classified according to their alcohol consumption found that tremors, time spent with the neonate's head turned to the left, and low activity levels increased progressively with the level of maternal alcohol intake. Infants of women who consumed two to four drinks per day during pregnancy had a lower score for mental and psychomotor development.[74] A 10-year, long-term follow-up study[75] showed severe growth deficiencies and intellectual limitations in those children diagnosed with FAS. Kalberg and colleagues completed a study of 14 children with FAS, ranging in age from 20 to 68 months, in which they assessed motor function in children exposed prenatally to alcohol and in children who had no prenatal alcohol exposure. A majority of these FAS-affected children showed clinically important delays in their motor development.[79] In a longitudinal study of children born to 500 women who were heavy smokers and drinkers,[80] a 7-point decrease in IQ was associated with maternal consumption of more than two drinks per day during pregnancy. A recent behavioral study involving 537 children showed that those who were exposed prenatally to alcohol during maternal binge drinking were 1.7 times more likely to have IQ scores in the mentally retarded range and 2.5 times more likely to exhibit clinically significant levels of delinquent behavior.[81] Postnatal exposure of infants to alcohol also may be harmful. In that regard, infants exposed to alcohol through breast milk scored lower on motor development tasks than unexposed infants at 1 year of age.[82]

Neonatal alcohol withdrawal and neurobehavioral disturbances have been documented in otherwise clinically normal neonates born to women who drank throughout pregnancy.[1] Ethanol exposure during the third trimester increases the probability that the newborn will experience postpartum ethanol withdrawal. In a study by Coles and colleagues,[83] abnormalities were observed in motor performance, autonomic regulation, and reflexive behavior during the first postpartum month in neonates exposed to alcohol in utero. Hyperactivity, hyperacusis, hypotonia, and tremulousness were commonly described in young infants, in addition to withdrawal symptoms characteristic of narcotic withdrawal in neonates.[72,74]

Clarren and associates[84] described multiple brain malformations attributable to fetal alcohol exposure. The most frequently seen malformations were leptomeningeal and neuroglial heterotopias. These investigators found aberrant neural and glial tissue covering large parts of the surface of the brain, as well as extensive brain disorganization from errors in neuronal and glial migration and rudimentary cerebellum and brain stem disorganization.

Abnormalities on the electroencephalogram (EEG) consisting of prominent δ bands and atypical slow waves in the posterior head region have been observed in neonates with FAS.[85] The intellectual deficit secondary to abnormalities in brain growth is the most important component of FAS. Full expression of FAS generally occurs with long-term daily consumption of at least 2 g/kg of alcohol.

Another investigation[86] studying the effect of maternal alcohol ingestion on the incidence of respiratory distress syndrome suggested that among infants born before 37 weeks of gestation, the incidence of respiratory distress syndrome decreased with increased maternal alcohol consumption. The researchers proposed that maternal alcohol ingestion enhanced fetal lung maturation. No direct or indirect epidemiologic evidence or basic scientific information either supports or refutes an association between sudden infant death syndrome (SIDS) and maternal alcohol consumption during pregnancy.[87]

Optic nerve hypoplasia is a nonprogressive congenital anomaly associated with a decreased number of axons in the involved nerve.[88,89] The mother's use of alcohol during pregnancy has been associated with the development of optic nerve

hypoplasia.[90] Optic nerve hypoplasia has been reported in 48% of children with FAS.[91]

Clinical Management of Heavy Drinkers During Pregnancy

It is well known that self-reports of drinking have a definite tendency to minimize the real incidence of drinking episodes and amounts of alcohol consumed.[92] In view of that limitation, accurate determination of the amount of alcohol consumed by the mother during pregnancy is essential because the extent of fetal damage is dose-dependent. The age of the mother, other disease conditions, dietary deficiencies, use of other drugs, heavy smoking, and emotional stress are additional teratogenic factors that must be evaluated when the risk to fetal development from maternally consumed alcohol is assessed.
