where n = the number of moles of oxygen required for the complete oxidation of substrate:

Substrate	n
Glucose	6.0
Lactate	3.0
Glycerol	3.5
Palmitic acid	23.0
β–Hydroxybutyrate	4.5
Acetoacetate	4.0

Using Equation 5, the blood flow terms in numerator and denominator (F_{umb}) cancel out, leaving the ratio of the venoarterial concentration differences of substrate versus oxygen. Thus, as adapted for fetal metabolic studies under steady-state conditions, this method of estimating substrate requirements for energy has the advantage of not requiring measurement of umbilical blood flow or fetal mass. The demonstration of a substrate-oxygen quotient near or equal to 1.0 suggests that if the particular substrate measured were completely oxidized, it could provide 100% of the carbon necessary for the measured fetal VO_2. A substrate-oxygen quotient significantly less than 1.0 would indicate the requirement for other carbon sources to be used to sustain metabolic rate even if the measured substrate were completely oxidized. It then follows that substrate-oxygen quotients greater than 1.0 indicate use of a significant portion of measured substrate for purposes other than energy production (i.e., for synthesis or transformation into other substrates). In fetal sheep, substrate-oxygen quotients measured under steady-state conditions[9] include glucose, 0.5; total amino acids, 0.25; and lactate, 0.25 with negligible fatty acid uptake. In other species including the human, estimates vary from 0.5 to 0.8 (Table 50-3) for glucose-oxygen quotients.

Although useful conceptually and in situations in which steady-state umbilical blood flow is difficult or impossible to determine, substrate-oxygen quotients that have been measured have had limited usefulness. Major limitations to the interpretation of this method include (1) the inability to trace metabolic pathways of

TABLE 50-3

Umbilical Glucose Uptake and Glucose/Oxygen Quotient

Species	Umbilical Glucose Uptake ($mg/kg^{-1}/min^{-1}$)	Umbilical Glucose/O_2
Sheep[69,114]	6.4	0.45
Cow[137]	5.2	0.57
Horse[138]	6.8	0.69
Human[19a,69,81]	4.2-5.0	0.80-1.2

degradation or transformation and (2) the necessity for conditions of steady state (i.e., no change in metabolic rate or blood flow) to be fulfilled to determine V-A differences accurately.

Substrate Utilization

The application of radioactive and nonradioactive isotope ("tracer") methodology[62] has provided interesting new insights into fetal metabolic processes and added substantially to the body of knowledge obtained from interpreting substrate-oxygen quotients and substrate umbilical uptakes via the Fick method. Fetal infusion of substrates such as glucose or lactate,[63] labeled with such tracers as ^{13}C or ^{14}C, can be performed and the fluxes of both radioactive and nonradioactive substrates then measured across the umbilical circulation. In addition, the transformation into other substrates or carbon dioxide can be quantified. Using this method calculation of fetal glucose utilization (i.e., glucose used for oxidation and storage from exogenous and endogenous sources) can be accomplished. As discussed later, under nonstressed conditions in ruminants uptake studies are either in agreement with (glucose) or underestimate (lactate, amino acids) actual fetal uptake and utilization. Limited data have also become available[64-65] in humans using stable isotopes, particularly related to fetal gluconeogenesis (see later). Additional techniques are being perfected for the study of fetal organ metabolism, particularly the brain. For example, positron-emission tomography (PET) has been used in fetal sheep to explore cerebral glucose uptake via estimation of intracellular glucose phosphorylation.[66] Additionally, a recent study by Kok and colleagues[67] has demonstrated that cerebral metabolic information may be obtained noninvasively in human fetuses using proton magnetic resonance spectroscopy.

Respiratory Quotient

In the nongrowing adult mammal, the ratio between generated carbon dioxide and consumed oxygen, the RQ, can provide some indirect information regarding the relative oxidation rates of carbohydrates, fats, and proteins. For example, the RQs of adult subjects oxidizing either carbohydrates or fat are 1.0 or 0.7, respectively, with those on a mixed diet having an RQ of 0.85. In the resting state, the RQ of the fetal lamb is approximately 0.94, suggesting little fetal oxidation of fat. Because of the rapid rate of fetal growth, however, the inequity between carbon uptake and excretion across the umbilical circulation invalidates this method as providing a sensitive measure of differential substrate utilization by the fetus.

Substrate Uptake: Carbohydrate

In most species studied a significant relationship is present between maternal and fetal levels of glucose, the carbohydrate present in highest concentration in fetal blood.[68,69] Other carbohydrates, such as fructose (ruminants) or galactose, are present in fetal blood but appear to play relatively minor roles in oxidative metabolism during fetal life. Fetomaternal transfer of glucose has been best studied (although not exclusively so) in ruminant species, in which determinants of transfer include (1) the maternal glucose concentration, (2) the fetomaternal glucose gradient, (3) the fetal endocrine milieu (specifically fetal insulin and glucagon secretion), and (4) the degree of placental metabolism of glucose. In several other species, including humans, these general determinants of glucose transfer also appear to be applicable. In humans, since the advent of periumbilical blood sampling (PUBS), fetomaternal substrate relationships have been examined more closely,[68] and these have documented that in both midgestation and late-gestation human pregnancies, a high degree of correlation between maternal and fetal blood glucose concentrations exists under relatively steady-state conditions. Marconi and associates[68] have also demonstrated in humans that the fetomaternal glucose gradient increases with advancing gestational age in normal pregnancies (Figure 50-5) and that this difference is more pronounced in growth-restricted fetuses. Using ^{13}C-labeled glucose injected before cesarean section or PUBS, fetal glucose utilization has been estimated in pregnant humans.[70] Although the measured glucose disposal rate of the human conceptus included placenta as well as fetus, glucose disposal rate related directly to the maternal plasma glucose concentration and increased with increasing conceptus mass. Furthermore, estimates of fetal glucose disposal were in agreement with studies in neonatal humans as well as fetuses of several other species.

Understanding of mechanisms of placental glucose transport has been expanded with the discovery of two families of specific membrane associated carrier proteins: the glucose transporter proteins, now labeled GLUT-1-14, and sodium-dependent glucose transporters 1-2 (SGLT 1-2).[71,72] Specifically the GLUT-1 isoform, known also as the brain erythrocyte glucose transporter, is expressed on both the maternal and the fetal facing sides[73] of human placentas. Although the density of transporters on the maternal side (microvillous membranes) remains constant after the first trimester, the concentration of transporters on the fetal facing (basal) side increases at least two-fold after the first trimester.[74] Furthermore, measured rates of placental glucose uptake in vitro match the density of placental GLUT-1 transcripts. In addition, GLUT-1 expression is inhibited by glucose but is not regulated by insulin.[56] In both humans and sheep, it has been estimated that glucose transport capacity is considerably higher than necessary given the normal range for maternal serum glucose concentrations. This suggests that changes in fetal and maternal glucose concentration or metabolism are key factors in determining fetal glucose transport. Within certain tissues, GLUT expression is important for determining the overall contribution of glucose as a major substrate for the fetus. In addition, various factors including insulin and glucose concentrations may modify synthesis of these proteins. For example, acute hyperinsulinemia or glycemia in the sheep fetus leads to an increase in muscle GLUT-4 expression, with a commensurate increase in hindlimb glucose uptake. However, chronic hyperglycemia in the sheep fetus promotes a state of relative insulin resistance, presumably due to a depression of muscle GLUT-4.[56,75] The complex roles and interactions between these tissue-specific GLUTs in regulation of glucose utilization and metabolic rate are not yet fully understood.

The placenta metabolizes glucose derived from both mother and fetus.[73] The rate of placental glucose consumption is not static and appears to be related to the fetal glucose concentration as studied in the fetal sheep.[69] The placental contribution to total uterine glucose uptake is significant and approximates 50% of uterine glucose uptake when measured in the sheep. In addition to concentration gradient, a number of studies have documented that the fetus is capable of exerting some hormonal control over glucose uptake, at least in the last trimester. Several investigators[76,77] have shown that fine control of glucose uptake under steady-state conditions is also mediated by changes in the endogenous fetal insulin concentration. In addition, surgical or chemical ablation of fetal insulin release induces relative

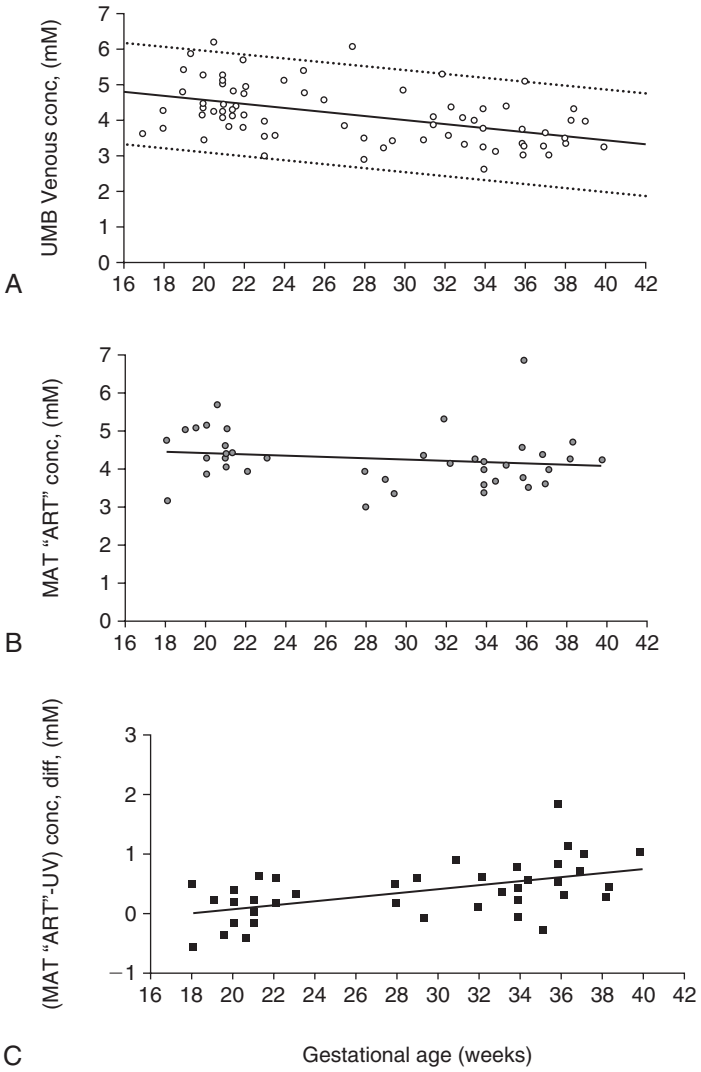

Figure 50-5 Human maternal versus fetal blood glucose concentration changes during gestation. **A,** Umbilical venous glucose versus gestational age in normal fetuses (UV = 5.66-0.56 GA); **B,** maternal arterial glucose versus gestational age; **C,** maternal-fetal glucose difference versus gestational age *(Marconi AM, et al:* Obstet Gynecol *87:937, 1996.)*

hyperglycemia and a decline in umbilical glucose uptake and fetal glucose utilization.[55,78,79] As noted earlier, Hay and colleagues[56] have shown conclusively that changes in circulating insulin concentration act as the principal regulator of glucose oxidation (versus other potential substrates in the fetus), but that regulatory control is more related to the combined factors of glucose and insulin concentrations than either taken separately. Other potential glucose regulatory hormones, such as glucagon, cortisol, and thyroid hormones, have been studied to a lesser extent in the fetus. In the absence of maternal or fetal disease, changes in physiologic concentrations of these hormones in fetal blood do not seem to be major factors in regulating steady state fetal glucose uptake until late gestation. It is highly likely that they are important coregulators of glucose metabolism during parturition and may also be very important in providing glucose homeostasis during times of stress, such as during maternal fasting or malnutrition.[57,57a,80]

Glucose Uptake and Utilization

Because of estimates of the fetal RQ approaching 1.0 as well as the relatively high concentrations of glucose in fetal blood, it was previously thought that a significant fetal uptake of glucose occurred. To test this hypothesis, a number of investigators measured glucose uptake in the fetus using classic Fick principle techniques (net umbilical uptake, Equation 2) as well as radiolabeled glucose transfer (fetal uptake and utilization). In one comparison of the two methods, Hay and colleagues[69] reported essentially identical results—measured net umbilical uptake of glucose was similar to the rate of fetal glucose utilization in the sheep, and both were related to the maternal glucose concentration. These results in the sheep fetus imply negligible endogenous fetal glucose production in the resting nonstressed state (see later discussion).

Studies in a variety of species, including human, show that net umbilical glucose uptake near term is between 4 and 7 mg (22 to 39 μmol)/kg/minute. This equates to approximately 6 to 10 g glucose/kg/day or roughly 32 kcal/kg/day in potential energy production. It is, however, significantly less than the energy estimated to be required by the measured fetal VO_2, which is approximately 55 kcal/kg/day. In fact, in estimates of umbilical glucose-oxygen quotients obtained in several ruminant species, the complete oxidation of glucose accounted for only roughly 50% of the fetal VO_2 (i.e., umbilical $G/O_2 = 0.5$; see Equation 5). These estimates, however, represent only the maximum percent

of the fetal VO_2 accounted for by complete oxidation of glucose and therefore overestimate the actual fraction if any significant glucose conversion or storage (such as to glycogen, fatty acids, or triglycerides) occurs. Only a few similar studies in humans are available for comparison[19a,70,81] (see Table 50-3) but are remarkably similar to data obtained in animals. Thus, although glucose represents a quantitatively significant source of fetal energy (fuel), it probably does not supply enough carbon to support the total oxidative demands of fetal life. Studies suggest that at least 80% of measured fetal glucose uptake can be accounted for by brain and striated (skeletal plus cardiac) muscle. Although the fetal liver consumes and oxidizes glucose, net consumption as measured in the sheep is small,[82,83] with significant concomitant hepatic outputs of pyruvate and glutamate. Use of other methods may provide more information. For example, Thorngren-Jerneck and associates[66] using PET scans, have determined that the global cerebral glucose metabolic rate (rate of intracellular cellular glucose phosphorylation) in near-term fetal lambs was 37.8 μmol × min^{-1} × 100 g^{-1}. Calculation of the cerebral glucose/O_2 quotient from Table 50-2 and Equation (5) yields a value of 1.1, similar to previous estimates measured more directly.

Unfortunately similar measurements of glucose uptake and oxidation are not available in other species. Less direct work in species such as the rat, pig, or guinea pig,[59,84,85] however, is in agreement with these estimates. In the human, demonstration of glucose uptake and utilization by fetal brain, liver, and placenta has also been documented. Estimates of glucose production (not utilization) in normal term and preterm newborns[65] using stable isotopes have suggested values of 3 to 5 mg/kg/minute. Although cord blood venoarterial differences of glucose in human studies[68,81] are positive, that is, suggesting net umbilical uptake, direct measurements of uptake or oxidation are limited. As noted previously, however, measurement of glucose disposal rate in human fetuses appears in the range of 5 mg (28 μmol)/kg/minute.[70]

GLUCOSE STORAGE

Glycogen

In the fetus as in the adult, the major storage form of glucose is glycogen, a glucose polymer stored intracellularly as a precipitate, with an average molecular weight of 500,000 daltons or greater. In fetal life, glycogen is stored in significant concentration in liver, skeletal and cardiac muscle, kidney, intestine, brain, and placenta. From the work of Shelley,[86] it is apparent that glycogen storage in most fetal species reaches a maximum concentration at term gestation in organs such as liver and skeletal muscle. In most other storage sites (i.e., lung, myocardium, kidney, and placenta), however, peak values are attained somewhat earlier (50% to 70% gestation), with a gradual decline near term to adult levels. The factors responsible for glycogen synthesis and induction of enzymes necessary for glycogen synthesis are complex (Figure 50-6) and reviewed elsewhere.[87]

Of importance are the following generalizations: (1) Activity of the enzyme necessary for glycogen synthesis (glycogen synthase) correlates well with the relative presence or absence of glycogen in fetal tissues. (2) Fetal liver glycogen synthesis appears to be regulated by both endogenous fetal insulin production and intactness of the fetal pituitary-hypothalamic-adrenal axis. Studies show lack of hepatic glycogen accumulation in decapitated fetal rats or rabbits with little effect on glycogen synthesis in other organs.[88,89] Fetal thyroid function may also be an important contributor to hepatic glycogen storage.[57,57a] (3) Significant fetal glycogen turnover with active degradation probably occurs in the last trimester but with relative net accumulation in tissues such as liver. (4) Certain organs, such as the placenta, accumulate glycogen in response to maternal stimuli such as human placental lactogen or insulin with little response to changes in fetal hormonal levels.[90] Maternal nutritional sufficiency plays a major role in late fetal glycogen deposition, but some discrepancies in the literature currently exist, probably as a result of species differences as well as differences in experimental design. In general, when studied in the rat or sheep,[91,92] significant maternal malnutrition causes a decrease in maternal hepatic glycogen stores but inconsistent changes in fetal hepatic glycogen.[93] Interestingly, in late gestation fetal leptin infusion in fetal sheep was shown to inhibit glycogen storage as well as enzymes of gluconeogenesis, suggesting an important role for the less well-characterized hormone in control of glucose homeostasis.[94] (5) Glycogen synthesis is highly energy dependent: both glycogen stores and glycogen synthase activity are depressed in experimentally induced intrauterine growth–restricted rats (IUGRs).[95] The mechanism appears to be related to impaired oxidative phosphorylation in liver and muscle, leading to depressed levels of ATP. Synthesis of glycogen classically derives from glucose. It has been demonstrated, however, that a significant portion of glycogen in the postabsorptive adult actually is synthesized from precursors of gluconeogenesis such as lactate and pyruvate (see Figure 50-6). This also appears to be the case in the sheep fetus.[96]

Another potential pathway for glycogen production (transformation of glycolytic intermediates through serine for the production of glycogen) has been documented in fetal hepatocytes.[97] This pathway allows for bypass of the gluconeogenic step oxaloacetate to phosphoenolpyruvate (which is rate limiting because of the developmental lag in fetal gluconeogenic enzyme synthesis (see later). It has been estimated that the alternative serine pathway could account for up to 25% of the glycogen produced.[97] In addition, serine and glycine are cycled between fetal liver and placenta,[60,61] providing another convenient source of precursor for fetal glycogen deposition.

Glycogen breakdown (glycogenolysis) with resultant availability of glucose for use as fuel substrate is an obvious important factor contributing to glucose homeostasis during the perinatal period and has significant survival value for the fetus in times of stress. The regulation of the activity of the enzyme involved in glycogenolysis (glycogen phosphorylase) is reciprocal to that of synthase. Thus when one is stimulated (as when phosphorylase expression is stimulated by catecholamines or glucagon), the other (synthase) is inhibited. In fetal tissues such as liver and kidney, glycogen breakdown can be induced by such hormones as catecholamines or glucagon or by stimuli such as cold stress or hypoxia. In these tissues the presence of glucose-6-phosphatase allows for glucose dephosphorylation and net glucose exit from intracellular stores. Thus free glucose can be released into the peripheral circulation for use at sites (e.g., brain) distant from the original storage tissue. In other organs such as lung, placenta, and myocardium, phosphorylase, but not glucose-6-phosphatase, is present, and stored glycogen is available only for intracellular consumption within the storage site. For some tissues such as myocardium and placenta, which have large obligate glucose requirements, this offers a distinct degree of protection against the sudden onset of hypoglycemia. For whatever reason, central nervous system glycogen storage in fetal life is minimal. In the late-gestation fetus it is possible to demonstrate glycogenolysis in response to pharmacologic doses of such secretagogues as glucagon.[98] In malnourished sheep, however, as in humans with intrauterine growth restriction, there is inconsistent evidence as to whether significant glucose production may occur from stored glycogen.[64,96] However, growth-restricted rat fetuses[99] have been shown to have markedly diminished glycogen synthesis, due to deficiencies in pyruvate oxidation and mitochondrial ATP generation.

GLUCONEOGENESIS

Another major pathway for the endogenous production of glucose is via synthesis from nonglucose precursors, such as certain amino acids, lactate, or pyruvate (see Figure 50-6)

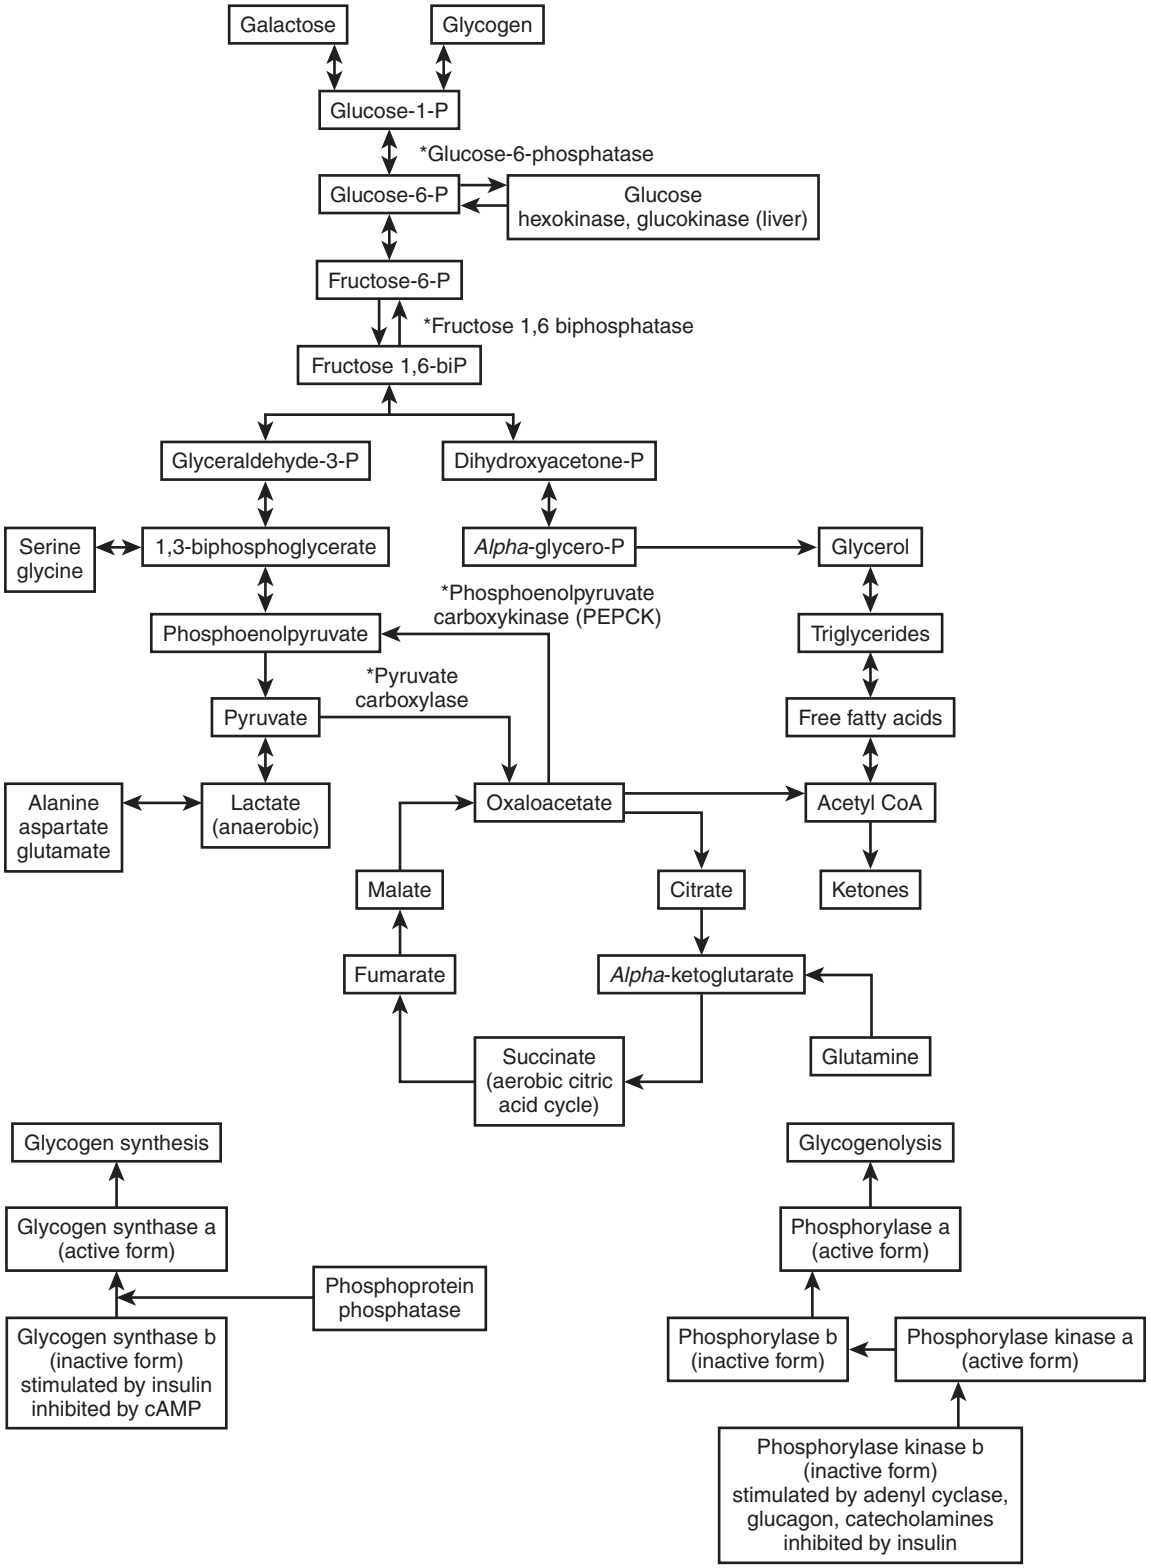

Figure 50-6 Metabolic pathways involving fetal metabolic substrates. Key gluconeogenic enzymes (*) include (1) glucose-6-phosphatase, (2) fructose-1,6-biphosphatase, (3) phosphoenolpyruvate carboxykinase, and (4) pyruvate carboxylase, and metabolic pathways involved in glycogen synthesis and degradation. *(Redrawn after Pagliara AS, et al:* J Pediatr *82:365, 1973; Milner RDG: In Beard RW, Nathanielsz PW [eds]:* Fetal Physiology and Medicine. *New York, Marcel Dekker, 1984. In Devlin TM [ed]:* Textbook of Biochemistry, *6th ed: with clinical correlations. Hoboken, NJ, Wiley-Liss, 2006.*

(i.e., gluconeogenesis). Although the regulation of gluconeogenesis has been extensively studied in adult humans, significant capacity for gluconeogenesis in the human fetus has not been documented. For glucose to be synthesized from substrates such as glutamate or lactate, key enzymes located largely in liver and kidney must be present. Activities of phosphoenolpyruvate carboxykinase (PEPCK), pyruvate carboxylase (PC), fructose-1, 6-biphosphatase, and glucose-6-phosphatase have been measured in fetal liver from several species, including the human and are summarized elsewhere.[65] Although glucose-6-phosphatase activity is present from the twelfth week of gestation in the human, PEPCK activity is considerably less than in postnatal life and appears to be rate limiting in terms of glucose production. Activities of the other two gluconeogenic enzymes appear to be intermediate. In animal studies of gluconeogenic enzyme capacity, such as in the rat, similar patterns of activity are present. When the rate of gluconeogenesis has been measured via either in vivo or in vitro studies, variable results have been obtained, but the consensus is that significant gluconeogenesis does not occur under nonstressed conditions in the fetus.[65] For example, even though the liver extracts significant amounts of lactate from the umbilical circulation,[82] gluconeogenesis in fetal sheep or rat liver in vitro is nil unless stimulated by glucagon in the incubation medium. Small but significant rates of gluconeogenesis have been documented using either fetal rat kidney or liver from pig, guinea pig, and monkey. Even in these species, however, there appears to be a developmental increase in gluconeogenic activity only after approximately 90% of gestation. In vivo radiolabeled tracer studies in sheep and rats before term fail to detect significant gluconeogenesis in the resting state,[96,100] although glucagon has recently been shown to stimulate gluconeogenesis in the near-term fetal sheep.[101]

The reasons for these inconsistencies have recently been elucidated by Fowden and colleagues,[96] who have shown in the fetal sheep that the capacity for gluconeogenesis is restricted until the last few days of gestation, when it rises to account for roughly 50% of the glucose utilization rate and parallels the rate of rise in fetal blood concentrations of cortisol and catecholamines. In these studies maternal fasting induced endogenous glucose production only in late gestation fetuses, but 5 to 6 days earlier than would normally have been observed in nonfasted animals. As noted earlier, thyroid hormone, cortisol and catecholamines are all likely to mediate gene regulation and stimulation of synthesis of enzymes involved in hepatic gluconeogenesis. As stress hormones, this may explain the recently proven link between gluconeogenic enzyme synthesis and hypoxic stress (see later).

It is probable (but as yet unproved) that significant endogenous glucose production occurs in the stressed human fetus, such as during maternal hypoglycemia or starvation or in some states of intrauterine growth restriction. In human growth-retarded fetuses exposed to a maternal overnight fast, Marconi and colleagues[64] were unable to detect endogenous fetal glucose production when a maternal infusion of ^{13}C glucose was used. Whether the near-term human fetus has the capacity for significant glucose production under stress conditions such as intrauterine growth restriction is as yet unknown.[11]

MATERNAL DISORDERS: FETAL EFFECTS

In common clinical situations that affect the maternal milieu, fetal metabolic changes may occur as well. These may include (1) fetal hypoxemia induced by maternal hemorrhage or by maternal hypoxemia, (2) fetal hyperglycemia as a consequence of maternal diabetes, and (3) fetal hypoglycemia due to maternal malnutrition or insulin therapy. The majority of information available was derived from studies performed in animals under steady-state conditions. Such studies, in addition to clinical observations, have allowed for some insight into adaptive mechanisms by which the fetus may respond to potentially damaging insults.

Fetal Hypoxemia

Deterioration of umbilical venous oxygen content may occur due to a number of different adverse events. The predominant factors responsible for oxygen transport across the placenta include uterine and umbilical blood flow, the fetomaternal oxygen tension difference, and the hemoglobin concentration in fetal blood.[9] Thus clinically relevant abnormalities that could affect fetal oxygenation include (1) abnormal uterine or placental blood flow as may occur in hypertensive diseases of pregnancy, abruptio placentae, cord occlusion, or following nicotine or cocaine use; (2) maternal hypoxemia due to maternal pulmonary or cardiac disease, seizures secondary to eclampsia, or living at high altitude; and (3) fetal disorders such as sepsis, hemorrhage, anemia, or heart block and certain other tachy- or bradyarrhythmias.

Acute fetal hypoxemia is known to produce a variety of circulatory adaptations that may improve the chances for fetal survival[33,39,102-104] (Box 50-2). These fetal responses include the development of reflex bradycardia, hypertension, redistribution of blood flow (toward central nervous system, myocardium, and adrenals and away from intestine and muscle), depression of fetal breathing and skeletal muscle activity, and increase in fetal oxygen extraction from umbilical blood. Some of these processes are mediated by endothelial NO[105] and may be even noted in relatively immature fetuses.[106] In addition, Gardner and co-workers[104] have demonstrated that hemoglobin concentration rises rapidly by as much as 10% to 15% during controlled cord occlusion. This cannot be explained on the basis of newly generated red cells or splenic sequestration. Such an increase could work to ameliorate the concomitant reduction in transplacental oxygen transport.

Fetal hypoxemia also induces changes in fetal metabolic processes, particularly if it is of acute onset. Theoretically depression of oxygen delivery to respiring tissues increases the ADP-ATP ratio. This acts to stimulate glycolysis (the Pasteur effect), with the effect of subsequently increasing ATP production anaerobically.[87] Thus acute hypoxia would be expected to produce relatively high rates of glucose uptake and lactic acid production in most fetal tissues. If hypoxia is severe, both hypoglycemia and metabolic acidosis with ultimate tissue necrosis result. Several factors, however, appear to lessen the effect of hypoxemia on fetal metabolic processes. When oxygen transport is limited experimentally in the sheep fetus, by partial occlusion of uterine blood flow[107] or by mild maternal hypoxemia,[108] redistribution of blood flow occurs, but little change in fetal VO_2 is noted. In sheep fetuses exposed to severe hypoxemia, whether by occlusion of uterine blood flow or by maternal hypoxemia, fetal oxygen consumption

Box 50-2

Fetal Response to Acute Hypoxemia or Ischemia

Redistribution of blood flow

Skin
Muscle
Increased umbilical O_2 extraction
Decreased fetal movement
Selective decrease in VO_2 (muscle)
Bradycardia
Selective shift toward increased anaerobic glycolysis

declines by 25% to 40%.[33,104,107] Because, as mentioned earlier, the metabolic rate of fetal muscle is related to the ambient oxygen tension, it is not surprising that carcass VO_2 declines more than that of the whole fetus. Although not yet determined, it is likely that the decline in overall fetal oxygen consumption is due to depressed metabolism in other nonessential organs as well, such as fetal intestine, liver, and kidney, and that decreased metabolic work of skeletal muscle (decreased activity) and myocardium (bradycardia)[33,104] also may play a role.

Long-term fetal hypoxemia, as demonstrated in both simulated and true high-altitude animal experiments induces an acclimatization, with increases in fetal erythropoiesis, cerebral blood flow, and oxygen extraction, at the expense of a significant decrease in blood flow to carcass and other organs and a modest fall in cerebral metabolic rate at very low oxygen tensions.[31,32,108] The acclimatization of fetal cerebral arteriolar structure and changes in sensitivity to adrenergic agents both allow for stable cerebral oxygen delivery (product of cerebral arteriolar blood oxygen content and cerebral blood flow). Interestingly, this adaptation, particularly of structure, has been suggested as having long-term consequences on cerebrovascular contractility later in life. The above responses of the fetus to a superimposed potentially hypoxic environment are in contrast to those of animals apparently genetically adapted to living at high altitude,[30] where hypoxic stimuli superimposed on high altitude do produce more significant changes in fetal cerebral VO_2.

In contrast, at sea level, fetal cerebrum and myocardium appear relatively protected from generalized acute fetal hypoxemia because of the increase in blood flow to these organs, probably induced by catecholamine secretion as outlined earlier. In studies of hypoxemia in fetal guinea pigs[109] and sheep,[110] relatively small changes in cerebral VO_2 occur (at the expense of other organs). An increased rate of anaerobic glycolysis can also be demonstrated, allowing for the ongoing production of high-energy phosphates such as ATP. The fetal heart also has a greater capacity for anaerobic glycolysis than that of the adult.[84] It has also been suggested that elevated levels of adenosine 5-monophosphate (AMP) (the precursor for adenosine) constitute an important regulator of blood flow in brain and heart (i.e., that increased levels of AMP and ADP result in increased local concentrations of adenosine, a potent vasodilator). Several investigators have documented a greater dependence of fetal compared with adult myocardium on energy supplied via glycolysis.[13,111] As proof of this concept, inhibitors of glycolysis affect fetal myocardial function to a much greater degree than adult function is altered, but inhibitors of oxidative phosphorylation depress both equally.

Lastly, in states of chronic maternal hypoxemia, such as may occur in a variety of clinical situations, fetal growth restriction is not uncommon.[19a,112,113] Depression of potent fetal growth factors such as insulin-like growth factor I during hypoxic states may have an important protective effect by conserving fetal substrate for energy as opposed to accretion needs.[112]

Another factor that provides protection against the effects of hypoxia is an increased fetal availability of glucose, particularly during late gestation. Hypoxia, and concomitant secretion of catecholamines and cortisol, are major stimuli for glycogenolysis in the adult and probably in fetal life as well.[103] In fetal lambs and monkeys at term, hypoxia causes a fall in hepatic glycogen content and concomitant rise in blood glucose concentration.[86] In fetal lambs exposed to severe hypoxemia, the net fetal glucose uptake doubles within 30 minutes, as hepatic glucose output rises to equal umbilical glucose uptake, and suggests active fetal glycogenolysis. However, in more chronic states of hypoxemia, replenishment of glycogen stores appears unlikely. For example, in the rat fetus exposed to maternal hypoxia, fetal hepatic glycogen synthase mRNA levels fall to approximately 60% of control with a concomitant 50% fall in hepatic glycogen content.[95] Using adult rat hepatocytes raised in tissue culture, recent studies have demonstrated a link between gene expression of key glucogenic enzymes, such as PEPCK, and specific nuclear modifying transcription factors, such as hypoxia and normoxia regulatory elements (HREs and NREs).[19a,36,114] For example, the gene regulating PEPCK has been shown to contain an oxygen-sensing element that modulates action of glucagon in stimulation of gluconeogenesis. Although, not yet proven, it is likely that HREs and other transcription factors play significant roles in modulating fetal responses to stress.[19a,38a] In summary, the simultaneous actions of increased cerebral blood flow (to preserve fetal cerebral oxygen delivery), decreased overall fetal oxygen consumption, and rapid fetal glycemic response ensures adequate substrate and oxygen delivery to vital tissues such as brain and myocardium and provides at least some measure of fetal tolerance to an interruption of placental oxygen transport.

Maternal Hyperglycemia

The diabetic state in pregnancy is associated with a number of specific fetal and neonatal abnormalities, some structural and some metabolic. The development of fetal hyperglycemia as a result of excessive fetomaternal glucose transfer has been well documented in a number of species, including the human, and appears to be the major but not sole factor in the development of such neonatal complications as macrosomia, hyperinsulinemia, and postnatal hypoglycemia. Evidence in sheep[56,115] and monkeys[116] suggests that fetal hyperglycemia or hyperinsulinemia may accelerate fetal metabolism. As noted above in the fetal sheep, changes in the circulating concentrations of glucose and insulin appear to have independent stimulatory effects on fetal VO_2 and glucose oxidation.[56] In relatively short-term studies, direct fetal glucose infusion over 3 to 4 days caused increases in fetal insulin concentrations, fetal glucose and lactate uptake and placental lactate production as well as 20% to 30% increase in fetal VO_2, all suggestive of a significant increase in fetal metabolic rate.[115] More severe fetal hyperglycemia induced a pronounced fetal metabolic change, including fetal acidosis and ultimate death. These latter findings are all consistent with the effects of glucose-induced hypoxia. However, in other work by Hay and co-workers,[56,117] prolonged maternal glucose infusions (2 to 5 weeks) were performed in sheep that induced similar levels of fetal glycemia to those of the more acute studies. These investigators observed considerably lower fetal plasma insulin concentrations during the study and no significant changes in fetal VO_2 despite large increases in glucose uptake and uteroplacental lactate production.

The differences in fetal metabolic responses between the acute and more chronic studies are not clearly understood, but may have to do with the blunting of fetal insulin response to more prolonged glycemia or to the difference between glucose infusions given directly to the mother or fetus. One possible conclusion would be that intermittent, repetitive glycemic insults to the late gestation fetus might be more injurious than chronic sustained hyperglycemia, but this remains only speculation at present. In humans, fetuses and infants of diabetic mothers have been thought to exhibit signs of in utero oxygen deprivation, such as late fetal demise, increased hematopoiesis occasionally leading to polycythemia, and neonatal hyperbilirubinemia. However, conclusive proof of a link between maternal and fetal hyperglycemia and in utero oxygen deficiency remains speculative. Glucose infusion in human pregnancy, however, does result in cord blood metabolic changes that mirror those in sheep studied over the long term.[118] It is presumed that the increase in fetal fuel needs for sustaining the increased VO_2 are met by increased uptake of glucose, placentally derived lactate, and perhaps amino acids and ketones. Interestingly, although human fetuses of diabetic mothers who exhibit excessive growth in utero remain at risk for late fetal demise, macrosomic fetuses of nondiabetic women appear not to be at risk.[119]

The factors responsible for the increase in fetal metabolic rate noted in some studies are unclear, although as mentioned, both glucose and insulin appear to be codependent factors.[117] Fetal hyperglycemia is known to increase the rate of fetal breathing movements in sheep and humans,[54] which might serve to increase muscular work and thus increase the Vo_2. In addition, specific organ responses to accelerated substrate influx or hyperinsulinemia, particularly in liver and brain, may play important roles. For example, fetal glucose infusion in the sheep may accelerate cerebral VO_2 by as much as 70%, with a concomitant increase in cerebral blood flow and glucose entry as well as changes in fetal electrocortical activity.[120] Catecholamine secretion[121] is likely to be responsible for at least some of these changes. The demonstration in prematurely delivered neonates of stimulation of VO_2 by intravenously administered nutrients[122] suggests that metabolic rate may be altered by increased delivery of substrates other than glucose.

Maternal Hypoglycemia

Because the major factor responsible for placental glucose transport to the fetus is the fetomaternal glucose concentration gradient,[73] it follows that induction of maternal hypoglycemia should ultimately depress fetal glucose uptake. In the sheep, maternal hypoglycemia induced by fasting is associated with a fall in fetal plasma glucose concentration and in depression of both umbilical glucose uptake and fetal glucose utilization.[63] Because fetal VO_2 does not change during hypoglycemia induced by maternal fasting[123] or maternal insulin infusion,[124] it is likely that other fuel sources, particularly amino acids and endogenously produced glucose and lactate, are used instead. For example, myocardial lactate uptake alone in the fetus may account for the majority of oxygen consumption in this organ,[111] even in steady state. Fetal muscle and brain also have the capacity to use ketones.[125] In addition, endogenous glucose production has been demonstrated in fetal sheep,[96,117] probably secondary to hepatic glycogenolysis and gluconeogenesis[93] under such circumstances. Chronic fetal hypoglycemia induced by infusing pregnant sheep with insulin was associated with fetal hypoinsulinemia, endogenous glucose production, fetal stunting and marked increases in fetal expression of key enzymes of gluconeogenesis.[63,93] During hypoglycemia of short duration, intracellular stores of glycogen, particularly in myocardium, liver, and kidney, clearly offer an available source of glucose for cellular metabolic processes. More prolonged chronic hypoglycemia caused by malnutrition, however, depletes cellular stores of glycogen in a variety of organs, particularly in brain, liver, and heart.[91,92] Lastly, expression of glucose transporter proteins[71,126,127] (see Substrate Uptake: Carbohydrate) such as GLUT-1 in placenta and GLUT-4 in muscle may also up-regulate in response to changes in circulating glucose (and insulin) concentration and act to increase the cellular uptake of glucose during relative glucose deprivation.

During induction of maternal hypoglycemia, evidence also suggests that other fetal counterregulatory mechanisms can blunt the fall in fetal blood glucose. For example, in sheep fetuses whose mothers were made hypoglycemic either by fasting[76] or by insulin infusion,[128] endogenous fetal insulin levels fell significantly. In the latter case, chronic fetal hypoglycemia appears also to render the fetus less sensitive to later challenges of glucose or arginine, suggesting a state of insulin resistance. In the fetal rat exposed to insulin-induced maternal hypoglycemia, catecholamines rise rapidly[129] and may be elevated in some newborn humans with hypoglycemia.[130] These effects act to stimulate both fetal glycogenolysis and gluconeogenesis. The role that other potential glucose regulatory hormones, such as glucagon, growth hormone or cortisol, play in defense against fetal hypoglycemia is not known, but seems more limited in scope.[131]

The effect of fetal hypoglycemia on fetal metabolism, particularly fetal cerebral metabolism, has not been studied in great depth. As the principal cerebral substrate, glucose is of major importance in maintaining neuronal and white matter integrity. Postnatal hypoglycemic brain damage and resultant neuronal and white matter necrosis have been well documented. Theoretically similar damage should result from sustained fetal hypoglycemia as well. In sheep, however, modest hypoglycemia of 2 to 4 hours' duration produces no changes in fetal cerebral metabolic rate or in cerebral glucose uptake.[132] Richardson and co-workers[133] have proposed an enhancement of cerebral glucose transport in the fetus during hypoglycemia that may have protective value. In addition, use of fetal brain lactate, fatty acids, and ketone bodies as alternate substrates for cerebral oxidative needs have been demonstrated in the fetal and neonatal rat under steady-state conditions.[134]

SUMMARY

The integration between substrate uptake and metabolic rate, as well as the interactions between maternal and fetal environments, makes for a very complex subject. The topics reviewed in this chapter included (a) basic concepts of how metabolic studies may be performed (and interpreted) in the fetus, with examples and a summary of information derived from organ and whole fetus information; (b) fetal carbohydrate metabolism, including the topics of glycogen deposition and breakdown and gluconeogenesis; and (c) several clinically relevant disorders and the fetal responses to them. In all, it is apparent that the fetal mammal in late gestation is able to some extent to partition and control energy needs under most circumstances through a variety of interconnected means to maintain homeostasis when the maternal milieu is altered adversely.

Role of Glucoregulatory Hormones in Hepatic Glucose Metabolism During the Perinatal Period

In terms of metabolism in general and carbohydrate (glucose) metabolism in particular, the neonate is considered to be in transition between the complete dependence of the fetus and the complete independence of the adult.[1-3] In this transitional state, the neonate must become capable of balancing between glucose deficiency and excess, to maintain euglycemia. The dependence of the conceptus on the mother for continuous substrate delivery in utero contrasts with the variable and intermittent exogenous oral intake that is the hallmark of the neonatal period and beyond. Development of carbohydrate homeostasis results from a balance between the morbidities to which the neonate is subject and the factors involved in the development of regulatory control. The maintenance of euglycemia, especially in the sick or low-birth-weight neonate, is difficult. This difficulty reinforces the concept that the neonate is vulnerable to dysequilibrium. This issue recently has become a topic of hightened interest. Hyperglycemia has been identified as an associated pathophysiologic factor in the compromised neonate, infant, and older child in an ever-increasing number of published studies.[4-10] The etiopathogenesis of hyperglycemia has been evaluated relative to whether it relates to primarily hepatic (glucose production) versus pancreatic (insulin secretion) mechanisms, and whether a peripheral mechanism is in play as well in those tissues responsive to the effects of insulin such as muscle and fat. Many of these issues are highlighted in the following discussion. What is not evaluated in this physiologically oriented discussion is the increasing number of clinical studies focusing on the infusion of insulin as a treatment modality—a topic that is of considerable importance as the mechanisms of the dysequilibrium become better understood.[11-18] Whereas Chapter 50 focuses on carbohydrate metabolism in the fetus, this chapter concentrates on the control of glucose homeostasis in the neonatal period, specifically by regulatory hormones.

INSULIN AND GLUCAGON INFLUENCES ON GLUCOSE HOMEOSTASIS

Numerous investigations have focused on the measurement of insulin and glucagon singly and in combination with each other relative to development of glucose homeostasis in the perinatal-neonatal period. Ktorza and associates[19] evaluated insulin and glucagon secretion during the perinatal period. They noted that insulin and glucagon are detected in most species early in gestation. The insulin-glucagon molar ratio is high in the fetus at term, but then it decreases dramatically after birth and remains low during the first hours after birth. This change favors glycogenolysis and gluconeogenesis after birth.

King and colleagues[20] studied postnatal development of insulin secretion in the premature neonate (born at 26 to 30 weeks of gestation) for 110 days after birth and in the full-term neonate for up to 47 days after birth. Insulin levels were measured before and 30 minutes after the beginning of a glucose infusion given parenterally or enterally. The premature neonate exhibited a small response to glucose on day 1 that gradually increased over the course of the study; the full-term neonate was more responsive. The investigators concluded that the premature neonate may take up to 18 weeks to respond fully to an increase in plasma glucose concentration.

Ghiglione and associates[21] measured immunoreactive glucagon (IRG) levels in dogs between 12 hours and 60 days of age relative to four peaks—designated IRG >20,000, IRG 9000, IRG 3500, and IRG 2000—obtained by gel filtration. Changes with age were confined to IRG 9000 and IRG 3500. IRG 9000 was nine times higher in 12- to 36-hour-old dogs than in adults (108 ± 24 pg/mL versus 12 ± 3 pg/mL), decreasing to two times higher (27 ± 5 pg/mL) at 31 to 60 hours. IRG 3500 was higher in the adult only during the first 36 hours after birth (36 ± 5 pg/mL versus 15 ± 3 pg/mL). Insulin infusion (0.2 units/kg, administered intravenously) produced hypoglycemia, but no change was noted in any IRG component in the neonate. In response to an arginine infusion (0.5 g/kg over 15 minutes), an increase in plasma concentrations of IRG 9000 and IRG 3500 was observed in the neonate; however, only IRG 3500 increased in adults. An impaired secretory response to hypoglycemia was noted in the neonate—a conclusion revisited later in the chapter.

Grasso and colleagues[22] infused either glucose (1 g/kg) or saline in 37 term and 35 preterm neonates and measured plasma glucagon, serum insulin, and blood glucose concentrations on the first day of life before feedings were initiated or during the first week after birth. Glucose infusion diminished plasma glucagon secretion by 61% ± 6% in the term neonate and 38% ± 4% in the preterm neonate. Serum insulin response to glucose infusion was variable—attesting to the heterogeneity that exists in the neonatal period.

Mehta and associates[23] reported data for four neonates with severe hypoglycemia in whom the glucose production rate and the plasma concentrations of insulin and glucagon were measured. The hepatic glucose production rate was less than 20% of normal, and plasma insulin concentration was never greater than 12 μU/mL. Two of the four neonates had low plasma glucagon concentration as well (i.e., less than 60 pg/mL); however, a bolus infusion of glucagon restored the glucose production rate toward normal. In one neonate, use of diazoxide further depressed an already low plasma insulin concentration from 4.2 to 1.6 μU/mL. These investigators speculated that the insulin-glucagon ratio may be more important than the absolute concentration of insulin in controlling glucose metabolism.

Glucagon responsiveness of the preterm neonate to glucagon was studied by Jackson and co-workers in a two-phase study comprising 78 premature neonates born at 25 to 36 weeks of gestational age.[24] In the first phase, the neonates were fasted until they became hypoglycemic or were fasted maximally for 8 hours. In the second study, a bolus of glucagon (100 mcg/kg) replaced one omitted feeding. Specific differences identified in those neonates who exhibited an inadequate response to glucagon (i.e., a glucose concentration less than 1 mmol/L) included the following: relative fasting hyperglycemia and hyperinsulinemia; an increased insulin-glucagon ratio; and a lower insulin

sensitivity index. These workers concluded that some premature neonates, without a distinctive phenotype, mount an inadequate response to glucagon and demonstrate features of insulin resistance.

OTHER COUNTERREGULATORY HORMONE INFLUENCES ON GLUCOSE HOMEOSTASIS

Glucocorticoids and insulin mediate the rate of glycogen accumulation in fetal life. In the presuckling period, muscle glycogenolysis supplies lactate moieties that are subsequently oxidized by neonatal tissue and act as alternative substrate until glucose and ketones are available. The subsequent increase in plasma catecholamines and the decrease in the insulin-glucagon ratio result in liver glycogenolysis and gluconeogenesis to maintain euglycemia postnatally. During suckling, oxidation of free fatty acids, ketone body utilization, and gluconeogenesis supply energy for anabolism. Subsequently, the increase in the insulin-glucagon ratio (which occurs during feeding) promotes lipogenesis.

Padbury and colleagues[25] evaluated the catecholamine surge at birth in the preterm and term lamb using an exteriorized fetal lamb preparation in which the preterm animals were treated with surfactant before the first breath. Similar baseline concentrations of catecholamines and a marked rise in circulating epinephrine and norepinephrine were found in both groups after cord cutting. The preterm lamb, however, exhibited a delayed but exaggerated elevation of both catecholamine concentrations compared with those in the term lamb. Changes in heart rate were less profound and more gradual. Likewise, a blunted elevation in blood glucose concentration was noted. These data suggest that the catecholamine surge at birth represents an important adaptive physiologic response.

Hägnevik and associates[26] evaluated the immediate postnatal adaptation and sympathoadrenal activation in neonates delivered vaginally versus in those delivered by elective cesarean section. As expected, the vaginally delivered neonates exhibited higher catecholamine concentrations at birth than those measured in neonates delivered by cesarean section using either epidural or general anesthesia. Likewise, glucose concentration in the umbilical artery was higher in the former group of infants than in those delivered by cesarean section. The investigators speculated that in view of the marked differences in catecholamine concentrations, the differences in metabolic adaptation were unexpectedly small. This finding implied an attenuated metabolic response to sympathoadrenal stimulation in the neonate.

Gripois and colleagues[27] evaluated the interrelationships between thyroid secretion and adrenal medullary secretion in the neonatal rat. The adrenal medulla of normal, hypothyroid, and hyperthyroid rats were stimulated by insulin-induced hypoglycemia. In the euthyroid animal, insulin-induced epinephrine secretion increased during the first 10 days of postnatal life. Hypothyroidism retarded the development of that response, and hyperthyroidism accelerated the response. During adrenal medullary depletion after insulin-induced hypoglycemia, recovery was slower for the hyperthyroid animal than for the hypothyroid or euthyroid animal.

Finally, Hume and associates[28] found that up to 20% of preterm neonates about to be discharged home are at risk for hypoglycemia if a feeding is delayed. Cortisol, corticotropin, and epinephrine concentrations were higher in those neonates who were hypoglycemic, whereas insulin, glucagon, and human growth hormone concentrations in the hypoglycemic neonates were not different from those in the normoglycemic neonates. These workers concluded that hormonal dysfunction in the pretem neonate may contribute to the failure in postnatal development of glucose homeostasis, specifically, the postnatal expression of hepatic enzymes.

KINETIC ANALYSES OF HORMONAL CONTROL OF GLUCOSE HOMEOSTASIS

Kinetic analyses have been used to evaluate hormonal control of neonatal glucose metabolism. Originally, an indirect technique of stepwise incremental glucose infusion was used to infer the rate of basal glucose output or glucose turnover in the neonate compared with the adult.[29] This inference assumed that the neonate was as sensitive as the adult to minimal changes in glucose concentration. Subsequently, studies in the puppy by Varma and associates[30] indicated that fine control is not developed during the neonatal period. Kornhauser and colleagues[31] first used the Steele steady-state infusion technique to show that basal glucose production in the newborn puppy was two to three times the adult rate when expressed per unit of body weight. The data of Varma and colleagues substantiated this observation.

Cowett and associates[32] hypothesized that the insensitivity of the hepatocyte to insulin appeared to have a dominant effect in controlling the turnover (i.e., production) rate of glucose. In the initial series of experiments, it was expected that the newborn lamb, unlike the adult sheep, would exhibit a developmentally blunted hepatic response with a persistent output of glucose in response to a glucose infusion. After a 7-hour fast, basal plasma glucose, insulin, and glucagon concentrations were determined in term (newborn) lambs and in adult sheep, after which the lambs received 0, 5, 6, 11.7, or 21.7 mg glucose/kg/minute over a period of 6 hours. Older sheep received either saline or 5.7 mg glucose/kg/minute. Glucose turnover was determined by the prime constant infusion technique of Steele using D-[6-3H] glucose. Both newborn and adult animals maintained a constant plasma glucose concentration and glucose-specific activity during the turnover period. Glucose production rates persisted in the term newborn lambs until an infusion rate of 21.7 mg/kg/minute was reached. By contrast, in the adult lambs, the glucose production rate was reduced with a glucose infusion rate of 5.7 mg/kg/minute. At the point when the glucose production rate was significantly reduced, the plasma insulin concentration in the newborn lamb was five times greater than in the adult (270 μU/mL versus 56 μU/mL). Blunted hepatic responsiveness to insulin appeared to be a major factor explaining the inefficiency in glucose homeostasis in the neonatal lamb.

In these studies, hyperglycemia and hyperinsulinemia were produced simultaneously. Therefore the effect of peripheral hyperinsulinemia could not be differentiated from that of hyperglycemia. Subsequently, varying concentrations of glucose and insulin were infused in six groups of newborn lambs for sufficient time to produce steady-state equilibrium conditions of euglycemia and hyperinsulinemia.[33] Glucose production rates and gluconeogenesis from lactate were measured. The latter measurement was accomplished by determining the ratio of U-[^{14}C]lactate to D-[6-3H]glucose (*r* in Figure 51-1).

Increasing the rate of glucose infusion without administering insulin (groups II and III in the figure) produced a stepwise increase in plasma glucose and insulin concentrations when compared with controls (group I). Elevation of the plasma insulin concentration induced by hyperglycemia was associated with a significant reduction in the glucose production rate, but it was seen only when marked hyperglycemia and hyperinsulinemia were achieved (group III). With insulin administration, a significant and stepwise increase in plasma insulin concentration was observed, depending on the dose of insulin administered. By simultaneous glucose infusion, a state of euglycemia or hyperglycemia was produced with concomitant hyperinsulinemia. With a slight increase in plasma insulin (61 μU/mL) (group IV), a significant reduction in gluconeogenesis was noted, together with a slight but insignificant reduction in the rate of glucose production. When hyperinsulinemia was moderate to marked (236 and 481 μU/mL) (groups V and VI), there was a significant reduction

of gluconeogenesis and the rate of glucose production. Insulin is known to inhibit glycogenolysis and gluconeogenesis (while enhancing glycogenesis), and it suppresses glucose production in the adult.[34-36] These data suggested that a moderate elevation of plasma insulin concentration effectively reduced gluconeogenesis (groups II and IV) but did not influence the endogenous glucose production. The latter was reduced only when a much higher insulin concentration was achieved (groups II, V, VI). The investigators concluded that insulin, rather than glucose, controls the rate of glucose production in newborn lambs.

In neither of the studies cited was the pancreatic beta cell secretory activity evaluated. It was subsequently hypothesized that the pancreatic beta cell response to glucose concentration was comparable in the term neonate and the older adult (i.e., secretory activity by the neonatal beta cell is normal). To confirm this hypothesis, a steady-state insulin secretion study was performed using [^{131}I]insulin as the tracer.[37] Plasma glucose and insulin concentrations and insulin-specific activity were determined. Endogenous posthepatic insulin secretion and the metabolic clearance rate were derived in the spontaneously delivered term lamb, the betamethasone-treated preterm lamb, and the 4- to 5-month-old adult sheep. After a 7-hour fast, animals received 0.45% saline or glucose (5.7 mg/kg/minute) for 6 hours, followed by the tracer insulin infusion for 11 minutes. Posthepatic insulin secretion rates after infusion of 0.45% saline did not differ among any of the three groups—term, premature, or adult. Correspondingly, similar posthepatic insulin secretion rates also were noted in the three groups after infusion of 5.7 mg/kg/minute of glucose. The metabolic clearance rate did not differ among the groups. The investigators concluded that the posthepatic insulin secretion rate and the metabolic clearance rate were similar in the term gestation lamb, the prematurely delivered lamb, and the 4- to 5-month-old adult sheep. It had been previously suggested that precise control of the rate of glucose production is characteristic of the mature (adult) animal, whereas the neonate evidences a decreased ability to suppress the rate of glucose production when glucose is infused. The investigators suggested that this immaturity may be explained by hepatic unresponsiveness to insulin in the neonate and probably is not related to secretory capacity of the pancreatic beta cell.

The neonatal lamb is metabolically comparable to the human, and it frequently is used to evaluate perinatal glucose homeostasis. Kinetic studies in the human neonate, however, are more physiologically relevant. After the development of stable isotope methodology, it became possible to study the human neonate.[38] Figure 51-2 depicts the glucose production rate for preterm and term neonates and adults who were studied using stable isotope techniques. Five of 13 preterm and 2 of 7 term neonates had persistent glucose production rates (above 1 mg/kg/minute) during glucose infusion. By contrast, the glucose production rate in adults was not measurable. No correlation was found between plasma glucose concentration and the glucose production rate in the neonate or the adult (Figure 51-3). In both the neonate and the adult, however, a correlation was found between the plasma insulin concentration and the glucose production rate, but with considerable variability in the neonate (Figure 51-4). These data point to significant developmental differences in neonatal glucose homeostasis and suggest that insulin is important in neonatal hormonal control of glucose production.

The studies described earlier raise the question of when maturation (i.e., adultlike control) of glucose homeostasis is achieved in the newborn. As noted previously, suppression of the endogenous glucose production rate (Ra) is the adult response to glucose infusion. Persistent endogenous glucose production (i.e., 1 mg/kg/minute or greater, or less than an 80% decrease in Ra) in response to glucose infusion is evidence of a transitional homeostatic state in the neonate during the first days after birth. To determine when an adult-like response developed, Ra was measured in 11 prematurely born neonates (33 ± 0.3 weeks) at 2 to 5 weeks after birth. In these paired studies, 4 μg/kg/minute D-[U-^{13}C]glucose tracer was infused by prime constant infusion to determine Ra, during saline or

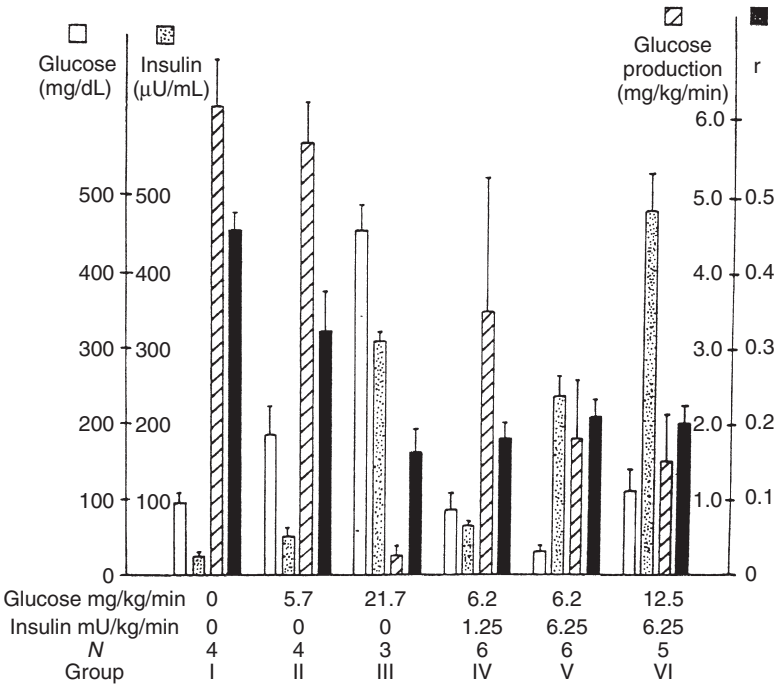

Figure 51-1 Plasma glucose and plasma insulin concentrations, glucose production rates, and ratio of U-[^{14}C]lactate to D-[$^{6\text{-}3}$H]glucose for all groups. *(From Susa JB, Cowett RM, Oh W, Schwartz R: Suppression of gluconeogenesis and endogenous glucose production by exogenous insulin administration in the newborn lamb,* Pediatr Res *13:594, 1979.)*

glucose infusion, the latter at a rate of 5.3 ± 0.2 mg/kg/minute. In comparison with that during the saline infusion turnover period, the plasma glucose concentration increased significantly during the glucose infusion turnover period, from 88 ± 3 to 101 ± 4 mg/dL. Plasma insulin concentration remained unchanged (12 ± 5 μU/mL versus 8 ± 3 μU/mL). Ra was heterogeneous during glucose infusion, and persistent Ra was present in 6 of 11 neonates (Figure 51-5). Of the 5 infants who showed decreased Ra during glucose infusion, 3 received glucose at a rate exceeding basal Ra. Of the remaining 6 infants who exhibited persistent Ra during glucose infusion, 3 received glucose at a rate equal to or in excess of basal Ra. These data suggest that glucose homeostasis in low-birth-weight infants is transitional throughout the neonatal period.[39]

A decreased response to epinephrine in the neonate (a decreased rate of production and decreased plasma glucose concentration) has been reported.[40,41] This lack of response to epinephrine has been correlated with the lack of response to insulin discussed earlier. It is possible, as noted by Hetenyi and colleagues,[42] that the decreased neonatal response to insulin and other hormones (e.g., glucagon or epinephrine) may protect the neonate from rapid fluctuations in substrate supply and may ensure ready availability of glucose for the developing brain. Diminished responsiveness to both insulin and counterregulatory hormones should assist in maintaining glucose homeostasis in the neonate. Other investigators, in more recent studies, examined the hypothesis that the imprecise control of glucose production by insulin is mirrored by a corresponding lack of response to the various counterregluatory hormones. In 30 spontaneously delivered term lambs, glucose kinetics were measured after administration of radiolabeled isotope using the prime constant infusion technique. Insulin infusion at 2.0 mU/kg/minute produced hyperinsulinemic hypoglycemia. Endogenous insulin, glucagon, and growth hormone release were blocked by administration of somatostatin. The addition of metyrapone blocked cortisol release. The control animals received only the isotope. The results suggested that insulin exerted a greater effect on glucose uptake than on glucose production. Glucagon, growth hormone, and cortisol did not affect Ra during hyperinsulinemic hypoglycemia. The imprecise effect of these counterregulatory hormones on neonatal glucose production mirrors the previously documented imprecise control by insulin.[43]

Plotted values are for individual patients. *(From Cowett RM, Oh W, Schwartz R: Persistent glucose production during glucose infusion in the human neonate,* J Clin Invest *71:467, 1983.)*

INSULIN RESISTANCE AND SENSITIVITY IN THE NEONATE

Lack of the precise control of glucose homeostasis in the human neonate has been postulated as secondary to either a decreased sensitivity or a decreased resistance to insulin compared with that in the adult.[38,44] Although methods for assessing insulin resistance have varied considerably, most studies evaluated only the insulin effect on plasma glucose concentration in the hyperglycemic, stressed neonate.[11-18] Fewer studies have evaluated the effects of insulin (or glucose) on glucose production in the healthy term or preterm neonate.[38,45,46]

Hulman and Kliegman[47] and Kliegman and colleagues[48] are credited with the initial use of the euglycemic hyperinsulinemic clamp in the neonatal period in a beagle puppy model, as first published by DeFronzo and associates.[49] Graded insulin infusions ranging from 3.75 to 100 mU/kg/minute were used to generate a dose-response curve. Complete suppression of glucose production was observed in the adult group, whereas an 80% reduction was achieved in the newborn puppy group. These workers attributed a lack of complete suppression of glucose production in the neonate to hepatic resistance to insulin and persistent gluconeogenesis.

Kahn[50] defined insulin resistance and provided a distinction between insulin insensitivity and insulin unresponsiveness: *Insulin insensitivity* is characterized by a shift to the right on the insulin dose-response curve such that a higher concentration of insulin is necessary to produce a half-maximal effect, with a maximal effect achieved eventually. This shift usually is the result of decreased affinity or a decreased concentration of insulin receptors. With *insulin unresponsiveness,* all responses to insulin are reduced (including the maximal response), but the dose-response relationship remains normal (i.e., the insulin concentration required to produce a half-maximal response is normal). This condition usually is the result of a postreceptor defect. A combination of both forms of insulin resistance may exist simultaneously, so that a higher insulin concentration would be required to produce a half-maximal effect, and the maximal effect would be reduced compared with that of a normal response.

In fact, the euglycemic hyperinsulinemic clamp technique to study in vivo insulin sensitivity and the hyperglycemic clamp technique to assess insulin secretion are being used to investigate a number of conditions featuring evidence of insulin resistance.[51]

Farrag and colleagues[52] performed the euglycemic hyperinsulinemic clamp in the human preterm neonate to evaluate insulin sensitivity in the neonatal period. As noted in Figure 51-6, hepatic glucose production was reduced in the preterm neonate at a relatively low insulin concentration. This effect did not significantly change despite the use of higher insulin infusion rates that resulted in as much as 10-fold higher plasma insulin concentrations. The percent reduction in endogenous glucose production ranged from 41% to 58% of basal rates, and persistent glucose production (i.e., at a rate of 1 mg/kg/minute or greater) during steady-state insulin infusion was noted throughout the study. If complete suppression of glucose production is considered to be the maximal effect of insulin on the liver, the data demonstrate that this maximal effect could not be reached in the human preterm neonate. This pattern of response to insulin is most consistent with a postreceptor defect.[53] This mechanism

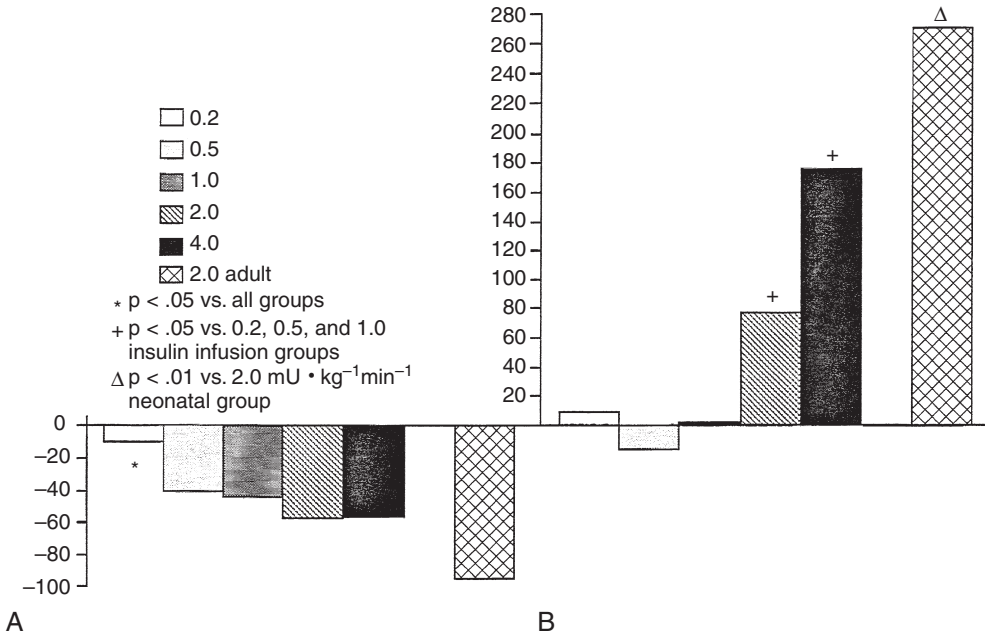

Figure 51-6 The percent decrease in endogenous glucose production and the percent increase in glucose utilization for the various insulin infusion rates of administration in the neonate as well as the insulin rate of administration in the adult (2 mU/kg/minute). *(From Farrag HM, Nawrath LM, Healey JE, et al: Persistent glucose production and greater peripheral sensitivity to insulin in the neonate vs. the adult,* Am J Physiol *272:E86, 1997.)*

may include factors at the membrane level (aside from receptor concentration and affinity) such as (1) the state of aggregation of the receptor, (2) its ability to interact with other membrane proteins required for signal generation, or (3) a variety of intracellular factors including all of the events that occur at site distal to the membrane, including the stimulatory or inhibitory effect of insulin on glucose transporters or key enzymes in the glycolytic, glycogenolytic, or gluconeogenic pathways. Decreased receptor concentration or affinity is an unlikely explanation, because at least in the human adult, plenty of "spare" insulin receptors are available after the number of receptor sites required to achieve a maximal response are occupied.[47,54] Second, an increase in both receptor concentration and affinity is seen in the human neonate compared with those in the adult.[55] Finally, a reduction in receptor concentration to less than that required for a maximal response will result not only in decreased responsiveness but also in decreased sensitivity, which was not apparent in Kahn's investigation.[50]

In the study by Farrag and colleagues just described, a significant increase in peripheral glucose utilization from basal rates occurred at insulin infusion rates of 2 and 4 mU/kg/minute.[52] It was not possible to determine whether a maximal effect on glucose utilization was achieved, because a plateau was not reached. The data denote a significant increase in glucose utilization at a higher insulin concentration than that required to reduce the rate of glucose production significantly (Figure 51-7). Even though that plateau was not ultimately reached at these insulin infusion rates, the neonatal glucose utilization response to insulin, even at a lower plasma insulin concentration, far exceeded that reported in the literature as the maximal response in the adult.[54]

The indirect effect of insulin on endogenous glucose production has been evaluated.[56] Inhibition of lipolysis (in adipose tissue) and reduction of free fatty acid concentrations were shown to act as signals to the liver to suppress endogenous glucose production. This particular issue is of current interest, but the limited amount of adipose tissue in the preterm neonate may potentially interfere with the indirect effect of insulin on endogenous glucose production.

As noted previously, Goldman and Hirata[13] suggested that an attenuated response to insulin in the very-low-birth-weight neonate is the reason for the occurrence of hyperglycemia. They attributed this response to insulin resistance, rather than lack of the beta cell response. In other studies, by contrast, abrupt and sustained improvement in glucose tolerance has been reported to occur in response to short-term and long-term insulin infusions.[11-18] Insulin infusion rates and plasma insulin concentrations used were higher than in the study by Goldman and Hirata, and no evaluation of glucose production or glucose utilization was documented.

An approximate 50% reduction in glucose production has been reported in response to an exogenous glucose infusion rate of approximately 4 to 6 mg/kg/minute (i.e., similar to the basal glucose production rate in the neonate), which resulted in a plasma insulin concentration of approximately 19 mU/mL.[39,46] The literature is unclear whether this reduction in glucose production is primarily a response to a higher plasma insulin concentration or plasma glucose concentration.[32,46] Kalhan and associates[46] suggested that the decline in the glucose production is secondary to a higher plasma glucose concentration, in contrast with the conclusions of Cowett and associates, as noted earlier.[38]

The data of Farrag and colleagues[52] are in accord with those reported by Hertz and associates,[57] supporting a strong positive correlation between plasma insulin concentration and glucose utilization. Hertz and associates noted a complete suppression of glucose production in stable, extremely premature infants when a high glucose infusion rate (i.e., 9.5 mg/kg/minute) was used. The glucose load resulted in a significant increase in both plasma glucose and insulin concentrations. At a similar plasma insulin concentration, a 41% reduction in glucose production was noted, so the combined effect of glucose and insulin seems necessary for complete suppression of glucose production. By contrast, a subsequent investigation from that laboratory suggested that infusion of glucose at a rate of 5.5 mg/kg/minute resulted in a 90% suppression of glucose production during intravenous infusion administered with or without lipid.[58] Suppression was achieved at a glucose

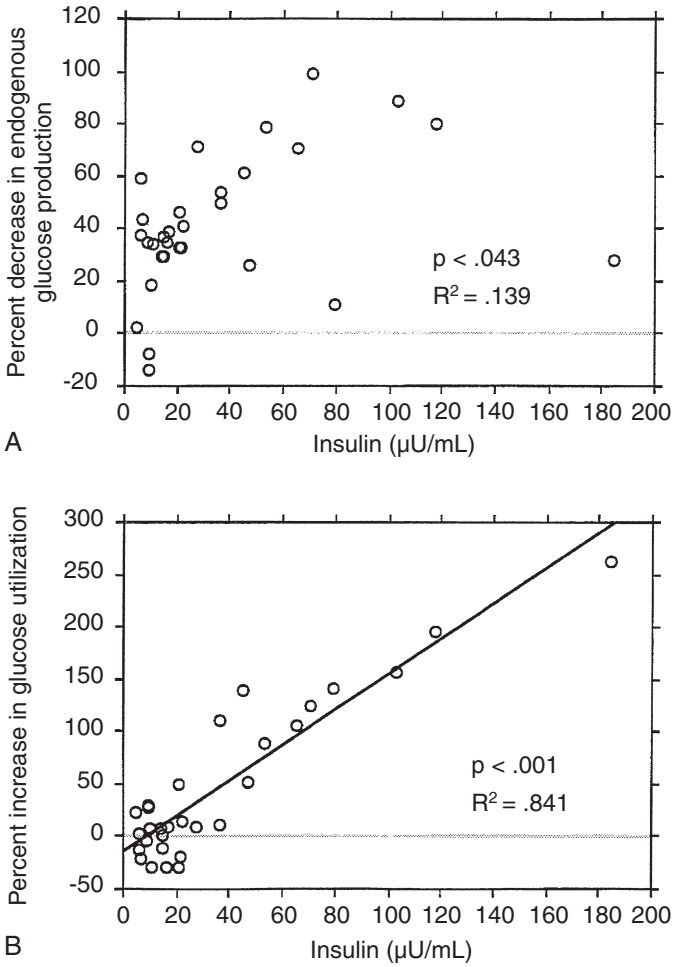

Figure 51-7 **A,** Regression correlating the percent decrease in endogenous glucose production relative to plasma insulin concentration in the neonate. **B,** Regression correlating the percent increase in glucose utilization relative to plasma insulin concentration in the neonate. *(From Farrag HM, Nawrath LM, Healey JE, et al: Persistent glucose production and greater peripheral sensitivity to insulin in the neonate vs. the adult,* Am J Physiol *272:E86, 1997.)*

concentration of approximately 90 mg/dL and an extremely low insulin concentration of approximately 6 μU/mL. The mechanisms explaining the dichotomy that exists in the two datasets are unclear.

It is difficult to compare neonatal with adult data, especially when basal glucose production rates, glucose utilization rates, and plasma insulin concentrations are different. As in the adult, a strong positive linear correlation has been found between plasma insulin concentration and the glucose utilization rate. The insulin effect on the glucose production rate begins at a lower insulin concentration than that required for the glucose utilization rate. If insulin sensitivity is calculated at euglycemia (that is, not confounded by non–insulin-mediated glucose utilization),[59] it is apparent that the neonate has a greater peripheral sensitivity to insulin than that in the adult. This increased sensitivity may result from a higher receptor concentration and affinity, provided that the postreceptor cascade is intact peripherally. Conversely, unlike in the adult, complete suppression of glucose production could not be achieved in the human neonate by Farrag and colleagues.[52]

Gelardi and associates,[60] using a lamb-sheep model, performed the euglycemic hyperinsulinemic clamp studies in two specific age-groups: 3- to 6-day-old lambs and 31- to 35-day-old sheep. Initially, the younger animals needed a higher rate of glucose infusion (15.87 ± 3.47 mg/kg/minute; p <.05) to maintain euglycemia compared with the older animal group (4.30 ± 1.11 mg/kg/minute) receiving the same amount of insulin—100 mU/kg/minute. In fact, endogenous glucose production persisted in both groups; however, the percent decrease compared with that in aged-matched controls receiving no insulin was greater in the younger group (53%; p <.001) than in the older group (34%; p <.01). The younger animals exhibited greater glucose utilization than that seen in the older animals (215% versus 90%, respectively; p <.01) (Figure 51-8). As in the human neonate, endogenous glucose production was not completely suppressed in the lamb despite very high plasma insulin concentrations. The younger animal group appeared to be more responsive to insulin, resulting in a significantly greater percent decrease in endogenous glucose production than in the older animals. The older animals also required significantly lower glucose infusion rates to maintain euglycemia during insulin infusion compared with the 3- to 6-day-old lambs. These data are consistent with findings in human preterm neonates, who exhibited persistent glucose production and greater peripheral sensitivity to insulin.

The appropriate distribution of whole-body glucose is regulated, at least in part, by the tissue-specific expression and regulation of several glucose transporter isoforms with distinct kinetic properties.[61] GLUT2 is the major glucose transporter isoform expressed in hepatocytes, beta cells, and the kidney. The distinguishing feature of this isoform is that it is a low-affinity, high-turnover transport system. GLUT2 forms part of a glucose-sensing apparatus that responds to subtle changes in blood glucose uptake with alterations in the rate of glucose uptake into the cell. GLUT4 glucose transporter is expressed in adipocytes and muscle cells. These are the "insulin-sensitive" cell types, so called because they respond to insulin with a rapid and reversible increase in glucose transport. Glucose transport in insulin-sensitive tissues has received attention because of the importance of this process in the maintenance of whole-body glucose homeostasis.[61]

In the study by Gelardi and associates, an apparent developmental increase in GLUT2 was noted in the older animal groups versus the neonatal groups (p <.05). This increase may signal the onset of an insulin-resistant state in the ruminant.[62] After an initial decrease, GLUT2 expression increased with time. The reduction in the expression of GLUT2 with euglycemic hyperinsulinemia is in agreement with findings in clamp studies in the diabetic rat. However, acute euglycemic hyperinsulinemia caused no change in the expression of GLUT4. This finding is consistent with previous studies showing that acute hyperinsulinemia does not regulate GLUT4 expression.[63] The investigators speculated that changes in GLUT4 expression are not directly responsible for the changes in insulin sensitivity (Figure 51-9). Increased GLUT2 expression with age, as well as decreased expression with hyperinsulinemia, is consistent with the development of an insulin-resistant state in the adult.

SUBSTRATE AVAILABILITY IN THE NEONATE

Several investigations have focused on the differential effects of substrate availability versus physiologic hormonal control in the human.[64-66] Jahoor and associates[64] suggested that in the adult, reduction in glucose turnover after an 86-hour fast was not secondary to a lack of gluconeogenic substrates. Conversely, dependence of gluconeogenesis on an adequate supply of precursors was demonstrated. When dichloroacetate was used to reduce lactate and alanine concentrations, a decrease in the rate of glucose production was observed. Bennish and associates[65] suggested that defective gluconeogenesis was the origin of the hypoglycemia in older children with diarrhea. Haymond and colleagues[66] studied differences in circulating gluconeogenic substrates in

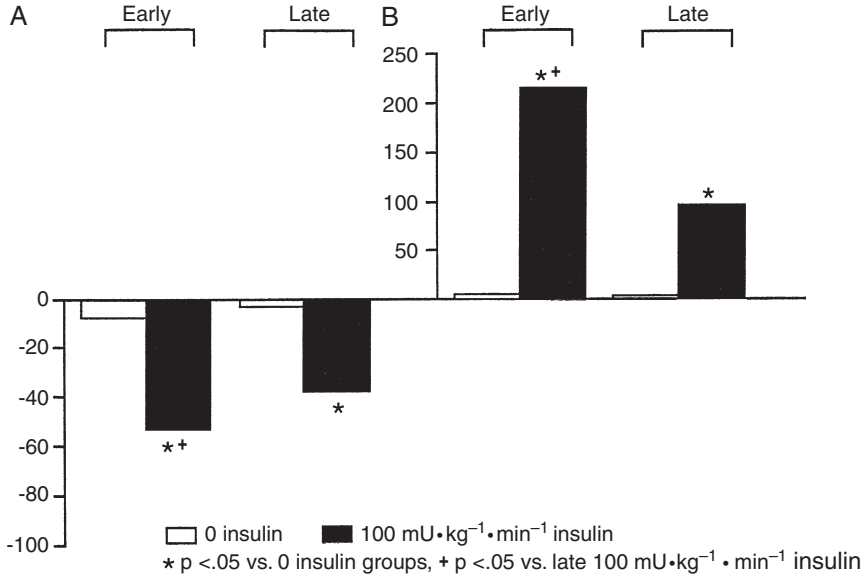

Figure 51-8 The percent decrease in endogenous glucose production **(A)** and the percent increase in glucose utilization **(B)** during the clamp period in the early (3-6 days old) and late (31-35 days old) groups. *(From Gelardi NL Rapoza RE, Renzulli JF, Cowett RM: Insulin resistance and glucose transporter expression during the euglycemic hyperinsulinemic clamp in the lamb,* Am J Physiol *277:E1142, 1999.)*

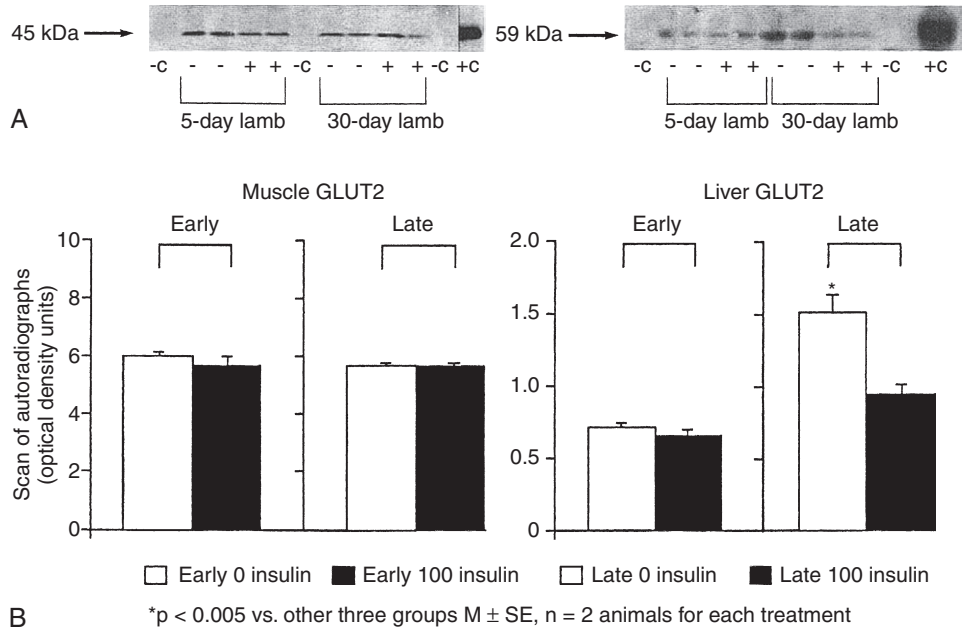

Figure 51-9 A, Representative Western blots for muscle *(left)* and liver *(right)* of 5- and 30-day-old 0 (–) and 100 (+) insulin-infused groups, showing also positive (+C) rat membrane and negative (–C) protein controls. **B**, Results of scans of autoradiograms from Western blots for muscle *(left)* and liver *(right)* for early (3-6 days old) and late (31-35 days old) groups. *(From Gelardi NL, Rapoza RE, Renzulli JF, Cowett RM: Insulin resistance and glucose transporter expression during the euglycemic hyperinsulinemic clamp in the lamb,* Am J Physiol *277:E1142, 1999.)*

men, women, and children subjected to short-term fasting and suggested that differences in glucose requirements among the three groups could be responsible for the differences noted in plasma substrate responses to fasting. The men and women evidenced nearly identical plasma lactate and pyruvate concentrations; the initial venous lactate and pyruvate concentrations were highest in children and increased during the 6 hours of fasting. The investigators speculated that lactate production may be accelerated in the pediatric patient in whom hepatic substrate uptake is normal. Neonates were not studied in that investigation. Cowett and Wolfe evaluated the potential for gluconeogenesis from lactate and found it to be accelerated in the preterm neonate compared with the adult.[67] These workers speculated that substrate acquisition may not be the primary problem in the neonate.

One of the issues of substrate availability related to glucose homeostasis involves the effect of glucose (with or without other substrates) on glucose production. In one series of investigations,

the Ra was negligible under conditions in which glucose was infused as part of the hyperalimentation mixture before administration of an intravenous fat emulsion.[68] However, a clear dichotomy is seen for data evaluating the ability of the neonate to diminish endogenous glucose production, which occurs regularly in the adult.[44] In studies in the term neonate,[38] the infant of the diabetic mother,[69] and the premature neonate,[38] persistent endogenous glucose production greater than 1.0 mg/kg/minute was reported in response to administration of exogenous glucose infusion alone. Similar results were observed in the newborn canine model using the euglycemic hyperinsulinemic clamp technique.[47] In other investigations using different techniques such as the glucose clamp[70] or glucose and amino acid infusion,[71] no persistent endogenous glucose production was reported in the neonate. For the second technique, both an amino acid mixture and glucose at a relatively moderate rate were infused (approximately 8 mg/kg/minute).As pointed out by Lafeber and colleagues,[71] suppression may be incomplete under conditions in which insufficient glucose is administered or glucose is the sole constituent of the infusate.The data reported in another study supports this conclusion in the latter condition. No endogenous glucose production was noted when 6.8 mg/kg/minute of glucose with amino acids was administered during the basal state or after administration of glucose, amino acids, and an intravenous fat emulsion combined.[68] Further work is necessary to determine whether the quantity of glucose administered or the addition of amino acids or lipid emulsion is the primary cause of the observed decline in endogenous glucose production in the neonate. In addition, the relative role of each of these substrates as a secretagogue for insulin is unknown. Such studies should assist in differentiating hormonal control of neonatal glucose metabolism from availability of substrate as a limiting factor in homeostatic maturation.

In another study, Cowett and associates investigated whether glucose alone tightly controls neonatal glucose homeostasis.[72] Fifteen spontaneously delivered term lambs were studied after receiving radiolabeled glucose for isotope-based measurement of glucose production. To isolate the contribution of glucose, after a baseline period five lambs received glucose at a rate of 8.5 mg/kg/minute in combination with the following: somatostatin to block insulin, glucagon, and growth hormone release; metyrapone to block cortisol release; phentolamine to block α-adrenergic release; and propranolol to block β-adrenergic release. Under conditions of glucose infusion at a rate 49% greater than the basal rate, the endogenous glucose production persisted; only an evanescent decrease from levels in the control group, which was not statistically different over time, was observed.As a substrate, glucose did not tightly control neonatal glucose homeostasis.

In conclusion, it is apparent that hormonal control by glucoregulatory hormones (including insulin and the various counterregulatory hormones) and possibly glucose plays a significant role in the developing regulation of glucose homeostasis in the neonatal period. Further research will be required to determine the relative contribution of the various factors important in the development of carbohydrate (glucose) homeostasis in the neonatal period.

The multiplicity of factors that influence both the treatment of neonatal hyperglycemia and its prevention resulted in two rigorous evaluations using the highly regarded Cochrane Collaborative methodology to evaluate randomized or quasirandomized clinical trials.[73,74] Because of the paucity of studies, the reviewers concluded that it remained uncertain whether the hyperglycemia per se was a cause of adverse clinical outcomes or how the hyperglycemia should be treated.[73] Relative to the issue of prevention, a parallel conclusion was adopted because of a similar paucity of studies—namely, that the evidence reviewed did not support the routine use of insulin infusion to prevent hyperglycemia in very-low-birth-weight neonates.[74] In both reviews, additional randomized clinical trials were advocated to answer the questions at hand.[74,75] Finally, a major issue in this ongoing area of research is the interrelationship of hormonal control of glucose homeostasis and the presence or development of insulin sensitivity or insensitivity.These studies are germaine to the study of an increasingly important area of metabolic investigation—namely, the fetal origins of adult disease.[73] This topic is evaluated in Chapter 18 by the investigator credited with originating the hypothesis.

52 Cell Glucose Transport and Glucose Handling During Fetal and Neonatal Development

Rebecca Anne Simmons

Glucose is a vital substrate for the growing and developing fetus. It is required by most cells for oxidative and nonoxidative adenosine triphosphate (ATP) production and serves as a precursor for other carbon-containing compounds. It is the primary fuel used for several specialized cells and is the major fuel used by the brain. Its storage in the liver as glycogen provides a means by which glucose homeostasis can be maintained, particularly during the neonatal period. Glycogen stores also represent the primary source of energy for muscle tissue during exercise in postnatal life. Because of the diverse metabolic roles played by glucose, defects in its uptake or metabolism can alter cellular functions and can lead to significant morbidity and even death. This chapter focuses on the molecular biology and regulation of glucose transporters in the fetus and newborn.

The plasma membranes of most mammalian cells, except those of the proximal kidney and small intestine, have a passively mediated transport system for glucose. Facilitative entry of glucose into the cell is controlled by glucose transporters (GLUTs), structurally related proteins that are encoded by a *SLC2A* gene family[17] and are expressed in a tissue-specific manner. A different family of proteins, sodium-coupled glucose transporters (SGLTs), actively transport glucose across the apical membranes of polarized intestinal and renal epithelial cells.[8-13] The driving force for active glucose absorption is the electrochemical sodium gradient across the membrane.

Most cells contain at least one glucose transporter isoform, and many contain more than one. In most cell types, glucose transporters mediate a net uptake of glucose. Under some circumstances, glucose is transported out of the cell. For example, the sodium-coupled transporter actively transports glucose into epithelial cells of the small intestine, and a facilitative transporter mediates the efflux of glucose from the cell into the interstitium. In hepatocytes, facilitative glucose transporters are responsible for the uptake of glucose from the portal circulation and for the release of glucose generated by glycogenolysis or gluconeogenesis. Thus glucose transporters ensure efficient tissue uptake and distribution of glucose.

SODIUM-DEPENDENT GLUCOSE TRANSPORTERS

It has long been known that dietary sugars are actively absorbed from the small intestine; however, only recently has the molecular mechanism been elucidated. Active absorption of glucose across epithelial cells of the small intestine and the kidney proximal tubule is accomplished by sodium-glucose cotransporters located in the brush border membranes. Transport of each glucose molecule is coupled to the cotransport of two Na^+ ions (SGLT1) or of one Na^+ ion (SGLT2). This transport system uses the energy from an extracellular to intracellular Na^+ ion electrochemical gradient, generated by Na^+,K^+-ATPases, to drive the accumulation of glucose into the cell. These transporters belong to a major class of membrane proteins called co-transporters (or symporters). The sodium-dependent glucose transporter (SGLT) family, with the gene name *SLC5A,* comprises sodium-dependent glucose cotransporters (SGLT1 and SGLT2), the glucose sensor SGLT3, the widely distributed inositol,[14] the multivitamin transporters SGLT4 and SGLT6,[15] and the thyroid iodide transporter SGLT5.[16] These exist in bacteria, plants, and animal membranes, and they actively transport sugars, amino acids, carboxylic acids, and some ions (chloride, phosphate, sulfate, iodide) into cells.

SGLT1 is a hydrophobic integral membrane protein with approximately 12 membrane-spanning domains. The gene encoding the human intestinal SGLT has been localized to the q11.2–qter region of chromosome 22.[17] SGLT1 is abundantly expressed in the brush border of the small intestine and at lower levels in kidney, lung, and liver. The transporter has the same affinity for both glucose and galactose. An excellent review of the molecular regulation of SGLT1 is available.[18]

Clinical interest in the intestinal brush border sodium-glucose cotransporter has focused on diarrhea and malabsorption. Glucose-galactose malabsorption is a rare autosomal recessive disorder characterized by onset of severe, watery diarrhea in the newborn period. Unless glucose and galactose are eliminated from the diet, death rapidly ensues. Wright and colleagues demonstrated that a single missense mutation in the gene encoding the intestinal sodium-glucose cotransporter is sufficient to cause a syndrome of life-threatening diarrhea.[19]

SGLT2 complementary DNA (cDNA) originally was isolated by Hediger and colleagues from a human cDNA library.[8] The SGLT amino acid sequences are approximately 60% identical with those of SGLT1, and the proteins have the same predicted secondary structure. The expression of this cotransporter is restricted to the renal cortex, and it is located in epithelial cells of proximal tubule S1 segments. The bulk of the filtered glucose is believed to be reabsorbed in the proximal convoluted tubule by a low-affinity, high-capacity SGLT2, with reabsorption of the remainder by the high-affinity cotransporter SGLT1.

SGLT3 is expressed mainly in cholinergic neurons of the small intestine and in skeletal muscle at the neuromuscular junctions.[20] SGLT3 may act as a glucosensor by conveying information to the cell about external glucose concentration directly through the membrane potential or indirectly coupled through another molecule such as a G-protein.

Disorders of sodium coupled glucose transport are rare. Familial renal glycosuria is an autosomal dominant disorder (an autosomal recessive mode of inheritance has not been excluded in all cases) affecting 0.2% to 0.6% of the general population and is characterized by the excretion of large amounts of glucose into the urine in the presence of normal blood glucose concentrations. The molecular basis of benign renal glycosuria has not been determined. It is possible that mutations in the low-affinity sodium-glucose cotransporter, SGLT2, may be responsible for the defect in renal absorption of filtered glucose.

Sodium-glucose cotransporters appear to be active prenatally, and as a consequence, the intestine is ready to absorb the first ingested glucose.[21] The cloned cDNAs and specific antibodies for the different sodium-glucose cotransporters can be expected to be valuable tools for identifying the specific cells in the intestine and kidney that express these proteins and for studying the

regulation of their expression during development and in altered metabolic states such as diabetes mellitus or pregnancy.

FACILITATED GLUCOSE TRANSPORTERS

The energy-independent process of transporting glucose across the cell membrane occurs by facilitative diffusion. Transport of glucose is saturable, stereoselective, and bidirectional. The kinetics of glucose transport inward and outward are not necessarily identical,[22] and in fact, in the erythrocyte, the rate of exchange flux for glucose is faster than net flux rate.The primary function of the facilitative glucose transporters is to mediate the exchange of glucose between blood and the cytoplasm of the cell.This mechanism may involve a net uptake or output of glucose from the cell, depending on the type of cell, its metabolic state, and the metabolic state of the organism. In most cells, cytoplasmic glucose is rapidly phosphorylated by hexokinase or glucokinase, and levels of glucose-6-phosphatase are low, so little intracellular free glucose is available.These cells are involved only in net uptake and metabolism of blood glucose. The hepatocyte also is a net producer of glucose in the postabsorptive state. Glycogenolysis and gluconeogenesis increase intracellular free glucose to levels greater than its concentration in the blood, resulting in net efflux of glucose from the cell. In the postprandial state, glucose is transported into the hepatocyte to replenish glycogen stores.

The facilitative glucose transporters constitute a family of structurally related proteins. Several facilitated glucose transporter isoforms have been identified and are designated GLUT (with the gene symbol SLC2A, for *sol*ute *c*arrier family *2*).[2,3,23-32] The GLUT family of proteins has been subdivided into three classes: Class I consists of GLUT1 to GLUT4; class II contains GLUT5, GLUT7, GLUT9, and GLUT11; and class III consists of GLUT6, GLUT8, GLUT10, and GLUT12. These proteins vary in size, ranging from 492 to 524 amino acids long.They exhibit 39% to 68% sequence identity and 50% to 76% sequence similarity in pairwise comparisons.[1,3,24,25,33-38] A topology map of the GLUTs has been proposed based on analysis of the primary amino acid sequence of GLUT1.[25] Each isoform consists of 12 membrane-spanning domains, an intracytoplasmic hydrophilic loop, and an exofacial loop bearing a single *N*-glycosylation site. Both the amino-terminal (N-terminal) and carboxyl-terminal (C-terminal) ends are exposed intracellularly (Figure 52-1). Comparisons among the different isoforms have revealed that the sequences of the transmembrane segments and the short cytoplasmic loops connecting these transmembrane regions are highly conserved. Most likely, these regions are responsible for the transport of glucose.The N terminus and C terminus are unique for each of the different isoforms and may contribute to isoform-specific properties, such as kinetics, hormone sensitivity, and subcellular localization.[1,3,23-25,27,34-37]

STRUCTURE AND PROPERTIES OF FACILITATIVE GLUCOSE TRANSPORTERS

GLUT1

GLUT1 was the first glucose transporter to be cloned. Antibodies were raised against the purified erythrocyte glucose transporter to screen antigen expression cDNA libraries from RNA from the human hepatoblastoma cell line (HepG2). The amino acid sequence of GLUT1 is highly conserved, with 98% identity between the sequences of human and rat GLUT1 and 97% identity between the sequences of human and mouse, rabbit, or pig GLUT1. This high degree of sequence conservation implies that all domains of this 492-residue protein are functionally important.

GLUT1 is the most ubiquitously distributed of the transporter isoforms. It is found in virtually all tissues in the fetus and in many tissues and cell types in the adult.[39-46] GLUT1 has a very high affinity for glucose. These properties make it likely that GLUT1 is responsible for constitutive glucose uptake. In many organs, GLUT1 is concentrated in endothelial cells of blood-tissue barriers. Thus one of the specialized roles of GLUT1 is to shuttle glucose between blood and organs that have limited access to small solutes through passive diffusion.

GLUT1 is the predominant isoform in the fetus.This transporter also is expressed in fetal tissues that fail to express it significantly in the adult. Most fetal cells exhibit rapid growth and differentiation, necessitating an increased supply of energy-producing substrates. This energy need may be the reason for the prevalence of GLUT1 in fetal tissues. After birth, GLUT1 levels decrease, and levels of other isoforms such as GLUT2 in the liver and GLUT4 in the muscle increase.[39,42,45,46] The signals responsible for the decline in GLUT1 expression during the neonatal period are not known. It is hypothesized that the switch from a carbohydrate to a fat source of fuel may induce this change in some organs.[45]

Most of the studies concerning the regulation of GLUT1 have been carried out in cultured cells and cell lines from humans and rodents. Growth factors, insulin, insulin-like growth factor-I (IGF-I), growth hormone, glucose, estrogen, transforming growth factor-β, thyroid hormone, cyclic adenosine monophosphate (cAMP), fibroblast growth factor, and oncogenes increase GLUT1 expression in many different cell types.[47-56] Cellular ATP decreases GLUT1-mediated sugar import capacity.[57] GLUT1-mediated sugar transport displays acute and adaptive regulation. *Acute* responses occur within seconds to minutes and involve stimulation of existing cell surface glucose transporters.[58] *Adaptive* responses occur over several hours in response to hypoxia and hypoglycemia and involve changes in glucose transporter expression.[59]

GLUT1 deficiency syndrome was first described by De Vivo in 1991.[60] To date, more than 100 cases have been reported. It is caused by a defect of glucose transport into the brain, mediated by the facilitative glucose transporter GLUT1. A seizure disorder is the most common clinical manifestation. Other potentially associated clinical features include developmental delay, ataxia, and spasticity. The diagnosis is suggested by hypoglycorrhachia, defined as a cerebrospinal fluid (CSF) glucose value less than 2.2, with a CSF–plasma glucose ratio generally less than 0.4. The disease is treated effectively with a ketogenic diet, because ketone bodies easily penetrate the blood-brain barrier and serve as an alternative fuel for the brain.

GLUT2

GLUT2 is the major transporter isoform expressed in adult liver, pancreatic beta cells, and epithelial cells of the intestinal mucosa and kidney.[34-36] Levels of this isoform are quite low in the fetus. GLUT2 has 55% amino acid identity with sequences of GLUT1, and it has a similar structure and orientation in the plasma membrane. In contrast with GLUT1, whose sequence is highly conserved, only 81% identity between the sequences of human and rat GLUT2 has been documented.The most characteristic feature of this isoform is its low affinity for glucose. GLUT2 and glucokinase form a glucose-sensing apparatus in hepatocytes and beta cells that responds to subtle changes in blood glucose concentrations by altering the rate of glucose transport into the cell.The transport capacity of GLUT2 is in excess of the glucokinase trapping reaction, thus making phosphorylation of glucose the rate-limiting step for glucose uptake in hepatocytes and beta cells. In the intestine and kidney, the high-capacity, low-affinity system is necessary to transport glucose under conditions of large transepithelial substrate fluxes that occur after meals.

Mutations in the gene encoding GLUT2 in the human give rise to Fanconi-Bickel syndrome, caused by a rare autosomal-recessive inborn error of metabolism, which resembles type I glycogen storage disease.[61,62] More than 100 patients with this syndrome

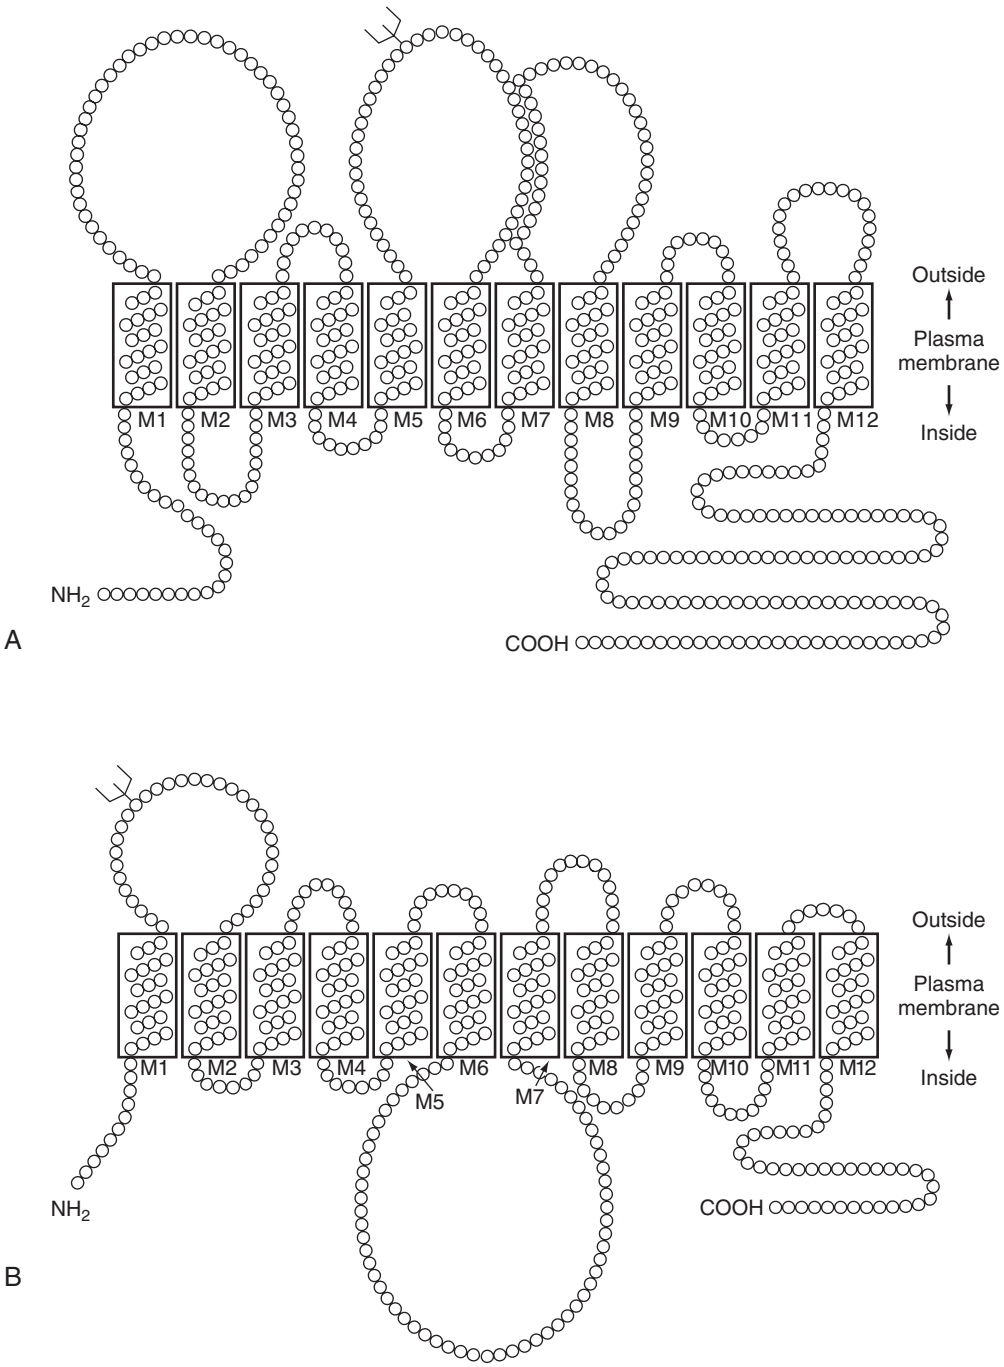

Figure 52-1 Models for the orientation of the human sodium-glucose cotransporter SGLT1 **(A)** and the facilitative glucose transporters GLUT1 to GLUT5 in the plasma membrane **(B).** The 12 potential membrane-spanning α-helices are shown as *boxes,* numbered M1 to M12.

and 34 different GLUT2 mutations have been reported in the recent literature. Because GLUT2 is the predominant glucose transporter in hepatocytes, pancreatic beta cells, enterocytes, and renal tubular cells, a loss of GLUT2 leads to a typical clinical syndrome of hepatorenal glycogen accumulation, glucose and galactose intolerance, fasting hypoglycemia, a characteristic tubular nephropathy, and severely stunted growth.[61]

Expression of GLUT2 appears to be developmentally regulated. Beta cell content of GLUT2 protein in the fetus is approximately half that in the adult rat.[63] Despite the reduction in GLUT2 content, the blunted insulin secretory response seen in fetal islet cells is not the result of a limitation of glucose transport. At least a 10-fold decrease in transport activity would be required to reduce metabolism of glucose sufficient to perturb glucose-induced insulin secretion.[64,65] Other factors appear to be responsible for the blunted insulin secretory response observed in the fetus.

Studies done in fetal rats have demonstrated that GLUT2 levels are markedly diminished in fetal hepatocytes compared with the adult cells.[66-69] Shortly after birth, GLUT2 protein content dramatically rises and increases again, coinciding with weaning of the newborn pup from high-fat maternal milk.[68] Although an altered hormonal or substrate milieu often is implicated etiologically in

the metabolic maturation associated with birth, the mechanism of this change is still unknown.

Glut3

GLUT3 was first isolated from human fetal skeletal muscle.[70] Human GLUT3 has 64% and 52% identity with human GLUT1 and GLUT2, respectively, with 83% amino acid sequence identity between the sequences of human and mouse GLUT3. Thus, as with GLUT2, the sequence of GLUT3 is not as highly conserved among species as that of GLUT1. GLUT3 messenger RNA (mRNA) is present at variable levels in all human tissues and is most abundant in brain, kidney, and placenta. The ubiquitous distribution of GLUT3 in human tissues suggests that it, together with GLUT1, may be responsible for basal glucose transport. In other animals such as rats, monkeys, and mice, the pattern of expression of GLUT3 is much different from that observed in humans.[3] In these animals, GLUT3 is abundant only in brain. The expression of GLUT3 in brain indicates that two facilitative glucose transporters are involved in the uptake of glucose. GLUT1 is primarily responsible for transport of glucose across the blood-brain barrier, and GLUT3 controls the uptake of glucose into the neuron.

Relatively little information is available about the regulation of GLUT3 in the fetus. Studies done in fetal rat brain suggest that glucose concentrations do not regulate expression of this transporter isoform.[71] This finding is in contrast with those for GLUT1, in which high levels of glucose down-regulate GLUT1 protein and mRNA abundance.[49] In contrast with the findings for glucose, chronic hypoxia increases GLUT3 mRNA expression in embryonic (day 14) rodent brain.[72]

Glut4

GLUT4 is expressed primarily in adult tissues that exhibit insulin-stimulated glucose transport, such as adipose tissue and skeletal and cardiac muscle.[49] It also is expressed at low levels in fetal rat brain.[72] In comparison with adult levels, little GLUT4 is expressed in fetal muscle[47] and brown fat,[73] and levels do not increase until well after birth.[43,45,73]

The sequence of GLUT4 is highly conserved, with 95% and 96% identity between the sequences of human and rat or mouse GLUT4.[74] GLUT4 contains unique sequences in its N-terminal and C-terminal cytoplasmic domains that direct its characteristic membrane trafficking capability. GLUT4, unlike other facilitave glucose transporters, is localized primarily intracellularly in the unstimulated state and is acutely redistributed to the plasma membrane in response to insulin and other stimuli.[74,75]

Glucose transport in insulin-sensitive tissues has received considerable attention because of the importance of this process in the maintenance of whole-body glucose disposal in the adult. The transport step is rate-limiting for glucose uptake into fat and muscle under most conditions.[76,77] A central role for GLUT4 in whole-body metabolism is strongly supported by a variety of genetically engineered mouse models. Heterozygous GLUT4$^{+/-}$ mice, which display decreased GLUT4 protein in muscle and adipose tissue, are insulin-resistant and develop diabetes later in life.[78,79]

Glut5

GLUT5 is the most divergent member of the glucose transporter family.[27] Human GLUT5 shares 42%, 40%, 39%, and 42% identity with human GLUT1, GLUT2, GLUT3, and GLUT4, respectively.[80] GLUT5 is expressed at high levels in the apical membrane of intestinal enterocytes and mature spermatocytes in adults.[81] Fructose is transported across intestinal epithelial cells by passive transport. A high rate of fructose utilization by testes also has been documented. In view of these findings, it seems likely that GLUT5 is the major mammalian fructose transporter.

GLUT5 also is found in smaller quantities in adult human kidney, brain, muscle, and adipose tissue.[81,82] The physiologic significance of GLUT5 in these tissues is unknown.

Novel Glucose Transporters

The facilitative glucose transporters GLUT1 to GLUT4 have considerable sequence similarity and different tissue distributions. Although the diverse tissue distribution and the specific functions of GLUT1 to GLUT5 appear to indicate that these transporters are sufficient to control glucose uptake in all mammalian tissues, it is likely that additional sugar transport facilitators exist. By searching the expressed sequence tag (EST) databases and taking advantage of the conserved sugar transporter signatures, several novel GLUT-like genes have been identified.

GLUT7, GLUT9, and GLUT11 are considered to be class II facilitative glucose transporters. GLUT7 is a high-affinity transporter for glucose and fructose and can be detected in small intestine, colon, testis, and prostate; within the small intestine, GLUT7 is expressed predominantly in enterocyte brush border membrane.[83]

GLUT9 exhibits highest expression levels in kidney and liver; lower mRNA levels were detected in small intestine, placenta, lung, and leukocytes.[30] GLUT9 has been detected in the mouse at a preimplantation stage of development and may be critical for early preimplantation development.[29] Three different isoforms have been identified that seem to be differentially expressed during development.[29] Two of the mouse GLUT9 isoforms demonstrate glucose transport activity when expressed in *X. laevis* oocytes.[28]

GLUT11 exhibits a low affinity for glucose and is thought to be a fructose transporter with low affinity for glucose. GLUT11 is expressed predominantly in pancreas, kidney, and placenta and also exhibits moderate expression in heart and skeletal muscle.[84]

GLUT6, GLUT8, GLUT10, and GLUT 12 are the family of class III transporters. The low-affinity glucose transporter GLUT6 is expressed predominantly in brain, spleen, and peripheral leukocytes.[27,85] GLUT8 is a high-affinity glucose transporter but also may transport fructose and galactose.[28,86] This transporter exhibits significant sequence similarity with the GLUT1 (29.4%).[28] In human tissues, it is found predominantly in testis, and lower amounts are detected in most other tissues including skeletal muscle, heart, small intestine, and brain.[23] GLUT8 is expressed in testis only from adult but not prepubertal, rats, and expression is markedly inhibited by estrogen treatment.[28,87] Thus GLUT8 may be involved in the provision of glucose required for DNA synthesis in male germ cells. GLUT8 also has been found to be the glucose transporter responsible for insulin-stimulated glucose uptake in the blastocyst.[88] In addition, GLUT8 may play a role in glucose uptake of adipocytes.[89]

GLUT10 (35% sequence identity with human GLUT1 to GLUT8) is expressed in human heart, lung, brain, liver, skeletal muscle, kidney, and placenta.[32] It also is detected in fetal brain and liver.[32] GLUT12 is expressed predominantly in heart and prostate and exhibits glucose transport activity when expressed in *X. laevis* oocytes.[90] This activity is competitively inhibited by D-galactose and to a lesser extent by D-fructose.[91]

LOCALIZATION AND REGULATION OF FACILITATIVE GLUCOSE TRANSPORTERS

Embryo

An excellent review of the role of facilitative glucose transporters in preimplantation development has recently been published.[92] GLUT1 is expressed in all stages of embryonic development of the mouse, rat, rabbit, cow, and human, including the oocyte and the blastocyst. It is readily detectable in trophectoderm and inner cell mass cells of the mouse blastocyst, and it is associated with intracellular membranes as well as plasma membranes of all cell

types.[93-96] During organogenesis in the rat embryo, GLUT1 can be found in the neural tube, as well as in the heart tube, gut, and optic vesicle.[97]

GLUT2 also appears to be an important mediator of glucose uptake in the early embryo, although this role is somewhat controversial.[98,99] GLUT2 is expressed as early as during the eight-cell blastocyst stage. It is reportedly expressed on trophoectoderm membranes facing the blastocyst cavity and on the plasma membrane of the inner cell mass.[93,94] The function of GLUT2 at these locations in the blastocysts has yet to be elucidated. It has been speculated, however, that GLUT2 may be responsible for glucose transport into the blastocoele cavity.[100] Other studies also conducted in mice did not demonstrate GLUT2 expression.[98,99] In addition, studies conducted in other species—namely, rabbit and cow—did not find GLUT2 to be expressed during the preimplantation period.[101,102]

Expression of GLUT3 appears by day 4 of gestation (in rat), and it is found on the apical membranes of trophoectoderm cells and seems to be responsible for the uptake of maternal glucose.[97,100] Both knock-down and knock-out of GLUT3 significantly impair preimplantation development, suggesting that at least in the mouse, GLUT3 is essential for preimplantation development.[92,103]

GLUT8 is expressed primarily within vesicles in the cells lining the blastocoele.[29] Insulin and IGF-1 stimulate translocation of GLUT8 to the plasma membrane of these cells through binding to the IGF-1 receptor.[29] Studies suggest that GLUT8 expression and translocation in response to insulin are critical for blastocyst survival.[104] However, the physiologic role that insulin-regulated glucose transporters play in vivo in the human blastocyst remains to be determined.

Recently, two additional facilitative glucose transporters have been identified in the preimplantation embryo: GLUT9 and GLUT12.[29,105] Down-regulation of a GLUT9 isoform does not decrease glucose uptake in blastocysts. When antisense-treated embryos are transferred into pseudopregnant female mice, however, an increase in pregnancy loss is noted.[29]

GLUT12 is abundantly expressed at the two-cell stage and decreases to low levels in the morula and blastocyst stages.[91] Because the promoter region of murine GLUT12 contains sequences that are homologous to known insulin response elements,[105] this transporter may be an insulin-responsive glucose transporter.

One of the characteristics of preimplantation embryos is a metabolic shift from a dependence on the tricarboxylic acid cycle during the precompactation stages to a metabolism based on glycolysis after compactation.[106] This change in substrate utilization is coincident with the rapid proliferation that occurs during this developmental stage. Similar changes in substrate preference occur in numerous other cells as they undergo proliferation. Therefore high-affinity glucose transporters such as GLUT1 and GLUT3 can be assumed to be required for glucose uptake.

Pregnant women with diabetes are at increased risk for both first-trimester spontaneous abortions and major fetal malformations. Data suggest that hyperglycemia-induced apoptosis in the embryo may contribute to early pregnancy loss.[107,108] Preimplantation studies have shown that maternal hyperglycemia down-regulates GLUT1, GLUT2, and GLUT3 at the blastocyst stage of development,[109] which is associated with increased apoptosis.[107] Only 40% of the cells showed evidence of apoptosis, which has been shown to result in neural tube defects, limb abnormalities, and abdominal wall malformations similar to those seen among infants of diabetic women.[110]

Placenta

In the human placenta, placental villi are in direct contact with maternal blood. The surface of the placental villus is covered with a single syncytiotrophoblast layer, formed by the fusion of the underlying cytotrophoblast elements. Fetal capillaries lie directly beneath the syncytiotrophoblast. Transfer of glucose from maternal to fetal blood occurs by way of the placental villi and probably is mediated by GLUT1. GLUT1 is abundantly expressed in the plasma membranes of both the basal and apical sides of the syncytiotrophoblast. GLUT1 may facilitate the entry of glucose into the cytoplasm of the syncytiotrophoblast from maternal blood, whereas GLUT1 at the basal plasma membrane may aid in the exit of glucose from the cytoplasm of the syncytiotrophoblast to the pericapillary space of the fetus. GLUT1 on the endothelial cell of the capillary then transfers glucose into the fetal circulation.[111-114] Protein and mRNA levels of GLUT1 increase in the placenta as the fetus matures, underscoring the importance of this transporter in fetal development.[112]

GLUT3 is distributed throughout placental villous tissue and decreases during gestation.[112,114-116] Although GLUT3 mRNA is abundantly expressed in villous tissue, GLUT3 protein is localized primarily to the vascular endothelium. GLUT3 may play a role in transporting glucose from mother to fetus after transsyncytial transport. This hypothesis is supported by the finding that decreased GLUT3 expression (from knockdown of a single allele) in murine placenta causes fetal growth restriction.[103]

A body of data regarding the regulation of glucose transporter expression in human placenta is beginning to accumulate. An excellent comprehensive review of placental nutrient transport by Jones and co-workers is available.[117] A number of studies have been carried out in placentas from pregnancies complicated by intrauterine growth restriction and diabetes. Growth-restricted fetuses often are hypoglycemic, and impaired placental glucose transport has been implicated as a pathophysiologic mechanism. Growth-restricted fetuses have a reduced umbilical venoarterial concentration difference in glucose and lower fetal weight–specific umbilical volume flow.[118,119] However, placentas from preterm and term infants with intrauterine growth restriction have not shown a difference in levels of GLUT1 protein.[120]

Gestational diabetes is associated with placenta overgrowth and an increase in transplacental glucose transfer to the fetus. Levels of GLUT1 protein are increased in the basal membranes and lead to an increase in glucose transport activity of syncytial basal membranes.[121,122] Microvillous expression and activity are unaffected by hyperglycemia.[123,124] Likewise, levels of GLUT3 and GLUT4 are not altered in placentas of women with diabetes during pregnancy.[123,124] Thus it appears from these studies that increased glucose transport to the fetus of the diabetic mother is facilitated by increased levels of GLUT1. Illsley proposed that this process leads to fetal hyperglycemia, which in turn stimulates the production of IGF-1, leading to excess fetoplacental growth.[125]

Brain

Brain glucose utilization accounts for approximately 80% of whole-body glucose disposal in humans.[126] Furthermore, heterogeneity in glucose utilization has been observed among different regions of the brain. Circulating glucose crosses the blood-brain barrier and enters brain parenchyma cells by means of facilitative glucose transporters. Most studies of GLUT expression in the nervous system of the developing animal have been performed in the rat. Before the formation of the blood-brain barrier, GLUT1 is abundant in the germinal neuroepithelium, which gives rise to both neurons and neuroglia cells.[127] Just before birth, GLUT1 is abundant in the brain vasculature, meninges, ependyma, and choroid plexus. After birth, GLUT1 also is found in glial cells.[127] GLUT1 is developmentally regulated in rat and rabbit brain.[39-41] Its expression is highest in adult brain, followed by fetal and neonatal brain, respectively.

Few localization studies have been done in the human fetus. One report demonstrated that the localization of GLUT1 in the mid- to late-gestation human fetus is similar to the rat—that is,

it is located primarily in the microvascular endothelial cells that constitute the blood-brain barrier.[82] A more recent study, however, suggested a much wider distribution of GLUT1 in the developing brain.[128] From 10 to 21 weeks of gestation, GLUT1 is expressed in all regions of the fetal brain and is present primarily in the endothelial cells of the brain capillaries, in the epithelial cells of the choroid plexus, and in neurons.[128] GLUT 2 is not expressed until midgestation (21 weeks), and at that time it is highly expressed in the granular layer of the cerebellum.[128] No study to date has been able to detect GLUT3 or GLUT4 in human fetal brain.

In the rodent, after birth, GLUT3 is found in the cerebellum in neurofilament-positive cellular transverse fibers, cell bodies of Purkinje cells, and other neuronal elements in close proximity to the Purkinje layer.[82] This region-specific pattern of GLUT3 expression may reflect the differing glucose needs of anatomically distinct regions of the brain. Localization of GLUT3 is similar to the distribution of glucose utilization, which during early infancy is mainly infratentorial, and later in development occurs in supratentorial structures as well.[129,130]

Regulation of glucose transport in the fetal brain is uniquely different from that in the adult. Before birth, low levels of glucose (in vivo or in vitro) fail to up-regulate glucose transport in whole fetal rat brain[71] or isolated glial cells. After birth, however, hypoglycemia induces a marked increase in GLUT1 expression[131] in whole-rat-brain isolated glial cells. Furthermore, glucose transport in the fetal brain does not respond to insulin or IGF-I,[47] two hormones that increase GLUT1 expression in glial cells of older animals.[132,133] The mechanisms underlying these differences in regulation of glucose transport that occur with maturation are unknown.

Hypoxia during gestation induces a marked increase in both GLUT1 and GLUT3 levels in fetal rat brain.[72] Hypothyroidism decreases protein levels of GLUT1 but not GLUT3 in postnatal rat brain.[134]

Lung

Glucose is an important metabolic substrate for the lung and provides carbon moieties for energy production and synthesis of surfactant. In adult lung, transport of glucose across the apical membrane of the type II pneumocyte occurs by sodium-coupled transport,[135-137] and it occurs across the basolateral membrane by facilitative glucose transport. To date, GLUT1 is the only isoform found to be expressed in type II pneumocytes of fetal rats and humans.[138] It is hypothesized that SGLT1 also is expressed in type II pneumocytes; however, no study has thus far been able to localize this transporter in fetal lung.

GLUT1 is abundantly expressed in the fetal lung when compared with that of the juvenile and adult rat.[46] Glucose utilization and levels of GLUT1 mRNA and protein dramatically decline as the animal matures.[46,139] By day 14 of life, GLUT1 is undetectable in rat pups. The factors responsible for this significant decrease in the synthesis of GLUT1 are unknown.

Insulin and IGF-I are important modulators of glucose transport in type II pneumocytes of fetal rats. Physiologic levels of insulin and IGF-I stimulate glucose transport,[47] whereas higher levels of insulin inhibit glucose uptake.[140] Several animal studies suggest that hyperinsulinemia, through its inhibitory effects on glucose transport, contributes to the decrease in surfactant synthesis observed in infants of diabetic mothers. In a model that somewhat mimics human gestational diabetes, diabetes is induced in pregnant rats by streptozotocin. Fetal rats are hyperglycemic, hyperinsulinemic, and large for gestational age. Type II pneumocytes from these animals exhibit markedly diminished glucose uptake and GLUT1 expression.[141] It is possible that the decrease in glucose uptake diminishes the supply of glucose available for surfactant synthesis. This limited synthesis could be one factor that increases the risk for respiratory distress syndrome in infants of diabetic mothers.

Male fetuses exhibit delayed lung maturation and surfactant production in comparison with female fetuses. This delay may be related to sex hormone effects: Estrogen enhances and androgens delay lung development. The uptake of glucose, an important precursor for surfactant synthesis, appears to be differently affected by estrogen and androgens. In vitro studies performed in fetal rat have shown that estradiol and dehydrotestosterone differentially regulate glucose uptake in fetal rat lung tissue. This regulation of substrate supply (glucose) by estradiol and dehydrotestosterone may be another mechanism underlying the sexual dimorphism observed in lung development and surfactant synthesis.[142]

Liver

Transport of glucose across the hepatocyte does not appear to be rate-limiting for glucose metabolism. However, glucose transport is developmentally regulated in the human and rat, and glucose transport contributes to the changes in glucose metabolic capacity from fetal to extrauterine life. The major glucose transporter in the adult hepatocyte is GLUT2. GLUT1 is expressed only in perivenous hepatocytes.

By contrast, in the fetus, GLUT1 and GLUT2 are abundantly expressed in hepatocytes.[66-68] In this context, the fetal to neonatal transition is characterized by a shift from abundant GLUT1 in the hepatocyte to an adult pattern of little GLUT1 expression.[39,68] Many metabolic and hormonal factors dramatically change during the perinatal period. The factors responsible for the switch in GLUT1 expression remain to be delineated.

Acute hyperglycemia and hyperinsulinemia are associated with increased expression of GLUT1 in fetal ovine liver,[143] whereas chronic hyperglycemia is accompanied by decreased GLUT1 levels.[144] Thus chronically elevated circulating glucose concentrations appear to induce an adaptive mechanism to prevent entry of excess glucose, which is toxic to the cell.

Muscle

Most of the studies regarding glucose transport in muscle have been carried out in adults. As described earlier, GLUT4 is the predominant isoform expressed in adult muscle. In response to insulin, this transporter isoform significantly increases the transport of glucose into the myocyte. In contrast with the marked insulin responsiveness observed in the adult, fetal muscle responds only modestly to insulin.[145] Both acute and chronic adminstration of glucocorticoids to fetal sheep increase GLUT4 expression, which is associated with increased insulin sensitivity.[146] Insulin and IGF-I increase GLUT1 expression 1.5-fold in normal fetal rat muscle explants,[47] compared with the 20-fold increase observed in adult muscle.[147,148] Insulin does not stimulate GLUT1 expression in isolated myoblasts from fetal rats,[45] suggesting that stimulation of glucose transport by insulin requires tissue-specific additional factors.

GLUT1 is localized to the myoblast, and levels are quite high in the fetal and newborn rat pup. GLUT1 decreases significantly during weaning.[45,149] It appears that the switch from GLUT1 to GLUT4 expression during this period is secondary to dietary factors. If rats are weaned to a diet rich in fat, the normal increase in GLUT4 is prevented.[45,149,150] The molecular mechanisms responsible for this effect are unknown.

Kidney

The kidney, small intestine, and liver all can release glucose during periods of decreased glucose availability. Although the liver is the principal supplier of glucose during short fasts, the kidney also produces glucose during prolonged starvation. The

sodium-glucose cotransporter, SGLT1, transports glucose into the brush border cell of the proximal tubule of the kidney. GLUT2, localized on the basolateral membrane of epithelial cells lining renal tubules, is involved in the net release of glucose into the blood during absorption of renal glucose.

No data are available concerning the regulation of glucose transport in the fetal kidney, and only a few reports have described the ontogeny of renal glucose transport. SGLT1 is expressed in lower quantities in fetal than in adult kidney. GLUT2 also is present in the fetal kidney, and its expression increases with maturation.

SUMMARY AND FUTURE DIRECTIONS

Glucose transporters have acquired distinct physiologic and biochemical properties that allow them to serve specific functions in the tissues in which they are expressed. An understanding of the mechanisms underlying tissue-specific expression of these transporters will facilitate an understanding of in vivo glucose utilization and clearance processes that occur normally and in disease states. Although studies in adults provide insight into the regulation of glucose transport, similar studies are required in the fetus and newborn for full elucidation of the role of the glucose transporter in fetal and neonatal development.

Pathophysiology of Hypoglycemia

Hypoglycemia is more common in the newborn than at any other age, particularly in the first 12 to 24 hours of extrauterine life. After the first 24 hours of life, true neonatal hypoglycemia is uncommon; once detected, it must be investigated and treated appropriately. The importance of detecting and treating neonatal hypoglycemia is two-fold: First, hypoglycemia deprives the brain of its primary source of metabolic fuel and can lead to seizures and brain damage; and second, hypoglycemia is a presenting feature of numerous endocrine disorders and inborn errors of metabolism that require specific diagnosis and treatment.

The finding of hypoglycemia in a neonate mandates urgent investigation to define the cause, together with rapid restoration of physiologically optimal blood glucose levels. Neonatal hypoglycemia invariably reflects a failure of fasting adaptation; therefore, this chapter focuses on the metabolic and hormonal systems involved in fasting homeostasis and abnormalities of the fasting systems that result in hypoglycemia in the newborn period.

CHARACTERISTICS OF HYPOGLYCEMIA

Despite the frequency with which low blood glucose is encountered, considerable controversy surrounds the definition of hypoglycemia in the newborn. On the basis of the finding that low blood glucose levels are common in the first 12 to 24 hours of life, it has been argued that low blood glucose in the neonate represents a physiologic phenomenon[1-4] and that the newborn has unique physiologic adaptation to low blood glucose levels.[5,6] No evidence for this hypothesis, however, has been offered. Although transient hypoglycemia may occur during the first 12 to 24 hours in otherwise normal neonates[7] (particularly with a delay in feeding), it is essential to ensure that the condition does not persist. Hypoglycemia that does not respond to feeding, or that emerges after the first 24 hours of life, needs to be investigated promptly, to avoid overlooking endocrine disorders or inborn errors of metabolism with consequent exposure of the infant to the risk of cerebral damage.

Plasma glucose is determined by a balance between glucose supply and glucose utilization. In the newborn, a large proportion of glucose utilization is accounted for by cerebral metabolism.[8] Glucose transport into the brain occurs by a carrier-mediated facilitated diffusion process dependent on circulating arterial glucose concentration[9-11]; therefore a fall in the arterial glucose concentration places the infant at risk for neuroglycopenia. By depriving the brain of an important metabolic fuel, hypoglycemia can result in acute symptomatic cerebral dysfunction with manifestations that include lethargy, poor feeding, and seizures, among others, as listed in Box 53-1. These signs and symptoms are particularly common in circumstances in which alternative metabolic fuels such as lactate and ketone bodies are not available. However, many infants with low blood glucose may not exhibit obvious clinical signs. If the hypoglycemia is prolonged, permanent damage to the brain can occur. No universally accepted level or duration of hypoglycemia has been recognized to be associated with the risk of cerebral damage.[12,13]

PHYSIOLOGY OF FASTING GLUCOSE HOMEOSTASIS

Studies using radioisotope tracer techniques in fetal sheep[14] and in humans[15] have demonstrated that the fetal glucose supply is derived from the mother, with no endogenous glucose production in the fetus. The time of birth is marked by an abrupt change from a high-carbohydrate, low-fat diet to a high-fat, low-carbohydrate diet[16] The neonate must make the transition from an environment of continuous glucose supply from the placenta to one of intermittent periods of feeding and fasting.

The healthy neonate who is able to absorb nutrients from oral feedings uses glucose for metabolic processes, with storage of part of the surplus glucose in the form of glycogen in the liver and muscle and conversion of the remainder to fat, which is stored in adipose tissue. Hypoglycemia in the newborn occurs in the fasted state. Fasting hypoglycemia can result from developmental delays in the maturation of fasting metabolic systems, or it may be caused by endocrine disorders or inborn errors of intermediary metabolism. Five systems are required for successful fasting adaptation:

- Hepatic glycogenolysis
- Hepatic gluconeogenesis
- Adipose tissue lipolysis
- Fatty acid oxidation and hepatic ketogenesis
- Hormonal regulation of these systems

BOX 53-1

Signs and Symptoms of Hypoglycemia in Neonates

- Cyanotic episodes
- Apnea
- Respiratory distress
- Refusal to feed
- Myoclonic jerks
- Seizures
- Somnolence
- Staring spells
- Sweating

Glycogenolysis

Breakdown of glycogen stored in the liver occurs as soon as intestinal digestion of carbohydrate is exhausted, at 2 to 3 hours postprandially. Glycogenolysis results in the production of glucose-6-phosphate, which can be released as free glucose by the action of glucose-6-phosphatase. Muscle glycogen cannot be released into the circulation, because muscle cells lack glucose-6-phosphatase. Conditions that promote glycogenolysis are those associated with suppressed insulin levels or elevated glucagon and epinephrine levels. Liver glycogen accumulates in utero and is readily available to maintain plasma glucose in the immediate postnatal period. The stored glycogen is, however, depleted within 12 hours in a healthy term neonate, and more rapidly in a preterm or stressed neonate,[17] if there is no other source of glucose. Congenital defects in the enzymes of glycogenolysis are referred to as glycogen storage diseases (GSDs), and the one most likely to be associated with hypoglycemia is GSD type III.

Gluconeogenesis

During periods of fasting, the neonate is dependent on active gluconeogenesis to maintain plasma glucose levels. *Gluconeogenesis* is the production of glucose from precursors such as lactate, amino acids, and glycerol. This process requires four enzymes to bypass the unidirectional steps in glycolysis: glucose-6-phosphatase, fructose-1,6-bisphosphatase, phosphoenolpyruvate carboxykinase (PEP-CK), and pyruvate carboxylase. Most gluconeogenesis occurs in the liver, with a minor contribution from the kidney. Gluconeogenesis requires the provision of gluconeogenic substrates from peripheral tissues. The principal substrates for gluconeogenesis are lactate, alanine, and glutamine; during prolonged fasting, associated with increased adipose tissue lipolysis, glycerol becomes a major substrate for gluconeogenesis.

The normal newborn is not able to carry out gluconeogenesis in the first few hours of life.[18] Gluconeogenesis increases rapidly after birth in parallel with the activation of PEP-CK transcription, the rate-limiting enzyme of this pathway. The rise in plasma glucagon and the fall in plasma insulin that occur immediately after birth are the main determinants of liver PEP-CK induction. Levels of this enzyme in liver reach adult values approximately 24 hours after birth.

Adipose Tissue Lipolysis

The release of free fatty acids from adipose tissue occurs in physiologic conditions similar to those favoring gluconeogenesis (e.g., low plasma insulin, elevated plasma epinephrine and growth hormone). Plasma free fatty acid concentrations rise rapidly soon after birth. Although free fatty acids cannot be converted to glucose, they can be oxidized in place of glucose in heart and skeletal muscle. They are oxidized by the liver to produce ketones—acetoacetate and β-hydroxybutyrate (see later). By supplying an alternative source of fuel, fatty acid oxidation has a glucose-sparing effect.

Hepatic Ketogenesis

The liver produces the ketones β-hydroxybutyrate and acetoacetate as its major end products of fatty acid oxidation. These ketones are exported and metabolized by the brain,

TABLE 53-1

Hormonal Regulation of Fasting Metabolic Systems

Hormone	Hepatic Glycogenolysis	Hepatic Gluconeogenesis	Adipose Tissue Lipolysis	Hepatic Ketogenesis
Insulin	Inhibits	Inhibits	Inhibits	Inhibits
Glucagon	Stimulates	—	—	Stimulates
Cortisol	—	Stimulates	—	—
Growth hormone	—	—	Stimulates	—
Epinephrine	Stimulates	Stimulates	Stimulates	Stimulates

which cannot use fatty acids as a source of fuel. Infants born at a weight appropriate for gestational age (AGA) and those born small for gestational age (SGA) fail to show the increase in plasma ketone bodies during hypoglycemia that is observed in older children. This delay in development of hepatic ketogenesis probably is the result of delayed expression of two enzymes that catalyze the first and last steps in hepatic ketogenesis: carnitine palmitoyl-transferase-1 and β-hydroxy-β-methylglutaryl–coenzyme A synthase. Delayed expression of these enzymes has been demonstrated in animal models.[17] Fatty acids provided by the first feeding appear to play a critical role in activating transcription of key fatty acid oxidation and ketogenesis enzymes.[19-22]

Hormonal Regulation

A fall in blood glucose is the stimulus for a series of hormonal changes that act to restore blood glucose toward normal and to increase the supply of precursors for gluconeogenesis and alternative fuels.[23-25] The most important mechanism is the suppression of insulin secretion by hypoglycemia. The counterregulatory hormones become important if blood glucose levels continue to fall: Glucagon release is stimulated, followed by the release of epinephrine, cortisol,[26] and growth hormone.[27] The combined action of these hormone suppresses glucose utilization, stimulates hepatic glycogenolysis, activates gluconeogenesis, promotes adipose tissue lipolysis, and stimulates ketogenesis. These effects on carbohydrate metabolism serve to increase plasma glucose levels, and the effects on lipolysis and ketogenesis provide an alternative source of fuel for tissue metabolism. The overlapping effects of the counterregulatory hormones means that the loss of one can be partly compensated by other hormones that have a similar counterinsulin action.

At the time of birth, major changes occur in the concentrations of the hormones that regulate plasma glucose concentrations. An abrupt increase in glucagon concentration is observed within minutes to hours after birth.[8,28] This increase is accompanied by an increase in catecholamine concentrations and a fall in plasma insulin concentration. Together, these hormonal changes promote hepatic glycogenolysis and gluconeogenesis and mobilization of free fatty acids from adipose tissue. The hormonal regulation of fasting systems is summarized in Table 53-1.

TRANSIENT HYPOGLYCEMIA IN NEONATES

Delayed Development of Fasting Systems in Appropriate-for-Gestational-Age Term and Preterm Neonates

Physiologically normal AGA infants are highly susceptible to the development of hypoglycemia on the first day of life if feedings are delayed. For example, if the first feeding is not given until 6 to 8 hours after birth, 30% of term AGA neonates cannot maintain plasma glucose levels higher than 50 mg/dL, and in 10% to 15% of these infants, glucose values may drop to below 30 mg/dL. In normal newborn infants, the risk of hypoglycemia declines quickly after 12 to 24 hours, and by the second day of life, the frequency of blood glucose levels lower than 50 mg/dL drops to less than 0.5%.[7,29]

This susceptibility to transient hypoglycemia is associated with developmental lags in the capacity for both hepatic ketogenesis and hepatic gluconeogenesis in the newborn, as described earlier, and is aggravated in infants who have limited stores of glycogen.[30] (A classification of the various pathophysiologic mechanisms in neonatal hypoglycemia, both transient and persistent forms, is presented in Box 53-2.) Studies performed in the guinea pig and rat have shown delays for up to 12 hours after birth in expression of the gluconeogenic enzyme PEP-CK, as well as those enzymes mediating the first and last steps in the pathway of hepatic ketogenesis, carnitine palmitoyl-transferase-1 and β-hydroxy-β-methylglutaryl–coenzyme A synthase.[19,20,31,32]

Premature infants have an increased risk for hypoglycemia as a result of markedly reduced glycogen stores, in addition to the usual low activity of key gluconeogenic and glycolytic enzymes.[33] It has been shown that up to 20% of preterm infants who were about to be discharged home were at risk for hypoglycemia if a feeding was delayed.[33] SGA infants also have demonstrated similar mechanisms for the development of hypoglycemia (low glycogen stores in addition to usual delayed activation of fatty acid oxidation and induction PEP-CK).[34,35]

BOX 53-2

Classification of Hypoglycemia in the Newborn

Neonatal Transient Hypoglycemia
- Developmental lags in gluconeogenesis and ketogenesis
- Transient hyperinsulinism
  - Infant of diabetic mother
- Perinatal stress-induced hyperinsulinism
  - Small for gestational age
  - Discordant twin
  - Birth asphyxia
  - Infant of toxemic mother

Neonatal Persistent Hypoglycemia
- Hyperinsulinism
  - Potassium-ATP (K_{ATP}) channel hyperinsulinism (recessive, dominant, focal)
  - Glucokinase hyperinsulinism (dominant)
  - Glutamate dehydrogenase hyperinsulinism (dominant)
  - Short-chain L-3 hydroxyacyl–coenzyme A dehydrogenase deficiency (recessive)
  - Beckwith-Wiedemann syndrome
- Counterregulatory hormone deficiency
  - Panhypopituitarism
  - Isolated growth hormone deficiency
  - Cortisol deficiency
- Glycogenolysis disorders
  - Debrancher enzyme deficiency (small for gestational age)
- Gluconeogenesis disorders
  - Glucose-6-phosphatase deficiency (GSD type IA)
  - Glucose-6-phosphatase translocase deficiency (GSD type IB)
  - Fructose-1,6-diphosphatase deficiency
  - Pyruvate carboxylase deficiency
- Fatty acid oxidation disorders

ATP, Adenosine triphosphate; *GSD,* glycogen storage disease.

Hyperinsulinism in Birth Asphyxia and in Small-for-Gestational-Age Infants

Among SGA newborns and infants born in circumstances of perinatal stress, a high incidence of prolonged neonatal hypoglycemia has been reported. Up to 10% of SGA infants in one series continued to have hypoglycemia beyond the first week of life.[36] For reasons that are not clear, the incidence of hyperinsulinism, which may persist for weeks to months, is increased in these infants.[37-40] This perinatal stress-induced hyperinsulinism is responsive to diazoxide and is not related to genetic forms of hyperinsulinism such as mutations in the adenosine triphosphate (ATP)-dependent potassium (K_{ATP}) channel or glutamate dehydrogenase (GDH) enzyme.The specific pathomechanism for hyperinsulinism in SGA infants and in those with birth asphyxiaor erythroblastosis fetalis has yet to be elucidated.

Infants born to diabetic mothers have an increased incidence of hypoglycemia, which results from hyperinsulinism.[41] Fetal insulin secretion increases in response to maternal hyperglycemia; accordingly, the degree of fetal hyperinsulinemia correlates with maternal diabetic control during pregnancy.[40] The condition tends to be short-lived and usually resolves over the first few days of life. Deficiencies of the counterregulatory hormones, epinephrine and glucagon, also have been demonstrated in infants born to diabetic mothers, particularly women with poor control of their disease during pregnancy.[42,43]

CONGENITAL HYPOGLYCEMIC DISORDERS MANIFESTING IN THE NEONATE

Congenital Hyperinsulinism

The term *hyperinsulinism* is applied when hypoglycemia results from inadequate suppression of the plasma insulin. Hyperinsulinism in infancy usually is a congenital defect in the regulated release of insulin from pancreatic beta cells associated with inappropriate secretion of insulin. Both sporadic and familial genetic forms of the disease are recognized, with an incidence ranging from 1 in 50,000 births in Western Europe to 1 in 2500 births in societies with high rates of consanguinity.[44]

Congenital hyperinsulinism is both clinically and genetically heterogeneous. The clinical presentation ranges from extremely severe, life-threatening disease to very mild clinical symptoms, which may even be difficult to identify. Furthermore, clinical responsiveness to medical and surgical management is extremely variable and genotype-specific.[45] Early diagnosis and therapy are essential to prevent brain damage.[46]

The diagnosis of hyperinsulinism cannot rely solely on the measurement of plasma insulin levels at the time of hypoglycemia, because the insulin assays are not sufficiently sensitive in the low range to reliably distinguish a normal from an inadequately suppressed insulin level. Normally insulin concentrations are suppressed to values that are undetectable when plasma glucose levels fall to less than 65 mg/dL (less than 3 μU/mL for conventional assays). Thus an insulin level in the "normal" range when the blood glucose is 50 mg/dL or less is consistent with hyperinsulinism.

Therefore, in addition to plasma insulin measurements at the time of hypoglycemia, other markers of excessive insulin action should be sought, including demonstration of inappropriately low plasma ketones and free fatty acids and an inappropriately large glycemic response to glucagon.[47,48] At a plasma glucose level less than 50 mg/dL, evidence of hyperinsulinism includes the following: plasma insulin level greater than 3 μU/mL, plasma β-hydroxybutyrate less than 2 mmol/L, plasma free fatty acids less than 1.5 mmol/L, and occurrence of glycemic response to 1 mg of glucagon measured as a change in serum glucose greater than 30 mg/dL within 15 to 20 minutes.[49] These values reflect insulin suppression of adipose tissue lipolysis and ketone body production and preservation of glycogen stores despite falling plasma glucose levels.

The genetic basis of hyperinsulinism continues to be elucidated; mutations in five different genes have been identified. Most cases are caused by mutations in either of the two subunits of the beta cell adenosine triphosphate (ATP)–sensitive potassium channel (K_{ATP}), SUR1 (sulfonylurea receptor-1) and Kir 6.2 (inward-rectifying potassium channel protein 6.2).[50] Others are caused by mutations in the beta cell enzymes GDH and glucokinase and in short-chain L-3-hydroxyacyl–CoA dehydrogenase (SCHAD).[51-54] In as many as 50% of the cases, no genetic defect has been determined.[55]

Insulin Secretion

The regulation of insulin secretion is under the control of at least four mechanisms: (1) substrate-mediated mechanisms involving glucose, amino acids, and fatty acids; (2) neural control by the autonomic nervous system; (3) paracrine control by glucagon and somatostatin secreted within the pancreatic islets; and (4) endocrine control by intestinal incretins such as glucagon-like peptide (GLP-1). All of the currently known genetic forms of hyperinsulinism involve abnormalities in substrate-mediated pathways of insulin release (Figure 53-1).

The mechanism of insulin release that is best characterized is substrate-mediated insulin release by way of the K_{ATP} channel and the voltage-gated calcium channel. Glucose stimulates insulin release by metabolism to increase the ratio of ATP to adenosine diphosphate (ADP), leading to inhibition of the plasma membrane K_{ATP} channel, depolarization of the plasma membrane, activation of voltage-gated calcium channels, and influx of calcium to activate insulin release from storage granules.[56] An increase in the ATP-ADP ratio also can be generated by an increase in the oxidation of glutamate, a reaction catalyzed by the enzyme GDH. GDH activity is controlled allosterically by guanosine triphosphate (GTP) inhibition and is stimulated by ADP or leucine.[57,58] Activating mutations in the GDH gene causes the hyperinsulinism and hyperammonemia syndrome.

K_{ATP} Channel Hyperinsulinism

Recessive K_{ATP} Hyperinsulinism

In recessive K_{ATP} hyperinsulinism, previously referred to as nesidioblastosis, affected infants typically are large for gestational age (LGA), with severe hypoglycemia manifesting soon after birth. The genetic defect impairs either the SUR1 or Kir6.2 component of the K_{ATP} channel; most mutations discovered to date affect the SUR1 gene.[55,59,60] The genes for SUR1 *(ABCC8)* and Kir6.2 *(KCNJ11)* are located on the short arm of chromosome 11 (11p), immediately adjacent to one another.[61] Therapeutic interventions that act by way of the K_{ATP} channel, such as diazoxide, usually are ineffective. Thus many of these infants require near-total pancreatectomy.

Focal K_{ATP} Hyperinsulinism

In the focal form of hyperinsulinism, the area of abnormality is in a specific region of the pancreas; the characteristic histopathologic entity is described as focal adenomatous hyperplasia. The clinical presentation is indistinguishable from that in the recessive form of hyperinsulinism, described earlier, that involves the entire pancreas. The focal lesions are an area of beta cell adenomatosis caused by loss of heterozygosity for the maternal 11p15 region and expression of a paternally derived K_{ATP} channel mutation.[62-67] Approximately half of infants with hyperinsulinism requiring surgery may have focal lesions and are therefore potentially curable. Positron emission tomography (PET) scans using ^{18}F-fluoro-L-dihydroxyphenylalanine ([^{18}F]-dopa) have proved to be an accurate noninvasive technique to diagnose the condition and localize the focal lesion.[68-70]

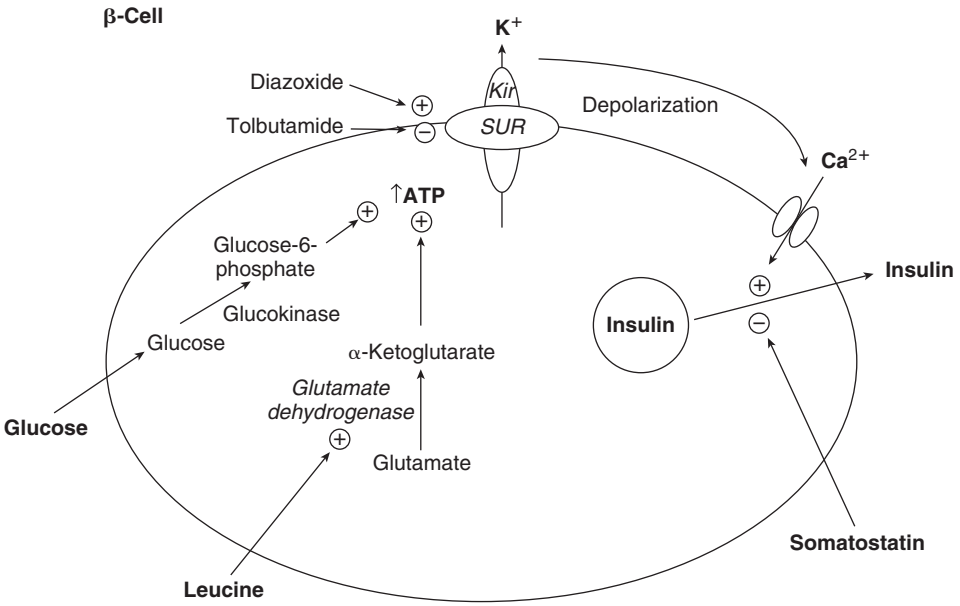

Figure 53-1 Pancreatic beta cell insulin secretion. Glucose stimulates insulin secretion through its oxidation, which increases levels of intracellular adenosine triphosphate (ATP), which in turn inhibits the potassium efflux through the potassium (K_{ATP}) channel (the sulfonylurea receptor [SUR]–inward-rectifying potassium channel [Kir] protein complex). Closure of the K_{ATP} channel depolarizes the plasma membrane, which activates the voltage-gated calcium channel (Ca^{2+}) to increase intracellular calcium and to trigger exocytosis of insulin granules. Leucine is an allosteric activator of glutamate dehydrogenase (GDH); increased activity of GDH increases glutamate oxidation, which also increases intracellular ATP. Diazoxide inhibits insulin release by preventing closure of the K_{ATP} channel. Tolbutamide stimulates insulin secretion by closing the K_{ATP} channel. Somatostatin decreases insulin release by downstream mechanisms.

Patients with the focal form have the best chance of successful treatment when managed at a center that can provide a multidisciplinary approach with a team including an endocrinologist, radiologist, pathologist, and surgeon.[71]

Dominant K_{ATP} Hyperinsulinism

Several families have been described with dominantly inherited congenital hyperinsulinism, associated with SUR1 and Kir 6.2 mutations.[72-74] Many of these patients have a less severe presentation than that typical for other forms of K_{ATP} hyperinsulinism, and all cases have been responsive to diazoxide.

Glutamate Dehydrogenase Hyperinsulinism

The hyperinsulinism and hyperammonemia syndrome has been reported as a cause of moderately severe hyperinsulinism with diffuse involvement of the pancreas.[75] GDH is a mitochondrial matrix enzyme that functions in the beta cell to mediate leucine-stimulated insulin secretion (see Figure 15-1). The mutations causing hyperinsulinism impair allosteric inhibition of GDH by GTP and result in uninhibited insulin release.[76-78] Clinical manifestations have included normal birth weight, late onset of hypoglycemia, diazoxide responsiveness, and protein-sensitive hypoglycemia.[77,79]

Glucokinase Hyperinsulinism

A less frequent form of hyperinsulinism, glucokinase hyperinsulinism (GK-HI), is caused by activating mutations in *GCK,* which encodes glucokinase.[80] GK-HI is inherited in an autosomal dominant manner, and five mutations have been identified to date.[81] In beta cells, glucokinase controls the rate-limiting step of glucose metabolism and is responsible for glucose-stimulated insulin secretion.[82] In GK-HI, activating mutations result in increased affinity of glucokinase for glucose, closure of K_{ATP} channels and inappropriate insulin secretion. The beta cell glucose threshold for glucose-stimulated insulin secretion in children with GK-HI can be as low as 27 mg/dL, much lower than the normal glucose threshold (90 mg/dL). The age at onset and severity of symptoms, as well as response to diazoxide treatment, vary markedly.[80,83-85]

SCHAD Hyperinsulinism

A mutation in *HADHSC,* the gene encoding the mitochondrial enzyme SCHAD, has been reported to be associated with hyperinsulinism.[51-54] SCHAD catalyzes the conversion of 3-hydroxyacyl-CoA to 3-ketoacyl-CoA, the third of four steps in the mitochondrial fatty acid oxidation spiral. SCHAD hyperinsulinism is inherited as an autosomal recessive trait, and patients have hypoketotic hypoglycemia with normal free fatty acids, 3-hydroxyglutaric acid in the urine, and raised plasma levels of 3-hydroxybutyryl carnitine and exhibit responsiveness to diazoxide. The clinical presentation of SCHAD hyperinsulinism is heterogeneous, ranging from late onset of mild hypoglycemia to severe onset of early hypoglycemia in the neonatal period. Patients do not have evidence of hepatic dysfunction, cardiomyopathy, or skeletal muscle involvement typically seen with fatty acid oxidation disorders.[54] The mechanism for increased insulin secretion in patients with SCHAD deficiency remains unknown but is thought to involve a K_{ATP} channel–independent pathway.[86]

Other Conditions with Hypoglycemia Resulting From Hyperinsulinism

Beckwith-Wiedemann syndrome is a congenital overgrowth syndrome associated with isodisomy for 11p that includes fetal overgrowth, hypoglycemia, and increased risk for some cancers. The incidence of hypoglycemia in affected children is approximately 50%.[87] The hypoglycemia can be transient but in approximately 5% of the cases can extend beyond the neonatal period, necessitating either continuous feeding, medical therapy, or in some

cases, partial pancreatectomy.[88,89] The cause of this hypoglycemia is unclear but may involve genes in the 11p region: either deficiency of K_{ATP} channels or excessive insulin-like growth factor-2 (IGF-2) activity.

Congenital disorders of glycosylation (CDGs) comprise a group of inherited multisystem disorders that are due to defects in the synthesis of the carbohydrate moiety of glycoproteins. In CDG type Ib, caused by phosphomannose isomerase (PMI) deficiency, clinical features include protein-losing enteropathy, liver disease, and hyperinsulinemic hypoglycemia. Mannose treatment bypasses the PMI deficiency and can be successful in correcting the clinical and biochemical abnormalities seen in affected patients.[90,91] Additional variants of CDG also have been found to be associated with hypoglycemia. These disorders can be detected by identifying the transferrin isoelectric focusing pattern.

Counterregulatory Hormone Deficiencies

Neonatal hypoglycemia occurring secondary to counterregulatory deficiency usually results from pituitary deficiency with various combinations of cortisol and growth hormone deficiency. The clinical presentation of neonates with panhypopituitarism can be identical to that seen in hyperinsulinism, requiring a high glucose infusion rate to maintain euglycemia, inappropriate hypoketonemia, and a positive glycemic response to glucagon at the time of hypoglycemia. Physical features such as micropenis or midline facial malformations such as cleft palate should suggest pituitary dysfunction as the cause of hypoglycemia.[92] Neonatal hypopituitarism sometimes is associated with cholestatic liver jaundice.[93] A low cortisiol or growth hormone value obtained at the time of hypoglycemia does not prove hormone deficiency. Therefore stimulation testing often is required to exclude pituitary insufficiency, because the critical sample may miss the peak hormonal response, thereby providing misleading results.

Defects in Gluconeogenesis

GSD IA, due to glucose-6-phosphatase deficiency, and GSD IB, secondary to glucose-6-phosphate translocase deficiency, result in a complete inability of the liver to release glucose into the circulation, because the formation of glucose from glucose-6-phosphate is the final step in both glycogenolysis and gluconeogenesis. Affected infants present with hypoglycemia, hepatomegaly, lactic acidemia, hyperuricemia, hypertriglyceridemia, and growth failure.

Deficiency of the enzyme fructose-1,6-diphosphatase blocks gluconeogenesis from precursors below the level of fructose-1,6-diphosphate (fructose, lactate, glycerol, alanine). The disease, which is inherited as an autosomal recessive trait,[94] can manifest in the neonatal period and can be fatal. Affected infants present with hypoglycemia, lactic acidemia, and hepatomegaly.[95] Hypoglycemia occurs later in this disorder and in pyruvate carboxylase deficiency (described next) than in G6Pase deficiency, because glycogenolysis is unimpaired.

Fasting hypoglycemia can occur in infants and children with deficiency of pyruvate carboxylase, the enzyme mediating the first step in gluconeogenesis.[96] Depending on the severity of the deficiency, the clinical presentation can range from devastating neurologic damage, lactic acidemia, hyperammonemia, and ketosis in early infancy to intermittent attacks of fasting-induced hypoglycemia accompanied by lactic acidemia in childhood.[97]

Deficiency of the last of the four gluconeogenic enzymes, PEP-CK, has not been convincingly demonstrated, despite several reported "cases."[98] Part of the reason for confusion in this area is that both mitochondrial and cytosolic enzymes with PEP-CK activity, encoded by two separate genes, are known to exist. True PEP-CK deficiency has yet to be described, but the clinical presentation is likely to include features similar to those of fructose-1,6-diphosphatase and pyruvate carboxylase deficiencies, such as lactic acidemia and hypoglycemia.

Glycogen Storage Diseases

GSDs are a group of disorders characterized by abnormal glycogen synthesis or degradation. Hypoglycemia is a feature of several but not all of these disorders. The two disorders in this group most likely to manifest in the neonatal period with hypoglycemia are GSD type I (glucose-6-phosphatase deficiency) and GSD type III (debrancher enzyme deficiency). GSD I is better classified as a disorder of gluconeogenesis (see earlier), because the enzyme catalyzes the final common step in glycogenolysis and gluconeogenesis.

Debrancher enzyme deficiency results in an inability to degrade stored glycogen. Inheritance is autosomal recessive, with more than 30 mutations reported. Clinical manifestations include hepatomegaly and hypoglycemia; skeletal myopathy and cardiomyopathy may develop in later childhood and adolescence in one third to two thirds of cases.

Fatty Acid Oxidation Defect

Fatty acid oxidation defect is the term applied to an error in the pathway of fatty acid mitochondrial oxidation. Such errors disturb oxidative phosphorylation and ATP generation from fat stores and result in loss of hepatic ketogenesis.[99] Episodes of illnesses are provoked by fasting and result in hypoglycemia associated with inappropriate hypoketonemia. The manifestations may be multisystemic, involving liver, heart, and skeletal muscle, leading to a Reye-like syndrome eventuating in coma and death.[100] The diagnosis of some but not all disorders of fatty acid oxidation can be made by mass spectrometry determination of the plasma acyl-carnitine profile.

Medium-chain acyl coenzyme A dehydrogenase (MCAD) deficiency is the most common fatty acid oxidation defect, with a frequency of 1 in 8000.[101,102] This disorder is now included in newborn screening protocols in many states. The gene for MCAD is located on chromosome 1 (1p31). An A985G point mutation causing a change from lysine to glutamate at position 304 in the mature MCAD protein has been found in 90% of patients with MCAD who were identified retrospectively,[103] although the frequency of this mutation may be lower among patients identified by neonatal screening.[104,105] The disorder is readily managed by avoidance of prolonged fasting.

Miscellaneous

Reactive hypoglycemia associated with late dumping syndrome is a frequent sequela of Nissen fundoplication. Treatment with acarbose to delay carbohydrate digestion often is helpful.[106] Finally, an atypical clinical presentation should raise the possibility of factitious hypoglycemia (Munchausen syndrome by proxy) secondary to surreptitious administration of insulin or insulin secretagogues. In such cases the infant will have elevated insulin levels with suppressed C-peptide values. However, some new insulin analogues do not demonstrate reactivity on the insulin assay.

SUMMARY

The occurrence of hypoglycemia in the neonate reflects failure of fasting adaptation. The endocrine and metabolic systems required during fasting and their normal developmental sequence are emphasized in this chapter. Neonatal hypoglycemia secondary to maturational delay in two of these fasting systems, gluconeogenesis and ketogenesis, is likely to occur if feeding is delayed after birth. Beyond 12 to 24 hours, neonatal

hypoglycemia requires specific diagnosis, to permit institution of appropriate treatment and to avoid adverse outcomes. Persistent neonatal hypoglycemia most commonly is the result of transient hyperinsulinism in infants with birth asphyxia, in SGA infants, and in infants of diabetic mothers. Genetic causes of persistent neonatal hypoglycemia such as congenital hyperinsulinism, hypopituitarism, and gluconeogenesis disorders also need to be considered. Inborn errors of metabolism often do not manifest as hypoglycemia in the newborn period; of those that do, fatty acid oxidation defects are the most common.

SECTION VIII

Protein Metabolism

54

Dwight E. Matthews and Johannes (Hans) B. van Goudoever

General Concepts of Protein Metabolism

This chapter describes the methods used to evaluate dynamic changes in protein metabolism in the newborn infant. In a consideration of the relevant kinetics, the fundamental point of interest is that amino acids—the building blocks of protein—differ from carbohydrate and fat *only* by the inclusion of nitrogen. Alanine without its lone nitrogen atom is pyruvate, which is half a glucose molecule. It is the nitrogen atom or atoms in amino acids that set protein apart from carbohydrate and fat, and this distinction is the basis for investigation of amino acid and protein metabolism.

NITROGEN BALANCE

The oldest (and most widely used) method to follow changes in body protein is the nitrogen balance method, which has been the standard modality for defining minimum levels of dietary protein and essential amino acid intake in humans of all ages.[1-3] Of note, however, nitrogen balance defines only the difference between that going in and that coming out of the body. This determination is done by carefully recording all food consumed and collecting all material excreted: urine, feces, sputum, and so on. The nitrogen from aliquots of each food, urine, and fecal collection is tediously converted to ammonia by boiling the specimens in concentrated acid. The ammonia content is determined, and nitrogen intake and excretion are calculated. This simple nitrogen balance technique is fraught with technical difficulties: Nitrogen losses are routinely *underestimated* because of incomplete collections of urine and feces and insensible losses through skin, sweat, and so on, and nitrogen intake is routinely *overestimated* because of variable content or availability of protein in foods consumed, inaccurate recording of ingested amounts, and so on.[4,5]

Alternatively, the anthropometric measure of growth may be used to determine efficacy of the level and quality of protein in the diet of infants. Measurement of growth is an indication of well-being but gives no information specific to protein metabolism. Although measures of nitrogen balance and growth often have been used to study infant nutrition,[2,6] both methods require days or weeks to measure effects. Neither method provides any information concerning the turnover of nitrogen *within* the body. For example, an infant may be receiving adequate protein but insufficient energy intake for growth. Owing to this restricted intake, the child is not growing and has a nitrogen balance of zero. When more calories are provided, the infant starts growing and shows a positive nitrogen balance. How does the child's body respond to produce this effect? Nitrogen balance and growth measurements do not provide this information.

Figure 54-1 shows four possible responses to the original clinical situation. Case 0 is the starting zero nitrogen balance. Positive nitrogen balance could be obtained by increasing protein synthesis (case A in the figure), decreasing protein breakdown (case C), increasing or decreasing (cases B and D). The effect is a positive nitrogen balance for all four scenarios, but the energy implications are considerably different. Because protein synthesis costs energy, cases A and B are more "expensive," whereas cases C and D require less energy than in the starting scenario (case 0). Investigation of these possible mechanisms requires direct assessment of rates of protein breakdown, protein synthesis, and amino acid turnover within the body. Such assessment can be accomplished with the use of stable, isotopically labeled tracers.

MODELS FOR WHOLE-BODY AMINO ACID AND PROTEIN METABOLISM

The simplest approach to the study of amino acid and protein kinetics is to hypothesize a single, free pool of amino acid nitrogen, with *two inflows*—amino acid from dietary protein and amino acid released from protein breakdown—and *two outflows*—amino acid oxidation to end products (carbon dioxide [CO_2], urea, and ammonia) and amino acid uptake for protein synthesis (Figure 54-2). This model can be considered either for whole-body protein turnover, in which the pool is the total free amino acid pool (see Figure 54-2), or for the kinetics of a single amino acid, in which the pools are for a particular amino acid (illustrated for a ^{13}C tracer in Figure 54-3). The difference between the two approaches is related to how the system is viewed: looking at protein turnover, on the one hand, versus

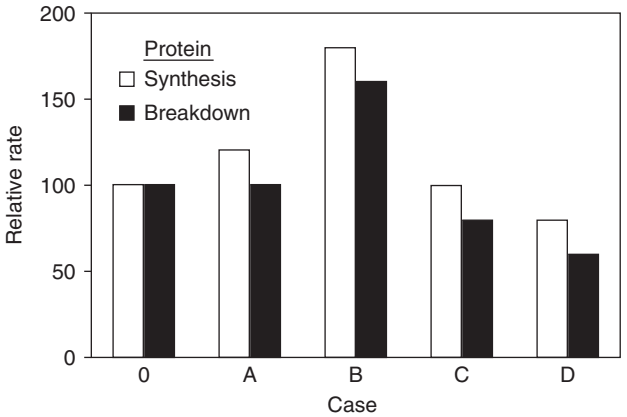

Figure 54-1 Four different hypothetical responses to a change from a zero balance (case *0*) to a positive nitrogen balance (cases *A to D*). A positive nitrogen balance can be obtained by increasing protein synthesis, as in case *A*; by increasing synthesis more than breakdown, as in case *B*; by decreasing breakdown, as in case *C*; or by decreasing breakdown more than synthesis, as in case *D*. The nitrogen balance method does not distinguish among any of the four possibilities.

looking at the kinetics of a specific amino acid from which inferences to whole-body protein turnover are drawn, on the other hand.

All protein in the body (structural, enzymes, and so on) is constantly being made and broken down. For most of the protein in the body (e.g., muscle protein), this turnover process occurs slowly, and can be considered to consist of a large amorphous inflow of amino acid from protein breakdown and a large amorphous uptake of amino acid from the fast-turnover free amino acid nitrogen pool. This system defines the traditional single-pool model of protein metabolism. The single pool is the free amino acid pool. Because of the size and slow turnover of the body protein pool, it is considered to be both a *sink* via extraction of amino acids for protein synthesis and a *source* for amino acid entry via protein breakdown. Whatever tracer enters this protein pool during the time course of the study is not likely to come out. Therefore, even though a box or circle may be used to depict this hypothetical compartment in diagrams of models for whole-body protein turnover, mathematically it is not considered to constitute a "pool" at all.

Lumping all body protein into a single entity is a gross oversimplification. Each of the many different tissues of the body is made up of a wide range of proteins with different turnover rates. Obviously, following the individual rates of hundreds of proteins would be impracticable. Because most of the important stores of nitrogen in the body turn over at similarly slow rates, it is possible to simplify the system into a conceptual model of clinical and experimental utility.

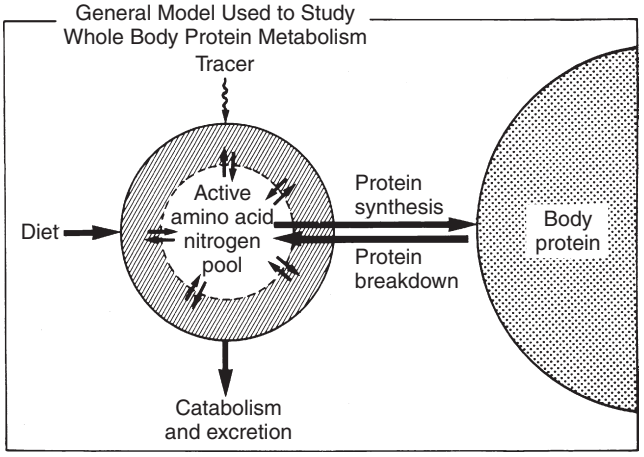

Figure 54-2 Single-pool amino acid model for whole-body protein metabolism. The model is applied without requiring definition of individual pools. All free amino acid nitrogen is lumped together. The *shaded outer circle* indicates interchange of free amino acids with various intracellular free amino acid pools and with incorporation into and release from faster-turnover proteins. Slower-turnover protein, such as muscle protein, appears as an exit from the system for free amino acid by way of protein synthesis and as a source of free amino acid entry by way of protein breakdown. Amino acids also leave the system by oxidation to the end products (carbon dioxide, urea, and ammonia) and can enter through absorption of dietary protein or amino acids. *(From Matthews DE: Stable isotope applications in human metabolism research. In Duncan WP, Susan AB, editors:* Synthesis and Applications of Isotopically Labeled Compounds, *Amsterdam, 1983, Elsevier, pp 279-284.)*

METHODS FOR MEASURING PROTEIN METABOLISM IN HUMANS

Box 54-1 lists the methods used to measure protein and nitrogen metabolism in humans. As already discussed, measurements of growth and nitrogen balance do not provide information on how protein balance is regulated. Changes in amino acid metabolism for a specific tissue can be inferred by measuring the difference between the amino acids delivered to the tissue (arterial blood levels) and the amino acids released from the tissue (venous blood levels). In adults, this technique has been applied to studies of forearm, leg, liver, kidney, and brain metabolism.[7-9] In animals and more recently in pregnant women, this model has been important in dissecting fetal and placental metabolism.[10,11] Measuring an arterial-venous difference, however, is similar to the nitrogen balance technique—it provides information about the balance across the tissue bed but tells nothing about the mechanism within the tissue affecting the balance. Most exciting is the combination of tracer infusion with the measurement of amino acid balance across the tissue bed. This technique allows for a complete solution of the various pathways operating in the tissue for each amino acid tracer used and can measure tissue-specific rates of protein synthesis and balance.[12-14] However, the use of arterial and venous catheters restricts the applicability of this method primarily to animal models.[10,15-21]

Only a limited number of investigations have addressed human fetal amino acid metabolism by infusing amino acid tracers into the mother before delivery and obtaining cord blood at delivery to determine fetal metabolism.[22] The only way to get to specific tissue amino acid metabolism in human neonates is with the simultaneous use of enteral and intravenous tracers. First-pass amino acid metabolism of the small intestine and liver is measured by comparison of the tracer enrichments of

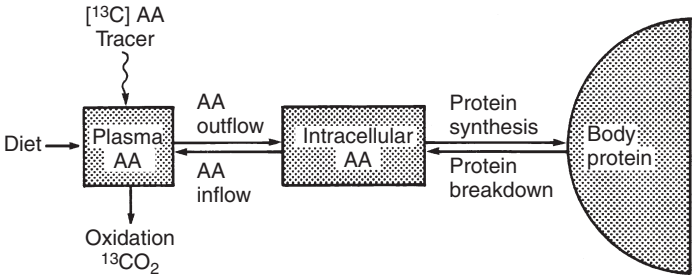

Figure 54-3 Simplified model for following the kinetics of an individual essential amino acid (AA) using a 13C label. The ^{13}C-labeled amino acid is infused intravenously. The tracer equilibrates with the free amino acid in plasma and in intracellular compartments. Amino acid is taken up from and released into the intracellular compartment through protein synthesis and breakdown. Amino acid oxidized intracellularly to form carbon dioxide (CO_2) is released into plasma as bicarbonate, and then into exhaled breath as CO_2. *(From Bier DM, Matthews DE, Young VR: Interpretation of amino acid kinetic studies in the context of whole-body protein metabolism. In Garrow JS, Halliday D, editors:* Substrate and Energy Metabolism in Man, *London, 1985, John Libbey, pp 27-36.)*

BOX 54-1

Methods for Measuring Protein and Nitrogen Metabolism in Humans

- Growth assessment
- Nitrogen balance method
- End product method
- Turnover of individual components
- Essential amino acids turnover (index of protein breakdown)
- Nonessential amino acids turnover (de novo synthesis and gluconeogenesis)
- Urea production (protein oxidation)
- Arteriovenous measurement of amino acids across a tissue bed
- Protein synthesis of a specific protein by following tracer incorporation
- Protein degradation of a specific protein by following disappearance of tracer from the protein

both tracers in plasma. The plasma enrichment of the enteral administered tracer will be lower than that of the intravenously infused tracer by the amount of material sequestered by the gut and liver on the first pass during enteral absorption of the tracer. The ratio between the enrichment of the intravenous administered tracer and that of the enteral administered tracer is used to calculate the first-pass uptake.[23]

End Product Approach to Measurement of Protein Metabolism

Because glycine is the only amino acid without an optically active α-carbon center, [^{15}N]glycine is the easiest labeled amino acid to synthesize and was the earliest tracer used for measuring protein turnover in the body. Using this tracer, Sprinson and Rittenberg[24] performed pioneering studies of protein metabolism based on a compartmental analysis of a single pool. As indicated in Figure 54-2, the free amino acid nitrogen pool is far too complex to be forced into a single kinetic pool when the metabolism of multiple amino acids is considered. The problem lies not in conceptualizing a single amino acid pool but in applying mathematical equations specific to a single pool. Therefore almost no progress was made in studying protein metabolism in humans from the time of the initial description by Sprinson and Rittenberg until 1969, when Picou and Taylor-Roberts[25] proposed a significant and simple alternative. Conceptually, the same single-pool approach was used, but no specific single-pool kinetic restriction was applied—that is, the system was viewed in stochastic fashion.[26] The [^{15}N]glycine tracer is given, and the ^{15}N-glycine mixes (scatters) among the free amino acids. The ^{15}N in the free amino acid pool is diluted with unlabeled amino acid entering from protein breakdown and from dietary intake. Using the rate of ^{15}N infusion and after measuring the dilution of ^{15}N in the free amino acid pool, the rate of unlabeled nitrogen appearance is readily calculated:

$$Q = 100 \bullet i/E$$

where Q is the free amino acid nitrogen pool turnover rate (typically expressed as mg nitrogen/kg/day), i is the rate of [^{15}N]glycine infusion (mg ^{15}N/kg/day), and E is the ^{15}N enrichment (dilution of ^{15}N by unlabeled nitrogen, expressed as *atom* or *mole % excess*). The 100 factor converts mole % to mole fraction. The dilution of the ^{15}N-glycine tracer (i.e., enrichment in the free amino acid nitrogen pool) is sampled indirectly via either the urea or ammonia end products, which are produced from the free amino acids. According to the standard precursor-product relationship,[26] a product (i.e., urinary urea or ammonia) formed from a single precursor will have an enrichment equal to the precursor (i.e., the free amino acid nitrogen pool).

The rate of whole body protein breakdown *(B)* is determined from the turnover *(Q)* by subtracting the known rate of dietary nitrogen intake *(I)*:

$$B = Q - I$$

In these calculations, the standard value of 6.25 g protein = 1 g nitrogen is used to interconvert protein and N. Attention to the units (g of *protein* versus g of *nitrogen*) is important, because both units often are used concurrently in the literature.

Like most of the kinetic methods, the end product method assumes steady-state conditions with respect to the free pool (i.e., the free nitrogen pool is neither expanding nor contracting). Obviously, the free pool does both, but over the period of most measurements, increases cancel decreases so that the steady-state assumption is reasonable. When *inflows* equal *outflows*,

$$Q = I + B = C + S$$

where the outflows are amino acid nitrogen oxidation *(C)* to end products urea and ammonia, and amino acid nitrogen uptake for protein synthesis *(S)*. Amino acid nitrogen oxidation is simply the sum of the ammonia and urea production rates, which are determined by urine collection. Therefore the rate of whole-body synthesis is

$$S = Q - C$$

Occasionally encountered in the literature[27] is the term *net protein balance* or *net protein gain,* which refers to the difference between the measured synthesis and breakdown rates ($S - B$). Rearranging the balance equation for Q shows that

$$S - B = I - C$$

and $I - C$ is simply the difference between intake and excretion, that is, *nitrogen balance*. Therefore the $S - B$ term is a misnomer in that it is based solely on the nitrogen balance measurement and not on the administration of the ^{15}N tracer.

The overwhelming advantage of the end product method of Picou and Taylor-Roberts[25] is that it can be completely noninvasive; accordingly, it became the cornerstone method for protein metabolic research in pediatrics. This method, however, is not without its problems.

As described by Picou and Taylor-Roberts,[25] the [^{15}N]glycine tracer is given orally at short intervals (e.g., every 3 hours) until a plateau for ^{15}N is reached in urinary urea. The time required to reach this plateau is approximately 60 hours, regardless of whether adults,[28] children, or infants[29-31] are studied. The delay in attaining a plateau results from the time required for the ^{15}N tracer to equilibrate within the free glycine, serine, and urea pools.[28,32] An additional problem is plateau definition. Often the urinary urea ^{15}N time course does not show, either on visual inspection or with curve-fitting regression, the anticipated single exponential rise to plateau.

Although [^{15}N]glycine tracer is the cheapest amino acid to purchase, any ^{15}N-labeled amino acid can be used in the end product method, but widely divergent results have been obtained when different tracers have been used.[33-35] Table 54-1 shows the values of protein turnover measured for a single adult subject receiving different ^{15}N-labeled amino acid and protein preparations on different days and highlights the differences in the metabolism of the different amino acid tracers and distribution of the ^{15}N in the free amino acid pool. Glycine, for example, rapidly transfers its ^{15}N to serine, glutamate, and glutamine.[28] That distribution is not changed with changing dietary protein intake.[32] Although it may be fortuitous that [^{15}N]glycine is the best label for use with the end

TABLE 54-1

Rates of Protein Turnover Determined on Different Occasions for the Same Patient Using the End Product Method but Different ^{15}N-Labeled Tracers*

	PROTEIN TURNOVER (g/kg/day)	
^{15}N Tracer	*From Urea*	*From Ammonia*
Glutamine	2.6	3.1
Alanine	2.8	2.6
Wheat protein	3.5	5.8
Glutamate	3.5	8.0
Glycine	4.5	4.8
Leucine	9.6	4.7
Lysine	11.8	21.7
Aspartate	17.8	7.5

Data from Fern EB, Garlick PJ, McNurlan MA, Waterlow JC: The excretion of isotope in urea and ammonia for estimating protein turnover in man with [^{15}N]glycine, *Clin Sci* 61:217-228, 1981.

*The whole-body protein turnover rate was calculated using urinary urea and urinary ammonia ^{15}N enrichments.

product method,[36] an important point is that a change in end product ^{15}N enrichment may be attributable either to a real change in protein turnover or to an artifactual change in the distribution of ^{15}N resulting from changes in glycine metabolism, which can be *independent* of changes in protein metabolism. Another clue to difficulties with the end product method is that the urinary ammonia ^{15}N enrichment usually is different from the urinary urea ^{15}N enrichment,[31,36,37] because the amino acid ^{15}N precursor for ammonia synthesis is of renal origin, whereas the amino acid ^{15}N precursor for urea synthesis is of hepatic origin. Of the two types of enrichment, probably the urea ^{15}N should be used, but no direct evidence for either one is available.

In two studies,[31,38] an interesting observation was reported: ^{15}N could not be measured in urinary urea of some preterm infants receiving [^{15}N]glycine, but ^{15}N was observed in urinary ammonia. These results suggest that glycine may be inadequate in the diet of the preterm infant to meet growth requirements.[38] This event could happen only if glycine synthesis was limiting, that is, if glycine was conditionally indispensable.[1,39] Alternatively, the amount of ^{15}N-glycine given could have been too low to produce detectable levels of ^{15}N greater than the natural abundance in urea. Other groups of investigators,[40,41] however, have had no difficulty measuring ^{15}N enrichment in urinary urea when [^{15}N]glycine was administered to infants or synthesis of glycine,[42] suggesting that glycine can be considered an essential amino acid for preterm and possibly SGA infants.

As with all methods, limitations are recognized. The best approach with the end product method is to design the experiment to minimize the obvious problems of changes in ^{15}N tracer distribution within the pool or changes in ammonia metabolism. The utility of the method is readily apparent from its application.[43] For example, Nissim and co-workers have used the end product method to study protein turnover as a function of conceptual age[44] (Figure 54-4). Energy is required for turnover (i.e., synthesis and breakdown) of protein in the body, and energy is required for accretion of new protein in the growing infant. Therefore growth is intimately tied to both energy and nitrogen intakes, and both must be considered.[6,27]

In view of all of the foregoing evidence, it seems reasonable to conclude that the potential pitfalls with using [^{15}N]glycine outweigh the benefits of using the end product method in infants to study protein metabolism.

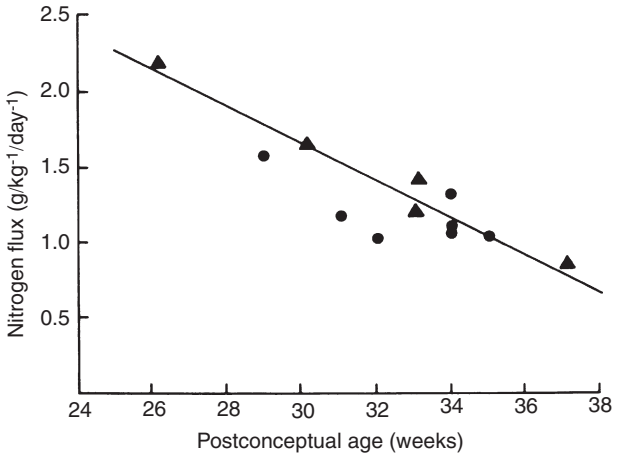

Figure 54-4 Whole-body nitrogen flux versus conceptual age measured using a single dose of [^{15}N]glycine given intravenously to eight infants, some studied twice. Triangles indicate five infants who received a diet of the same energy and protein content based upon infant body weight when studied. The significant correlation of whole body nitrogen flux in these infants further emphasizes that the correlation is indicative of postconceptual age, not level of dietary energy or protein intake. *(From Nissim I, Yudkoff M, Pereira G, Segal S: Effects of conceptual age and dietary intake on protein metabolism in premature infants,* J Pediatr Gastroenterol Nutr *2:507-516, 1983.)*

TURNOVER OF INDIVIDUAL COMPONENTS OF NITROGEN METABOLISM

Discussion up to now has considered the turnover of whole-body protein metabolism per se. Alternatively, the kinetics of individual components can be considered (see Figure 54-3). As outlined in Box 54-1, the interesting components are (1) the essential (or indispensable) amino acids, (2) the nonessential (or dispensable) amino acids, and (3) end products such as urea. Essential amino acid kinetics can be extrapolated to rates of protein metabolism. An essential amino acid enters the free pool from dietary intake (I_{aa}) and protein breakdown (B_{aa}); it disappears from the free pool by oxidation (C_{aa}) and uptake for protein synthesis (S_{aa}). These are the same components (*I, B, C,* and *S*) discussed previously, but cast in terms of the turnover, or *flux,* of a specific individual amino acid:

$$Q_{aa} = I_{aa} + B_{aa} = C_{aa} + S_{aa}$$

The turnover rate (or flux, Q_{aa}) of a metabolite is measured by the tracer dilution measured directly in the free pool. Typically, a tracer of an essential amino acid is infused until isotopic steady state (constant dilution) is reached in the blood free amino acid pool. Knowing the tracer enrichment and infusion rate and measuring the tracer dilution in blood from samples taken at plateau allow determination of the rate of unlabeled metabolite appearance (Q_{aa}):

$$Q_{aa} = i_{aa} \bullet [E_i / E_p - 1]$$

where i_{aa} is the infusion rate of tracer with enrichment E_i (mole % excess), and E_p is the plasma or blood amino acid enrichment.[45-47]

For a ^{13}C-labeled tracer, the amino acid oxidation rate can be measured from the rate of $^{13}CO_2$ excretion.[45,46] This approach assumes that the label is *quantitatively* released with the oxidation of the amino acid. For example, the ^{13}C of an L-[1-^{13}C] leucine tracer is removed at the first irreversible step of leucine catabolism[47] (Figure 54-5), and leucine oxidation is determined directly from $^{13}CO_2$ excretion. Even phenylalanine, for which the pathway to oxidation is not direct, has been used to define phenylalanine-tyrosine oxidation.[48-50]

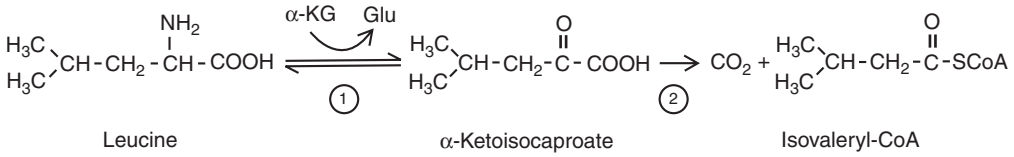

Figure 54-5 Leucine metabolism. *1,* Leucine is first transaminated to α-ketoisocaproate. This reaction is rapid and reversible. *2,* The ketoacid is then decarboxylated, releasing a carbon dioxide (CO_2) and an organic acid, which is further oxidized. The other two branched-chain amino acids, valine and isoleucine, also are metabolized by the same enzymes in these first two metabolic steps. *CoA,* Coenzyme A; *Glu,* glutamate; *KG,* ketoglutarate.

Determining an amino acid flux does not require a ^{13}C label per se. Any label (e.g., ^{15}N, ^{2}H, ^{18}O) can be used, but the caveat is that the label must follow the metabolic pathway expected. For example, a deuterium label in the tail of leucine or any ^{13}C label will trace leucine metabolism through the critical, irreversible second step of catabolism (see Figure 54-5), but an [^{15}N]leucine tracer is removed with transamination.[51] Because more than 70% of the leucine transaminated to α-ketoisocaproate (KIC) is immediately reaminated to leucine,[51] the ^{15}N label measures a leucine nitrogen turnover rate that is considerably faster than the leucine carbon flux. Therefore the ^{15}N-leucine tracer cannot be used to follow leucine carbon metabolism. For all metabolites to be studied, the biochemistry of the tracer must be carefully considered when choosing an isotopic label.

The rates of amino acid release from protein breakdown (B_{aa}) and uptake for protein synthesis (S_{aa}) are calculated by subtracting dietary intake and oxidation from the flux, respectively, just as is done with the end product method. The primary distinction is that the measurements are for a specific amino acid, not protein. Flux components typically are determined in units of μmol/kg/hour and then extrapolated to whole-body protein kinetics by dividing the amino acid rates by the assumed concentration of the amino acid in body protein (μmol of amino acid/g of protein).

The principal *advantages* of following individual metabolite kinetics are that (1) the results are specific, improving confidence in the measurement, and (2) the turnover time of the free pool usually is fast. With use of a priming dose to reduce the time required to come to isotopic steady state, the tracer infusion study can be completed in less than 4 hours.

The principal *disadvantages* are that (1) the method is invasive, (2) the true intracellular precursor pool usually is not sampled, and (3) dietary intake often is through a route different from that of the tracer. The amount of blood drawn is not an issue; blood loss can be kept below 1 mL total. However, placing catheters for sampling of blood amino acids or for tracer administration is almost unavoidable. Catheters may already be in place in the seriously ill infant, but invasive procedures are not warranted for studying healthy infants. Yet it is in the healthy infant that the tracer techniques offer the greatest tool for defining normal metabolism and nutritional requirements.

The bioavailability of dietary urea nitrogen has been determined in infants noninvasively by adding ^{15}N-urea tracer to the feeding solution and collecting and measuring the tracer in the urine.[52-54] The purpose of the studies using this technique was to determine what fraction of the urea nitrogen was retained in the body, rather than passing into the urine. Retention of urea nitrogen would reflect gut microorganism hydrolysis of the urea and incorporation of the resulting ammonia (presumably by the liver) into other nitrogen-containing compounds, including essential amino acids. This result has been demonstrated in both adults[55] and infants.[56] Because a significant portion of human milk nitrogen is urea nitrogen, urea nitrogen represents a potentially important nitrogen source. Because that the major portion of the urea ^{15}N consumed by infants is recovered in the urine, not much of the urea nitrogen will be bioavailable.

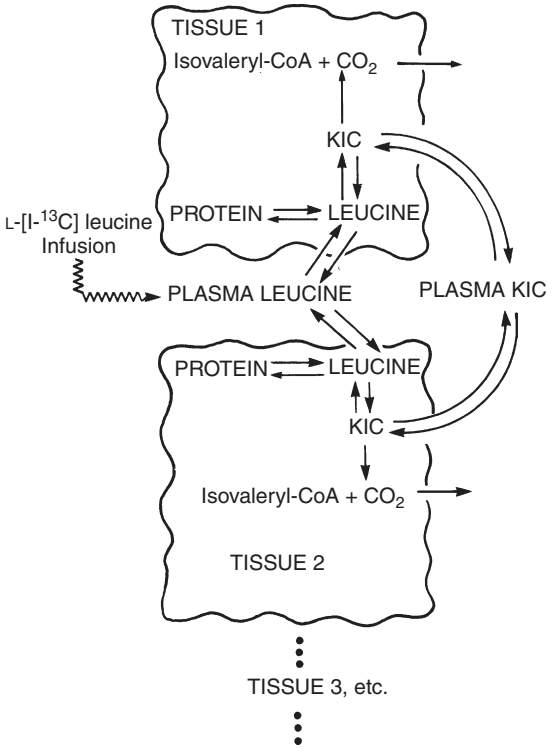

Figure 54-6 Multitissue model of whole-body leucine metabolism. Leucine is transported into and out of cells of various tissues in the body (e.g., muscle, kidney, liver, adipose tissue). α-Ketoisocaproate (KIC), formed within cells from leucine by transamination, is released into plasma. During an infusion of [1-^{13}C]leucine, the plasma KIC ^{13}C enrichment is the weighted average of the intracellular leucine ^{13}C enrichment of those tissues releasing KIC. *CO_2,* Carbon dioxide; *CoA,* coenzyme A. *(From Matthews DE, Schwarz HP, Yang RD, et al: Relationship of plasma leucine and alpha-ketoisocaproate during a L-[1-13C]leucine infusion in man: A method for measuring human intracellular leucine tracer enrichment,* Metabolism *31:1105-1112, 1982.)*

To measure amino acid kinetics, the amino acid tracer is infused into the blood and sampled from the blood, but the metabolic action takes place within cells. Amino acids do not freely pass through cells as does urea; amino acids are transported.[57,58] For the neutral amino acids, which are leucine, isoleucine, valine, phenylalanine, and tyrosine, transport into and out of cells is rapid, with only a small concentration gradient between plasma and intracellular milieus.[46] Still, the intracellular enrichment of leucine, as measured by plasma KIC, which is formed from intracellular leucine and then released into plasma (Figure 54-6), is approximately 20% lower than plasma leucine enrichment.[59] Using the plasma leucine enrichment to calculate leucine turnover underestimates whole-body flux by approximately 20%.

The plasma KIC enrichment can be used during the leucine tracer infusion to resolve the question of intracellular leucine enrichment for calculating leucine kinetics. For amino acids such as glutamate and glutamine, which have extremely large intracellular to extracellular gradients, very little intracellular glutamate or glutamine exchanges with plasma, and the sampled plasma amino acid enrichment reflects primarily interorgan transport of amino acid, rather than whole-body flux.[60] The partitioning of amino acid between intracellular and extracellular milieus must therefore be considered carefully for every individual amino acid studied.

Adults are commonly studied in the postabsorptive state after an overnight fast. The purpose usually has been to study the effect of mediators such as hormones or of specific interventions on protein metabolism. In the past several years, a few reports of amino acid metabolism using tracers in infants have appeared.[40,61-75] In terms of nutrition, many of the questions to be addressed in infants are related to oral or enteral feeding. However, the fed state complicates calculating kinetics more than by just adding a dietary intake term to the flux equation. Any dietary amino acid oxidized or taken up for protein synthesis by either gut or liver during absorption of food will not have mixed with the systemic circulation in which the tracer is administered. The flux of amino acid released from protein breakdown will therefore be underestimated by an amount equal to the amount of amino acid sequestered on the first pass through the splanchnic bed. It is possible under some circumstances to have a *negative* protein breakdown after dietary amino acid inflow has been subtracted from the flux. This problem is negated if the tracer is administered with the food, that is, orally or by intragastric tube feeding.[76] Oral feeding will not provide a constant flow of tracer into the system, however, unless tube feeding is used.[76]

Addition of the tracer to the enteral feeding solution solves the problem of following the metabolism of the enteral amino acids. An enteral tracer does not necessarily help, however, when the goal is to compare the effects of parenteral and enteral feeding regimens. For those kinds of studies, the tracer may be administered intravenously with the parenteral formula or enterally with the enteral formula. The use of two different administration routes for delivery of the amino acid tracer yields data that do not allow direct comparison—the proverbial apples and oranges.[40] A more elaborate design is required for comparing enteral and parenteral feeding regimens. For example, if two tracers of the same amino acid are available that give identical measures of metabolism (e.g., [1-^{13}C]leucine and [5,5,5-$^{2}H_3$]leucine), they can be administered simultaneously by both enteral and intravenous routes.[23,46] This approach gives direct measurement of tracers by both routes simultaneously during both parenteral and enteral feeding regimens.[15,69,77] More recent studies have shown that turnover rates may vary up to 80%, depending on the route of tracer.[78,79] Enterally administered tracer will yield a much higher turnover rate, reflecting first-pass removal by gastrointestinal tract and liver.

An alternative to invasive blood sampling is sampling amino acids from urine.[76] Small amounts of amino acids are continually filtered through kidney and normally appear in the urine. Because urinary amino acids are derived from blood, they should be a reasonable substitute for blood amino acids measured by means of tracer enrichment under isotopic steady-state conditions. De Benoist and colleagues[76] demonstrated in 1984 in that urinary leucine enrichments in infants were nearly identical to plasma leucine enrichments during infusion of [1-^{13}C] leucine, indicating that the urinary leucine came directly from plasma and was not contaminated significantly with unlabeled renal-derived leucine. Since then, several applications using this technique have been described in the literature.[40,72,80] In some commercial preparations of stable isotopically labeled L-amino acid tracers, however, D-amino acid tracer also will be present in variable amount. Because D-amino acids are not metabolized by the same pathways as for L-amino acids, but usually are removed by kidney and excreted in the urine, D-amino acid tracer may accumulate in urine, resulting in distortion of L-amino acid tracer measurements in urine. This problem can be avoided by using a chiral column to separate the D and L forms before measurement of amino acid tracer enrichment using the mass spectrometer.[81]

REQUIREMENTS FOR SPECIFIC AMINO ACIDS

Current dietary recommendations for essential amino acids are based on nitrogen balance studies and short-term growth studies. More recently, the indicator amino acid oxidation (IAAO) method has been developed to establish specific amino acid requirements.[82-84] It has been validated extensively in animal models of infancy.[85-87] This technique is based on the partitioning of essential amino acid outflow under steady-state conditions between oxidation and protein synthesis ($Q_{aa} = C_{aa} + S_{aa}$, as defined earlier). When a single essential amino acid is present in limited quantity in the diet, the amount of protein that can be synthesized likewise is curtailed. With an essential amino acid in limited supply, the use of all other dietary amino acids for protein synthesis also will be limited, and the body will have no choice but to oxidize the excess amounts of these amino acids. If the dietary amount of the limiting amino acid is increased, protein synthesis will increase, and so will the utilization of the other dietary amino acids—which in turn reduces their oxidation. Once the requirement for the limiting amino acid is reached, further increases in its dietary intake will cause no further increase in protein synthesis, nor decrease in the oxidation of the other essential amino acids.

The IAAO method works on this principle.[84,88] Subjects are given a series of diets containing various amounts of the amino acid for which the requirement is to be determined. The amounts vary below and above requirement. All other amino acids are furnished at constant amounts *above* requirement. At the end of each diet period, a dose of another essential amino acid with a ^{13}C or ^{14}C label (the indicator amino acid) is given, and its oxidation is measured. The oxidation of the labeled indicator amino acid will decrease as the amount of test amino acid increases, until requirement is reached, and then the oxidation will plateau. As shown in Figure 54-7, plotting the oxidation of the labeled indicator amino acid against test amino acid intake should show a breakpoint at the requirement level for the test amino acid. More recent studies have used the IAAO technique to determine sulfur (methionine and cysteine) amino acid requirements for neonates both in a piglet model[89,90] and in human infants.[91] Providing preterm infants with different intakes of cysteine while methionine (the sulfur donor of cysteine) and serine (the carbon donor of cysteine) were supplied in adequate amounts did not influence the oxidation rate of the indicator amino acid, suggesting that cysteine can be adequately synthesized from serine and methionine and is not conditionally essential.[91]

A different indirect technique yielded similar results, demonstrating that glucose carbon (labeled with ^{13}C) is incorporated into cysteine. This finding indicates that cysteine synthesis is not limited by serine availibility.[92]

FREE, EXTRINSICALLY OR INTRINSICALLY LABELED AMINO ACIDS

Almost all tracer studies have been performed using labeled amino acids as *free* amino acids, rather than amino acid tracers incorporated into proteins. When amino acids and proteins are given enterally, differences in the time course of hydrolysis and absorption of the amino acids and small peptides have been documented.[93] Although it takes time to hydrolyze enterally delivered proteins to peptides, peptides are absorbed more rapidly than free amino acids.[94] The net effect is that free amino

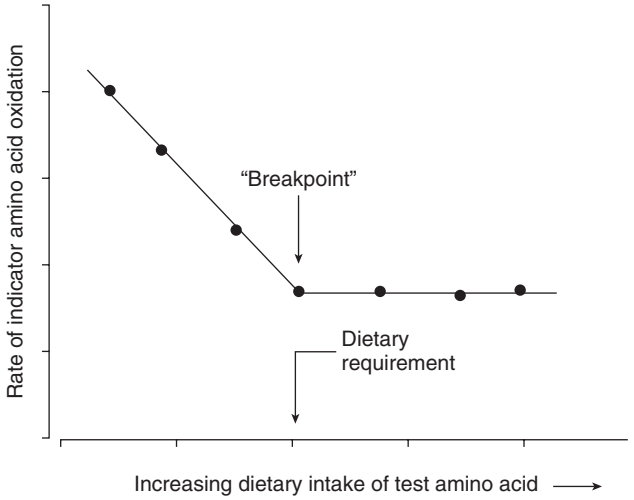

Figure 54-7 The rate of oxidation of an indicator amino acid in response to various dietary intakes of a test amino acid. The inflection or breakpoint in the rate of indicator oxidation represents the physiologic requirement of the test amino acid for the individual patient. *(From Brunton JA, Ball RO, Pencharz PB: Determination of amino acid requirements by indicator amino acid oxidation: Applications in health and disease,* Curr Opin Clin Nutr Metab Care *1:449-453, 1998.)*

acids still appear in systemic blood more quickly than amino acids arising from intact proteins, but that different proteins are hydrolyzed at different rates. Thus an enterally delivered labeled free amino acid will have different absorption kinetics from those for the corresponding protein-bound amino acids it is meant to trace.

Metges and co-workers[95] measured the prandial metabolic fate of ^{13}C-labeled dietary leucine when it was ingested as an intrinsically labeled component of mixed meals either incorporated into casein protein or as a free amino acid (extrinsically labeled) in a mixture of crystalline free amino acids defined to simulate the casein amino acid pattern. To serve as control data, leucine kinetics also were measured when free labeled leucine was given together with the intact casein. Leucine oxidation was higher for the free ^{13}C-leucine tracer combined with a free amino acid mixture than for an intrinsically ^{13}C-leucine–labeled casein. This result, together with the finding of a higher uptake of leucine for protein synthesis with the intrinsically labeled casein, suggests that protein-bound leucine was better utilized for whole-body protein synthesis than as a free amino acid. Such studies have not yet been performed in neonates but may prove to be important in defining infant formulas in terms of amino acid and protein composition.

SYNTHESIS OF SPECIFIC PROTEINS

Some proteins are readily sampled. Lipoproteins, albumin, and other plasma proteins are obtained from blood; muscle can be obtained by biopsy. If a protein or group of proteins can be sampled, the synthesis rate can be determined directly from the rate of tracer incorporation into the protein. For proteins with slow turnover (e.g., muscle protein or albumin), incorporation of tracer is linear with time during the first several hours of tracer infusion.[30,96-98] If the tracer infusion was continued for several half-lives of turnover, the tracer concentration in the protein would rise exponentially to match that of its precursor, the intracellular amino acid enrichment.[99,100] For proteins with slower turnover, then, it is more convenient to measure the synthesis rate from the initial rate of tracer incorporation into the protein.

To convert the initial rate of tracer incorporation in protein into a protein synthesis rate requires knowledge of the intracellular amino acid precursor enrichment for synthesis. For muscle protein synthesis, L-[1-^{13}C]leucine often is used as the tracer,[101] because plasma KIC ^{13}C enrichment approximates the intracellular muscle leucine enrichment. Various other schemes have been used to estimate intracellular liver amino acid tracer enrichment.[102-104]

For proteins such as very-low-density lipoprotein apolipoprotein B for which turnover occurs within the period of tracer infusion (typically 4 to 8 hours), tracer incorporation into the protein rises exponentially to reach a plateau. If the tracer enrichment in the protein does not reach plateau during the time course of the tracer infusion, curve fitting usually can predict the plateau. If the enrichment plateau can be defined, then the precursor enrichment (the enrichment of the intracellular free amino acid from which the protein was made) will now have been measured directly.[102] Several groups of investigators have used plateau enrichment of tracers in apolipoprotein B as a surrogate measure of intracellular hepatic tracer enrichment in both a piglet model[17,105,106] and human infants.[92]

Garlick and colleagues have proposed an alternative method to measure protein synthesis of slow turnover proteins.[107] Their method is to administer a "flooding dose" of tracer amino acid, producing a large momentary concentration gradient between the extracellular and intracellular spaces. The gradient pushes the amino acid rapidly into cells, "flooding" them with the tracer. This scheme is meant to force the intracellular tracer enrichment (which cannot be readily measured) to equalize with the extracellular enrichment (which can be measured), thereby removing the uncertainty of what is the precursor enrichment for protein synthesis.[108-112] An obvious drawback is that the administered dose is a *pharmacologic* dose of material that may alter metabolism and induce secretion of various hormones (e.g., insulin) and factors that are known to regulate protein metabolism. Nevertheless, the flooding dose approach is a convenient method for determining protein synthesis of slow-turnover proteins, which can be sampled readily in a short period of time.

DEGRADATION OF SPECIFIC PROTEINS

Measurement of protein degradation is much more difficult. It usually requires prelabeling a protein and following its disappearance over time. The first problem arises with prelabeling the protein. Prelabeling can be done for plasma proteins using radioactive iodine. When the protein degrades, the radioactive iodine is no longer present in the system. If the protein is labeled by synthesizing it with one or more labeled amino acids, a second problem emerges in relation to recycling of amino acid tracer. As the protein degrades, the newly released amino acids can again be taken up for new protein synthesis; that is, some of the amino acids are *reutilized* or recycled back into protein. This recycling greatly complicates interpretation of the labeled protein data.

A few amino acids cannot be reutilized for protein synthesis. Hydroxyproline, methyl lysine, and 3-methylhistidine are examples. No transfer ribonucleic acid exists for these amino acids. Proline is hydroxylated and histidine and lysine are methylated after the protein has been synthesized. This posttranslational process occurs in very specific proteins—for example, collagen for hydroxyproline and actin and myosin for 3-methylhistidine. When the proteins degrade, these modified amino acids are not reutilized. Hydroxyproline has been used to follow collagen kinetics,[113] and 3-methylhistidine has been used extensively to follow myofibrillar protein breakdown.[114,115] Because most of the myofibrillar protein is in muscle, muscle should be the principal source of urinary 3-methylhistidine. However,

3-methylhistidine also is present in gut actin. Although the gut actin pool is very small relative to muscle protein, protein turnover within the gut is rapid and therefore can be a significant contributor to urinary 3-methylhistidine output. Assay of urinary 3-methylhistidine to reflect muscle protein breakdown requires cautious interpretation because of the gut 3-methylhistidine source.[116]

Fetal Requirements and Placental Transfer of Nitrogenous Compounds

INTRAUTERINE GROWTH AND PROTEIN (NITROGEN) ACCRETION

Nutritional requirements for fetal protein accretion depend directly on the rate of fetal growth. Because direct measurements of fetal growth are not possible, fetal growth rates have been estimated by inference from anthropometric measurements of infants born at different gestational ages and chemical composition studies of infants who died close to birth but appeared normally grown at autopsy. The better of these studies have excluded obviously abnormal infants and have involved defined, relatively homogeneous populations. Even with such precautions, however, there has been no assurance that infants born preterm had grown normally, making suspect whether their weights represent those of normally growing fetuses. Furthermore, anthropometric measurements have their own inherent range of accuracy, and cross-sectional, static size-for-gestational-age groupings of neonates may not accurately reflect the dynamics of fetal growth. In addition, population means of fetal growth rate do not necessarily reflect growth of a given fetus or the changes in body composition with growth that occurs with advancing gestational age.[1]

Despite such concerns about the reliability of data, most composite evaluations of human fetal growth based on neonatal anthropometric measurements at birth are relatively similar. Most mean percentiles among the many different growth curves differ by ± 5% or less and can be accounted for primarily by factors such as suboptimal pregnancy dating, adverse maternal and/or fetal medical and obstetric complications of pregnancy, and variations in maternal race, ethnicity, socioeconomic status, altitude, and diet.[2] Such neonatal-derived fetal weight curves appear as sigmoidal functions of weight versus gestational age. In some studies that accounted for many of the factors that can affect fetal growth and fetal size, fetal weight gain appears to be a linear function of gestational age through to term (12 to 13 g per day for white race, middle-class pregnancies), with only slight increases for male versus female gender and for maternal obesity.[3] In contrast, weight change (the rate of weight gain per kg body weight per day) is relatively linear at 1.5% per day from 24 to 37 weeks but tapers off to a plateau between 37 and 42 weeks, and a decrease may occur after 43 to 44 weeks.

Chemical composition studies of allegedly normal human infants have been accomplished in relatively few cases. Sparks[1] reviewed data from 15 studies with a combined 207 infants. Based on the data from these studies, nonfat dry weight and nitrogen content (both reasonably good predictors of protein content) show a linear relationship with fetal weight (Figure 55-1) and an exponential relationship with gestational age (Figures 55-1 and 55-2).[1] However, at each gestational age, a variety of fetal weights is observed. Thus nonfat dry weight and nitrogen content for a given fetus can also be compared with the "average" fetus. When these comparisons are made, larger fetuses grow faster than smaller fetuses at the same gestational age; protein accretion and therefore protein nutritional requirements follow accordingly.

Tables 55-1 and 55-2 present nitrogen, protein, and selected amino acid composition and accretion rates, respectively, in reportedly normal human fetuses.[4] According to data from sheep and guinea pigs, however, 80% of the nitrogen content of the fetus in these species is found in protein; the remainder largely occurs in urea, ammonia, and free amino acids. The data for human fetal protein content and accretion in these tables thus may be high because they are based solely on nitrogen content. Additional nitrogen requirements for urea excretion (and for other possible nitrogen excretion products) are not known for human fetuses. An analysis of complete nitrogen balance of this sort has been accomplished only in fetal sheep and is discussed later. Several items of comparative chemical and physical growth in six species are summarized

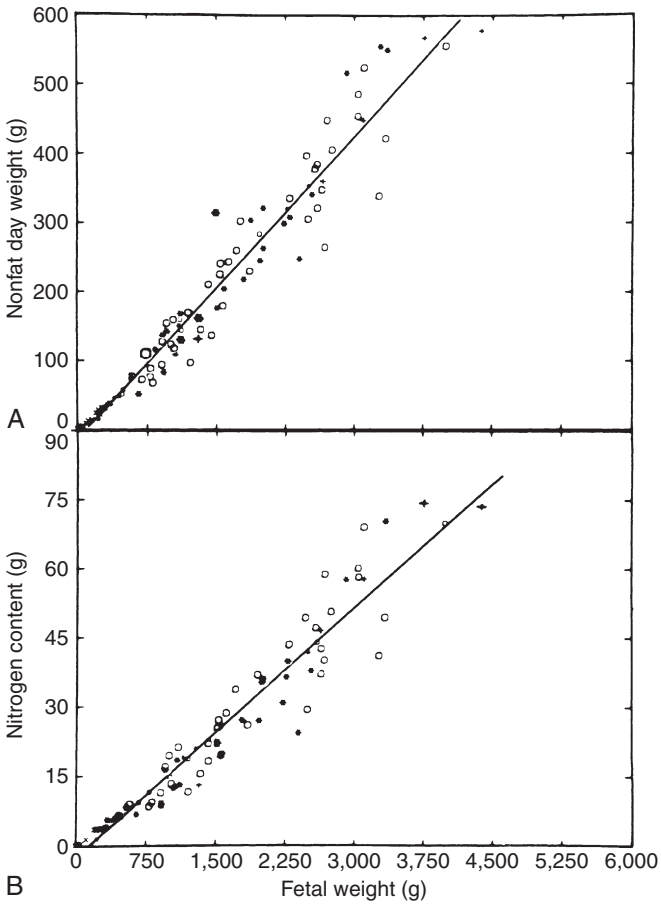

Figure 55-1 **A,** Relationship of nonfat dry weight (NFDW) to fetal weight in 169 human fetuses. *, Small-for-gestational-age (SGA) infants; +, large for gestational age (LGA) infants; ○, appropriate for gestational age (AFA) infants. NFDW = 0.0589 g. **B,** Relationship of nitrogen (N) content to fetal weight in the same infants. N = 0.00665 g. *(From Sparks JW: Human intrauterine growth and nutrient accretion,* Semin Perinatol *8:74, 1984.)*

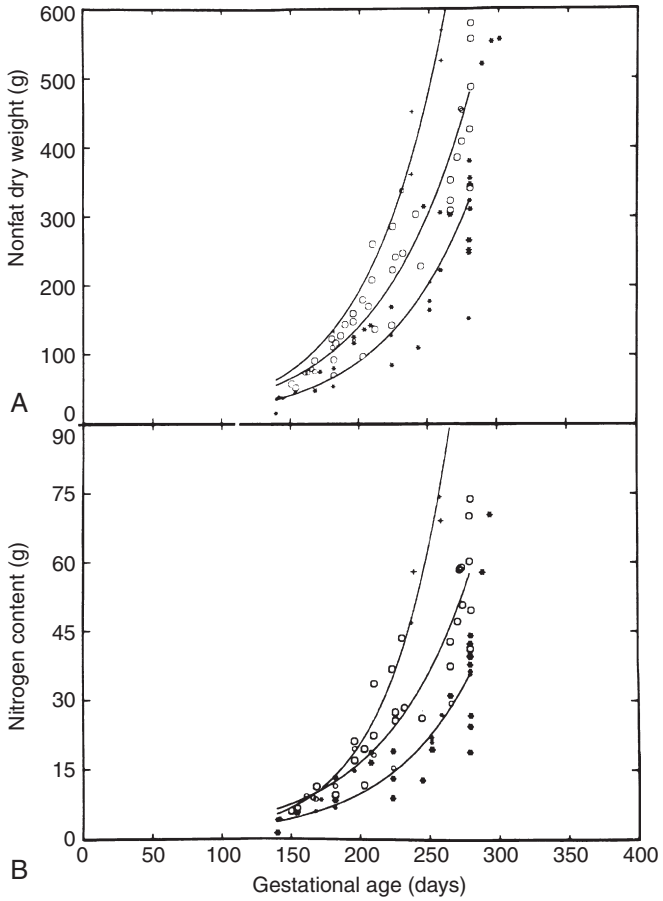

Figure 55-2 ***A,*** Relationship of nonfat dry weight (NFDW) to gestational age in 97 human fetuses (see Figure 55-1 for explanation of symbols). Increase in NFDW:LGA-NFDW (g) = $4.78 \cdot e^{(0.0184 \cdot GA)}$, r = 0.9869; AGA-NFDW (g) = $6.38 \cdot e^{(0.01548 \cdot GA)}$, r = 0.9511; SGA-NFDW (g) = $3.60 \cdot e^{(0.0161 \cdot GA)}$, r = 0.9380. ***B,*** Relationship of nitrogen content to gestational age in the same infants. Increase in total body nitrogen (N); LGA-N (g) = $0.227 \cdot e^{(0.0225 \cdot GA)}$, r = 0.9870; AGA-N (g) = $0.703 \cdot e^{(0.0157 \cdot GA)}$, r = 0.9385; SGA-N (g) = $0.377 \cdot e^{(0.0163 \cdot GA)}$, r = 0.9351. *(From Sparks JW: Human intrauterine growth and nutrient accretion,* Semin Perinatol *8:74, 1984.)*

in Table 55-3.[5] The variation among certain parameters is considerable; for example, growth rate variation is 20-fold and weight-specific content of fat at term varies 16-fold. In contrast nonfat dry weight and protein weight specific contents (as percentage of total weight) at term are constant. Limited chemical analyses at different gestational ages indicate that in other animals, as in the human, fetal protein content is linearly related to fetal weight and, therefore, fetal protein requirements are linearly related to fetal weight gain. Species-related differences in fetal weight gain are remarkable; for example, protein accretion in the fetal rat occurs approximately 23 times as fast as it does in humans. The rat must possess a placental amino acid transport system with enormous capacity to support this high protein accretion rate, as well as mechanisms to process and support the high fetal protein synthetic rate.

PLACENTAL AMINO ACID SUPPLY: PLACENTAL TRANSPORT SYSTEMS

Placental amino acid supply involves active, energy-dependent transport of amino acids through molecular transporter protein systems across the placental membranes. The transport of

amino acids is altered qualitatively and quantitatively by transport system location and activity, competition among amino acids, placental metabolism of amino acids, and relative concentrations of the amino acids in maternal and fetal plasma, as well as by changes in the overall size of the placenta, architecture of the placental tissues, and developmental and pathologic changes in placental transport capacity. In addition, various aspects of placental-fetal amino acid exchange can be affected by specific metabolism within certain fetal organs and tissues, demonstrating a unity of function of the conceptus.

For most (but not all) of the amino acids, transport from maternal to fetal plasma occurs against a concentration gradient among all mammalian species studied and involves energy-dependent transport mechanisms.[6-17] However, quantitative differences exist among species. For example, the fetal/maternal ratio in humans for the basic amino acids lysine and histidine is greater than 1.0, whereas in sheep the ratio is less than 1.0. Even for amino acids with a fetal/maternal concentration ratio of less than 1.0, overall transport may be energy dependent because the concentration of a specific amino acid (e.g., citrulline) within the trophoblast tissue is greater than in the maternal plasma.[12,13,18] This is especially true for the very high intracellular trophoblast concentrations of taurine, glutamate, and aspartate, as well as for moderately increased intracellular concentrations of alanine, glycine, serine, glutamine, and threonine in the trophoblast.[16] For most amino acids, placental transport is sufficiently rapid that despite high concentrations of the amino acids in the trophoblast and the requirement for energy to promote amino acid uptake and transport, maternal concentrations of at least some amino acids can affect transport. This has been shown primarily for certain essential amino acids (e.g., leucine[6,19] and lysine[9]), providing reasonable evidence for how maternal diet and metabolic condition that determine maternal plasma amino acid concentrations directly affect fetal amino acid supply.

The syncytial epithelium of the human placenta, the *syncytiotrophoblast,* is a polarized multinucleate epithelium. The maternal-facing, apical surface of this epithelium has a microvillous plasma membrane; the basal surface facing the fetus is a relatively smooth membrane. The transport of amino acids across the syncytiotrophoblast involves three steps: (1) uptake from the maternal circulation across the microvillous membrane; (2) movement through the trophoblast cytoplasm; (3) transport out of the trophoblast, across the basal membrane into the umbilical circulation. Transport systems are required at

TABLE 55-4

Placental Amino Acid Transport Systems, Substrates, Conditions and Location

System	Substrates	Conditions	Membrane
Sodium Dependent			
A	Neutral amino acids: alanine, glycine, serine, proline, threonine, glutamine, MeAIB	Na^+ dependent, slowed by extracellular H^+ Excludes anionic and cationic amino acids, BCH, and leucine	M, F
ASC	Alanine, serine, cysteine, anionic (acidic) amino acids	Na^+ dependent, slowed by extracellular H^+ Excludes MeAIB, cationic aminoi acids, and proline	F
N	Glutamine, histidine, asparagine	Na^+ dependent Excludes cysteine, MeAIB, transstimulated	M
X-AG	Anionic (acidic) amino acids, glutamate, aspartate	Na^+ dependent Uptake from fetal blood; noncompetitive with other amino acids Excludes nonanionic amino acids	M, F
β	Taurine	Na^+, CI^- dependent Highest trophoblast intracellular concentration of all amino acids Excludes α-amino acids	M
B^o	Neutral amino acids	Excludes cationic and anionic amino acids	M, F
Gly	Glycine	Na^+ dependent	M
Sodium Independent			
L(l)	Branched chain amino acids: (leucine, isoleucine, valine), tryptophan, BCH, phenylalanine, tyrosine, alanine, serine, threonine, glutamine	Na^+ independent, enhanced by extracellular H^+ Excludes anionic amino acids, proline, MeAIB	M, F
y^+	Lysine, arginine	Major cationic amino acid transporter excludes anionic amino acids inhibited by neutral amino acids (fetal side > maternal side)	M, (F?)
$b^{o,+}$	Lysine, arginine	Excludes anionic amino acids	(F?)
y^+L	Lysine, arginine	Excludes anionic amino acids	(M?), F
Asc	Small neutral amino acids	Excludes cationic and anionic amino acids	ND

the two steps that involve transport across plasma membranes (i.e., the maternal and fetal surfaces). Molecular transporter systems for amino acid uptake by placental tissues have been identified (Table 55-4).[10,14,20-22] Specific amino acids transported by each system, conditions favoring or inhibiting or affected by each system, and location (maternal or fetal trophoblast membrane) for each system are presented in Table 55-4.

PLACENTAL AMINO ACID TRANSPORTER PROTEINS

Historically placental amino acid transport has been described in terms of systems (see Table 55-4). More recently, the ability to clone, sequence and study the expression of individual transporter proteins has led to an explosion of data concerning

the molecular basis of amino acid transporter systems and their function.[10,20,23,24] Transport systems operate in one of two ways, either in a monomeric manner, or in a heterodimeric manner.[24-26] Monomeric systems transport amino acids via single membrane proteins, similar to amino acid uptake mechanisms associated with permeases in microorganisms.[27,28] Heterodimeric systems on the other hand involve the grouping together of two proteins through the formation of disulfide bridges[25,29] to facilitate amino acid transport.[23,24,30] Presently monomeric transport systems in placental tissues include System A y+31 and most likely the X_{AG}^- system, whereas heterodimeric transport systems include System L, y^+L,[32] and the Asc system.[33,34] Those systems that operate in a heterodimeric manner are generally made up of a common heavy chain, a type II membrane glycoprotein, such as 4F2hc (comparable with the CD98 surface antigen, CD98hc[35,36]), NBAT (equivalent to rBAT or D,[26,37-40]), or as yet undefined heavy chains,[41] and associate with one of a variety of light chain transport proteins to yield a range of differing amino acid transport systems.[25,30,32,34] A summary of the traditional transport systems and their heavy and light chain associations that have been reported in placental tissues and membranes is presented in Table 55-5, and a brief description of them follows.

Neutral Amino Acid Transporter Light Chain Proteins

The placental system A amino acid transporter is encoded by three members of the SLC38 gene family giving rise to three subtypes: SNAT1 (SLC38A1), SNAT2 (SLC38A2), and SNAT4 (SLC38A4). System A activity has been demonstrated in microvillous and basal membranes.[42-44] The SNAT1 isoform is expressed predominantly in the placenta and heart and is responsible for the transport of small short-chain neutral amino acids, such as alanine, serine, methionine, asparagine, and glutamine.[45] The functional characteristics of SNAT2 are similar to those of SNAT1, although it is found in a wider range of tissues, including the placenta.[45,46] SNAT4 appears to have a unique tissue distribution predominantly in hepatic and skeletal muscle tissues,[47] although recent reports also place it in the placenta, in both microvillous and basal membranes, and being expressed in the human placenta from early pregnancy onwards, similar to SNAT1 and SNAT2.[48]

Regulation of this system has been demonstrated through amino acid deprivation and interaction with the well characterized phosphatidylinositol 3-kinase (PI3K), mammalian target of rapamycin mTOR, and S6Kinase-dependent pathways, hypoxia, cortisol exposure,[49-52] and recently insulin-like growth factor (IGF) interactions through both mitogen-activated protein MAP kinase-dependent and independent pathways.[53] Additionally, angiotensin II has been demonstrated to decrease System A activity in human placental villous fragments through activated AT1 receptor.[54] Additionally of particular interest is that imprinted genes control the supply of nutrients to the fetus, and in the mouse, the *Slc38a4* gene has been shown to be imprinted. In studies utilizing the placental-specific *Igf2* transcript (P0) knockout, placental growth is compromised, although fetal demands are likely met through an up-regulation of transporter genes *Slc2a3* (glucose transporter) and the imprinted *Slc38a4*.[55,56] Interestingly when fetal demands for nutrients are removed through removal of the fetal *Igf2*, the up-regulation does not occur, providing evidence of regulation of placental transport activity via fetal growth demand genes. Both the *Igf2* and *Slc38a4* are paternally expressed, and this interaction is seen as a display of paternally inherited genes maximizing extraction of maternal nutrients.[56]

A related system, System N, shares many characteristics of System A, although it differs in its preference for amino acids containing nitrogen-bearing side chains and transports only glutamine, asparagine, and histidine.[57] System N activity has been localized in the human placenta,[58] and the gene SNAT3 (SLC38A3) has been identified as being associated with this activity.[23] In terms of amino acid movement in and out of trophoblast cells, it is interesting to note that SNAT1 and SNAT2 are sodium coupled and function under physiological conditions as influx transporters. On the other hand, SNAT3 and its other system N isoform, SNAT5 (SLC38A5) are coupled to a sodium gradient as well as a proton gradient and mediate a transport process in which sodium and glutamine move in one direction and H+ moves in the opposite direction; this suggests the importance of considering and studying transport systems as a collective, rather than as individual systems in isolation. Furthermore, the direction of glutamine flux through these transporters can be altered, even under normal physiological conditions.[59,60]

The β transporter, which transports taurine, has been found in placental microvillous and basal membrane vesicles.[61-63] Basal membrane activity is only approximately 6% of that in the microvillous membrane[64] and the cDNA associated with this activity, TAUT (SLC6A6), has been reported in placental cell lines.[64,65] Classical ASC transport of neutral amino acids—alanine, serine, and cystine—is reported in the microvillous membrane and in the basal membrane.[42,66] The cDNA, ASCT-1 (SLC1A4), sequences this classical sodium dependent ASC transport system and has been localized to human placental tissue[67] with other related activity also being weakly associated.[68] Another member of this family of sodium dependent neutral amino acid transport systems, the B° system, is responsible for

neutral amino acid transport, including the branch chain amino acids.[69-71] The cDNA, ASCT-2 (SLC1A5), represents this system in human placental choriocarcinoma cell lines,[70,72] and hypoxia has also been reported to play a role in its expression.[73] The sodium independent Asc system is responsible for the transport of small neutral amino acids and is comprised of Asc-1 and Asc-2 components, both of which have been isolated in placental mRNA.[33,74] Although Asc-1 forms a heterodimeric complex with 4F2hc,[33] Asc-2 appears to interact with a presently unknown heavy chain.[41]

Functional System L activity occurs through specific light chain proteins associating with 4F2hc,[75,76] catalyzing the uptake of a wide range of neutral amino acids in a sodium-independent manner, and System L activity is reported on both microvillous and basal membrane.[43,77,78] Regulation of placental System L activity does not seem to be under the control of hypoxia,[52] although evidence exists that it may not be the case in other cell preparations.[79,80] Although evidence is lacking in placental preparations, IGF appears to regulate System L activity where chronic infusions of IGF-I have corrected impaired transport of leucine in the brush-border of the rat intestine.[81]

Four associated light chains have been reported in placental tissues: System L-amino acid transporter-1 LAT-1 (SLC7A5); LAT-2 (SLC7A8); LAT-3 (SLC43A1); and LAT-4 (SLC43A2).[31,34,76,82-88] Immunological and functional studies suggest that at term, the light chain LAT-1 is located predominantly in the microvillous membrane and the syncytiotrophoblast layer of the villi.[84,86] Furthermore, the L transport system phenotype associated with the microvillous membrane occurs when the LAT-1 catalytic subunit is co-expressed with the 4F2hc, not LAT-2.[66] Human LAT-2 mRNA also has been found in the human choriocarcinoma BeWo cell line and placental villous tissues.[34,87-89] Placental basal membrane studies concerning the inhibition of specific amino acid and/or synthetic amino acid uptake have determined that the basal membrane L transport system phenotype is that which is associated with the co-expression of LAT-2 and 4F2hc, and not LAT-1, as observed to occur in the microvillous membrane.[76,89,90] LAT-1 and LAT-2 function as classic obligatory exchangers, moving substrates in exchange for other amino acids.[91] The two additional system L light chains, LAT-3 and LAT-4, have recently been reported in placental tissues. These appear to transport a restricted group of system L substrates (leucine, isoleucine, and phenylalanine) and also differ from the traditional system L transport in that they do not appear to require the co-expression of 4F2hc and therefore likely function as facilitative diffusion transporters.[82,92]

Cationic Transport System Light Chain Proteins

The transport of cationic amino acids occurs though the y^+ and the y^+LAT systems. System y^+ activity has been extensively studied in the human placenta.[93] This system operates in a sodium-independent manner and accumulates cationic amino acids within the placenta aided through the negative trophoblast potential. Activity is primarily localized to the microvillous membrane,[7,35] as opposed to the basal membrane, though there is conflicting data as to which CAT isoform is responsible for system y^+ activity in either trophoblast membrane.[35,94] The system y^+ activity is dependent only on the expression of these monomeric proteins (or CAT gene products),[95] unlike systems L and y^+L, which require expression of both a common heavy chain and a related light chain.[31]

System y^+L activity is localized to both the basal and microvillous membranes.[7,31,35] This system appears to provide an essential role in supplying cationic amino acids to the fetal circulation by exchanging cationic amino acids from within the trophoblast, for neutral amino acids such as glutamine and leucine from fetal circulation. This mode of operation provides a route of efflux, overcoming the trophoblast potential.[23] Similar to system L, placental y^+L system activity is also determined by which light chain, system y^+L-amino acid transporter-1 (y^+LAT-1, SLC7A7) or system y^+L-amino acid transporter-2 (y^+LAT-2, SLCA76), forms a heterodimer with the 4F2hc.[30,32,96] The y^+LAT-1 mRNA is detected in human placental Poly(A)$^+$ RNA and when co-expressed with 4F2hc in oocytes, displays characteristics similar to y^+L system.[96] Discrepancies concerning the expression of y^+LAT-2 in placenta have been reported.[31,94]

Anionic Transport System Light Chain Proteins

Five cDNAs encoding for proteins capable of mediating high-affinity sodium-coupled transport of anionic amino acids have been reported,[97] and three of these have been cloned from rat and human placenta and are present on both the microvillous and basal membranes of the placenta.[97,98] The rat basal membrane preparation is reported to have a higher maximal velocity,[98] an observation that is consistent with the predominant flux of glutamate from fetus to the placenta as has been demonstrated in the sheep.[99] These proteins—excitatory amino acid transport EAAT-1 (SLC1A3, GLAST1), EAAT-2 (SLC1A2, GLT1), and EAAT-3 (SLC1A1, EAAC1)—mediate placental sodium dependent D-aspartate-inhibitable anionic amino acid transport or system X_{AG}^- activity.[100] EAAT-1, EAAT-2, and EAAT-3 have been detected in human placental tissue.[101] The regulation of these proteins appears to be under the control of growth hormone (GH) and IGF family members,[102] and up-regulation of the placental system has been demonstrated through nutrient deprivation studies.[98] These later studies demonstrated that EAAT-1 and EAAT-3 play a key role in the basal anionic amino acid transfer, whereas EAAT-2 may be involved in conditions of amino acid depletion.[98] Of interest is that in rat cardiac myocytes, X_{AG}^- system activity is up-regulated after hypoxia,[79] although similar experiments are yet to be conducted in placental tissues or lines.

With a greater number of studies now using molecular biology to determine the specific transporter proteins in the plasma membranes, it is likely that the identification of individual transporter proteins in the trophoblast will be expanded considerably as sequence data for specific transporters permit rapid identification of other members of the same family of transporters. Thus the information provided in Table 55-5 should be regarded as an interim report in a rapidly changing field.

DEVELOPMENTAL AND ADAPTIVE CHANGES OF PLACENTAL AMINO ACID TRANSPORT

Development and Growth of Amino Acid Placental Transport Capacity

As pregnancy advances, the increasing nutrient demands of the developing conceptus must be met through an appropriate increase in placental nutrient transport capacity. This enhanced performance, as it relates to amino acid transport, is facilitated through alterations in placental perfusion, including increased uteroplacental blood flow and changes in membrane exchange area together with changes in amino acid transporter concentrations and activity in the plasma membrane (see Box 55-1).

In conjunction with the dramatic increases in uteroplacental blood flow during pregnancy (six-fold in sheep[103]) the developing surface area of the trophoblast is an important factor regulating total placental nutrient transport. Between week 16 and term of pregnancy, human fetal weight increases approximately 20-fold, whereas the peripheral villous surface area increases only nine-fold.[104-106] It should be emphasized, however, that only a few careful ontogenetic studies are available on how total surface area, including microvillous surface, changes

Box 55-1

Factors Affecting Placental Amino Acid Transfer

1. Transporter proteins in the trophoblast membranes: ontogeny, location (maternal-facing microvillus, fetal-facing basal, or both), regulation by local or circulating factors
2. Ion channel activity, ion gradients: Na^+, K^+-ATPase; Na^+, H^+, Cl^- gradients: (e.g., inward Na^+ gradient with system A co-transport)
3. Transport capacity, measured by V_{max} (maximum transport rate, affected by number of active transporters, the number of transporters per unit membrane area, and total membrane surface area)
4. Transporter-substrate binding affinity, measured by K_m (plasma amino acid concentration at half V_{max})
5. Placental disease, for example, fetal growth restriction and preeclampsia
6. Intracellular concentrations of amino acid, maternal amino acid concentrations, fetal amino acid concentrations, maternal-fetal amino acid concentration gradients leading to competition for transporters among amino acids
7. Turnover of transporters (rates of synthesis, degradation, or both)
8. Metabolism of amino acids by the trophoblast (e.g., oxidation of glutamate, conversion to other amino acids or substrates such as serine to glycine and leucine to KIC, protein synthesis, deamination-producing NH_3)
9. Uterine/umbilical blood flows: absolute rates (substrate delivery), the ratio of their flows (substrate delivery versus uptake and transport capacity), and the role of vasoactive substances (local or circulating) that alter uterine and/or umbilical blood flow (e.g., reduction in flow with epinephrine, enhancement of flow with nitric oxide)
10. Circulating hormone concentrations, placental receptors, and second messengers (e.g., hormone stimulation of cAMP-responsive increase in calcium channel and intracellular calcium release, activating amino acid metabolism and transporter activity)
11. Diffusional leaks into or out of cells or via paracellular pathways
12. Inhibitory effects of drugs (e.g., alcohol, nicotine, cocaine)

over gestation.[105-107] Although some more recent surface area studies have been more detailed,[106-108] they have not yet been conducted in conjunction with in vivo amino acid flux studies. The demonstrated increases in total surface area of the placenta, however, alone cannot account for the exponential fetal growth occurring over this time period. These data suggest that fetal growth is supported not by changes in villous surface area alone, rather the total transport capacity of the trophoblast is likely to be determined by changes in surface area and the concentration and activities of specific amino acid carrier proteins on the cell membrane surface.

As amino acids require active transport, they fit into the category of substances transported by the placenta according to diffusion-limited clearance. As such, placental transport rates of amino acids most likely are not affected much by moderate fluctuations in uterine or placental blood flow. More severe reductions in flow may affect their transport (but this has not been observed or measured) and, if it does occur, it may be mediated through flow-reduction effects on placental energetics and ion gradients, rather than by a direct reduction of delivery. Furthermore, changes in flow may alter transport of certain amino acids more than others, potentially leading to changes in the relative proportions of amino acids delivered to the fetus.[109] Such highlighted energetics and ion gradient deficiencies may be as, or more, important than amino acid delivery as the means by which amino acid uptake and transport are altered by deficient placental blood flow.

In addition to changes and the placental exchange surface area, capacity for amino acid transport is also affected by the differing expression and transport parameters of transport systems that appear to change through gestation.[35,44,110-112] For example, in the first trimester and term human microvillous membrane preparation, L-arginine transport is through both y^+ and y^+L systems, whereas in the basal membrane, transport may be restricted to only the y^+L system at term.[35] In addition, the kinetic properties of transport systems may also change as gestation advances. First-trimester microvillous membrane has increased y^+L transport activity compared with term placenta vesicles,[111] and y^+ activity appears to be related to gestational age, increasing with gestational age.[93] Additionally, 4F2hc protein levels differ between early pregnancy and term placenta.[35] Such studies highlight the complex interactions that occur between developing microvillous and basal membranes, within the trophoblast, and between the two circulations to facilitate an increase in nutrient delivery to the growing fetus as gestation advances.

Changes in Amino Acid Transport in Intrauterine Growth Restriction

Both in vitro and in vivo studies indicate that reduced fetal amino acid concentrations lead to enhanced amino acid transport (increased V_{max}, reduced K_m).[113-115] Furthermore this adaptive increase in transport can be blocked by selective inhibition of protein synthesis, indicating that the synthesis of new transporter proteins is potentially responsible for this altered amino acid transport pattern. The in vivo studies have been conducted in pregnant rats made hypoaminoacidemic by glucagon infusion. In these studies, fetal weight was not compromised until the mother became hypoglycemic while fasting.[116] These results were interpreted as indicating placental compensation for the hypoaminoacidemia to maintain fetal amino acid supply and concentrations. In contrast, no placental compensation for hypoglycemia (which reduced the fetal energy [glucose] supply) that was unaccompanied by hypoaminoacidemia was apparent.

These results take on added importance relative to the observations by Cetin and colleagues,[117] who showed that plasma concentrations of α-amino nitrogen were lower in growth restricted infants and their mothers, whether the measurements were made at the time of term delivery or many weeks before term. Furthermore, these investigators have shown that amino acid concentrations were lower in pregnancies with intrauterine growth restriction (IUGR), even if the fetuses had normal fetal heart rate and velocimetry monitoring, suggesting that the decrease in amino acid concentrations preceded other clinical pathologic changes in these pregnancies and in the fetuses.[118] Data collected from babies with IUGR at delivery show reduced total amino acid concentrations,[119,120] also suggesting alterations in amino acid transporter systems.

Although changes in amino acid concentrations have been used to interpret reduced supply and decreased utilization rates for amino acids, these values actually represent a balance among the rates of amino acid supply, synthesis into protein, release by protein catabolism, and oxidation. As such, reliance on concentration data alone in assessing the transport capacity of a placenta may not be entirely accurate. For example, it is interesting to note that more recent studies of fetal plasma amino acid concentrations in well defined groups of human fetuses with IUGR, where samples were derived from fetal blood sampling, have not repeated earlier observations of reduced values for fetal amino acid concentrations.[121] Similarly, recent studies in models of sheep with IUGR have not shown reductions in all of the fetal

plasma amino acid concentrations, especially the branch chain essential amino acids noted by the earlier studies.[122,123] These more recent placental amino acid transport studies in human and sheep IUGR, using radioactive and stable tracer techniques, do support the earlier conclusions of reduced placental transport, but together they highlight that tissue uptake and fetal metabolism of amino acids might also be impaired in IUGR, as there appear to be situations of IUGR in which fetal concentrations are maintained despite decreased placental transport.

In vitro observations, in which microvillous membrane vesicles from babies who were appropriate-for-gestational-age (AGA) and small-for-gestational-age (SGA) were prepared, demonstrated markedly lower activity (by 63%) of the A-system transporters in the infants who were SGA.[124] A number of investigators have described that, in cases of human IUGR, System A membrane activity per milligram of microvillous membrane is reduced, suggesting a positive association between fetal growth and System A activity.[110,125,126] Also, in placentas in the context IUGR, the sodium-dependent and -independent transport of taurine from maternal to fetal circulation also is reduced, thereby reducing fetal taurine concentration.[64]

Regarding the essential amino acids, the uptake of leucine in both microvillous and basal membranes of the placenta with IUGR is reduced, suggesting alterations in the placental L-transport system.[127] In these studies, basal membrane uptake was also reduced, suggesting that the changes in the basal membrane could be an important adaptive response by the trophoblast, limiting the backflux from the fetal circulation to the placenta. In vivo studies of ovine IUGR placental transport have indeed shown a reduced backflux of leucine and additionally threonine from the fetal circulation to the placenta, indicating that changes in basal membrane function may be the case.[122,123] In addition, under steady state in studies of stable isotopic tracer leucine infusion into the mother, the fetal/maternal enrichment ratio of leucine in normal human pregnancies is approximately 0.8, a much higher ratio than that 0.4 in sheep.[123,128] However, in both species, this ratio is significantly lower in pregnancies with IUGR, suggesting similarly reduced placental transport and metabolism characteristics. Clinical studies have shown that the fetal/maternal leucine enrichment ratio is significantly lower in human IUGR compared with normal pregnancies.[128] Furthermore, the magnitude of its reduction correlates with a clinical classification of IUGR severity based on a completely different set of clinical data, namely fetal arterial velocimetry and fetal heart rate data.[118] Interestingly the uptake of another essential amino acid—lysine—is not altered in IUGR placental preparations.[127] This amino acid uses the y^+ system and further studies confirm that the y^+ and also y^+L system activities are not altered in IUGR placental vesicles.[93] Finally, by way of additional species comparison studies in rats, in which IUGR was induced through maternal protein deprivation, have demonstrated a down-regulation of placental amino acid transport through reductions in system A, X_{AG}^-, and, interestingly, y^+ transport.[129,130]

One final component of change in IUGR that relates to placental amino acid transport is that of surface area,[107,108,131] indicating that morphometric changes also are likely to contribute to the overall reduction in placental amino acid transport capacity. Thus it currently appears that both reductions in surface area for exchange and reductions in specific transporter activity and/or number contribute to the reduction in amino acid transport in pregnancies with IUGR.

UTERINE UPTAKE AND PLACENTAL CONSUMPTION OF AMINO ACIDS

The greater bulk of amino acid in vivo studies have occurred in the sheep model. Net uptake rates of amino acids by the uterus have been difficult to measure because of small arteriovenous concentration differences and relative inaccuracies in the determination of the high rate of uterine blood flow (600 to 1600 mL/minute in late gestation pregnant sheep). In the pregnant sheep, the uterine arteriovenous concentration differences are positive, indicating net uptake by the uterus for all amino acids tested except glutamate; furthermore, the ratio of umbilical/uterine arteriovenous differences (1.9:1) is approximately equal to the uterine/umbilical blood flow ratio.[132] This evidence indicates that most of uterine amino acid uptake is transported to the fetus and that uterine requirements for amino acids are small relative to those of the fetus. In contrast, the placenta is highly active in amino acid utilization and modification; examples including leucine, threonine, glycine, alanine, and glutamate[99,122,123,133,134] are discussed in more detail in Placental-Fetal Amino Acid Cycling section, later. Quantitative aspects of placental amino acid requirements at any gestational age have yet to be determined. Early in gestation, the placental/fetal weight ratio is several-fold higher than at term, and placental growth (by increase in surface area relative to weight or by absolute increase in mass, depending on species and gestational age) is greatest at this period, indicating that placental amino acid metabolism might be quantitatively significant relative to that of the fetus. As examples of the high metabolic rate of the placenta for amino acids, based on placental nitrogen content at term in the human placenta, Lemons[135] estimated that placental growth over gestation would require 10.6 g of nitrogen (or 66 g of protein). Also, infusions of certain radioactively labeled amino acids (lysine, leucine, glycine, aspartate, and MeAIB) into the in situ perfused guinea pig placenta showed 12% to 16% of the label incorporated into placental proteins. This process was inhibited (81% to 96%) by cycloheximide, suggesting that an active process of placental synthesis of proteins was, in fact, occurring.[136]

The placenta near term contains a large variety of enzymes that are capable of metabolizing amino acids through pathways such as gluconeogenesis, glycogen synthesis, protein synthesis, amino acid oxidation, ammoniagenesis, and so forth.[135] Amino acid flux through these pathways has been demonstrated in vitro. So far, amino acid oxidation by human placental mitochondria has been demonstrated for alanine, aspartate, glutamate, and glycine.[137] Ammoniagenesis occurs in vivo in the placentas of sheep,[138,139] rabbit,[140] and guinea pig.[141] Other amino acid requirements include at least a small amount for oxidation and an undetermined amount for synthesis of secreted protein products (e.g., hormones such as human chorionic gonadotropin, luteinizing hormone, and placental lactogen).

UMBILICAL (FETAL) AMINO ACID UPTAKE

The net uptake of amino acids by the umbilical circulation represents the dietary or nutritional supply of amino acids for fetal growth and protein metabolism. Although net protein uptake by the fetus has been observed, this additional amount of protein supply to the fetus probably provides little nutritional value in that total amino nitrogen uptake, at least in the fetal lamb, is not different from the total amino nitrogen uptake in the form of amino acids. Protein molecules as small as albumin and as large as γ-globulin pass from maternal to fetal plasma with increasing efficiency as gestational age progresses.[142,143]

The uptake of amino acids by the fetus via the umbilical circulation has been studied in only one experimental animal (fetal sheep) because only this well-characterized large animal model has allowed accurate quantification of plasma amino acid concentrations in both the umbilical artery and vein. Specifically, the coefficients of extraction for several amino acids (umbilical venous-umbilical artery concentration/umbilical artery concentration) across the umbilical circulation are near zero. Therefore a high degree of accuracy is needed to measure the venous, arterial, and umbilical venous-umbilical artery concentration

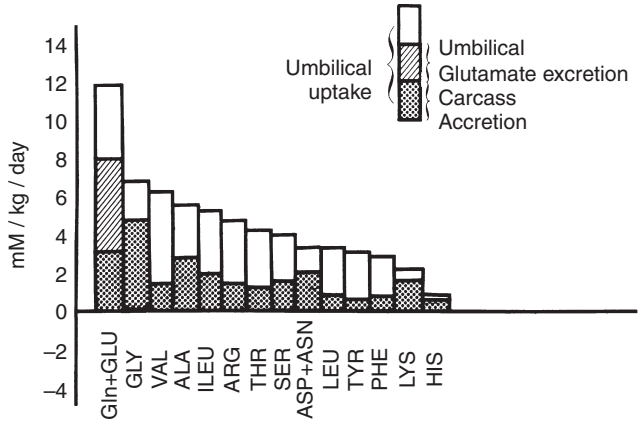

Figure 55-3 Umbilical uptake of individual amino acids by the late gestation fetal sheep, partitioned into amino acid utilization for carcass accretion *(lower, dotted portion of bar)* and that presumably used for oxidation *(upper, open portion of bar).* There was a net excretion to the placenta from the fetus for glutamate in this study. *ALA,* Alanine; *ARG,* arginine; *ASP,* aspartate; *ASN,* asparagines; *Gln,* glutamine; *GLU,* glutamate; *GLY,* glycine; *HIS,* histidine; *ILEU,* isoleucine; *LEU,* leucine; *LYS,* lysine; *PHE,* phenylalanine; *SER,* serine; *THR,* threonine; *TYR,* tyrosine; *VAL,* valine. *(From Lemons JA, Adcock EW 3rd, Jones MD Jr: Umbilical uptake of amino acids in the unstressed fetal lamb,* J Clin Invest *58:1428, 1976.)*

differences to estimate net uptakes of these amino acids by application of the Fick principle,[132,144,145] whereby the product of umbilical blood flow times the umbilical venous-arterial blood concentration difference for each amino acid yields the *net* uptake of each amino acid by the fetus.[12] Figure 55-3 illustrates the net uptake for each amino acid in fetal sheep studied during the last 20% of gestation (net uptake equals the total height of each bar). In a recent study in fetal sheep at term,[13] total fetal umbilical nitrogen uptake was 0.91 g nitrogen/kg/day (± 2 SD; range 0.56 to 1.27 g nitrogen/kg/day). This value is not very different from the calculated total fetal nitrogen requirement of approximately 1 g nitrogen/kg/day) based on nitrogen accretion data and estimated fetal urea production rates in near-term fetal sheep.[13] Figure 55-3 also shows, in the solid portion of the bars, the net accretion of each amino acid in the fetal carcass. The net uptake of most of the basic amino acids exceeds their net accretion by considerable amounts. In contrast, the net uptakes of the two basic amino acids, lysine and histidine, and the neutral amino acid glycine barely exceed net accretion. Similarly, the combined accretion of asparagine and its product aspartate and the combined accretion of glutamine and its product glutamate are very close to the net uptakes of asparagine and glutamine, respectively. For these amino acid pairs, no net uptake of the acidic forms, glutamate and aspartate, occurs. This is true not only in sheep[146,147] but also in primates and in humans.[148] These forms are derived in the fetus from deamination. These observations demonstrate that for these amino acids fetal requirements must be met by production within fetal tissues. Limitation of supply of these five amino acids (lysine, histidine, glycine, glutamine, and asparagine) very likely would lead to reduced protein accretion and growth.

PLACENTAL-FETAL AMINO ACID CYCLING

The placenta and fetus interact in a variety of ways to ensure amino acid supply to vital developmental, metabolic, and signaling processes that are unique to fetal growth and development[149] (Figure 55-4). For example, in addition to net transport of amino acids to the fetus, the placenta contributes to fetal amino acid and nitrogen balance by contributing to selective interorgan cycling,[9] an important concept in fetal physiology. For example, the placenta actively produces ammonia, which is delivered into both the uterine and umbilical circulation.[139,150] This process appears to be normal and occurs over a large part of gestation; for example, in sheep, the absolute rate of uteroplacental ammonia production (~25 μmol/min) at 73 to 97 days gestation is as high as that estimated from data collected in sheep near term,[151] which is consistent with in vitro studies demonstrating negligible urea cycle activity in sheep placental tissue over the entire length of gestation.[150,152] This relatively high placental ammonia production rate in midgestation probably also accounts for the higher concentration of ammonia (approximately two-fold) in fetal blood at midgestation. At that stage of development, fetal weight and the capacity of the fetus to clear ammonia are markedly reduced relative to term,[150,153] despite an in vitro fetal hepatic capacity for urea synthesis at midgestation that is equal to that near term.[154] A fraction of the net umbilical ammonia uptake is extracted by fetal tissues in sheep, perhaps contributing to hepatic urea formation and to other specific metabolic pathways. However, the ammonia taken up by the fetal sheep liver near term (~6.5 μmol/min) is 1.5 to 1.8 times that taken up by the umbilical circulation, demonstrating considerable fetal endogenous ammonia production, consistent with observations of net ammonia efflux across the fetal hind limb.[13]

Measurements of umbilical and fetal hepatic concentrations of amino acids in fetal sheep have demonstrated reciprocal relationships among three sets of amino acids.[13] Glutamine and glycine are taken up in net by the fetus from the placenta and by the liver from the umbilical vein, whereas their metabolic products glutamate and serine, respectively, are produced in net by the fetal liver and are taken up in net by the placenta (although net fetal-to-placental transfer of serine in the fetal sheep is more characteristic of midgestation than near-term gestation). Similar but less marked relationships have been found for net hepatic uptake of asparagine and release of aspartate with a reciprocal change across the umbilical circulation. Thus, for these three amino acids, it is clear that fetal requirements must be met by net production within fetal tissues during all or at least a major portion of gestation.

For serine, tracer studies in near-term fetal sheep indicate that 30% of fetal hepatic serine production is derived from glycine and that approximately 30% of the glycine uptake by the fetal liver is directed to serine production.[155] However, only 5% of fetal plasma serine is derived from plasma glycine, indicating that most of fetal serine is derived from fetal production in peripheral tissues. The bulk of fetal plasma serine oxidation occurs in extrahepatic tissues.[156] These data confirm the interorgan cycling of glycine and serine between the placenta and at least one fetal organ, the liver. Fetal serine production and uptake by the placenta from the umbilical circulation are much larger at 50% of gestation than at term; however, the source of such a relatively higher serine production rate early in gestation (greater synthesis or decreased incorporation into protein) is not known.

Glycine entry into the fetal pool is principally derived from umbilical uptake (30%) and from protein breakdown (56%). Glycine production in the placenta utilizes serine derived from both maternal and fetal circulations.[157] An additional source of glycine (14%) is derived from fetal glycine synthesis. The production of this nonessential amino acid in late fetal life[158] confirms the importance of the fetal glycine synthetic pathway found in liver and other organs. The hepatic amino acid–oxygen quotient is significantly higher than the umbilical amino acid–oxygen quotient (0.63 ± 0.87 VS. 0.13 ± 0.03), which indicates a high rate of amino acid utilization by the fetal liver.[13] The

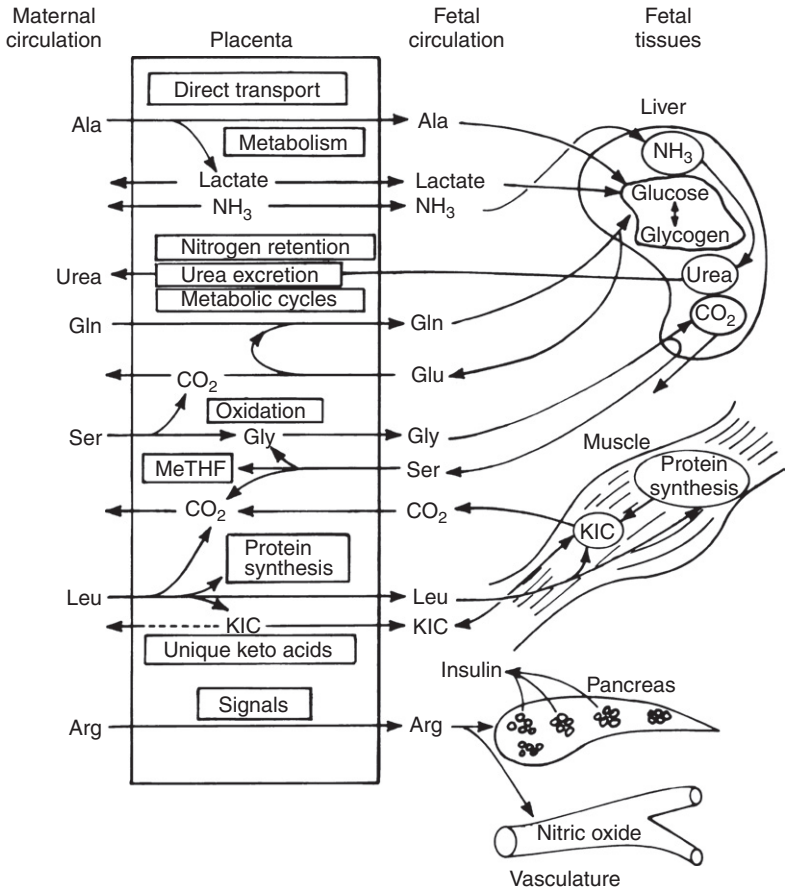

Figure 55-4 Schematic representation of a variety of placental-fetal metabolic interactions with respect to amino acid uptake by the placenta, metabolism in the trophoblast cells, direct transfer to the fetus, signaling of fetal vascular and metabolic processes, and utilization in fetal tissues. *Ala,* Alanine; *Arg,* arginine; *Gln,* glutamine; *Glu,* glutamate; *Gly,* glycine; *KIC,* α-ketoisocaproic acid; *Leu,* leucine; *MeTHF,* methyltetrahydrofolate; *NH_3,* ammonia; *Ser,* serine. *(From Hay WW Jr: Metabolic interrelationships of placenta and fetus,* Placenta *16:19, 1995.)*

oxidation rate for glycine is high in the fetus, and occurs almost exclusively in the fetal liver. Fetal hepatic glycine oxidation and serine production from glycine are linked by the enzyme systems, glycine oxidase and serine hydroxymethyl transferase.[159] A byproduct of placental glycine production via serine hydroxymethyl transferase is methylene tetrahydrofolate, which can be involved in a variety of methylation reactions within the placenta.[157,159]

The actual release of glutamate and serine from the fetal liver could be a direct reflection of the uncoupling of gluconeogenesis from amino acid oxidation.[99,157] Ordinarily, glutamine produces glycogen as well as glutamate in the fetal liver.[160] Almost 100% of fetal glutamate production is accounted for by fetal hepatic production from glutamine.[160] Placental oxidation of glutamate serves as its principal pathway of disposal. At birth, this pattern shifts so that with the loss of the placenta and the development of net hepatic production of glucose, glutamine carbon can be shunted directly to gluconeogenesis. Placental glutamate oxidation also provides nicotinamide adenine dinucleotide phosphate, which is required for placental lipid metabolism and steroidogenesis, particularly that of progesterone.[160] It is noteworthy that the term human trophoblast lacks an active pentose phosphate pathway, which is another pathway for nicotinamide adenine dinucleotide phosphate production.[161]

The ovine placenta takes up glutamine from maternal plasma. Most is transported directly to the fetus, and some is deaminated to glutamate in the trophoblast.[162] The ovine placenta also contains glutamine synthetase, and a small fraction of glutamate that is taken up by the placenta from the fetal circulation is returned to the fetus as glutamine. No proof is available, however, of a direct placental-fetal cycle for glutamine and glutamate. The amount of glutamine produced from glutamate in the placenta accounts for less than 10% of the total glutamate uptake by the placenta and represents less than 10% of placental glutamate output.[163] It is the oxidation of glutamate in the placenta that appears to be the predominant pathway of glutamate disposal in the fetal-placental system (70% to 80% of that taken up from the umbilical circulation is oxidized).[99] The ovine placenta receives two major influxes of glutamate: the placental uptake of fetal plasma glutamate at approximately 4.8 μmol/kg/min, and the placental production of glutamate from deamination of branched-chain amino acids at 3.2 μmol/kg/min.[164,165] In the sheep, practically no uptake of glutamate by the placenta from the maternal circulation occurs and thus no contribution of maternal plasma glutamate to placental-fetal glutamate metabolism. Conditions may be different in the human placenta, which has glutamate transporters on both maternal and fetal surfaces.[166,167]

Another example of placental-fetal amino acid cycling involves the relatively high concentrations and activities of branched-chain amino acid aminotransferases found in the placenta (sheep, human).[168,169] The transamination of a branched-chain amino acid provides the placenta with nitrogen which, in addition to other placental metabolic functions, is used to

sustain a high rate of glutamate production rather than the direct placental utilization of branched-chain amino acids as energy substrates.[127,170] Studies in sheep suggest that net placental uptake and transamination to the corresponding α-ketoacid can occur for leucine,[171] with 10% to 15% of leucine carbon transferred to the fetus as ketoisocaproic acid (KIC). The existence of these pathways implies a complex level of regulation in fetal-placental amino acid metabolism and clearly indicates that the placental-free amino acid pool, whether derived from protein breakdown in the placenta or from the maternal circulation, cannot be treated as a single homogeneous pool.[172]

Alanine also is consumed by the ovine placenta.[133,173] Placental metabolism of alanine may contribute significantly to placental lactate production[174] and also to placental carbon oxidation, accounting for 20% of alanine oxidation by the entire conceptus. The placental oxidation of alanine is much higher than the decarboxylation rate of leucine in the placenta.[175] Furthermore, alanine entering the placenta is metabolized and exchanged for placental alanine. In fact most of the alanine delivered to the fetus is of placental origin.[133] As the fetus matures, fetal hepatic urea cycle enzyme activity and production rates increase, approaching 0.4 g nitrogen excretion/kg/day.[139] In addition, the sheep fetus,[176] like the preterm human infant,[177] responds to an increased intake of ammonia and nitrogen with increased urea production. These observations indicate that the fetus responds effectively to a varied rate of amino acid supply (uptake or degradation) by appropriate forms of nitrogen excretion (e.g., serine and glutamate uptake by the placenta with placental ammonia and hepatic urea production). The higher ratio of ammonia production to urea excretion rate ratio that occurs earlier in gestation may be an advantage to the smaller fetus, providing nitrogen for reincorporation into amino acids and amines essential for rapid fetal growth.[178] The lower urea cycle activity in earlier gestation may also favor conversion of ornithine to polyamines that are essential in development.[179] All five enzymes of the urea cycle are present in the human fetus by 10 to 12 weeks postconceptional age; however, the levels of arginase are lower than those of the other urea cycle enzymes and may be rate-limiting for fetal urea production.[180] Arginase may provide a mechanism in the placenta for urea production from arginine in spite of undetectable levels in the human placenta of ornithine carbamyltransferase.[181] Quantitative aspects of ammonia and urea production in the human fetus are as yet unknown. This knowledge will become important as efforts persist to increase nitrogen intake as a therapy for fetal growth restriction and to help determine the developmental capacity of the preterm infant to metabolize amino acids and protein and excrete nitrogen in response to allegedly growth-promoting, high-protein diets.

NUTRITIONAL ASPECTS OF FETAL AMINO ACID UPTAKE FROM THE PLACENTA

The nutritional requirement for amino acids is high in the mid gestation to early trimester fetus and very preterm infant (24 to 30 weeks gestation). This requirement for amino acids is necessary to provide for the exceptionally high fractional protein synthetic and growth rates at this early developmental age.[182] Estimates of amino acid requirements at this period of development in fetal sheep range from 3.5 to 4.5 g/kg/day when scaled to human fetal growth rates, values comparable with that of 4 g/kg/day determined by the factorial method.[183] Amino acid and protein insufficiency has produced growth failure of the whole fetus and preterm infant.[123,184] Protein deficits in the growth restricted fetus (primarily based on animal studies) also adversely affect the growth and development of the individual organism. For example, in rats, IUGR produced by low protein diet in the mother during pregnancy decreases the growth of the fetal kidney.[185] Such changes appear to last into adulthood, leading to hypertension and diabetes, respectively; mechanisms have not been determined, although reduced glomerular development and associated reductions of the rennin-angiotensin system have been noted in adult rats that were born after IUGR.[185] IUGR from placental insufficiency in fetal sheep reduces the growth of the pancreas and the secretion of insulin in response to normal secretagogues.[186] This model of IUGR produces fewer islets with fewer insulin-producing β-cells in the pancreas due to cell cycle arrest and thus reduced rates if mitosis.[187]

FETAL AMINO ACID OXIDATION

Studies in the fetal sheep have demonstrated that the net uptake of amino acids by the fetus in excess of accretion requirements for growth. This observation implies that this excess portion of amino acid uptake is used for oxidation. More direct evidence for the fetal oxidation of amino acids comes from two observations: the high fetal urea production rate[137,138,143,176,188] and the direct measurement of labeled carbon dioxide production and excretion during fetal infusions of carbon-labeled amino acids.[147] Estimates of fetal urea production rate ranging from 0.4 mg/minute/kg in humans[143] and rhesus monkeys[138] to 0.7 mg/minute/kg in sheep.[176] The urea production rate in sheep could account for approximately 0.36 g/kg/day of nitrogen excretion (or 25% of fetal nitrogen uptake in amino acids) and 0.2 g/kg/day of carbon (or 2% of total fetal carbon uptake and 6% of fetal carbon uptake in amino acids). Such fetal urea production rates are large, exceeding neonatal and adult body weight–specific rates, indicating relatively rapid protein turnover and oxidation in the fetus.

Direct measurement of fetal amino acid oxidation with carbon-labeled isotopic tracers of selected amino acids, quantifies oxidation as the net excretion of labeled carbon dioxide from the fetus via the umbilical circulation relative to the plasma labeled amino acid–specific activity.[145] An important refinement of this methodology is to use the plasma amino acid reciprocal pool–specific activity; for example, for leucine, the plasma KIC pool should be used because it equilibrates with the intracellular specific activity that represents the dilution of intracellular leucine by cellular protein degradation and the final pathway to oxidation.[189]

Central to this methodology has been the documentation that, at least in the fetal lamb, almost 100% of fetal carbon dioxide production (e.g., that produced by fetal infusion of $NaH^{14}CO_3$) is excreted via the umbilical circulation.[145] One limitation of this methodology is its overestimation of fetal oxidation of a specific substrate to the extent that carbon-labeled nonoxidative products derived from placental and maternal metabolism of the substrate reenter the fetus and are oxidized.[190] For example, the carbon dioxide production rate from tracer leucine may include carbon dioxide derived from the decarboxylation of KIC molecules reentering fetal plasma after the placental deamination of fetal leucine.[171] Although estimates of this additional labeled carbon dioxide suggest that it is a fraction of an amino acid's direct oxidation, experimental verification has not been accomplished.

Several ^{14}C-labeled amino acids have been infused into fetuses in vivo, documenting $^{14}CO_2$ production (leucine, lysine, alanine, tyrosine, glycine, serine, threonine, glutamate).[99,122,123] Oxidation rates have been calculated for leucine (25% of utilization), lysine (10% of utilization), and glycine (13% of utilization), demonstrating that the oxidation/disposal ratio is directly related to the excess of umbilical uptake that is greater than accretion and to the plasma concentration of the amino acid.[12,13] Leucine oxidation occurs largely in muscle, whereas glycine oxidation occurs in liver as well. The net umbilical uptake of alanine in

the sheep fetus is approximately 5 μmol/kg/minute, which is less than the amount of plasma alanine that is decarboxylated by the fetus (9 μmol/kg/minute), emphasizing the need for a relatively high rate of fetal alanine production.[173]

AMINO ACID METABOLISM IN MIDGESTATION

Studies of the fetal lamb in midgestation have emphasized several important developmental characteristics of fetal amino acid metabolism. First, at midgestation the fetal uptake of amino acid and ammonia nitrogen via the umbilical circulation is comparable with fetal nitrogen requirements estimated from nitrogen accretion and urea excretion data.[153] Second, the contribution of amino acid carbon to energy needs and carbon accretion is comparable with that of glucose.[191] Similar observations have been made near term. However, in relation to fetal dry weight (a comparison made necessary by the large decrease in fetal water content over gestation), the umbilical uptake of amino acid nitrogen at midgestation is approximately four-fold greater than it is near term. This much higher dry weight–specific nitrogen uptake at midgestation agrees with measurements of protein synthetic rate and oxygen consumption. Third, leucine oxidation at midgestation is at least as great as it is at term, indicating that amino acids provide carbon for fetal oxidative metabolism over a large part of gestation.[191]

FETAL PROTEIN SYNTHESIS AND TURNOVER

In the growing fetus, net protein synthesis exceeds net protein degradation, although both processes continue simultaneously. Protein synthetic rate equals the protein accretion rate together with the amount of protein degradation, where protein accretion has been measured in fetuses by whole carcass protein analysis at different gestational ages. The protein synthetic rate has been determined using isotopic tracers of various amino acids. The rate of incorporation of tracer amino acid into proteins is the difference between infusion rate and the combined loss of tracer to catabolic pathways (oxidation) and diffusional loss to the placenta.[145,175,192] Such tracer methodology is limited in vivo by several factors. First, it calculates a whole body protein synthetic rate, which does not address the markedly different rates of growth and protein synthesis that occur among organs. Also, the protein synthetic rate is calculated using the plasma-specific activity (unless a reciprocal pool product is available, such as KIC for leucine), which may be greater than the intracellular-specific activity because of intracellular reutilization of amino acids released by protein degradation.[193] Thus the protein synthetic rate is frequently underestimated.

Fractional protein synthetic rate (K_S, or the fraction of body proteins that are synthesized/unit time) can also be calculated and compared with fractional growth rate (K_G). K_S is calculated by infusing an amino acid tracer until a plateau-specific activity (SA) in proteins and in the plasma is reached,[143,194] thus $K_S = SA_{proteins}/(SA_{plasma} \times \text{time of infusion})$. This calculation can be made more accurate by calculating the rate at which steady-state SA is obtained and by accounting for the recycling of tracer from degradation of newly synthesized (thus tracer-containing) proteins. In the fetal lamb, K_S and K_G have been compared using two tracers, ^{14}C-leucine and ^{14}C-lysine, at different gestational ages.[182,191] Figure 55-5 is a composite of data from these studies, demonstrating that both K_S and K_G decrease with gestational age, but the decline in K_S is greater. The higher protein synthetic rate in the midgestation fetus is proportional to the higher metabolic rate and the greater glucose uptake and utilization rates at that stage of gestation. Thus protein synthesis per mmol of oxygen consumed is essentially constant from midgestation until term.[191] The same appears to be true for the relationship between protein synthesis and glucose consumption.[1] Because other studies in pregnant sheep have shown increasing placental nutrient transport capacity with advancing gestational age, these data suggest that the reduced rate of fetal growth toward term is an intrinsic quality of fetal development and not the result of placental limitation of nutrient supply. The mechanisms underlying the reduction in protein synthetic rate over gestation remain to be determined. At least a partial explanation can be offered according to the changing proportion of body mass contributed by the major organs (Table 55-6). Based on the relatively increased mass of skeletal muscle (which has a relatively lower fractional synthetic rate in late gestation), for example, it is logical that the whole body fractional synthetic rate should decrease.[148] It is clear, however, that a direct relationship with anabolic endocrine-paracrine factors, such as insulin, pituitary and placental growth hormone, placental

lactogen, insulin-like growth factors (somatomedins), epidermal growth factors, and so forth, cannot be proposed because most studies suggest an increasing concentration or secretion of these substances over gestation.[1]

Role of Insulin in Fetal Amino Acid Metabolism

Insulin is an important growth hormone for the fetus. All studies have shown that a reduction in fetal insulin concentration—from genetic defects in human infants that produce pancreatic agenesis or from experimental surgical removal of the pancreas or chemical ablation of pancreatic islets or β cells—decreases the rate of fetal growth. Growth still occurs in all of these conditions, just at a slower rate. Insulin action in the fetus and newborn infant has the same general properties as it does later in life. With respect to growth, the primary action of insulin is to increase amino acid uptake by the cells, promoting their direct synthesis into protein and, when energy is deficient, into oxidative metabolism and energy production. Insulin also acts to decrease protein breakdown. This is observed consistently in adults,[1,195,196] but less so in the fetus and the preterm newborn who is receiving only intravenous glucose for energy requirements.[197] For example, stable isotopes of glucose, leucine, and phenylalanine/tyrosine have been used to study glucose and protein metabolism during a euglycemic, hyperinsulinemic clamp in preterm infants receiving only parenteral glucose.[198] These infants demonstrated a doubling of glucose utilization with high doses of insulin. Protein breakdown was decreased by 20%, but protein synthesis was also diminished by 20%, resulting in no net protein gain. In contrast insulin may be anabolic and induce a net gain in protein balance in the fetus and preterm infant when given with amino acids as well as glucose.[198,199] A potentially confounding factor in assessing the specific effect of insulin in such studies, however, is that insulin also increases glucose utilization and oxidation at the same time it enhances amino acid utilization. This occurs by insulin's effect to translocate GLUT4 to cell membranes, increasing the capacity for cellular glucose uptake. A recent study in fetal sheep, however, showed that when glucose uptake was reduced to normal rates in the presence of continued amino acid infusion during a hyperinsulinemic clamp, leucine oxidation did not increase significantly, indicating that the acute effect of insulin on amino acid utilization for protein synthesis, net protein accretion, and oxidation is largely independent of simultaneous glucose utilization.[198,200,201]

Several studies have addressed the interactive roles of insulin and glucose, the principal energy substrate in the fetal metabolism, in fetal skeletal muscle metabolism of amino acids.[202-207] Under hyperinsulinemic conditions in which glucose and amino acids were also infused to maintain their concentrations relatively in the normal range, an increased net uptake of most amino acids by the hind limb occurred, reflecting reduced rates of proteolysis more than increased rates of protein synthesis. Protein synthesis was more strongly regulated by the plasma concentration of amino acids than by insulin alone. Glucose uptake also plays a role, indicating that a positive energy balance, as well as the provision of amino acids, allows insulin to promote nitrogen accretion most effectively.[12,202,204]

Hormonal/Nutrient Regulation of Protein Translation

More recent studies of fetal amino acid metabolism have shown that insulin can enhance the MAPKinase (mitogen activated pathway) in fetal skeletal muscle[208] and that both insulin and IGF-I regulate protein synthesis through well-recognized intermediates in their signal transduction pathways, including mTOR (mammalian target of rapamycin) and the eukaryotic initiation factors[209] (Figure 55-6).

Translation initiation and protein synthesis in mammalian cells are regulated through mTOR. In mammals, this evolutionary-conserved protein functions as a sensor for growth factors,

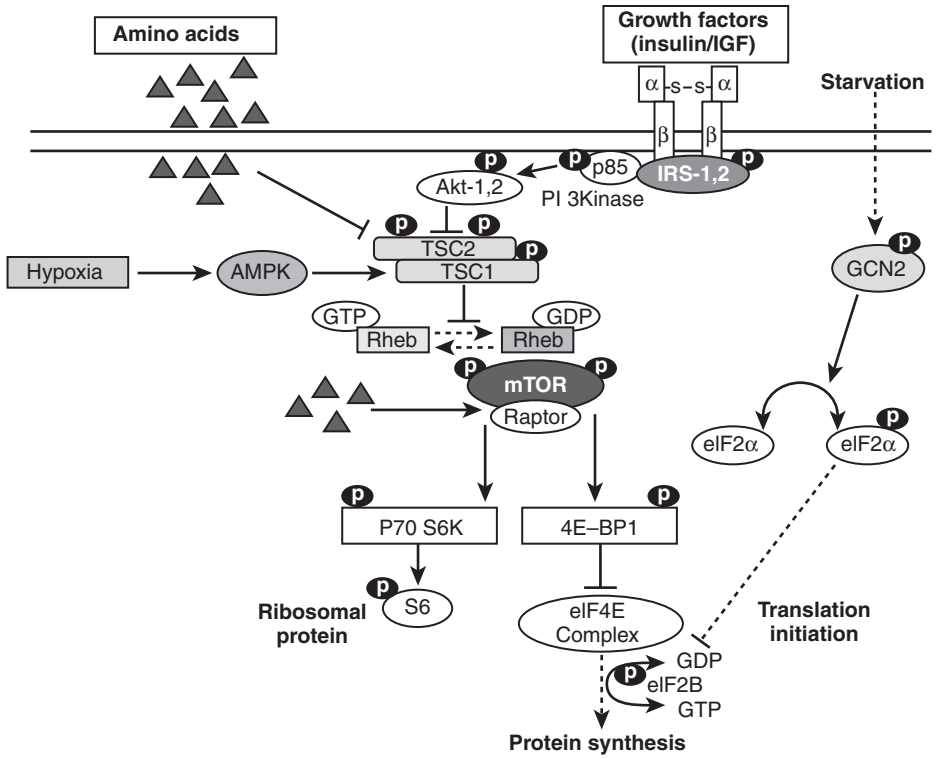

Figure 55-6 Schematic representation of the cellular signal transduction pathways of regulatory proteins leading from stimulation by amino acids, growth factors such as insulin and IGF, or energy substrate supply to protein synthesis.

nutrients, energy and stress, and coordinates these signals to regulate cell growth and proliferation.[210]

Insulin, via a well-described cascade of serine/threonine phosphorylation events, activates mTOR.[211] Amino acids also function as direct-acting nutrient signals that activate mRNA translation initiation via mTOR through what appears to be a separate pathway not as well defined.[212] Activated mTOR is able to phosphorylate eukaryotic translation initiation factor 4-binding protein (4E-BP1), releasing it from one of the eukaryotic initiation factors eukaryotic translation initiation factor 4E (eIF4E). This enables eIF4E to form the eIF4E translation initiation complex, which binds mRNA and the ribosome to initiate protein synthesis. mTOR also phosphorylates ribosomal protein p70S6 kinase, which in its phosphorylated (activated) form will increase the translation of 5'-TOP mRNAs that encode for ribosomal proteins and other translation factors. In addition, hypoxic regulation of mTOR, independent of energy metabolism, also is emerging as an important signal for modulating cellular translation.

Several other signaling pathways contribute to the regulation of mammalian growth. Phosphorylation of eukaryotic translation initiation factor 2α (eIF2α) by cellular stress is recognized as a suppressor of global protein synthesis and is regulated by general control nonrepressed 2 (GCN2), a kinase activated specifically by amino acid starvation.[213] Detailed analysis in drosophila and mammalian cells has revealed that tuberous sclerosis protein 1/2 (TSC1/2) complex negatively regulates mTOR signaling.[210] Several environmental factors act either positively or negatively on TSC2, thereby inhibiting or stimulating mTOR. TSC2 is phosphorylated and functionally inactivated by Akt in response to insulin.[214] Insulin also activates the Ras/extracellular signal-regulated kinases (ERK) pathway, leading to both inhibition of TSC1/2 and activation of p70S6 kinase.[215] Low cellular energy of any stress that depletes cellular ATP, such as hypoxia, oxidative stress or nutrient deprivation will activate 5'AMP-activated protein kinase (AMPK) and decrease mTOR activity. Finally, mTOR signaling is inhibited by hypoxia (through hypoxia-inducible factor [HIF1] and REDD), and protein synthesis is downregulated.[216]

In vitro studies have demonstrated that insulin and amino acids interact to regulate translation initiation downstream of mTOR. Insulin, independent of external amino acid supply, decreases the amount of 4E-BP1 associated with eIF4E and increases formation of the translation initiation complex.[217] Leucine deprivation of L6 myoblasts causes dephosphorylation of p70 S6 kinase, and leucine replenishment restores the phosphorylation state to control patterns.[218] These studies show insulin and amino acids to be positive and/or permissive regulators for mTOR signaling.

In vivo studies also have shown positive effects of insulin and amino acids on the stimulation of translation initiation and muscle protein synthesis. Several studies in the neonatal piglet have demonstrated that insulin and amino acid infusion independently promote muscle protein synthesis with additive effects. Amino acids will signal the phosphorylation of 4E-BP1, increase eIF4E translation initiation complex information, phosphorylate p70S6 kinase and increase muscle protein synthesis, but only in the presence of fetal serum insulin at postprandial concentrations.[219,220] Leucine infusion alone will stimulate the phosphorylation of p70S6 kinase and 4E-BP1.[221] A series of studies in the sheep fetus have shown that insulin, IGF-1, and amino acid infusions have significant effects on whole fetal protein synthesis and accretion. Acute fetal infusions of insulin and IGF-1 increase whole body protein accretion and stimulate muscle protein synthesis[222] and insulin infusion leads to phosphorylation of 4E-BP1 and p70S6 kinase.[209] Acute amino acid infusion, independent of insulin, increases amino acid disposal by means of stimulating both protein synthesis and catabolism.[223]

Additional studies in late gestation fetal sheep have shown that insulin and amino acids act independently to modulate key signal transduction proteins in the mTOR pathway. Recent studies observed a tendency for a greater proportion of mTOR protein to be in a phosphorylated, activated state, and phosphorylation states of ERK1/2 and p70S6 kinase were increased three-fold and four-fold when both amino acids and insulin were present. Amino acids alone did not activate the phosphorylation of any of these proteins or the phosphorylation of 4E-BP1. Thus insulin appears to be a more effective regulator of the mTOR signaling pathway, at least acutely.[224]

Independent Regulation of Signal Transduction by Amino Acids in the Fetus With Intrauterine Growth Restriction

Studies similar to those in normal fetuses described above also have been applied to the fetus with IUGR. In such studies, total 4E-BP1 protein did not change, but significantly less 4E-BP1 in its phosphorylated, activated form relative to the total protein amount in the animals with IUGR compared with the control animals was seen.[225] Giving amino acids to these animals with IUGR failed to restore the ratio of phosphorylated to total 4E-BP1 back to control animal proportions. Because 4E-BP1 is downstream from mTOR, these data indicate that translation initiation in IUGR may be inhibited through selective inactivation of 4E-BP1. These results also indicate that persistent fetal growth deficits that are programmed in utero may not be easily up-regulated or corrected simply by giving more amino acids, particularly when the growth restriction has been chronic and the rate of fetal growth and its regulatory mechanisms have adapted to the long-standing conditions in IUGR of reduced amino acids supply and low plasma concentrations of anabolic hormones (insulin, IGF), glucose, and perhaps oxygen. It also is possible that the adaptation in IUGR might simply be, in part, due to a decrease of amino acid–stimulated insulin secretion; other studies have documented reduced endocrine pancreas development and insulin secretion in IUGR. Thus a simultaneous increase in fetal insulin concentrations with amino acid stimulation or an independent insulin infusion might be required to reactivate the intracellular protein synthesis initiation pathways in fetuses with chronic IUGR (and, presumably, neonates).

FETAL PROTEIN METABOLISM IN RESPONSE TO MATERNAL FASTING

Because protein synthetic and growth rates are high in fetal life, it is appropriate that a number of investigators have studied changes in fetal protein and amino acid metabolism in response to maternal conditions that restrict amino acid, energy supply, or both to the fetus. As described earlier, for example, sustained fetal amino acid concentrations and fetal growth have been observed during selective maternal hypoaminoacidemia in pregnant rats; fetal growth was reduced only when maternal fasting reduced the fetal glucose (energy) supply. Similarly, normal to increased fetal amino acid concentrations have been observed during maternal fasting in pregnant sheep.[226] Fetal uptake of amino acids did not change with fasting, indicating either a reduced fetal protein synthetic rate or an enhanced rate of proteolysis that was directly related to fetal glucose energy supply. Other studies have demonstrated enhanced hind limb release of alanine and glutamine[227] (major potential sources of gluconeogenesis) in fasted sheep. Evidence for fetal gluconeogenesis during prolonged maternal fasting–induced hypoglycemia and reduced glucose supply have been demonstrated.[228]

The balance among energy supply, amino acid supply, protein synthesis, and protein catabolism has been further investigated in two separate models. In fasted, pregnant sheep, no change was seen in leucine disposal rate, but a doubling of the leucine oxidation/disposal rate ratio that occurs after a week of maternal fasting was observed (Figure 55-7).[147] In acutely fasted pregnant rats, fetal proteolysis is enhanced but rates of protein synthesis are normal.[229] These animals had relatively

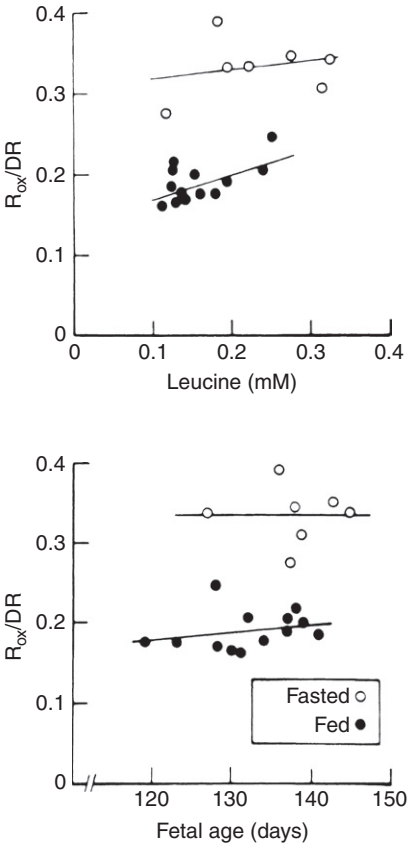

Figure 55-7 Oxidation/disposal rate ration for leucine in fetal sheep near term, studied during fed and fasted conditions compared with fetal arterial plasma leucine concentration *(top)* and fetal age *(bottom). (From van Veen LC, Teng C, Hay WW Jr, et al: Leucine disposal and oxidation rates in the fetal lamb,* Metabolism *36:48, 1987.)*

normal concentrations of amino acids but markedly reduced glucose concentrations.[230] In a subsequent study, prolonged maternal malnutrition with both energy (e.g., glucose) and protein restriction resulted in decreased protein synthesis and proteolysis, but in this case, protein synthesis was reduced to a greater extent.[231] Together these data support the concept that fetal protein synthesis is both amino acid and energy dependent, whereas fetal protein catabolism may be more specifically regulated by nonprotein energy substrate supply. Furthermore, certain amino acids released by proteolysis can be oxidized to maintain fetal energy balance at the expense of growth, whereas others can be directed toward gluconeogenesis to maintain glucose energy requirements.

AMINO ACID, PROTEIN, NITROGEN, AND CARBON BALANCE

Amino acid balance has been determined for several amino acids, including leucine, glutamine (and glutamate), alanine, glycine, and serine, but thus far in only one species, the fetal sheep. Details of these studies for these amino acids were discussed earlier and are presented schematically in Figure 55-4. More complete results for leucine from fetal sheep studied near term and at 50% to 60% of gestation have been determined.[232] Protein turnover/wet weight is higher in the early-gestation fetus, accounted for primarily by relatively increased rates of umbilical leucine uptake (exogenous entry) and protein synthesis. This results in a 50% higher rate of net protein accretion.

TABLE 55-7

Metabolic Balance for the Late Gestation Fetal Sheep

	Carbon Calories	
	Carbon-Caloric Balance (g/kg/day) (kcal/kg/day)	
Requirement		
Accumulation in carcass	3.2	32
Excretion as CO_2	4.4	0
Excretion as urea	0.2	2
Excretion as glutamate	0.3	2
Heat (oxygen consumption)	0.0	50
TOTAL	8.1	86
Uptake		
Amino acids	3.9	45
Glucose	2.4	17
Lactate	1.4	14
Fructose	1.0	7
Acetate	0.2	3
TOTAL	8.9	86
Nitrogen Balance Requirement		
Urea nitrogen excretion	0.4	
Nitrogen accretion	0.6	
TOTAL	1.0	
Uptake (in amino acids)	1.0	
TOTAL	1.0

Oxygen and carbohydrates. *An Introduction to Fetal Physiology.* Orlando, Academic Press, 1986, pp 49-99.

Table 55-7 summarizes the contributions of amino acids to fetal carbon, calories, and nitrogen balance compared with other known substrates in the late-gestation fetal sheep.[143,232,233] Differences among species can be expected based primarily on the capacity of the placenta to transfer fat to the fetus and on the contribution of fat to fetal body composition. Even in those species that take up fat from the placenta and deposit fat in fetal tissues, fatty acid oxidation is presumed low. This presumption has not been tested adequately and may provide a partial explanation for the difference between carbon and caloric requirements and carbon and caloric uptakes.

CONCLUSIONS

Important lessons for amino acid nutrition of the preterm infant are to be learned from evaluation of fetal amino acid uptake and metabolism. As emphasized here, amino acid supply to the fetus by the placenta is quantitatively large and qualitatively unique. Individual amino acids are actively transported into the fetal circulation at relatively high rates to meet the rapid growth and energy needs of the fetus. The active transport also produces amino acid concentrations in the fetal circulation that are generally higher than those in the maternal circulation. These concentrations also are higher than most preterm infants have in their plasma after birth. By way of comparison, the early third trimester fetal sheep uses approximately 6 g/kg/day of amino acids. When scaled to the fractional growth rate of lean body mass characteristic of the normally growing human fetus at the same stage of development,[234] this rate of amino acid utilization is 3.6 to 4.8 g/kg/day. This rate is similar to the required amino acid intake (4.0 g/kg/day) estimated for very preterm infants by the factorial method, but noticeably greater than the rate of amino acid or protein intake that these infants are usually fed.[184] Only

when amino acid intake rates and plasma concentrations are achieved in preterm infants that meet the fetal values do nitrogen and protein balance as well as oxidation rates of the preterm infant match those of the normally growing fetus.[235] The relative concentrations of amino acids achieved in the fetal circulation also are unique. This occurs as a combined result of unique transport characteristics for each amino acid and for groups of amino acids in the placenta, unique rates of placental metabolism of amino acids and unique amino acid derivatives produced by placental amino acid metabolism, and unique placental-fetal hepatic amino acid metabolic cycles. Such information from animal models needs to be expanded by human studies to help determine the optimal supply of each of the amino acids and the unique concentrations that should be achieved in the circulation of the preterm infant in order to optimize preterm neonatal amino acid metabolism and nitrogen and protein anabolism.

56 Protein and Amino Acid Metabolism and Requirements

Sudha Kashyap and William C. Heird

Proteins are the major structural and functional components of all cells of the body. Enzymes, membrane carriers, blood transport molecules, intracellular matrix, and even hair and fingernails are proteins, as are many hormones. Proteins also constitute a major portion of all membranes, and the constituent amino acids of protein act as precursors of many coenzymes, hormones, nucleic acids, and other essential molecules. An adequate supply of dietary protein is therefore necessary to ensure cellular integrity and function.

PROTEIN AND AMINO ACID CHEMISTRY AND METABOLISM

Proteins are among the most complex molecular compounds of the body and of the diet. They consist of chains of amino acid subunits joined together by peptide bonds between the carboxyl group of one amino acid and the amino group of the adjacent amino acid. The chains range from two (dipeptide) to thousands of amino acids, with molecular weights ranging from hundreds to hundreds of thousands daltons.

Proteins are not simply long straight chains of amino acids. Rather the chains fold intospecific three-dimensional structures depending on the function of the protein and its intended interaction with other molecules. Many proteins have several separate peptide chains held together by ionic or covalent links. From a nutritional perspective the most important aspect of a protein is its amino acid composition. However, its structure may influence its nutritional availability. Some proteins are insoluble and hence are resistant to digestion, and others are resistant to the hydrolytic enzymes of the intestine.

The amino acid components of mammalian proteins are α-amino acids. They have a carboxyl group, an amino nitrogen group, and a side chain attached to a central α-carbon. The structure of the side chains determines the functional differences among amino acids. The side chains also have different charges at physiologic pH, and they may be either hydrophobic or hydrophilic. The side chains therefore are important determinants of how the protein structure is stabilized and hence how the protein functions. Attractions between positive and negative charges, for example, pull different parts of the molecule together, with hydrophobic groups tending to cluster in the center of globular proteins and hydrophilic groups tending to remain at the periphery. The formation of disulfide bonds between the thiol groups of cysteine is another important factor in stabilization of the folded structure of a polypeptide and is crucial for formation of interpolypeptide bonds. Some proteins contain complex oligosaccharide side chains attached to the hydroxyl and amide groups of amino acids. Ion-binding proteins (e.g., calcium binding proteins, iron-binding proteins) contain large amounts of histidine and the dicarboxylic acids.

Some amino acids are classified as "indispensable" or "essential," and others are classified as "dispensable" or "nonessential." The carbon skeletons of the former cannot be synthesized by humans from simpler molecules and hence must be provided in the diet, whereas the latter can be synthesized from other amino acids or from other precursors. Some amino acids also are classified as "conditionally indispensable" or "conditionally essential." These can be synthesized from other amino acids, but their synthesis is limited under some conditions.[1-3] These may be particularly important for the preterm LBW infant in whom developmental delays in several enzymes involved in amino acid synthesis have been demonstrated.[4-8] Dietary amino acids classified as essential, nonessential, and conditionally essential are shown in Table 56-1.

Protein Digestion and Absorption

Ingested proteins are denatured by gastric acid and are cleaved into smaller peptides by the enzyme pepsin, which is activated by the feeding-induced increase in gastric acidity. In the small intestine, the peptide bonds of the proteins and peptides are hydrolyzed by various bond-specific proteolytic enzymes of pancreatic origin. This process results in a mixture of free amino acids and small peptides that are transported into the enterocytes by substrate-specific carrier systems. The free amino acids are secreted into the portal blood and pass into the liver, where some are removed and used. The remaining amino acids reach the systemic circulation and are transported to specific sites throughout the body.

The efficiency of digestion of most common dietary proteins (e.g., casein, whey, grain, and legume proteins), measured as removal of labeled amino acids from the small intestinal lumen, is thought to be at least 90%. Nonetheless, nutritionally significant quantities of indispensable amino acids appear to be metabolized by the splanchnic tissues, including the enterocytes.[9] Thus all amino acids removed from the intestine do not reach the peripheral circulation, and the amounts that do not vary from amino acid to amino acid, with intestinal threonine metabolism being particularly high. Absorbed amino acids that reach the systemic circulation are transported into tissues throughout the body, where they are either metabolized to other amino acids, glycogenic or lipogenic precursors, or are used for protein synthesis.

Protein Synthesis

Amino acids destined for protein synthesis bind with transfer ribonucleic acid (tRNA). Information concerning the amino acid sequence of each protein to be synthesized is contained in the sequence of nucleotides in messenger RNA (mRNA) molecules that are synthesized in the nucleus from regions of the deoxyribonucleic acid (DNA). The mRNA molecules then interact with different cytoplasmic tRNA molecules to synthesize protein by linking the individual amino acids. The specific proteins expressed in any cell and the rates at which they are synthesized are determined by the relative abundances of the different mRNAs (i.e., the rates of transcription) and the stability of the messages. Changes in the rate of translation alter the number of tRNA molecules or the efficiency of the tRNA and, hence, alter the rate of synthesis of total cellular protein without altering the composition of the mixture of proteins produced.

TABLE 56-1

Indispensable, Dispensable, and Conditionally Indispensable Dietary Amino Acids

Indispensable	Dispensable	Conditionally Indispensable
Histidine	Alanine	Arginine
Isoleucine	Aspartic acid	Cysteine
Leucine	Asparagine	Glutamine
Lysine	Glutamic acid	Glycine
Methionine	Serine	Proline
Phenylalanine		Tyrosine
Threonine		
Tryptophan		
Valine		

Protein synthesis is a continuing process that occurs in most cells of the body. In the absence of either growth or protein loss, it is balanced by an equal amount of protein degradation.

Protein Degradation

The mechanism by which intracellular protein is hydrolyzed to free amino acids is more complex than that of protein synthesis and has not been as well characterized. Although various enzymes that can hydrolyze peptide bonds are present in cells, the bulk of hydrolysis is thought to be shared by two multienzyme systems: the lysosomal and proteasomal systems. The lysosome, a membrane-enclosed intracellular vesicle, contains proteolytic enzymes called *cathepsins*. This system appears to be relatively unselective, hydrolyzing all engulfed proteins. It is thought to operate when entire areas of the cell or complete organelles need to be degraded (e.g., to provide a rapid supply of free amino acids as substrates for gluconeogenesis). The system is also highly regulated by hormones and amino acids.[10]

The second system, the adenosine triphosphate–dependent ubiquitin-proteasome system, is present in the cytoplasm. The first step is to combine molecules of the very basic 76-amino acid peptide, ubiquitin, with lysine residues of the target protein. This process, which selectively targets proteins for degradation by a second component, the proteasome, involves several enzymes. The proteasome is a very large complex of proteins with numerous different proteolytic activities. The system is very selective and hence can account for the wide range of degradation rates (e.g., half-lives ranging from minutes to days) among proteins. It is thought to be responsible for degrading abnormal or damaged proteins as well as regulatory proteins, which typically are synthesized and degraded very rapidly.[11,12]

Protein Turnover

The process of continuous degradation and resynthesis of protein is known as *protein turnover*. It has been estimated that the human adult synthesizes and degrades approximately 250 g of protein daily despite a mean daily protein intake of only 60 to 100 g. The rate of protein turnover on a body weight basis is considerably greater in infants, particularly preterm LBW infants, and is lower in older adults.[13] The liver and intestine, despite their small contribution to the protein content of the body, are thought to account for approximately 50% of whole body protein turnover.[9,14] In contrast, skeletal muscle, which comprises about 50% of body protein mass, accounts for only about 25% of total body protein turnover.[13]

Total body protein turnover of adults as well as both term and preterm infants has been studied using stable isotope tracers. This method assumes a simple two-pool model of protein metabolism in which amino acids are either free or protein bound. Amino acids enter the free pool from the diet, I, from protein breakdown, B, or from endogenous synthesis (e.g., dispensable amino acids). They leave the pool to be incorporated into newly synthesized protein, S, or to be catabolized, E. Because I and E can be measured, S and B can be calculated from the flux of a single amino acid, which also can be measured: Q = I + B = S + E. Isotopic tracers of both essential ([1-^{13}C] leucine; [^{13}C] or [$^{2}H_5$] phenylalanine) and nonessential amino acids ([^{15}N] glycine) have been used to label the amino acid pool, which is usually assumed to be represented by plasma. However, use of a single amino acid tracer to calculate body protein kinetics may not adequately represent whole body protein metabolism.[15,16]

PROTEIN REQUIREMENTS

Methods for studying the protein requirements of any population (including preterm infants) include nitrogen balance, stable isotope tracer kinetics, and the factorial method. All these methods have advantages as well as inherent shortcomings and limitations.

Net gain or loss of protein, that is, the difference between nitrogen intake and nitrogen output, can be determined by the nitrogen balance technique. Although nitrogen intake can be determined precisely, accurate determination of all nitrogen losses, particularly losses from the skin and breath,[17,18] is difficult. In infants nitrogen output is usually measured as the sum of nitrogen lost in the urine and stool. Losses from the skin and breath are quantitatively small and either are not taken into account or are estimated.

The most commonly used stable isotope tracer method allows assessment of the dynamic aspects of protein metabolism and estimation of protein accretion as the difference between rates of synthesis and breakdown. Protein accretion calculated in this way usually is very close to retention calculated by a carefully conducted, conventional nitrogen balance.

The factorial method requires determining obligatory nitrogen losses (i.e., those that occur on a diet that meets energy needs but lacks protein) and adding to these the protein needs for growth, including a correction for incomplete use of dietary protein. This latter factor is usually assumed to be approximately 70% (as has been suggested by several sets of data).[19-21]

Alternatively, because human milk is considered the ideal food for term infants less than 6 months of age, the protein requirement of infants can be assumed to be the amount in the average intake of human milk by normally growing infants. This is the method used by the Food and Nutrition Board of the Institute of Medicine to establish an adequate intake of protein for term infants less than 6 months of age.

Numerous studies provide considerable insight into the growth and nutrient accretion rates incident to different protein intakes as well as the effects of these protein intakes on other indices of protein adequacy or excess. Thus it is possible to define the protein intake required to achieve various goals. In this regard it is quite clear that the protein intake of preterm infants fed a reasonable volume (i.e., 180 mL/kg/day) of either term (~2 g/kg/day) or preterm human milk (~2.5 g/kg/day) is insufficient to support the intrauterine rate of nitrogen accretion as recommended by the American Academy of Pediatrics Committee on Nutrition,[22] the Canadian Pediatric Society,[23] and the European Society for Pediatric Gastroenterology, Hepatology, and Nutrition.[24] These intakes also are insufficient to maintain plasma concentrations of albumin and transthyretin at more than 3.25 g/dL and 10 mg/dL, respectively.[25]

Increasing nitrogen retention has been reported with increasing protein intake.[26,27] It appears that a protein intake of 2.8 g/kg/day is close to the minimal intake needed to ensure rates of

TABLE 56-2

Composition of Available Preterm Infant Formulas

Component*	Similac Special Care Advance	Enfamil Premature Lipil

*Amount/120 kcal.

†Protein content of the formulas is composed of bovine milk and whey proteins with a 60:40 ratio of whey proteins–caseins.

‡Similac Special Care Advance contains medium-chain triglycerides and a mixture of soy and coconut oils, and Enfamil Premature Lipil contains medium-chain triglycerides and a mixture of soy and high-oleic vegetable oil; both formulas have less than 0.5% of *Crypthecodinium cohnii* oil and *Mortierella alpina* oil as source of docosahexaenoic acid (DHA) and arachidonic acid (ARA). The DHA and ARA content (mg/120 kcal) of Similac Special Care Advance is 16.3 and 26.1 and of Enfamil Premature Lipil is 20.4 and 40.8, respectively.

§Carbohydrate content of the formulas is lactose and corn syrup solids.

weight gain and nitrogen retention at least equal to intrauterine rates and also to maintain acceptable plasma albumin and transthyretin concentrations.[28,29] Moreover, the blood urea nitrogen concentration and the plasma concentration of most amino acids in infants receiving this intake are only minimally different from concentrations observed in infants fed preterm human milk.[25]

A protein intake of 3.5 to 4 g/kg/day results in rates of both weight gain and nitrogen accretion well in excess of intrauterine rates and also maintains acceptable plasma albumin and transthyretin concentrations.[28,29] Although blood urea nitrogen and plasma amino acid concentrations of infants fed these intakes are higher than those of infants fed lower intakes, blood urea nitrogen concentrations greater than 10 mg/dL are uncommon and the plasma concentration of only a few amino acids exceeds the concentration of cord plasma[30] or plasma obtained at fetoscopy.[31]

Today most LBW infants in the United States are fed either preterm human milk fortified with protein and other nutrients, one of several formulas designed specifically for LBW infants, or a combination of human milk and one of the preterm formulas. When volumes sufficient to provide an energy intake of 120 kcal/kg/day are fed, the LBW infant formulas available in the United States provide a protein intake of 3.6 g/kg/day (Table 56-2). Infants fed these formulas gain weight and retain nitrogen at rates equal to or slightly in excess of intrauterine rates,[32-34] without appreciable "metabolic stress." However, data indicate that most conventionally managed infants who weigh less than 1500 g at birth, although of appropriate size for gestational age at birth, weigh less than the 10th percentile of intrauterine standards at hospital discharge.[35] This finding suggests that most of these infants fail to compensate for the lack of growth or actual weight loss during the first 2 to 4 weeks of life.

The Life Sciences Research Office Expert Panel on Assessment of Nutrient Requirements for Preterm Infant Formulas[36] recommends minimum and maximum protein contents of 2.5 and 3.6 g/100 kcal, respectively. At an energy intake of 120 kcal/kg/day, these recommendations equate to protein intakes of 3 to 4.3 g/kg/day.

SPECIFIC AMINO ACID REQUIREMENTS

The intake of each indispensable amino acid required to maintain nitrogen equilibrium in adults[37,38] and, to a lesser extent, normal growth and nitrogen retention in term infants[39] has been defined as the amounts necessary to restore growth, nitrogen balance, and plasma concentration values observed before elimination of each amino acid from an otherwise adequate diet.

More recently a number of oxidation techniques using ^{13}C-amino acids (i.e., direct amino acid oxidation; 24-hour amino acid balance; indicator amino acid oxidation) have been used to determine indispensable amino acid requirements of adults,[40] children,[41] and parenterally fed term infants.[42] The theoretic basis of all these methods is that the nutritional indispensability of an amino acid is a function of its carbon skeleton; thus administration of a test amino acid labeled with ^{13}C results in production of breath $^{13}CO_2$, which is a measure of the irreversible oxidative loss. For the direct amino acid oxidation method, a break point in the relationship between carbon catabolism of the amino acid, that is to say, breath $^{13}CO_2$, and its intake is determined. When intake is less than the requirement, the amino acid is conserved and when the requirement is reached, oxidation increases.

The 24-hour amino acid balance method is similar but involves measurements over an entire 24-hour period rather than a shorter period thus encompassing both fed and fasting periods. It is used less frequently because it is labor and time intensive. Moreover, to measure balance, turnover must also be measured. The indicator amino acid oxidation method also is based on measurement of amino acid oxidation but measurements of the catabolism of a nonlimiting amino acid, the indicator amino acid, is used as the carbon analogue of nitrogen balance. If a single indispensable amino acid is provided at intakes of less than its requirement, the ability to retain other nonlimiting amino acids in body protein is limited. Thus the other amino acid, including the indicator amino acid, are present in excess and are oxidized. When intake of the test amino acid is zero, protein retention is minimal and oxidation of the indicator amino acid is maximal. As the intake of the test amino acid increases, oxidation of the test amino acid decreases until the requirement is reached, after which oxidation of the test amino acid is lower and essentially constant. Data are analyzed to obtain estimates of the intersection of the constant and linear portions of the relationship.

To date these methods have not been used to determine specific amino acid requirements of LBW infants. Rather, the requirements of this population have been estimated by a variety of other methods. Snyderman defined the amino acid requirements of the LBW infant as the amount of each provided by an intake of protein that results in a normal plasma amino acid pattern.[43] Based on observations of "normal" plasma concentrations of most amino acids in LBW infants fed 2 g/kg/day of bovine milk protein, the intake of each amino acid provided by this intake was proposed by Snyderman as the minimum requirement for that amino acid.

TABLE 56-3

Recommendations for Minimum and Maximum Amino Acid Requirements for Low-Birth-Weight Infants

Amino Acid Requirement*	Minimum (mg/kg/day)	Maximum (mg/kg/day)
Isoleucine	245	171
Leucine	434	303

Data from Widdowson EM, et al: In Visser HKA (ed): *Fifth Nutricia Symposium: Nutrition and Metabolism of the Fetus and Infant.* The Hague, Martinus Nijhoff, 1979, pp 169-177.

Infants receiving this intake, however, have a low plasma concentration of lysine and a somewhat elevated plasma concentration of glycine, findings that are often associated with deficient protein intakes.[44] Thus considering these plasma amino acid data and the more recent evidence that a protein intake of approximately 2.8 g/kg/day is required to ensure intrauterine rates of nitrogen retention and weight gain as well as "normal" plasma protein concentrations (see earlier),[28] the amount of each amino acid provided by a protein intake of 2.8 g/kg/day seems more reasonable.

This essentially is the approach proposed by Fomon and Filer,[45] who defined the range of requirements of each amino acid for term infants as the range of intake of each amino acid provided by the amount of commonly used proteins sufficient to support normal growth. For the preterm infant, the range of specific amino acid requirements (per kilogram per day) may reasonably be assumed to encompass the amounts of each amino acid present in 2.8 g of human milk, bovine milk, or modified bovine milk protein. This approach relies heavily on the assumption that a protein intake of 2.8 g/kg/day is adequate, but this has been demonstrated only for modified bovine milk.[28]

The Life Sciences Research Office Expert Panel on Assessment of the Nutrient Requirements of Term Infant Formulas[46] defines the minimum and maximum contents of each amino acid for these formulas as the amount of each present in the amounts of human milk protein corresponding to the recommended minimum and maximum protein contents—1.7 and 3.4 g/100 kcal, respectively. The Expert Panel on Assessment of the Nutrient Requirements of Preterm Infant Formulas adopted the same approach, defining the minimum and maximum amino acid contents for preterm infant formulas (mg/100 kcal) as the amounts of each present in 2.5 and 3.6 g/100 kcal of human milk protein, the minimum and maximum protein contents (g/100 kcal) recommended for preterm infant formulas. Because the panel envisioned the energy intake of the "average" preterm infant to be 120 kcal/kg/day, these recommendations for the amino acid contents of preterm formulas can be translated to a range of requirements (mg/kg/day) as shown in Table 56-3.[47-50]

Widdowson and associates[51] suggested that the amino acid requirements of LBW infants could be estimated as the amount of each that accumulates during normal intrauterine development. These investigators also provided data concerning the accretion of almost all amino acids during intrauterine development, thus making this approach feasible. As illustrated in Table 56-4, the rates of amino acid accretion during different stages of intrauterine development vary somewhat. However, this variation results from variation in rates of protein accretion at different stages of development, rather than from variation in the pattern of amino acid deposited. Thus the amount of each amino acid deposited during any interval can be calculated by assuming a constant rate of growth over the interval of interest. The amount of each amino acid that accumulates as the fetus grows at a constant rate (~15 g/kg/day) from 900 to 2400 g and the estimated intake of each necessary to ensure deposition rates equal to those of the fetus, assuming retention of 70% of total protein intake, can be calculated. However, the latter estimate does not include an allowance for "maintenance" requirements or obligatory losses (i.e., the amounts necessary to maintain nitrogen equilibrium in the absence of nitrogen intake). According to a recent study, maintenance protein needs of preterm infants are 0.55 to 0.75 g/kg/day.[27] Assuming that the amino acid pattern of the maintenance protein needs is the same as that accumulating during development, the intake of each amino acid required to ensure intrauterine rates of growth and nitrogen retention can be calculated (shown in Table 56-5).

A major assumption inherent in this approach is that the various amino acids contribute proportionally to maintenance needs for protein and the roughly 30% of total nitrogen intake lost in the stool and urine. Another is that the increments of amino acids in the body during development reflect the sole need for amino acids. Both are unlikely to be completely valid. For example, as discussed in more detail later, the content of aromatic amino acids (phenylalanine, tyrosine, tryptophan) in most acute phase proteins is roughly double the content of these amino acids in endogenous protein stores. Hence the stressed infant may require greater intakes of these amino acids to support an adequate acute phase protein response to stress without increasing breakdown of endogenous protein stores.

TABLE 56-5

Amino Acid Requirements (mg/kg/day) of the Low-Birth-Weight Infant as Predicted from Fetal Rates of Amino Acid Accretion and Obligatory Losses

†Data concerning fetal accretion rate of cyst(e)ine, tryptophan, asparagine, and glutamine are not available.

Because of metabolic immaturity, preterm/LBW infants require some amino acids (e.g., cysteine and tyrosine) that are not considered indispensable for the older infant and adult. The basis for the preterm infant's and, perhaps, the young term infant's requirement for cysteine/cystine is thought to be low hepatic activity of cystathionase,[4-6] a key enzyme in conversion of methionine to cysteine. In addition, removal of cysteine/cystine from an otherwise complete synthetic diet has been shown to decrease rates of weight gain and nitrogen retention as well as plasma cysteine/cystine concentration, all of which return to control values when the cysteine/cystine intake of the control diet (85 mg/kg/day) is restored.[43] In this study, lower cysteine/cystine intakes (44 and 66 mg/kg/day) were not effective; hence it appears that the cysteine/cystine requirement of LBW infants is near 85 mg/kg/day.

The intake of tyrosine necessary to maintain control rates of weight gain and nitrogen retention as well as normal plasma tyrosine concentrations was shown in a similar fashion to be 50 mg/kg/day,[43] slightly less than the estimate based on the intrauterine accretion rate. The reason for the infant's requirement for tyrosine is not as clear as that for cysteine/cystine. Hepatic activity of phenylalanine hydroxylase, the key enzyme in conversion of phenylalanine to tyrosine, is substantial throughout the last two trimesters of gestation.[52] Moreover, studies using stable isotopes show that even very immature infants can convert phenylalanine to tyrosine.[53,54]

The probable requirement for each amino acid, estimated both as the amount provided by an intake of 2.8 g/kg/day of human milk, bovine milk, or modified bovine milk protein and as the amount theoretically necessary to ensure deposition of each at the intrauterine rate, is shown in Table 56-6. It is obvious that estimates of requirements derived by the various approaches are quite different. In general, the requirements for indispensable amino acids as estimated from the intake of 2.8 g/kg/day of human milk, bovine milk, or modified bovine milk protein are greater than those estimated from fetal accretion rates, whereas the requirements for many dispensable amino acids (arginine, alanine, and, particularly, glycine) estimated from this intake are lower. This finding raises the intriguing possibility that the dispensable amino acid content of proteins commonly used for feeding LBW infants may be limiting, particularly if the infant is unable to synthesize adequate amounts of one or more indispensable amino acid(s). Jackson and co-workers[55] reported that some preterm infants fed banked human milk do not form [^{15}N]urea from administered [^{15}N]glycine, suggesting that the availability of glycine is limited, although perhaps not sufficiently to interfere with growth. Miller and colleagues[56] showed that LBW infants also have a limited capacity for synthesizing proline from glucose.

Studies in animals and in human adults suggest that glutamine becomes conditionally essential during catabolic illness.[57] However, addition of glutamine to enteral feedings of very LBW infants results in no difference in growth, mean hospital stay, or prealbumin concentrations. On the other hand, feeding tolerance appears to be better, and the risk for infection lower in glutamine-supplemented infants.[58]

Further research concerning the LBW infant's requirement for individual amino acids is needed. Moreover, the requirements are likely to depend on the goal for which they are calculated. For example, if the goal is to produce rates of nitrogen retention and weight gain in excess of the intrauterine rate, the additional requirement for each amino acid over that required to support intrauterine rates of nitrogen retention and weight gain will be greater in proportion to the increase in protein intake necessary to achieve the goal.

AMINO ACID REQUIREMENTS FOR PARENTERAL NUTRITION

Because at least 10% of the nitrogen content of most enterally ingested intakes is lost in stool whereas fecal loss of parenteral nitrogen intake is minimal, it follows that the minimal parenteral nitrogen intake required to support the intrauterine rate

of nitrogen retention should be less than the minimal enteral intake. However, this does not appear to be the case. Zlotkin and co-workers[59] found that the minimal parenteral amino acid intake required to achieve the intrauterine rate of nitrogen retention was 3 g/kg/day, approximately 10% more than the required minimal enteral intake (2.8 g/kg/day).[28] The reason appears to be greater urinary nitrogen losses with parenteral versus enteral nutrition. Although 70% or more of most enteral intake is retained despite fecal losses of at least 10%,[19-21] no more than 60% to 65% of most parenteral nitrogen intakes is retained (see later) despite minimal fecal losses. This finding suggests that the quality of available parenteral amino acid mixtures is lower than that of human milk and the proteins commonly used in infant formulas.

In contrast to the relative lack of differences in the overall amino acid pattern of the proteins commonly used in enteral feeding of LBW infants (Table 56-7), the overall quality of available parenteral amino acid mixtures varies considerably, as shown in Table 56-8. In large part, the plasma amino acid pattern of infants receiving parenteral nutrition infusates reflects the pattern of the amino acid mixture used to formulate the infusate.[60,61] Most of the older mixtures, now referred to as general purpose mixtures, result in low plasma concentrations of several indispensable amino acids (e.g., the branched-chain amino acids, tyrosine, and cysteine/cystine) and high concentrations of others (e.g., phenylalanine, methionine), as well as elevated concentrations of some dispensable amino acids (e.g., glycine).[60] Based on conventional theory, these mixtures provide insufficient amounts of the amino acids that are present in low concentrations in plasma and excessive amounts of those that are present in high concentrations.

The indispensable amino acid pattern of most early parenteral amino acid mixtures mimicked the pattern of a high-quality dietary protein (e.g., egg yolk protein) and little attention was given to the dispensable amino acid pattern. Glycine comprised the bulk of the dispensable amino acid content of many mixtures (see Table 56-8). Parenteral amino acid mixtures designed for use in pediatric patients are available. The amino acid pattern of one of these (Neopham, Kabi-Vitrum, Sweden) is similar to that of human milk protein. The amino acid pattern of another mixture (TrophAmine, B. Braun Laboratories, Irvine, CA) is that predicted by a mathematic model to result in plasma concentrations of all amino acids similar to those of normally growing, 30-day-old, breast-fed, term infants. The pattern of yet another pediatric parenteral amino acid mixture (Aminosyn-PF, Abbott Laboratories, Chicago, IL) is a modification of the pattern of the older, general purpose mixture, Aminosyn (Abbott Laboratories).

These pediatric parenteral amino acid mixtures, like human milk protein and the combinations of bovine milk proteins used in most LBW infant formulas (see earlier discussion), provide more indispensable and less dispensable amino acids than the protein deposited by the developing fetus (Table 56-9). Whether a parenteral amino acid mixture with a pattern identical or similar to that of the protein deposited by the fetus may be used more efficiently is not known. The amino acid pattern of TrophAmine is that predicted mathematically to result in normal plasma

*As 17 mg tyrosine and 50 mg *N*-acetyl-L-tyrosine.

concentrations of all amino acids. Hence, by this criterion, the infant appears to be able to convert the indispensable amino acids to the needed dispensable amino acids. Exceptions include cysteine/cystine and tyrosine.

Because tyrosine and cystine are insoluble and cysteine is unstable in aqueous solution, none of the mixtures contains more than trace amounts of these two amino acids. TrophAmine contains *N*-acetyl-L-tyrosine, a soluble tyrosine derivative, but approximately 50% of this derivative is excreted unchanged in urine and is not available to meet the apparent tyrosine needs.[62,63] Because both tyrosine and cysteine/cystine are thought to be indispensable for the infant, their absence in parenteral amino acid mixtures may be cause for concern.

Cysteine/cystine, in addition to being a component of protein, also is a component of glutathione, a tripeptide that is an important biologic antioxidant. The plasma concentration of this antioxidant is low in LBW infants,[64] and although cysteine/cystine supplementation does not appear to increase plasma glutathione concentration,[65] it does increase whole blood glutathione concentration.[66] Because oxidant stress has been implicated in several neonatal disorders, clarification of the role of cysteine/cystine in maintaining plasma and tissue levels of glutathione is important. The lack of adequate tyrosine in parenteral amino acid mixtures may also be important. As discussed, because of the high content of tyrosine in most acute phase proteins, inadequate tyrosine intake may necessitate endogenous protein breakdown to supply adequate tyrosine for ongoing synthesis of these important proteins.

Few studies have examined either the relative efficacy of the available pediatric parenteral amino acid mixtures or the efficacy of any of these mixtures versus that of the general purpose parenteral amino acid mixtures. One exception is the study of Helms and co-workers,[67] showing that LBW infants who received a regimen containing TrophAmine gained weight more rapidly and retained a greater percentage of administered nitrogen than did similar infants who received an isocaloric, isonitrogenous regimen containing a general purpose parenteral amino acid mixture (i.e., 78% versus 66%). The nutritional benefits of TrophAmine were attributed to a greater intake of tyrosine (as *N*-acetyl-L-tyrosine) and cysteine/cystine (as cysteine hydrochloride, added when the infusate was prepared). However, other explanations, including the more normal plasma amino acid pattern of the group that received the TrophAmine regimen, are equally feasible. This latter explanation was proposed by Duffy and co-workers[68] to explain the better utilization of a crystalline amino acid mixture versus a protein hydrolysate.

FACTORS AFFECTING PROTEIN UTILIZATION

Many factors can affect protein and amino acid metabolism and, hence, protein and amino acid requirements. These include clinical status, quality of protein intake, concomitant energy intake (quantity and quality), concomitant intake of other nutrients, and some hormones. Each of these factors is discussed in the sections that follow.

Clinical Status

Clinical status affects protein metabolism and requirements for protein as well as requirements for all other nutrients. Although data from infants are limited, it is likely, as has been established for adults, that any type of stress increases protein requirements. In adults, trauma and sepsis result in increased protein degradation (proteolysis) and, as reflected by higher rates of urinary nitrogen excretion and higher rates of oxidation of essential amino acids, irreversible catabolism of free amino acids.[69,70] The severity of trauma also is directly associated with nitrogen excretion.[71,72] The increased nitrogen excretion incident to stress appears to be mediated, in part, by catecholamines and glucocorticoids. Concentrations of both are elevated in stressed subjects, and increased urinary nitrogen excretion has been reported after infusion of these hormones in healthy volunteers.[73] However, although the infusion of glucocorticoids alone results in increased protein degradation,[74] infusion of catecholamines alone does not have a significant effect on proteolysis.[75]

One mechanism by which stress increases urinary nitrogen losses may be related, in part, to synthesis of acute phase proteins. Waterlow[76] estimated that the mixed acute phase protein response of an infected adult is approximately 1.2 g/kg/day. Although similar data for neonates are not available, it is likely that the response of term as well as preterm infants is similar qualitatively, if not quantitatively. Because maintenance of an appropriate acute phase protein response obviously is important for survival, the amino acids needed to support this response, if not provided exogenously, must be derived from breakdown of endogenous protein stores. Reeds and colleagues[77] estimated that roughly 2 g of endogenous protein must be mobilized to support an acute phase protein response of 1 g. Primarily this is because the aromatic amino acid content of endogenous protein stores is only about half that of most acute phase proteins. Because the other amino acids released from endogenous protein stores cannot be used for endogenous protein synthesis, they are catabolized, thereby increasing urinary nitrogen excretion. The specific cellular and molecular mechanisms involved have not been completely elucidated.

The extensive studies of Knutrud[78] in the 1960s demonstrated that infants subjected to operative stress respond qualitatively in the same manner as adults but to a lesser degree. Although the subjects of these studies were primarily term infants (<1 year of age), there is little reason to believe that the LBW infant does not behave similarly. More recent studies[79] indicated that rates of whole body amino nitrogen flux, synthesis, and breakdown in postsurgical LBW infants are approximately 25% higher than expected. Boehm and colleagues,[80] comparing the metabolic responses of LBW infants (birth weight <1500 g) who experienced bacterial sepsis during the first week of life with those of healthy control infants and infants with respiratory distress syndrome, found that the urinary nitrogen excretion of infants with septicemia was double that of the other groups. In addition, decreasing nitrogen balance with increasing degree of illness has been reported in infants, with the lowest balances observed in infants with sepsis.[81]

Although many clinicians maintain that it is impossible, regardless of nitrogen intake, to achieve positive nitrogen balance during periods of stress, it is clear that this is not the case. Positive nitrogen balance is achievable in stressed patients, even in adults with severe burns; however, the nitrogen intakes required to achieve positive balance are considerable. The LBW infant with sepsis, for example, would require a nitrogen intake of at least 400 mg/kg/day (equivalent to a protein or amino acid intake of approximately 2.5 g/kg/day) to achieve nitrogen equilibrium and an even greater intake to promote nitrogen accretion. Whether provision of smaller amounts of specific amino acids (e.g., aromatic amino acids as discussed earlier) would be beneficial remains to be determined.

Reasonably stable LBW infants who receive no exogenous nitrogen intake during the first week of life excrete, on average, 150 to 200 mg/kg/day of nitrogen,[26,82-85] equivalent to a daily protein loss of 0.94 to 1.25 g/kg, or about 1% of endogenous protein stores. However, these data must be interpreted cautiously because it is likely that the study populations included some nonstressed as well as some moderately (but not severely) stressed infants. Thus the daily nitrogen losses of some infants may be considerably greater and those of others considerably smaller. However, in the studies cited, a parenteral amino acid intake of 1.5 to 2.5 g/kg/day effectively reversed negative nitrogen balance and, in fact, resulted in achievement of positive balance, although not of the magnitude achieved in older, growing, enterally fed infants. Because conditions associated with greater endogenous excretion of nitrogen are usually short-lived (e.g., infection), such intakes over the short term may be adequate.

Based on the usual interpretation of nitrogen balance, a parenteral amino acid intake of 1.5 g/kg/day should preserve lean body mass and a higher intake should support at least modest rates of protein accretion. Further, because the catecholamines, glucocorticoids and cytokines released in response to stress also interfere with utilization of energy substrates, particularly carbohydrate, it is unlikely that stressed infants can tolerate the energy intake required for normal growth. If the period of stress is not long, the effects of less than optimal anabolism for a short time usually can be corrected once the infant has recovered from the precipitating clinical insult. Conversely, if the infant can tolerate a nonprotein energy intake of 80 to 90 kcal/kg/day, a greater amino acid intake very likely will result in the intrauterine rate of nitrogen retention.[59]

Although it is clear that the rate of weight gain of infants with chronic conditions such as congenital heart disease and chronic pulmonary disease is less than optimal, it is not clear that the nutrient requirements of these infants are much greater than those of healthy infants. A thorough evaluation of the cause of the less than optimal rate of weight gain often reveals that the infant's intake is less than that of the normally growing infant with no underlying disease. Thus although the protein requirement of infants with these conditions, as well as their requirements for other nutrients, may be somewhat greater than the requirements of the healthy infant, it is unlikely that they are considerably greater. However, the data on which this statement is based are scarce.

Quality of Protein Intake

An important factor in defining the protein requirement of any population is the overall quality of the protein intake. In large part this is a function of the amino acid pattern of the protein. For example, the initial use of soy protein formulas resulted in lower rates of weight gain and nitrogen retention than did the use of formulas with a similar content of bovine milk protein.[86] Hence the intake of soy protein required to produce a specific rate of nitrogen retention was considerably greater than the required intake of bovine milk protein. The reason for this was related to the lower methionine content of soy versus bovine milk protein. Modern soy protein preparations are supplemented with methionine, and their intake results in rates of weight gain and nitrogen retention equivalent to those resulting from a similar intake of bovine milk protein.

LBW infants fed similar intakes of human milk protein, unmodified bovine milk protein, and modified bovine milk protein (whey predominant) experience similar rates of both weight gain and nitrogen retention. Thus the overall quality of these three proteins appears to be similar. Although the amino acid patterns of the three proteins differ somewhat (see Table 56-7), all contain a greater percentage of indispensable amino acids than does the protein synthesized by the fetus during development; further, all contain more of each indispensable amino acid as a percentage of total indispensable amino acid content than does newly synthesized fetal protein. An intake of only approximately 2 g/kg/day of any of the three proteins provides the requirements of all indispensable amino acids, as estimated from fetal accretion rates of individual amino acids (see Table 56-5). This intake does not provide sufficient amounts of some dispensable amino acids (e.g., glycine, alanine, and arginine) to ensure intrauterine accretion rates. This finding raises the intriguing possibility that these proteins may be limiting with respect to dispensable amino acids, particularly if energy intake is sufficient to favor maximal protein deposition. Indeed, as discussed, Jackson and co-workers,[55] studying [^{15}N]glycine turnover in infants fed human milk, found that glycine intake was inadequate (see previous discussion).

Despite the apparent lack of difference in the overall quality of modified and unmodified bovine milk proteins, most available LBW infant formulas contain modified bovine milk protein. One reason for this is that the plasma amino acid pattern of infants fed modified versus unmodified bovine milk protein is somewhat more desirable. For example, because plasma tyrosine concentrations during infancy appear to be related inversely with neurodevelopmental outcome,[87] the lower plasma tyrosine concentration of infants fed modified (i.e., whey predominant) versus unmodified bovine milk protein[88] may be desirable. In addition, because cysteine/cystine is thought to be an indispensable amino acid for the LBW infant and, perhaps, the term infant, the greater cysteine/cystine content of modified bovine milk protein and the associated higher plasma cysteine/cystine concentrations of infants fed this protein[88] may be another advantage of modified bovine milk protein. Additional data suggest that metabolic acidosis may be less common in infants fed modified versus unmodified bovine milk protein.[89] Modified bovine milk protein, conversely, results in higher plasma threonine concentrations than either human milk or unmodified bovine milk protein.[88]

The quality of protein intake needed in all situations may not be the same. For example, if more aromatic amino acids are needed to support the acute phase protein response to stress (see earlier discussion), a protein with an amino acid pattern resembling the endogenous protein stores of the developing fetus is not likely to be the best quality to provide during periods of stress. However, until the possibility that increasing the intake of aromatic amino acids during stress reduces endogenous nitrogen losses is tested directly, recommendations cannot be made.

Concomitant Energy Intake

The effect of concomitant energy intake on protein, or nitrogen, utilization has been studied extensively in animals and to some extent in human adults,[90,91] but few data from human infants are available. The usual concept is that any nitrogen intake is used better if it is accompanied by a higher versus a

lower concomitant energy intake. For any specific nitrogen intake, however, there is a concomitant energy intake beyond which further increases will not improve nitrogen retention. Although the few reported studies of the effect of energy intake on nitrogen utilization of LBW infants fall short of defining the precise quantitative aspects of this interaction, all suggest that the same principle outlined earlier applies.

Zlotkin and associates,[59] studying LBW infants receiving parenterally delivered nutrients, found that utilization of amino acid intakes of both 3 and 4 g/kg/day was greater with a concomitant energy intake of 80 versus 50 kcal/kg/day. Duffy and co-workers[68] and Pineault and associates[92] also observed a beneficial effect of intakes of 80 to 90 versus 60 to 70 kcal/kg/day on utilization of parenterally delivered amino acid intakes of 2.5 to 2.9 g/kg/day.

Kashyap and co-workers[29] found no statistically significant difference in nitrogen retention of LBW infants fed an enteral protein intake of 3.5 to 3.6 g/kg/day with a concomitant energy intake of 150 vs 120 kcal/kg/day. However, the blood urea nitrogen concentration and the plasma concentration of several amino acids were somewhat lower in the group that received the higher energy intake, suggesting that this energy intake was at least minimally beneficial in enhancing nitrogen utilization. In subsequent studies these investigators found that nitrogen retention of infants who received enteral protein intakes of either 3.8 to 3.9 g/kg/day or 4.2 to 4.3 g/kg/day with a concomitant energy intake of 140 to 150 kcal/kg/day was significantly higher than that of infants who received the same protein intakes with a concomitant energy intake of 120 kcal/kg/day.[28,93]

These data from LBW infants, summarized in Table 56-10, are insufficient to permit definitive conclusions concerning the precise energy intake required to ensure maximal utilization of a specific protein or amino acid intake. Nonetheless, it appears that a concomitant energy intake of 80 kcal/kg/day is sufficient to ensure near-maximal utilization of a parenterally administered amino acid intake of 2.7 g/kg/day and that a concomitant energy intake of 60 kcal/kg/day is sufficient to ensure reasonable utilization. Similarly it appears that a concomitant energy intake of 120 kcal/kg/day is sufficient to ensure at least near-maximal utilization of an enterally administered protein intake of 3.6 g/kg/day.

TABLE 56-10

Nitrogen Retention and Weight Gain of Low-Birth-Weight Infants Receiving Various Protein (Amino Acid) and Energy Intakes

Protein (Amino Acid) Intake (g/kg/day)	Energy Intake (kcal/kg/day)	Nitrogen Retention (mg/kg/day)	Weight Gain (g/kg/day)
Zlotkin et al[59]			
3	50	256 ± 20	2 ± 4
3	80	320 ± 8	16.2 ± 2.4
4	55	274 ± 11	1.5 ± 3.2

3.8	120	420 ± 31	19.1 ± 3.2
3.9	142	473 ± 20	21.5 ± 2.2

*Data from high-fat (3 g/kg/day) groups at each energy intake are combined; there were no effects of quality of energy intake on either nitrogen retention or weight gain.

Extrapolating from these data, it seems safe to conclude that utilization of the amino acid content of a parenterally administered regimen will be efficient, although perhaps not maximally efficient, if the energy–amino acid ratio of the regimen is at least 20 to 25 kcal/g and, similarly, that utilization of the protein content of an enterally administered regimen will be efficient if the energy-protein ratio of the regimen is at least 30 kcal/g. These energy-protein ratios, however, may not be optimal for maximal utilization of protein and amino acid intakes outside the range for which they were calculated. In addition, the ratio may be different if the distribution of energy intake between carbohydrate and fat is different from the distribution of these nutrients in the regimens for which the ratios were calculated. In this regard, there is considerable evidence that carbohydrate is more effective than fat in promoting nitrogen retention.[91,94,95] There is no apparent benefit of an energy intake much in excess of that necessary to ensure utilization of the concomitant protein intake. Such intakes result simply in excessive fat deposition relative to protein deposition.[21,28,96-99]

Concomitant Intake of Other Nutrients

In theory, an inadequate intake of any nutrient required for production of new tissue also limits the extent to which protein can be deposited as new tissue. The best example of this phenomenon is a study in adults receiving only parenterally administered nutrients showing that withdrawal of sodium, potassium, or phosphorus from an otherwise complete parenteral nutrition regimen resulted in retention of less nitrogen and a lower rate of weight gain.[100] There is no reason to believe that this result is not applicable to all subjects. If so, an inadequate intake of any nutrient required for production of new tissue is likely to interfere with utilization of protein and amino acid intake.

Kashyap and colleagues[29] suggested this possibility to explain apparent differences between the results of their studies and those of Räihä and associates.[89] The latter investigators found no difference in rates of weight gain of LBW infants fed protein intakes of 2.25 versus 4.5 g/kg/day (with an energy intake of 120 kcal/kg/day), whereas Kashyap and colleagues[29] found a marked difference in rates of weight gain as well as nitrogen retention between infants fed protein intakes of 2.25 g/kg/day versus 3.6 g/kg/day, both with an energy intake of 120 kcal/kg/day. The only apparent difference between the two studies concerned sodium and phosphorus intakes, which were considerably lower in infants studied by Räihä and associates.[89] Based on the intrauterine relationships between sodium and phosphorus accretion and the accretion of nitrogen,[101] the sodium and phosphorus intakes of the infants studied by Räihä and associates, even if 100% absorbed, were insufficient to permit deposition of the higher protein intake. In contrast, the sodium and phosphorus intakes of the infants studied by Kashyap and colleagues were generous, and retention of sodium and phosphorus relative to the retention of nitrogen was roughly the same as the intrauterine relationships.

Unfortunately, few data concerning this potentially important relationship are available. Nonetheless, it seems reasonable to conclude that inadequate intake of any nutrient required for synthesis of new tissue is likely to inhibit utilization of nitrogen for production of lean body mass. If so, excessive losses of nutrients required for synthesis of new tissue (e.g., electrolyte losses with chronic diuretic usage) also are likely to inhibit utilization of protein and amino acids for production of new tissue.

Hormones

Insulin and insulin-like growth factor I (IGF-I) are important regulators of fetal and postnatal growth.[102] Secretion of insulin is dependent on the plasma concentration of glucose as well

as that of certain amino acids, namely arginine and leucine. In adults, reduction in proteolysis has been reported with plasma insulin concentrations within the physiologic as well as the pharmacologic range.[103,104] In newborn infants, pharmacologic concentrations of insulin (79 ±13 μU/mL) result in reduction of proteolysis, but concentrations within the physiologic range do not.[105] Further, the anabolic effect of insulin on protein synthesis has not been demonstrated consistently in infants, possibly because the effect of insulin on protein synthesis may be underestimated if its effect on protein degradation significantly reduces amino acid availability.

IGF-I also has been shown to enhance protein anabolism.[106] Although IGF-I infusion under conditions of adequate substrate supply enhances protein synthesis, it does not affect proteolysis,[107] whereas insulin infusion appears to decrease proteolysis without affecting protein synthesis. When amino acid concentrations are maintained, infusions of both insulin and IGF-I increase protein accretion of the ovine fetus, but the greatest increase is observed with combined infusion.[108]

Growth hormone (GH) increases lean body mass and promotes growth of GH-deficient individuals.[109,110] It also stimulates muscle and whole body protein synthesis of healthy adults.[111] At least some of these effects of GH are thought to be mediated through IGF; however, the exact mechanism for GH-stimulated protein synthesis remains unclear. Although GH has been shown to prevent glucocorticoid-induced protein wasting in adults,[112] administration of recombinant human GH does not appear to prevent the catabolic side effects of dexamethasone in extremely low birth weight infants with bronchopulmonary dysplasia.[113]

CONCLUSION

Given the sparsity of available data and the fact that much of the data available are confusing and often in conflict with other data, it is difficult to make concrete statements concerning the LBW infant's requirement for protein and amino acids. However, the available data appear to support the following conclusions:

1. The "average" LBW infant who receives no nitrogen intake loses approximately 1% of endogenous protein stores daily, or approximately 1.25 g/kg.
2. A parenteral amino acid intake of approximately 3 g/kg/day or an enteral protein intake of about 2.8 g/kg/day is required to achieve the intrauterine rate of nitrogen accretion.
3. Enteral protein intakes as high as 4.2 to 4.3 g/kg/day are well tolerated by LBW infants and result in rates of weight gain and nitrogen accretion that exceed intrauterine rates.
4. An enteral protein intake in excess of 3.5 to 3.6 g/kg/day is not used maximally unless accompanied by an energy intake greater than 120 kcal/kg/day.
5. There are no major differences in the overall quality of the proteins used in modern preterm infant formulas. In addition, the biologic quality of these proteins differs minimally, if at all, from that of human milk protein.
6. The overall quality of most available parenteral amino acid mixtures appears to be less than optimal.

If these conclusions are warranted it seems reasonable to conclude further that the LBW infant who can tolerate enteral feedings immediately after birth requires a protein intake of at least 2.8 g/kg/day to ensure continued accretion of nitrogen at the intrauterine rate. If the infant cannot be fed enterally, the parenteral amino acid intake required to achieve the same goal is about 3 g/kg/day (this requirement may be somewhat less if a parenteral amino acid mixture designed specifically for infants is used; however, further data are required to confirm the superiority of the pediatric mixtures).

For various reasons some LBW infants receive little or no protein or amino acids for the first few days of life. Because these infants lose at least 1% of their endogenous protein stores daily (or >1 g/kg/day), their subsequent protein and amino acid needs are greater than required simply to support the intrauterine rate of protein accretion. Otherwise this early loss will not be replaced until well after discharge. In other words if the infant receives no protein or amino acid intake for the first several days of life, the minimum requirement is no longer simply the amount required to ensure the intrauterine rate of nitrogen accretion; rather, it is this amount *plus* that required to replace the earlier endogenous losses.

Viewed in this way, the protein (amino acid) requirement of individual infants is variable, depending on the extent of endogenous losses prior to feeding. For example, the infant who receives no amino acid or protein intake for the first week of life sustains endogenous protein losses during this time of at least 7 to 8 g/kg. Assuming that only 70% of intake is retained, these losses increase the infant's subsequent enteral protein requirement by at least 10 g/kg. If this loss is replaced over a period of 40 days, the daily increment in protein requirement is about 0.25 g/kg. If it is replaced over a period of 20 days, the daily increment, of course, is 0.5 g/kg. Thus once the "average" LBW infant is able to tolerate full enteral feeding, it is likely that the protein requirement will be at least 3 g/kg/day. The protein content of available LBW infant formulas is sufficient to provide the minimal protein needs (assuming, of course, that a sufficient volume to provide 120 kcal/kg/day is ingested). A greater protein intake is likely to be tolerated by most LBW infants. Moreover, a greater protein intake also will result in a greater rate of weight gain. Such an intake therefore may be particularly desirable for the infant who has sustained extensive endogenous protein losses.

SECTION IX

Thermoregulation

57

Gordon G. Power and Arlin B. Blood

Perinatal Thermal Physiology

The temperature of any living organism at equilibrium with its surroundings is a balance between heat produced as an inevitable product of metabolism within the organism and the net movement of heat from the organism into the environment. Regulation of body temperature is accomplished by a combination of control over rates of heat flow to the environment and heat production by the body. Newborns and adults use a number of sensory and control mechanisms to balance heat loss with production in order to hold core body temperature relatively constant over a wide range of environmental temperatures. For example, in response to a cold environment, blood flow patterns are altered in order to minimize heat loss, and metabolic processes are increased for the sole purpose of generating additional warmth. Indeed, thermoregulatory responses of endothermic animals are extremely sensitive, constituting one of the most tightly controlled feedback systems known to biology.

At birth the thermoregulatory responses of the mammalian newborn are rapidly activated in order to defend core body temperature against dramatic heat loss due to evaporation of amniotic fluid from the skin and decrease in ambient temperature. Although thermogenic mechanisms are developed in the fetus weeks before birth, they are held for the most part inactive in utero. As a result, the fetus can be considered ectothermic, its temperature fluctuating passively with that of the uterine environment. Indeed, as is discussed in this chapter, heat transfer from the fetus to the mother is so efficient and tightly linked to gas exchange in the placenta that any attempts by the fetus to alter the fetal-maternal temperature gradient would be futile. Much of what is known about fetal and neonatal thermoregulation has been learned using the chronically instrumented sheep as an experimental model, due in part to its large size and tolerance to surgical instrumentation. Comparative studies in other mammals, including humans, suggest that most observations made in sheep can be extrapolated qualitatively to the human. This chapter discusses (1) fetal metabolic heat production and the pathways of heat exchange between the fetus and mother in utero; (2) the metabolic rate of the fetus and placenta and how they pertain to fetal heat production and oxygen consumption; (3) the development and control of thermoregulatory mechanisms in the fetus; and (4) factors controlling thermogenesis in utero and during parturition and in the immediate newborn period.

BASAL FETAL HEAT PRODUCTION AND DISSIPATION

Because the mother provides a warm environment for the fetus in utero, it is tempting to think of heat as flowing from mother to fetus. In fact, the net flow of heat between the two is from fetus to mother due to heat production by the fetus (Figure 57-1). For purposes of this chapter, it is helpful to note that "heat production" is a generic term referring to the generation of heat as a by-product of any biochemical reaction, whereas "thermogenesis" is a more specific term referring to biochemical reactions whose primary purpose is to generate heat to maintain core body temperature. As is discussed later, fetal thermogenesis is suppressed in utero such that fetal heat production stems solely from biochemical processes vital to the growth and function of the fetus. During the last third of gestation, the fetus produces heat at a rate of 3 to 4 W • kg-1, roughly twice that of the adult. At this rate, balanced with the resistance to flow of heat from fetus to mother, fetal body temperature is maintained at approximately 0.5° C greater than that of the mother.

Basal Fetal Heat Production

Fetal heat production has been measured experimentally by two different experimental methods, *indirect* calorimetry and *differential* calorimetry. More than 200 years ago it was observed that fertile chicken eggs produced more heat and consumed more oxygen than did spoiled ones.[1] It has since become widely accepted that these two variables are directly related to each another in a proportion that remains constant across most aerobic organisms, such that 4.9 calories (20.5 joules) of heat are produced for every milliliter of oxygen consumed. Using this assumption, the method of indirect calorimetry calculates fetal heat production based on measurements of oxygen consumption. Measured oxygen consumption of the fetal sheep is approximately 8 mL • min^{-1} • kg^{-1} during the last third of gestation.[2] Thus by indirect calorimetry, fetal heat production can be estimated at 39.2 calories • min^{-1} • kg^{-1}, or 2.7 W • kg^{-1}.

The other means of measuring fetal heat production, differential calorimetry, relies on measurement of changes in the fetal-maternal temperature gradient following administration of known quantities of heat to the fetus.[3] The method is based on the idea that when maternal temperature and resistances to heat flow between the fetus and mother are stable, only changes in fetal heat production can alter the fetal-maternal temperature gradient. Administration of heat into the core of the fetus widens the fetal-maternal temperature gradient just as normal metabolic heat production by the fetus does. As a result, the ratio of a known quantity of heat administered centrally to the fetus and the resulting change in fetal temperature is equal to the ratio of overall fetal metabolism and the fetal-maternal temperature gradient as follows:

$$H_{heater} / \Delta T_{heater} = H_{fetus} / \Delta T_{fetus}$$

where H_{heater} is the known amount of heat produced by a heater implanted within the fetal body, ΔT_{heater} is how much the implanted heater raises fetal temperature above baseline, H_{fetus} is the amount of heat produced by the fetus, and ΔT_{fetus} is the fetal-maternal temperature gradient. The heat production of the fetus is derived by solving the equation for H_{fetus}. In using this equation, experiments in sheep have resulted in measurements of 3.1 W • kg^{-1}, which is within 15% of measurements by indirect calorimetry.[3]

Pathways of Fetal Heat Dissipation

Heat travels within the body by either conduction (the diffusive transmission of heat through matter) or convection (the transfer of heat within moving fluids, i.e., blood). Therefore heat

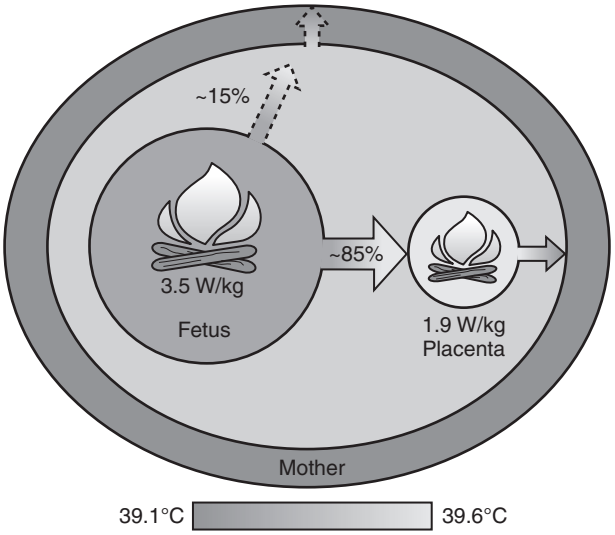

Figure 57-1 A stylized illustration of the net movement of heat from the fetal sheep to the mother. About 85% of total heat produced by the fetus passes to the mother through the placenta, with the remaining 15% passing through the fetal skin, amniotic fluid, and uterine wall. At equilibrium, the temperature of the fetus is approximately 0.5° C more than that of the mother. Temperatures average 2° C lower in the human.

produced by metabolically active tissues leaves the organ where it is produced via conduction to the surface or by entry into the bloodstream, where it is carried away by convection in the venous blood. Heat flows from the fetus to the mother by either conduction through the fetal skin and into the amniotic fluid and uterus, or by convection in the blood to the placenta, where it is conductively transferred to the placental tissues and maternal blood.[4]

The fraction of overall fetal heat dissipation accounted for by each of these pathways has been determined experimentally in fetal sheep by measuring changes in fetal, maternal, and amniotic fluid temperatures following injection of known quantities of ice-cold saline into the amniotic fluid. The rate of heat exchange among these three compartments was measured with the fetus either alive or dead, and the difference between the two taken as the contribution of convective heat exchange due to umbilical blood flow. The results of these experiments suggest that approximately 85% of fetal heat production is dissipated through the placenta and 15% is dissipated through the fetal skin (see Figure 57-1).[4]

Placental Heat Production and Exchange

As mentioned, the placenta handles approximately 85% of the overall heat flux from the fetus to the mother. The overall permeability of the placenta to heat (0.8×10^6 W • C^{-1} • kg^{-1}) is very high compared with the amount of heat produced by the fetus and the permeability of the placenta to the molecules it exchanges.[5,6] Paradoxically, however, the placenta appears to be much more efficient at transferring matter than heat. For example, the capacity of the isolated perfused guinea pig placenta to transfer water from fetus to mother is much greater than its capacity for heat transfer despite the fact that heat diffuses through tissue much faster than water.[5,7] This counterintuitive finding can be explained by assuming that heat exchange is not limited to the same utero-umbilical interface area as that of matter exchanged in the placenta. Instead, due to its extremely diffusive nature, heat likely also shunts from the umbilical arterial

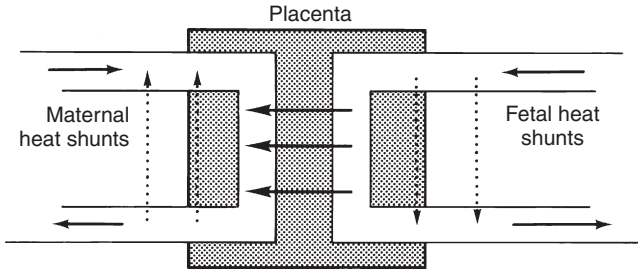

Figure 57-2 An illustration of heat exchange and shunting in the placental circulation. Because heat is highly diffusible, shunts may develop between vessels supplying and returning from the placenta. Such shunts diminish the efficiency of the placenta as a heat exchanger.

circulation across to the umbilical vein, where it is carried back into the fetus. It may also enter the amniotic fluid from vessels in the umbilical cord and on the surface of the placenta. These factors result in decreased efficiency of the placenta to transfer heat to the mother (Figure 57-2).

The transfer of heat across the placenta is also affected by the heat production of the placenta itself. The placenta is very metabolically active, consuming as much or more oxygen per kilogram of tissue weight as the fetus itself. Therefore, assuming normal fetal and placental weights of 3.5 and 0.7 kg, respectively, a fetal and placental heat production of 3.5 W • kg^{-1}, and that 85% of fetal heat dissipation passes through the placenta, it can be seen that 25% of the heat passed from the placenta to the mother is derived from the placenta itself. By lowering the temperature gradient between umbilical and uterine blood, this locally produced placental heat diminishes the efficiency of the placenta as a heat exchanger.

Simulating Heat Movement in the Fetus

As a result of the predictable physical properties of heat, the movement of heat from the fetus to the mother can be expressed in rather simple equations defining the flow of heat by either conduction or convection. For example, the rate of heat conduction across the fetal skin and the placenta can be defined by

$$H_s = (T_f - T_a) \bullet G_s$$

and

$$H_p = (T_f - T_m) \bullet G_p$$

respectively, where H_x is the heat flux across the skin (H_s) and placenta (H_p) in watts, T_f is the fetal core temperature, T_a is the mean temperature of the amniotic fluid surrounding the fetus, and G_x is the experimentally measured conductance of the skin (G_s) or placenta (G_p) in W • kg^{-1} of tissue weight per degree C temperature difference. Equations describing heat convection must include the rate of flowing matter and its specific heat, or capacity of the matter to hold heat. Using the umbilical cord as an example, heat carried in blood flowing from the fetus to the placenta can be defined by the equation

$$H_{umb} = Q\,(T)\,(SH_{blood})$$

where H_{umb} is the heat flux, in watts, of the flowing blood, Q is the blood flow rate (mL/min), T is the temperature of the blood (C), and SH_{blood} is the specific heat capacity of the blood (3.6 joules • mL^{-1} • C^{-1}).

By using equations such those described to define the transfer of heat in the fetal-maternal unit, it is possible to create computer models capable of taking data from multiple experiments into account and to accurately predict experimental measurements.

In this manner, the use of computer modeling of fetal-maternal thermal homeostasis has improved the understanding of pathophysiologic disturbances in fetal heat production or dissipation.[8] For example, by varying simulated umbilical blood flow, heat production, and conductances individually while holding maternal temperature constant, it can be demonstrated that changing umbilical flow and fetal heat production are the only two means by which the fetus could alter its temperature significantly from that of the mother. As a result, any attempt by the fetus to raise its temperature in response to cold is met with the impossibility of simultaneously *increasing* heat production (hence oxygen consumption) and *decreasing* umbilical blood flow (hence oxygen supply). These models thus emphasize the futility of the fetus to regulate its own temperature in utero.[7]

Changes in Maternal Temperature

The fetus is largely ectothermic, its temperature at equilibrium approximately 0.5° C more than that of the mother despite changes in maternal temperature. This is demonstrated by a number of studies examining the effects of maternal hyperthermia or hypothermia on the fetal-maternal temperature gradient. Because it lacks the ability to regulate its own body temperature independently, the fetus is vulnerable in situations in which maternal temperature varies significantly from normal body temperature.

Maternal Hyperthermia

Following an unusually severe heat wave in 1965 that caused a number of the pregnant guinea pigs in his laboratory to abort prematurely, Marshall Edwards observed an increase in birth defects in guinea pigs who continued on to parturition.[9,10] Subsequent studies established that hyperthermic insult during the first or second trimester of pregnancy is teratogenic, leading to a long list of birth defects including anencephaly, microcephaly, neural tube defects, microphthalmia, talipes, arthrogryposis, heart defects, renal anomalies, abdominal wall defects, and limb reduction defects.[11,12] The teratogenic effects of maternal hyperthermia have been observed in a number of species including guinea pigs, rats, mice, pigs, sheep, and monkeys. Hyperthermia as a result of maternal fever or hot tub or sauna exposure has also been linked to human birth defects in a number of studies,[13-19] making hyperthermia the first human teratogen discovered through animal studies.[11]

In humans the precise thresholds at which hyperthermia results in birth defects are not well defined. However, animal experiments in a number of different species indicate that temperature elevations of more than 2° to 2.5° C for an hour or more are necessary. Exposures to hyperthermia of less than 2° C do not appear to be teratogenic regardless of duration. Evidence that avoiding spas and hot tubs during the first trimester of pregnancy results in decreased birth defects together with the overwhelming amount of animal data has resulted in recommendations that spa temperatures 39° C for more than 15 minutes and 40° C for more than 10 minutes should be avoided by women during the first and second trimesters of pregnancy.[20]

The mechanisms underlying the teratogenic effects of hyperthermia are likely related to the effects of heat on protein conformation and function. Mitotic cells appear to be the most susceptible to heat stress, dying in a pseudo-apoptotic manner 6 to 8 hours post insult. Cells in S-phase are also especially sensitive, dying apoptotically 12 to 15 hours after exposure.[12] Interestingly, there also appear to be cellular protective response mechanisms to heat stress. Exposure of rat embryos to subteratogenic levels of hyperthermia results in significant protection against subsequent heat stress that would be teratogenic in nonpreconditioned embryos. These protective effects persist for up to 8 hours following insult and are likely related to a family of proteins transcribed in response to heat, aptly termed heat shock proteins. These proteins serve to protect nascent proteins against aggregation as they are being synthesized, as well as aiding in the folding of new or denatured proteins to their functional configurations. In this manner, heat shock proteins serve to rescue and protect proteins from heat denaturation.[21]

Although the teratogenic effects of hyperthermia appear to be limited mainly to the first half of gestation when cell differentiation is most prevalent, heat stress in the latter half of gestation can also be detrimental to the fetus. During strenuous exercise or exposure to elevated ambient temperatures, maternal temperatures may rise by as much as 2° C above normal. Fetal temperatures, being inexorably linked to those of the mother by the heat-clamp function of the placenta discussed earlier, also increase under these circumstances but tend to lag behind maternal changes. As a result, the difference between fetal and maternal temperature is decreased or even reversed during the first 30 to 40 minutes of heat exposure.[22,23] This thermal buffering may be partly due to a phenomenon known as thermal inertia, which refers to the time required for additional heat to build up in or escape from tissues as a result of alterations in heat production or dissipation. The transient decrease in fetal-maternal temperature gradient occurring soon after maternal heat accumulation might also be explained by increases in placental blood flows, but this does not seem likely because both uterine and umbilical blood flows of sheep decrease in response to transient hyperthermia.[22,24,25]

The effects of chronic mild hyperthermia are known to be deleterious in the fetal sheep. In fact, exposure to chronic 0.6° to 0.8° C elevations in maternal body temperature for the final 0.75 of gestation is a well-validated animal model of placental insufficiency and intrauterine growth restriction.[26] These conditions result in decreased placental and fetal weight, mild to severe fetal hypoxemia, and decreased placental amino acid, oxygen, and glucose transport. Uterine and umbilical blood flows are also decreased, although the decrease is proportional to fetal body weight and it is not clear whether this is the primary cause of fetal growth restriction and hypoxia.[27]

Maternal Hypothermia

Compared with the harmful effects of even 1° or 2° C of hyperthermia, hypothermia in utero is better tolerated by the fetus and occurs less frequently. Hypothermia applied selectively to the fetus has been well studied and is discussed in later portions of this chapter devoted to thermogenesis. Maternal hypothermia finds clinical relevance in cases of cardiopulmonary bypass surgery or medical complications such as hypoglycemia or septic shock.

Cardiopulmonary bypass surgery usually involves administration of hypothermia to the patient to temperatures as low as 25° C or less. When the procedure is required in pregnant women, reports of fetal survival rates range from 71% to 91%.[28,29] Clinical studies that include measurements of fetal heart rate report profound fetal bradycardia during bypass. However, it is not clear whether the primary cause of the bradycardia is hypothermia or perhaps fetal hypoxia secondary to changes in placental oxygen exchange. In sheep, mild hypothermia results in increased sympathetic activity and heart rate, but this response is overridden by superimposed hypoxia, which causes bradycardia that is mediated vagally by central chemoreceptors (Figure 57-3).[30] Likewise, in at least one clinical case in which maternal temperatures were held normothermic during cardiopulmonary bypass surgery, fetal bradycardia occurred abruptly on ligation of the maternal aorta, suggesting bradycardia may not be caused by hypothermia per se.[31] In a study of cardiopulmonary bypass performed on pregnant sheep, fetal heart rate increased initially on initiation of maternal cooling, but then fell as body temperatures were lowered to more than 5° C below normal.[32] However, arterial hypoxia was also observed in lambs held at 20° to 24° C, making

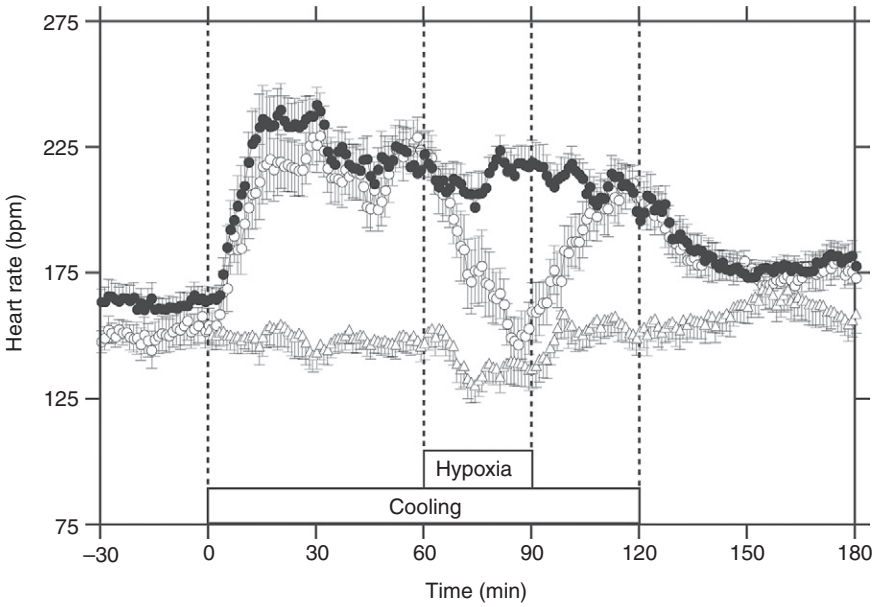

Figure 57-3 The effects of mild cooling (decrease in core body temperature of 1.5° C) hypoxia (maternal Fio_2 of ~0.12) or hypoxia superimposed during cooling on heart rate of the fetal sheep in utero. Cooling alone *(closed circles)* results in rapid and profound tachycardia. In contrast, hypoxia alone *(open triangles)* results in bradycardia, mediated vagally by central chemoreceptors. When superimposed on cooling *(open circles),* hypoxic bradycardia is overriding.

it difficult to distinguish between low arterial Po_2 or cooling of the sinus node as the primary cause of bradycardia. The distinction may be important because the latter indicates fetal distress, whereas the former tends to be protective. It is worth noting that the lambs were not acidotic and maintained normal Pco_2 levels throughout the procedure, suggesting that stress as a result of hypoxia or poor placental exchange was minimal. At any rate, although further studies are needed on the fetal effects of maternal hypothermic cardiopulmonary bypass, available reports suggest that deep cooling of the mother (20° to 24° C) is safer than very deep cooling (<20° C). In addition, cooling as low as 25° C may not be any more harmful or is perhaps even less harmful to both the fetus the mother than normothermia during bypass by virtue of the lowered metabolic demands during the procedure.

PERINATAL THERMOREGULATION

Homeotherms are often categorized based on the developmental stage of thermoregulatory systems at the time of birth as immature, altricial, or precocial. Immature newborns, such as marsupials and hamsters, are largely poikilothermic during early postnatal development. Body temperature thus varies as a function of ambient temperatures during at least the first 2 weeks of life, at which time thermogenic responses develop only in those animals exposed to hypothermic stress. Altricial (which means "nesting") newborns, such as rodents, dogs, and rabbits, are born with little or no thermogenic capacity during the first 1 to 6 days of life, after which responses develop only if exposed to hypothermic stress. Precocial newborns, such as humans, guinea pigs, and lambs, develop the capacity for thermogenic responses in utero capable of being activated immediately at birth and which are vital to the survival of species born in cold environments.

Fetal Thermosensory Development

Control of thermoregulatory mechanisms begins with sensory input from either sensory neurons located in the preoptic chiasma/anterior hypothalamic nuclei (POAH), or from peripheral cutaneous receptors that send information to the POAH. Thermosensitive cells within the POAH fire at frequencies that vary with changes in temperature. Signals from the POAH are subsequently processed through a number of central inhibitory and stimulatory steps en route to activation of nonshivering thermogenesis by sympathetic norepinephrine-secreting nerve fibers that innervate brown adipose tissue (BAT), and to activation of shivering thermogenesis via the posterior hypothalamic nucleus.[33,34]

The in utero development of central thermoregulatory controls has not been fully explored, although these mechanisms do appear to be in place long before the time of parturition in some species. By cooling fetal sheep in utero, researchers have observed thermoregulatory responses such as shivering[35] and increased sympathetic activity as demonstrated by tachycardia, hypertension, and increased circulating concentrations of epinephrine and norepinephrine.[36] As is discussed later, sympathetic output is the key stimulus of thermogenesis by BAT. Interestingly, cutaneous cooling but not central cooling of the premature fetal sheep also results in coordinated breathing movements, suggesting cutaneous cold sensors also play a role in the initiation of ventilation at birth.[35] Although less studied than the sheep, premature human infants as young as 25 weeks gestation also demonstrate thermoregulatory responses to cold stress at birth, although the responses are clearly not as vigorous as those of the term infant.[37]

Behavioral Thermoregulation

Although initial studies of thermoregulation in animals focused primarily on physiologic changes in blood flow and metabolism to control heat loss and production, behavioral mechanisms of thermoregulation are a key factor for many nesting animals. For example, although rat pups in isolation appear relatively poikilothermic, in a litter they move closer and farther apart in response to changes in ambient temperature, a behavior known as thermotaxis. By dynamically changing the overall surface-to-volume ratio of the group in this manner, the litter as a whole is able to maintain euthermic body temperatures and conserve metabolic energy of the individual pups within.[38] These thermoregulatory behavioral responses are developed at the time of

birth. Interestingly, isolated 1-day-old rats in a cool environment are even capable of learning head-turn movements that result in brief rewards of heat.[39]

The full extent to which behavioral mechanisms of thermoregulation interact with physiologic responses remains to be determined, but it is clear that in many cases they are closely linked. For example, endogenous thermogenic mechanisms such as BAT activation are required for huddling behavior to be fully effective in newborn rats.[40] Likewise, exposure of infants to mild cold stress results in increased sympathetic nervous activity that not only activates thermogenesis but also increases crying, which in turn attracts the attention of caregivers.[41]

Mechanisms of Thermogenesis

Thermogenic responses fall naturally into three broad categories: shivering of skeletal muscle, nonshivering thermogenesis in BAT, and futile cycling of ions in specialized heat-producing tissues. Each has a distinctive mechanism of action. During shivering, for example, small random muscle contractions hydrolyze adenosine triphosphate (ATP), stimulate respiration, and dissipate the free energy as heat, without doing useful mechanical work.[42] During nonshivering thermogenesis, energy from mitochondrial respiration is not conserved as ATP but rather is released as heat. During futile ion cycling, respiration remains coupled, but significant amounts of heat are dissipated from specialized tissue by cycling of Ca^{2+} in the sarcoplasmic reticulum with associated use of ATP.[43] It has been speculated that similar mechanisms may be associated with malignant hyperthermia in humans, but whether aberrant Ca^{2+} cycling contributes to cold-induced thermogenesis in newborn mammals remains unknown. Other nonshivering thermogenic mechanisms include protein synthesis–degradation cycling of proteins and K^+-ATPase cycling, but again their importance in the neonatal period is unknown.[44]

The proportion of thermogenesis provided by shivering or nonshivering means varies widely across species. In the newborn lamb, nonshivering thermogenesis provides the first line of defense against cold exposure, with shivering commencing only after body temperature falls significantly. However, although shivering is a second line of defense, it accounts for nearly 50% of maximal heat production during cold exposure, with nonshivering thermogenesis accounting for more than 30%.[45] In the human newborn, the relative importance of the different mechanisms is not well established, but is thought to vary with gestational age and severity of the temperature stress. Nonshivering thermogenesis is clearly not essential for survival in all species, demonstrated by the fact that it is lacking altogether in the newborn pig and ox.

Carbohydrate metabolism is also stimulated by cold exposure. Evidence for augmented carbohydrate metabolism includes a fall in hepatic glycogen stores and increased glucose turnover. During summit metabolism, when cold-induced increases in metabolic rates are at a maximum, glucose, glycogen and lipid energy stores are adequate for 8 to 12 hours in the newborn lamb.

Shivering Thermogenesis

Shivering is mediated by information processed in the primary motor center for shivering located in the posterior hypothalamus. This center receives inhibitory signals from the POAH when euthermic or hyperthermic and excitatory signals from cutaneous nerve endings during hypothermia. The POAH stimulates general increases in skeletal muscle tone via motor neurons. Although shivering is a primary thermogenic response to cold in the adult and can increase body heat production by four- or five-fold, in most newborns (human included) it is a second line of defense.[45,46]

The shivering response of the fetal sheep to hypothermia is present in utero as early as 106 days gestation (~0.75 of 147 days full term).[35] Shivering is inhibited by hypoxia in the fetal sheep and, as in the newborn and adults of many species,[47] during rapid eye movement (REM)–like sleep electrocortical activity. This inhibition emerges at approximately 120 days in the sheep.[35]

Nonshivering Thermogenesis

The importance of nonshivering thermogenesis in thermoregulation was not widely acknowledged until it was observed that animals treated with curare paralytics to block shivering retained an ability to produce significant amounts of heat in response to cold.[48] The findings were supported in human infants when cold-induced increases in metabolic rate were still observed in pharmacologically sedated infants displaying no signs of shivering.[46] These observations were made in the context of growing acceptance that BAT was, in fact, a thermogenic organ responsible for a predominant portion of nonshivering thermogenesis, thus creating an entirely new field of study. As a result, over the past 30 years much progress has been made toward understanding the regulation and contribution of nonshivering thermogenesis to thermal homeostasis.

In utero, BAT first appears in the fetal sheep less than halfway through gestation,[49] and for the last trimester of gestation constitutes 0.5% to 1.5% of total human infant body weight.[50] BAT is found near highly perfused organs or along the course of large vessels, with a distribution that has been described to resemble a "high-collared vest."[50] In the human infant the most predominant deposits are around the kidneys and in the intrascapular area of the back, extending up the dorsal neck.

The oxygen consumption of BAT cells in vitro is increased by 10-fold on exposure to norepinephrine, which mediates its effects primarily via β_3 but also via α_1 receptors on the cell surface.[33,51] The thermogenic properties of BAT are a result of the action of uncoupling protein 1 (UCP1), which is found only in BAT. Activation of β_3 receptors results in increased G_s subunit activity, leading to adenylate cyclase activation and increased cyclic adenosine monophosphate (cAMP) production, which ultimately results in the simultaneous release of free fatty acids from cytosolic stores and activation of UCP1 (Figure 57-4). UCP1, which is located in the mitochondrial membrane, facilitates the free movement of protons into the mitochondrial matrix, allowing them to bypass ATP synthase, and hence uncoupling oxidative respiration from the production of ATP. The result is unhindered oxidative metabolism with the resulting energy released as heat rather than being captured in the form of ATP.[33]

In vivo, functional innervation of BAT by sympathetic neurons occurs as early as gestational day 120 in the fetal sheep and increases gradually until birth.[52] Thus BAT is not only readily activated immediately on birth at term, but can also play an important role in thermoregulation of premature infants, as is discussed later.

In addition to sympathetic input are a number of hormonal regulators of BAT growth and activation. BAT is rich in 5′-monodiodinase, the enzyme that converts thyroxine (T_4) to (T_3). Plasma T_4 concentrations increase gradually during the last half of gestation, and then double abruptly at birth, with corresponding increases in both plasma and BAT-localized T_3. Increases in circulating concentrations of T_4 result in increased UCP1 content in BAT, an effect likely mediated by local conversion of T_4 to T_3 within the BAT rather than by circulating T_3.[53,54]

Leptin, a 16 kDa protein member of the cytokine family, is released primarily from white adipose tissues, but also by BAT and the placenta.[55] Leptin concentrations in the fetal sheep rise abruptly within days of birth and then fall just as abruptly following parturition, when UCP1 levels are at a peak.[56] In the adult rat, plasma leptin concentrations stimulate increases in UCP1 levels.[57] In contrast, leptin administration in the newborn lamb results in decreased UCP1 and UCP1 mRNA concentrations

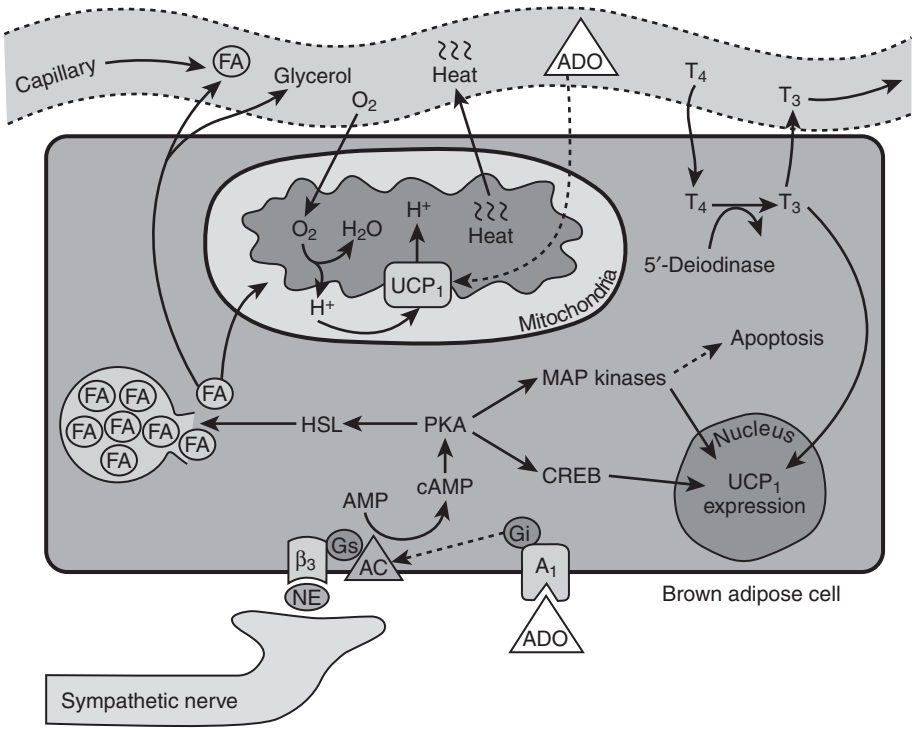

Figure 57-4 Some metabolic and hormonal controls of brown adipose tissue (BAT). *Solid arrows* indicate stimulatory influences, *dashed arrows* indicate inhibitory ones. The principal means of BAT activation is through norepinephrine (NE) released from sympathetic nerve endings. NE binds to β_3 receptors on the cell surface, activating G_s and adenylate cyclase (AC), resulting in increased concentrations of cyclic adenosine monophosphate (cAMP). cAMP activates protein kinase A (PKA). PKA phosphorylates hormone-sensitive lipase (HSL), which in turn liberates free fatty acid (FA) from triglyceride droplets. FA stimulates the activation of uncoupling protein 1 (UCP1), resulting in increased oxygen consumption and heat production. PKA also activates myosin-activated protein (MAP) kinases responsible for inhibiting apoptosis, and stimulates expression of UCP1 by activation of MAP kinases and the transcription factor cAMP responsive element binding protein (CREB), thyroxine (T_4) from the circulation is converted to triiodothyronine (T_3) by 5′-monodeiodinase. Activation of BAT results in increased concentrations of circulating FA, glycerol, and T_3, and increased consumption of oxygen (O_2). Adenosine (ADO) is thought to inhibit BAT activation by binding to A_1 receptors on the cell membrane, resulting in G_i activation and decreased AC activity. ADO may also have a direct inhibitory effect by binding to UCP1.

with little effect on thermoregulatory capability,[55] and although leptin concentrations appear to rise and fall in advance of those of UCP1 in the fetal and newborn lamb, whether leptin actually effects BAT remains uncertain.

Plasma concentrations of cortisol, a corticosteroid released by the adrenal gland, surge during the 72 hours prior to birth of the fetal sheep. Cortisol appears to have a direct effect on BAT, by stimulating increased production of UCP1, and indirect effects by stimulating the release of T_4 from the thyroid.[58]

Prolactin is a single 24 kDa chain of 199 amino acids secreted from the anterior pituitary. Its effects are mediated by cell surface receptors located on a number of tissues, including BAT. Plasma prolactin concentrations and BAT prolactin receptor numbers increase shortly before birth, peaking at 6 hours after birth in the newborn lamb. Recent evidence suggests that prolactin may have potent BAT-activating effects because its intravenous infusion into newborn lambs results in rapid increases in core body temperature and circulating concentrations of fatty acids and glycerol.[59] These metabolites are reliable indices of BAT activity as is discussed in the following text.

INDICATORS OF THERMOGENIC RESPONSE

After birth the temperature of the mammalian newborn typically falls, and the newborn responds by increasing O_2 consumption and thus heat production. These responses begin within a matter of minutes and can persist for many hours.[45] They are particularly strong in the lamb, calf, and rabbit,[60] species in which heat production increases three- to five-fold, and are less powerful in the human, in whom heat production approximately doubles. When at their maximum level, these responses are called *summit metabolism*.

Much of what is known about the control of nonshivering thermogenesis in utero and at parturition has been determined from the fetal sheep model represented in Figure 57-5. In these experiments fetal sheep are surgically instrumented with tracheal intubation for mechanical ventilation, cooling coils wrapped around the thorax to simulate cutaneous cooling, and an umbilical cord snare to eliminate placental blood flow. After allowing the fetus to recover from the surgery for 2 to 3 days, the stimuli of birth can be administered in utero in a stepwise manner and in any combination, while responses of oxygen consumption, temperatures, and circulating concentrations of thermogenic mediators and metabolites are sampled.[61,62]

Glycerol and fatty acids are the two major biochemical products of lipolysis, and their plasma concentrations provide useful indicators of nonshivering thermogenesis (Figure 57-6). With glycerol, only negligible quantities of glycerol kinase are present in brown adipose tissue.[33] Therefore, glycerol released within the adipocyte spills into the circulation and is metabolized elsewhere, principally in the liver. Once released into the circulation, glycerol is cleared slowly from the blood and does not pass freely across the ovine placenta. For these reasons circulating concentrations of glycerol have proved to be a useful index of lipolysis, and serve as an index of nonshivering thermogenesis in the fetus and newborn.[63]

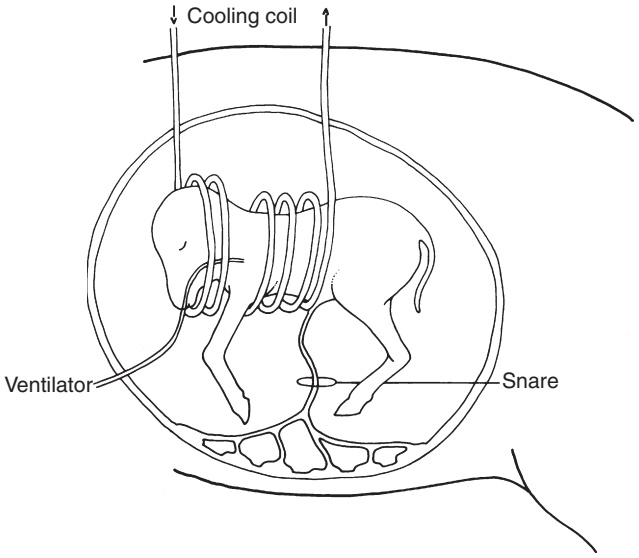

Figure 57-5 Method to study thermogenesis in fetal sheep. Responses to cooling ventilation, and oxygenation, cord occlusion, and the infusion of hormones can be tested separately. *(From Power GG, Gunn TR, Johnston BW, Gluckman PD: Oxygen supply and the placenta limit thermogenic responses in fetal sheep,* J Appl Physiol *63(5):1896, 1987.)*

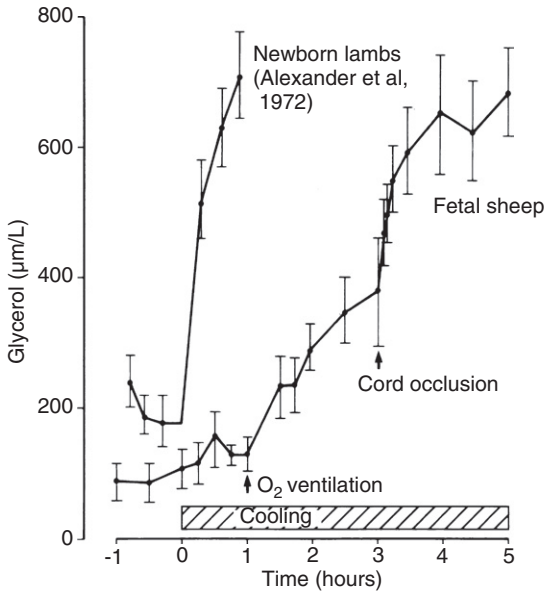

Figure 57-6 Plasma glycerol, an indicator of nonshivering thermogenesis, rises rapidly and markedly in newborn lambs exposed to cold. It rises only negligibly, however, in cooled fetal sheep and only moderately after supplemental oxygen is given. Only after cord occlusion do responses approach newborn levels. This result suggests an intrauterine inhibitor of fetal thermogenesis, possibly of placental origin.

Fatty acids differ from glycerol in several important respects. Most are oxidized or re-esterified locally within the fat itself. Some, however, enter the circulation and are transported to the heart, brain, diaphragm, and skeletal muscle in which they provide metabolic fuel and serve as the predominant substrate for shivering. This dispersal of lipid energy reserves permits a more generalized and prolonged thermogenic response than would otherwise be

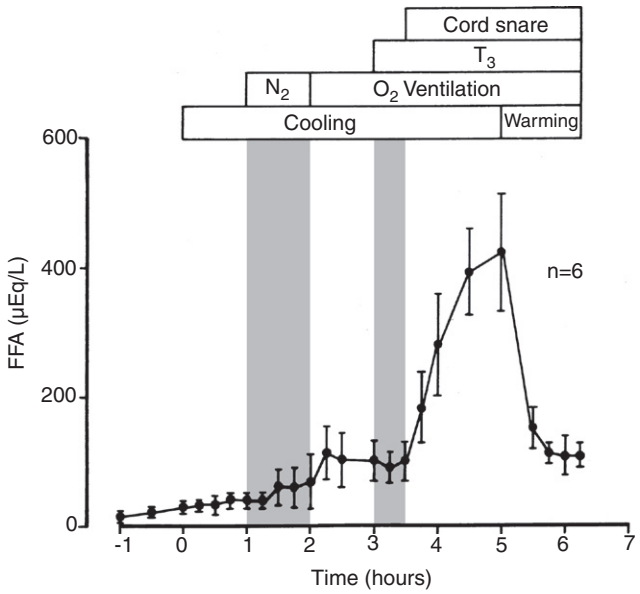

Figure 57-7 Plasma free fatty acids, an index of nonshivering thermogenesis, do not rise appreciably in response to cooling and nitrogen (N_2) ventilation in fetal sheep. Supplemental oxygen and infusion of large quantities of triiodothyronine induce only modest responses. Only after cord occlusion do responses approach a significant fraction of newborn levels. These results suggest that a metabolic inhibitor of placental origin circulates before birth. *(From Power GG, Gunn TR, Johnston BM, Nichols G, Gluckman PD: Umbilical cord occlusion but not increased plasma T_3 or norepinephrine stimulate brown adipose tissue thermogenesis in the fetal sheep,* J Dev Physiol *11(3):171, 1989).*

possible and links shivering in skeletal muscle with nonshivering thermogenesis in BAT. As is the case with glycerol, plasma concentrations of fatty acids are closely related to nonshivering thermogenic activity in the newborn period (Figure 57-7).[64]

Thermogenesis In Utero and at Birth

Fetal thermogenesis is normally inactive despite the ability of fetal BAT to be activated when studied in vitro[65] and despite the fact that even the prematurely delivered lamb can achieve thermoregulation. A number of studies indicate that both shivering[35] and nonshivering[63,66] thermogenic responses to cold are minimal in utero. This is shown in Figure 57-6, in which cold-induced responses in plasma glycerol in newborn lambs are compared with those in fetal sheep. Despite intense cooling by artificial means, and despite reductions in fetal core temperature of more than 2° C, the fetal response can be seen to be relatively weak. Responses in plasma free fatty acids and other indicators of thermogenesis (Table 57-1) are also attenuated and are not stimulated by ventilation with either nitrogen or oxygen nor by exogenous triiodothyronine (see Figure 57-7). Infusions of norepinephrine to the fetus in utero also result in only minimal BAT activation.[67,68] All these observations suggest a functionally capable but unused heat-producing capacity in the fetus.

Inhibition of Thermogenesis In Utero

The inability to activate fetal thermogenesis despite intense stimulation and supplemental oxygenation raises the possibility that nonshivering thermogenesis is suppressed in utero. It can be seen from Figures 57-6 and 57-7 that maximal responses are not observed until the umbilical cord is clamped. In fact, in the

presence of cooling and oxygen ventilation in utero, BAT can be activated and deactivated repeatedly by occluding the umbilical cord with a reversible occluder.[69] Likewise, newborn lambs exposed to cold are unable to initiate lipolysis if patency of the umbilical cord is maintained.[70] These studies suggest the presence of one or more circulating inhibitors of thermogenesis produced by the placenta that suppress BAT.

There is evidence that adenosine and certain prostaglandins (such as prostaglandin [PG] E_2) are circulating inhibitors of fetal thermogenesis. Both adenosine[71] and PGE_2[72] are produced by the placenta and have short plasma half-lives. The short effective biologic half-life of these compounds is consistent with the onset of thermogenesis within minutes after placental separation at birth. Pharmacologic blockade of these compounds in utero during oxygenation and cooling stimulates BAT activation without umbilical cord occlusion.[72,73] Conversely, administration of either of these compounds or their analogues following cord occlusion inhibits the activity of BAT.[61,72] These findings provide strong evidence of thermogenic inhibitors that circulate before birth. An alternative mechanism is that cord occlusion may stimulate BAT by diverting blood flow from the placenta to the BAT, though this possibility has not been studied thoroughly. Current knowledge about potential stimuli and suppressors of nonshivering thermogenesis at the time of birth is summarized in Table 57-2.

CAESAREAN SECTION AND THERMOGENESIS OF THE NEWBORN

The route of delivery influences the strength of thermoregulatory responses immediately following birth. Full-term infants delivered by cesarean section have lower body temperatures that average approximately 0.3° C less than temperatures of infants delivered vaginally.[74] BAT activation and UCP1 levels are depressed in newborn lambs delivered by cesarean section compared with those delivered vaginally.[75] Sympathetic activity, plasma levels of catecholamines,[75,76] and plasma levels of thyroid hormones[77] are reduced in infants and lambs delivered by cesarean section. The ability of the newborn lamb to regulate its temperature is improved by intravenous administration of norepinephrine, T_3, or thyrotropin-releasing hormone at the time of cesarean section delivery.[78] The potential benefit of similar treatments in the human newborn appears not to have been tested in a controlled study.

TABLE 57-1

Indicators of Thermogenic Activity in the Mammalian Fetus and Newborn

Sign	Usefulness and Comment
Plasma free fatty acid concentration	Fatty acids are products of lipolysis; many re-esterified without being oxidized; rapid turnover and quick response
Plasma glycerol concentration	Glycerol is also a product of lipolysis; slow turnover and damped response
Body temperature	Nonspecific; thermal inertia causes delays; insensitive
Difference between brown adipose tissue and body core temperature	Highly specific; difficulty arises in verifying location of brown adipose tissue temperature sensor
Oxygen consumption	Relatively nonspecific because measurement includes basal oxygen use as well as shivering and nonshivering components
Direct calorimetry	Research laboratory procedure requiring specialized equipment

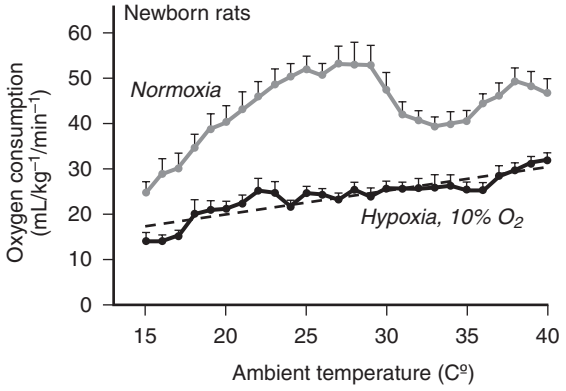

Figure 57-8 An illustration of the relationship between ambient temperature and oxygen consumption of the normoxic *(open circles)* and hypoxic *(closed circles)* 2-day-old rats. Normoxic rats respond to cooling with a marked increase in oxygen consumption due to thermogenic efforts, resulting in a summit metabolic rate at approximately 28° C. These thermogenic increases in oxygen consumption are abolished by hypoxia. *(From Mortola JP: Implications of hypoxic hypometabolism during mammalian ontogenesis,* Respir Physiol Neurobiol *141(3): 345–356, 2004.)*

TABLE 57-2

Sources and Effects of Major Mediators of Nonshivering Thermogenesis in the Mammalian Newborn

Compound	Concentration Changes During Gestation and Parturition	Major Fetal/Newborn Source	Effect on Brown Adipose Tissue
Norepinephrine	Increases after placental separation and in response to cooling	Sympathetic nerve endings within BAT	Stimulates activation of BAT through the β_3 and α_1 receptors
Triiodothyronine	Rises gradually during gestation, then rises sharply at birth	Conversion of thyroxine within BAT by 5′-monodeiodinase	Stimulates production and increases activity of UCP1 within BAT
UCP1	Rises gradually during gestation, peaking at birth, declines thereafter	BAT	Mediates the uncoupling of oxidative phosphorylation in BAT
Prostacyclin	Low during gestation, then increases with onset of ventilation	Lungs	Stimulates lipolysis
Cortisol	Rises near the end of gestation	Adrenal gland	Stimulates thyroid activity and UCP1 production in BAT
Adenosine	High during gestation then falls sharply at birth	Placenta and other organs	Inhibits BAT activation
Prolactin	Increases during gestation, peaking within hours after birth	Anterior pituitary	Activates BAT, increases UCP1
Prostaglandin E_2	High during gestation, then falls sharply at birth	Placenta and other organs	Inhibits BAT activation

BAT, Brown adipose tissue, brown fat; *UCP1,* uncoupling protein 1.

HYPOXIA AND THERMOGENESIS OF THE NEWBORN

Thermogenic responses are costly in terms of oxygen and substrate use. In the newborn pig, dog, rat, and sheep, exposure to cold can increase oxygen use by 100% or more. This increase in metabolic rate is attenuated if hypoxia accompanies exposure to cold (Figure 57-8).[79] The inhibition of thermogenic activity by hypoxia appears to be an adaptive response in that it conserves oxygen that would otherwise be used to generate heat.[80,81] Normally thermogenic activity occurs when temperature in the hypothalamus drops below the normal setpoint. Hypoxia may decrease thermogenic metabolism by reducing or overriding the activation of BAT by sympathetic outflow in response to cold.[82] By allowing body temperature to remain at lower than normal levels, the organism also rations the limited oxygen available by depressing the rate of enzymatic processes due to the Q_{10} effect. This phenomenon of metabolic hibernation in response to hypoxia is particularly prominent in smaller, younger, and more metabolically active newborns of many species[83] and has been demonstrated in the fetal sheep.[84] Careful clinical testing is needed to evaluate its presence and possible use in medical practice.

Temperature Control in Newborn Infants

This chapter is an updated revision of Dr. Kurt Brück's comprehensive treatise on neonatal thermal regulation presented in earlier editions; it is not an original synthesis of the current authors. Brück remains the senior contributor despite his death in 1995. We have immense admiration for his many contributions to our understanding of the physiology of human neonates. His classic study of temperature regulation[1] provided fundamental knowledge, which has been validated and refined in subsequent years. Using continuous measurements of heat production and cutaneous blood flow, before, during, and after discrete and timed environmental cold stress, Brück defined the fundamental features of the neonatal response to chilling and its dependence on gestational and postnatal ages. These important observations concerning the basic responses of infants to cold—increased heat production and decreased heat loss, as well as the timing of these events and their development pattern—remain central to our understanding of how best to care for human neonates.

CURRENT MODELS AND TERMINOLOGY

It is useful to model the temperature control system of newborn infants using the basic biocybernetic concept of a passive (i.e., controlled) system, the temperature of which depends on metabolic heat production and heat transfer to the environment. The controller consists of sensor, integrator, and effector components (Figure 58-1). Current understanding is that information about heat storage and heat gradients within the body is monitored continuously by various central and peripheral thermal sensors. These multiple inputs are transmitted to an integrating neural control network, located in the hypothalamus and limbic systems, which, in turn, is linked by means of efferent neuronal pathways to effector mechanisms that are capable of controlling heat storage. The earlier concept that the controlled variable is a single temperature at a single site within the body has been refined to take into account evidence that temperatures at multiple sites provide important input to the controller.[2-5]

For clarity, the following discussion is structured according to this controller model, reviewing information about the sensors, integrator, and effectors as separate components followed by a consideration of how the integrated control system functions in response to environmental thermal transients, how the system changes during development, and how it operates under special circumstances, such as fever, heart failure, and hypoxia.

PRINCIPLES OF PHYSIOLOGIC TEMPERATURE REGULATION

The maintenance of a stable body temperature that is much warmer than the environmental temperature is a property of the two higher classes of the animal kingdom: birds and mammals.

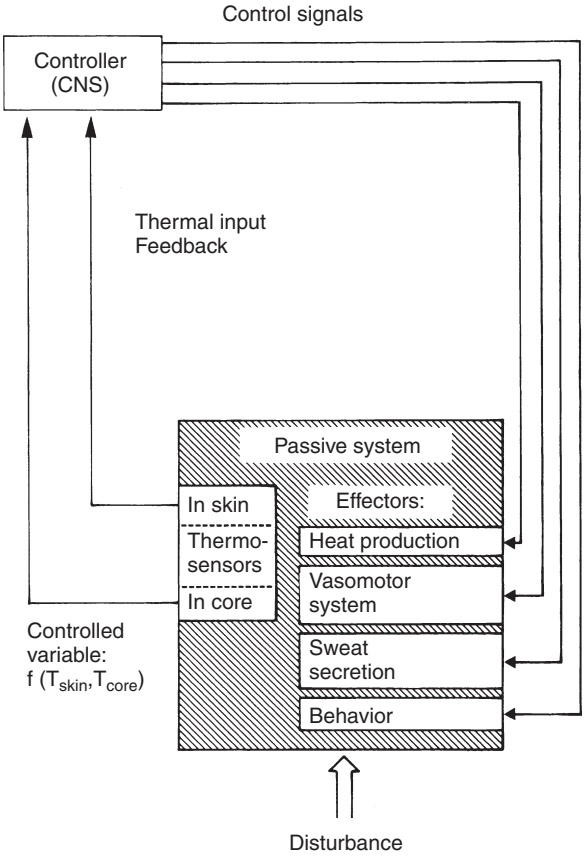

Figure 58-1 Diagram representing the biocybernetic concept of temperature regulation in humans. Temperature is sensed at various sites of the body, and the temperature signals are fed into the central controller *(multiple-input system)*.

These classes form the group of *homeothermic* beings, all others designated as *poikilothermic*. A prerequisite of *homeothermy* is a basal rate of metabolism several times higher than that in poikilothermic animals. The former are thus referred to as *tachymetabolic* and the latter as *bradymetabolic* organisms. Furthermore, homeothermy requires a balance among heat production, skin blood flow, sweating, and respiration in such a way that changes in heat loss or gain from the environment are precisely compensated.

METABOLISM AND HEAT PRODUCTION

Metabolic processes that provide energy for maintenance of homeostasis and physical exercise are closely linked with heat production. The overall efficiency of energy transformation in homeotherms is only on the order of 10% to 25%, meaning that most of the energy transformed during metabolic activities is liberated as heat and must either be eliminated or stored depending on the needs of the organism. For organisms that are tachymetabolic (including human neonates), the at rest metabolic rate alone is sufficient to increase body temperature by several degrees Celsius greater than the ambient temperature. The at rest metabolic rate is of great importance for the state of the controlled system (see Figure 58-1).

Standard Metabolic Rate

The at rest metabolic rate depends on several factors, including physical activity, environmental temperature, feeding, thermic effect of food, diet-induced thermogenesis (formerly called *specific dynamic action*), time of day (diurnal rhythmicity), age, and growth rate. By convention, the conditions used for the measurement of at rest metabolic rate have been standardized: (1) subjects must be awake and have fasted at least 12 hours; (2) they must be fully relaxed; and (3) thermoneutral conditions should be maintained.

Metabolic rate measured under these standard conditions is termed the *basal metabolic rate* (BMR). Neonates are unlikely to fulfill the first and second standard conditions at the same time; thus special conditions for measurement must be defined. The following conditions have been suggested[6]:

1. The infant should remain on a normal feeding schedule (this suggestion is not unreasonable because the maximum increase in energy metabolism in infants is only 4% to 10% after an ordinary feeding).
2. The measurements must be made in a period of 5 to 10 minutes, during which the infant is fully relaxed (in contrast with the BMR standard conditions, the infant does not have to be awake). The metabolic rate determination may even be made during postprandial sleep.[7]
3. The measurements must be made under thermoneutral conditions.

The minimum metabolic rate measured in this way is called the standard metabolic rate (SMR) or minimum observed metabolic rate.[8] The designation BMR should be used only for determinations performed under standard conditions as employed in adults. Depending on why the metabolic rate is being measured, longer periods of observation (i.e., 3 to 6 hours) are required.[9,10]

Standard Metabolic Rate in Relation to Body Mass and Age

Total heat production is related to body size; for example, the overall metabolic rate of sheep is greater than that of rabbits. Because body temperatures of homeothermic species are close to one another at similar preferred environmental temperatures, it can also be anticipated[11] that the metabolic rate per kilogram of body mass will be larger in a rabbit than in a sheep. In fact, the correlation of the logarithm of body weight and the logarithm of at rest metabolic rate (oxygen consumption) is close and has a slope of 0.75 for adult animals of various sizes. This means that the metabolic rate per kilogram$^{3/4}$ of at rest animals of different sizes, including adult humans, is independent of body size. This relationship has been termed the *law of metabolic reduction* by Kleiber[11] and has been found useful by some observers for cross-species comparisons of the physiology of metabolism.

Although the Kleiber equation can be useful for predicting metabolic rates when comparing different species, attempts to predict metabolic rates for a group of individual organisms within the same species but of different body sizes reveals its limited applicability. Several deviations from the law of metabolic reduction must be introduced. Age, sex, body shape, and body composition affect metabolic rate. The age dependency of metabolic rate makes it impossible to predict the metabolic rates of neonates and adults from an individual species with a single exponential function of weight, even if a higher exponent than Kleiber's is used.[1]

As illustrated in Figure 58-2, newborn infants to 1 week of age have a SMR that is lower than that predicted by Kleiber's equation; that is, the SMR is lower in a 3-kg human newborn than in a 3-kg rabbit. Conversely, in the weight range of 5 to 20 kg, the SMR is higher in human infants than in adult animals of the same weight. During this period of growth, the SMR demonstrates a nearly linear relationship to body weight. Mathematically, this relationship can be expressed by an exponent of $b = 1$ in the equation $SMR = a \times m^b$ where a is age and m is mass. During the

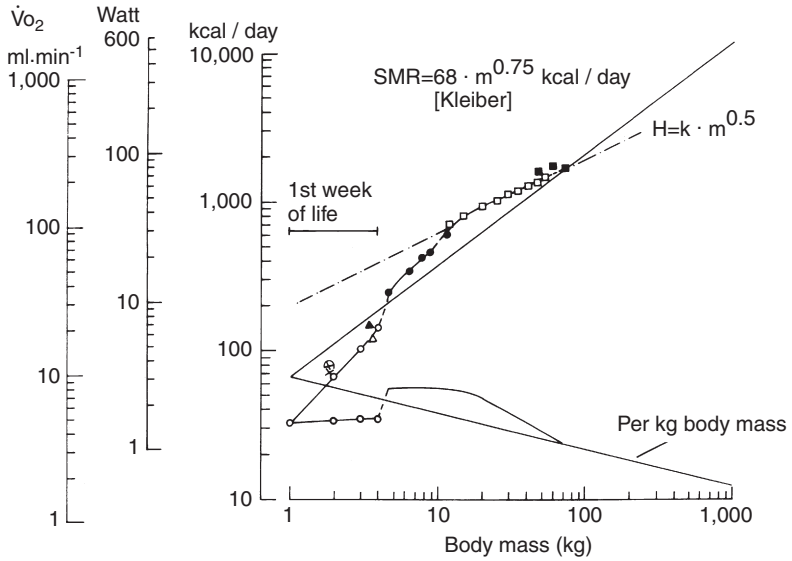

Figure 58-2 Relationship of standard metabolic rate (SMR) to body mass and age. *Top curve,* SMR and the corresponding $\dot{V}o_2$ in relationship to body mass. *Bottom curve,* The same data but expressed in relation to unit of body mass. — = SMR according to Kleiber's equation; ·—·—·—, heat production that would yield equal temperature differences between body core and environment. (See text for further discussion.) ○, first week of life[1]; △, 0-6 hr[123]; ▲, 18-30 hr[123]; ×, 4-12 hr[109]; ⊗, 1-2 days[109]; ●, 1-36 mo[124]; □, 3-15 yr[125]; ■, 14-30 yr.[126] *(Modified from Brück K: Heat production and temperature regulation. In Stave U [ed]:* Perinatal Physiology. *New York, Plenum Publishing, 1978, pp 455-498.)*

period that corresponds to the weight range of 20 to 70 kg, the SMR approaches data in Kleiber's curve.

An exponent close to 1, or somewhat larger than 1, should also be used to calculate the SMR for infants weighing between 1 and 4 kg. This means that during the neonatal period, the SMR/body mass unit is almost independent of weight, whereas a decrease would be expected with increasing weight according to Kleiber's equation (see Figure 58-2). These SMR values demonstrate a relatively large amount of scatter during the first day of life. A survey of these data and a discussion of the possible reasons for the scattering may be found in the references.[7,12] Given these limitations, attempts to refer observations of the metabolism of human neonates to standards derived for other mammals should be avoided.

Certain quantitative changes in the SMR during early postnatal development are worth keeping in mind:

1. Immediately after birth, the SMR/kg body mass is lower in human infants than in adult animals of the same weight (see Figure 58-2).
2. After birth, the SMR/kg body weight increases and eventually attains a value that is up to 50% higher in infants than in adult animals of the same body mass. The time course of this process appears to be variable. It may take 2 days to a few weeks (particularly in premature infants) to attain values that are characteristic of the postneonatal period.[7,12]

The seeming violation of the law of metabolic reduction (see Figure 58-2) during the early neonatal period may be only a fictitious problem if one takes into account the considerable change in extracellular water content (extracellular fluid [ECF]) that occurs from the early fetal to the adult stage. Sinclair et al[13] have suggested using body weight minus ECF as the reference value in metabolic reference standards. According to their calculations, ECF composes as much as 44% of body weight in a 4000-g newborn infant and 58% in a 1000-g premature neonate. The corresponding average value for ECF in the adult is only 20%. Because the ECF does not participate in oxidative metabolism, the expression "body weight minus ECF" may be considered representative of the active tissue mass. Thus it seems theoretically justified to relate metabolic rate to this active tissue mass rather than to total body weight. In contrast, the lean body mass (i.e., total body mass minus fat mass) has not been found to be a suitable reference value.

One can also relate metabolic rate in a neonate to the expression "active tissue mass plus adult ECF," that is, to a body mass that corresponds in composition to that of the adult organism. Metabolic rates related to this calculated value closely approximate Kleiber's curve, whereas the metabolic rate related to the actual body weight remains less than the predicted values.[7]

Metabolic Rate in Relationship to Body Temperature

All chemical reactions in an organism are temperature dependent and obey van't Hoff's law. According to this law, oxygen uptake and body temperature of a poikilothermic animal are expected to decrease with decreasing environmental temperature. This decrease has, in fact, been demonstrated in frogs, reptiles, and other poikilothermic animals without exception. The ratio of the reaction rates at temperatures differing by 10° C is called the Q_{10}. In general, the Q_{10} for the metabolic rate in poikilothermics is approximately 2 to 3. van't Hoff's law applies to homeotherms in the same way but is masked by regulatory processes.

Thus, in the intact homeothermic organism, the metabolic rate increases initially with decreasing body temperature (Figure 58-3). This *regulatory metabolic rise* can be prevented by pharmacologic intervention, in particular by deep general anesthesia. As shown in Figure 58-3 (which illustrates the relationship between metabolic rate and rectal temperature in anesthetized dogs), metabolic rate decreases with decreasing body temperature in both cold-induced and basal conditions (bottom curve in figure). In other words, van't Hoff's law is obeyed. The slope of the curve corresponds to a Q_{10} of 2 to 3. At body temperatures less than 30° C, the metabolic rate may drop steeply to the basal curve (*dashed line* in Figure 58-3) because the thermoregulatory drive generated in the thermointegrative areas of the central nervous system vanishes with increasing hypothermia. The body temperature range at which this reduction occurs may be species dependent.

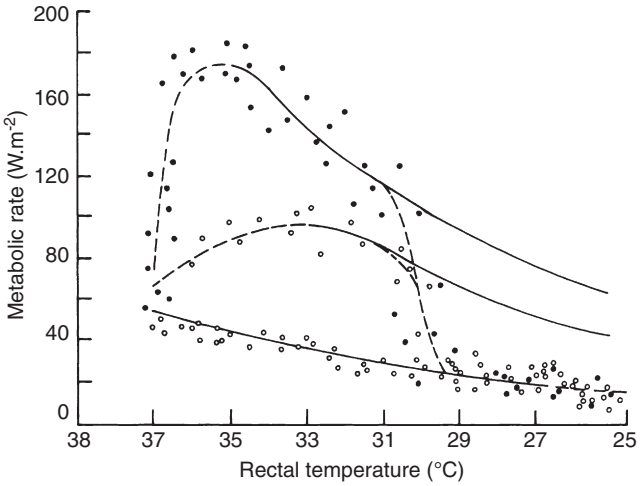

Figure 58-3 Relationship between metabolic rate and rectal temperature in anesthetized dogs, the body temperatures of which were manipulated by intravascular heat exchangers. *Top curve,* Light anesthesia; thus a marked cold-induced increase in heat production with decreasing body temperature was observed. *Middle curve,* Moderate anesthesia; the response of heat production to cooling is reduced. *Lower curve,* Deep anesthesia; no cold defense reaction. After having reached a maximum, thermoregulatory heat production follows van't Hoff's law. Note that the upper and middle curves tend to approach the lower curve as soon as the rectal temperature drops below a critical temperature (about 30° C). (*From Behmann FW, Bontke E: [Regulation of heat formation in artificial hypothermia. I. Experimental studies on the effects of depth of anesthesia.]* Pflügers Arch *266:408, 1958.*)

Before describing the response of the integrated system to changes in environmental temperature, we review what is known about the individual components of the biocybernetic model.

THERMAL SENSORS: THERMORECEPTIVE STRUCTURES AND THE THERMOAFFERENT SYSTEM

Location and Properties of Cutaneous Thermal Receptors

The cutaneous thermal receptors are a group of structures that function as temperature sensors in the temperature control system (the term *sensor* is gaining preference to *receptor* to avoid confusion with chemical structures reacting with specific substances. Both terms are used interchangeably within this section). It is generally agreed that the cutaneous thermosensors in the thermoregulatory system are identical with those mediating thermal sensation. The distribution of the cutaneous thermoreceptors can thus be studied in adult humans by stimulation of so-called warm and cold spots using fine temperature probes. There is scarcely any area of the skin that does not respond to cold stimulation, although the number of cold spots/cm^2 may vary between one and five on the palm of the hand and more than 15 on the face. The number of warm spots/cm^2 is much less in all skin areas (0.3 to 1.7). This agrees with the better spatial resolution of cold stimuli, but it does not mean that cutaneous warm sensitivity is any less developed than is cold sensitivity. In fact, with larger stimulus areas (using thermodes of 10- to 100-cm^2 contact areas), warm sensitivity can be demonstrated on all skin areas with few exceptions (cornea, glans penis).[14] Employing electrophysiologic methods (recording single-receptor activity from nerves), warm and cold receptors have been demonstrated on the faces of cats and other species and on the lower arms and legs of monkeys.[14] By inserting fine metal electrodes through the intact skin into a branch of the radial nerve, it has even been possible to record the activity of single warm and cold receptors in humans in response to thermal stimulation on the skin of the back of the hand.[15]

The morphologic correlate of cold sensors is the fine unmyelinated nerve endings penetrating into the basal layer of the epidermis.[16] These endings contain numerous mitochondria, providing energy for a temperature-sensitive Na^+, K^+ pump, which seems to be part of the transduction of the cold stimulus into an electrical signal.[17]

Figure 58-4 illustrates the average response characteristics of cold and warm receptors from different species (including humans) under static conditions (i.e., after the temperature of the skin had been constant for several minutes). Minimum activity occurs at a skin temperature of 35° C. The maximum discharge frequency of cold receptors is found between 35° and 20° C and that of warm receptors takes place between 40° and 45° C. At temperatures greater than 45° C, warm-receptor activity decreases. At temperatures lower than approximately 25° C, the activity of cold receptors may also be reduced.

Sensor activity during temperature changes is noteworthy in that receptor discharges may reach frequencies that are two- to threefold greater than under static conditions. Irrespective of the initial temperature, a warm receptor will always show an overshoot of its discharge on sudden warming and a transient inhibition on cooling, whereas a cold receptor will respond in the opposite way (with an inhibition on warming and an overshoot on cooling). Correspondingly, sensitivity to temperature changes is amplified and increases with the size of the exposed area. With exposure of larger areas (e.g., the whole hand), a temperature change of less than 0.01° C per second may evoke a thermal sensation[18] and probably a regulatory reaction.

In summary, thermoregulatory responses elicited through cutaneous thermoreceptors are determined by the average skin temperature (T_{skin}), the rate and direction of temperature change ($\Delta T_{skin}/\Delta t$), and the size of the stimulated area.[14,18] Because of the temperature discharge characteristics (see Figure 58-4), warm receptors may contribute to the stimulation of heat dissipation actions only when mean skin temperature is considerably increased higher than normal levels.

Location and Properties of Internal Thermosensitive Structures

Evidence for the existence of deep body thermosensors has been obtained in three ways: (1) by demonstrating that there is poor correlation between body temperature and the action of the final control elements if only skin temperature is taken into consideration,[19] (2) by observing thermoregulatory actions after heating and cooling of circumscribed areas within the body using implanted thermodes and vascular heat exchangers,[20] and (3) by recording the activity of single units of the central nervous system and relating these responses to their own local temperatures.[21]

Hypothalamus

According to thermal stimulation studies (using thermodes implanted on a long-term basis), deep body thermosensors are located in the preoptic area and the anterior hypothalamus. Local warming of this region stimulates heat-dissipating mechanisms (i.e., vasodilation, panting, sweating), whereas it inhibits heat production (i.e., metabolic reactions [Figure 58-5] and vasoconstriction). Inversely, cooling evokes heat production and vasoconstriction, whereas heat dissipation mechanisms are inhibited.

Thermal stimulation does not permit discrimination between internal cold and warm receptors (e.g., the effects of local

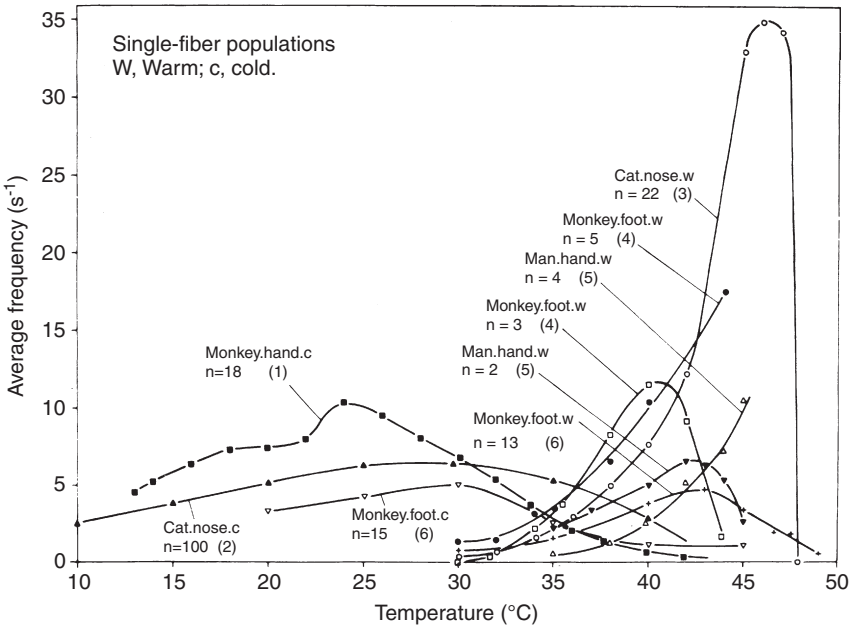

Figure 58-4 Average static discharge frequency of populations of cutaneous cold and warm receptors as a function of skin temperature obtained from various species and body sites by several authors. (*From Hensel H:* Thermoreception and Temperature Regulation. *New York, Academic Press, 1981.*)

cooling might be ascribed to actuation of central cold receptors and to the inhibition of central warm receptors). Here further clarification is obtained from single-unit studies.[21] As shown in Figure 58-6, warming of the preoptic area results in markedly increased activity of one single unit and leads to an increase in respiratory frequency (panting). Units like this are considered to be warm sensors.

In vitro studies of hypothalamic slices[22] and of cell cultures[23] have addressed the question of whether hypothalamic thermosensitivity is tied to individual thermosensitive ganglion cells or is based on the temperature dependence of synaptic transmission between afferent and efferent neurons (Figure 58-7). After synaptic transmission is blocked by electrolyte solutions with a low Ca^{2+} content and a high Mg^{2+} content, the structures in question remain sensitive to thermal stimuli. This implies the existence of thermosensitive cells within the preoptic region and anterior hypothalamus. Both areas contain not only warm-sensitive cells but also thermosensitive and cold-sensitive cells, the latter two being less numerous than the warm-sensitive cells.

Lower Brain Stem and Spinal Cord

Thermosensitive structures have also been demonstrated in the lower brain stem (midbrain and medulla oblongata), and thermoregulatory reactions can be initiated by local warming of these areas.[24] However, the thermosensitivity of this region is distinctly less than in the preoptic region and anterior hypothalamus.[20] In contrast, the spinal cord is extremely thermosensitive. When the temperature of the spinal cord is raised only a few tenths of a degree along its entire length in dogs and other animals, the results include panting, vasodilation, and inhibition of thermogenesis.[20,25] Cooling of the spinal cord elicits shivering, but in this case a greater temperature change is required. In newborn and young guinea pigs, a local temperature change in the region of the cervical cord suffices to trigger thermoregulatory reactions.[3]

Other Thermosensors

Quantitative considerations suggest the existence of thermoreceptive structures outside the central nervous system and the skin.[20] Experimental evidence for the presence of thermosensors in the region of the dorsal wall of the abdominal cavity and in the musculature exists. Evidence for the existence of subcutaneous thermosensors has also been confirmed.[26]

Afferent Thermosensitive Pathways

The cutaneous thermoreceptors are served by thin myelinated and unmyelinated axons belonging to the slowly conducting group III and group IV nerves. Warm fibers are mostly unmyelinated (group IV). The axons run within the afferent cutaneous nerve bundles, and they enter the spinal cord through the segmental dorsal root ganglia. Those axons cross over to the contralateral side and ascend within the spinothalamic tract in the anterolateral section of the spinal cord. On their way to the thalamus, the ascending thermal fibers join the medial lemniscus and are accompanied by the afferents coming from the trigeminal region. From the medial lemniscus, collaterals diverge and project to the hypothalamus through a pathway not definitively described. Evidence has been obtained that part of the cutaneous thermal input is conveyed through the spinoreticular pathway to the reticular formation; from there, it is projected to the hypothalamus through the raphe nuclei and the ventral noradrenergic system, which passes the subcerulean area.[24,27-29]

The spinal cord thermal sensors are connected to the posterior hypothalamus through axons running in an anterolateral pathway of the spinal cord, as has been shown in young guinea pigs[30] and in cats.[31,32] The thermosensors of the preoptic area also end in the posterior hypothalamus; however, these short pathways have not yet been identified.

INTEGRATION OF THERMAL INPUTS

Integration of Multiple Thermal Inputs

The theoretic concepts of thermoregulation require the demonstration of some elements that "process" the thermal information originating at the receptors in various sites of the body (multiple-input system) and that transform these inputs from the sensors into effector outputs.

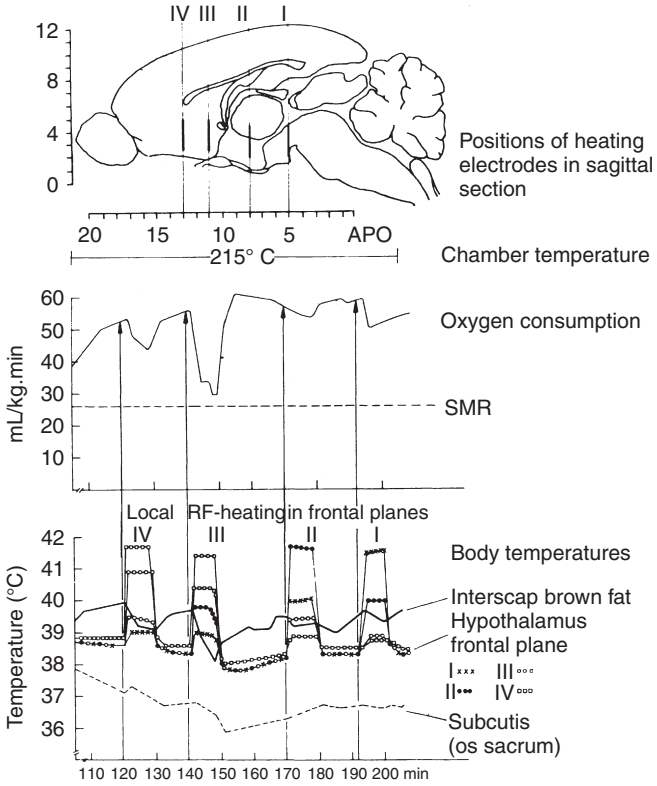

Figure 58-5 Effect of local radio frequency (RF) heating in different frontal planes of the hypothalamus on nonshivering thermogenesis (NST) induced by external cooling in a newborn guinea pig (for these small animals, an ambient temperature of 21.5° C is below neutral temperature). The upper part of the figure shows the projection of the four implanted electrodes on the sagittal section of the brain. The different frontal planes were locally heated in succession. Only heating of plane III, corresponding to the preoptic area and anterior hypothalamus, resulted in an almost complete suppression of the cold-induced NST (note reduction of the temperature within the interscapular brown fat). *SMR,* Oxygen uptake corresponding to standard metabolic rate. (*From Zeisberger E, et al: In Jansky L (ed):* Depressed Metabolism and Cold Thermogenesis. *Prague, Charles University, 1977, pp 182-187.*)

There are many experimental studies implicating the hypothalamus (especially the posterior hypothalamic area, which has no appreciable thermosensitivity) as an integration center for thermoregulation. This premise is further supported by electrophysiologic findings. For example, neurons exist in the posterior hypothalamic area, the activity of which (discharge rate) is influenced by local thermal stimulation in either the preoptic region or the cervicothoracic part of the spinal cord.[33] At the boundary between the anterior and posterior hypothalamus, neurons have been found that respond to changes in the skin temperature on the limbs and trunk.[24] The posterior hypothalamus, therefore, is characterized by the presence of thermoresponsive cells (i.e., cells that respond to changes in the temperature of distant structures but are not sensitive to changes in their own temperature). However, there is no absolute spatial separation of receptive and integrative functions. In the preoptic region and anterior hypothalamus, cells shown to be thermosensitive have also been found to be affected by skin temperature changes and thus are simultaneously thermoresponsive.[4,34]

A special feature of biologic thermoregulation (compared with the familiar simple technical system) is that two kinds of sensors in different locations (the cold and warm receptors) interact antagonistically. The cutaneous cold receptors are activated when the temperature decreases to less than the lower limit of the thermoneutral zone. This reaction is counteracted by heat-activated internal thermosensors when the body temperature increases as a result of overshooting cold-protective mechanisms or after bodily activity. This circuitry enables the protective mechanisms to be set in motion rapidly in case of external cooling, long before the core temperature has begun to decrease and internal thermoreceptors can be influenced.

Conversely, heat dissipation processes (vasodilation, sweating) may be activated by internal warm receptors, which are primarily stimulated when body core temperature increases. This effect is counteracted by cold activation of the cutaneous cold receptors. When the body is heated externally, sweat secretion is stimulated by the combined action of cutaneous and internal warm receptors.

Figure 58-8 shows a simplified model of the neuronal circuitry underlying the central nervous system integrative processes. Three kinds of neuronal elements are distinguished: (1) efferent neurons located in the hypothalamus, the axons of which activate the peripheral controlling elements (Figure 58-9) either directly or, more probably, by way of a chain of interneurons; (2) facilitative and inhibitory interneurons within the hypothalamus; and (3) thermal afferents, arising in part from the cutaneous thermoreceptors and in part from internal receptors (e.g., those of the preoptic region).

Cold receptors directly activate the effectors for thermogenesis. The inhibitory action on the efferents to heat loss effectors is exerted through interneurons. Activation of warm receptors excites the efferents to the heat loss effectors, simultaneously inhibiting (through interneurons) the efferents to the effectors for heat production. The various effector neurons may receive different combinations of thermal afferents. Thus, as shown in studies of newborn guinea pigs, nonshivering thermogenesis is driven by cutaneous cold receptors and is inhibited by hypothalamic warm receptors, whereas the inhibitory influence of shivering is exerted mainly by spinal cord warm-receptive structures (Figure 58-10). The cervical spinal cord is the region that preferentially receives (through vascular connections) the heat that is generated in the interscapular brown adipose tissue.[3,7,35] As a result of this "meshed control" of the two heat-generation mechanisms, shivering remains suppressed in neonates so long as sufficient heat is supplied from the interscapular brown adipose tissue to the spinal cord warm-sensitive structures and to intrathoracic organs.

Principles Guiding the Actions of the Integrator

Given that the thermosensitive structures are distributed over the entire body, the thermoregulatory effector actions (see Figure 58-9) cannot be described as a function of a single local temperature (e.g., the rectal temperature). Thus the goal of thermophysiology is to describe thermoregulatory actions as a function of as many as possible of the temperatures associated with the various thermosensitive parts of the body. Systems of equations with several variables are required for such a description. The data must be collected by experiments on animals in which spatially circumscribed temperature changes are produced by means of thermodes and heat exchangers[20]; in humans, limited opportunity exists for experimental manipulation of local temperature while the temperature of the rest of the body is kept constant. Only an approximate description is possible; the thermoregulatory parameters are presented as a function of two temperatures, the temperature of the interior of the body (measured at a representative site) and the mean skin temperature.[2,28,36] Shivering and sweating threshold temperatures, as well as the temperature pairs

yielding equal magnitudes of shivering and sweating, are represented by contour lines in a coordinate system with mean skin temperature and core temperature as the coordinates (Figure 58-11). Blood flow through the skin follows similar contour lines located between shivering and sweating threshold lines.[37] The contour plots portrayed in Figures 58-11 and 58-12, although involving only two temperatures, are good semiquantitative illustrations of the performance of the multiple input control system. Note that the relative impact of the sensors increases as temperatures become increasingly "out of range," and that the whole contour plot depends on other attributes such as the warm/cold adapted state of the animal. Within a certain range of temperatures (i.e., near the set point), at which the contour lines can be approximated by straight lines, it is possible to express the effector responses and the threshold temperature conditions for the elicitation of effector responses in terms of a weighted mean body temperature, T_b, calculated with the following linear equation:

$$T_b = a \times T_{core} + b \times T_{skin}$$

Data from human adults can be best fitted if values of 0.9 and 0.1 are chosen for the coefficients a and b, respectively.[28] Figure 58-12 shows the shivering threshold contour lines of adult humans, rabbits, goats, and young (4-week-old) guinea pigs. In addition, the threshold contour line for nonshivering thermogenesis in newborn guinea pigs is given. The curvilinear contour lines in small animals do not allow the use of arithmetic mean body temperature except for small sections of the temperature ranges that may be approximated by straight lines.

SET POINT AND NORMAL BODY TEMPERATURE

In a multiple-input system, the control actions of the thermoregulatory system can be ineffective at various combinations of temperatures. For instance, shivering remains suppressed so long as the combination of body surface and body core temperatures stays at or greater than the threshold contour line (see Figures 58-11 and 58-12). Conversely, heat dissipation actions will be ineffective so long as the combination of surface and internal temperature values remains less than the heat dissipation threshold hyperbola (see Figure 58-11).

Under environmental conditions that allow the control actions to reach ineffective levels, the deep body temperature will stabilize at a value typical for the species (if enough time is allowed to attain steady-state heat flow). This temperature, whether measured within the tympanic canal, the rectum, the esophagus, or

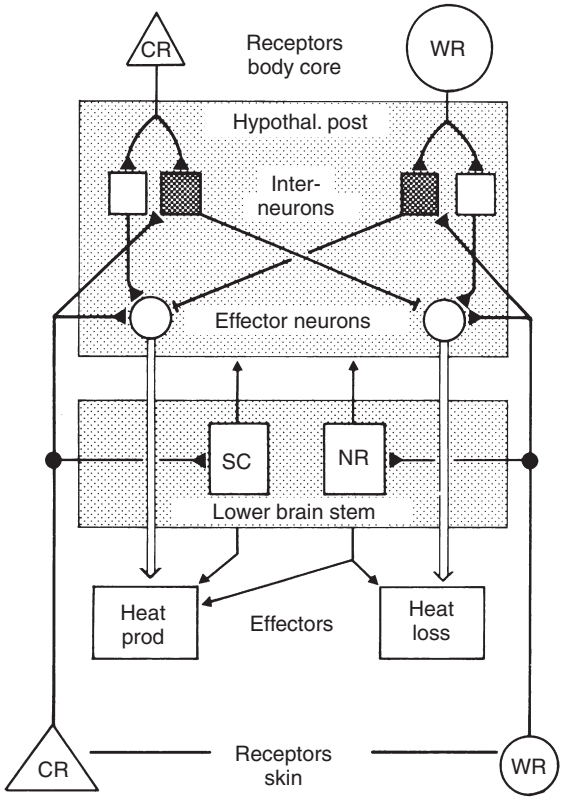

Figure 58-8 Highly simplified model of the connections between thermal afferents and the efferent neuronal networks that control the thermoregulatory effector elements. *Shaded areas* represent the thermointegrative regions of the hypothalamus (mainly the posterior hypothalamus) and the lower brain stem, which contain crucial structures for the processing of thermal information from the skin (*RN,* raphe nuclei; *SC,* subceruleus region). The inhibitory neurons shown *(cross-hatched squares)* mediate the reciprocal inhibition of the heat-losing and heat-generating processes. *CR,* Cold receptors; *WR,* warm receptors (size of the symbols indicates roughly the difference in numbers); ◀, activating; ⊣, inhibitory synaptic connections. The symbols for neurons represent not single neurons but neuron pools. Some details of the connections in the SC, RN, and hypothalamus are known but are not within the scope of this diagram. The *arrows* pointing down from the lower brain stem represent pathways to mononeurons and dorsal horn neurons in the spinal cord; the latter can suppress input from the warm afferents. (*Data from Brück K, Hinckel P: Thermoafferent systems and their adaptive modifications,* Pharmacol Ther *17:357, 1982.*)

elsewhere, may then be called the *normal body temperature*. Deviations of such a representative temperature from an empirically attained normal value may be described as a set-point displacement or, more specifically, as a deviation of the threshold temperatures for the respective control actions.

EFFECTOR RESPONSES OF THE THERMOREGULATORY SYSTEM

The effector outputs of the thermoregulatory controller restore the system to the desired set point by regulating both heat production and heat loss. After a brief review of the relationship between metabolic rate and environmental temperature, control of heat production and heat loss are discussed separately.

Metabolic Rate and Environmental Temperature

The cold-induced increase in metabolic rate (see Figure 58-3) is the most characteristic feature of homeothermic organisms. In the neonates of all homeothermic species studied thus far (except for the ground squirrel and golden hamster, which are hibernators), a cold-induced increase in metabolic rate has been demonstrated immediately after birth. Although this response may be small during the first hours of life, neonates should not be considered poikilothermic.

The influence of postnatal age on cold-induced thermogenesis is shown in Figure 58-13. As demonstrated by several investigators, oxygen uptake (directly proportional to thermogenesis) is distinctly greater at 28° C ambient temperature than at 32° to 35° C, even during the first few hours of life. At an ambient temperature of 23° C, oxygen consumption is even greater. Depending on the species, this cold-induced metabolic response increases to a greater or lesser extent during the first week of life. Preterm and small-for-date infants also increase their metabolic rate with cooling, and on average their response is not much less than that in full-term infants (see Figure 58-13). Oxygen uptake values of 15 mL/kg/minute measured at an ambient temperature of 23° C[1] and of 16.8 mL/kg per minute measured at 26° C[38] appear to represent the maximum (summit) metabolic response to cold in 1-week-old full-term infants. For comparison, in well-trained young adults, summit oxygen consumption may increase to five times the at rest level, that is, to 17 to 20 mL/kg per minute, when the environmental temperature is maintained at 0° to 5° C.

The maintenance of a constant body temperature requires that heat loss and heat production be equal in the steady state. Figure 58-14 illustrates the possible ways in which body temperature can be kept constant when the environmental temperature changes. According to Newton's law, dry (nonevaporative) heat loss is proportional to the temperature difference between the body core and the surroundings. Therefore, in humans, heat loss should be nonexistent at an ambient temperature of 37° C, and it should increase linearly with decreasing ambient temperature. Because heat loss also depends on heat conduction and convection within the body, and thus on peripheral blood flow, two heat loss curves may be generated (see Figure 58-14), one for peripheral vasodilation and another for vasoconstriction. Within the thermoneutral zone, heat production (corresponding to the at rest [basal] metabolic rate) is in equilibrium with heat loss only if skin blood flow is progressively reduced as the temperature decreases from the upper end of the thermoneutral zone *(T_3)* to its lower end *(T_2)*. At temperatures less than T_2, body temperature can be kept constant only if heat loss is exactly compensated for by increasing thermoregulatory heat production (cold-induced thermogenesis). The maximum thermogenesis (which amounts to three to five times the BMR in adults but only two to three times the SMR in neonates) determines the lower limit of the thermoregulatory range (T_1 in Figure 58-14). The value for T_1 is approximately 5° C in adults and 23° C in full-term neonates.[1] When this limit is exceeded, hypothermia ensues.

At temperatures greater than T_3, thermal equilibrium can be achieved only by an additional heat loss mechanism—the secretion and evaporation of sweat. It is not possible for the organism to down-regulate BMR. In Figure 58-14, point T_4 indicates the upper limit of the range of regulation, which is determined by the sweat rate capacity. Between points T_3 and T_4, body temperature inevitably increases because of a load error typical for a proportional control system, resulting in an increasing metabolic rate according to van't Hoff's rule.

The term *thermoneutral zone* was originally defined solely with respect to metabolic rate, and some problems arose concerning its use in perinatal physiology.[39] The thermoneutral zone is now defined as "the range of ambient temperature at which metabolic rate is at a minimum, and within which the

temperature regulation is achieved only by control of sensible ("dry" or "nonevaporative") heat loss, that is, without regulatory changes in metabolic heat production or evaporative heat loss."[8] This range is delineated by the symbols T_2 and T_3 in Figure 58-14. In unclothed at rest adults, the lower range limit of the thermoneutral zone (T_2) is 26° to 28° C (50% relative humidity, still air); however, it is 32° to 35° C (operative temperature, 50% relative humidity, still air) in naked full-term newborn infants.[1,39] This difference is of importance because it shows that environmental temperature conditions that do not require any thermoregulatory effort in adults may seriously overtax the metabolic thermoregulatory system of neonates.

In small premature infants (1 kg), the lower limit of the thermoneutral zone may be as high as 35° C.[39] The lower end of the thermoneutral zone may change with postnatal development as body size increases[39] and as small changes in the sensitivity of the thermoregulatory system occur. It is thus extremely difficult to provide exact standard values for the thermoneutral zone in neonates.

CONTROL OF HEAT PRODUCTION

Modes of Extra Heat Production

The ability to produce extra heat in a cool environment is one of the characteristic features of homeothermy. There are three principal modes of heat production that are responsible for the increase of heat production with decreasing environmental temperature: (1) voluntary muscle activity, (2) involuntary tonic or rhythmic muscle activity (the latter may be manifest as shivering or may be invisible and detectable only by electromyography), and (3) nonshivering thermogenesis. The existence of nonshivering thermogenesis was originally evidenced by the demonstration of a cold-induced increase in oxygen uptake that persisted after neuromuscular blockade with curare.

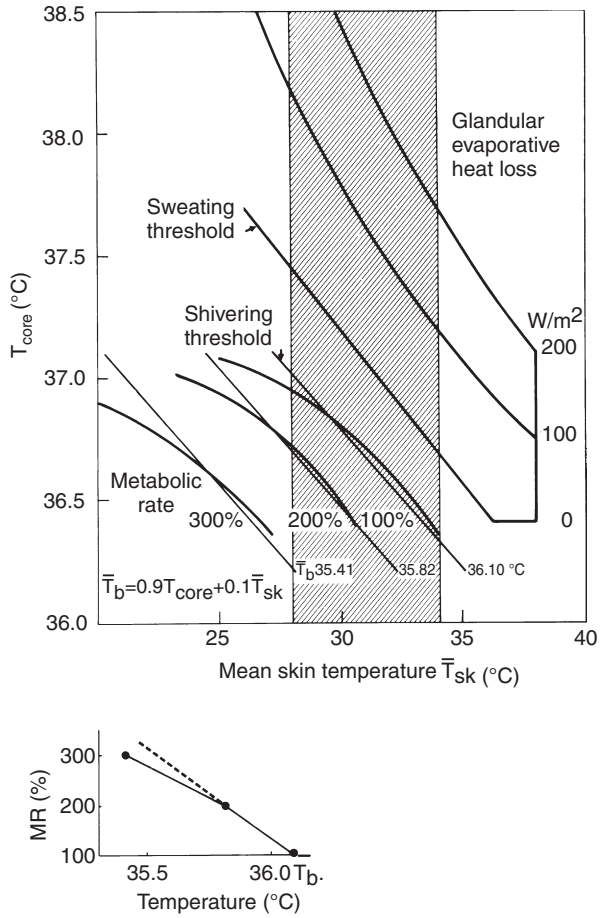

Figure 58-11 Contour plot of metabolic rate and sweat rate (glandular evaporative heat loss) as a function of core temperature and mean skin temperature. The *curved lines* for metabolic rate were approximated by *straight lines* (and so might be the 100 and 200 W curves for evaporative heat loss). Each *straight line* represents all pairs of core and skin temperature with equal $\overline{T}_b$ calculated from the inset equation. *Hatched area* indicates range of mean skin temperatures relevant for the comparison of shivering threshold values. Percentage metabolic rate (MR) in relation to $\overline{T}_b$ is shown at the bottom of the figure. (*Data from human adults in Benzinger TH: Heat regulation: homeostasis of central temperature in man.* Physiol Rev *49:671, 1969. and Nadel ER, Bullard RW, Stolwijk JA: Importance of skin temperature in the regulation of sweating,* J Appl Physiol *31:80, 1971.*)

Shivering and Nonshivering Thermogenesis

In adult humans and in larger adult mammals, shivering is quantitatively the most important involuntary mechanism of thermoregulatory heat production. In contrast, nonshivering thermogenesis is an important and effective mechanism of heat production in the neonates of many mammalian species, including human infants. In comparison with nonshivering thermogenesis, shivering is a less economical form of heat production in that it inevitably increases convective heat loss because of the body oscillations. Moreover, shivering interferes with body movement. This economical aspect becomes more important in smaller organisms (high surface-to-mass ratio) with poorer thermal insulation. Thus it is satisfying, from a teleologic point of view, to find that the maximum extent of nonshivering thermogenesis available in one species is inversely related to its order of body size (Figure 58-15). Extrapolating the regression line in Figure 58-15, one can conclude that subjects with body weights heavier than 10 kg lack the capacity for nonshivering thermogenesis.

Loss of Nonshivering Thermogenesis

In relatively mature newborns, such as guinea pigs, the extent of nonshivering thermogenesis is greatest at the time of birth and it vanishes within a few weeks (Figure 58-16). This involution of nonshivering thermogenesis can be retarded and partly inhibited by rearing the animals in a cold environment. After nonshivering thermogenesis has been extinguished through exposure to a warm environment, it can again be evoked by exposing older guinea pigs to a cool environment. In human neonates, no experimental data are available to document the process of the disappearance of nonshivering thermogenesis. It may be assumed that nonshivering thermogenesis is the prevailing mechanism of thermoregulatory heat production during the first 3 to 6 months of life.[12] By contrast, in rats, the extent of nonshivering thermogenesis increases during the postnatal period.[40,41] Such behavior may be expected to occur in other altricious neonates that, like rats, are born in a relatively immature stage. This would explain the gradual increase in the maximum cold-induced heat production that can be observed during the first few weeks of life in premature infants.[1]

Lack of Nonshivering Thermogenesis

At least one example exists of a species in which the neonates, although small, do not possess nonshivering thermogenesis—pigs. Piglets shiver vigorously when exposed to cold, even on the first day of life.[42] Miniature piglets have no demonstrable nonshivering thermogenesis even when they are reared for a few weeks in a cold environment.[43] In agreement with the data depicted in Figure 58-15, calves (a larger neonate) have no metabolic response to norepinephrine, indicating the lack of nonshivering thermogenesis.[44]

Sites of Nonshivering Thermogenesis

For many decades, the liver, other intestinal organs, white subcutaneous adipose tissue, and the skeletal musculature were suggested as sites of nonshivering thermogenesis. During the early 1960s it was suggested that brown adipose tissue was the primary site of nonshivering thermogenesis.[40,45-47]

Shivering

Newborn animals and newborn infants are rarely seen to shiver in response to cooling, although the metabolic rate is considerably increased. As shown in Figure 58-17, no muscle activity is demonstrable by electromyography on day 2 of life in the cold-stressed guinea pig. In contrast, on day 12 of life, exposure to the same ambient temperatures (16° and 8° C) evokes bursts of electrical muscle activity that are accompanied by visible muscle oscillations. This does not mean, however, that the shivering mechanism is not developed in the immediate postnatal period. To the contrary, it has been shown that shivering can be elicited in the guinea pig on the first day of life when nonshivering thermogenesis is blocked by a β-receptor-blocker (Figure 58-18) and body temperature is thereby allowed to fall. One may conclude, therefore, that the shivering mechanism is well developed at the time of birth but is normally suppressed by nonshivering thermogenesis. Shivering has also been observed in human neonates with severe hypothermia after birth. It has thus been concluded that the shivering threshold is displaced in neonates to a lower body temperature in comparison with the adult.

The control of the thermoregulatory effector responses (thermogenesis, skin blood flow changes, sweat secretion, and behavioral responses) is predominantly exerted by the nervous system (see Figure 58-9); hormonal transmission has a role only in long-term modifications of the thermoregulatory system.

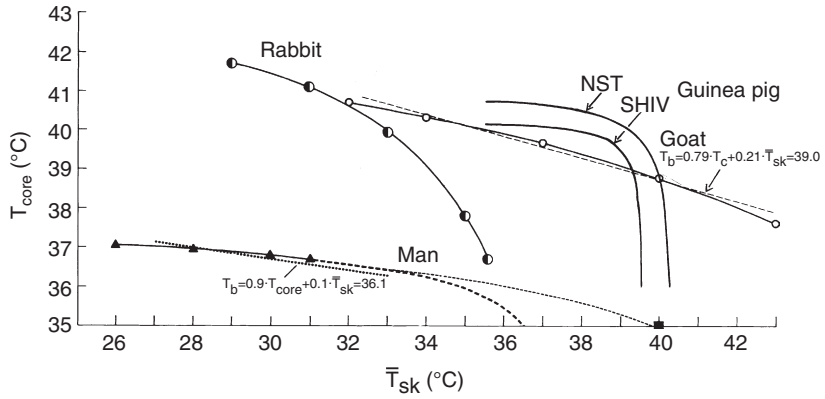

Figure 58-12 Thresholds for shivering *(SHIV)* and nonshivering thermogenesis *(NST)* as a function of core *(T_{core})* and mean skin temperature *($\bar{T}_{skin}$)*. Compared are the shivering threshold contour lines from adult humans, rabbits,[127] goats,[20] and 4-week-old guinea pigs[3] as well as the contour line representing threshold conditions for NST in newborn guinea pigs.[128] Note that core temperature is the local hypothalamus temperature in the case of rabbits and newborn guinea pigs and the spinal cord temperature in the case of 4-week-old guinea pigs.The *stippled* and *dashed straight lines* represent pairs of T_{core} and $\bar{T}_{skin}$ with equal $\bar{T}_b$, *36.1* and *39,* as calculated from the respective inset equations. Two neuronal systems participate in thermoregulation: (1) the somatomotor system and (2) the sympathetic system.

Metabolic Responses: Neural Control of Shivering and Nonshivering Thermogenesis

Shivering is controlled by means of the somatomotor system. The descending axons of the central shivering pathway project from the posterior hypothalamus to the reticular formation of the midbrain and pons.There they contact the supraspinal pathways and descend to the motor neurons in the anterior horns of the spinal cord. From there the musculature is rhythmically actuated through the motor nerves that leave through the anterior roots.

Nonshivering thermogenesis is controlled from the hypothalamic ventromedial nucleus[48] through the sympathetic nervous system.The transmitter in the target system (in particular, brown adipose tissue) is norepinephrine, which acts on adrenergic β-receptors located in the cell membranes. Nonshivering thermogenesis can thus be blocked by β-receptor-blocking agents (see Figure 58-18).The norepinephrine released at the nerve endings liberates free fatty acids from the lipid droplets and stimulates their subsequent oxidation.

CONTROL OF HEAT LOSS

Vasomotor Responses

Thermoregulatory control of blood flow varies regionally.[49] At least three functionally different regions can be distinguished: (1) acral areas (e.g., fingers, hands, ears, lips, nose), (2) trunk and proximal limbs, and (3) head and brow. Blood flow through the acral areas is controlled exclusively through noradrenergic sympathetic nerves.An increase in sympathetic tone causes vasoconstriction, and a decrease in tone results in vasodilation. In contrast to the distal extremities, heat-induced reflex vasodilation in the trunk and proximal limbs results in a much larger blood flow than that observed after sympathectomy.[50] It has been suggested that in these areas there are specific vasodilator nerves that inhibit the vascular smooth muscles (active vasodilation).[50] Conversely, additional vasodilation has been ascribed to an enzyme secreted in sweat that catalyzes the formation of a vasoactive mediator, possibly bradykinin. The latter concept is supported by the frequent occurrence of a second phase of vasodilation coinciding with the onset of sweat secretion in the forearm (Figure 58-19) and by the observed lack of substantial vasodilation in people congenitally lacking sweat glands.[45] Vasomotor nerves exert only a slight effect on the forehead, and practically no vasoconstriction occurs in response to cold stress; however, vasodilation does occur in these regions along with sweat secretion in response to heat stress.

Well-developed vasomotor responses to environmental temperature changes have been demonstrated in full-term and premature newborn infants.[7]

Sweat Secretion

Apocrine sweat glands, as found in various mammals such as the Bovidae and Equidae, are controlled by an adrenergic sympathetic mechanism. However, in humans, apocrine sweat glands are controlled by cholinergic sympathetic fibers.[51,52] Consequently, sweat secretion can be inhibited by atropine.Acetylcholine, pilocarpine, and other parasympathetic drugs evoke sweat secretion.

Behavioral Regulation

Behavioral measures must not be neglected in considering the constancy of body temperature. In adults of various species, particularly humans, behavioral measures may have a more important part in temperature constancy than do the autonomic reactions, and under some circumstances they may be the only way to maintain thermal comfort.A civilized human is rarely seen to shiver; he or she would rather increase the set temperature of the air conditioning system or decrease it before perspiration begins.

Behavioral regulation has been generally looked on as a highly developed type of thermoregulation in comparison with the autonomic regulatory measures described previously. More recent studies, however, have shown that behavioral regulation is, from a phylogenetic point of view, the more primitive state of thermoregulation. Behavioral thermoregulatory actions may even be manifested in a species that is not at all able to respond by autonomic effector actions.Thus numerous fish species have been shown to seek out a preferred water

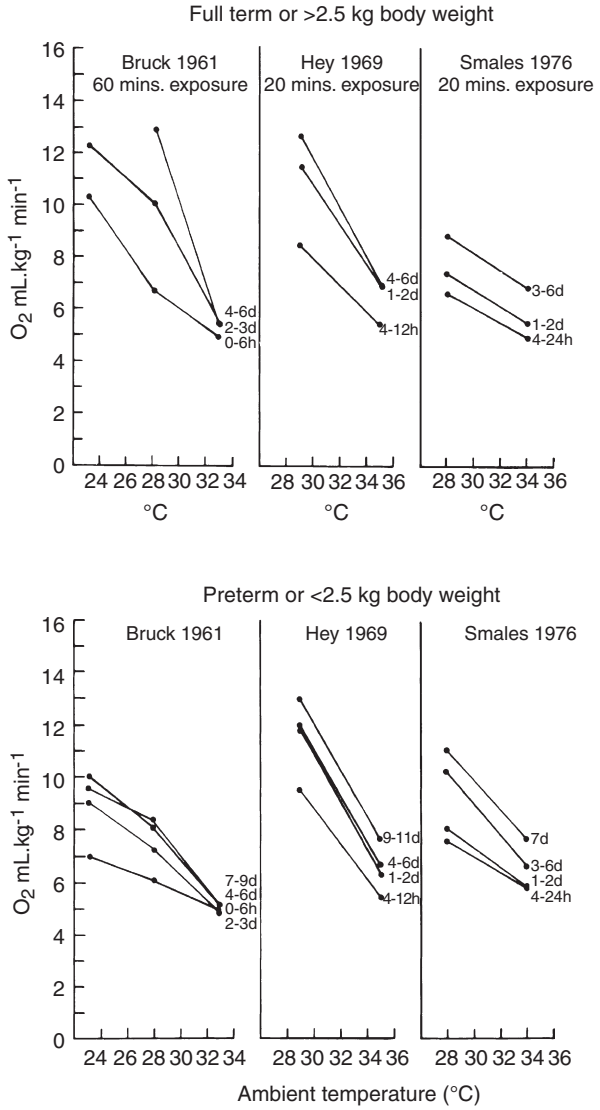

Figure 58-13 Average rates of oxygen consumption of mature *(top panels)* and premature infants *(bottom panels)* at different ages and different ambient temperatures as measured by Brück,[1] Hey,[38] and Smales.[129] (*From Hull D, Smales ORC: Heat production in the newborn. In Sinclair JC [ed]:* Temperature Regulation and Energy Metabolism in the Newborn. *New York, Grune & Stratton, 1978, pp 129-156.*)

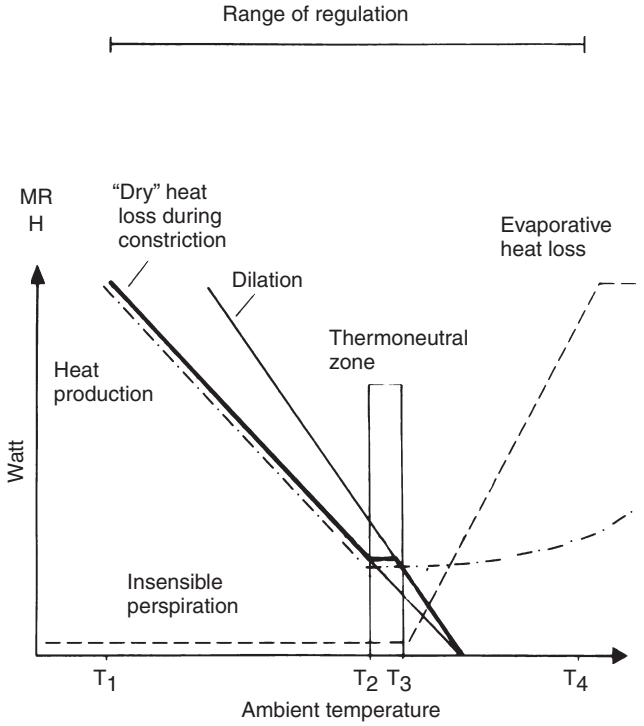

Figure 58-14 Schematic representation of thermal balance in a homeothermic organism. In the range between T_1 and T_3, heat loss is matched by heat production; between T_3 and T_4, evaporative heat loss matches heat production plus heat gain from the environment. In the range T_2 to T_3 (thermoneutral zone), heat loss can be matched to at rest heat production by vasomotor adjustments. Less than T_1, heat loss exceeds the thermogenetic capacity. Greater than T_4, the production and influx of heat exceed the capacity for evaporative heat loss. *MR,* Metabolic rate; *H,* heat loss. (For further discussion, see text.)

temperature when they are given a choice, thereby stabilizing body temperature at a certain level. The "sunbathing" of reptiles is another well-known behavioral thermoregulatory response by which the body temperature is increased to, and precisely maintained at, a level comparable with that of homeothermic animals.[53]

Neonates also make considerable use of behavioral measures. Both piglets and newborn rabbits[54] reduce heat loss by huddling together. Moreover, when newborn rabbits are put into a temperature-gradient environment (a tube with steadily increasing temperature from one end to the other), they will move to a section of the tube warm enough to cause their body temperatures to stabilize near the adult level.[55-57]

In human neonates, postural reactions against overheating have been described.[58] Moreover, babies may cry to signal "thermal discomfort." This would represent another type of behavioral thermoregulation, namely, one mediated by the parents.

ADAPTIVE AND DEVELOPMENTAL CHANGES IN THERMOREGULATION

Unlike engineered physical regulatory systems, thermoregulation by living organisms is not invariant; its properties are influenced by thermal loading itself—its duration, frequency, and intensity. Some of the so-called long-term thermoadaptive phenomena may be traced to changes in the thermoregulatory system. As for the "passive system" (see Figure 58-1), heat insulation may change with development because of an increase in the size of the subcutaneous fat layer or growth of a fur coat. The capacity of the effector systems (nonshivering and shivering thermogenesis) and some regulatory characteristics (namely, alterations in the threshold and gain of the relationship between effector response and body temperature)[28,59] can also undergo changes with development. As a consequence of these thermoadaptive modifications, the range of regulation (see Figure 58-14) may increase, and the thermal discomfort evoked by thermal stress may be relieved.

Acclimation Versus Maturation

So long as the neonatal temperature control system was considered merely as deficient, it was thought that thermal acclimation, in addition to maturational processes, improved this system postnatally. With regard to nonshivering thermogenesis, however, the capacity of this cold defense mechanism is already maximized at birth in some species (see Figure 58-16). Only a narrow margin exists for improving cold resistance by adaptive modifications in the metabolic system during the neonatal period.

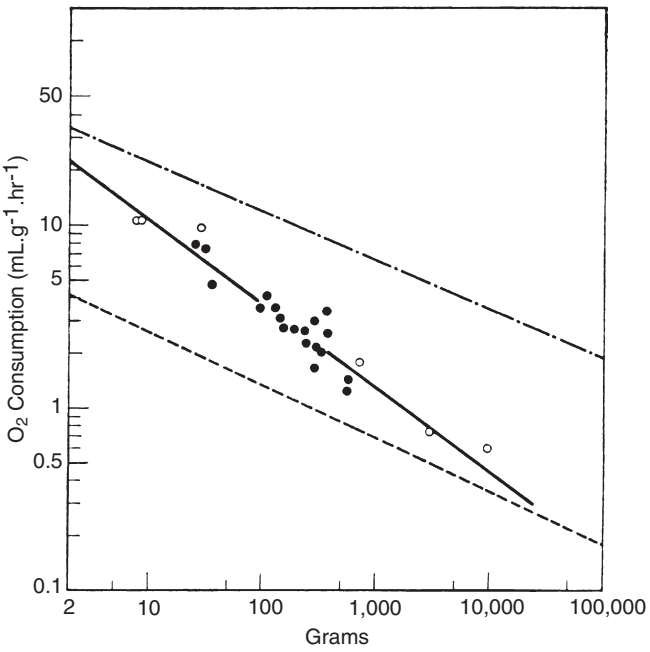

Figure 58-15 Maximum amount of nonshivering thermogenesis, measured as increase in O_2 uptake after norepinephrine injection, in relation to body mass (various species in the adult age). ----, Minimum O_2 uptake at neutral temperature; ——·——·——, calculated maximum O_2 uptake for exercise; ●, rodents; ○, other mammals. Figure 58-16 Reduction of the maximum extent of nonshivering thermogenesis (NST) with increasing age and the dependence of this process on the environmental temperature at which the guinea pigs were reared. *White area,* Minimal oxygen consumption; *shaded area,* NST; *striped area,* shivering. The inset figures indicate the percentage mass of interscapular brown adipose tissue, which is closely related to the maximum extent of NST. Based on data from Zeisberger et al.[130] (*From Brück K: Heat production and temperature regulation. In Stave U (ed):* Perinatal Physiology, *New York, Plenum Publishing, 1978, pp 455-498.*)

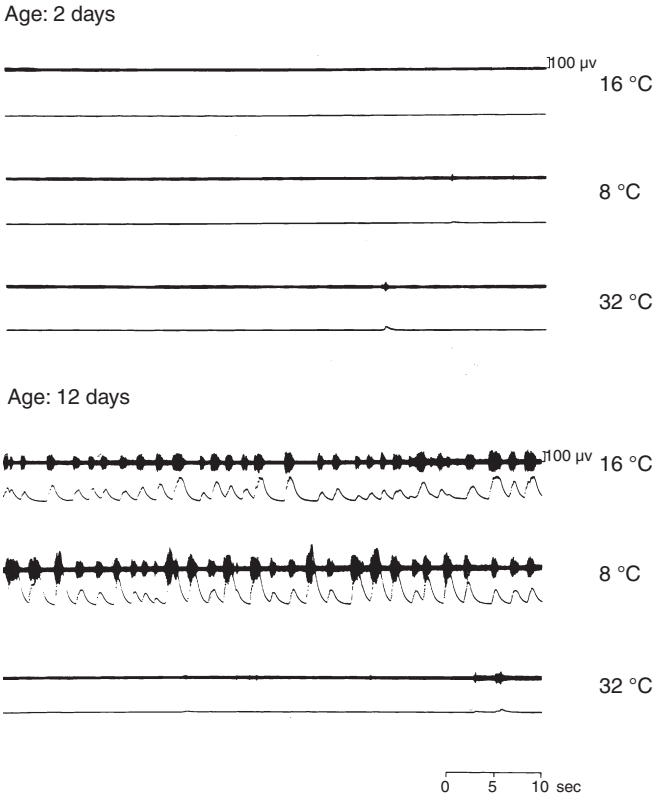

Figure 58-17 Electromyograms from a guinea pig examined on days 2 and 12 postnatally at three different environmental temperatures (indicated on the right side). The lower traces on each record represent the integrated electrical muscle activity. Note that no shivering occurred on day 2 (although oxygen uptake was increased to three times standard metabolic rate). (*From Brück K: In Linneweh F [ed]:* Fortschritte der Pädologie, *Berlin, Springer-Verlag, 1965, pp 96-108.*)

In neonates born in a less mature state, development of nonshivering thermogenesis and brown adipose tissue may proceed postnatally (even at thermoneutral conditions) and contribute to an improvement in temperature regulation. Thus the increasing summit metabolic rate in response to cold during the first few days of life in full-term and premature infants (see Figure 58-13) may be due to postnatal development of nonshivering thermogenesis and an increase in brown adipose tissue. In hamsters and rats, which are born in a rather immature state, guanosine diphosphate binding (as a measure of the thermogenic concentration) has also been shown to increase postnatally (altricious animals).[41,60]

Long-Term Threshold Temperature Displacement

Modifications in the threshold temperature for the elicitation of thermoregulatory effector actions have been demonstrated in animals other than humans. In guinea pigs reared in the cold, the shivering threshold is shifted to a temperature level about 1° C lower than in controls reared at neutral temperature (Figure 58-20).[28,59] This shift enables these animals to make full use of nonshivering thermogenesis before the less economical shivering mechanism is evoked. A similar shift in the shivering threshold can be produced in adult humans by repeated short-term cold exposure (Figure 58-21). Linked with the change in shivering threshold in humans is a shift in the threshold temperature for the experience of thermal discomfort, estimated by the subjects being studied on the basis of a subjective rating scale.[61]

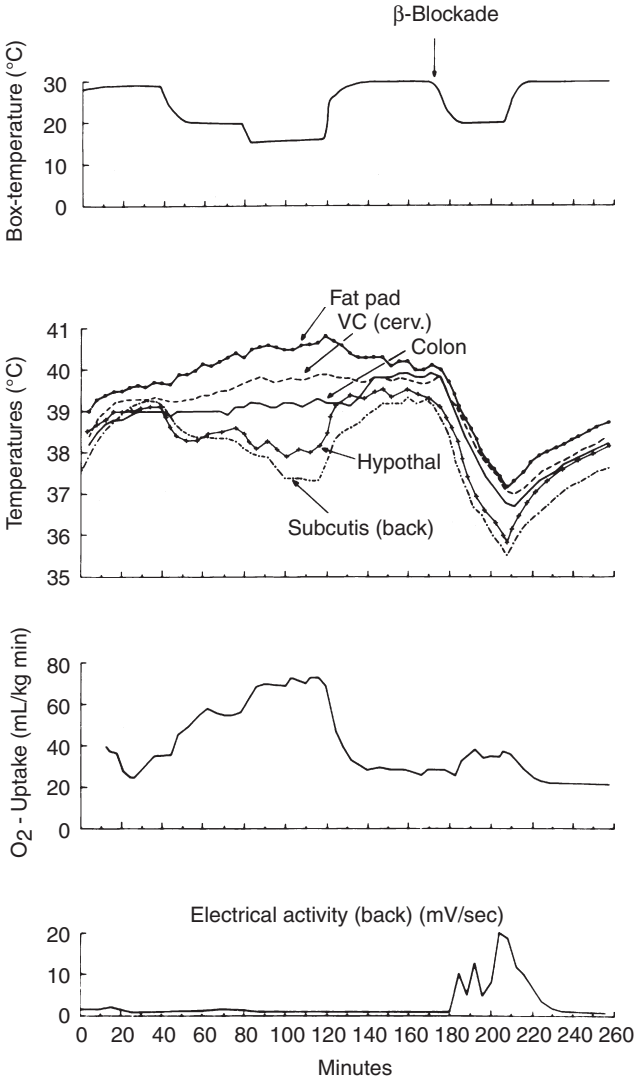

Figure 58-18 Demonstration of shivering and nonshivering thermogenesis (NST) in a newborn guinea pig, age 0 days, body mass 101 g. In the first part of the experiment, only NST occurs during cold exposure. After administration of a β-receptor-blocker and blockade of NST, shivering takes place and can be recognized by the increased electrical activity of the back muscles. NOTE: Increasing temperature in the area of the interscapular adipose tissue *(Fat Pad)* and in the cervical part of the vertebral canal *(VC [cerv])* occurs before, but parallel decrease of all temperatures occurs after blockade of NST. (For further explanation, see text.) (*Adapted from Brück K, Wünnenberg W: Beziehung zwischen Thermogenese im "brounen" Fettgewebe, Temperatur im cervicalen Anteil des VertebralKanals und Kgiltezittem,* Pflügers Arch *290:167, 1966.*)

This type of adaptation has been called *tolerance adaptation*, that is, larger deviations in body temperature are tolerated before actuation of the appropriate thermoregulatory effectors occurs. In other words, the precision in temperature regulation is reduced, but at the same time cold discomfort is diminished.

Repeated heat exposure has been known to decrease the sweating threshold, that is, a sensitization occurs in the course of repeated heat exposure rather than development of tolerance. The load error of the thermoregulatory system is thereby diminished, that is, a tendency occurs to keep body temperature at less than a critical level. The sweating threshold shift as it occurs during heat adaptation is accompanied by similar changes in the threshold temperatures for shivering and vasodilation (Figure 58-22). Such concurrent shift of the thresholds for all autonomic effector systems corresponds to a resetting of the set point of the thermoregulatory control system.[28,62] In some instances the threshold deviation may be accompanied by alterations in the gain of the temperature-response relationship.

Short-Term Threshold Temperature Displacement

In addition to the described threshold changes that occur during repeated or continuous cold-heat exposures for several days or weeks, threshold deviations developing on the order of minutes have been demonstrated in humans as well as in animals. Short-term shivering threshold displacement in men exposed twice to a low climatic chamber temperature with an interposed 20-minute rewarming period has been observed. During the second cooling phase, shivering occurred at a 0.4° C lower mean body temperature, whereas the slope of the temperature-response relationship was unchanged. In addition, the thresholds for skin blood flow and for sweating were shifted to lower values when the subjects were exposed to cold before they started an exercise test; this shift led to vasodilation and sweating. Thus a short cooling period causes a concurrent displacement of the threshold temperatures for all autonomic thermoregulatory responses in adult humans. In animals' adapted to normal room temperature (21° C), this phenomenon of short-term acclimation is even more pronounced.

Previous observations in premature infants who were maintained at ambient temperatures so low as to yield steady-state body core temperatures near 35° C without arousing any cold defense have been ascribed to such short-term acclimation. In a subsequent study on a group of premature infants (i.e., those weighing less than 1500 g), minimal oxygen uptake was compatible with rectal temperatures in the range of 35° to 36° C. As judged from the time spent in quiet sleep, these babies did not show any signs of thermal discomfort.[63] Thus the discomfort threshold can also shift to a lower level of body temperature. Moreover, the infants in that study exhibited a slight tendency toward vasodilation, indicating a decreased threshold for vasomotor responses. However, these effects may be related to postnatal maturation.

Maturation

Although the control system (passive system; see Figure 58-1) undergoes considerable alteration during ontogenesis, the thermoregulatory system tends to maintain deep body temperature from birth onward at a value typical for the species. This maintenance requires a number of adjustments by the thermoregulatory system to the smaller body size of neonates. These adjustments may be mediated by an increased thermogenic capacity, an additional heat production mechanism (nonshivering thermogenesis), and special changes in threshold conditions for eliciting effector responses. Conversely, modifications developing during thermal adaptation may consist of intrinsic mechanisms functioning in a neonatal organism that has not been stimulated by any environmental factor. These same mechanisms may serve to adjust the regulatory system either to body size or to special environmental conditions.

Stability of Deep Body (Core) Temperature During Ontogenesis

As shown in Figure 58-23, colon temperature in newborn guinea pigs or rabbits is maintained close to the adult level, even during severe cold exposure. Remarkably, thermostability seems to be even greater during the first few days of life than it is later on. In guinea pigs, this enhanced stability can be accounted for by

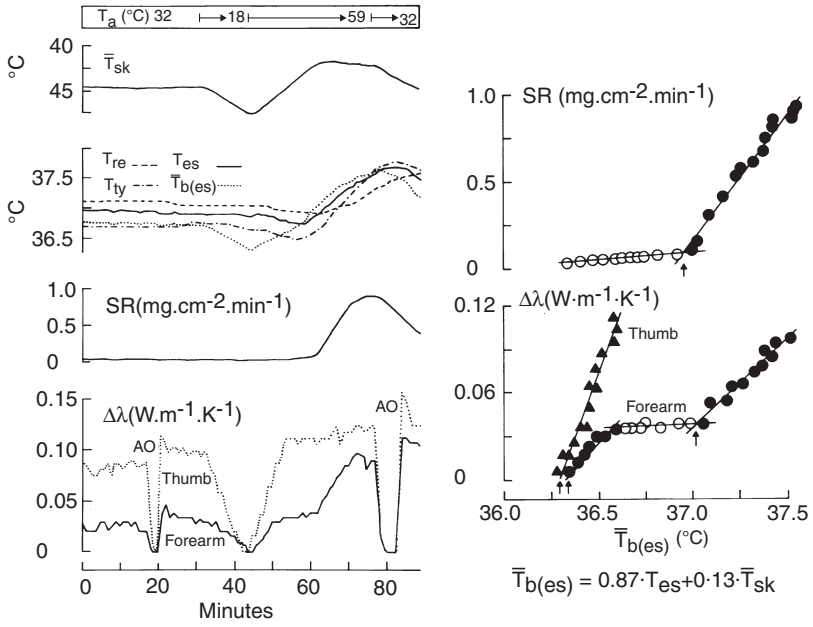

Figure 58-19 Temperature-induced changes in skin blood flow and local sweat secretion (chest) in an adult. *Left,* Before body heating, ambient temperature *(T_a)* was decreased from 32° to 18° C for establishing initial skin vasoconstriction (skin blood flow estimated from heat conductivity increment [Δλ]); thereafter T_a was raised to 59° C. *Right,* Skin blood flow and sweat secretion in relation to mean body temperature, $T_{b(es)}$ (calculated from esophageal temperature [T_{es}] and mean skin temperature[T_{sk}] as shown previously). Note second vasodilation on forearm *(arrow)* coinciding with onset of sweat secretion. *AO,* Arterial occlusion at upper arm; T_{re}, rectal temperature; T_{ty}, tympanic temperature; *SR,* local sweat rate (chest). (*Adapted from Hessemer V, Brück K: Influence of menstrual cycle on shivering, skin blood flow, and sweating responses measured at night,* J Appl Physiol *59:1902, 1985.*)

a greater metabolic response in the younger and smaller animal (Figure 58-24). As shown in Figure 58-16, newborn guinea pigs maintain body temperature mainly by nonshivering thermogenesis. In other species, for example, pigs or miniature pigs, nonshivering thermogenesis does not occur. In these species, shivering supplies the extra heat for stabilizing body temperature at ambient temperatures as low as 20° C in the neonates.[43] In human neonates exposed to ambient temperatures of 33° to 23° C, the thermoregulatory effort is much larger than in adults for a given ambient temperature (Figure 58-25). The metabolic increase is mainly due to nonshivering thermogenesis.

Changes in the Passive System

The neonatal passive system is characterized by a large body surface area-to-volume ratio and by decreased heat insulation resulting from the smaller absolute thickness of the body shell. With growth, the surface area-to-volume ratio decreases by a factor of 2.7. Comparison of data from neonates[64] and adults[65] indicates that overall insulation *(I_{a+cl})* (Figure 58-26) increases by a factor of 1.8 as body mass increases from 3.5 to 70 kg. In a cool environment, maximum tissue insulation *(I_t)* changes by a factor of 3, and air insulation *(I_a)* increases by a factor of 1.2 because of the change in the curvature radii of the trunk and extremities.

The heat production *(H)* required for equilibrium heat flow at any given overall temperature difference would therefore have to be nearly five times as large in neonates as in adults (per unit of body mass). From the preceding data, an equation is derived that predicts heat loss in relation to body mass *(m)* at a given temperature difference between body core and environment (see Figure 58-2):

$$H = k \times m^{0.5}$$

The SMR is actually lower in the neonates of various species than heat loss predicted from the preceding equation. It even falls short of Kleiber's equation in which metabolic rate is related to body mass to the 0.75th power (see Figure 58-2). In humans, beginning with the second year of life (corresponding to a body mass of more than 10 kg), the SMR is a function of the body mass to the 0.5th power. In the first year of life (especially during the first week of life), the SMR in relation to body mass is only 1.5 to 2 times larger than in adults. This means the overall temperature difference (ΔT) that can be maintained in full-term neonates under the condition of SMR is less than half that of adults (and even less in premature infants) (Figure 58-27). At an ambient temperature less than 33° C, deep body temperature will drop unless heat production is increased. In fact, metabolic rate is increased at such high ambient temperature that the lower limit of the neutral temperature range is shifted to a higher level of ambient temperature.

Adjustment of Effector Threshold Temperatures

Because of the small amount of tissue insulation, the difference between core and mean skin temperature is considerably smaller in neonates than in adults. Thus cold defense reactions should be elicited at higher mean skin temperatures than in the adult to maintain core temperature at the adult level (Figure 58-28). In other words, the threshold for increasing vasoconstrictor tone and for the metabolic reactions is shifted to a higher level in neonates, thereby adjusting the thermoregulatory system to the smaller body size.

The displacement of the neonatal threshold temperature can be explained in two ways. First, because of the increased body surface area to body mass quotient, the number of cutaneous cold receptors/unit body mass is increased (assuming that the density of the distribution of cold receptors is the same in adults and neonates). Second, the central processing of thermal input signals (see Figures 58-1 and 58-8) in neonates is different from that noted in adults. In any case, the increased cutaneous sensitivity is

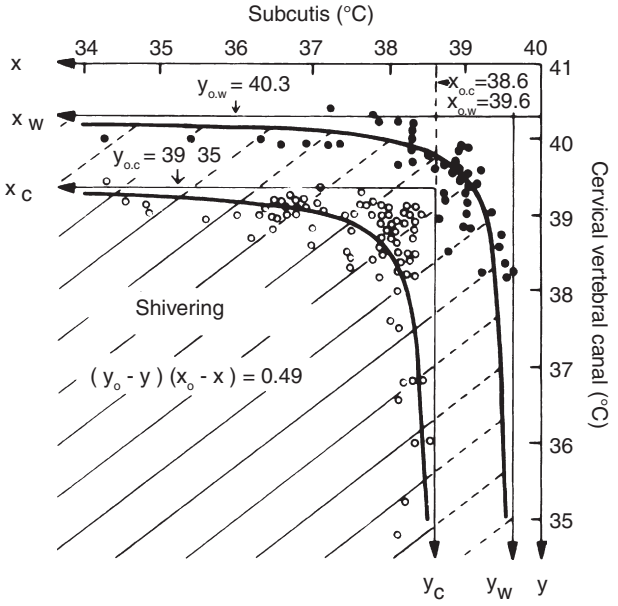

Figure 58-20 Shivering threshold curves for two groups of guinea pigs (aged 4 to 8 weeks) reared at different environmental temperatures. The values were obtained by independent changes of the body surface temperature and the temperature in the cervical vertebral canal. The diagram shows, for instance, that at a certain body surface temperature, which corresponds to a subcutaneous temperature of 37° C, shivering begins in warm-adapted animals *(•)* when the hypothalamic temperature drops below 40° C. In the cold-adapted animals *(small circle),* however, shivering does not occur until the hypothalamic temperature has reached a value slightly below 39° C. (*From Brück K, Wünnenberg W: Meshed control of two effector systems: nonshivering and shivering thermogenesis. In Hardy JD, Gagge AP, Stolwijk JAJ, et al [eds]:* Physiological and Behavioral Temperature Regulation, *Springfield, IL, Charles C Thomas, 1970, pp 562-580.*)

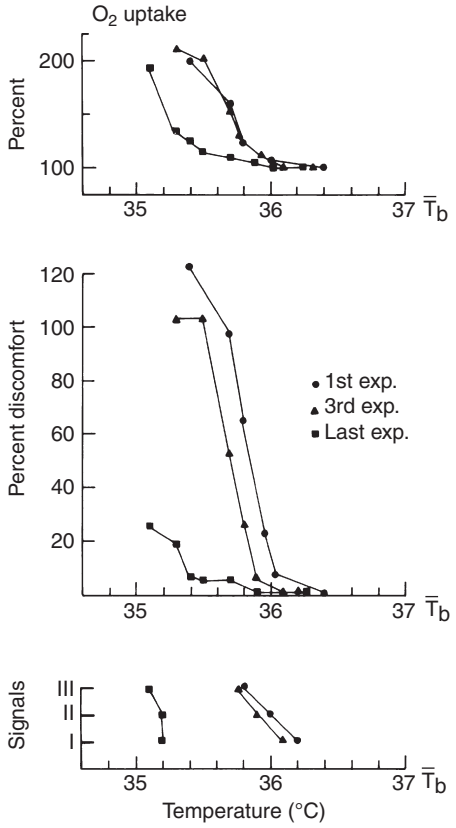

Figure 58-21 Responses of a young man wearing only shorts on exposure to cold (ambient temperature decreasing from 28° C to 5° C in 45 minutes) in the course of an acclimatization series. Note that shivering threshold (onset of increase in $\dot{V}o_2$) and discomfort threshold were shifted to lower mean body temperatures at the last (sixth day of the acclimatization period) exposure. Signals indicate subjective rating of cold sensation: *I,* Cool; *II,* cold; *III,* very cold. (*From Brück K, Baum E, Schwennicke HP: Cold-adaptive modifications in man induced by repeated short-term cold-exposures and during a 10-day and-night cold-exposure,* Pflügers Arch *363:125, 1976.*)

a prerequisite for enabling newborn infants to maintain core temperature (within a limited range of environmental temperature) at the same level and with the same accuracy as occurs in the adult.

Stage of Maturity of the Thermoregulatory System at Birth

Temperature regulation is frequently referred to as immature at the time of birth. However, one should be cautious in asserting immaturity of the thermoregulatory mechanisms even though neonates show greater fluctuations in body temperature than adults. Greater fluctuations of body temperature are to be expected in smaller organisms because of their large surface area-to-volume ratio, the relatively small insulating body shell, and the smaller body mass that acts as a heat buffer in large organisms. Because of these peculiarities in body size and shape, a reduced range of regulation (see Figure 58-14) should be expected in neonates.

The degree of maturity of the thermoregulatory system should be evaluated according to the following three criteria:

1. What is the capacity of the effector system (a) in comparison with adults and (b) in relation to body size?
2. What is the qualitative and quantitative (threshold, gain) responsiveness of the effector systems to thermal stimuli?
3. Are there qualitative or quantitative differences in the central thermointegrating system between adults and neonates?

Regarding the first criterion, the capacity of the metabolic system in full-sized human neonates is comparable with that of an adult system when the metabolic rate is related to body mass, but it is too small to compensate for heat loss in as wide a range of ambient temperatures as in adults. Therefore the tolerated ambient temperature range (range of regulation) (see Figure 58-14) is reduced. Full-term neonates are, at best, able to maintain a stable body temperature at an ambient temperature as low as 23° C (Figure 58-29), at which point maximum thermogenesis is required for thermal balance. In adults, by contrast, maximum thermogenesis (although smaller/unit body weight) is sufficient to balance heat loss at an ambient temperature as low as 0° to 5° C. It is notable that adults and neonates can maintain thermal balance under these extreme conditions only for restricted periods (30 to 60 minutes). More extended exposure results in exhaustion of the metabolic system and hypothermia. In neonates born at full-term gestation, the lower limit of the range of regulation (see Figure 58-14; T_1) comes closer to that of adults than it does in preterm neonates.

Regarding the second criterion, the threshold and gain for the metabolic reactions are adjusted to the smaller body size of neonates (see Figure 58-28). The sweating threshold is comparable with that in adults, except in premature and

small-for-gestational-age neonates[66] in whom the threshold is shifted upward. Even in the very small premature infant, metabolic and vasomotor control responses are developed at birth,[1,67] although the threshold for elicitation of these responses may not be appropriately adjusted to body size. In addition, the capacities of the effector systems may be smaller than in adults. In neonates, maximum evaporative heat loss is in the range of the SMR,[66,68] whereas in adults it is five times the SMR.

As for the third criterion, no substantial neuronal or hormonal differences have yet been described between the neonatal and adult thermoregulatory systems.

According to these criteria, one may distinguish three groups of mammals according to their functional stage of temperature regulation immediately after birth. The first group exhibits a thermoregulatory system more or less completely adjusted to a smaller body size. The body temperature is stable within a certain control range. This range is narrower, however, than in the adults. Members of this group include full-term human neonates, guinea pigs,[69] pigs,[42] miniature pigs,[43] lambs,[70] and larger mammals such as calves.[71]

The second group of mammals has the following characteristics: Thermoregulatory responses can be evoked at birth, but the capacity of the effector systems, the threshold temperatures, or both are not sufficiently adjusted to the smaller body size. Body temperatures drop on exposure to environmental temperatures slightly less than thermal neutrality. Mammals in this group include low-birth-weight human newborns,[1] kittens, rabbits,[72] puppies,[73] and rats.[74]

In the third group, thermoregulatory responses are not evocable, and oxygen uptake does not increase with decreasing environmental temperatures, but follows van't Hoff's law (see Figure 58-3). These animals (e.g., ground squirrels[73] and golden hamsters[60,75]) behave as poikilothermic animals do. This group is presumably restricted to the neonates of hibernators.

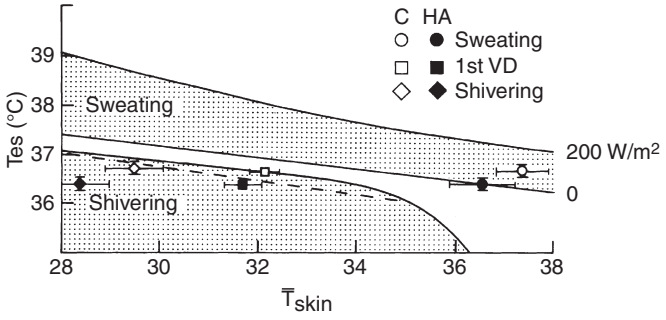

Figure 58-22 Concurrent shift of the threshold temperatures of all autonomic thermoregulatory effectors to lower body temperatures in the course of a 5-day heat adaptation series. Means of seven subjects. Each subject was exposed to heat for approximately 90 minutes daily. Shivering threshold was determined 1 day before and 1 day after the 5 heat-exposure days. (For explanation of lines, see Figure 58-12.) *C,* Control studies before acclimation; *HA,* after heat acclimation; *1st VD,* first vasodilation (see text). PATHOPHYSIOLOGY

Sudden Infant Death Syndrome

A possible role for hyperthermia in sudden infant death syndrome (SIDS) has been hypothesized because some victims are found in unusually warm environments, are warm and sweating when found dead, are wrapped tightly in clothing or bedding, have a history of febrile illness before death, or have high rectal temperatures at examination or autopsy.[76,77] Given the association between SIDS and another important risk factor, prone body positioning,[78] investigators have recently begun to examine the relationships in body position, body temperature, state of sleep, and cardiorespiratory activity. Infants sleeping prone have a higher peripheral skin temperature.[79,80] Heat loss is lower in infants sleeping prone than in those sleeping supine, perhaps because of less heat loss from the head. Thus prone infants take longer than supine infants to reach the lower rectal temperature that occurs after the onset of sleep and rectal temperature remains

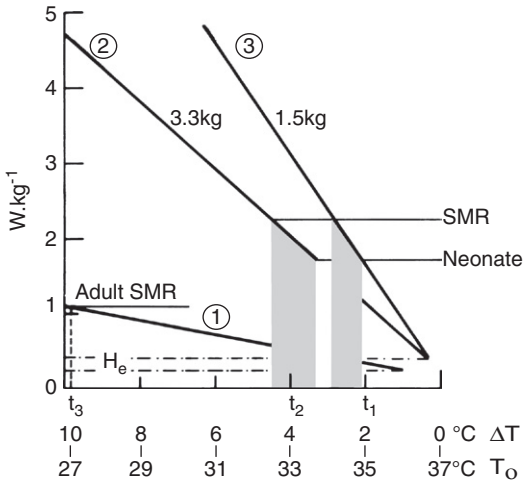

Figure 58-27 Schematic representation (based on data given in Figures 58-2 and 58-26) of heat production/unit body mass required to maintain the temperature differences (ΔT) in body core (37° C) and environment (operative temperature, T_O, Weighted mean of air and radiation temperature) in the adult (1) and in a 3.3-kg (2) and a 1.5-kg (3) infant (with maximum vasoconstriction). With the actual standard metabolic rate (SMR) given, the temperature differences T_1, T_2, and T_3 can be maintained under conditions of thermal neutrality; conversely, the neonates require an environmental temperature of about 33° C (2) or even 34° to 35° C (3) to maintain a deep body temperature of 37° C, whereas this level is much lower in the adult, 27° C (T3). H_e, Minimum evaporative heat loss. (*From Brück K: Heat production and temperature regulation. In Stave U [ed]:* Perinatal Physiology, *New York, Plenum Publishing, 1978, pp 455-498.*)

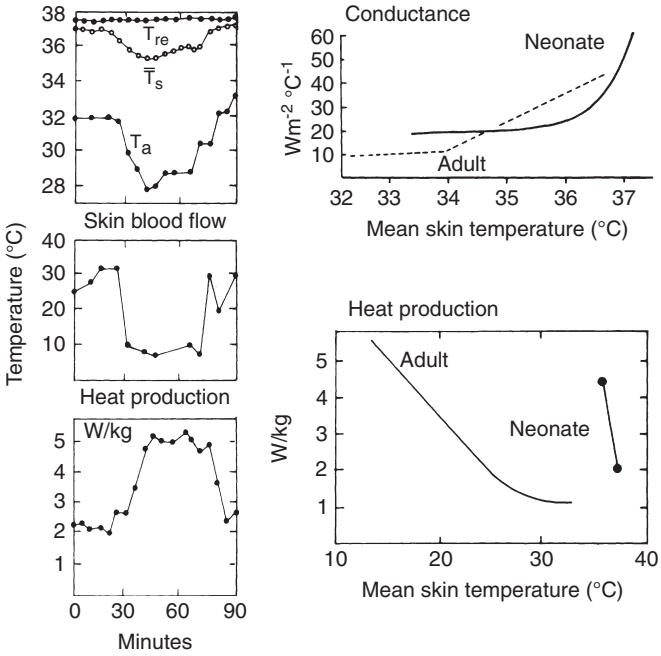

Figure 58-28 *Left,* Simultaneous response of skin blood flow (heel) and heat production to a slight drop in mean skin temperature ($\bar{T}_{skin}$) evoked by a decrease in ambient temperature (T_a) from 32° to 28° C. (*From Brück K: Heat production and temperature regulation. In Stave U [ed]:* Perinatal Physiology, *New York, Plenum Publishing, 1978, pp 455-498.*)

higher during sleep.[81,82] The weight of evidence obtained from term and low-birth-weight infants and infants a few months old also suggests that prone positioning is associated with reduced heat production. Even so, heart rate,[83,84] blood pressure,[85] and absolute skin temperatures[79,80] are higher and temperature gradients from central to peripheral skin are narrower.[86] Taken together, these data suggest that despite attempts to eliminate heat through adjustments in the peripheral circulation (narrowing central-peripheral gradients) infants are unable to maintain set-point temperature(s). Alternatively, the prone position may be linked to an elevation in the set point. Either way, the evidence points toward probable differences in autonomic control of metabolism and cardiorespiratory function in the prone versus the supine position.

Fever

It is well known that newborn infants may suffer severe infection without increased body temperature. In contrast, clinical reports show body temperature elevations higher than 38° to 39° C in newborn infants with septicemia, purulent meningitis, and pneumonia.[87] Experimental studies suggest that some peculiarities of fever mechanisms exist during the neonatal period. Newborn lambs fail to respond with fever after the administration of bacterial pyrogen or leukocyte pyrogen during the first few days of life.[88] Newborn guinea pigs have been shown to react to adult doses of pyrogen no sooner than a few days after birth, but they do respond with fever immediately after birth when this pyrogen is administered at much higher doses than in the adults.[87] If one takes certain precautions (e.g., providing an ambient temperature that does not overwhelm thermogenesis, sufficient nutrition, and so on), a pyrogen fever comparable to that of the adults may be evoked in the neonates of many species. However, many species-related differences in the pattern of the febrile response exist. For example, newborn guinea pigs demonstrate a biphasic response when endotoxin is administered intraperitoneally (Figure 58-30). In contrast, 0- to 3-day-old rabbits exhibit a short-lasting monophasic fever, and 3- to 6-day-old kittens show a more sustained monophasic fever. A hypothermic response is commonly observed in 8- to 10-day-old rats.[87] In most cases, pyrogen administration causes heat production to increase; as in thermoregulation, nonshivering thermogenesis is a prevailing mechanism of extra heat production during febrile response.

Mechanism of Fever

Set-point displacement. Fever develops as a result of an activation of cold defense reactions as they normally occur when an organism is exposed to cold. Generally the process begins with peripheral vasoconstriction and is followed by enhanced thermogenesis. In adults, the latter response is accompanied by shivering, whereas in neonates, nonshivering thermogenesis prevails. With increasing body temperature, these thermoregulatory effector actions, thermogenesis and vasoconstriction, are diminished just as if the organism aimed to reach a new target temperature. Recovery from the fever is induced by the activation of heat dissipation mechanisms—vasodilation and sweating. During the constant fever phase, thermal disturbances (see Figure 58-1) are compensated for by the appropriate control processes. It appears from this description that the thermoregulatory effector system remains completely functional but that the organism aims to

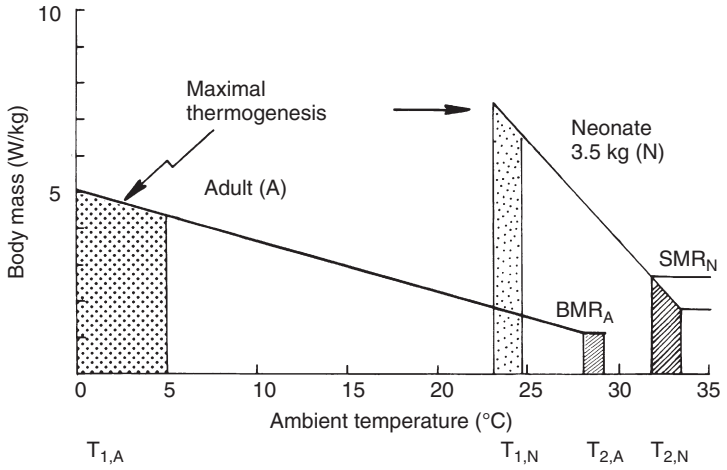

Figure 58-29 Minimal (basal or standard) and maximum metabolic rate in relation to ambient temperature in neonates *(N)* and adults *(A)*. The inflection point of each curve marks the lower limit of the thermoneutral zone *(T_2),* which is shifted to a higher temperature in neonates because of relatively low standard metabolic rate (*SMR*). As the SMR increases during the first few days of life, $T_{2,N}$ shifts to lower ambient temperature. The lower limit of the range of regulation, T_1 (see Figure 58-14), is determined by the maximal rate of heat production and is about 23° C in newborns and 0° to 5° C in adults. (*Data from Brück K: Heat production and temperature regulation. In Stave U [ed]:* Perinatal Physiology, *New York, Plenum Publishing, 1978, pp 455-498.*)

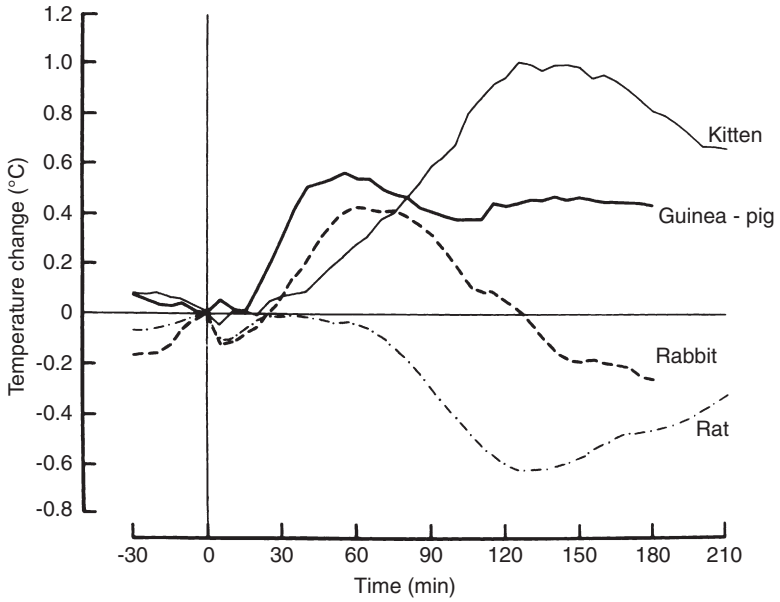

Figure 58-30 Average body temperature changes in the newborn of four species after two intraperitoneal injections of 20 mcg/kg *Escherichia coli* endotoxin at the individual thermoneutral ambient temperature. assume and sustain a higher body temperature during fever. This phenomenon has been termed *set-point displacement*, thereby excluding other conceivable interpretations, for example, a toxic effect on one or more effector systems (see Figure 58-9). Current fever research is focusing on the question of how bacterial and viral toxins (exogenous pyrogens) act to finally affect the thermointegrative system (see Figure 58-8) in such a way that the body temperature is shifted to a higher level.

Pathogenesis of Fever

Fever is considered an immunoreactive process.[89,90] Certain fever-producing substances of external origin (e.g., exogenous pyrogens), such as the heat-stable lipopolysaccharides of bacterial membranes (endotoxins), stimulate granulocytes and macrophages of the reticuloendothelial system to produce a heat-labile peptide called *endogenous pyrogen*. Endogenous pyrogen is identical to the cytokine interleukin-1. Microinjection of endogenous pyrogen into small regions of the hypothalamus triggers typical fever reactions that are not observed when it is injected into other parts of the brain. Endogenous pyrogen initiates a cascade of processes by activating phospholipase A_2, which then converts phospholipids in cell membranes to arachidonic acid. This compound may then be converted to prostaglandins.

One of the prostaglandins, prostaglandin E_2 (PGE_2), has a pyrogenic action when injected into the hypothalamus in minute

amounts.[91] PGE_2 produces the set-point shift already described by interacting with thermosensitive, integrative structures (see interneurons; Figure 58-8), or both in the hypothalamus. Antipyretics (e.g., acetylsalicylic acid) inhibit cyclooxygenase activity and thus prostaglandin formation. However, PGE_2 is not the only fever mediator because specific PGE_2 antagonists do not prevent pyrogen-initiated fever.[92] Evidence suggests that endogenous pyrogen may penetrate, in minute amounts, into the hypothalamus through a special transport system located in the organon vasculosum of the upper brain stem,[91] which belongs to the so-called circumventricular system. Based on evidence that PGE_2 appears before the increase in plasma cytokine concentration and the increases in related enzymatic activity, it has been suggested that rapid neural pathways may be involved in the pyrogenic sensing and signaling.[93] A more complex model for the genesis of fever is warranted and a search is under way for other fever mediators, particularly circulating products of oxidative stress and their interactions with nitric oxide (NO) and the thermointegrative networks.[94] Interest in the role of NO in body temperature control is expanding. This ubiquitous molecule appears to mediate both peripheral (vasomotor tone and brown fat metabolism) and central (set-point) responses of the thermal control system to a variety of stimuli, including exogenous pyrogens, psychologic stress, and exercise.[95] Studies based on intradermal administration of nitric oxide synthase (NOS) inhibitors via microdialysis probes during hyperthermia have found that active vasodilation during heat stress was significantly attenuated by NOS inhibition.[96,97] These studies suggest that an active vasodilator requires functional NOS to achieve full expression. Alternatively, Farrell and Bishop[98] noted that nitroprusside could restore the vasodilation inhibited by previous NOS blockade during hyperthermia in rabbit ears, but the same dose of nitroprusside infused into the ear circulation in normothermia did not raise ear blood flow. This implies that active vasodilation in rabbit ears requires both NO production and activation of the vasodilator nerves, and that these two elements not arranged in series (vasodilator activity did not increase NO production), and suggests a "permissive" role of NO in active vasodilation. Human studies based on NO breakdown products during hyperthermia have shown that both skin blood flow and bioavailable NO concentrations begin to increase at the same core temperature. This indicates that NO could well be an active effector of cutaneous vasodilation during heat stress.[99,100] Also, Shibasaki et al[101] have shown that acetylcholine-mediated NO production via muscarinic receptor activation was only possible early in heat stress, and then only before the occurrence of substantial cutaneous vasodilation. Although, both neuronal NOS and endothelial NOS have been detected in human skin,[102,103] it is unclear which isoform produces the increased NO required for active vasodilation. Wong et al[104] reported evidence that H_1 histamine receptors may play a role in the generation of NO during cutaneous active vasodilation in hyperthermia. The source of histamine remains to be identified; however, work by Wilkins et al[105] suggests that (1) vasoactive intestinal peptide–induced release of histamine from mast cells could be involved, and (2) vasoactive intestinal peptide and histamine have NO dependent components to their vasodilatory effects. Thus several pathways may be involved in the generation of NO in the skin during hyperthermia.[101,104,105] The students of thermoregulation will want to follow developments in this area closely.

Behavioral Fever

In newborn rabbits, which are born in a very immature state, the thermogenic response to a standard pyrogen dose may be weak or even lacking. Nevertheless, these animals have been shown to experience fever when they are put into a temperature-gradient tube in which they are able to move to an area so hot as to cause their body temperatures to increase.[56] This response has been termed *behavioral fever* in contrast to the fever produced by the activity of the autonomous thermoregulatory effectors (see Figure 58-9).

Temperature Regulation in Heart Failure

Thermal instability is a common accompaniment of cardiac disease in newborns, often leading to unnecessary treatment for infection. It should be remembered that circulatory changes are central to control of body temperature and thus dependent on cardiac function. Cardiac dependent changes are noted within and outside the thermoneutral zone, and these alterations are likely to differ with the severity and etiology of heart failure. Unfortunately, there are limited studies addressing this issue, particularly during the neonatal period. The upper boundary of the zone of hypothermia is elevated to include environments that, at worst, are only mildly chilling for normal patients but induce shivering in patients with heart failure. The cardiac stress associated with the onset of shivering is likely to be compounded by increased thermal stress through enhanced rate of decline of core temperature and a further stimulus to shivering.[106] In the neutral zone, where core temperature is maintained by control of skin blood flow, pharmacologic interventions have the potential to deprive the individual of the ability to vasodilate appropriately and could lead to a 2° C decline in core temperature.[107] In the zone of hyperthermia, both skin and core temperatures are likely to increase. Thermal steady states are possible when reflex sweating and cutaneous vasodilation are adequate to achieve thermal balance. The vasodilator component of this response is undoubtedly influenced by the physiologic changes and pharmacologic interventions associated with heart failure and its treatment. Interestingly, a vasodilator response has been shown experimentally to result in improvement of cardiac function because of afterload reduction,[108] similar to that observed with pharmacologic vasodilator treatment. In this situation the increase in cardiac output is entirely diverted to the cutaneous vasculature. Although it has not been well studied, it is likely that monitoring central and peripheral temperatures would provide useful information about the about the adequacy of cardiac reserve of children with congenital heart disease.

Hypoxia

Acute and Chronic Hypoxia

Considerable impairment of temperature regulation should be anticipated if the oxygen supply is critically reduced to the tissues subserving thermoregulatory heat production (skeletal tissues, musculature, and brown adipose tissue). Anaerobic metabolic processes are quantitatively insufficient to provide enough heat for thermoregulation. In fact, a reduction of oxygen content in the inspired gas to 10% has been shown to completely block thermogenesis in newborn kittens exposed to an ambient temperature that is lower than neutral.[109,110] As a result, body core temperature drops. Remarkably, the at rest metabolic rate as measured at neutral temperature remains unaffected by this degree of hypoxia. Similar results have been obtained in newborn lambs,[111] rhesus monkeys,[112] guinea pigs,[109] and rabbits.[113] By contrast, in larger adult organisms that do not possess nonshivering thermogenesis (e.g., adult humans[114] and dogs[115]), cold-induced thermogenesis (shivering) is only transiently reduced by hypoxia. With sustained hypoxia, shivering thermogenesis appears to be almost unimpaired. Thus nonshivering thermogenesis appears to be more vulnerable to the effect of hypoxia.

This view is supported by a study in newborn rabbits.[113] As shown in Figure 58-31, oxygen uptake increases on cold exposure without shivering. Offering a 10% oxygen gas mixture immediately abolishes the cold-induced nonshivering thermogenic

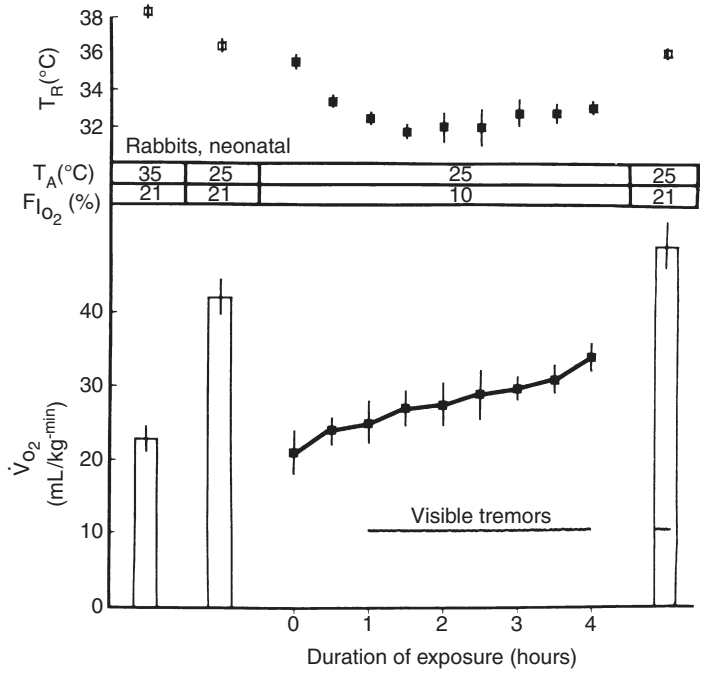

Figure 58-31 Effect of cold and hypoxia on the oxygen consumption and colonic temperature of unanesthetized newborn rabbits. Exposure to 25° C in air caused an increase in oxygen consumption, which was produced without shivering. This increase was abruptly abolished when the inspired oxygen content was decreased to 10%. During the next 4 hours, oxygen consumption gradually increased. Visible shivering developed after 1 hour and persisted into the posthypoxic period. (*From Blatteis CM: Shivering and nonshivering thermogenesis during hypoxia. In Smith RE [ed]:* Bioenergetics. Proceedings of the International Symposium on Environmental Physiology, *Bethesda, MD, 1988, pp 151-160.*)

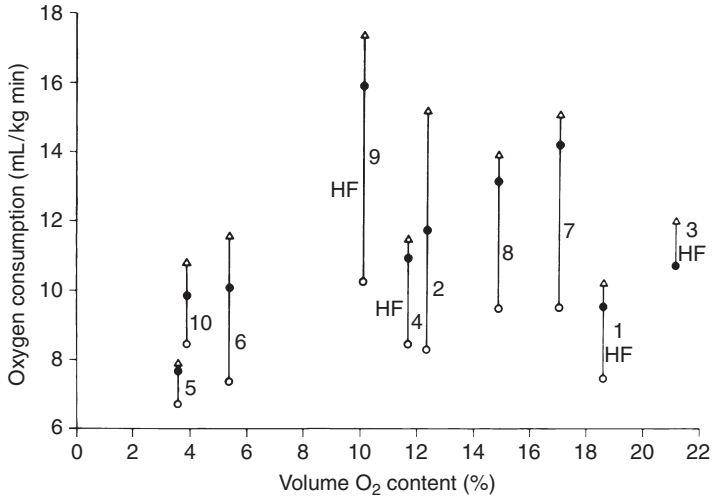

Figure 58-32 Responses of oxygen consumption on cold exposure (ambient temperature drop from 32° to 28° C) in relation to arterial oxygen content. ○, Minimal oxygen consumption *(MOC)* at neutral temperature; ●, average oxygen consumption during cooling period; △, peak oxygen consumption during cooling period. Three infants designated with heart failure (*HF*) had suffered severe heart failure. Note that oxygen consumption increased on cooling even in infants with arterial oxygen content as low as 5% vol. (*From Brück K, Adams M: Temperature regulation in infants with chronic hypoxemia,* Pediatrics *30:350, 1962.*)

response. In the subsequent hours, however, oxygen uptake steadily increases and is accompanied by shivering. Because the interscapular brown adipose tissue is a major site of thermogenesis and the heat produced in this organ inhibits shivering through cervicospinal warm-sensitive structures, the appearance of shivering during hypoxic blockade of nonshivering thermogenesis is understandable. With prolonged hypoxia, the capacity for nonshivering thermogenesis may more or less recover. Normal thermogenic responses without obvious shivering have been observed in some neonates and infants with cyanotic congenital heart disease in whom arterial oxygen contents range 10 to 20 mL/dL (Figure 58-32). Even with arterial oxygen content as low as 5 mL/dL, thermogenic responses can be evoked, although they are reduced in magnitude. These results suggest that in chronic hypoxia, adjustments take place that restore the capacity for nonshivering thermogenesis.

As for the mechanism of the hypoxic reduction of cold-inducible thermogenesis, two possibilities have been suggested: (1) reduced oxidative capacity from the lowered oxygen tension at the level of mitochondria in the organs involved in thermogenesis (brown adipose tissue, skeletal musculature) and (2) central inhibition of the effector systems. As shown by Blatteis,[113] the effect of norepinephrine infusion on nonshivering thermogenesis is abolished or grossly reduced during hypoxia. This would support the first hypothesis.

In hibernators, hypoxia and hypercapnia have been shown to displace the threshold for the elicitation of cold defense reactions to a lower body temperature level through a central action.[116,117] In a study in conscious adult cats,[118] hypoxia caused by inspiration of 11% oxygen reduced shivering. This suppression of shivering was partially reversed, however, when the end-tidal carbon dioxide concentration was returned to normal by addition of carbon dioxide to the inspired gas. These data would argue against the first possibility, at least with regard to moderate grades of hypoxia. Thus those authors concluded that "brain hypoxia lowers the regulated body temperature during cold stress." More recent observations suggest that, as in the case of fever, molecular mediators of the central effector response are likely to be important. Murine hypoxic hypometabolism and associated hypoventilation have been ameliorated by inhibitors of NOS.[119] Depending on the experimental design and species under study, various, often contradictory effects of NO have been reported. Overall, the evidence points toward a fundamental, but complex, role for NO in the control of metabolism, cardiorespiratory function, and temperature during hypoxia.

Effects of Fetal Hypoxia on Neonates

Fetal hypoxia has been shown to increase the plasma norepinephrine concentration. This, in turn, results in peripheral vasoconstriction and circulatory centralization of cardiac output.[120] Moreover, increased norepinephrine levels have been shown in guinea pigs to cause a downward displacement of the shivering threshold temperature.[121,122] Neonates who had fetal asphyxia may thus display a delayed metabolic response to cold exposure as well as a delayed cutaneous vasodilation on heat exposure. This has been demonstrated in neonates who have undergone severe asphyxiation during delivery.[1]

Physics and Physiology of Human Neonatal Incubation

During fetal life, water and electrolytes are exchanged between the mother and the fetus through the placental circulation. The fetus contributes to the formation of amniotic fluid with urine[1] and with water transported through the respiratory epithelium and the airways.[2-5] During gestation, body water gradually decreases, and extracellular water and the contents of sodium and chloride decrease proportionally. The water content of a term newborn infant is approximately 77% of the body weight.[6] In preterm infants, the total body water at birth is higher, namely, 82% at 32 weeks gestation and 86% at 24 weeks.[6] Heat produced by the fetus results in a fetal temperature that is approximately 0.5° C higher than the maternal temperature and results in a transfer of heat from the fetus to the mother through the placental circulation and through the amniotic fluid and fetal membranes.[7,8]

Immediately after birth, the skin of the infant is covered with amniotic fluid and usually vernix caseosa. Evaporation from the body surface of amniotic fluid[9] and of water in amniotic fluid[10] causes a loss of heat. At the same time, the infant is exposed to a colder temperature than was experienced in utero. The body temperature will then be lowered, a change that is at least partially physiologic, because the body temperature at birth is higher than that in subsequent life.To make it possible for a newborn infant to maintain an almost constant body temperature, heat production and heat exchange with the environment have to balance each other. Exposure to cold may give rise to thermogenic responses that will increase basal heat production,[11-18] and the skin circulation may decrease to lower the heat losses.[19] Seriously ill and very preterm infants are usually nursed in an environment in which a normal body temperature can be maintained, either in an incubator at an ambient temperature within the thermoneutral zone[14,15,20] or under a radiant heater. Heat balance in newborn infants is, however, not dependent solely on the ambient temperature and the radiant energy but also on many other factors that determine the heat transfer between the infant and the environment.* One of these factors is water exchange between the infant and the environment.† With every gram of water evaporated from the body surface or the respiratory tract, the infant will lose heat because of the latent heat of evaporation.

ROUTES OF WATER EXCHANGE

The newborn infant loses water insensibly through the skin and respiratory tract and sensibly with the urine and stools.‡ Water is gained by the body through the intake of fluids and food and as a result of metabolism.

Water loss from the skin surface involves two processes: continuous diffusion of water vapor through the epidermis and losses from the sweat glands in term and near-term infants. In the absence of forced convection, that is, with airflow velocity lower than 0.2 m/second, the human body is surrounded by a boundary layer of water vapor,[67] which constitutes a transition zone for transportation of moisture and heat from the body to the ambient air. In this zone of diffusion, a linear relationship exists between the water vapor pressure and the distance from the evaporating surface.[68] Evaporation of water from the skin and from the respiratory tract implies transfer of mass and of energy.[16,24] Insensible water loss (IWL) has been studied by gravimetric methods§ and with the ventilated chamber technique.[15,51,63] Hey and Katz[15] found that the IWL from the skin (IWL_s) in term infants comprised about 75% of the total IWL.[15] It has also been shown that the IWL is influenced by the ambient humidity[15,31,51,63] and is

*References 9, 11, 12, 14-16, 20-32.

§References 33, 46, 54, 57, 58, 59, 61, 62, 69, 70.

high in low-birth-weight infants.[62] Techniques for determining water loss from the skin[36,47,71] and from the respiratory tract[42,49] have made it possible to determine the relative contributions of these two routes of water loss to the total IWL in infants of different gestational ages* (under different conditions) and to calculate the different modes of heat exchange.[9,25,26,53,72]

Determination of Water Loss From the Skin

In the absence of forced convection, and if the effect of thermal diffusion is disregarded, the process of water exchange through a stationary water-permeable surface can be expressed in terms of the vapor-pressure gradient immediately adjacent to the surface, as

$$\text{Water exchange} = -D' \frac{\delta\rho}{\delta\chi}$$

where D' is the diffusion coefficient and $\delta r/\delta\chi$ is the gradient.

This expression includes both a diffusive mass flow caused by a vapor-concentration gradient and a convective mass flow caused by a temperature gradient.

D' varies with the temperature (T) and the atmospheric pressure (P_{atm}), as follows[73]:

$$D' = \frac{DM}{RT} \frac{T^{1.75}}{300} \frac{101 \times 10^3}{P_{atm}}$$

where M is the molecular weight and R the gas constant (8.314 J/mol-K).

Within the ranges of temperatures and atmospheric pressures in question, the maximal variation in D' is limited. D' can then be approximated by a constant given the value 0.670×10^{-3} g/mhPa, which is valid for the water vapor pressure at a temperature of 300 K and an atmospheric pressure of 101 kPa.

The evaporation rate (ER; g/m^{2}h) can thus be determined by a method based on calculation of the water vapor pressure in the layer of air immediately adjacent to the skin surface. In this zone, a linear relationship exists between the vapor pressure and the distance from the evaporating surface.[68] If the gradient in this layer is known, the amount of water evaporated per unit time can be calculated according to the following equation[47,71]:

$$\frac{I}{A}\frac{dm}{dt} = D' \frac{dp}{dx} \text{ (g/m}^2\text{h)}$$

where A is the area.

The gradient method (Evaporimeter; ServoMed AB, Kinna, Sweden) allows measurements of free evaporation and quick measurements without disturbing the infant.[36,47] Transepidermal water loss (TEWL; grams per square meter), which is a mean value of cutaneous water loss, can be calculated according to the following equation:

$$\text{TEWL} = 0.92 \bullet ER_{(a,b,c)} + 1.37$$

Measurements of Respiratory Water Loss

Respiratory water loss (RWL) is usually included in the measurements of total IWL when measurements are made with ventilated chambers, but in a few studies it has been estimated separately.[15,31,63] These authors all found that the RWL was higher at low ambient humidity than at high humidity.

In most of the more recent studies of RWL, an open flow-through system has been used with a mass spectrometer to measure the gas concentrations.[42] Ambient air is then sucked through a specially constructed Teflon funnel attached to the infant (or the lamb), so that all expired air is collected without inclusion of evaporation from the surrounding skin.[42,49] This system provides data on RWL, oxygen consumption, and carbon dioxide (CO_2) production.*

ROUTES OF HEAT EXCHANGE

Heat exchange between the infant and the environment occurs through the skin and to some extent through the respiratory tract. Heat exchange through the skin takes place through conduction (H_{cond}), evaporation (H_{evap}), radiation (H_{rad}), and convection (H_{conv}). Its magnitude depends on the body surface area of the infant and the proportions of the body surface in direct contact with the mattress or clothing and exposure to the air and surrounding surfaces. To determine the heat exchange between the infant and the environment, it is thus necessary to know the heat loss from the skin per unit surface area, the total body surface area, and the proportion of the surface area participating in the different modes of heat exchange.†

Calculation of Heat Exchange Between the Infant's Body Surface and the Environment

Heat exchange through conduction, evaporation, radiation, and convection can be calculated with knowledge of the TEWL, the temperature of the material on which the infant is placed (T_{bed}), the temperature of the infant's skin (T_{skin}), the temperature of the ambient air (T_{amb}), the temperature of the walls facing the infant (T_{wall}), and characteristics of the material in the infant's environment, by using the following equations[9,25]:

Heat exchange through conduction:

$$H_{cond} = K_0(T_{skin} - T_{bed})(\text{W/m}^2)$$

where K_0 is the conductive heat transfer coefficient. H_{cond} is dependent on the thermal characteristics of the skin, but even more on those of the mattress. T_{skin} is the temperature of the skin (K), and T_{bed} (K) is the temperature of the bed (mattress). With the thermal conductivity characteristics of most regular mattresses, the heat loss through conduction in incubators and under radiant heaters is very low.

Heat exchange through evaporation:

$$H_{evap} = K_1 \bullet \text{TEWL} \, (3.6 \times 10^3)^{-1} (\text{W/m}^2)$$

where K_1 is the latent heat of evaporation ($2.4 \cdot 10^3$ J/g), TEWL is the transepidermal water loss (g/m^{2}h), and $3.6 \cdot 10^3$ is the correction factor for time (seconds). TEWL is a mean value of evaporation of water from the skin surface measured with the gradient method.‡

Heat exchange through radiation:

$$H_{rad} = S_0 \bullet e_1 \bullet e_2 \bullet (T_1^4 - T_2^4)(\text{W/m}^2)$$

In this equation, S_0 is Stefan-Boltzmann's constant ($5.7 \cdot 10^{-8}$ W/m^{2}K^4), e_1 is the emissivity of the skin, e_2 is the emissivity of the surrounding walls (0.97), T_1 is the mean temperature of the skin (K), and T_2 is the mean temperature of the surrounding wall (K).

Heat exchange through convection can be calculated as follows:

$$H_{conv} = K_2 \, (T_1 - T_3)(\text{W/m}^2)$$

where K_2 is the convection coefficient (2.7 W/m^{2}K), T_1 is the mean temperature of the skin (K), and T_3 is the mean temperature of the ambient air (K). This calculation does not include fast convections, which in adults occur at air velocities greater than 0.27 m/second.[24] The coefficient for convection given earlier

*References 29, 36-41, 49, 50, 65.

†References 9, 25-27, 32, 35, 48, 71.
‡References 30, 36-41, 52, 53, 77, 78.

and used in many studies referred to in this chapter has usually been determined in measurements on adult human skin. A convection coefficient suggested to be more valid for newborn infants[79] can be used; however, H_{conv} will then be 48% higher.

The extent of heat exchange between the body surface area and the environment depends on the type of heat exchange, on the position and geometry of the body, and on the magnitude and frequency of body movements. Because the different modes of heat exchange are unequally influenced by a change of body position, the relative contributions of the different modes of heat exchange may vary with time. When heat exchange is compared among different environmental conditions and among infants of different gestational and postnatal ages, it is often presented as heat exchange per unit area of body surface exposed to the ambient air or facing the walls of the incubator.

Heat Exchange Through the Respiratory Tract

The expired air is usually more humid (i.e., it has a higher water vapor pressure) than the inspired air. This implies an evaporative loss of water and of heat from the respiratory tract. A usually low degree of convective heat transfer also takes place in the respiratory tract. Often, these two processes are considered together.[16] In the newborn, heat may also be gained through the respiratory tract if the infant inspires warm air with a high humidity.

Because of the alternating displacement of air during the respiratory cycle, convective and evaporative heat transfer in the respiratory tract is complex. When ambient air, which is cooler than the body, passes along the mucosa during inspiration, it gains heat by convection and gains water vapor by evaporation from the mucosa. On reaching the alveoli, the air is at thermal equilibrium with the central body temperature and is saturated with water. During expiration, the expired air may become a little cooler than the body temperature before it leaves the infant.

Calculation of Heat Exchange From the Infant's Respiratory Tract and the Environment

The exchange of heat through convection in the respiratory tract, $H_{conv\text{-}r}$, is calculated from the air volume ventilated per unit time (V = ventilation volume) and from the temperature difference between expired and inspired air ($T_E - T_I$) according to the following relationship:

$$H_{conv\text{-}r} = V \bullet \rho \bullet c \bullet (T_E - T_I) m^{-1} (W/kg)$$

where V is the ventilation volume per unit time, ρ is the density of the air (1 g = 0.880 L), c is the specific heat (1 J/g/° C), m is the body weight (kilograms), and T_E and T_I are the temperatures of the expired and inspired air.[16]

Because of the alternating inspiratory warming and expiratory cooling of the air, the convective heat exchange in the respiratory tract depends mainly on the temperature of the inspired air. In human infants nursed in incubators, only a small difference exists between the temperatures of the inspired and expired air, and convective losses are therefore small.

Evaporative heat exchange from the airway ($H_{evap\text{-}r}$) depends on the difference in water content between expired and inspired air. This is the RWL.[29,42,49,50,65] Because the formation of water vapor in the respiratory tract requires thermal energy, the amount of heat exchange by evaporation per unit time will be as follows:

$$H_{evap\text{-}r} = K_1 \bullet \text{RWL} (3.6 \bullet 10^3)^{-1} (W/kg)$$

where K_1 is the latent heat of evaporation of water ($2.4 \bullet 10^3$ J/g), RWL is the respiratory water loss (milligrams per kilogram minute), and $(3.6 \bullet 10^3)^{-1}$ is the correction factor for time.

Heat Exchange in Incubators, Under Radiant Heaters, and in Heated Beds

Incubators

The first incubators were constructed when it was realized that a good thermal environment increases the chances of survival of newborn infants. Budin[80] found higher survival in infants whose temperature had never been lower than 32° C. Later studies by Silverman and co-workers,[81,82] Hey and Mount,[27] Hey,[14] Hey and Katz,[15,28] and Dahm and James[83] widened the knowledge concerning the influence of T_{amb} on the survival rate, oxygen consumption, and respiration of newborn infants.

In a convectively heated incubator, the warm air supplied is usually directed so that both the air temperature of the incubator and the incubator walls are kept warm. If the airflow velocity close to the infant is less than 0.2 m/second, a normal convective pattern will exist around the infant, and, at an airflow velocity lower than 0.1 m/second, the convective heat transfer will depend on the gradient between the skin and the air temperature. In this condition, the vapor-pressure gradient close to the skin surface will also be maintained, avoiding increased evaporative water loss resulting from airflow velocity.* In incubators available today, both the airflow velocities and the humidification capacity vary markedly.[85] The wall temperatures also vary among different incubators.[85] It is therefore necessary to determine airflow velocities, humidity, and wall temperatures carefully before calculations of heat exchange are performed.

Radiant Heaters

Infrared radiation energy was first used by Agate and Silverman[86] to control the body temperature of small newborn infants and has since become widely used in neonatal intensive care. The radiant warmer placed over an open bed platform provides a good accessibility and visibility for the care of the newborn infant. When nursed under a radiant heater, the infant gains heat but may also have extensive heat losses through evaporation and convection and, from some surfaces, through radiation.[14,46,54,57,70] It is thus difficult to estimate the relative contributions of different modes of heat exchange when the infant is nursed under a radiant heater. Because free air movements may occur above the body surface of the infant, both evaporative and convective heat loss may increase as a result of a high air velocity. Williams and Oh[57] and Bell and Oh[60] suggested that the vapor pressure of the ambient air may be lower under a radiant heater than in an incubator and that this could result in higher insensible loss of water from the skin or the respiratory tract. Baumgart[22] considered convective heat loss to be the major component of net heat loss under a radiant heater. It was also found that in critically ill preterm infants nursed under a radiant heater the IWL increased when the radiant power density was increased to the level required by these small infants.[33] In addition, Baumgart and co-workers pointed out that convective air currents under the radiant heater could cause an increase in evaporative water loss and heat exchange.[21,33,34] Determinations of heat exchange in infants nursed under a radiant heater are difficult to perform because of the variations in humidity and air velocities and in the proportion of the body surface facing the walls of the nursery.

Heated Beds

Sarman and co-workers showed that infants weighing 1000 to 2000 g can be kept warm by placing them on a heated water-filled mattress.[87] In infants with a low body temperature, heat can be gained by conduction. By covering most parts of the body except the head, direct heat exchange between the infant's skin and the environment through other modes will be almost eliminated for a large proportion of the body surface. The water and

*References 16, 24, 35, 48, 79, 84.

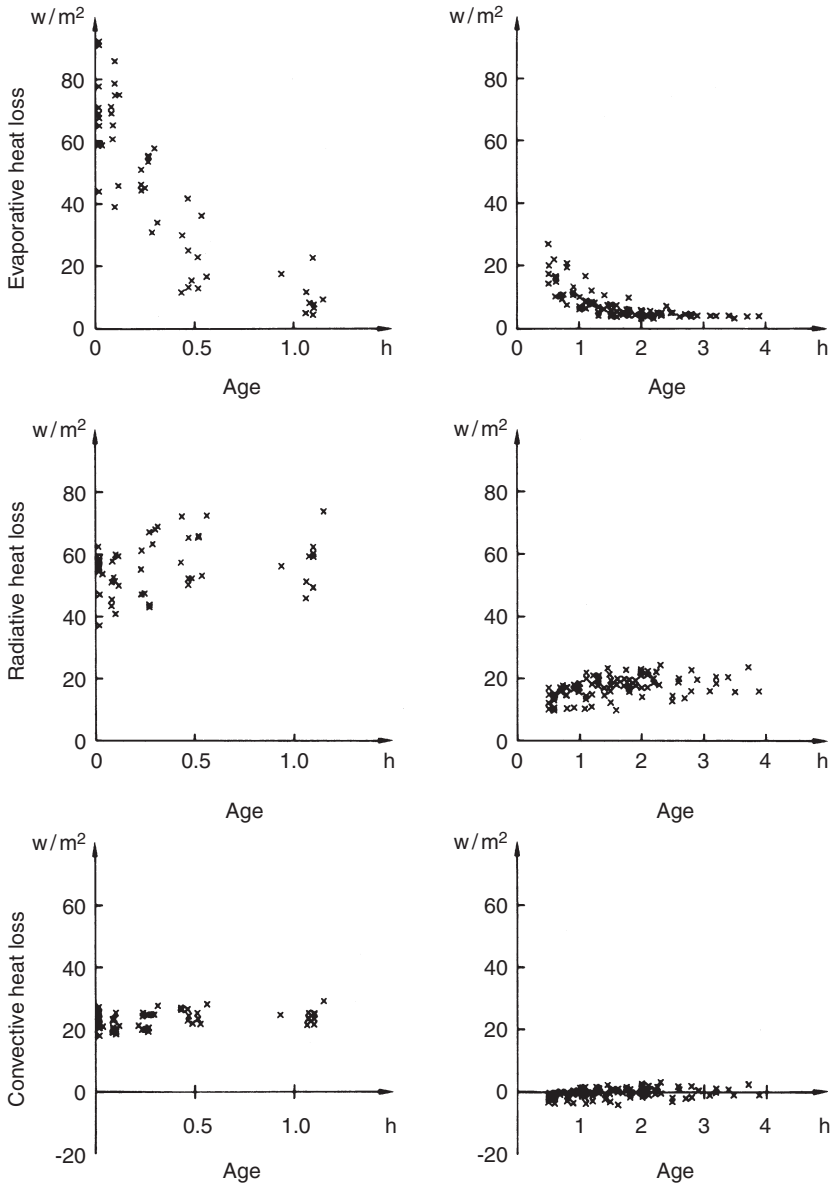

Figure 59-1 Heat exchange between the skin of term infants and the environment immediately after birth and during the first 1 to 4 postnatal hours. Data presented in the *left-hand scatter diagrams* are based on measurements in infants who were not washed or wiped. After the measurements at 1 and 5 minutes after birth, the infants were covered with a towel between the measurements. Data in the *right-hand diagrams* are based on measurements in infants who after birth were covered with a towel until they were placed in an incubator. *(From Hammarlund K, Nilsson GE, Oberg PA, Sedin G: Transepidermal water loss in newborn infants. V. Evaporation from the skin and heat exchange during the first hours of life,* Acta Paediatr Scand *69:385, 1980.)*

heat exchange through the respiratory tract will depend on the temperature and humidity of room air.

WATER AND HEAT EXCHANGE BETWEEN THE SKIN AND THE ENVIRONMENT

Water evaporation from the skin surface of infants nursed in incubators has been determined by use of the gradient method* (Evaporimeter; ServoMed AB, Stockholm, Sweden). TEWL[36-38,40,41,53] and heat exchange[9,25,26] have also been calculated. In these studies, the body temperature has been maintained at 36° to 37° C, except when the effect of warming has been investigated, and the ambient humidity has been kept at 50%, except when the effects of different humidities have been analyzed. Evaporative heat loss is usually insensible, but it may become sensible when term infants are nursed in a warm environment[59] and start to sweat.[37,55,56] In preterm infants, the sweat glands are nonfunctional, and no sweating occurs even when preterm infants are nursed in a warm environment.[15] Not all infants born at term and nursed in a warm environment start to sweat.[56] In infants who do, the sweating is preceded by an increase in skin blood flow, as measured with the laser Doppler technique,[55,56,88] and feeding cold glucose can then inhibit both sweating and vasodilatation.[56]

Heat Exchange During the First Hours After Birth

An enormous evaporative heat loss takes place early after birth, when the infant's skin is covered with amniotic fluid, and it gradually decreases during the first hours of postnatal life (Figure 59-1).[9] In the delivery room, heat loss to the environment

*References 10, 36-41, 43, 45, 52, 53, 55, 56.

through radiation is also considerable if the infant's skin surface is exposed to the room air and faces the walls of the delivery room. This early loss of heat through evaporation, radiation, and convection can usually be kept at a moderate level even when the infant is nursed in the mother's arms,[9] provided adequate precautions are taken to prevent excessive loss of heat, such as by gently wiping the infant's skin[10] and covering the infant with warm towels.[9]

Transepidermal Water Loss During the First Day After Birth and During the First 4 Postnatal Weeks

The TEWL from the skin surface of the newborn infant depends on certain factors, such as the gestational age at birth,[38] the postnatal age,[40,41] and being small[39] or appropriate for gestational age.[38,39,41,53] TEWL is also dependent on ambient factors such as the air temperature and humidity.[36,38-40,52,53] TEWL is 15 times higher in infants born at 25 weeks gestation than in term infants. An exponential relationship exists between TEWL and gestational age when measurements are made during the first day after birth.[38] This type of relationship prevails over the first 4 weeks after birth (Figure 59-2),[41] even though the difference in TEWL between the most preterm and term appropriate–for–gestational age infants gradually diminishes with age. However, at a postnatal age of 4 weeks, TEWL is still twice as high in the former as in the latter (see Figure 59-2). The loss of water from the skin surface also depends to a higher degree on the ambient relative humidity, with much higher losses at a low humidity than at a high humidity (Figure 59-3).[38] This relationship seems to be valid for all gestational ages and all postnatal ages studied.[36,38-40,52,53]

In very preterm infants, at an ambient humidity of 50%, water loss through the skin (Table 59-1) is the most important route early after birth. As seen in Table 59-1,[41] in infants born at 25 to 27 weeks gestation, the water loss amounted to 129 g/kg body weight per 24 hours during the first day after birth, after which a gradual decrease occurred, which was most marked during the first 7 days. These losses, however, depended on the ambient humidity, which meant that the IWL_s during the first day after birth in infants born at 25 to 27 weeks gestation was 205 g/kg per 24 hours at an ambient humidity of 20% and only 53 g/kg at an ambient humidity of 80% (Table 59-2). Therefore water balance in very preterm and extremely preterm infants is best maintained if excessive evaporative losses of water are prevented by nursing the infants in a humid environment.[66]

Heat Exchange During the First Day After Birth

Because the evaporative heat exchange between the infant's skin and the environment during the first day after birth is directly proportional to the amount of water evaporated from the infant's skin, evaporative heat loss shows the same kind of relationship with gestational age as TEWL (Figure 59-4). In the most preterm infants, the evaporative heat exchange may reach 50 W/m^2 of the body surface area,[25] whereas in term infants it is close to 5 W/m.^{2} Because of the high evaporative heat loss in very preterm infants, a high T_{amb} is needed to maintain a normal body temperature of between 36.0° and 37.0° C. To keep the infant's thermal balance at steady state, the servocontrol system of the incubator, which controls the skin temperature, increases the temperature of the air, which leads to an increase in the temperature of the incubator walls. Thus the loss of heat to the environment through convection and radiation decreases, and the most preterm infants can even gain heat through these modes of heat exchange (see Figure 59-4). Because these data were obtained while the infants were being nursed in an incubator with a relative humidity of 50%, the preterm infants who needed a higher T_{amb} were nursed at a higher ambient vapor pressure than more mature infants. The difference in evaporative heat exchange between very preterm and term infants would have been even greater if the comparison

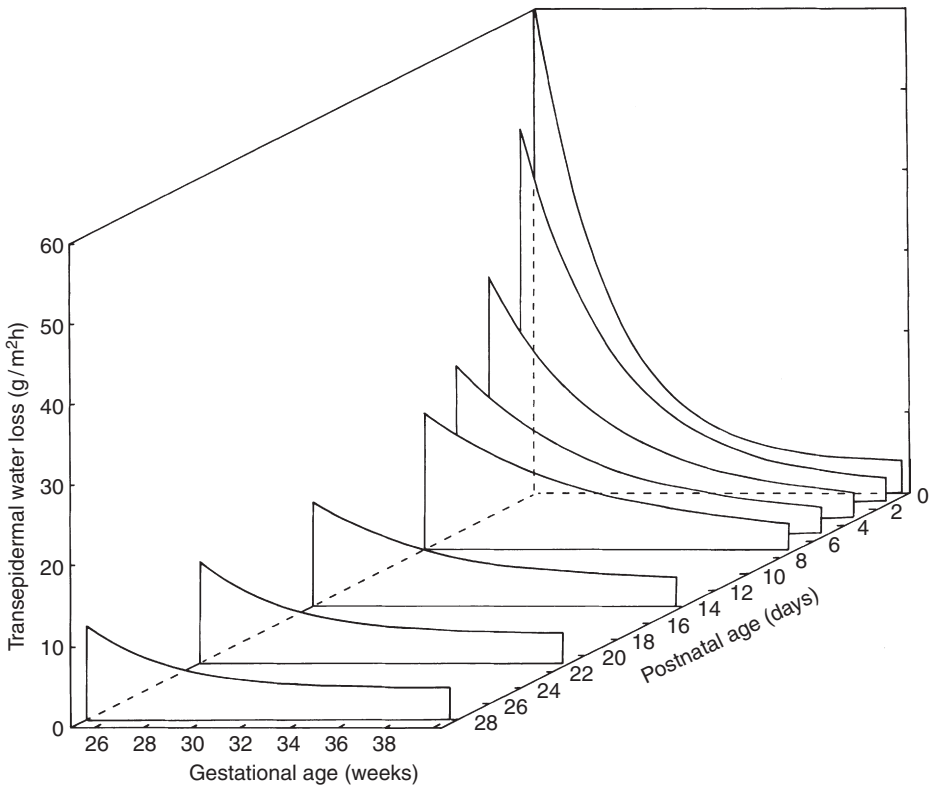

Figure 59-2 The regression of transepidermal water loss on gestational age at birth at different postnatal ages in appropriate–for–gestational age infants. *(From Hammarlund K, Sedin G, Strömberg B: Transepidermal water loss in newborn infants. VIII. Relation to gestational age and post-natal age in appropriate and small for gestational age infants,* Acta Paediatr Scand *72:721, 1983.)*

had been made at equal ambient vapor pressures instead of equal ambient humidities. Infants born at a gestational age of less than 28 weeks need a T_{amb} of approximately 40° C to maintain a normal body temperature at an ambient humidity as low as 20%, whereas term infants need a T_{amb} of approximately 34° C at this ambient humidity (Figure 59-5). At a higher ambient humidity, a somewhat lower T_{amb} is required to maintain a normal body temperature in the most immature infants.[25]

When calculations of heat exchange are made for three different ambient humidities, it is found that the evaporative heat exchange between the skin of very preterm infants and the environment is highest at a low humidity.[25] At a relative ambient humidity (RH) of 60%, the heat exchange through evaporation in these infants is only 50% of that at a RH of 20% (Figure 59-6). Other modes of heat exchange are also influenced by the ambient humidity (see Figure 59-6). Because the evaporative heat exchange is highest at a low humidity, the T_{amb} has to be kept high, and the infant will gain heat both through radiation and through convection. At higher ambient humidities, the evaporative heat exchange will be lower, especially in preterm infants, and, if the body temperature is kept constant, radiative heat loss will be higher and heat gain through convection will be somewhat lower.[25]

If the different modes of heat exchange from the skin surface are added together, the sum will be fairly constant throughout the gestational age groups. The total heat loss cannot, however, be calculated in this way, because the proportions of the body surface area exchanging heat in different ways are not exactly known.

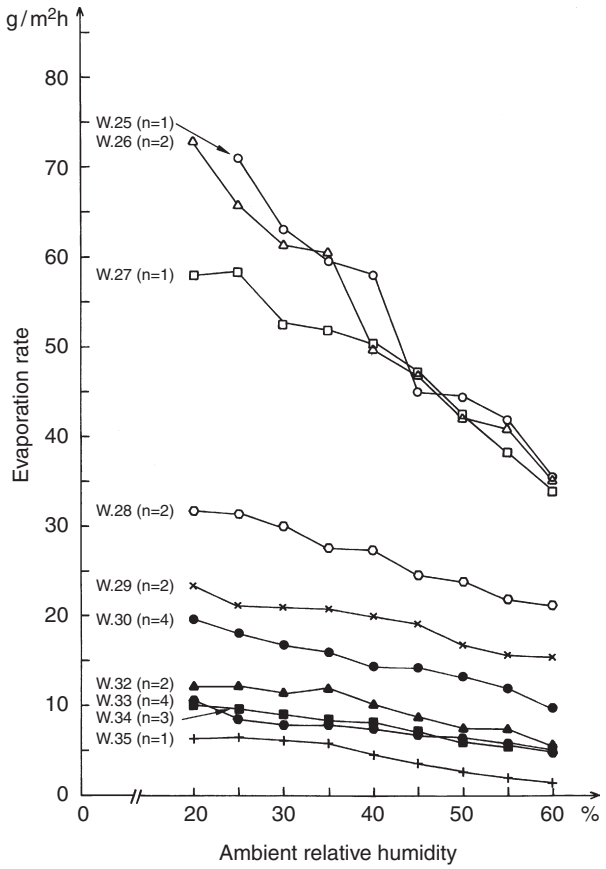

Figure 59-3 The relation between evaporation rate and ambient relative humidity in preterm appropriate–for–gestational age newborn infants in different gestational age groups on the first day after birth. *W,* Completed weeks gestation. *(From Hammarlund K, Sedin G: Transepidermal water loss in newborn infants. III. Relation to gestational age,* Acta Paediatr Scand *68:795, 1979.)*

Heat Exchange During the First Weeks After Birth

During the first weeks after birth, the temperature of the incubator air can gradually be lowered for both preterm and term infants.[26] The high evaporative losses of heat from the infant's skin on the first days after birth will gradually decrease with increasing postnatal age (Figure 59-7).[26] Heat loss through radiation, which is low early after birth in the most preterm infants born at 25 to 27 weeks gestation, will be the most important mode of heat exchange after the first postnatal week. In infants born at more than 28 weeks, radiative heat exchange is the most important mode of heat exchange from birth. The heat loss through radiation will gradually increase with age. The smallest preterm infants will gain heat through convection over the first 10 days, after which a low loss of heat will occur through convection.

During the first weeks after birth, the relative magnitude of the different modes of heat exchange will depend on the ambient humidity (Figure 59-8). In a dry environment, in infants born at 25 to 27 weeks gestation, evaporative heat exchange will be the most important mode of heat exchange for more than 10 days, whereas, at an ambient humidity of 60%, this mode of exchange will be much lower and will be exceeded by heat exchange through radiation from the fifth day after birth.[26]

Total Heat Exchange Between the Infant's Skin and the Environment

To calculate the total heat exchange between the infant's skin and the environment, the body surface area of the infant and the fractions of this area that participate in each mode of heat exchange must be calculated. With the available methods, it is difficult to determine how different fractions of heat exchange vary over a longer period.[26] The total heat exchange is basically dependent on the metabolic rate.

Ambient Humidity and Skin Barrier Maturation

In our previously performed longitudinal studies on water and heat exchange between very preterm infants and their environment early after birth, we have during regular care always kept the RH at 85% during care in incubators. Before performing measurements of ER from the skin, the RH in the incubator is lowered to 50% and stabilized at this level. Then measurements of ER and calculation of transepidermal water loss are performed at 50% ambient humidity[89] with the aim to investigate whether the level of RH in which the infants are nursed influences the maturation of their postnatal skin development.

In 22 preterm infants born at a gestational age of 23 to 25 weeks, TEWL was determined at postnatal ages of 0, 3, 7, 14, and 28 days. The infants were nursed at a RH of 85% during the first week after birth. At a postnatal age of 7 days the infants were randomly assigned to continued care at either 50% or 75%. The results of the measurements were corrected to a RH of 50% ($TEWL_{50}$). $TEWL_{50}$ was very high on the first day after birth (62 ± 5 g • m^{-2} • h^{-1}) and decreased with increasing postnatal age. At postnatal days 3 and 7 no differences in $TEWL_{50}$ were seen between the two groups. At a postnatal age of 28 days $TEWL_{50}$ was twice as high in infants nursed at 75% RH (22 ± 2 g • m^{-2} • h^{-1}) as in those nursed at 50% RH (13 ± 1 g • m^{-2} • h^{-1}; $p < .001$). These results indicate that the level of RH influences the development of the skin barrier (Figure 59-9), presumably through its effect on transepidermal water flux. These findings are relevant for nursing strategies promoting barrier integrity in extremely preterm infants. The study has resulted in a shorter duration of nursing very preterm infants at a very high humidity. After 1 postnatal week, the RH can be lowered to 50%, promoting skin barrier development in extremely preterm infants.

Nonionizing Radiation and Evaporative Water and Heat Exchange Between the Infant's Skin and the Environment

Radiant Heaters

In studies of the ER in term, moderately preterm, and very preterm infants nursed in incubators with 50% ambient humidity and under a radiant heater, it was found that the ER from the skin surface of term infants was significantly higher under the radiant heater than in the incubator.[45] Preterm infants were observed both at 50% ambient humidity and at a lower ambient humidity of 30% to 40% in the incubator and then under a radiant heater. No significant difference was found between ER values obtained in the incubator at the lower ambient humidity and ER measured under the radiant heater. When using the measured values of ER and water vapor pressure in the incubator and the theoretical values of ER = 0 and the water vapor pressure in the incubator at a RH of 100% at incubator air temperature, the highest possible ER was calculated from the linear regression line for the value water vapor pressure = 0 (Figure 59-10). A calculated value for ER during care under a radiant heater could then be obtained on the line between the maximum ER value at water vapor pressure = 0 and ER = 0, that is, at the saturated vapor pressure for the air temperature under the radiant heater (see Figure 59-10).[45] The calculated values for ER determined in this fashion were always higher than the measured values, a finding that suggests that, even if the measured ER under the radiant heater is higher than the ER in the incubator on account of the higher humidity in the latter, no indication exists of an increased water loss resulting from a direct effect of nonionizing radiation on the barrier function of the infant's skin,[45] as suggested previously.[90]

In investigations of the effects of nonionizing radiation in an incubator equipped with a radiant hood warmer, a device that heats the incubator roof and ceiling independently of the incubator's main heat source, no change in TEWL in term and preterm infants was observed with use of this device.[30,78] This finding further supports the view that an isolated change in radiative heat exchange does not influence the evaporative water and heat exchange if the ambient air temperature and ambient humidity (i.e., the vapor pressure) are unaltered.

Phototherapy

An increase in the IWL during phototherapy was reported in several publications.[58,60,61,64,70] This could be caused either by increased water loss from the skin as a result of altered barrier properties or by increased RWL. In thermally stable term and preterm infants,[43] no increase in the ER from the skin surface was found during phototherapy. In that study, a significant increase was seen in the temperature of the ceiling of the incubator. T_{body}, T_{skin}, heart rate, and respiratory rate were unchanged in term and preterm infants. T_{amb} was unchanged during the studies in term infants, whereas T_{amb} sometimes had to be lowered in preterm infants to avoid heat stress.[43]

WATER AND HEAT EXCHANGE BETWEEN THE RESPIRATORY TRACT AND ENVIRONMENT

Water and Heat Loss From the Respiratory Tract

When an infant is nursed in room air, water is lost from the respiratory tract with each expiration. With use of indirect methods for the determination of RWL, it has been shown that RWL depends on the humidity of inspired air, with lower losses at a high humidity.[15,31,54,63] In a series of studies of RWL (milligrams per kilogram per minute) using a flow-through system with a mass spectrometer for measurements of gas concentrations,* we found that, in an environment with 50% ambient humidity, the evaporative heat loss from the airway will be of moderate magnitude.[49] Actually, in term appropriate–for–gestational age infants who are nursed in an environment with 50% ambient humidity, the IWL from the respiratory tract (IWL_r) and that from the skin (IWL_s) will be of equal magnitude.[49] Therefore the evaporative heat loss from the respiratory tract and the evaporative heat loss from the skin will also be of equal magnitude under these conditions.

The evaporative loss of water and heat from the airway has been found to depend on the ambient humidity in both lambs[42] and infants,[49] with lower losses at higher humidity. Whereas IWL_s decreased from 9 to 2 g/kg per 24 hours in term infants when the ambient humidity was increased from 20% to 80%, the corresponding change in IWL_r was much smaller, that is, from

*References 19, 29, 42, 49, 50, 65.

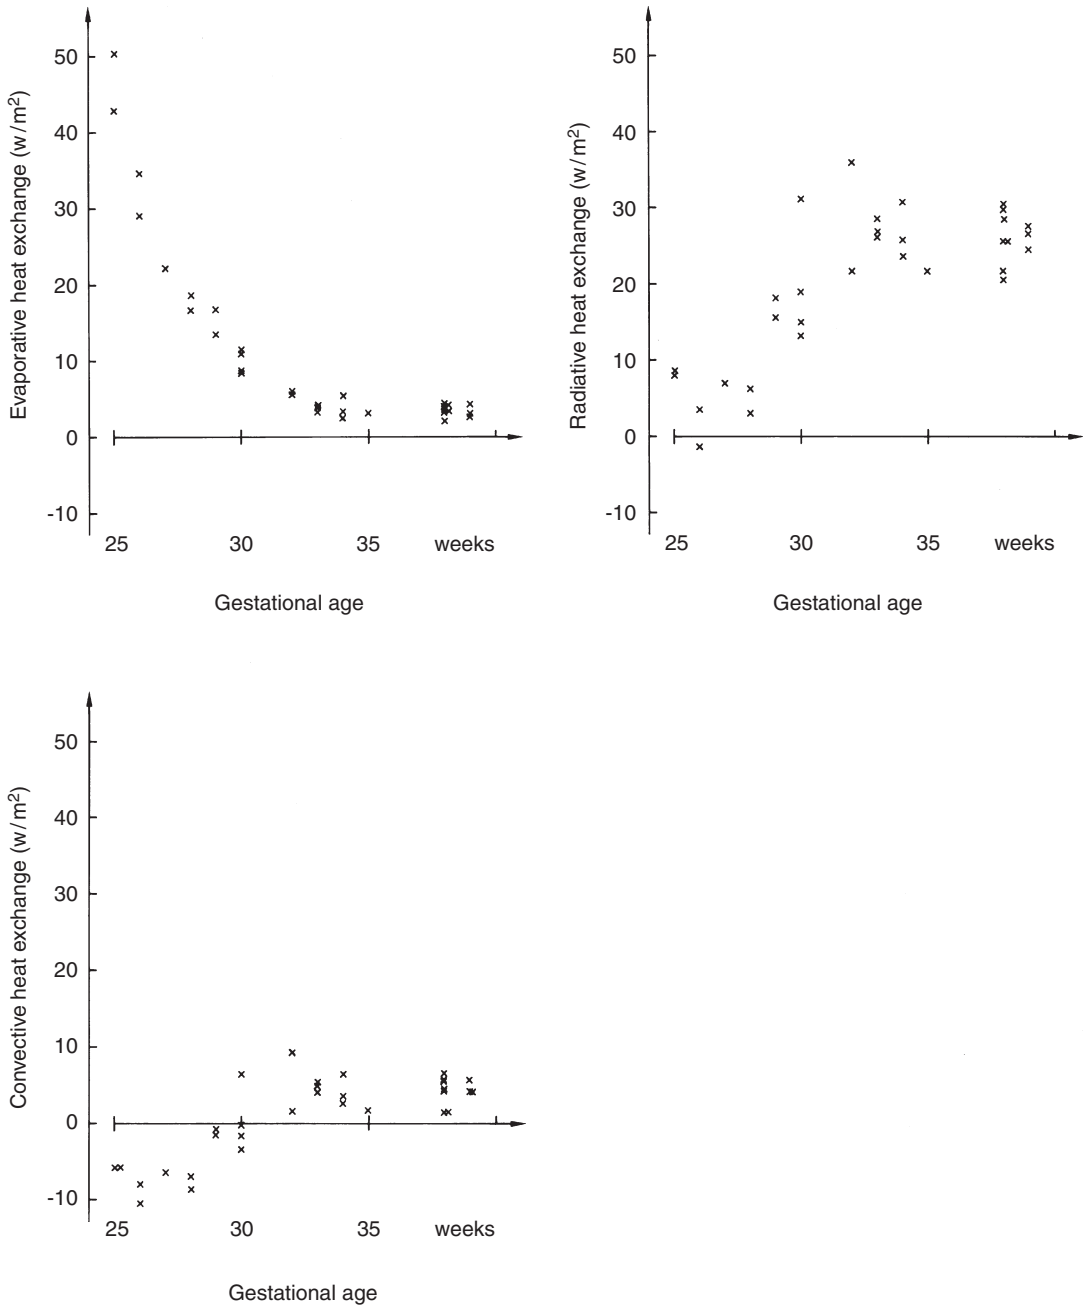

Figure 59-4 Heat exchange through evaporation, radiation, and convection at an ambient humidity of 50% in relation to gestational age. Measurements were made during the first 24 hours after birth in preterm infants and during the first 30 hours in term infants. *(From Hammarlund K, Sedin G: Transepidermal water loss in newborn infants. VI. Heat exchange with the environment in relation to gestational age,* Acta Paediatr Scand *71:191, 1982.)*

9 to 5 g/kg per 24 hours.[49] When measuring evaporative heat loss and respiratory heat loss in infants placed in a calorimeter, Sulyok and associates[31] found that both the total evaporative heat exchange and respiratory heat exchange were related to the ambient humidity; the respiratory heat loss ranged between 0.07 and 0.22 W/kg, or 3% to 10% of the total heat production from metabolism and approximately 40% of the insensible heat loss. In term infants, RWL and evaporative heat loss from the respiratory tract may increase during activity by up to 140% of the values at rest.[50] In Table 59-3, data on IWL_s and IWL_r and their sum, the total IWL, are given for the hypothetical situation in which the infant spends 24 hours at the same level of activity. The oxygen consumption will also increase with higher levels of activity.[50]

Infants are able to tolerate moderate heat stress without increasing their RWL.[29] In addition, both lambs and infants can increase their RWL and evaporative heat loss without increasing their oxygen consumption and CO_2 production.[29,75,76] An example is given in Figure 59-11, which shows how exposure to radiant heat can alter the RWL in a lamb while leaving the oxygen consumption and CO_2 production unchanged. The RWL is directly proportional to the rate of breathing,[29,75,76] and this means that lambs and infants will lose more water and heat when they have a high rate of breathing (Figure 59-12). Respiratory water and evaporative heat losses also decrease with postnatal age, at least in lambs.[42] In both lambs and infants, we observed irregular breathing during a period before a significant increase in RWL occurred.[91]

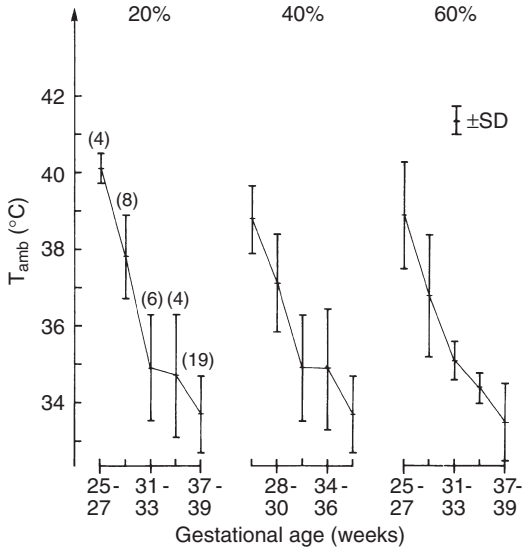

Figure 59-5 Ambient temperature *(T_{amb})* in relation to gestational age at ambient relative humidity of 20%, 40%, and 60%. *(From Hammarlund K, Sedin G: Transepidermal water loss in newborn infants. VI. Heat exchange with the environment in relation to gestational age,* Acta Paediatr Scand *71:191, 1982.)*

Respiratory Water and Evaporative Heat Exchange Before and After Intubation

Hammarlund and colleagues[74] studied young lambs exposed to heat stress before and after intubation. In nonintubated lambs exposed to a radiant heat source, the RWL increased from 10.5 to 33.4 mg/kg per minute, whereas the respiratory rate increased from 54 to 161 breaths/minute; oxygen consumption and CO_2 production were unaltered.[74] During exposure to the same heat source, intubated lambs increased their respiratory water loss from 8.1 to 18.7 mg/kg per minute and their rate of breathing from 46 to 125 breaths/minute. In intubated lambs, both oxygen consumption and CO_2 production increased significantly. RWL per breath did not change with intubation but increased significantly after extubation; the reason for this may be a larger tidal volume after intubation or to some extent a higher water content in the expired air resulting from a higher body temperature after heat stress.[74]

Respiratory Water and Evaporative Heat Loss in Relation to Gestational Age

RWL was found to be highest in the most preterm infants and lower in more mature infants observed in incubators with 50% RH and a T_{amb} that allowed the infant to maintain a normal and stable body temperature. The infants were usually asleep during the measurements. RWL per breath (milligrams per kilogram) was almost the same at all gestational ages. Therefore the higher RWL found in the most preterm infants as compared with the more mature infants was the result of the higher rate of breathing. As can be seen in Table 59-4, an increase in respiratory rate causes an increase in the loss of water and evaporative heat through the respiratory tract.[65]

Respiratory Water and Evaporative Heat Exchange During Phototherapy

When term and preterm infants[44] underwent phototherapy, no significant changes in RWL, oxygen consumption, CO_2 production, or rate of breathing were found (Table 59-5). In studies in term infants, the T_{amb}, T_{body}, and T_{skin} rose significantly. When preterm infants were studied, T_{amb} did not change; however, T_{roof} increased, and a small increase occurred in T_{body} and T_{skin}. Thus, in the absence of heat stress, no increase occurs in RWL, oxygen consumption, or CO_2 production during phototherapy in term or moderately preterm newborn infants.[44]

Respiratory Water and Heat Exchange During Mechanical Ventilation

In clinical neonatal care with a warm and humid environment or with warm and humidified gas supplied from a respirator, heat exchange through evaporation and convection between the respiratory tract and the environment will be low.[31,42,49] Infants who inspire cold air with a low water vapor pressure will have high evaporative loss from the respiratory tract and will also lose heat through convection. These losses may become clinically significant, for instance, during transport in a cold climate. Under these conditions, the total heat loss from the respiratory tract may increase to up to 20% of the total heat production of the infant.[72]

Skin-to-Skin Care and Heat Exchange

In skin-to-skin care, infants are placed lying naked, except for a diaper, on the mother's or father's chest, and they are covered with the parent's clothing or a blanket.[92-94] Only the head or parts of the head are exposed to the environmental air.[93-95] Several studies have shown that preterm infants can maintain a normal body temperature during skin-to-skin care even if no heat gain by conduction occurs. In an infant in a thermoneutral state, skin-to-skin care should cause loss of heat.[95] Covering the infant's trunk and extremities with a blanket will eliminate convective and radiative heat losses from these parts of the body. Little is known about the evaporative heat exchange between the infant and the environment under these conditions. The heat exchange between the infant's head and the environment can be reduced by using a cap or by partly covering the head, but from areas of the head that are exposed to the environmental air significant heat losses will occur through radiation, evaporation, and convection.

Studies of body and skin temperatures and oxygen consumption in infants have revealed that in preterm infants with a weight less than 1500 g and at an postnatal age less than 1 week and who are nursed in incubators the rectal and skin temperatures increase during 1 hour of skin-to-skin care with no increase in oxygen consumption.[96] In a later study, Bauer and colleagues[97] also found that infants born at 28 to 30 weeks gestation studied during the first and second week after birth have an increase in body temperature during 1 hour of skin-to-skin contact with no significant change in oxygen consumption. More immature infants (25 to 27 weeks gestation) showed no increase in oxygen consumption but a decrease in rectal temperature during the same duration of skin-to-skin contact during the first week after birth. During the second postnatal week, the body temperature did not change in infants born at 25 to 27 weeks gestation during skin-to-skin care.[97] The authors suggested that infants born at 25 to 27 weeks gestation may have a high evaporative heat loss during the first week after birth,[41] thus causing cold stress. Further studies on the different modes of heat exchange and oxygen consumption are needed to clarify the physiology of very preterm infants during skin-to-skin care.

SUMMARY AND CONCLUSION

The exchange of heat between the infant's skin and the environment is influenced by the insulation provided by the skin, the permeability of the skin, and environmental factors such as the T_{amb} and humidity, airflow velocity, and the temperature and characteristics of the incubator surfaces facing the infant. Evaporative heat loss from the skin is the major component of heat exchange

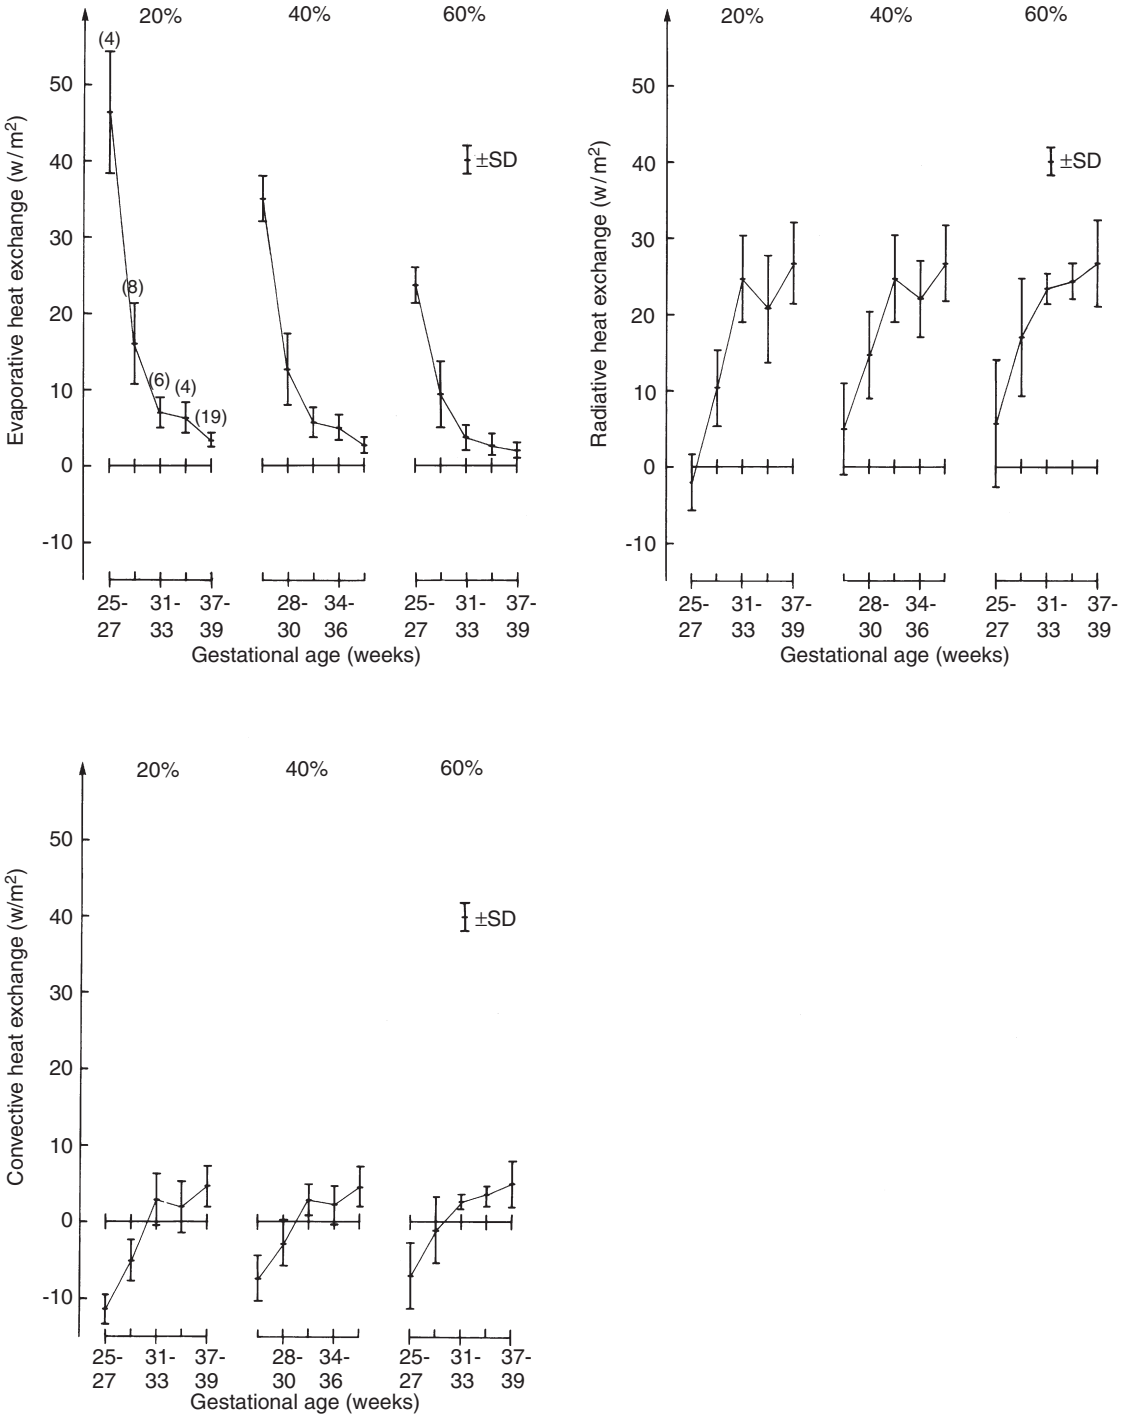

Figure 59-6 Heat exchange through evaporation, radiation, and convection in relation to gestational age at relative ambient humidities of 20%, 40%, and 60%. *(From Hammarlund K, Sedin G: Transepidermal water loss in newborn infants. VI. Heat exchange with the environment in relation to gestational age,* Acta Paediatr Scand *71:191, 1982.)*

in the most preterm infants early after birth. Infants gain heat through convection and, in a very dry environment, possibly also through radiation when they are nursed in incubators. As the water loss from the skin surface of these most preterm infants decreases with postnatal age, the heat loss through evaporation will also decrease. Concurrently, the need for a high T_{amb} diminishes, and, with the lower temperature of the incubator walls, the heat loss through radiation will increase and the heat gain by convection will change to a low loss of heat during the first weeks after birth. In infants nursed under a radiant heater, heat is gained through radiation, and, as a result of the low ambient humidity, evaporative loss of water and heat may be high in very preterm infants. The loss of heat through convection greatly depends on how the infant is protected from high air velocities by arrangements made under the radiant heater and also on the magnitude of air movements in the nursery.

In term infants nursed in incubators with an ambient humidity of 50%, the evaporative water and heat loss from the respiratory

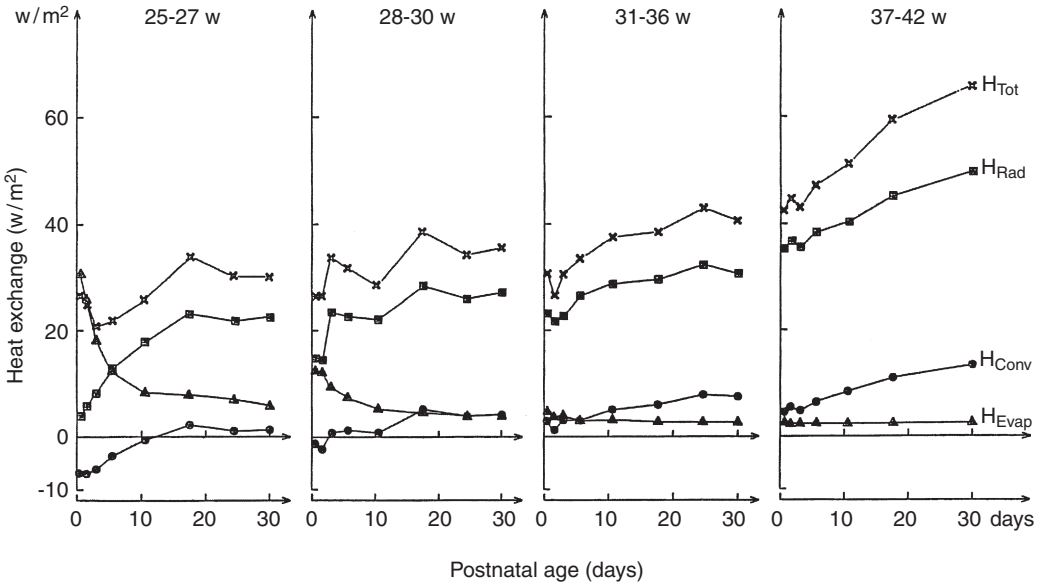

Figure 59-7 Heat exchange between the infant and the environment per square meter of body surface area in relation to postnatal age in different gestational age-groups at an ambient humidity of 50%. H_{Conv}, heat exchange through convection; H_{Evap}, Heat exchange through evaporation; H_{Rad}, heat exchange through radiation; H_{Tot}, total heat exchange; *w*, weeks. *(From Hammarlund K, Strömberg B, Sedin G: Heat loss from the skin of preterm and fullterm newborn infants during the first weeks after birth,* Biol Neonate *50:1, 1986.)*

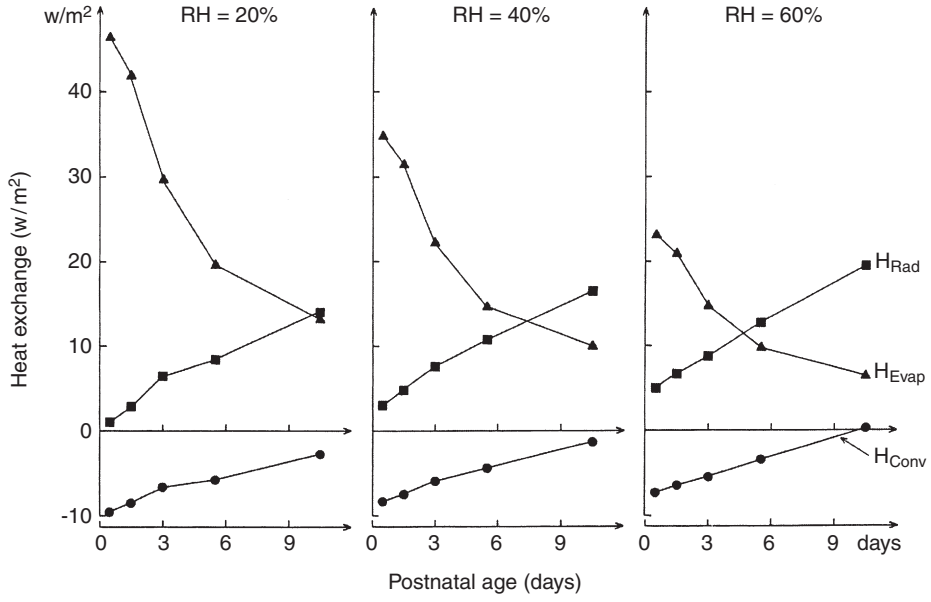

Figure 59-8 Heat exchange between the infant and the environment in relation to postnatal age at relative ambient humidity *(RH)* of 20%, 40%, and 60% in infants born at 25 to 27 weeks gestation. H_{Conv}, Heat exchange through convection; H_{Evap}, heat exchange through evaporation; H_{Rad}, heat exchange through radiation. *(From Hammarlund K, Strömberg B, Sedin G: Heat loss from the skin of preterm and fullterm newborn infants during the first weeks after birth,* Biol Neonate *50:1, 1986.)*

tract and that from the skin will be of about the same magnitude. Therefore respiratory water and evaporative heat losses are low in term infants. The respiratory evaporative water and heat loss per breath (milligrams per kilogram) is of approximately the same magnitude in calm preterm and term infants. In preterm infants, evaporative heat losses from the skin are much greater than such heat losses from the respiratory tract. The evaporative heat loss from the airway may be considered important only in infants with high motor activity or with tachypnea, especially if they are nursed in a very dry environment. Mechanical ventilation with dry and cold air will also result in a high loss of heat from the respiratory tract through evaporation and convection. Exposure to nonionizing radiation does not increase evaporative water or heat loss from the skin or the respiratory tract. Intubated lambs have a lower ability to increase respiratory water and evaporative heat loss during heat stress than nonintubated lambs.

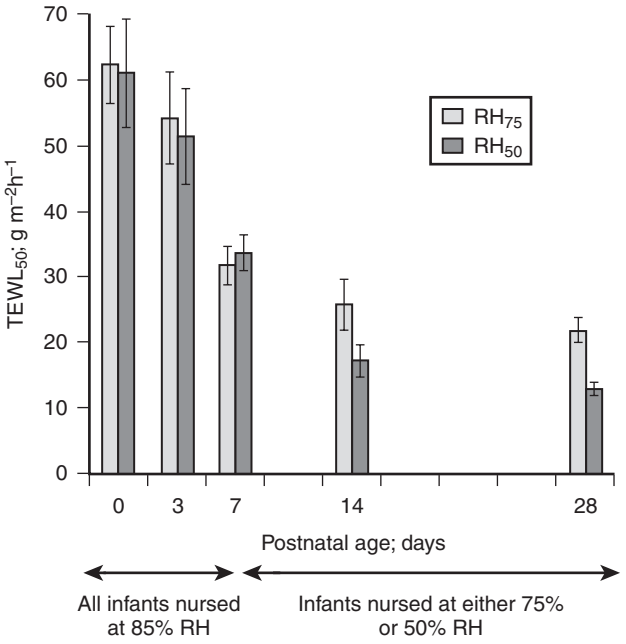

Figure 59-9 $TEWL_{50}$ in infants nursed at either RH_{75} or RH_{50} from postnatal ages of 7 to 28 days. During the first 7 days all infants were nursed at a relative ambient humidity (RH) of 85%, and no differences in TEWL were noted. After adjustment of RH at PNA of 7 days, skin barrier function improved more rapidly in infants nursed at a lower RH.

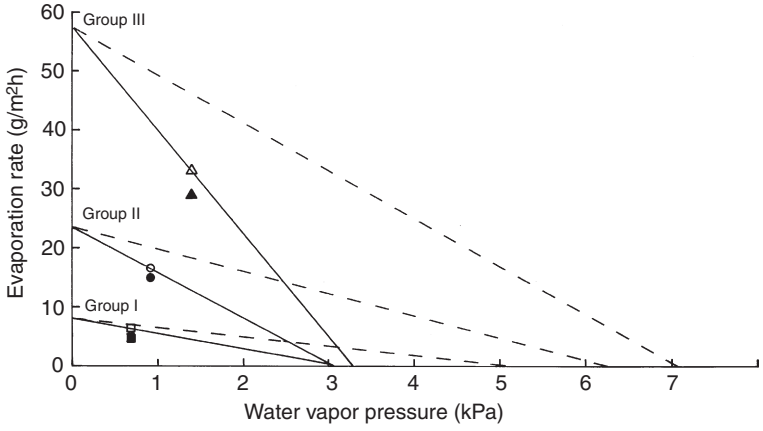

Figure 59-10 The calculated *(open symbols)* and measured *(filled symbols)* values for evaporation rate during care under a radiant heater together with corresponding regression lines for evaporation rate on water vapor pressure at the air temperatures of the incubator and the radiant heater in three infants, one from each of the studied groups: term infants (group I; n = 12), preterm infants born at 30 to 34 weeks (group II; n = 8), and very preterm infants born at 25 to 29 weeks (group III; n = 8). *(From Kjartansson S, Arsan S, Hammarlund K, et al: Water loss from the skin of term and preterm infants nursed under a radiant heater,* Pediatr Res *37:233, 1995.)*

TABLE 59-3

Insensible Water Loss From the Skin and From the Respiratory Tract and Their Sum and Oxygen Consumption, in Term Appropriate–for–Gestational Age Infants at Different Levels of Activity

Activity level	IWL_S	IWL_R	IWL_T	$\dot{V}O_2$
0	6	6	12	8
1	—	8	—	9
2	—	9	—	10
3	—	10	—	11
4	—	12	—	12
5	7	16	23	13

From Riesenfeld T, Hammarlund K, Sedin G: Respiratory water loss in relation to activity in fullterm infants on their first day after birth, *Acta Paediatr Scand* 76:889, 1987.

Water loss values expressed as grams per kilogram per 24 hours. Oxygen consumptions values expressed as liters per kilogram per 24 hours.

IWL_R, Insensible water loss from the respiratory tract; *IWL_S,* insensible water loss from the skin; *IWL_T,* total insensible water loss; *$\dot{V}O_2$,* oxygen consumption.

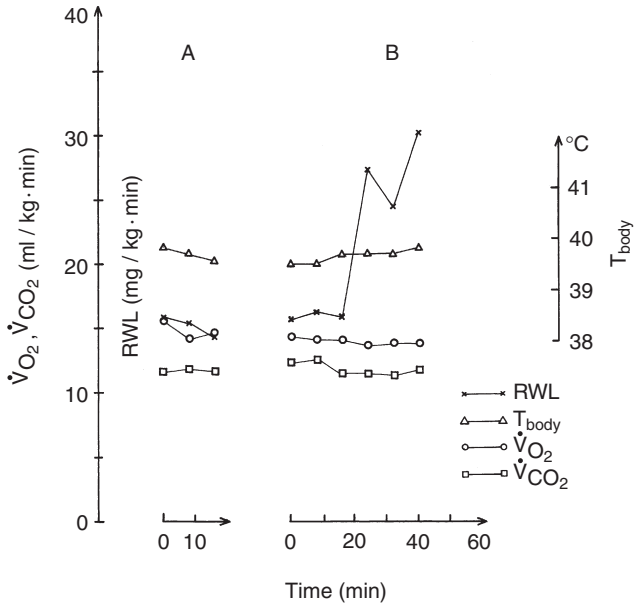

Figure 59-11 Respiratory water loss *(RWL),* body temperature *(T_{body}),* oxygen consumption *($\dot{V}O_2$),* and carbon monoxide production *($\dot{V}CO_2$)* in a 6-day-old lamb before **(A)** and during **(B)** heat stress. *(From Riesenfeld T, Hammarlund K, Jonzon A, Sedin G: Influence of radiant heat stress on respiratory water loss in new-born lambs,* Biol Neonat *53:290, 1988.)*

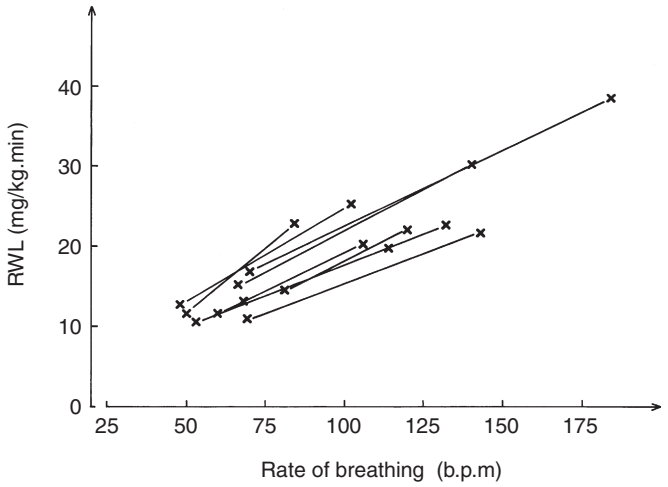

Figure 59-12 Respiratory water loss *(RWL)* in relation to rate of breathing before and during moderate radiant heat stress in lambs. For each lamb, the value before heat stress and the highest value during heat stress are joined. *(From Riesenfeld T, Hammarlund K, Jonzon A, Sedin G: Influence of radiant heat stress on respiratory water loss in new-born lambs,* Biol Neonat *53:290, 1988.)*

TABLE 59-4

Mean Respiratory Water Loss in Preterm and Term Infants on the First Day After Birth at an Ambient Relative Humidity of 50%

			RWL/min (mg/kg)		RWL/24 hr (g/kg)	
GA (wk)	RWL/breath (mg)	RWL/breath (mg/kg)	RR 40	RR 100	RR 40	RR 100
27-30	0.13 ± 0.05	0.12 ± 0.04	4.8	12	6.9	17
31-36	0.24 ± 0.12	0.11 ± 0.05	4.4	11	6.3	16
37-41	0.36 ± 0.06	0.10 ± 0.02	4.0	10	5.8	14

From Riesenfeld T, Hammarlund K, Sedin G: Respiratory water loss in relation to gestational age in infants on their first day after birth. *Acta Paediatr* 84:1056, 1995.
GA, Gestational age; *RR,* respiratory rate; *RWL,* respiratory water loss.
Values are expressed as mean ± SD.

TABLE 59-5

Respiratory Water Loss, Oxygen Consumption, and Carbon Dioxide Production in Term Infants Before, During, and After 60 Minutes of Phototherapy

	N	RWL (mg/kg/min)	$\dot{V}o_2$ (mL/kg/min)	$\dot{V}co_2$ (mL/kg/min)	RR (breaths/min)
Before	11	4.4 ± 0.7	5.9 ± 0.9	4.0 ± 0.7	48 ± 7
12 min	11	4.4 ± 0.6	5.9 ± 1.0	3.9 ± 0.6	
24 min	10	4.1 ± 0.8	5.5 ± 1.1	3.8 ± 0.7	
36 min	9	4.2 ± 1.0	5.4 ± 1.0	3.6 ± 0.6	
48 min	11	4.4 ± 0.7	5.9 ± 1.1	3.9 ± 0.7	51 ± 11
60 min	9	4.6 ± 0.9	5.9 ± 1.1	4.1 ± 0.8	
After	9	4.8 ± 0.8	6.1 ± 0.9	4.1 ± 0.4	

From Kjartansson S, Hammarlund K, Riesenfeld T, Sedin G: Respiratory water loss and oxygen consumption in newborn infants during phototherapy, Acta Paediatr 81:769, 1992.

Values are expressed as mean ± SD.

RR, Respiratory rate; *RWL,* respiratory water loss; $\dot{V}co_2$, carbon dioxide production; $\dot{V}o_2$, oxygen consumption.

Responses of the Fetus and Neonate to Hypothermia

Moderate to severe hypoxic-ischemic encephalopathy continues to be a significant cause of acute neurologic injury at birth, occurring in approximately 1 to 2 cases per 1000 term live births.[1,2] The possibility that hypothermia may be able to prevent or lessen asphyxial brain injury is a "dream revisited."[3] Early experimental studies, mainly in precocial animals such as kittens, demonstrated that hypothermia greatly extended the "time to last gasp."[4] This finding led to a series of small, uncontrolled studies in the 1950s and 1960s in which infants who were not breathing spontaneously at 5 minutes after birth were immersed in cold water until respiration began and then allowed to rewarm spontaneously over many hours.[5-7] Although outcomes were said to be better than for historical controls, this experimental approach was overtaken by two major developments: the introduction of active ventilation and resuscitation of infants exposed to asphyxia and the recognition that even mild hypothermia is associated with a wide range of potential adverse effects,[8] including greater mortality in the premature newborn.[9] Thus resuscitation guidelines for the newborn exposed to asphyxia have, until recently, simply emphasized keeping the newly born warm: that is to say, avoiding hypothermia.[10]

The early experimental studies just noted focused entirely on the effects of cooling *during* severe hypoxia, which is well known to be associated with potent, dose-related, long-lasting neuroprotection.[11] The central clinical question is, of course, whether cooling *after* asphyxial or hypoxic-ischemic injury is beneficial. This chapter reviews recent developments that helped to delineate the experimental parameters that determine whether postresuscitation cooling is successful.

PATHOPHYSIOLOGIC PHASES OF CEREBRAL INJURY

The critical advance has been the clinical and experimental observation in term fetuses, newborns, and adults that injury to the brain is not a single "event" occurring at, or just after, an insult but rather an evolving process that leads to cell death well after the initial insult.[12,13] Using magnetic resonance spectroscopy, Azzopardi and co-workers[14] showed that infants with evidence of moderate to severe asphyxia often had normal cerebral oxidative metabolism shortly after birth, but many then went on to have delayed energy failure 6 to 15 hours later. Those infants who did not show transient recovery had a very high mortality, whereas in survivors the degree of secondary energy failure after 24 to 48 hours was closely associated with impaired neurodevelopmental outcome at 4 years of age.[15] An identical pattern of initial recovery of cerebral oxidative metabolism followed by secondary energy failure was seen after hypoxia-ischemia in the piglet[16] and closely correlated with the severity of neuronal loss.[17] This delay between insult and injury raised the tantalizing possibility that asphyxial cell death may be prevented even well after the insult.

Pathophysiologically, several phases have been identified, as illustrated in Figures 60-1 and 60-2. The actual period of hypoxia and ischemia is the *primary* phase of cell injury. During this phase, progressive hypoxic depolarization of cells occurs, leading to severe cytotoxic edema, with failure of reuptake, leading to extracellular accumulation of excitatory amino acids *(excitotoxins).*[18] Excessive levels of excitatory amino acids cause activation of their ion channels and promote further excessive entry of salt, water, and calcium into the cells. After reperfusion (see Figure 60-2) or return of cerebral circulation during resuscitation from an asphyxial insult, the initial hypoxia-induced cytotoxic edema may transiently resolve over approximately 30 to 60 minutes, with at least partial recovery of cerebral oxidative metabolism *(latent phase).* This is followed by a secondary phase of deterioration (approximately 6 to 15 hours later) that may extend over many days.[15,19] At term gestation, this so-called *secondary phase* is marked by delayed-onset seizures,[20,21] secondary cytotoxic edema (see Figure 60-1),[22] accumulation of excitotoxins,[18] failure of cerebral oxidative energy metabolism,[16,19] and ultimately neuronal death.

The studies discussed in this chapter strongly suggest that it is the early recovery, or latent phase, that represents the key window of opportunity for intervention.

FACTORS DETERMINING EFFECTIVE NEUROPROTECTION WITH HYPOTHERMIA

Experimentally, the efficacy of hypothermia is highly dependent on certain factors, including the timing of initiation of cooling, its duration, and its depth.

Cooling During Resuscitation and Reperfusion

Brief hypothermia, for 1 to 2 hours, appears to be modestly neuroprotective, provided it is initiated immediately after the insult. For example, after 15 minutes of reversible ischemia in the piglet, mild hypothermia (2° to 3° C) for 1 to 3 hours significantly improved recovery and reduced neuronal loss 3 days later.[23,24] Critically, protection appears to be lost if the brief interval of hypothermia is delayed by as little as 15 to 45 minutes after the primary insult.[25-28] This extreme sensitivity to delay is consistent with the hypothesis that resuscitative hypothermia can suppress damage resulting from oxygen free radical production during reperfusion.[29,30] Alternatively, however, this strategy may merely represent intervention at the end of the primary phase, when cerebrovascular perfusion is being reestablished, cell function is just starting to recover, and levels of excitatory amino acids are still high.[18]

Even if such immediate cooling during resuscitation were consistently effective, it would be almost impossible to test in practice. It is simply not possible at present to identify reliably the few infants requiring resuscitation who will go on to have significant encephalopathy until some hours after birth.

Prolonged Cooling

A more recent approach has been to try to suppress the secondary encephalopathic processes by maintaining hypothermia throughout the course of the secondary phase. Such extended periods of cooling of between 5 and 72 hours appear to be more

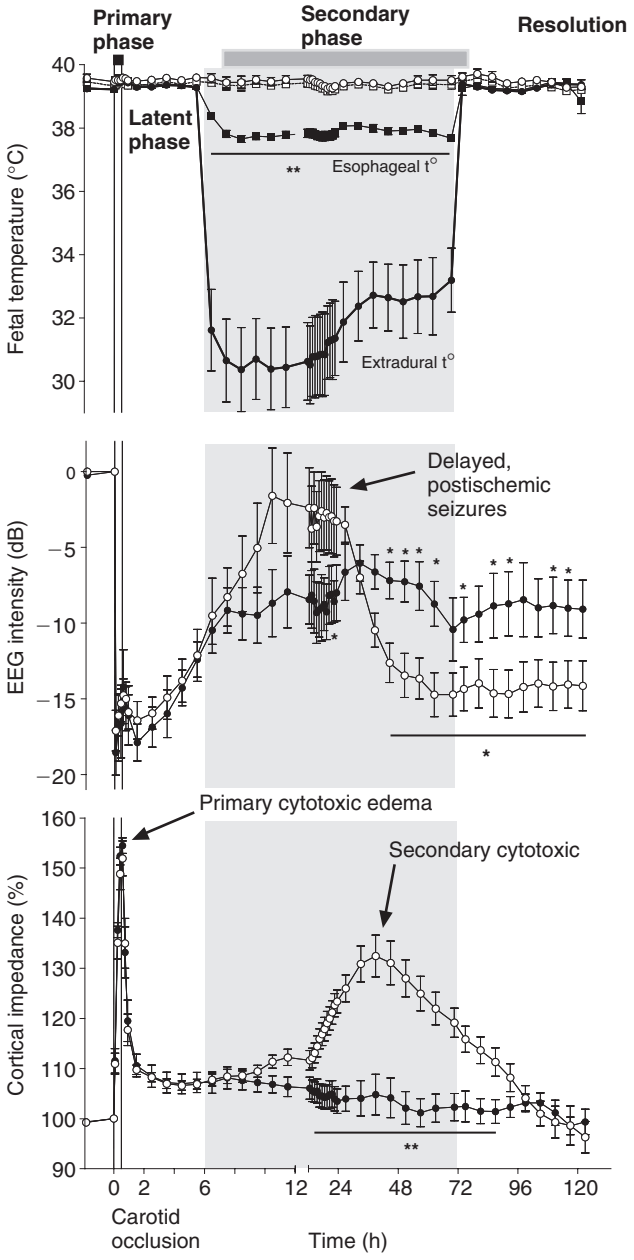

Figure 60-1 The effect of hypothermia started 5.5 hours after reperfusion from 30 minutes of cerebral ischemia in near-term fetal sheep. The period of ischemia is shown by *dotted lines*, whereas cooling is shown by the *bar*. The *top panel* shows changes in extradural *(solid circles)* and esophageal *(solid squares)* temperature in the hypothermia group and extradural *(open circles)* and esophageal *(open squares)* temperature in the sham-cooled group. The *lower two panels* show changes in electroencephalographic (EEG) intensity and cortical impedance (expressed as percentage of baseline) in the hypothermia *(solid circles)* and sham-cooled *(open circles)* groups. Impedance is a measure of cytotoxic edema (cell swelling). The hypothermia group shows greater recovery of EEG intensity after resolution of delayed seizures and complete suppression of the secondary rise in impedance. Mean ± SEM. $^{*}p < .05$, $^{**}p < .001$ hypothermia versus sham-cooled fetuses. *(Data from Gunn AJ, Gunn TR, Gunning MI, et al: Neuroprotection with prolonged head cooling started before postischemic seizures in fetal sheep,* Pediatrics *102:1098-1106, 1998.)*

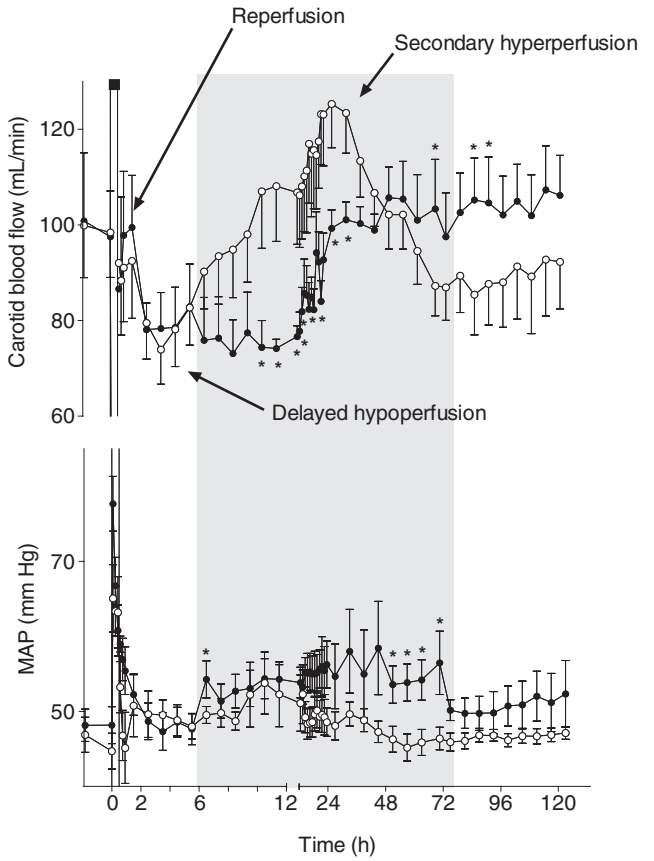

Figure 60-2 The effect of hypothermia started 5.5 hours after reperfusion from 30 minutes of cerebral ischemia in near-term fetal sheep on carotid blood flow and mean arterial blood pressure (MAP) in the hypothermia *(solid circles)* and sham-cooled *(open circles)* groups. Cerebral ischemia is shown by the *solid bar* at the top of the graph, whereas cooling is shown by the *highlighted region*. A significant increase in blood pressure occurred during cooling that rapidly resolved with rewarming. Both groups show a significant phase of secondary hypoperfusion that was beginning to resolve at 6 hours; hypothermia prolonged this phase and prevented the phase of secondary hyperperfusion such that carotid blood flow was significantly reduced in the hypothermia group between 10 and 36 hours. Mean ± SEM. $^{*}p < .05$ versus sham cooling. *(Data from Gunn AJ, Gunn TR, Gunning MI, et al: Neuroprotection with prolonged head cooling started before postischemic seizures in fetal sheep,* Pediatrics *102:1098-1106, 1998.)*

consistently effective.[31-33] For example, in a study of reversible middle cerebral artery occlusion in the adult rat, 21 hours, but not 1 hour, of mild hypothermia reduced the area of infarction after 48 hours recovery.[34] After severe global ischemia in the adult gerbil, 12 hours of mild hypothermia was ineffective, whereas extending the interval to 24 hours did afford protection.[32]

Newborn studies support these data. In unanesthetized infant rats subjected to moderate hypoxia-ischemia, mild hypothermia (2° to 3° C reduction in brain temperature) for 72 hours from the end of hypoxia prevented cortical infarction, whereas 6 hours of cooling had only intermediate, nonsignificant results.[35] In the same model greater reduction in body temperature (by 5° C) for 6 hours, starting immediately after the insult, gave significant neuroprotection after both 1 and 6 weeks survival, as well as neurobehavioral improvement.[36] Finally, in the anesthetized piglet

exposed either to hypoxia with bilateral carotid ligation or to hypoxia with hypotension, 12 to 48 hours of moderate whole-body hypothermia or head cooling with mild systemic hypothermia (started immediately after hypoxia) prevented delayed energy failure,[33,37] reduced neuronal loss,[38-40] and suppressed posthypoxic seizures.[39]

A Window of Opportunity for Treatment? Recent Evidence

At present, the window of opportunity for any particular therapy can be determined only empirically. However, some general principles can be discerned. For example, initiation of neuronal degeneration is accelerated by more severe insults. DNA fragmentation in the hippocampus can be detected as early as 10 hours after a 60-minute hypoxic-ischemic injury in the rat, whereas DNA fragmentation in the hippocampus is detectable only 3 to 5 days after a 15-minute hypoxic-ischemic injury.[41] However, the appearance of DNA fragmentation and classic ischemic cell change represent only the terminal events of this cascade and are thus not a good guide to determining when cell death may still be reversible. In vitro studies have distinguished *latent* and active or *execution* phases during the process of programmed or apoptotic cell death.[42] Whereas the active phase involves downstream factors that could induce DNA fragmentation and chromatin condensation within previously normal nuclei, the preceding latent phase is characterized by caspase activation (a large family of enzymes that mediate and amplify apoptosis)[43] confined to the cytoplasm, without downstream factors. These data suggest that activation of the downstream, intranuclear factors is the critical event that occurs at the transition from the latent to the execution phase of programmed neuronal death. Thus, in principle, it seems far more likely that intervention would be protective if applied during the initial, latent phase of programmed cell death rather than during the execution phase, even though the latter still precedes DNA fragmentation and cell death.[42]

Systematic in vivo studies support the central role of the latent phase. In the near-term fetal sheep, moderate hypothermia induced 90 minutes after reperfusion (i.e., in the early latent phase) and continued until 72 hours after ischemia prevented secondary cytotoxic edema and improved electroencephalographic recovery.[21] A concomitant, substantial reduction occurred in parasagittal cortical infarction, and neuronal loss scores improved in all regions. When the start of hypothermia was delayed in this paradigm until just before the onset of secondary seizures, 5.5 hours after reperfusion, only partial protection was seen (Figure 60-3).[44] With further delay (until after seizures were established 8.5 hours after reperfusion), no electrophysiologic or overall histologic protection occurred with cooling (see Figure 60-3).[45] Data from adult models are consistent with this concept. Thus 5 hours of moderate hypothermia (32.5° C) initiated under anesthesia in adult rats reduced selective neuronal loss when it was started up to 12 hours after brief global ischemia, although the degree and extent of neuroprotection markedly declined as the start of cooling was delayed beyond 2 hours.[46] In adult gerbils, when the delay before initiating a 24-hour period of cooling was increased from 1 to 4 hours after ischemia, neuroprotection in the CA1 field of the hippocampus after 6 months of recovery fell from 70% to 12%.[47] However, this deterioration could be largely overcome by extending the interval of moderate hypothermia (a reduction in body temperature of up to 5° C) to 48 hours or more, even when the start of cooling was delayed until 6 hours after reperfusion.[48,49]

Is Neuroprotection Maintained Long Term?

There have been reports that hypothermia may only delay, rather than prevent, neuronal degeneration after global ischemia in the adult rat[50-52] and after relatively mild hypoxia-ischemia in the 7-day-old rat.[53] The most likely explanation is that the duration or degree of hypothermia may have been inadequate, as suggested by the finding that 5° C of cooling for 6 hours[36] or 2° to 3° C for 72 hours in infant rats was associated with long-term improvement after carotid occlusion and hypoxia.[35] Subsequent studies both in the 7-day rat and in adult species have confirmed that a sufficiently prolonged phase of moderate cooling can be associated with persistent behavioral and histologic protection for many weeks and months.[36,48,49,54-57] Broadly, these studies tend to suggest that the later cooling is started, the more prolonged the treatment needs to be for neuroprotection.[58] An additional issue may have been rebound hyperthermia in the secondary phase. Even short periods of hyperthermia, 24 hours after either global or brief focal ischemia in the adult rat, exacerbated injury.[59,60] Similarly, in 10-day-old rat pups a 1.5° C increase in brain temperature for several hours during induced seizures after hypoxia-ischemia was associated with preventable exacerbation of neural injury up to 20 days later.[61] Further, when moderate hypothermia 2 to 9 hours after global ischemia in the rat was combined with prevention of spontaneous delayed pyrexia with antipyretics, histologic protection was seen after 2 months of recovery.[52] Each intervention alone had essentially short-term benefit only. Whether mild

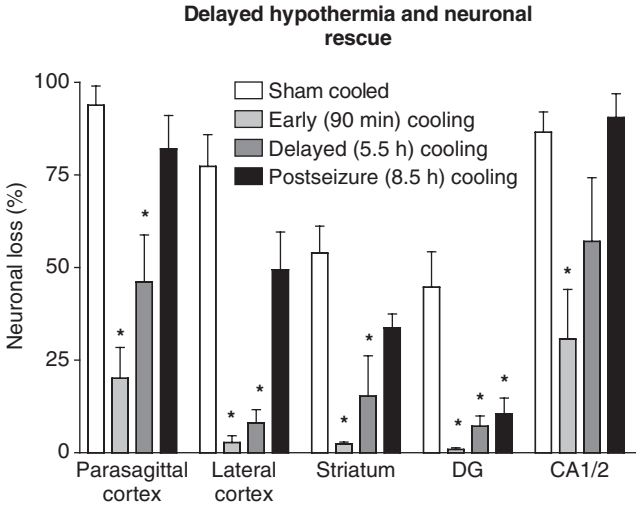

Figure 60-3 Comparison of the effect of cerebral cooling in the fetal sheep started at different times after reperfusion and continued until 72 hours on microscopically assessed neuronal loss in the neuronal regions of cortex after 5 days recovery from 30 minutes of cerebral ischemia. Compared with the sham-cooled group (n = 13), cooling that was started 90 minutes after reperfusion (n = 7) or just before the end of the latent phase (5.5 hours after reperfusion, n = 11) was protective, whereas cooling started shortly after the start of the secondary phase (8.5 hours after reperfusion, n = 5) was not. Only cooled fetuses in which the extradural temperature was successfully maintained at less than 34° C have been included. *DG,* Dentate gyrus. $^{*}p < .005$ compared with sham-cooled (control) fetuses, (Mann-Whitney *U* test; mean ± SEM). *(Data from Gunn AJ, Gunn TR, de Haan HH, et al: Dramatic neuronal rescue with prolonged selective head cooling after ischemia in fetal lambs,* J Clin Invest *99:248–256, 1997; Gunn AJ, Gunn TR, Gunning MI, et al: Neuroprotection with prolonged head cooling started before postischemic seizures in fetal sheep,* Pediatrics *102:1098–1106, 1998; Gunn AJ, Bennet L, Gunning MI, et al: Cerebral hypothermia is not neuroprotective when started after postischemic seizures in fetal sheep,* Pediatr Res *46:274–280, 1999.)*

hypothermia could have had additional benefit compared with normothermia in this late interval is, regrettably, unknown.

If Some Is Good, Is More Better?

A critical depth of cerebral hypothermia appears to exist between 32° and 34° C, that is required for effective neuronal rescue. In the fetal sheep cooled from 90 minutes after ischemia, substantial neuroprotection was seen only in fetuses that had a sustained fall in extradural temperature to less than 34° C (normal temperature in the fetal sheep is 39.5° C).[21] In the adult gerbil, cooling to a rectal temperature of 32° C was associated with greater behavioral and histologic neuroprotection than was 34° C.[56] Intriguingly, recent short-term recovery studies in the piglet suggest that the optimal depth of cooling may be greater for the cortex than for the basal ganglia.[40] Supporting this experimental observation, in a recent case series, head cooling but not whole-body cooling seemed to be associated with a reduction in the incidence of severe cortical lesions,[62] as examined by magnetic resonance imaging.

A trade-off is likely to occur between the adverse systemic effects of cooling, which increase below a core temperature of approximately 34° C,[8] and cerebral benefits. Although few specific perinatal data exist, in the adult dog, deep hypothermia (to a rectal temperature of 15° C) after cardiac arrest was detrimental, whereas mild hypothermia (34° to 36° C), from 10 minutes until 12 hours after cardiac arrest, was beneficial.[63]

Is It Possible to Cool the Head "Selectively"?

To provide adequate neuroprotection with minimal risk of systemic adverse effects in sick, unstable neonates, ideally only the brain would be cooled. Although this has been demonstrated experimentally by using cardiac bypass procedures,[64] it is clearly impractical in routine practice. More pragmatically, partially selective cerebral cooling can be obtained with use of a cooling cap applied to the scalp while the body is warmed by some method such as an overhead heater to limit the degree of systemic hypothermia.[65-67] In practice, mild systemic hypothermia is desirable during head cooling, first to limit the steepness of the intracerebral gradient that would otherwise be needed (avoiding excessively cold cap temperatures)[68] and second to provide greater cooling of the brain stem. This approach was demonstrated in studies in the piglet, with a substantial (median, 5.3° C) sustained decrease in deep intracerebral temperature at the level of the basal ganglia compared with the rectal temperature.[69,70] Similar results from studies of brief head cooling have been reported in the fetal sheep,[71] the young adult cat,[72] the newborn rat,[73] and the piglet.[74] Although direct temperature measurements are not feasible in asphyxiated newborns, head cooling has been shown to increase the gradient between nasopharyngeal and rectal temperature by nearly 1° C.[65]

In many ways, this approach is an extension of normal physiology. Even in the healthy neonate, no single cerebral temperature exists, but rather there is a gradient from the warmer deep regions to the cooler surface.[75] The brain is a major source of heat production, and it is cooled by a combination of surface radiation and blood flow convection.Thus the deep brain temperature is approximately 1° to 2° C higher than the scalp,[76] and it is 0.7° C higher than core body temperature.[75] Thus deep brain temperature is increased during reduced perfusion as occurs after severe asphyxia.[75]

MECHANISMS OF ACTION OF HYPOTHERMIA

The precise mechanisms of hypothermic neuroprotection are still unclear. Although this situation does not affect its pragmatic clinical use, it is critical to efforts to develop more effective strategies such as treatment in combination with other treatments.[77,78] Broadly, it is now well established that cooling suppresses many of the pathways leading to delayed cell death.

As well as reducing cellular metabolic demands,[79,80] hypothermia reduces excessive accumulation of cytotoxins such as glutamate and oxygen free radicals, suppresses the postischemic inflammatory reaction, and inhibits the intracellular pathways leading to programmed (i.e., apoptosis-like) cell death.

Cerebral Metabolism, Excitotoxins, and Free Radicals During the Primary and Reperfusion Phases

The combination of hypoxic depolarization and extracellular excitotoxin accumulation is a key factor in the initiation of neuronal injury in the primary phase. Hypothermia produces a graded reduction in cerebral metabolism of approximately 5% for every degree of temperature reduction[79] that delays the onset of anoxic cell depolarization.[81] However, the protective effects of hypothermia even in this phase are not simply the result of reduced metabolism, because cooling improves outcome even when the absolute duration of depolarization is controlled.[82] Cooling potently reduces postdepolarization release of numerous toxins including excitatory amino acids,[83] nitric oxide,[84,85] and other free radicals.[29,86] Similarly, cooling begun during reperfusion reduces levels of extracellular excitatory amino acids and nitric oxide production in the piglet.[30] However, these mechanisms are not active during the latent phase and thus cannot readily account for the protective effects of delayed cooling.

Intracellular Pathways in the Latent Phase

The effects of hypothermia on pathways distal to cell membrane ion channels are likely to be important. For example, intrainsult hypothermia did not prevent intracellular accumulation of calcium during cardiac arrest in vivo[87] or during glutamate exposure in vitro.[88] Indeed, evidence exists in the adult rat that the apparent neuroprotective effect of NBQX, a glutamate antagonist, administered from 1 hour after mild ischemia, was actually mediated by mild hypothermia.[51] In contrast, in vitro neuronal degeneration was prevented by cooling initiated after the excitotoxins had been washed out.[88] Thus the ability of hypothermia to reduce release of excitotoxins does not appear to be central to its postinsult neuroprotective effects; rather these data suggest that the critical effect of hypothermia is to block the intracellular consequences of excitotoxin exposure.

Suppression of Inflammatory Second Messengers

Brain injury leads to induction of the inflammatory cascade with increased release of cytokines and interleukins.[89] These compounds are believed to exacerbate delayed injury, either by direct neurotoxicity and induction of apoptosis or by promoting stimulation of capillary endothelial cell proinflammatory responses and leukocyte adhesion and infiltration into the ischemic brain.[90] Evidence is good that cooling can suppress this inflammatory reaction. In vitro, hypothermia potently inhibits proliferation, superoxide production, and nitric oxide production by microglia.[91] In the adult rat, hypothermia suppresses the posttraumatic release of interleukin-1β and accumulation of polymorphonuclear leukocytes.[92,93] Similarly, hypothermia reduces microglial activation after transient ischemia in the term-equivalent fetal sheep.[94] Thus these data suggest that the hypothermic protection against postischemic neuronal damage may be, in part, the result of suppression of microglial activation.

Does Hypothermia Specifically Prevent or Suppress Apoptosis (Programmed Cell Death)?

Some studies, particularly in adult species, show that hypothermia can prevent delayed necrotic cell death.[95] However, increasing data suggest that hypothermia has a particular role

in suppressing apoptotic processes, particularly in the developing brain. In neuronal culture, preconditioning using a brief period of hypoxia stimulated the expression of antiapoptotic gene products and regulatory components of the cell cycle; in contrast, induced hypothermia depressed cell activity and abolished hypoxia-associated protein synthesis.[96] Consistent with this, moderate hypothermia was associated with inhibition of apoptotic cell death and expression of apoptotic factors after cold-induced and ischemic brain injury in adult rats.[97,98] Similarly, in the piglet, hypothermia begun after severe hypoxia-ischemia reduced apoptotic cell death but not necrotic cell death,[38] and hypothermic neuroprotection in the near-term fetal sheep was closely linked with suppression of activated caspase-3.[94]

Summary

The experimental studies discussed earlier suggested that a prolonged duration of moderate cerebral hypothermia could improve long-term outcome if started as soon as possible, within approximately 6 hours of hypoxic-ischemic injury. On the basis of these extremely encouraging data, a number of clinical trials were undertaken.

CLINICAL TRIALS OF HYPOTHERMIA

Pilot Studies

A number of small controlled trials of head cooling with mild hypothermia[65,67,99,100] or whole-body cooling,[101] as well as case series using these techniques,[102-104] reported that cooling asphyxiated newborns was both feasible and apparently safe. Although none of these studies were powered to evaluate neurologic outcome, some suggestion was made of improved outcomes.[99,105,106] For example, in a controlled study of head cooling of infants with early stage II or III encephalopathy, mild systemic hypothermia was associated with a trend to reduced cerebral palsy in survivors (odds ratio 0.46 [0.08, 2.56] vs. normothermia).[99] A retrospective study of whole-body cooling to between 32° and 34° C in 10 infants found a significant reduction of major neurologic abnormalities and abnormal magnetic resonance imaging findings at follow-up compared with 11 historical controls.[105] A larger randomized pilot study of head cooling with mild hypothermia compared with normothermia found a significant reduction in neuron-specific enolase levels in cerebral spinal fluid with cooling, but only a marginal improvement in developmental outcome at 6 months of age.[106]

In the largest pilot study 65 infants were randomly assigned to normothermia or whole-body cooling to a rectal temperature of 33° C for 48 hours, initiated within 6 hours of birth. The relatively deep body cooling in this study was associated with some clinically manageable adverse effects, including longer dependence on inotropic agents, prolongation of prothrombin times, and lower platelet counts with more patients requiring plasma and platelet transfusions.[107] The combined outcome of death or severe motor scores was significantly lower in the hypothermia group (52%) than the normothermia group (84%) ($p < .02$).[108]

Large Randomized Controlled Trials

Two large multicenter randomized controlled trials of hypothermia for term infants with hypoxic-ischemic encephalopathy have been reported. In the CoolCap trial[109,110] infants with moderate to severe hypoxic-ischemic encephalopathy were randomly assigned to head cooling with mild systemic hypothermia, defined as a rectal temperature of 34° to 35° C (n = 116), or conventional care (n = 118). Death or disability at 18 months was reduced in infants with less severe electroencephalographic changes at trial entry (n = 172, odds ratio 0.42; 95% confidence interval 0.22-0.80, $p = .009$).[109] In contrast, however, no benefit was found in those with the combination of seizures and profound suppression of the amplitude integrated electroencephalogram (aEEG) recording before cooling was started. The improvement was primarily due to a reduction in motor disability with a more than 50% reduction in severe neuromotor disability in survivors and improved continuous Bayley Scale of Infant Development II scores, with no change in early neonatal mortality. The only consistent minor adverse effects were scalp edema under the cap, which resolved rapidly before or after removal of the cap; transient hyperglycemia from 4 to 24 hours compared with controls (mean ± SD, 7.6 ± 4.4 vs. 5.4 ± 3.1 mmol/L, at 4 hours, $p < .001$); and sinus bradycardia (which is a well-known, essentially normal response during hypothermia[111]) that did not require treatment. Conversely, an apparent reduction occurred in the incidence of elevated liver enzymes in the cooled group (38% of cooled infants vs. 53% of controls, $p = .02$).

In a further large multicenter trial of whole-body cooling from the National Institute of Child Health (NICHD), 208 were enrolled on the basis of clinical and laboratory criteria consistent with exposure to severe perinatal hypoxia plus moderate or severe hypoxic-ischemic encephalopathy.[112] Infants in the experimental group (n = 102) were cooled to a rectal temperature of 33.5° ± 0.5° C for 72 hours with use of a cooling blanket. The incidence of death and/or moderate-to-severe disability at 18 months of age was significantly reduced in the cooled infants (45%) compared with the normothermic group (62%; relative risk 0.72; 95% confidence interval, 0.55-0.93). No difference for death or disability alone was found.

Taken together, the remarkably similar effect sizes in two independent, well-controlled studies strongly suggest that induced hypothermia is beneficial. A recent meta-analysis of the CoolCap,[109] NICHD,[112] and Eicher[108] studies suggested that induced mild-to-moderate hypothermia is associated with a significant reduction (relative risk 0.76; 95% confidence interval, 0.65-0.89) in the incidence of death and disability after asphyxia.[113] However, as the authors emphasize, major differences exist between these studies including selection, method and duration of cooling, and outcome parameters.

Other Ongoing Trials

A number of trials are still in progress, including the Total Body Cooling trial (TOBY) in England, the NeoNetwork trial in central Europe, and the Infant Cooling Evaluation (ICE) trial in Western Australia. In a preliminary report Inder and colleagues[114] reported that whole-body–cooled infants had less cortical gray matter signal abnormality on magnetic resonance imaging (1 of 12 vs. 7 of 14 infants in the normothermic group; $p = .036$). Of interest, Rutherford and colleagues[62] have also reported a reduced incidence of severe cortical lesions in infants treated with head cooling. However, in that report, both head and whole-body cooling was associated with a decrease in basal ganglia and thalamic lesions that was significant in infants with moderate aEEG changes but not in those with severe aEEG findings.[62]

SYSTEMIC EFFECTS OF HYPOTHERMIA

Although the preceding studies have suggested that mild hypothermia is generally safe, they have also highlighted the clinical importance of understanding the physiologic changes associated with hypothermia.[8] In particular, a significant increase in blood pressure has been reported at initiation of cooling, both experimentally[44] and clinically.[102] This response is mediated by rapid peripheral vasoconstriction, that is, centralization of blood flow.[115] Further, hypothermia slows the atrial pacemaker and intracardiac conduction. Consequently, hypothermia to less than approximately 35.5° C is associated with mild but sustained sinus bradycardia; however, this has not required treatment.[67,101,109,112]

This relationship between heart rate and core temperature likely mainly reflects decreased metabolic demand with decreasing temperature. Some infants show markedly prolonged QT duration above the 98th percentile corrected for age and heart rate, without arrhythmia, during cooling, that resolves with rewarming.[116] Although such isolated prolonged QT does not seem to be associated with an increased risk of ventricular arrhythmias, other therapies that lengthen the QT interval (such as macrolide antibiotics) should be avoided.

One consistent metabolic effect associated with hypothermia was transient mild hyperglycemia, in both adult[117] and infant trials[109] but no increase in the rate of hypoglycemia. A similar transient rise in glucose concentrations has been observed in the piglet and near-term fetal sheep[21,118] and likely reflects hypothermia-induced catecholamine release.

It is also important to appreciate that although, for example, no increase occurred in the rate of complications such as infection in the newborn studies, this must in part reflect the routine screening and treatment for possible infection included in the trials.[109,112] Hypothermia has profound antiinflammatory effects and in older adults seems to increase the risk of infective complications such as pneumonia and bacteremia,[8,119] and thus this potential risk needs to continue to be carefully monitored in clinical use.

Although no increase in hemorrhagic complications was reported in either of the two large trials,[109,112] Eicher and colleagues[107] did find an increase. It is unclear at this time whether this difference was the result of deeper cooling or a rectal temperature of 33° C,[107] or was a chance finding in a small study. It is reassuring that in piglets where the cortex was cooled to less than 30° C no hemorrhagic changes were seen in the brain.[39,120] Finally, it is important to note that all the clinical studies have been in term infants. It is unknown whether, in the setting of modern intensive care, selected preterm infants with evidence of acute metabolic acidosis on cord blood and clinical encephalopathy would also benefit from hypothermia.[121] Studies in preterm fetal sheep, at an equivalent stage of neural maturation, now suggest that head cooling, started 90 minutes after profound asphyxia, can reduce neuronal loss in the striatum.[71]

CONCLUSION

Experimental evidence is now overwhelming that mild to moderate postasphyxial cerebral cooling can be associated with long-term neuroprotection. The key requirements are that hypothermia be initiated as soon as possible in the latent phase, within the first 6 hours, before secondary deterioration, and that it be continued for a sufficient period in relation to the evolution of delayed encephalopathic processes, typically 48 hours or more. These findings are now supported by large randomized trials of both head cooling combined with mild systemic hypothermia and whole-body cooling that found that cooling is safe, at least in the intensive care environment, and associated with a significant reduction in the incidence of death and severe disability after asphyxia. These studies show that although hypothermia is an important advance, as currently applied it is not a "magic bullet." Only approximately 15% have better outcome after cooling compared with standard care.

To further improve this outcome, it is vital to find ways of optimizing methods of applying hypothermia and of selecting infants who are most likely to benefit from treatment.[13] For example, increasing evidence exists that hypothermia can augment the effects of experimental neuroprotective therapies.[77,122] Further, the CoolCap trial suggested that EEG monitoring could identify a subgroup of infants with profound suppression of amplitude and onset of seizures at the time of randomization who did not respond.[109] It will be vital to refine these initial findings in focused experimental and clinical studies.

Thus, although many questions remain over how hypothermia should be best used and outcomes to school age or later are not yet known, we can now be cautiously optimistic that therapeutic hypothermia is here to stay and that greater understanding of the determinants of protection with ongoing studies will yield further improvements in outcome.

SECTION X

Skin

61

David H. Chu and Cynthia A. Loomis

Structure and Development of the Skin and Cutaneous Appendages

OVERVIEW

Skin is a complex organ that comprises many different cells and cell types; it forms a critical physical barrier that protects the body and maintains fluid homeostasis, temperature regulation, and sensation. Skin cells derive from both embryonic mesoderm and ectoderm, and development from these precursors is tightly regulated. Perturbations in the developmental process, either from genetic anomalies or as a result of exogenous (e.g., teratogenic) agents, can result in severe abnormalities that have important consequences in the care of infants. Understanding the normal progression of molecular and cellular events that underlie the development and differentiation of skin allows for a more rational approach to infants who have defects in these processes. For clinicians, this knowledge will direct the diagnosis, therapy, and parental counseling necessary for care of the patients.

As with all organs, organogenesis of the skin proceeds through three distinct but overlapping stages, from early embryonic through fetal and neonatal development.[1,2] These stages are as follows: *specification,* in which portions of superficial ectoderm and lateral plate mesoderm become distinct from other portions of the body wall; *morphogenesis,* in which the specific structural and biochemical characteristics of skin begin to appear; and *differentiation,* in which the skin tissue further develops to its mature form.

For the sake of clarity, we have organized the discussion of the developmental progression of the skin to follow each component sequentially, first with a discussion of the epidermis, followed by the dermis and subcutaneous tissue, the dermal-epidermal junction (DEJ), and, finally, epidermal appendages. Each of these sections discusses the structural and biochemical changes that occur during the particular stage of development, followed by a discussion of related clinical syndromes and genetic disorders that are related to defects in this developmental progression.[3] However, all these tissues of the skin are, in fact, developing in parallel, and in some cases they require interaction with adjacent tissues for development. A timeline is included to illustrate the sequence of events that are occurring simultaneously (Figure 61-1).

EPIDERMIS

Overview

The mature adult *epidermis* is a stratified squamous epithelium that develops from the ectoderm. Keratinocytes form 80% of the cellular composition. The germinative keratinocytes reside in the deepest portion of the epidermis, known as the *basal layer*, and these cells are known as *basal cells.* As differentiation of the basal cells proceeds, these cells migrate to more superficial cell layers and become progressively flattened; they also begin to express large insoluble proteins that ultimately become crosslinked along the exterior of the cell to form an insoluble shell or brick, known as the *cornified cell envelope*.

Above the basal cell layer rests the spinous layer, or stratum spinosum. The "spines" seen in this layer result from the abundance of desmosomes, specialized regions of the keratinocyte cell surface that promote adhesion between these cells in a calcium-dependent manner. Desomosomal proteins include plakoglobin, desmoplakins I and II, keratocalmin, desmoyokin, band 6 protein, and the cadherins—desmogleins 1 and 3 and desmocollins 1 and 2.[4]

The cell layer superficial to the stratum spinosum is the stratum granulosum. Granular cells begin to express some of the components that will contribute to the cornified cell envelope, a protein-lipid polymer that is found on the outer boundary of terminally differentiated keratinocytes.[5] The cornified cell envelope serves a critical role in the barrier function of the epidermis. Keratohyaline granules, found within the granular cells, are principally composed of two proteins, loricrin and profilaggrin. Profilaggrin undergoes sequential proteolytic cleavage into filaggrin oligomers and finally monomers, as well as desphosphorylation, during its processing. This process is initiated at the time of formation of the granular layer and continues even after its eventual extrusion from the cornified cell. Loricrin, another major component of the cornified envelope, is also initially localized to the keratohyaline granules. Lamellar granules, which are also abundant in the granular cell layer, contain the lipid components that will be extruded from the cells and crosslinked to the cornified cell envelope. Other proteins that contribute to the cornified envelope include involucrin, small proline-rich proteins, annexin, elafin, desmoplakin, envoplakin, periplakin, repetin, and trichohyalin. Modifying enzymes such as transglutaminases are important in the final crosslinking of the cornified envelope components. As described in another section, mutations in either the structural proteins or the enzymes involved in protein crosslinking and lipid and steroid metabolism can have clinically significant outcomes in genetic skin disease.

The stratum corneum contains the terminally differentiated keratinocytes, flattened dead "squames" that lack nuclei and other organelles. These cells are composed primarily of keratin filaments, tightly packed within the crosslinked cornified envelopes. Some specialized components within the epidermis maintain its architecture. Keratins are some of the most important structural proteins within the epidermal cells. They assemble as filaments composed of "basic" and "acidic" keratin peptides, which form *obligate heterodimers*; that is, different keratins are found to associate with a limited number of partners.[6,7] Their expression is regulated in a tissue-specific and developmentally selective manner. Mutations in these genes often exhibit clinical

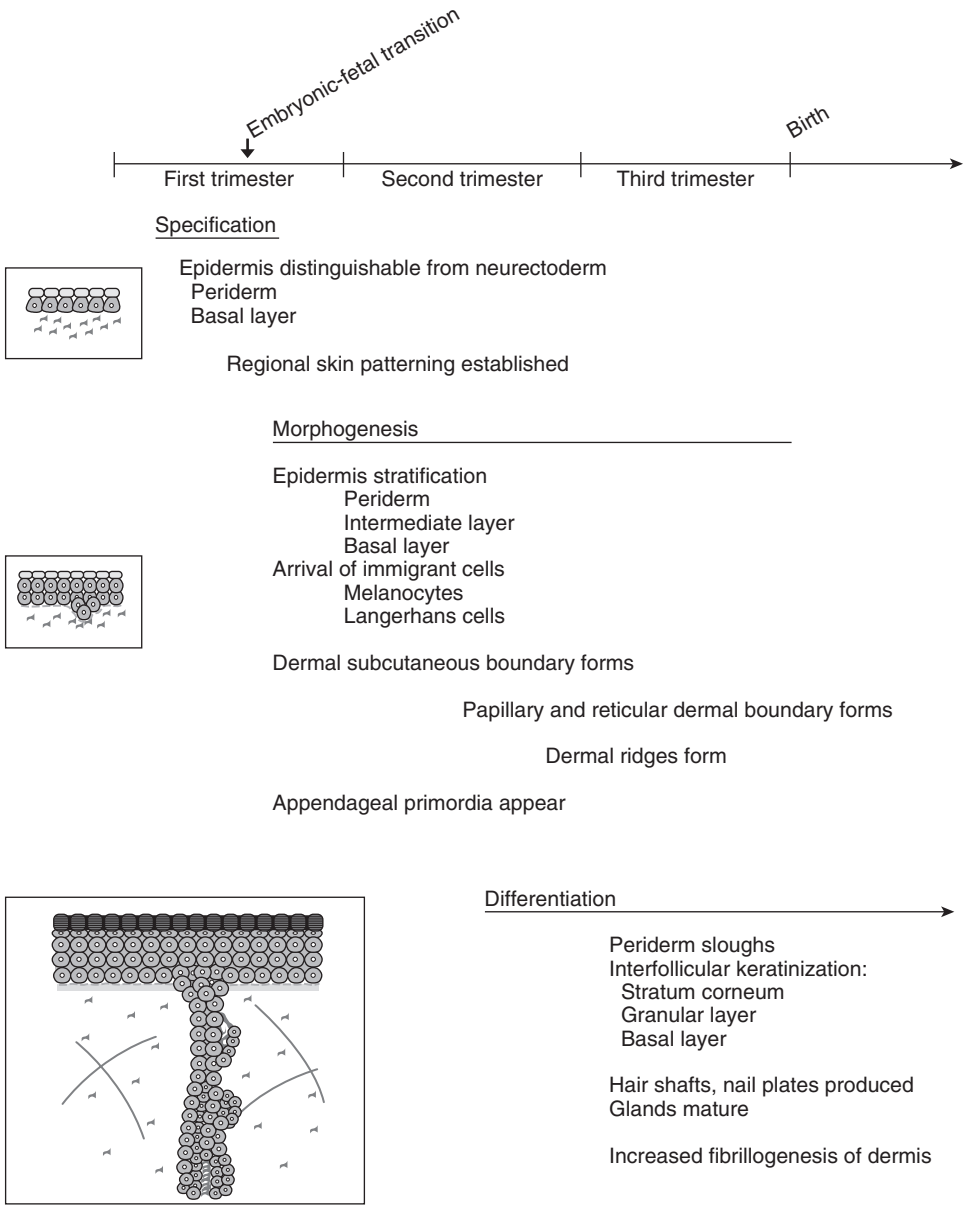

Figure 61-1 Timeline for the development of skin tissue. *(Adapted from Loomis CA, Koss T: Embryology. In Bolognia JL, Jorizzo JL, Rapini RP [eds]:* Dermatology. *Philadelphia, Elsevier, 2003.)*

phenotypes that reflect the tissue expression of the specific keratin gene. For example, whereas basal cells express K5 and K14, suprabasilar keratinocytes express the genes encoding K1 and K10 (K1 and K9 in palmoplantar epidermis).

Other critical structural elements of the epidermis are the cell-cell and cell-matrix adhesion systems. The major cell-cell adhesion junctions of the epidermis are desmosomes. The proteins in these complexes include specialized adhesion proteins (cadherins, calcium-dependent adhesion molecules) as well as intracellular plaque and adaptor proteins. An analogous adhesion structure, the hemidesmosome, attaches basal cells to the basement membrane at the DEJ. Although the proteins in the hemidesmosome are distinct from those of the desmosome, the plaque proteins have similar amino acid sequences, and both are tightly associated with the keratin filament network. Gap junctions form important intercellular bridges that allow small molecules to pass from one keratinocyte to another. These specialized junctions are formed by proteins known as connexins. Mutations in any of these molecules have effects on the normal formation of the epidermis that can result in certain genodermatoses, many of which have manifestations from birth.

Specification

Gastrulation of the embryo occurs during the third week after fertilization. This is a critical process that results in the generation of the three primary embryonic germ layers: endoderm, mesoderm, and ectoderm. The ectoderm then is further divided into the neuroectoderm and the presumptive epidermis. The epidermis is then subsequently specified into distinct regional domains, such as palmoplantar skin, scalp skin, and mammary skin.

The earliest presumptive epidermis consists of a basal cell layer, which covers the embryo.[8,9] By 6 weeks estimated gestational age (EGA), the surface ectoderm consists of two layers: basal cells and more superficial periderm cells. The periderm layer does not give rise to any portion of the definitive

epidermis, and as such it serves as a transient embryonic covering. This layer is ultimately sloughed during late gestation and contributes to the vernix caseosa, which covers the newborn.

Morphogenesis

The process of *morphogenesis* begins at approximately 8 weeks EGA, the classic transition between embryonic and fetal development, when hemopoietic production shifts to the bone marrow. At this point, the epidermis begins its process of stratification, by forming an intermediate layer between the basal cell and the periderm layers. This intermediate layer remains highly proliferative, and more layers are added as development proceeds over the next several weeks. In mice, it has been shown that this process of epidermal stratification requires the *p63* and *Dlx3* genes.[10-12] In humans, partial loss of function mutations in *p63* have been seen in various ectodermal dysplasias, as discussed in another section.

Differentiation

Maturation of the epidermal layers includes keratinization, which results in the *differentiation* of granular and stratum corneal layers and the formation of a water-impermeable barrier. Accompanying this stage of development is the sloughing of the periderm. Keratinization occurs first in the skin appendages between 11 and 15 weeks EGA, followed by the interfollicular epidermis between 22 and 24 weeks EGA.[13,14]

The process of keratinization involves the production of certain proteins, including filaggrin and loricrin. Posttranslational modification of the crosslinked proteins and production of specialized lipid and steroid components contribute to the water-impermeable matrix formed in the mature cornified layer. Structurally, the third trimester stratum corneum is similar to that of an adult, but functional studies have shown that it is much less effective at preventing water loss and is more permeable than the mature epidermis. It is actually not until the third week of life that the barrier function of a newborn's stratum corneum is comparable to that of an adult. Emollient use is of therapeutic benefit in many patients with defective epidermal barriers because the stratum corneum is insufficiently differentiated in very-low-birth-weight preterm infants.[15]

Clinical Relevance

Human mutations that inhibit the process of specification in the epidermis have not been reported, most likely because such mutations would be incompatible with further development of the embryo. However, experiments in animals have suggested that a group of proteins, the bone morphogenetic proteins (BMPs), as well as the Engrailed-1 transcription factor, may play an important early role in these processes.[16-18] Similarly, few mutations in humans have been found that affect epidermal morphogenesis although, as mentioned earlier, *p63* and *Dlx3* have been implicated in the process of epidermal stratification based on studies in mouse models.

In contrast to the relative lack of mutations that affect epidermal specification and morphogenesis, mutations that have an important impact on epidermal differentiation are quite numerous. In general, these genes are not required for development in utero, but they become critical for effective barrier function of the epidermis after birth. Thus defects in these genes can often cause significant postnatal morbidity.

Two groups of such diseases include the palmoplantar keratodermas and ichthyoses. The *palmoplantar keratodermas* are a diverse group of disorders that share a common presentation of hyperkeratosis of the palms and soles. These disorders commonly are also associated with other cutaneous as well as noncutaneous findings. The genetic bases of many of these disorders have been discovered, and they include defects in connexins, differentiation keratins, and desmosomal components.[19]

TABLE 61-1

Summary of Ichthyoses

Disease	Inheritance	Defective Protein(s)
Ichthyosis vulgaris	AD	Filaggrin
X-linked ichthyosis	XLR	Steroid sulfatase
Lamellar ichthyosis	AR	Transglutaminase 1
NBCIE	AR	Transglutaminase 1; ALOX12B;ALOXE3; CGI58
Bullous congenital ichthyosiform erythroderma	AD	Keratin 1; Keratin 10
Harlequin fetus	AR	ABCA12
Sjögren-Larsson syndrome	AR	Fatty aldehyde dehydrogenase
Refsum syndrome	AR	Phytanoyl-CoA Hydroxylase
Conradi-Hunermann syndrome	XLD	Emopamil binding protein
CHILD syndrome	XLD	NSDHL (NAD(P)H steroid dehydrogenase-like protein)
Netherton syndrome	AR	LEKTI (lymphoepithelial Kazal-type–related inhibitor)
Erythrokeratodermia variabilis	AD	Connexin 31; Connexin 30.3
KID syndrome	AD	Connexin 26

AD, Autosomal dominant; *AR,* autosomal recessive; *CHILD,* congenital hemidysplasia with ichthyosiform erythroderma and limb defects; *KID,* keratitis-ichthyosis-deafness; *NBCIE,* nonbullous congenital ichthyosiform erythroderma; *XLD,* X-linked dominant; *XLR,* X-linked recessive.

The *ichthyoses* are another diverse group of diseases that often present around the time of birth with diffuse scaly skin and defective epidermal barrier function.[20,21] These conditions differ in both pattern and morphology of scaling as well as extracutaneous features. Ichthyosis vulgaris, lamellar ichthyosis, and X-linked ichthyosis have phenotypes predominantly restricted to the skin (Table 61-1). Ichthyoses can also be a cause of erythroderma (e.g., in bullous and nonbullous congenital ichthyosiform erythroderma). Neurologic abnormalities can be associated with the skin condition, as in Sjögren-Larsson syndrome, Refsum syndrome, or Tay syndrome (IBIDS: ichthyosis, brittle hair, intellectual deficit, decreased fertility, and short stature). In X-linked dominant ichthyoses, female children inheriting the relevant mutation can develop asymmetry of limbs, as in congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD) syndrome or chondrodysplasia punctata (Conradi-Hünermann disease). Interestingly, certain mutations in the gene encoding filaggrin, a key component of the cornified envelope and the gene mutated in ichthyosis vulgaris,[22] also confer susceptibility to development of atopic dermatitis, a common inflammatory skin disease of childhood.[23]

One of the earliest phenotypic presentations of a group of these disorders is known as *collodion baby,* in which an infant is born encased in a parchment-like membrane. Over the next few days to weeks, the membrane is shed, eventuating in lamellar ichthyosis, nonbullous congenital ichthyosiform erythroderma, Netherton syndrome, Tay syndrome (IBIDS), Conradi-Hünermann disease, and occasionally, a normal baby.[3,20]

In contrast to the relatively benign outcome for collodion babies, the so-called *harlequin fetus* usually dies soon after birth. These babies are born encased in restrictive plates of thick, armor-like scale that have extremely poor barrier function, often resulting in fluid derangements, infections, sepsis, and death. Mutations in the gene ABCA12, which encodes an adenosine-5′-triphosphate (ATP) binding cassette transporter, have recently been discovered to be responsible for this condition.[24, 25]

Nonkeratinocytes in the Epidermis

Melanocytes

Although keratinocytes are the most abundant cell type that makes up the epidermis, other cell types migrate there early in development. In these are the melanocytes, neural crest-derived dendritic cells that synthesize and distribute pigment to the epidermis. Melanocyte precursors exit the dorsal region of the neural tube, migrate through the superficial mesenchyme, and ultimately come to reside in the epidermis by 7 weeks EGA.

Langerhans Cells

Langerhans cells are another migratory cell population that enters the epidermis before the embryonic-fetal transition. They are bone marrow-derived cells that, when mature, are important for antigen presentation within the skin. They remain relatively undifferentiated until the embryonic-fetal transition, at which time they begin to express CD1 on their cell surface and begin to produce their characteristic Birbeck granules, tennis racket-shaped intracellular vesicles that form during the processing of membrane-bound antigens. The density of Langerhans cells remains low until the third trimester, when it increases to those of a typical adult.

Merkel Cells

The third type of specialized cell within the epidermis is the Merkel cell, a highly innervated neuroendocrine cell type involved in mechanoreception. These cells are first detectable around 8 to 12 weeks in volar skin and slightly later in interfollicular skin. They are often associated with skin appendages. Merkel cells express both neural-specific markers and epithelial-specific proteins, such as keratins.

Clinical Relevance

Many mutations have been identified that are critical for melanoblast migration and survival and for melanocyte differentiation and function (summarized in Table 61-2). Defects in these genes result in disorders of pigmentation, which can be detected at an early age.

One of the most common abnormalities is that of albinism. There are variations in severity of depigmentation as well as associated abnormalities. These differences depend on the particular gene affected and its global function.

Defects in melanin synthesis result in oculocutaneous albinism (OCA), a set of disorders characterized by absent pigment in the skin, hair, and eyes at birth. Often associated with the skin findings are neurologic and ophthalmologic findings of nystagmus, photophobia, and visual disturbances, reflecting the neuroectodermal derivation of melanocytes. In OCA type 1, sequence alterations in the enzyme tyrosinase, critical for the conversion of tyrosine to melanin (either null or partial loss of function alleles), are responsible. In OCA type 2, tyrosinase functions normally (tyrosinase-positive albinism), but the P gene, a putative tyrosine transporter, is defective. This subtype can be distinguished from OCA type 1 because a child's skin and eyes begin to darken with age. The children usually have white, yellow, or red hair. OCA type 3 results from defects in tyrosinase-related protein-1. This condition is also known as *brown OCA*, featuring minimal to light brown skin pigmentation in some persons of African descent.[26]

Other genes result in a more patchy distribution of pigmentation defects, as in the white forelock (poliosis) seen in both piebaldism and Waardenburg syndrome. These diseases occur as a result of defective melanocyte specification, migration, or survival. The gene responsible for piebaldism encodes c-KIT, a growth factor receptor and protooncogene.[27] Waardenburg syndrome subtypes can be caused by defects in transcription factors Pax3, Sox10, MITF and in endothelin receptor B and endothelin 3 ligand. In Waardenburg syndrome, depending on the subtype, neural tube defects, heterochromia iridis, deafness, and Hirschsprung disease may be associated with depigmentation.[28]

Finally, defects in melanosome production result in the entities Hermansky-Pudlak, Chédiak-Higashi, and Griscelli syndromes. Patients with Hermansky-Pudlak syndrome have mutations in the HPS1 gene, which encodes a putative transmembrane component of a number of cytoplasmic organelles, or the AP3B1 gene, which is a protein subunit involved in the sorting of proteins in the exocytic/endocytic pathway. Patients present with creamy, light skin tones, dysfunctional platelets (prolonged bleeding time), pulmonary fibrosis, granulomatous colitis, and ceroid lipofuscinosis in phagocytic cells.[29] Chédiak-Higashi syndrome is characterized by nystagmus, decreased visual acuity, skin and respiratory infections, light skin tones, and silvery yellow to brown hair. Giant melanosomes are found in white blood cell smears and hair, and giant lysosomal inclusion granules are found in all leukocytes. The defect is in LYST, which encodes a protein proposed to be important in intercellular protein trafficking.[30] Griscelli syndrome also features hair shafts with large pigment granules and hypopigmentation with silver-gray hair. Patients have hemophagocytic syndrome and experience episodes of massive lymphocyte and leukocyte activation and organ infiltration. Polymorphonuclear leukocytes are morphologically normal, unlike in Chédiak-Higashi syndrome. The defect is in a guanosine triphosphate–binding protein involved in vesicular fusion and trafficking, RAB27A.[31]

TABLE 61-2

Disorders of Pigmentation

Disorder	Mutant Gene	Defective Protein/Function
Melanocyte specification, migration, or survival		
Piebaldism	KIT	Growth factor receptor, proto-oncogene
Waardenburg syndrome		
Types 1 and 3	PAX3	Pax3 transcription factor
Type 2	MITF	Transcription factor
Type 4	EDNRB	Endothelin receptor B
	EDN3	Endothelin 3
	SOX10	Sox-10 transcription factor
Melanin biosynthesis		
Oculocutaneous albinism		
Type 1	TYR, null alleles	Rate-limiting enzyme of pigment production
Type 1b	TYR, partially functional alleles	Rate-limiting enzyme of pigment production
Type 2	P gene	Putative tyrosine transporter
Type 3	TYRP1	Tyrosinase-related protein-1
Melanosome production		
Hermansky-Pudlak syndrome	*HPS1*	Putative membrane component of various organelles
	AP3B1	Putative component of endocytic protein trafficking pathway
Chédiak-Higashi syndrome	LYST	Putative involvement in protein trafficking
Griscelli syndrome	RAB27A	Guanosine triphosphate–binding protein involved in membrane fusion and protein trafficking

DERMIS AND SUBCUTIS

Overview

Unlike the epidermis, which is derived exclusively from ectoderm, the *dermis* originates from different tissues depending on the specific body site. Dermal mesenchyme of the face and anterior scalp comes from neural crest ectoderm, whereas that of the back is derived from the dermomyotome of the embryonic somite. Dermal mesenchyme of the limbs and ventral trunk, conversely, is likely derived from the lateral plate mesoderm.

Early fetal mesenchyme is highly cellular, containing few fibrillar elements. These fetal mesenchymal cells are thought to be pluripotent, able to give rise to adipose tissue, cartilage, and dermal fibroblasts. The superficial mesenchyme becomes visibly distinct from underlying skeletal elements by 60 days EGA. By 12 to 15 weeks, the different characteristics of the dermis can first be observed—the papillary dermis has a finer weave than the thicker reticular dermis. Collagen and elastic fibers begin to be assembled in the latter half of pregnancy, and a more rigid, fibrillar meshwork gradually forms.

Dermal repair shifts from nonscarring to scarring by the end of the second trimester. At birth, the dermis is thick and well organized but is still more cellular than in adults.

A distinct region identifiable as the subcutis can be seen by 50 to 60 days EGA. It is separated from the dermis by a plane of thin-walled vessels. By the end of the first trimester, the distinction between the fibrous dermis and the sparse matrix of the subcutis can be seen. Preadipocytes arising from the undifferentiated mesenchyme begin to mature and accumulate lipids by the second trimester. By the third trimester, the more differentiated adipocytes begin to aggregate into lobules separated by fibrous septa. Although the initial events leading to the commitment of mesenchymal cells to become adipocytes are not well understood, numerous regulators of later preadipocyte-adipocyte differentiation have been identified, including the hormone leptin.[32]

Blood Vessels, Lymphatics, and Nerves

Blood vessels and lymphatics begin to develop early in gestation but do not evolve into those of adults until a few months after birth. Initially, these vessels form horizontal plexuses within the subpapillary and deep reticular dermis, which are interconnected by groups of vertical vessels. This vascular framework has been shown to be in place by 45 to 50 days EGA. By the fifth month of EGA, arterioles and venules are able to be distinguished. Capillary loops, which supply the developing epidermal appendages and maintain thermoregulation, are established at the time of rete ridge formation at the DEJ. During the period of embryonic and fetal development, this framework changes constantly, depending on many factors, including site of the body and presence of associated adnexal structures.

Accumulating evidence suggests that lymphatics originate from endothelial cells that bud from veins, and the pattern of embryonic lymphatic vessel development parallels that of blood vessels. Studies using newly discovered molecular markers specific for lymphatics have allowed a more detailed understanding of lymphatogenesis. As described in another section, defects in some of the genes encoding some of these proteins have been found to result in congenital disorders of the lymphatic system.

Nerves, like blood vessels and lymphatics, are also present in early embryonic skin and continue to develop after birth. Nerves begin as large trunks at the dermal-subcutaneous boundary that branch into fibers and extend into the dermis. They form networks distinct from the cutaneous vasculature, although they become more closely juxtaposed in the fetal dermis. At 70 days EGA, an arrangement of nerves that is similar to the adult configuration can be detected, although the density and final distribution of fibers continue to be modified until after birth. Sensory receptors such as the pacinian and meissnerian corpuscles begin to develop in the fourth month of EGA. Although meissnerian corpuscles are fully developed only after birth, pacinian corpuscles are completed and are found in plantar and palmar skin in neonates.

Clinical Relevance

Few human mutations have been identified that result in defective dermal specification and differentiation, most likely because such mutations would be incompatible with life. However, experiments in animal model systems have suggested that the genes *Lmx1b*, *Wnt7a*, and *En1* may be important in specifying dorsal and ventral (palmoplantar) mesenchyme as distinct tissues.

Restrictive dermopathy is a clinical entity in which the dermis is universally abnormal, now found to be caused by mutations in LMNA and ZMPSTE24.[33] Some mosaic conditions also show localized defects in dermal development, most notably focal dermal hypoplasia (Goltz syndrome), as well as Proteus syndrome. In Goltz syndrome, dermal hypoplasia exists in Blaschkoid patterns.[34] Proteus syndrome is characterized by subcutaneous masses, lipomas, capillary malformations, plantar and palmar hyperplasia, varicose veins, and asymmetric soft tissue and bony hypertrophy of the hands, feet, and limbs.[35]

Connective tissue disorders are caused by mutations in genes encoding differentiation products of mature dermal fibroblasts and other mesenchymal cells. Ehlers-Danlos syndrome has many clinical subtypes, caused by a variety of mutations in genes affecting collagen types I, III, and V, collagen-modifying enzymes, and other important structural proteins (Table 61-3).[36,37] Mutations in the encoding elastin can result in cutis laxa, characterized by loose, redundant skin, a syndrome that can be complicated by lung hypoplasia, diaphragmatic hernias, gastrointestinal diverticula, bladder diverticula, and emphysema.[38] Osteogenesis imperfecta, characterized by multiple fractures in utero, beaded ribs, crumpled humeri and femora, limb avulsion during delivery, kyphoscoliosis, blue sclerae, and easily bruisable skin, has been found to result from defects in collagen type I.[39] Marfan syndrome results from mutations in fibrillin, which codes for a vital component of the microfibrillar elastic tissue network, resulting in defects in ocular, cardiovascular, and musculoskeletal systems.[40]

Defects in angiogenesis have also been identified. Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome) is a vascular dysplasia that leads to telangiectases and arteriovenous malformations of skin, mucosa, and viscera. Mucosal involvement often results in epistaxis and gastrointestinal bleeding. Visceral involvement includes that of the lung, liver, and brain. Mutations in endgolin, as well as activin receptor-like kinase 1 have been shown to cause this disease.[41,42] TIE2 is a tyrosine kinase, mutations in which have been shown to result in a dominantly inherited syndrome of venous malformations.[43,44]

Work on lymphangiogenesis has uncovered genetic mutations in some forms of hereditary lymphedema. The most common form of primary hereditary lymphedema, Milroy disease, is caused by mutations in vascular endothelial growth factor receptor 3. This disease is characterized by severe edema, especially below the waist.[45] Mutations in FOXC2, a transcription factor, have been implicated in lymphedema-distichiasis syndrome, featuring late-onset lymphedema and a double row of eyelashes (distichiasis).[46]

DERMAL-EPIDERMAL JUNCTION

The DEJ is a key interface for inductive interactions during early skin organogenesis. Defects in this region are also responsible for many well-studied congenital blistering diseases, the group

TABLE 61-3

Ehlers-Danlos Syndrome Classification

Type	Clinical Findings	Inheritance	Gene Defect(s)
Classic (I/II)	Skin and joint hypermobility, atrophic scars, easy bruising	AD	COL5A1, COL5A2
Hypermobility (III)	Joint hypermobility, pain, dislocations	AD	COL3A1, TNXB
Vascular (IV)	Thin skin, arterial or uterine rupture, easy bruising, small joint hyperextensibility	AD	COL3A1
Kyphoscoliosis (VI)	Scoliosis, joint laxity, ocular fragility and retinal detachment, skin laxity, muscle hypotonia	AR	PLOD1
Arthrochalasia (VIIA, VIIB)	Joint hypermobility, mild skin laxity, bruising, scoliosis	AD	COL1A1, COL1A2
Dermatosparaxis (VIIC)	Severe skin fragility, cutis laxa, bruising	AR	ADAMTS2 (procollagen N-peptidase)
Other			
X-linked EDS (V)	Skin laxity, bruising	XL	Lysyl oxidase
Periodontitis (VIII)	Periodontitis, blue sclerae, atrophic scarring, bruisability	AD	?
Fibronectin-deficient (X)	Striae distensae, joint laxity, skin laxity, scarring, bruisability, bleeding (platelet) disorder (petechiae)	?	?
Familial hypermobility (XI)	Recurrent joint dislocation, joint laxity	AD	?
Progeroid	Progeroid facies, short stature, osteopenia, skin laxity, atrophic scarring, hypermobile joints	?	B4GALT7

AD, Autosomal dominant; *AR,* autosomal recessive; *EDS,* Ehlers-Danlos syndrome; *XL,* X-linked.

of diseases known as epidermolysis bullosa (EB). This zone includes the adhesive structural elements along the basal surface of the basal keratinocyte plasma membrane, as well as the extracellular matrix proteins of the basal lamina and the most superficial fibrillar structures of the papillary dermis.

The most primitive form of the DEJ can be seen between the epidermis and the dermis by 8 weeks EGA. Laminin, collagen type IV, heparan sulfate, and proteoglycans, components common to all basal lamina, can be found at this stage. The more specific molecules that make up the basal lamina of stratified epithelia, such as hemidesmosomal components, begin to be detected at the time when the presumptive epidermis begins to stratify. It is at this time that such proteins as integrins (α6 and β4) become properly localized to the DEJ, even though the expression of some can be detected at earlier times.

Clinical Relevance

As alluded to earlier, several congenital disorders characterized by severe blistering occur as a result of mutations in the genes encoding the components of this region (Table 61-4).[47] The severity of the disorder, the plane of tissue separation, and the involvement of noncutaneous tissues depend on the specific proteins affected by the mutations. These diseases carry with them a high degree of morbidity and mortality, and as such they are frequent candidates for prenatal testing.

TABLE 61-4

Disorders of the Dermal-Epidermal Junction

Location	Disorder	Defective Protein(s)
Basal cell adhesion complex	EB simplex	K5, K14
	EB with muscular dystrophy	Plectin
Basal lamina	Generalized atrophic benign EB	BPAG2 (collagen type XVII)
	EB with pyloric atresia	β4 subunit of α6 or β4 integrin subunits
	Junctional EB, lethal and less severe forms	Laminin 5 subunits
Superficial dermis	Dystrophic EB (dominant and recessive)	Collagen type VII

EB, Epidermolysis bullosa.

The most superficial of these phenotypes is EB simplex. Keratins 5 and 14, the proteins defective in this disease subtype, are expressed by basal keratinocytes. Because of loss of adhesion at the level of the basal keratinocyte, the epidermis is fragile, and bullae develop. Depending on the particular mutation, the blistering phenotype can be more or less severe. These blisters can involve the mucous membranes and can result in a hoarse voice. One specific subtype of EB simplex is associated with muscular dystrophy. The mutation for this disease is within a protein called plectin, involved in adhesion within the hemidesmosome.

Junctional EB variants form bullae within the lamina lucida, the superficial portion of the DEJ. Affected patients have been found to have defects in laminin 5. One form of junctional EB, the Herlitz variant, is more severe: In addition to blistering, laryngeal and respiratory edema can be associated with the disorder, as well as anemia and hypoproteinemia. The non-Herlitz variant is less life-threatening, although, in this case, bullae heal with atrophic scarring. Nails and hair can also be affected. Another subtype is associated with pyloric atresia, which is caused by mutations in the genes encoding α6 and β4 integrins.

The most disfiguring form of EB is termed dystrophic EB. Because the blisters in this variant affect the superficial dermis, with defects in collagen type VII, they heal with scarring. In the more severe forms, extensive scarring can lead to digital fusions and so-called mitten deformities of the hands and feet, flexion contractures, mucous membrane scarring, dental abnormalities, and hematologic disorders.

SKIN APPENDAGES

Skin appendages include hair, nails, and sweat and mammary glands. These structures are derived from both an epidermal component and a dermal component. The epidermis contributes the physical structure of the unit, whereas the dermis provides signals for the unit's differentiation. During embryogenesis, interactions between the dermis and the epidermis are critical for normal development of these structures, disruption of which often results in defects in the formation of skin appendages.

Hair

Between 75 and 80 days EGA, dermal signals instruct the basal cells of the scalp epidermis to cluster together at regularly spaced intervals. This initial group is known as the follicular placode or anlage.[48] Although the specific mediators of this first "dermal signal" are not definitively identified, CTNNB1 (encodes β-catenin) has been implicated as a candidate gene based on its molecular localization.

From the scalp, the follicular placodes develop ventrally and caudally and eventually cover the skin. The epidermal placodes then signal back to the underlying dermis to form a dermal condensate, which occurs at 12 to 14 weeks EGA. The communication between the epidermis and dermis at this stage and the morphogenetic development are considered to be a balance between placode promoters and placode inhibitors.[48] Wnt family signaling molecules are proposed to mediate placode promoting effects via the molecules LEF and β-catenin, as well as fibroblast growth factor, transforming growth factor-β2, Msx-1 and -2, and ectodysplasin A (EDA) and EDA receptor (EDAR). BMP family molecules, conversely, act as inhibitors of follicle formation. In model systems, ectopic expression of this family of molecules tends to suppress the formation of follicles. In mice, EDAR and β-catenin expression are required for expression of BMP4 and sonic hedgehog (Shh), a finding implicating these molecules in early follicular morphogenesis. Furthermore, EDAR may be important for lateral inhibition of cells surrounding the follicles.

The dermal papilla is believed to be formed as a result of epithelial cell instructions transmitted to the underlying mesenchyme. Molecular candidates for this signal include platelet-derived growth factor and Shh. The dermal cells, in turn, instruct the epidermal cells to proliferate and invade the dermis. The dermal cells differentiate into the dermal papilla; the involved epithelial cells become the inner root sheath and hair shaft of the mature follicle.

In addition to the widened bulge at the base of the mature hair follicle, two other bulges form along the length of the developing follicle. The uppermost bulge is the presumptive sebaceous gland, whereas the middle bulge serves as the site for insertion of the arrector pili muscle. Accumulating evidence also suggests that hair stem cells reside in the middle follicular bulge.[49,50] These important multipotent cells are able to differentiate into any of the cells of the hair follicle and to reconstitute the entire epidermis, which has been reported in cases of extensive surface wounds or burns.[50-53] Although bulge cells from the hair follicle are capable of adopting all these different cell fates, recent work suggests that under normal homeostatic conditions, these cells restrict their contributions to the hair follicle.[51,54]

By 19 to 21 weeks EGA, the hair canal has completely formed, and fetal scalp hair becomes visible. These hairs continue to lengthen until 24 to 28 weeks, at which time they shift from the active growth (anagen) phase to the degenerative phase (catagen), then to the resting phase (telogen), thus completing the first hair cycle. With subsequent hair cycles, hairs increase in diameter and coarseness. During adolescence, vellus hairs of androgen-sensitive areas mature to terminal-type hair follicles.

Sebaceous Glands

Sebaceous glands, as mentioned earlier, mature during the course of follicular differentiation, beginning 13 to 16 weeks EGA.[55] At this time, the presumptive sebaceous gland is the most superficial bulge in the developing hair follicle. As the sebaceous gland develops further, the outer cells differentiate and proliferate, giving rise to cells that accumulate lipids and sebum.[56,57] These differentiated cells ultimately disintegrate to release their contents into the upper portion of the hair canal. The production of sebum is responsive to hormonal influences, including maternal steroids during the second and third trimesters and at adolescence, a finding suggesting a factor contributing to the increased incidence of acne at this age.[58]

Nail Development

The earliest nail structures begin to appear on the dorsal digit tip at 8 to 10 weeks EGA, slightly earlier than the initiation of hair follicle development.[59] The first sign is the delineation of the flat surface of the future nail bed. The proximal nail fold is formed from a portion of ectoderm that buds inward at the proximal boundary of the early nail field. The presumptive nail matrix cells ultimately differentiate to become the nail plate; these cells are present on the ventral side of the proximal invagination. At 11 weeks EGA, the dorsal nail bed surface begins to keratinize. By the fourth month of gestation, the nail plate grows out from the proximal nail fold and completely covers the nail bed by the fifth month.[60]

Eccrine and Apocrine Sweat Gland Development

Eccrine glands begin to develop on the volar surfaces of the hands and feet, beginning as mesenchymal pads 55 to 65 days EGA.[2] By 12 to 14 weeks EGA, parallel ectodermal ridges overlay these mesenchymal pads. The eccrine glands arise from the ectodermal ridge. By 16 weeks EGA, the secretory portion of the gland becomes detectable. The dermal duct is complete by this time, but the epidermal portion of the duct is not canalized until 22 weeks EGA. Dermatoglyphics are formed by the curvilinear patterns of the epidermal ridges, and these become visible on the volar surfaces of the digits by 5 months EGA.

Interfollicular eccrine and apocrine glands, in contrast to volar glands, do not begin to bud until the fifth month of gestation. Apocrine sweat glands usually bud from the upper portion of the hair follicle. By 7 months EGA, the cells of the apocrine glands become distinguishable, composed of both clear cells and mucin-secreting dark cells. Apocrine glands become transiently functional during the third trimester, but eccrine glands are not functional until the postnatal period.

Only a few genes have been identified that encode critical regulators responsible for the development and differentiation of these structures. Mutations in either the EDA or EDAR gene, which encode a TNF-related ligand and its receptor, have been demonstrated in individuals with hypohidrotic and/or anhydrotic ectodermal dysplasia associated with markedly impaired sweating. Animal studies have implicated additional genes in sweat gland formation and function, including *En1* and *Wnt10b*.

Clinical Relevance

As has been described in some of the genetic diseases affecting development of the skin, genes that affect cutaneous appendage formation can also have effects on noncutaneous tissues; findings suggest an early role for these factors or a more global role in development and differentiation.

Certain genetic syndromes with prominent hair defects, often associated with other ectodermal appendageal abnormalities, have been identified; some of the responsible genes have been cloned. Menkes kinky hair syndrome is an X-linked recessive syndrome featuring pili torti (twisted hair) that is sparse and brittle with a "steel wool" quality. The skin is doughy, and patients have skeletal abnormalities and general failure to thrive. The defect for this disease is an ATP-dependent copper transporter, ATP7A.[61-63] Argininosuccinic aciduria is an autosomal recessive disorder, resulting from defective argininosuccinate lyase, that may present neonatally with trichorrhexis nodosa and short, broken scalp hairs, neurologic deficits including lethargy and mental retardation, hepatomegaly, and failure to thrive.[64,65] The mechanism responsible for the hair defects is not known.

Other defects occur in the structural proteins of hair, such as hair keratins. Monilethrix is caused by defects in hair cortex keratins 1, 3, and 6 (HB1, HB3, and HB6), which result in beaded hair and brittle nails.[66,67] Diseases such as pachyonychia congenita present primarily with cutaneous and ectodermal appendageal defects, including hyperkeratotic nails, palmoplantar keratoderma, follicular hyperkeratosis, and

steatocystoma multiplex. These defects have been found to be mutations in genes encoding typical "soft" keratin genes: K6a, K6b, K16, and K17.[68] Trichothiodystrophy, or Tay syndrome, presents as short, brittle hair with alternating dark and light "tiger-tail" bands as well as trichoschisis.[69] Nails are dystrophic, skin is ichthyotic, and patients exhibit photosensitivity, short stature, intellectual impairment, and decreased fertility. Two genes have been identified that are involved in DNA repair and identical to the genes mutated in the xeroderma pigmentosum complementation groups B and D. The reasons for the cutaneous manifestations of this disease are not clear, but the hair and nail phenotypes have been proposed to be a result of low cysteine content.

Mutations in critical developmental regulatory genes, such as those encoding DNA binding proteins and growth factors, have also been found in congenital syndromes affecting skin appendage formation.[1,44] Hypohidrotic ectodermal dysplasia, a defect in either EDA or EDAR, features sparse hair, nail dystrophy, as well as hypohidrosis or anhidrosis, which can lead to poor thermoregulation. In contrast, hidrotic ectodermal dysplasia, which presents with sparse hair, dystrophic nails, palmoplantar keratoderma, and tufting of terminal phalanges, is associated with defects in connexin 30. Mutations in p63 affect nail development in syndromes such as ankyloblepharon, ectodermal defects, and cleft lip and ectrodactyly-ectodermal dysplasia clefting.[70] Functional p63 is required for the formation and maintenance of the apical ectodermal ridge, an embryonic signaling center essential for limb outgrowth and hand plate formation. The secreted factor Wnt7a and the transcription factor Lmx1b are important for dorsal limb patterning, including nail formation. Nail-patella syndrome results from mutations in LMX1B. In contrast, the transcription factor En1 is required for ventral limb patterning and eccrine gland formation. Other regulatory molecules important in appendage development include the secreted factor Shh, which is required for hair follicle formation but not nail plate formation, and the transcription factor MSX1, which is required for tooth and nail formation. *Hoxc13* is an important homeodomain-containing gene for later stages of follicular and nail differentiation, at least in murine models.

PRENATAL DIAGNOSIS

Identification of the genes involved in early cutaneous development and determination of associated mutations responsible for disease have allowed prenatal diagnosis of life-threatening or debilitating cutaneous disease.[71] Some techniques have been devised for such testing, such as chorionic villous sampling, which can be performed at 8 to 10 weeks EGA, or amniocentesis, which can be done at 16 to 18 weeks EGA. These diagnostic procedures can be performed earlier and are associated with less fetal morbidity and mortality than the only previously available technique—fetal skin biopsy—performed 19 to 22 weeks EGA. Even though chorionic villous sampling and amniocentesis are less invasive, certain diseases, such as harlequin fetus, still require fetal biopsy for diagnosis because no definitive genetic mutations have yet been identified. Candidates for prenatal testing include fetuses with an affected sibling or family member.

Physiologic Development of the Skin

Human skin is a complex structure with unusual functional diversity.[1] Topologically, the skin is continuous with the lung and intestinal epithelia. The lung and gut are generally viewed as exchange surfaces for gases and nutrients; the skin is more commonly considered a barrier.[2,3] The concept of an integumental barrier emphasizes the role of the skin as a protective boundary between an organism and a potentially hostile environment. This protective role is evident at birth as a fetus abruptly transitions from a warm, wet, sterile, protected sphere to a cold, dry, microbe-laden world filled with physical, chemical, and mechanical dangers. Focusing only on the barrier properties of the skin, however, minimizes the critical role of the skin in social communication, perception, and behavioral interactions. The skin, as the surface of an organism, is both a cellular and molecular structure as well as a perceptual and psychological interface.[4] This dual functionality befits a true boundary and must be kept in mind to fully appreciate the dynamic organization of the skin and its close kinship with the nervous system.

The skin also provides the physical scaffold that defines the form of an animal.[5] As a result of the action of the somatic musculature, a vertebrate's body continually changes shape. A wide variety of strategies have been devised by different animals to cope with the exigencies of different habitats (Table 62-1).[6] Arthropods have a largely inflexible body surface, covered with an exoskeleton. Many vertebrates, such as amphibians, live on land but are confined to humid or wet microhabitats. Reptiles and fish have a skin surface covered predominantly with scales; birds have evolved feathers; and most mammals are covered with a protective mantle of fur. In primates, humans are unique in possessing a nonfurred skin with a thick stratified interfollicular epidermis and a well-developed stratum corneum.[5,7]

The question of the presumptive advantage of losing a protective and insulating coat of fur has long intrigued evolutionary biologists and physical anthropologists.[8] Three of the most distinctive physical features distinguishing human beings are (1) a nonfurred skin surface; (2) a large, versatile, highly complex brain; and (3) opposable thumbs. The close embryologic connection between the epidermis and the brain (both are ectodermal derivatives) supports the contention that these peculiar

TABLE 62–1

Animal Body Covering

Type	Biologic Example
Simple membrane	Earthworm
Simple stratified epidermis, often mucus-secreting	Frog, toad
Exoskeleton	Insects, crustaceans
Scales	Reptiles, fish
Feathers	Birds
Fur	Most mammals (including all primates except humans)
Nonfurred complex stratified epidermis	
Thick interfollicular epidermis with separate functional strata and well-developed stratum corneum	Humans
Lipid droplets in stratum corneum	Dolphins

structural aspects of human development have co-evolved. We often overlook the direct participation of the skin in higher level functions, such as perception and behavioral interactions.[4,9] Cutaneous attributes form the basis for many readily observed biologic distinctions (age, race, sex) as well as multiple, overlapping sociocultural characteristics (tattooing, cosmetics, tanning). During recovery from illness, the skin forms a critical interface linking a patient with caregivers and a nurturing environment.

In this chapter, specific aspects of the physiologic development of fetal and neonatal skin are highlighted, focusing particularly on the development of the epidermal barrier and the functions subserved by the outermost layer of the skin, the stratum corneum. As relevant, new areas of skin biology pertinent to a fetus and a newborn are emphasized. Areas of active research and unanswered questions will be identified in hopes of spurring new investigation of this highly accessible but extraordinarily complex interface.

DEVELOPMENT OF THE EPIDERMAL BARRIER

Human epidermis consists of a number of renewing structures, including the interfollicular epidermis, the hair follicle, the sweat gland, and the sebaceous gland.[10] The bulk of human skin is composed of the dermis and consists of collagen and elastin fibers embedded in a hydrated matrix of glycosaminoglycans. Blood vessels and the majority of cutaneous nerve endings are present in the dermis. The cells of the dermis and subcutaneous fat derive from the embryonic mesoderm. In contrast, epidermal appendages, such as hair follicles, sweat glands, sebaceous glands, and the interfollicular epidermis, derive from embryonic ectoderm.

The epidermis is a composite tissue containing multiple cell types, including keratinocytes, melanocytes, Merkel cells, and Langerhans cells. Only the antigen-presenting Langerhans cells are of mesodermal origin. The epidermis is traditionally segmented into four separate structural and functional compartments (Figure 62-1): (1) the stratum basale, responsible for keratinocyte proliferation and epidermal renewal; (2) the stratum spinosum, consisting of tightly packed keratinocytes linked via desmosomal connections; (3) the stratum granulosum, responsible for barrier lipid synthesis and corneocyte production via programmed cell death; and (4) the stratum corneum, the anucleated outermost layer, which forms the physical interface with the environment.[11,12] The stratum corneum is markedly deficient in preterm human infants.[13-16] Protective functions of the stratum corneum are listed in Table 62-2.

Cornified Envelope and Epidermal Lamellar Body

During the latter part of gestation, epithelial surfaces at environmental interfaces undergo structural and functional changes, including synthesis of complex, proteolipid materials. These events are highly coordinated and can be influenced by prenatal hormone exposure, such as glucocorticoids given to a mother.[16-21] Skin development in a human fetus is separated into three stages that correlate with the major events in epidermal differentiation: stratification, follicular keratinization, and keratinization of the interfollicular epidermis.[10] The stratum corneum is generally formed after 23 to 24 weeks of gestation. The formation of a barrier to water loss and infection is a sine qua non for survival in the extrauterine environment. Figure 62-2 illustrates the complex stages in the assembly of the cornified envelope in human stratum corneum.[22,23] Of note, synthesis and secretion of epidermal barrier lipids occurs in the form of lamellar bodies. This process is similar to that occurring over a parallel time frame in the developing lung (Table 62-3).[16] Fusion of the intracellular lamellar body with the limiting plasma membrane results in extrusion of barrier lipids, which subsequently undergo extracellular organization providing the primary barrier to transepidermal water loss. The barrier lipids in the epidermis, unlike the lung, are generally devoid of phospholipids and consist primarily of free fatty acids, cholesterol, and ceramides (see Table 62-3).[2]

Covalent crosslinking of structural proteins and ceramides results in formation of a highly insoluble cornified envelope, typical of the mature mammalian stratum corneum.[22,23] Each corneocyte consists of a covalently crosslinked envelope, linked internally to structural proteins such as keratins and externally to other corneocytes via desmosomes, resulting in the assembly of a huge macromolecule.[12] The complexity and redundancy of the cornified envelope provide evidence for a highly organized and conserved molecular structure.[24,25] The cornified envelope, although only 10 nanometers thick and of uniform density, is highly insoluble, secondary to crosslinking by intracellular transglutaminases.[26] The isopeptide bond formed by these enzymes cannot be cleaved in vertebrate cells; therefore the resulting macromolecular protein complex is stable and essentially insoluble. This crosslinked assembly forms the scaffolding for the highly ordered lamellar lipid matrix. The very-low-birth-weight preterm infant lacks an effective epidermal barrier.[13,14] A better understanding of the mechanisms by which the stratum corneum forms in utero may offer insights and direction to therapeutic regimens aimed at epidermal barrier formation postnatally.

The Biology of Vernix

Scientifically, the development of epidermal barrier function has many similarities to surfactant production and lung development (see Table 62-3). Both epidermal keratinocyte and type II alveolar cell are lipid-synthesizing cells that secrete barrier lipids in the form of lamellar bodies. Both ultimately interface with a gaseous environment and both are under similar hormonal control at similar periods of development. A clear analogy exists between the mechanisms by which the lung develops a functionally mature epithelial surface ready for air adaptation and those by which the skin surface matures under total aqueous conditions for terrestrial adaptation to a dry environment. An unanswered question in epidermal biology, however, is by which mechanism the epidermal barrier forms under conditions of total aqueous immersion. Prolonged exposure of the skin surface to water in adults is harmful.[27] Growing evidence indicates that vernix caseosa, a complex proteolipid cellular cream, which forms primarily during the last trimester of gestation, interacts with the developing epidermis and facilitates

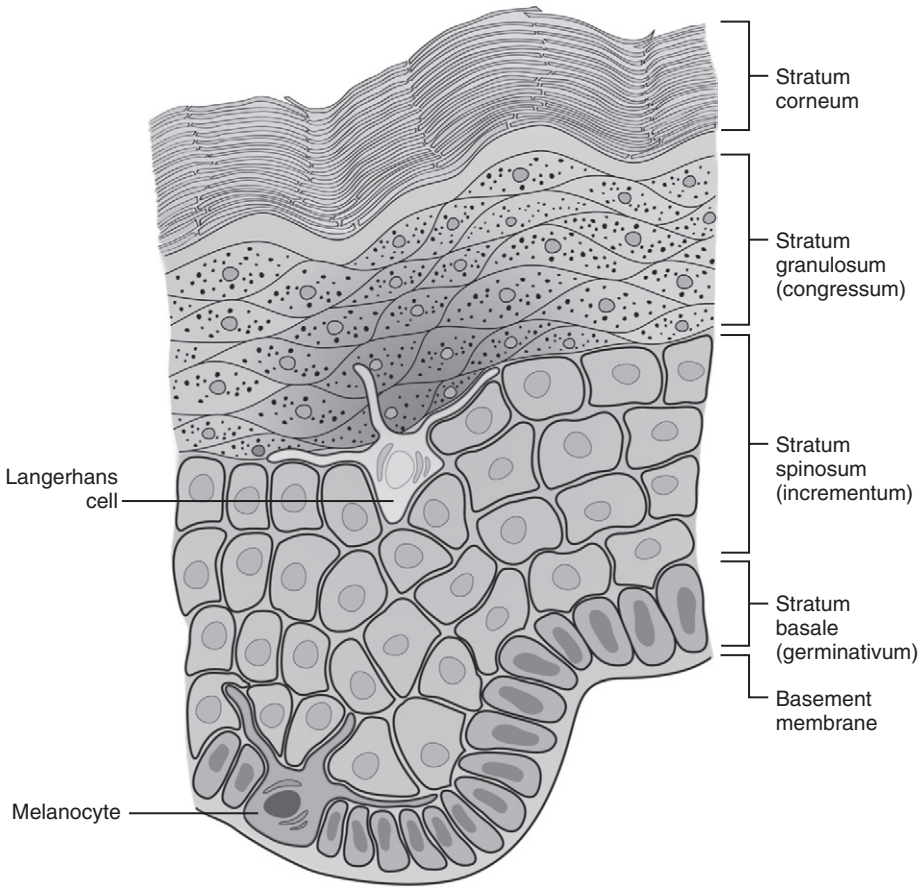

Figure 62-1 Organization of human epidermis. The interfollicular epidermis is traditionally considered a tetratomic identity incorporating four separate structural and functional epidermal strata. In humans, the epidermis between the hair follicles is much thicker than in furred animals. The epidermis is composed primarily of keratinocytes but includes other epidermal cells such as melanocytes, Langerhans cells, and Merkel cells (latter not shown). The outermost stratum, the stratum corneum, incorporates the transition from living, nucleated keratinocytes to terminally differentiated corneocytes. This diagram is schematic only and does not illustrate the important intercellular connections (desmosomes) converting single cells into integrated membrane structures. *(Modified from Hoath SB, Leahy DG: The human stratum corneum as extended, covalently cross-linked biopolymer: mathematics, molecules, and medicine,* Med Hypotheses *10:10, 2006.[12])*

TABLE 62–2

Protective Functions of the Stratum Corneum

Functions	Structural Basis	Biochemical Mechanisms
Mechanical integrity/resilience	Cornified envelope, cytosolic filaments	Crosslinked peptides (e.g., loricrin, keratin filaments)
Xenobiote defense	Lamellar bilayers, extracellular matrix	Acidic pH; free fatty acids; antimicrobial peptides
Antioxidant defense	Corneocytes and extracellular matrix	Keratins; sebaceous gland–derived vitamin E and other antioxidants
Cytokine signaling	Corneocyte cytosol	Storage and release of interleukins; serine proteases
Permeability barrier	Lamellar bilayers	Hydrophobic lipids
Hydration	Lamellar bilayers Corneocyte cytosolic matrix	Sebaceous gland–derived glycerol; filaggrin breakdown products (NMFs)
Waterproofing/repellency	Lamellar bilayers	Keratinocyte and sebum-derived lipids
Cohesion/desquamation	Corneodesmosomes	Acidic pH serine proteases
UV protection	Corneocyte cytosol	Structural proteins; urocanic acid; light scattering/absorption

Modified from Chuong CM, Nickoloff BJ, Elias PM, et al: What is the 'true' function of skin? *Exp Dermatol* 11:159, 2002.[5]
NMF, Natural moisturizing factor; *UV,* ultraviolet.

the in utero formation of the stratum corneum.[28,29] The macroscopic and phase contrast appearances of vernix are shown in Figure 62-3.

Recent studies in rodent and fetal human skin using the technique of methylene blue dye exclusion[30,31] have demonstrated the development of the epidermal barrier. Cellular tissue exposed to this dye turns blue, but an intervening cornified barrier prevents tissue staining. This technique offers a relatively straightforward method of determining the pattern and timing of permeability barrier formation. In rodents, epidermal barrier development begins dorsally and extends in a ventral direction during the sixteenth and nineteenth days of gestation

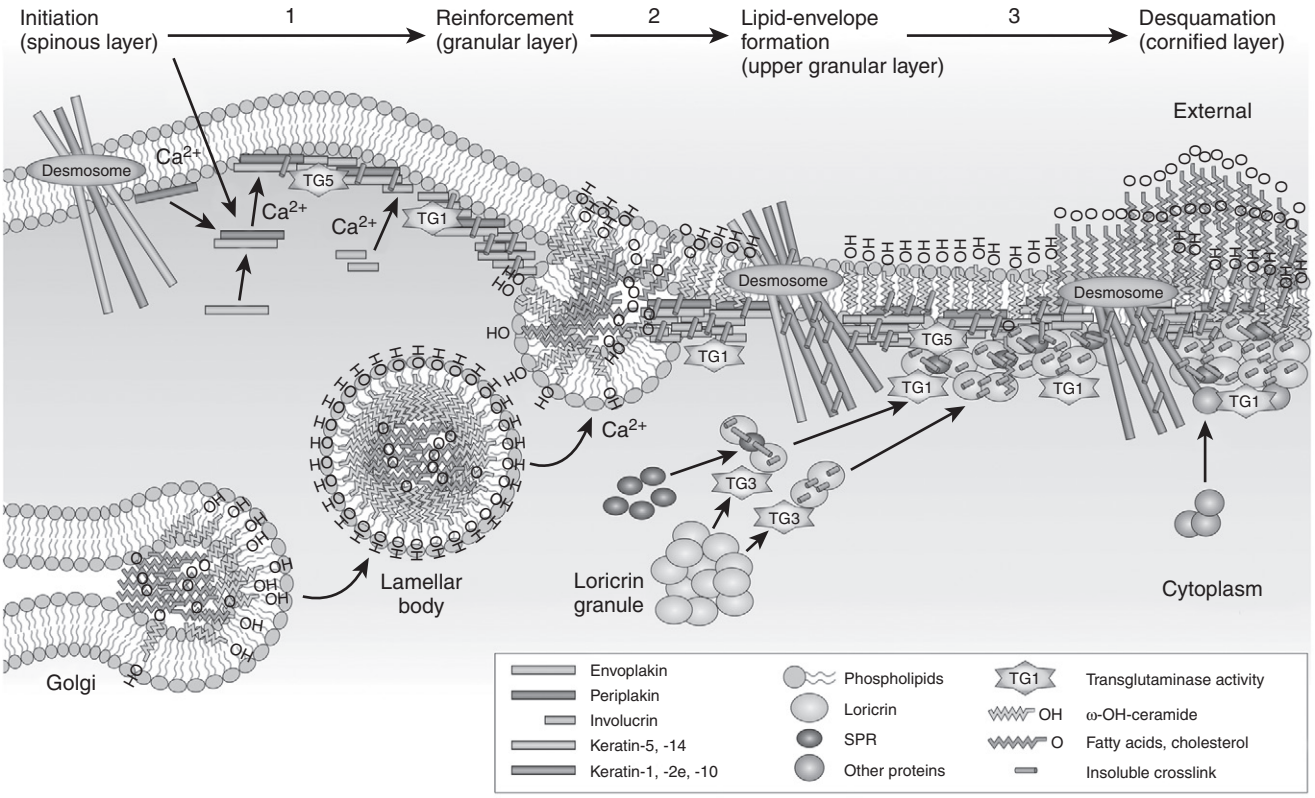

Figure 62-2 Stages in the assembly of the cornified envelope in human stratum corneum. 1, In the upper layers of the epidermis, rising levels of intracellular Ca^{2+} lead to expression of envoplakin, periplakin, and involucrin, as well as transglutaminase-1 with subsequent covalent crosslinking of the structural proteins along the inner surface of the plasma membrane. **2,** Synthesis, packaging, and extrusion of barrier lipids (free fatty acids, cholesterol, ceramides) in the form of lamellar bodies are accompanied by replacement of the plasma membrane with covalently bound ceramides that serve to interdigitate with and organize the extracellular lipids into the characteristic lamellar pattern. **3,** Covalent crosslinking of intracorneocyte proteins, including keratins, loricrin, and small proline-rich peptides, occurs via mediation of transglutaminase-1 and -3. The end product is the transformation of nucleated keratinocytes in the uppermost granular layer of the epidermis into a network of interlinked, terminally differentiated corneocytes embedded in a matrix of structured lipid lamellae, collectively called the stratum corneum. The stratum corneum provides the vital barrier to water loss and infection necessary for life after birth. *(Modified from Candi E, Schmidt R, Melino G: The cornified envelope: a model of cell death in the skin,* Nat Rev Mol Cell Biol *6:328, 2005.[22])*

TABLE 62–3

Comparison of Lamellar Bodies of Epidermal and Pulmonary Origins

	Epidermis	Lung
Cell type	Spinous and granular keratinocytes	Type II alveolar cell
Size/structure	Ovoid (0.25-0.5 micron) Disk-like lamellations	Spheroid (1.2-1.6 microns) Lamellated sacs with amorphous core
Lipid content	40% phospholipids 20% glycosphingolipids 20% free sterols 20% other neutral lipids	85% phospholipids 10% free sterols 5% other neutral lipids
Protein content	Acid phosphatase Glycosidases Proteases Lipases	Acid phosphatase Proteases Glycosidases Surfactant apoproteins
Function	Delivery of lipids to form extracellular matrix of stratum corneum Skin permeability barrier	Delivery of surfactant lipid to alveolar spaces Lower alveolar surface tension

in mice and rats, respectively.[31] This process leads to a slightly thicker stratum corneum over the back than the front in a late-gestation fetal rat.[32] Stratum corneum formation in a rat at birth requires approximately 3 cells/cm^2/s to undergo programmed cell death.[32] Corneocyte formation rate in humans has not been measured.

In humans, unlike rodents, which lack body hair at birth, the permeability barrier forms initially in the region of the pilosebaceous apparatus.[30] This finding strongly supports the hypothesis that vernix caseosa (in part a product of sebaceous secretions) participates in "waterproofing" the skin surface, thereby allowing cornification to occur initially in the area of the hair follicles and then over the interfollicular skin.[33] Standard skin culture systems are organizationally simpler than fetal skin and notably lack skin appendages. Such systems must be raised to an air-liquid interface to obtain adequate cornification.[34] A better understanding of vernix caseosa and fetal sebaceous gland physiology is biologically relevant and may be applicable to clinical situations in which the epidermal surface is inadequately developed, burned, or traumatized.

Sebaceous glands are found in the skin of all mammals except whales and porpoises.[35] Their primary function is the excretion of sebum, which is a complex mixture of relatively nonpolar

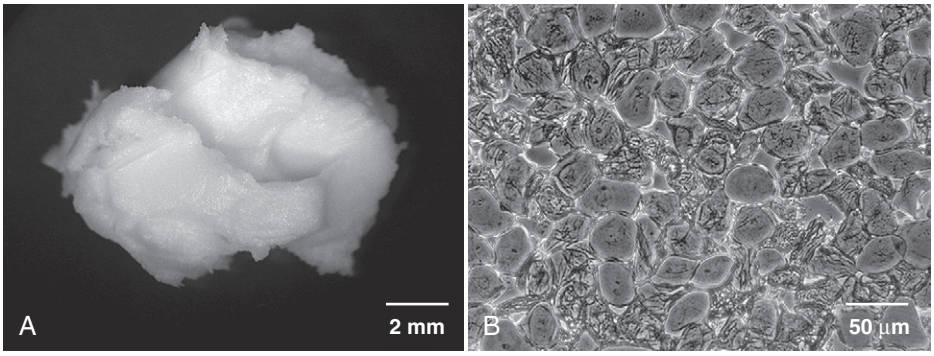

Figure 62-3 Vernix caseosa. A, Macroscopically, vernix is a thick, viscous, white paste. The phase contrast image of native vernix **B,** reveals a dense packing of fetal corneocytes. Vernix consists primarily of thin, hydrated, polygonal, terminally differentiated, fetal corneocytes embedded in a nonlamellar lipid matrix. The cells are heterogenous in size and structure. Many nuclear ghosts are evident. Scale bars are shown.

lipids, most of which are synthesized de novo by the glands.[36] Sebum provides a hydrophobic coating for the fur of mammals, which protects against overwetting. Sebaceous glands are multi-acinar, holocrine-secreting structures that occur in all areas of the skin except the palms and soles and only sparsely on the dorsal surfaces of the hand and foot.[37] The development of the sebaceous glands is closely related to the differentiation of hair follicles in the epidermis. In newborn infants, sebaceous glands are well formed, hyperplastic, and macroscopically visible over certain body areas, such as the nose. The close connection of vernix production in utero with the developing pilosebaceous apparatus supports a mechanism by which the surge in sebaceous gland activity during the last trimester of pregnancy leads to production of a thick, lipid-rich, hydrophobic film (the vernix caseosa) overlying the developing stratum corneum.[28,36,38] The hyperplasia of the sebaceous glands in term infants is putatively secondary to androgenic stimulation from the equally hyperplastic adrenal glands.[28] This hypothesis provides a working model that remains to be fully tested (Figure 62-4). It has the advantage of functionally integrating two disconnected facts—the mutual hyperplasia during the latter half of gestation of the sebaceous gland and the adrenal gland in a human fetus.

Other clinical observations are also explicable under this hypothesis. Obstetricians have long observed that the amniotic fluid becomes turbid during the last trimester of pregnancy.[39] In vitro, the addition of physiologically relevant amounts of pulmonary surfactant leads to emulsification and release of immobilized vernix. This finding is consistent with a mechanism by which vernix is progressively released from the skin surface after formation of an intact stratum corneum under the influence of lung-derived surfactant within the amniotic fluid.[39] The fetus subsequently swallows the detached vernix (see Figure 62-4). Measurements of the amino acids of vernix have demonstrated that it is rich in glutamine, a known trophic factor for the developing gut.[40,41] Further work is required to establish the degree to which epithelial surfaces "crosstalk" in preparation for birth. What emerges from the available data, however, is a coherent and intriguing glimpse of a new area in perinatal biology.

TRANSITION AT BIRTH

Few events in mammalian life are as physiologically abrupt as birth. As with other epithelial surfaces that interface with the environment after birth (lung, gut, and kidney), the skin must immediately perform multiple functions vital to the survival of the organism (Box 62-1).[14] Many of these functions, such as thermoregulation, were unnecessary before birth and largely performed by the placenta. Birth, however, marks a transition to a cold, nonsterile environment that includes high oxidative stress and exposure to ultraviolet light.

Physiologic mechanisms in the epidermis that contribute to formation of an adaptive environmental interface include activation of eccrine sweating, which is important for thermoregulation and bacterial homeostasis, and sebum production by hyperplastic sebaceous glands.[42] At birth, the epidermal barrier is essentially pH neutral, but it rapidly develops an acid mantle via mechanisms distinct from simple bacterial colonization.[43] Physiologically, the epidermis and its ultimate differentiation product, the stratum corneum, remain in balance via the reciprocal properties of renewability and self-cleaning, properties that reflect the distinct but tightly coupled processes of cornification and desquamation.[44] Recent data have indicated that transepidermal water flux is an important regulator of DNA and lipid synthesis within the epidermis.[45-47] Environmental humidity and maintenance of stratum corneum hydration are necessary for normal desquamation.[48,49] A preterm infant is vulnerable to disruption of all these physiologic mechanisms.

Prenatally, lipid synthesis is necessary for production of the vernix caseosa and formation of the interfollicular barrier lipids of the epidermis, which are required for successful postnatal adaptation. Postnatally, lipid synthesis and metabolism continue to subserve multiple functions (Table 62-4). Thus specific barrier lipids in the stratum corneum form the primary structural basis for the postnatal epidermal permeability barrier. The epidermis and the brain contain unusually high concentrations of ceramides.[50-52] This fact deserves further examination given the close embryologic and functional connection between these two ectodermal derivatives. Other skin lipids include sebum and triglycerides in adipose tissue. The latter functions primarily as a systemic energy reservoir in addition to providing cushioning and biomechanical support.

Water Loss, Temperature Control, and Blood Flow

Life in a dry, terrestrial environment necessitates protection against the constant dehydrating effects of air exposure. The formation of a barrier against transepidermal water loss is well known to be a direct function of gestational age.[53,54] As shown in Figure 62-5, transepidermal water loss decreases dramatically as term approaches, with levels in the near term infant equal to or less than adult values. This critical and vital postnatal function resides almost entirely in the outermost 20 microns of the skin surface—in the stratum corneum.[2] Heat exchange between the skin of an infant and the surrounding environment occurs via

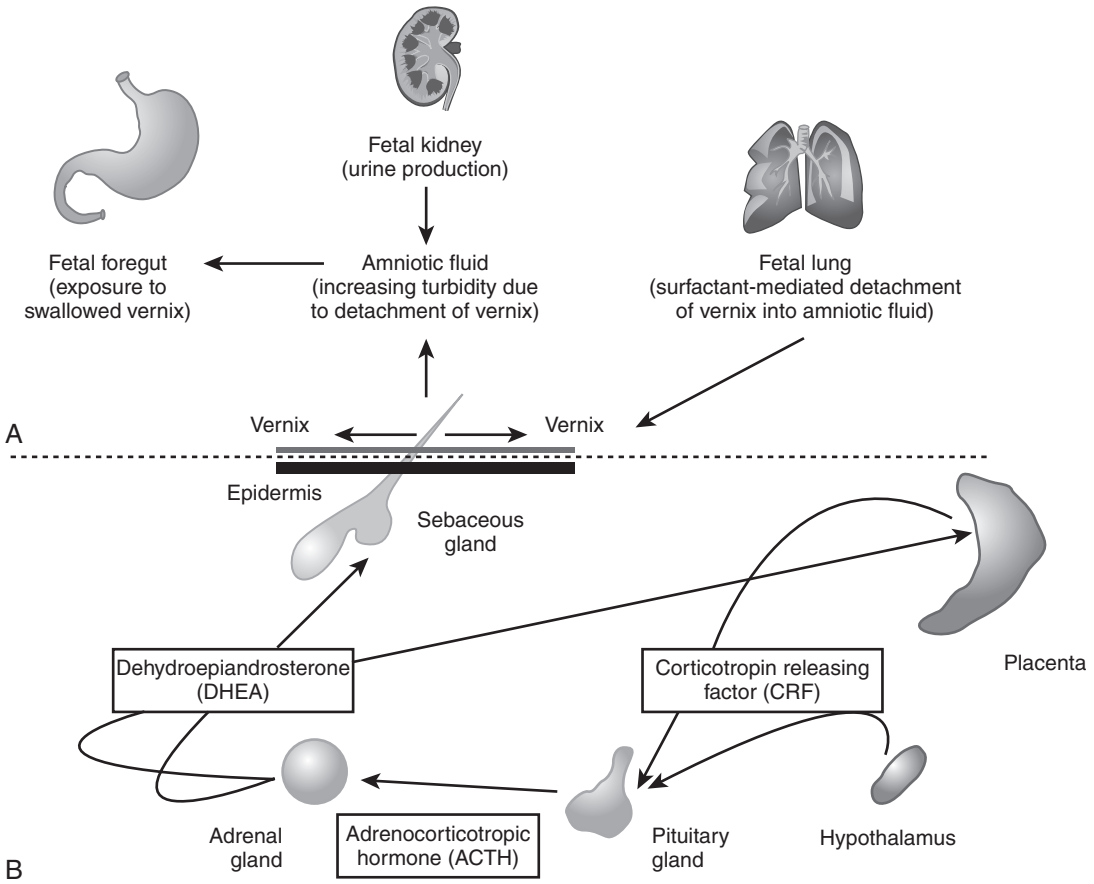

Figure 62-4 A, Proposed mechanism for pulmonary surfactant–mediated vernix detachment. The fetal kidney contributes significantly to amniotic fluid production. During the third trimester, vernix covers the developing epidermis and the fetal lung produces and secretes increasing amounts of pulmonary surfactant into the amniotic fluid. Vernix on the skin surface builds up and detaches into the surrounding milieu, leading to amniotic fluid turbidity.[39] Vernix within the amniotic fluid is subsequently swallowed by the fetus with potential effects on the fetal foregut and/or systemic absorption of vernix components. **B,** Endocrine-based model for vernix production and epidermal barrier maturation. In this working model, corticotropin-releasing factors from either the placenta or hypothalamus act to initiate adrenocorticotropic hormone release from the pituitary gland. Adrenocorticotropic hormone stimulation of the adrenal cortex promotes synthesis and release of androgenic steroids such as dihydroepiandrosterone (DHEA), which are subsequently converted enzymatically within the sebaceous gland to active androgens. Production of superficial lipid film (sebum) in the immediate vicinity of the hair follicle modulates the transepidermal water gradient with putative effects to facilitate cornification of the underlying epidermis.[31] Desquamation of corneocytes into the overlying lipid matrix results in formation of vernix. The recent finding by Ito et al[159] that human hair follicles synthesize cortisol and exhibit a functional equivalent of the hypothalamic-pituitary-adrenal axis raise interesting questions regarding local versus systemic control mechanisms in the schema. *(Modified and expanded from Hoath S, Pickens W: The biology of vernix. - Acid mantle formation
- Antioxidant function
- Ultraviolet light photoprotection
- Barrier to chemicals
- Tactile discrimination
- Attraction to caregiver

evaporation, radiation, conduction, and convection.[55] Of these, evaporative heat loss is the primary mode of temperature instability in very-low-birth-weight preterm infants and is the primary mode of heat loss in all infants at the time of birth. It is important to distinguish between evaporative heat loss from standing water or amniotic fluid on the skin surface and evaporative heat loss secondary to a poor epidermal barrier, which occurs after delivery in very-low-birth-weight preterm infants. The second mode of heat and fluid loss is ongoing and is exacerbated in nonhumidified, radiant-heated environments.

Given the critical importance of limiting evaporative water and heat loss in temperature control, it is surprising how little attention is given to the role of the stratum corneum in thermoregulation. Most reviews of body temperature control assume the presence of this water-retentive envelope. As with many other functions, the strategic position of the stratum corneum is taken for granted and focus is placed on more central mechanisms. In a newborn infant, however, it is important to

TABLE 62–4

Sources, Composition, and Presumed Functions of Skin Lipids in Neonates

Source	Composition	Functions
Stratum corneum	Ceramides, cholesterol sulfate, neutral lipids (free and esterified sterols, free fatty acids, triglycerides)	Permeability barrier, cohesion/desquamation, antibacterial
Sebaceous glands	Triglyceride, wax/ sterol esters/squalene	Antibacterial Moisturization
Adipose tissue	Triglyceride	Systemic energy reservoir

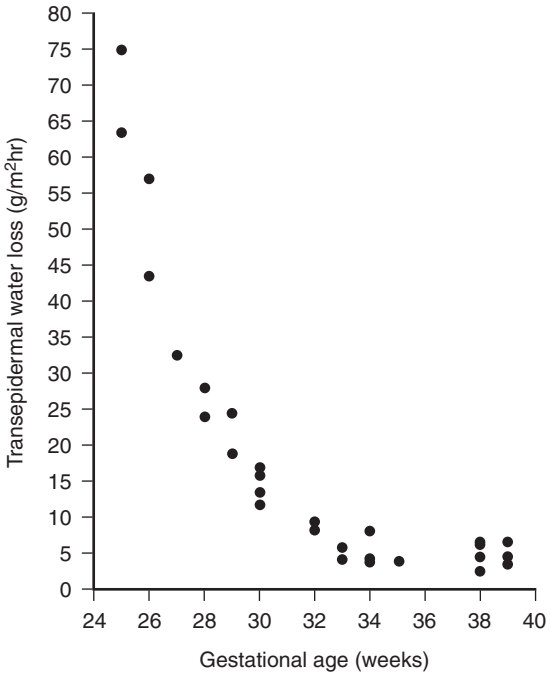

Figure 62-5 Transepidermal water loss as a function of gestational age. These data demonstrate the inverse relationship between transepidermal water loss (TEWL) and gestational age. Very-low-birth-weight preterm infants have extraordinarily high TEWL in the range of 50 to 70 g/m^2/hr. Term infants have low TEWL, in the range of 5 g/m^2/hr, which is comparable with or lower than adult values. *(Modified from Hammarlund K, Sedin G: Transepidermal water loss in newborn infants. III. Relation to gestational age,* Acta Paediatr Scand *68:795, 1979.[54])*

continually bear in mind the role of peripheral mechanisms in organizing, maintaining, and guiding central nervous system development.

The classic study by Adamsons et al[56] more than 40 years ago provides an example of the importance of the periphery in temperature control in newly born infants (Figure 62-6). Thus oxygen consumption, measured in term infants 4 hours after birth, is not a function of central body temperature as might be expected with warm-blooded endothermic organisms.[53] Systemic oxygen consumption is, rather, a function of heat exchange at the skin-environment interface. Central homeothermic mechanisms are not well developed at birth. A basic knowledge of skin-environment interactions, therefore, is key for infant caregivers. Preterm infants exhibit even more vulnerability to the environment owing to higher surface area to mass ratios, lower endogenous sources of heat generation such as brown adipose tissue, an incompetent epidermal barrier, and the inability to self-regulate with flexural positioning.[13]

The central control of body temperature also requires mechanisms such as eccrine sweating and vasodilatation/vasoconstriction, which are under autonomic nervous system control.[57] These mechanisms are generally not well established at birth. Newborn infants may exhibit vasoconstriction of the extremities (acrocyanosis) and may have wide fluctuations in red blood cell content (hematocrit) as well as blood volume. Peripheral cooling results in increased blood viscosity and decreased blood flow. After birth, considerable reorganization of the cutaneous vascular bed, with development of a subpapillary plexus in the first 3 months of life, occurs (Figure 62-7). The formation of a superficial vascular plexus is also associated with increased convolution of the undersurface of the epidermis (rete peg formation), which is a hallmark of the mature human epidermis. The development of the cutaneous vasculature and the role of growth factors, such as vascular endothelial growth factor have been reviewed elsewhere.[58]

Development of the Acid Mantle

A number of physiologic mechanisms are triggered at the time of birth, which persist into later life. Human skin, for example, is characterized by an acidic skin surface, the so-called acid mantle. At birth, the skin surface pH is relatively neutral and gradually becomes more acidic in the first few postnatal weeks (Figure 62-8). The first measurements of infant skin pH were performed by Taddei[59] in 1935, who reported surface skin pH in the range of 6.5 at birth. The use of alkaline soaps for infant bathing can markedly alter the development of the acid mantle, as can the local environment.[60] Acid mantle development is delayed in very-low-birth-weight preterm infants.[61] Surface skin pH measurements are generally higher under occluded sites, such as the diaper region.[62] Site-dependent differences in surface pH have also been reported in neonates.[63]

A number of different mechanisms for establishing the acid mantle have been proposed, including endogenous factors such as lactic acid from sweat, free fatty acid generation from metabolism of triglycerides in sebum, and metabolic byproducts of bacterial colonization.[43] Endogenous factors include the formation of lactic acid from epidermal cell metabolism and free fatty acid generation from phospholipid breakdown within the stratum corneum. Active proton pump mechanisms also have been proposed, as well as the controlled degradation of structural proteins such as filaggrin to form acidic byproducts such as urocanic acid.[43]

The presence of an acidic skin surface has advantages.[43] Proposed functions of the acid mantle include antimicrobial defense and maintenance of epidermal barrier integrity.[64] Enzymes involved in stratum corneum desquamation, which are pH sensitive, include cathepsin D, chymotryptic serine protease, and tryptic serine protease. Extracellular lipids involved in formation of the epidermal barrier are also processed via pH-sensitive enzymes, including beta-glucocerebrosidase. Thus the acid mantle is derived from multiple redundant sources and may regulate a number of processes essential for maintenance of a competent epidermal barrier. A newborn infant offers an exciting and accessible area for studying these multiple etiologic mechanisms and functions.

Bacterial Colonization and Skin Cleansing

Paramount in the many functions served by the skin is the prevention of infection. Before birth, a fetus resides in a putatively sterile environment. Colonization of newborn skin begins upon

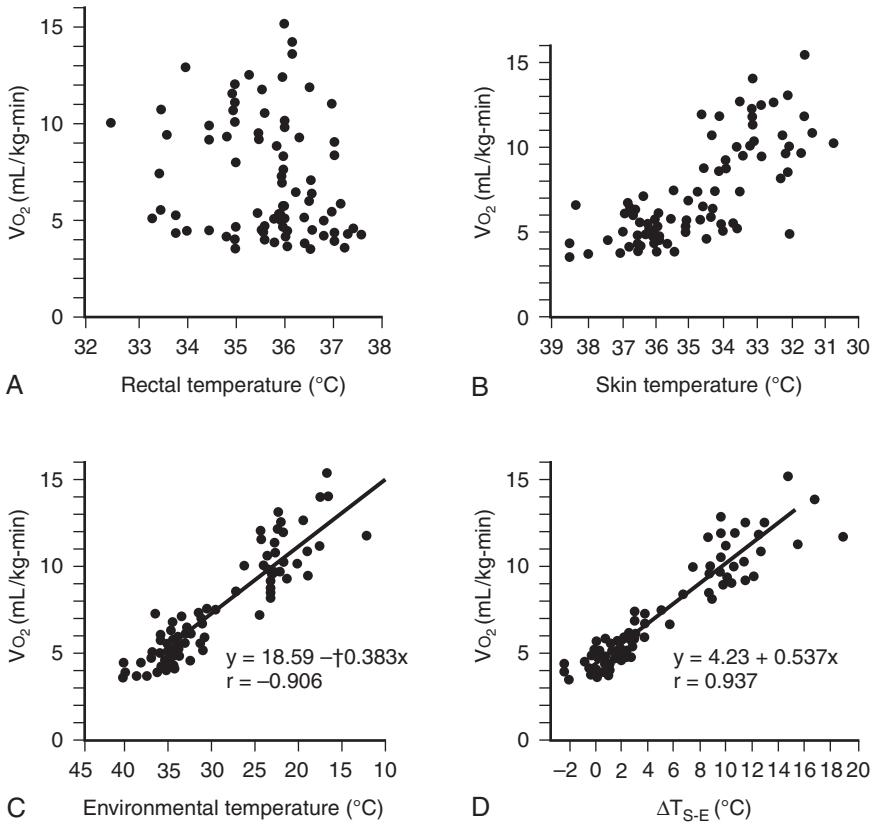

Figure 62-6 Oxygen consumption of term newborn human infants approximately 4 hours after birth. Systemic oxygen consumption correlates best with the skin-environment gradient, indicating the importance of peripheral heat flux in regulating body temperature in neonates. *(From Adamsons K, Gandy G, James L: The influence of thermal factors upon oxygen consumption of the newborn human infant,* J Pediatr *66:495, 1965.[56])*

first exposure to the external world. Infants born vaginally become colonized during passage through the birth canal, whereas infants born by cesarean delivery are typically sterile if the amniotic membranes were not ruptured before the onset of labor.[65] A list of the common skin-colonizing bacterial flora is given in Box 62-2.

Staphylococcus epidermidis, one of 13 species of coagulase-negative staphylococci, is the most common vaginal organism before birth and is ubiquitous in the environment. This organism rapidly colonizes the skin surface and is the predominate organism on the skin of most neonates.[66-70] In normal conditions, the resident flora of a neonate resembles that of adults after the first few weeks of life. These skin-colonizing flora are generally nonvirulent, stable in number, and only infrequently pathogenic given a normal epidermal barrier and immune properties.[71] In a very-low-birth-weight preterm infant, however, *S. epidermidis* is the most common cause of nosocomial sepsis.[71] This fact complicates the choice of appropriate skin care procedures and practices. Normally, commensal bacterial flora play a protective role, and recent evidence suggests that organisms such as *S. epidermidis* may up-regulate expression of antimicrobial peptides, such as human beta-defensin-2.[72,73]

The mechanisms leading to colonization of the skin are incompletely understood and involve a complex interplay among rapid growth of commensal organisms, the development of the acid mantle, local microenvironmental factors such as occlusion and humidity, and the choice of exogenous soaps and skin care practices.[73] There is a surprising lack of standard guidelines regarding optimal skin care in neonates.[74,75] Specific aspects of care include hand washing hygiene, bathing and choice of surfactants, regional skin care including the umbilical cord stump, and preparation of the skin before invasive procedures such as venipuncture.[74] Recently the use of alcohol-based disinfectants has been promoted as an alternative to routine hand washing.[76,77] It is important to recognize that such disinfectants have no cleansing function and will not remove soils on the skin surface. Recently, vernix caseosa has been reported to function as an endogenous skin cleanser that readily removes topical soils, such as carbon particles.[78] This finding is consistent with the view that the surface of a newly born infant possesses endogenous skin cleansing mechanisms (vernix, stratum corneum desquamation). These natural functions should be incorporated into the design of exogenous skin cleansing regimens.

Cutaneous Immunity

Given the plethora of bacteria and the multiple opportunities for superficial trauma, it is not surprising that the skin has a well-developed immune system.[5,79,80] Increasing evidence is available that innate immune function in term infants may be well developed, whereas such function in preterm infants is poor.[81] Once pathogenic bacteria or fungi have established adherence to the skin, a number of cutaneous mechanisms of host defense are called into play, including (1) the role of the stratum corneum as a mechanical barrier, (2) the establishment of an acid environment inhospitable for growth of pathogenic bacteria, and (3) the presence of metabolic products within the stratum corneum itself with antimicrobial activity.[82,83] Commensal organisms, such as the lipophilic corynebacteria, have

been reported to contribute to host defense by liberating antibacterial fatty acids from the triglycerides of sebum.[84] Cationic peptides may be elaborated in the skin with direct antimicrobial effects on the bacterial side of the cytoplasmic membrane.[85] A list of potential antimicrobial peptides in human epidermis is given in Box 62-3. Vernix caseosa has also been demonstrated to contain multiple antimicrobial peptides, including lactoferrin and lysozyme.[86-89]

Specific cell types within the epidermis play critical roles in host defense. In addition to terminal differentiation and formation of the stratum corneum, keratinocytes have been reported to internalize bacteria, leading to bacterial death and containment of infection.[90,91] The epidermis also contains migratory dendritic cells associated with antigen presentation.[92] These Langerhans cells are derived from the bone marrow and are located in the mid-to-lower epidermis, where they maintain a strategic position for immunosurveillance (Figure 62-9). Breach of the epidermal barrier leads to exposure of Langerhans cells to microorganisms and other potentially pathogenic material. After exposure, Langerhans cells migrate to regional lymph nodes. Their density and function within preterm epidermis have not been explored.

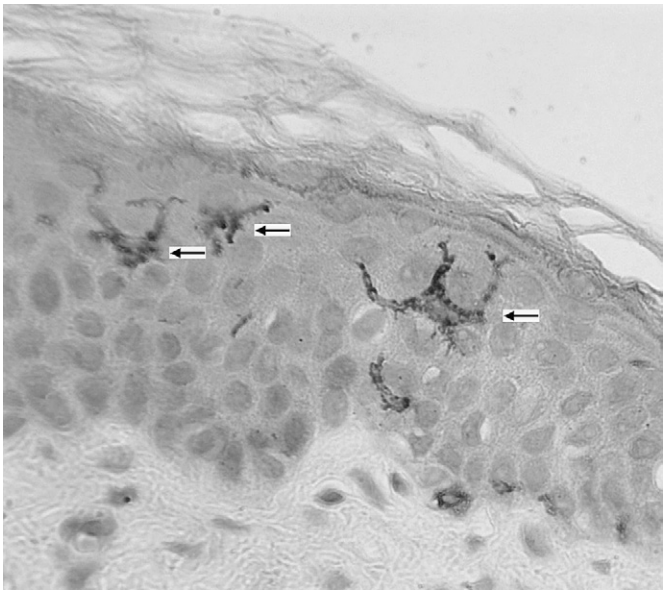

Figure 62-9 Immunolocalization of Langerhans cells in premature human epidermis (foreskin) by CD1a antibody staining (arrows). Langerhans cells are dendritic, antigen-presenting cells derived from the fetal bone marrow. They are typically located within the epidermis and function as a major component of the skin immune system. Skin specimen is from an approximately 32 week gestational age premature infant circumcised 1 month after birth.

PROBLEMS OF VERY-LOW-BIRTH-WEIGHT INFANTS

Ineffective Barrier

Without the prevention of water and heat loss provided by the stratum corneum, life in a terrestrial environment is impossible. Immaturity of the dermis and the cutaneous appendages poses problems of lesser magnitude for very-low-birth-weight infants. Exposure to air after birth in conjunction with other unknown stimulatory factors results in marked acceleration of barrier maturation (Figure 62-10). This effect is thought to be secondary to xeric stress imposed by the dry environment.[45,46] Similar effects are observed in cultured human skin, where lifting the culture system to an air-liquid interface is required for adequate barrier formation in vitro.[34] After preterm delivery, the normal slow intrauterine rate of epidermal barrier maturation is forgone. Birth of a very-low-birth-weight infant triggers immediate lipid and DNA synthesis, with subsequent cornification of the nucleated epidermal keratinocytes. The rapid transition from the sticky, wet, translucent skin surface of a very-low-birth-weight infant to the dry, opaque stratum corneum of an older preterm infant is familiar to infant caregivers. Such rapid formation of the stratum corneum often results in excessive desquamation and scaling several weeks after preterm birth. Measurements of transepidermal water loss and surface electrical capacitance have been used to track the rate of barrier formation after preterm birth.[53,93] Transepidermal water loss in immature infants (24 to 25 weeks gestation) decreases during the first few days after birth but remains elevated on the twenty-eighth postnatal day at 2 to 4 times the expected levels of 5 to 10 g/m^2/hr in term infants.[53] The etiology of the poor stratum corneum barrier in the infants is unclear but may relate to the extreme rapidity of barrier formation in this vulnerable population. Other skin conditions characterized by rapid epidermal turnover, such as atopic dermatitis and psoriasis, have similar high water loss rates.

The immature epidermal barrier of very-low-birth-weight infants is permeable to substances other than water. Care must be exercised to avoid toxic substances, which can enter the body via a transdermal route.[94,95] Respiratory gases can also move across the epidermal barrier under normal conditions. The immature barrier of a preterm infant, for example, allows the efflux of carbon dioxide[96] and the influx of oxygen[97] in a manner similar to that of water vapor. These findings support the contention that increasing ambient oxygen in a convective incubator during the first few postnatal days may lead to an appreciable augmentation of systemic oxygen. The rapid development of the stratum corneum, however, precludes long-term utility of this novel therapeutic approach.

Strategies for Epidermal Barrier Maturation/Repair

Therapeutic strategies for facilitating epidermal barrier development and protection of the preterm infant are listed in Box 62-4. Prematurity and infection are leading worldwide causes of neonatal morbidity and mortality.[98,99] Preterm infants are vulnerable to infection because of a poorly developed epidermal barrier combined with developmentally immature host defense mechanisms. The first week of life is a vulnerable period, particularly in developing countries, when 50% to 70% of fatal

BOX 62–4

Epidermal Barrier Repair Strategies

- Topical application of one or more nonphysiologic lipids (e.g., petrolatum)
- Topical application of mixtures of physiologic lipids (ceramides, cholesterol, free fatty acids) in appropriate molar ratios
- Topical dressings
- Vapor-permeable: Allow metabolic (repair) processes to continue in the underlying epidermis
- Vapor-impermeable (occlusive): Delay metabolic responses in the underlying epidermis

Modified from Chuong CM, Nickoloff BJ, Elias PM, et al: What is the 'true' function of skin? *Exp Dermatol* 11:159, 2002.[5]

and life-threatening neonatal illnesses occur, many of which are infectious complications associated with preterm birth.[74] Because the consequences of systemic infections are so devastating in premature and low-birth-weight infants, therapeutic options for preventing bacterial and fungal infections assume high priority as a means for improving neonatal outcomes.[98]

One of the earliest methods of improving outcome in preterm infants was the provision of a thermal neutral environment with increased ambient humidity.[100-102] Ambient humidity is inversely related to transepidermal water loss as a function of gestational age.[103] Increasing the humidity within a convective incubator, for example, creates a microenvironment in which transepidermal water loss is lessened. A similar microenvironment can be created under semipermeable membranes with the infant lying beneath radiant warming devices. High humidities, however, may result in "rain-out" with obscuration of an infant. Warm, wet environments are also associated with an increased risk for infection. Radiant warming devices increase transepidermal water loss and require a concomitant increase in fluid replacement rates. Recent studies have demonstrated that the increase in transepidermal water loss with infrared warmers is due entirely to the low humidity of the overlying air rather than any direct drying effect of the infrared radiation.[104]

Evaporation of amniotic fluid at the time of delivery coupled with an incompetent epidermal barrier may create severe fluid imbalances and heat loss in newborn infants. Vohra et al[105] studied the use of polyethylene films on premature infants in the delivery room. This study reported better temperature stability and a significant decrease in mortality in extremely-low-birth-weight infants treated with vapor-reducing occlusive membranes at birth. This approach highlights the "golden hour" concept of care originally developed for treatment of adult patients after stroke and myocardial infarction.[106] Unlike the latter events, however, the birth of a preterm infant often can be anticipated and prepared for with emergency personnel and equipment. Attention to environmental temperature, humidity, adhesive application, and the presence or absence of surface biomaterials such as vernix play a role in delivery room management. Therapeutic regimens should be tailored to begin in the delivery room with extension to the neonatal intensive care unit (NICU).

One innovative approach for enhancing epidermal barrier function is application of topical lipid-rich emollients to the skin surface.[107] These agents may contain a mixture of nonphysiologic lipids, such as petrolatum or a mixture of physiologic lipids, such as ceramides, cholesterol, and free fatty acids.[108] In addition to their ability to decrease transepidermal water loss and form a mechanical barrier to bacteria, the components of the emollient may serve as a source of material for active lipid metabolism in the epidermis.[109] In moderately preterm infants, petrolatum application to the skin surface has been reported to improve barrier function with concomitant reduction of the rate of nosocomial infections.[110] A large study of more than 1200 low-birth-weight preterm infants demonstrated an increase in late-onset nosocomial infections secondary to coagulase-negative staphylococci in extremely-low-birth-weight infants (500- to 750-g birth weight).[111] More therapeutic strategies involving topical emollient application intended to facilitate epidermal barrier development are needed.

In many developing countries, natural oils are applied topically after birth as part of a traditional oil massage regimen. A recent study by Darmstadt et al[112] examined the effects of a variety of naturally occurring vegetable oils on the skin barrier. The goal was to identify safe, inexpensive vegetable oils available in developing countries that might improve epidermal barrier function in very-low-birth-weight infants. When vegetable oils were applied to barrier-compromised skin of adult hairless mice, oils rich in linoleic acid enhanced epidermal barrier formation. In contrast, mustard oil, a topical emollient used routinely in newborn care throughout South Asia, had toxic effects on the epidermal barrier. The investigators noted that emollients containing a physiologic balance of epidermal lipids (3:1:1 molar ratio of cholesterol, ceramide, palmitate and linoleate) may be optimal for barrier repair.[108] Vegetable oils are readily available worldwide. Such oils provide a simple, inexpensive, and effective alternative for topical use. Clearly, this is a research area requiring further investigation.

Visscher et al[113] studied the effects of semipermeable films on human skin after a standardized superficial wound (removal of the stratum corneum by tape stripping), which mimics the immature epidermal barrier of the premature infant. Transepidermal water loss, skin hydration, rate of moisture accumulation, and erythema were measured. Wounds treated with semipermeable films had more rapid barrier recovery than either nonoccluded wounds or wounds under complete occlusion. This finding is consistent with a role for vapor permeability to regulate epidermal barrier formation.

Therapeutic strategies may result from a combination of individual methods optimized for a specific infant.[13] Prenatal steroid administration coupled with optimal delivery room management and a seamless transition to a controlled NICU environment using physiologic emollients and minimal adhesive injury may provide the optimal therapeutic interface between the preterm infant and the care environment.

Many questions remain unanswered. For example, the efficacy of prenatal glucocorticoid therapy to accelerate epidermal barrier maturation is well documented for rodent skin and for fetal lung maturation.[18-21,114] Studies in the neonatal clinical literature provide conflicting reports on the efficacy of steroids in mature fetal epidermis.[19] Similarly, the use of topical emollients has been questioned for very-low-birth-weight preterm infants.[111] Work thus far suggests that provision of a semipermeable membrane or dressing may be optimal for promoting epidermal maturation.[113] In contrast to petrolatum ointment, vernix is highly vapor permeable and may provide a more physiologically relevant prototype for development of a natural wound dressing for use in the low-birth-weight preterm infant. "Smart fabrics" with heat- and motion-activated transfer of topical emollients and wound-healing ointments to the skin surface have been developed for treatment of diaper rash.[115,116] An attractive concept is that clothing or bedding material, in addition to wound dressings, may contain physiologic emollients and growth factors for facilitation of epidermal barrier development. All these therapies draw attention to the role of the skin in environmental coupling and the close interconnection between the human skin surface and the caregiver.

THE SKIN AS A NEURODEVELOPMENTAL INTERFACE

In all vertebrates, touch is the first sense to develop, followed closely by vestibular or position sensing.[117] Human neonates, compared with neonates of other species, is relatively helpless in motor capabilities and relatively precocious in sensory capabilities.[118] Sensory and affective information is necessary for body orientation and the spatial organization required for proper motor output. Evaluation of sensory competency is difficult, however, and neonatal outcome studies typically use developmental scoring systems, which rely heavily upon tests of motor skills or behavior. The idea that the sensory system is precocious in early human development places the skin in a strategic location to affect subsequent development.[4] As an interface between the body and the environment, the skin links to the developing brain on the one hand and to external factors including light, heat, fabrics, and the interactions of caregivers and parents, on the other hand. Neonatal animals, such as kittens and rodents, have proved to be useful models to study the effect of sensory inputs on central nervous system development.[119-123] These models clearly suggest that sensory signals are required during critical developmental windows for proper central nervous system maturation. In humans, clinical studies have demonstrated various effects of tactile stimulation during infancy. Field et al[124] showed that tactile stimulation of hospitalized preterm infants results in greater weight gain and higher behavorial scores.

Cutaneous Receptors and Electrical Maturation

A useful concept for interpreting the functional role of the skin surface is the idea (derived from the engineering sciences) of a "smart material" interface.[125,126] The outermost layer of the epidermis, the stratum corneum, has many of the attributes of a smart material.[4,11] It is strategically positioned as part of a larger functional system and adapts readily to changes in the environment. This material is self-cleaning and self-assembling and possesses sensing and actuating properties putatively secondary to the piezoelectric and piezomechanical properties of the contained keratin filaments.[127] In its role as the limiting surface of the body, the stratum corneum simultaneously forms the perceived surface of the organism and the biologic boundary with the environment. Thus the stratum corneum and, by extension, the skin in general corresponds in a simple manner to the distinction between subject and object.[4]

Most textbooks on neurophysiology consider sensory signal processing to be mediated initially by specialized nerve endings (Figure 62-11). Nerve endings, however, never directly touch the environment. Interfacing with the environment is a function of the material in which the nerve endings are embedded.[4] This perspective applies an engineering view to the material properties of the skin surface[125] and is important for understanding innovative approaches to skin–central nervous system interactions as put forth by Ansel et al.[128] Thus the stratum corneum and the epidermal/dermal matrix are potential mediators of sensory signal processing. After birth, the physical properties of the epidermis change rapidly during adaptation to a gaseous environment.[93] Biophysical properties of the skin can be easily measured with noninvasive instrumentation.[129] These properties include skin viscoelasticity, hydrophobicity, thermal conductivity, color, transepidermal water loss, and pH. In particular, study of the electrical properties of the skin may be relevant for very-low-birth-weight preterm infants.[93] Table 62-5 shows the measured electrical resistance to direct current in human skin (adult) and various commonly used animal models.[130] Only newborn rats have an electrical resistance comparable with that seen in adult humans. By contrast, the electrical resistance of the epidermal barrier in very-low-birth-weight preterm infants is likely to be low owing to relative deficiency of vernix and stratum corneum.

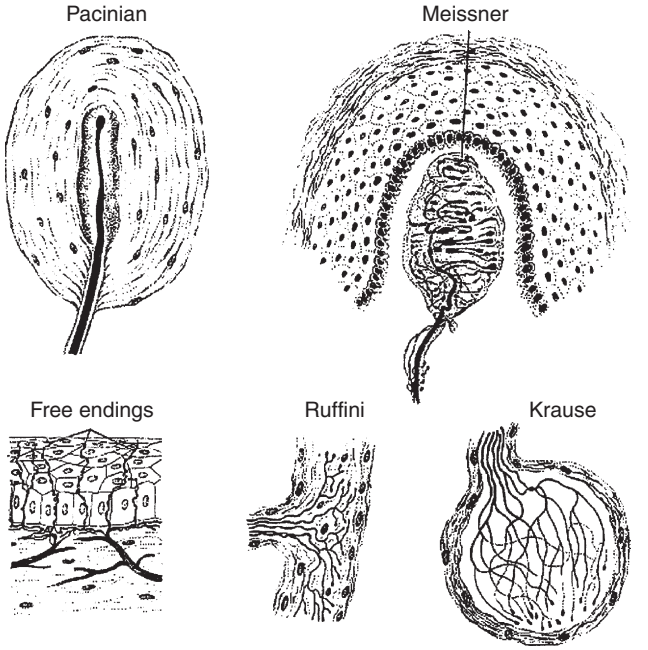

Figure 62-11 Types of cutaneous nerve endings. Pacinian corpuscles are deep cutaneous receptors for crude touch and vibration on both hairy and glabrous skin. Meissnerian corpuscles are superficially located, rapidly adapting nerve endings modulating light touch and vibration on primarily glabrous skin. Free nerve endings are associated with crude touch, tickle, and itch sensations. Ruffini organs are deep, slowly adapting structures for pressure sensing. The Krause end bulb is particularly associated with the perception of cold. Nerve endings typically are embedded in a material biomatrix and never touch the environment. The biomatrix surrounding the nerve endings directly contacts the environment.

TABLE 62–5

Electrical Resistance to Direct Current in Skin

Skin Specimens	Effective Resistance (kohms/cm^2)
Excised human skin	135 ± 54.0 (n = 40)
Newborn rat (day 0)	124 ± 24.2 (n = 18)
Infant rat (day 6)	27.7 ± 8.9 (n = 9)
Adult rat	28.3 ± 6.8 (n = 4)
Hairless mouse	9.3 ± 5.3 (n = 10)

Data from Shivanand P: Electrical and transport properties of neonatal rat skin [PhD thesis]. In *Division of Research and Advanced Studies,* College of Pharmacy, Cincinnati, Ohio, University of Cincinnati, 1995.[130]

Wakai et al[131] demonstrated the development of a high electrical impedance barrier in utero during the last trimester of pregnancy. During the first half of gestation, the amplitude of the fetal electrocardiogram can be measured directly from the surface of the maternal abdomen. After 26 to 27 weeks gestation, the amplitude gradually disappears, concomitant with the intrauterine development of an epidermal barrier consisting of vernix caseosa and the stratum corneum. Thus the gradual disappearance of the fetal electrocardiogram from the maternal skin surface is secondary to a film of high electrical impedance developing between fetus and amniotic fluid. This process presumably reflects growing fetal autonomy with electrical isolation of fetus from mother.

After birth, the electrical resistance of the skin of the term newborn is relatively high.[132] Surface electrical measurements are a common form of noninvasive monitoring in NICUs. New advances in monitoring, such as evoked potential testing of the brain, hold great promise for the assessment of multiple clinical conditions such as birth asphyxia.[133,134] In contrast to commonly performed electrocardiographic measurements, however, evoked potential testing of the electrical activity of the brain requires measurement of low amplitude voltages (microvolts versus millivolts), which are greatly affected by the skin-electrode contact surface.[130] It is common practice for electrical signals to be obtained after abrading the skin surface with a gritty contact paste. From a practical standpoint, the field of evoked potential testing in newborns could be improved by focus on the electrode/skin interface and the development of a seamless electrical contact, which avoids wounding the skin.

Skin as an Information-Rich Surface

Development of the immature central nervous system depends on sensory input during the immediate postnatal period. Experimental interference with several sensory modalities, such as vision, touch, and hearing, results in profound anatomic, functional, and biochemical impairment to the central nervous system structures that regulate such modalities. In newborn rats, tactile stimulation is an important regulator of somatic growth. Schanberg et al[121-123] have studied the link between tactile stimulation and the molecular regulation of internal cellular growth promoting enzymes, such as ornithine decarboxylase (ODC). ODC is a sensitive index of the maturation and growth of internal organs such as the heart, liver, and brain. Brain, liver, and heart ODC levels are decreased by 35%, 81%, and 53%, respectively, when rat pups are removed from their mothers for periods as short as 1 hour. Restoration of the pups to the litters rapidly normalizes enzyme activity. This normalization is specific for touch. Other potential mediators, such as nutrition, have no effect.

In other work, tactile stimulation of neonates influences circulating levels of lactate, an important energy substrate for brain metabolism.[119] In both newborn rats and human infants, lactate levels are high immediately after birth and decrease rapidly after the first few hours of age.[119,135] When newborn rat pups are removed from maternal contact and receive light tactile stimulation by means of rostral-caudal stroking with a camel hair brush (similar to the methodology established by Schanberg[122]), lactate levels increase significantly and the elevations persist for up to 30 minutes after cessation of the tactile stimulus. These same stimuli fail to elicit an increase in serum lactate at 1 week of age. These results are noteworthy because the brain of the early suckling rat uses lactate in preference to other metabolic fuels like glucose and 3-hydroxybutyrate.[136] Moreover, lactate levels increase without development of hypoxic metabolic acidosis. This experiment demonstrates, in an animal model, that sensory interaction between the organism and the environment is a potential regulator of the availability of cerebral energy substrates. Such studies have yet to be performed in humans.

The concept that human newborn infants is precocious in terms of sensory capabilities and relatively helpless in terms of motor capabilities[118] provides a conceptual framework within which to investigate the complex maturation of sensorimotor feedback loops. Preterm infants exhibit an age-dependent neurophysiologic response pattern similar to newborn rats insofar as the threshold for eliciting a motor response (flexor withdrawal) progressively increases with advancing gestational age (Figure 62-12).[137] This finding is usually attributed to increased inhibition of the reflex arc by central nervous system structures.

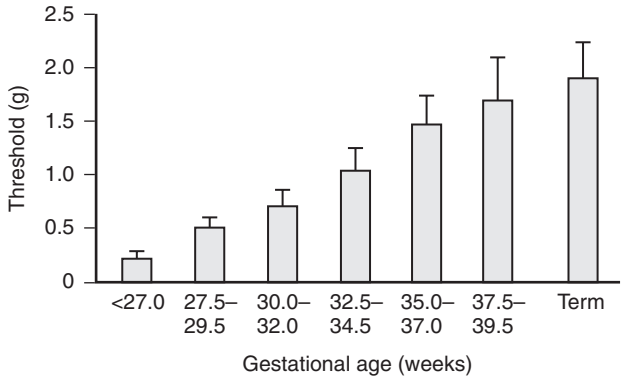

Figure 62-12 Threshold stimulus for eliciting flexor withdrawal in neonates of varying gestational age. Flexor withdrawal is elicited by stimulation of the foot with nylon filaments (von Frey hairs) of graded thickness. Preterm infants exhibit progressively lower thresholds for withdrawal than term infants. *(Data from Fitzgerald M, Shaw A, MacIntosh N: Postnatal development of the cutaneous flexor reflex: comparative study of preterm infants and newborn rat pups,* Dev Med Child Neurol *30:520, 1988.[137])*

The cutaneous flexor response is elicited by stimulation of the foot with nylon filaments (von Frey hairs) of graded thickness. In addition to maturation of central nervous system structures, the material properties of the interface (dermis, epidermis/stratum corneum) are changing concomitantly and may contribute to the effect observed in Figure 62-12. The accessibility of the skin surface and the availability of multiple biomedical instruments for noninvasive measurement[129] provide an open area for skin-based research in neonatology, with potential relevance for central nervous system organization and control. The concept of a smart material interface presumes that changes in the biophysical properties of the skin surface will have a direct influence on adaptive environmental interfacing and sensorimotor response loops.[4,9,126]

An area in which noninvasive monitoring of the skin surface may reveal important information on central nervous system response and behavioral state involves skin conductance measurements in newborn infants associated with eccrine (emotional/nonthermal) sweating.[57] Sweating is commonly viewed as secondary to the need for thermoregulation and evaporative cooling. It also occurs in response to arousal and pain in addition to temperature. This "emotional" sweating is easily measured from the palm or sole using a skin evaporimeter[138] but is usually estimated indirectly by measuring skin electrical conductance or resistance.[139] The presence of sweat within the eccrine ducts of the epidermis, and, to a lesser extent, the circumferential hydration of the stratum corneum surrounding the sweat glands, lowers the electrical resistance of the skin and raises its electrical conductance. Various instruments are now available for directly, simply, and noninvasively measuring skin surface conductance at the bedside. This technique has been widely used in psychological research for many years but has yet to be systematically applied in neonatology.

Figure 62-13 shows the increase in skin conductance after a painful stimulus.[139] In this case, a heel prick was administered to the foot, followed by skin conductance measurement over the sole of the other foot. Peak values are reached at approximately 1 minute after the heel prick. This response is characteristic of the change in skin conductance caused by arousal in a neonate. Confirmatory measurements also can be made using different techniques, such as transepidermal water loss. Figure 62-14 shows

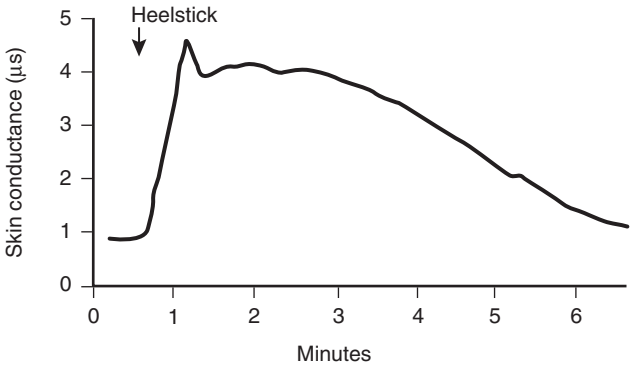

Figure 62-13 Effect of painful stimulus on skin conductance measurements in a term newborn infant. Skin conductance measured on the sole of the foot shows a sharp increase over the first minute in response to a heel prick on the other side. Values are in microsiemens (mcS). *(From Gladman G, Chiswick ML: Skin conductance and arousal in the newborn,* Arch Dis Child *65:1063, 1990.[139])*

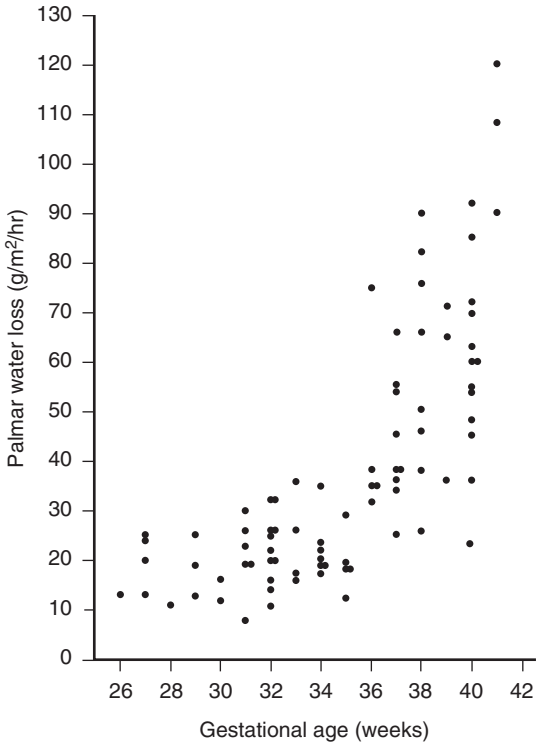

Figure 62-14 Palmar water loss in infants ranging from 25 to 41 weeks gestation, showing values at maximal arousal (vigorous crying). Results are displayed according to equivalent gestational age (gestation plus postnatal age). Values are 10 to 30 g/m^2/hr until the equivalent gestational age of 36 weeks is reached. Values then increase abruptly to 30 to 100 g/m^2/hr. *(From Rutter N: In Hoath SB, Maibach H [eds]:* Neonatal Skin: Structure and Function*, New York, Marcel Dekker, 2003.[57])*

palmar water loss in crying infants ranging from 25 to 41 weeks gestational age.[57,140] Of note, the profile for palmar water loss is *inversely* related to transepidermal water loss over the same age range (see Figure 62-4). This inverse relationship deserves further investigation. Recently, Storm[141,142] and Storm and Fremming[143] used conductance measurements of the skin surface to study behavioral state changes and developmental effects. This skin-based method, combined with sensory evoked potential testing, offers new techniques for assessment of central nervous system functioning in developing preterm infants.

Studies of epidermal barrier function may exhibit not only short-term responses secondary to autonomic nervous system activation of eccrine sweating, but also long-term consequences related to stress and glucocorticoid secretion. Denda et al[144,145] showed that stressful events such as immobilization, overcrowding, and abrupt change in physical environment can result in impaired epidermal barrier function in murine skin. Similarly, Garg et al[146] demonstrated a delay in recovery of epidermal barrier function after induced trauma in a group of psychologically stressed graduate students. These studies indicate a link between physiologic stress of the organism and epidermal barrier function. As presented earlier, a very-low-birth-weight preterm infant exhibits compromised barrier function up to 28 days after delivery.[53] Whether this increased transepidermal water loss is secondary to stress-related events is unclear but worthy of further investigation.

The idea of the skin as an information-rich surface can be extended to the intensive care or emergency room setting.[147,148] Indeed, cardiorespiratory and thermal monitoring, as well as transcutaneous blood gas measurements, are skin-based systems of clinical data retrieval. Given the ready accessibility of the skin surface and the plethora of noninvasive measurement techniques that have yet to be applied to the study of newborn physiology,[129] it seems reasonable to assume that a number of innovative and useful skin-based sensing systems will be designed for clinical decision making in the future. This concept extends Kligman's idea of "invisible dermatology"[149] to the NICU; early, objectively measured changes in the physical properties of the skin may herald illness in the term or preterm infant *before* such illness is apparent to the caregiver. De Felice et al,[150] for example, recently used skin colorimetry to provide a significant quantitative predictor of illness severity in hospitalized newborns. The work supports the hypothesis that noninvasive measurements of skin physical properties directly reflect the pathophysiologic state of infants. Such measurements can be used as objective adjuncts to clinical decision making and bedside assessment.

FUTURE DIRECTIONS

A better understanding of fetal and neonatal skin physiology and the targeted use of quantitative measures of skin structure and function is a laudable and needed goal for perinatal medicine.[44] Every patient care encounter involves the skin in some practical way: temperature regulation, electronic monitoring, bathing, infection control, touch and infant massage, skin-to-skin contact, pain management, catheter care, etc. Box 62-5 lists a number of roles of the skin in the provision of primary health care in neonatology. These functions are disease-independent but essential for the delivery of high quality care, whether the health care environment is hospital based or home based.

Importantly, the recognition of the skin as a primary care interface for patient care and parental satisfaction creates an opportunity for collaborative practice between nursing and medicine.[151] Many of the functions listed in Box 62-5 are scientifically complex and fall largely in the domain of nursing. The reciprocal coupling of the infant and the care environment is an assumption of fields such as "developmental care," which focus largely on brain maturation and neurodevelopment.[152-154] The dual nature of the skin as a boundary interfacing cellular and molecular domains with psychological and perceptual domains is consistent with this approach. A better understanding of skin development, especially the role of the epidermal barrier and

BOX 62–5

Aspects of the Skin as a Primary Care Interface

- Surface of interaction with soaps, surfactants, disinfectants, and bacteria
- Support for tapes and other adhesives
- Interface for bedding, clothing, and the environment
- Site of action of topical anesthetics and analgesics
- Surface for wound and ostomy care
- Barrier for transdermal drug delivery
- Site of most laboratory blood drawing
- Platform for percutaneous catheters
- Boundary for noninvasive monitoring and skin-based sensing techniques
- Medium of interaction in kangaroo care and massage therapy
- Basis for initial clinical evaluation of patient well-being (appearance)

Modified from Hoath S, Narendran V: Development of the epidermal barrier. *Neoreviews* 2:e269, 2001.[44]

infection control, has implications for improving infant care in developing countries.[155,156]

Finally, the critical role of the epidermal barrier, the plethora of antimicrobial peptides in innate immune function, and the early events in sensory transduction have scarcely been investigated in infants. Human skin is unique in all primates. Why? What is the connection between the skin and the brain? It is scientifically incontrovertible, for example, that the crosslinked envelope of the cornified epidermal cell is a single, extended, multigene molecule strategically located at the organism-environment interface.[12,22,23] This molecule forms the physical scaffolding of the stratum corneum and participates directly in multiple care interactions between a newborn and a caregiver. Successful postnatal transition of a very-low-birth-weight preterm infant requires the rapid formation and assembly of an organized, polymeric, molecular interface with the environment. These facts place the differentiated structure of the epidermis, an ectodermal derivative like the brain, front and center in the translation of molecular biology to clinical bedside care.

SECTION XI

Fetal and Neonatal Cardiovascular Physiology

63

Brian S. Snarr, Andy Wessels, and Tim C. McQuinn

Cardiovascular Development

The morphologic development of the heart from its first appearance as a tube heart to a four-chambered structure with fully septated ventricles occurs between days 20 and 44 of human gestation (Carnegie stages 9 to 18).[1] The same program of development occurs much more rapidly in the mouse (days 8.5 to 14 of gestation) and chick (days 1.5 to 5.5).[2,3]

Externally visible cardiac development starts with formation of the heart tube in a position cranial to the anterior intestinal portal of the embryo, but many critical determinative events occur before that. The earliest contributions to cardiogenesis are made during gastrulation.

Gastrulation creates the three cell layers of the embryo—ectoderm, mesoderm, and endoderm—by migration of cells through the streak, a visible groove that begins at the caudal end of the embryo and grows toward the cranial end. At the cranial tip of the streak is a structure called the node, or Hensen node, in chick embryos.[4] The cranial-caudal (anterior-posterior) axis of the embryo is first made apparent by the streak, and the node is a critical element in right-left axis determination. Cells from the embryonic epiblast migrate to the streak and pass into the interior of the embryo to form the mesoderm.

Precardiac cells gastrulate as a relatively broad swath in which the most anteriorly gastrulating cells contribute to the most anterior portion of the primitive heart tube.[5,6] Precardiac cells enter the streak uncommitted as to their developmental potential and only become committed to their cell type or migratory pathways in the mesoderm after leaving the primitive streak.[5] Once in the blastocoele cavity, the precardiac cells move laterally to join the lateral plate mesoderm at the level of the node. The lateral plate mesoderm then splits into two layers, a splanchnic layer directly above the endoderm and a somatic layer directly below the ectoderm. The endoderm and hypoblast induce splanchnic mesodermal cells to enter the precardiac lineage through mechanisms known to include a combination of Wnt, fibroblast growth factor (FGF), bone morphogenetic protein (BMP), and activin/nodal signaling pathways.[7]

The region of splanchnic mesoderm expressing precardiac markers is known as the heart-forming field.[8] Whether the earliest precardiac mesoderm consists of a single lineage or dual lineages is not entirely clear. Before 2001, the molecular markers most widely used to identify precardiac mesoderm (transcription factors such as NKX2-5, MEF2, HAND1 and HAND2, GATA4, and TBX5)[9-13] indicated that there were bilateral populations of precardiac cells that migrated to the midline and added myocardium sequentially to the venous pole of the heart. However, classic embryologic experiments in chick embryos suggested the presence of a population of myocardium that was added to the heart tube by migration from the arterial pole of the heart,[14] and recent molecular, morphologic, and genetic observations indicate that these cells originate from a distinct set of precardiac mesodermal cells now known as the second heart field (SHF), in distinction to the previously recognized first heart field (FHF).[15-18] Molecular markers for the SHF in the mesoderm include the transcription factors TBX1 and ISL1 as well as FGF8 and FGF10. However, it is not clear whether SHF and FHF cells pass through a common precursor lineage.[19] SHF-derived myocardium is the source of all the outflow myocardium of the primitive heart, whereas the left ventricular myocardium is derived entirely from the FHF. All other segments of the heart receive a mixed complement of FHF and SHF cells. SHF mesoderm also differs from current understanding of FHF mesoderm in its pluripotentiality; FHF cells exhibiting the premyocardial markers noted previously give rise only to myocardium, whereas SHF cells give rise to myocardium, vascular smooth muscle cells, and endothelial cells.

PRECARDIAC MESODERM AND THE AXIAL BODY PLAN

The cranial-caudal and left-right axial body plans are determined during gastrulation, and both are of major importance in establishing the molecular identity and the morphology of the cardiac segments. Left-right axis determination is a critical element of the vertebrate body plan,[20] and substantial impairment of cardiac structure and function occur in the absence of normal left-right axis determination, with the atria, atrioventricular (AV) junction, and outflow tract showing greater sensitivity than the ventricular chambers.[21-28] The signaling mechanisms identified include critical elements of cell movements and oriented ciliary motion in the node.[29-31] FGF influences this process through a role in ciliary growth,[32] and the ciliary movements lead to asymmetric calcium transients[33] as well as to asymmetric expression of nodal, sonic hedgehog, and lefty.[34-36] These signals in turn lead to asymmetric expression of the homeodomain transcription factor PITX2C.[25,27,28,37] As is true in general for developmental processes, most of the molecules involved in elaborating the left-right signaling process in mice have easily recognized counterparts in birds, *Xenopus* species, and other vertebrates and invertebrates. However, in an intriguing twist on that theme, some of the molecules required for left-sidedness in mice are determinants of right-sidedness in birds.[38] Many of the genes implicated in the mouse models are candidate genes for heterotaxies in the human population.[36]

The anterior-posterior (cranial-caudal) body axis is also established during gastrulation. Retinoid signaling pathways are critical to normal anterior-posterior axial patterning in general and cardiac development in particular.[39,40] Retinoids are also implicated in the regulation of SHF differentiation.[41] Failure of formation of atrial segments and systemic venous connections with the heart are observed in conditions of retinoid deficiency. Excess retinoids create cardiac malformations, often involving the outflow tract, and result in ventricular expression of several genes that are normally largely restricted to the atria at the equivalent stages of normal development.[42,43]

FORMATION AND GROWTH OF THE TUBE HEART

The precardiac mesodermal sheets on each side migrate to the midline cranial to the anterior intestinal portal, forming a horseshoe-shaped crescent (Figure 63-1). Precursors of the endocardium follow the same migratory pathways as the precardiac cells. As the precardiac cell masses move steadily to the midline, the endocardial cells begin to form a network of tiny channels that will coalesce into a complex endocardial network surrounded by a myocardial mantle. In normal development, the endothelial network quickly transforms into a single endothelial channel invested by a single myocardial mantle.

The tube heart is initially organized into three structural layers: a muscle layer two to three cell thick, an intermediate layer of acellular cardiac jelly, and a luminal passage formed by endothelial cells. The tube heart is a ventral structure and is initially tethered throughout its length on its dorsal aspect by the dorsal mesocardium. The dorsal mesocardium will regress in its center portion but remain attached at the arterial and venous poles as the heart grows in length and begins to curve into a C-shaped structure. As the length of the tube further increases, it assumes a more complex S-shaped bend. The tube is lengthened by migration of cells into both the arterial (SHF) and venous (FHF and SHF) poles of the heart (Figure 63-2).

Looping is a somewhat ill-defined term, referring in the most general sense to the bending of the heart tube before septation.[44] The initial bend results in a C-shaped structure, with the outer loop of the C to the right side of the embryo. As the heart elongates, the loop becomes more complex and has been described as S shaped (see Figure 63-1). Looping (in the context of this chapter) begins and ends with the AV junction connected solely to the left ventricle and the outflow tract connected only to the right ventricle.

The looped heart has an inner curvature and an outer curvature. By nature of the tight angulation of the inner curvature, the primitive atrial, AV, ventricular, and outflow segments are in close proximity for the remainder of cardiac development (Figure 63-3). The inner curvature is the site of the intricate morphologic events resulting in the right ventricle acquiring its inflow and the left ventricle its outflow—a morphologic process sometimes labeled *convergence*.

Concomitant with the realignment of the cardiac segments, the lumen of the heart begins to develop distinctive features along its length. While the atria and ventricles lose their cardiac jelly, an increase of cardiac jelly in the AV junction and the outflow tract develops into discrete mounds known as *endocardial cushions* (see Figure 63-3). The acellular jelly becomes populated by mesenchymal cells derived from various sources, the significance of which is discussed later. In both the AV junction and outflow tract, the cushions contribute to the propulsion of blood and protect against regurgitation.

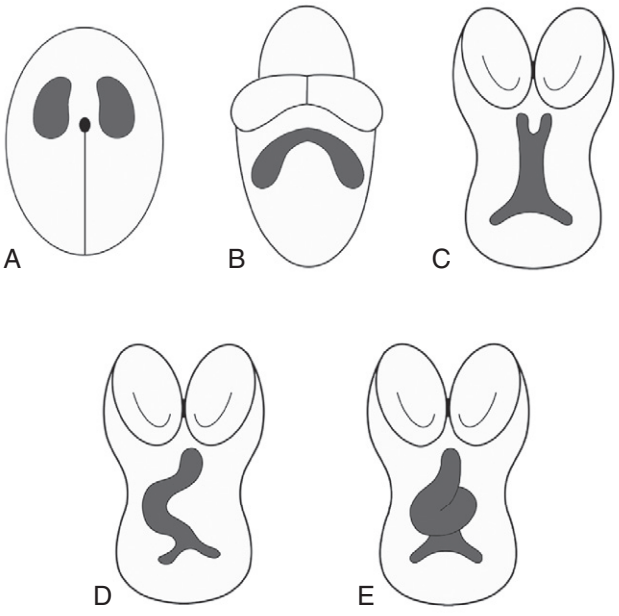

Figure 63-1 Schematic representing the early stages of heart development. **A,** Bilateral heart fields form from precardiac mesoderm after migration from the primitive streak. **B,** Formation of the cardiac crescent after fusion of the heart fields at the midline. **C,** The linear heart tube forms from fusion of the cardiac crescent. **D,** Regression of the dorsal mesocardium results in the formation of a C-shaped structure and permits further looping. **E,** The S-shaped primitive heart formed on completion of looping. *(Modified from Snarr BS, Kern CB, Wessels A. Origin and fate of cardiac mesenchyme,* Dev Dyn *237:2804-2819, 2008.)*

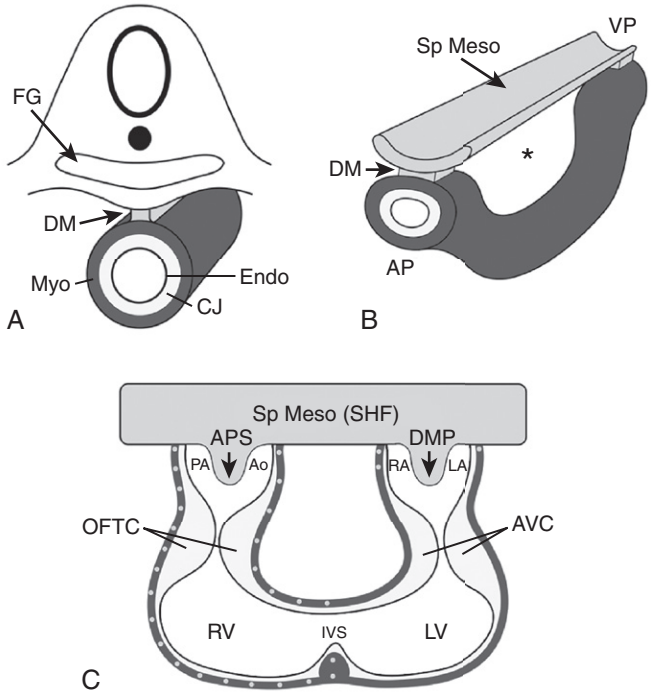

Figure 63-2 Involvement of the dorsal mesocardium in heart development. **A,** The heart tube is suspended along its length from the embryo by the dorsal mesocardium *(DM)*. **B,** After regression of the DM along the midsection *(asterisk)*, the heart tube remains connected to the embryo by the arterial and venous pole *(AP, VP)* attachments of the DM. The DM is continuous with the splanchnic mesoderm *(Sp Meso)* that lies ventral to the foregut *(FG)*. **C,** Cell populations derived from the Sp Meso, known as the second heart field *(SHF),* are added to the AP and VP of the heart through the DM attachments. These cells contribute to the developing aorticopulmonary septum *(APS)* and the dorsal mesenchymal protrusion *(DMP)*. *Ao,* Aorta; *AVC,* atrioventricular cushions; *CJ,* cardiac jelly; *Endo,* endocardium; *IVS,* interventricular septum; *LA,* left atrium; *LV,* left ventricle; *Myo,* myocardium; *OFTC,* outflow tract cushions; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle. *(Modified from Snarr BS, Kern CB, Wessels A. Origin and fate of cardiac mesenchyme,* Dev Dyn *237:2804-2819, 2008.)*

On the luminal surface of the heart, the fold in the heart at the inner curvature results in a small muscular ridge inside the heart between the AV junction and the outflow tract called the *ventriculoinfundibular flange* or *ridge*. Other key landmarks are the two endocardial cushions of the AV junction and two endocardial ridges of the outflow tract. The inferior endocardial cushion is attached to the dorsal AV myocardium, and the superior endocardial cushion is attached to the ventral AV myocardium. As convergence proceeds, small right and left lateral AV endocardial cushions become visible.

Two outflow tract endocardial cushions form extended spiral ridges from the end of the truncus distally to the body of the right ventricle caudally. The parietal endocardial ridge makes contact with the right lateral endocardial cushion, which itself becomes continuous with the superior endocardial cushion. The septal endocardial ridge will make contact with the inferior endocardial cushion. As the endocardial cushions fuse during septation, they create an unbroken chain of cushion tissue extending from the AV junction to the distal extent of the myocardial outflow tract and as a simplified description can be thought of as a tissue zipper that septates the heart. The endocardial cushion origins of the outlet septum and much of the ventricular septum are not apparent on inspection of the mature heart owing to the replacement of cushion mesenchyme by myocardium, in the process known as *myocardialization*.[45]

During convergence, the angle of the inner curvature of the heart becomes even more acute. The AV endocardial cushions approach each other in the center of the lumen of the AV junction, and the right atrial–right ventricular AV junction forms by rightward expansion of the AV orifice. The outflow endocardial ridges, although unfused, define distinct aortic and pulmonary channels. The aortic channel moves leftward and anterior to its original position. Because of the combined rightward expansion of the AV orifice and the leftward movement of the aortic outflow tract, the acute angle of the inner curvature now defines the region where the AV junction and the outflow tract are in continuity. These same morphogenetic movements result in rotation of the outflow ridges to a plane that more closely parallels the growing muscular septum.

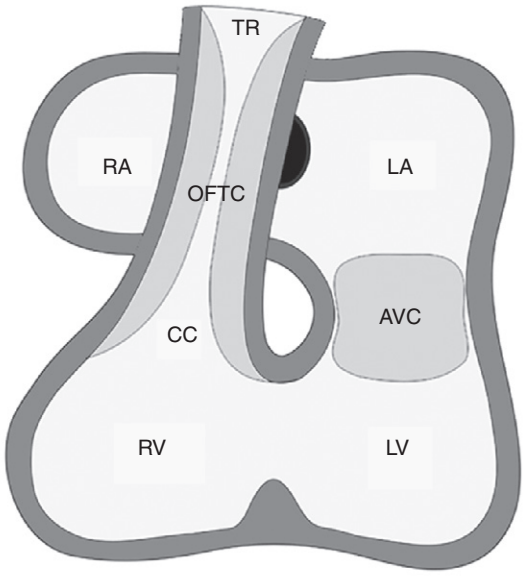

Figure 63-3 Schematic representation of the looped heart with chamber alignment in series. The cardiac jelly accumulates into discrete mesenchymal structures forming the endocardial atrioventricular cushions *(AVC)* and the outflow tract endocardial cushions *(OFTC)*. The *OFTC* may further be subdivided into proximal (conal cushions, *CC*) and distal (truncal ridges, TR) segments. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. *(Modified from Snarr BS, Kern CB, Wessels A. Origin and fate of cardiac mesenchyme,* Dev Dyn *237:2804-2819, 2008.)*

MESENCHYMAL CONTRIBUTIONS TO ATRIAL AND VENTRICULAR SEPTATION

Septation of the atrial and ventricular chambers is dependent on the proper formation of a mesenchymal complex of endocardial cushion tissues that becomes continuous from the AV junction to the outflow tract. Multiple lines of evidence now show that important contributions to the cellular population of the cushions are made by both endothelial-to-mesenchymal transformation of the endocardial lining and extracardiac cell populations. In the outflow tract, this includes cell populations derived from the neural crest as well as anterior splanchnic mesoderm (SHF). The AV cushions receive a mesenchymal cell contribution from the persisting venous pole attachment of the dorsal mesocardium, which derives from posterior splanchnic mesoderm, also part of the SHF (see Figure 63-2, *C*). Studies to this point clearly suggest that failure to incorporate these extracardiac cell populations into the cushions results in abnormal septation.[46]

ATRIAL SEPTATION

Atrial septation and connection of the common pulmonary vein to the left atrium are closely related events in the normal heart.[23] Recent investigations in mouse, chick, and human embryos highlight the importance of the dorsal mesocardium to these events. At the site where the dorsal mesocardium is in continuity with the atrium (about the level of the lung buds), there is a protrusion of mesenchymal tissue into the atrium. This tissue has been recognized for many years and by a variety of names—most recently, the *dorsal mesenchymal protrusion*, the terminology adopted here. The dorsal mesenchymal protrusion extends ventrally into the common atrium, forming the mesenchymal base of the developing septum primum. From the earliest stages at which it can be recognized, the dorsal mesenchymal protrusion is continuous with two endocardium-derived cell populations: the mesenchymal cap that extends along the tip of the septum primum (anteriorly) and the inferior AV cushion (posteriorly). In contrast to its endocardium-derived cushion cell counterparts, the dorsal mesenchymal protrusion undergoes a mesenchymal-to-myocardial differentiation and forms the myocardial base of septum primum. The importance of the dorsal mesenchymal protrusion has gained recent attention as studies have suggested abnormal development of this structure is associated with the pathogenesis of complete AV septal defects (Figure 63-4).[46]

The initial (myocardial) portion of the primum septum is derived from left atrial myocardium, as determined by molecular markers distinguishing between left and right atrial myocardium.[23] Growth of primum septum occurs by myocardial lengthening, and as it grows, the mesenchymal cap, dorsal mesenchymal protrusion, and major AV endocardial cushions come into close proximity and fuse. Fusion of these structures closes the primary interatrial foramen. Before the closure of the primary interatrial foramen occurs, the foramen secundum forms in the body of the septum primum. In humans, this process is initiated by the appearance of small fenestrations that increase in number and size until they coalesce into a definitive foramen secundum.[23]

The septum secundum forms as an infolding of the atrial myocardium between the left venous valve of the sinus venosus and the primum septum. The septum secundum marks the site of left

atrial–right atrial myocardial boundary. Left atrial myocardium of the septum secundum exhibits left atrial molecular markers, whereas the right atrial myocardial surface of the septum secundum exhibits right atrial markers.[23,47]

GROWTH OF VENTRICULAR MYOCARDIUM AND DEVELOPMENT OF THE VENTRICULAR SEPTUM

Early formation of the muscular septum of the ventricles and enlargement of the ventricular chambers are closely linked processes.[48] The overall process of ventricular growth has been described as "ballooning" of specialized myocardium with left or right ventricular molecular identity toward the outer curvature of the heart, whereas along the inner curvature, "primitive" myocardium persists, which will make an important contribution to the development of the conduction axis of the heart.[49] Much of the patterning of the primitive and ventricular myocardial molecular identities is linked to the expression of Tbox gene family members such as TBX1, TBX2, TBX3, TBX5, and TBX20.[50-55]

In the chick heart, the primitive muscular septum is initially formed by a coalescence of trabeculae. In the mammalian heart, the primitive muscular septum appears to be the product of infolding of the compact myocardium produced by growth of the ventricular apices. Lineage studies provide indication that the myocardium of the muscular septum is of combined right and left ventricular origins,[56,57] although data have also been presented indicating that the ventricular septum is of exclusively SHF derivation.[58]

The primitive muscular interventricular septum is initially a crescent-shaped structure that extends at its posterior limit to the inferior endocardial cushion and at its anterior limit to the superior endocardial cushion. Part of the process of closure of the primary interventricular foramen consists of expansion of the superior and inferior endocardial cushions toward each other, where they will make contact and fuse at about 6 weeks gestation in the human. The mechanism of fusion of the endocardial cushions despite the continuous mechanical activity of the heart is not known but certainly deserves respect. Further growth of the interventricular muscular septum results in fusion of the crest of the septum with the fused cushion. The boundaries between the original muscular septum and endocardial cushion–derived portions of the septum become obscured by myocardialization, except for the membranous septum between the left ventricle and right atrium. Normal inlet septum development is primarily determined by interactions between the inferior endocardial cushion–derived tissue and the muscular ventricular septum, whereas the smooth anterior interventricular septum is derived from interactions between the superior endocardial cushion and the muscular septum. The membranous septum is believed to be the approximate site of final union between the muscular septum and the superior and inferior endocardial cushions.[59]

From this discussion, it becomes plausible to hypothesize general mechanisms that might result in the various clinical types of ventricular septal defect. Perimembranous and AV canal–type ventricular septal defects may be the result of failure of normal growth and fusion processes between cardiac mesenchymal tissues of the endocardial cushions and myocardial septal tissue. Defects limited to the muscular outlet septum occur in myocardium derived from myocardialization after fusion of the mesenchyme of the outlet cushions and may therefore represent a localized failure of outlet cushion fusion. Muscular ventricular septal defects between the ventricular bodies could be hypothesized to arise when the trabecular mass is inadequate in either volume or signaling ability to appropriately undergo fusion.

Semilunar valve leaflet development begins shortly after septation. As studied in mice, the initial process is outgrowth of unexcavated cusps of tissue corresponding to the future leaflets from the arterial surface of the distal endocardial ridges and intercalated cushions.[60] Valve sinuses are formed by active endothelial excavation of the outlet surface of the leaflets. The initial valve leaflets are thickened structures filled with an abundant extracellular ground substance densely populated with endocardial and neural crest–derived mesenchymal cells, bordered by a cuboidal endothelium on the arterial surface and a flattened, streamlined endothelium on the ventricular surface. After the sinuses are fully excavated, the leaflets remodel into the delicate fibrous tissue characterizing mature semilunar valves.[61] Valve remodeling is a slow process that may be histologically incomplete at the time of birth.[60,62] The molecular biology of semilunar valve development shares many features with AV valve development.[63]

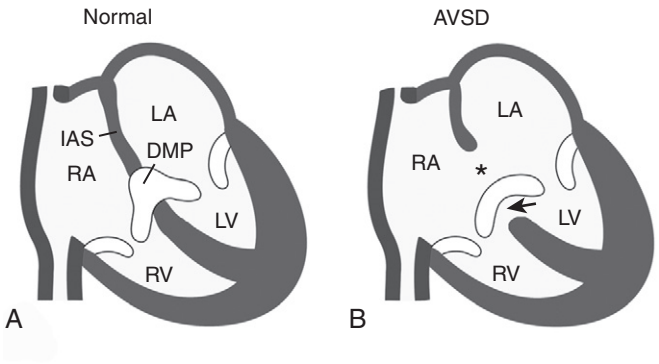

Figure 63-4 This diagram compares the anatomic features of a normal heart **(A)** to those of a heart with a complete atrioventricular septal defect *(AVSD)* **(B). A,** In the normal heart, the dorsal mesenchymal protrusion *(DMP)* forms a central component of the atrioventricular *(AV)* mesenchymal complex, a structure that serves as an anchor for both atrial and ventricular septa. **B,** In the heart with the AVSD, the DMP is missing, the AV mesenchymal complex is maldeveloped, there are communications between the atria *(asterisk)* and ventricles *(arrow)*, and there is a common AV valve.

ATRIOVENTRICULAR JUNCTION SEGMENT AND ATRIOVENTRICULAR VALVE DEVELOPMENT

Myocardial continuity among the AV junctional myocardium, atrial myocardium, and ventricular myocardium must be interrupted for the development of the fibrous crux of the heart and the correct function of the conduction system. This is accomplished by formation of a layer of fibrous insulation that will completely interrupt myocardial continuity between the AV myocardium and the ventricular myocardium, with the exception of the penetrating bundle of His specialized myocardium. In the mature heart, the remnants of AV junction myocardium become incorporated into the myocardium of the definitive atrium.[64]

Fibrous interruption of AV myocardial continuity results from the fusion of mesenchymal cell populations of the AV endocardial cushions with a mesenchymal cell population found in the AV sulcus on the external surface of the looped heart. AV sulcus mesenchymal cells are brought to the heart in the course of the epicardial cell migration, as discussed in greater detail later in this chapter in connection with coronary artery development (Figure 63-5). Morphologic studies suggest that the sulcus mesenchyme actively invaginates toward the base of the endocardial cushions; the mechanisms driving mesenchymal invagination and the parting of the myocardial layer are unknown. Interruption of myocardial continuity begins at 52 to 60 days gestation in the human heart and is normally "complete" by the 4th month of gestation.[64] Molecularly, a pathway linking FGF4 signaling to expression of scleraxis and transcriptional activation of tenascin

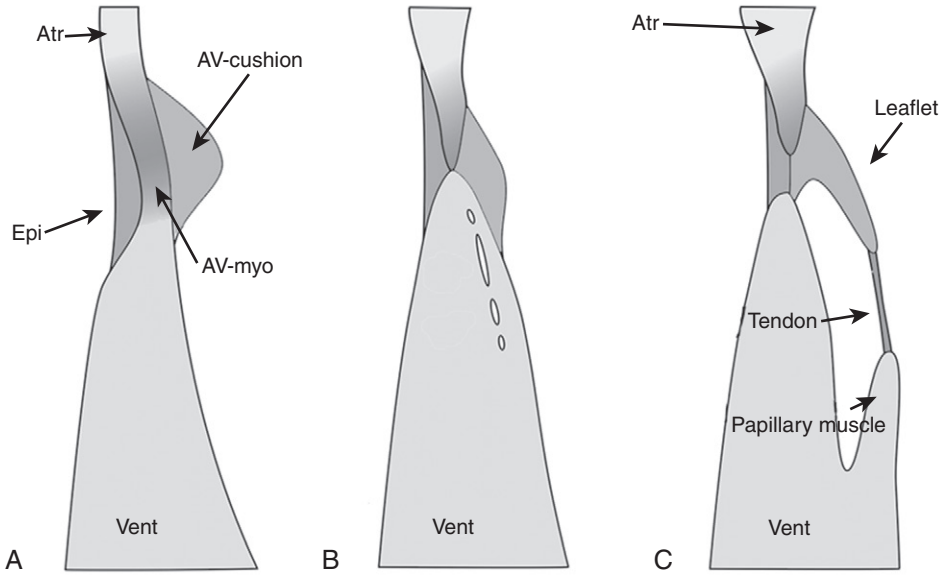

Figure 63-5 This schematic illustrates the accumulation of the subepicardial mesenchyme at the atrioventricular *(AV)* sulcus and its fusion with the AV cushion mesenchyme at the boundary of the AV myocardium *(AV-myo).* This process helps create an electrical insulation between myocardium of the atria and ventricles. *Atr,* Atrial myocardium; *Epi,* epicardium; *Vent,* ventricular myocardium. *(Modified from Snarr BS, Kern CB, Wessels A. Origin and fate of cardiac mesenchyme.* Dev Dyn *237:2804-2819, 2008; and Wessels A, Sedmera D. Developmental anatomy of the heart: A tale of mice and man,* Physiol Genom *15:165-176, 2003.)*

has been described in chick limb tendon[65] and is proposed to be active in normal chordae formation.[66-68]

As previously noted, there are four endocardial cushions in the AV junction. The superior and inferior cushions are the most prominent endocardial cushion masses from their first appearance, but the lateral endocardial cushions, which are visible only after Carnegie stage 17 (about 42 days), also have important contributions,.[64,69] A map of endocardial cushion contribution to definitive AV valve structure has been published (Figure 63-6).[46,70]

AV valve morphogenesis is one of the most prolonged aspects of human cardiac development. Recognizable elements of the tricuspid valve begin formation at 5 to 6 weeks gestation. The AV endocardial cushions are actively reconfiguring at this time, with fusion of the superior and right lateral AV endocardial cushions to each other. The conal cushions are also completing their fusion during this time. Despite the overall advanced stage of cardiac morphogenesis at this point, the tricuspid valve leaflets are still very primitive in appearance and not freely mobile. The inferior leaflet is fully delaminated by the end of the 8th week of gestation, the anterior leaflet by the 11th week, and the septal leaflet in the 12th week. The commissure separating the anterior and septal leaflets is not complete until the septal leaflet is fully delaminated.[71]

In development of the mitral valve, the inferior and superior AV cushions begin to fuse at roughly 5 weeks gestation; even before fusion, the enlarged trabecular complex that will evolve into the two mitral papillary muscles can be seen connecting the superior and inferior cushions. The left lateral cushion, the precursor to the posterior or mural leaflet, is visible by the 7th week of gestation. At about this time, initial delamination of the mitral valve structures becomes detectable and continues until the 10th week of development. Between the 10th and 14th weeks of development, myocardial elements of the leaflets are eliminated, the papillary muscles achieve their adult appearance, and chordae differentiate.[69]

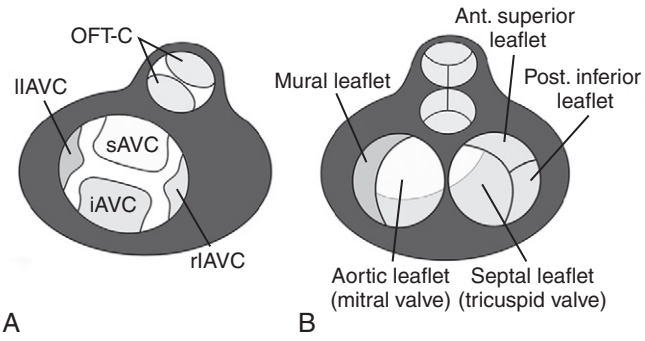

Figure 63-6 Fate map of the atrioventricular *(AV)* and outflow endocardial cushions. **A,** The major AV cushions consist of the superior and inferior AV cushions *(sAVC, iAVC).* The sAVC predominantly gives rise to the aortic leaflet of the mitral valve, whereas the iAVC gives rise to the septal leaflet of the tricuspid valve. The right lateral AV cushion *(rlAVC)* contributes to the anterior-superior and posterior-inferior leaflets of the tricuspid valve. The left lateral AV cushion *(llAVC)* contributes to the mural leaflet of the mitral valve. The outflow tract cushions *(OFT-C)* give rise to the semilunar valves. *(Modified from Snarr BS, Kern CB, Wessels A. Origin and fate of cardiac mesenchyme,* Dev Dyn *237:2804-2819, 2008.)*

DEVELOPMENT OF THE AORTIC ARCH

The embryonic arterial circulation is initially bilaterally symmetric and consists of multiple pairs of aortic arch vessels connecting the heart outflow to the paired dorsal aortae. Fusion of the originally separate right and left dorsal aortae into a single structure begins distally and progresses retrograde to the 7th somite. As development proceeds, the paired 1st, 2nd, 3rd, 4th, and

6th aortic vessels and their connections to the dorsal aortae undergo an intricate series of transformations. The 1st and 2nd aortic arch vessels regress, remaining patent only as capillary structures. The dorsal aorta between the 3rd and 4th aortic arch vessels (the carotid duct) regresses completely, leaving no remnant, resulting in the paired 3rd aortic arch vessels becoming the only source of blood flow from the aortic sac and truncus complex to the head of the embryo. The 3rd aortic arch vessels become the precursors of the definitive right and left common carotid arteries. The right dorsal aorta completely regresses at the site of dorsal aortic bifurcation; this leaves the right 4th aortic arch vessel to become a short stub connecting the right 7th intersegmental (future subclavian) artery to the aortic sac and truncus complex. The right 6th aortic arch vessel regresses fully. The left 6th aortic arch vessel becomes the ductus arteriosus connecting the pulmonary plexus–derived distal main pulmonary artery and left pulmonary artery to the left dorsal aorta at the junction of the left dorsal aorta and the left 4th arch vessel. The left dorsal aorta remains widely patent throughout its length but remodels so that the definitive left 4th aortic arch vessel, the ductus arteriosus, and the left 7th intersegmental artery (future left subclavian artery) all connect to the left dorsal aorta within a very short span.

The vertebral arteries are derived from anastomoses that form between the seven cervical intersegmental arteries. After continuity is established between the intersegmental arteries, their connections to the dorsal aorta regress, with the exception of the connection of the 7th intersegmental vessel (as noted previously, the 7th intersegmental artery becomes the subclavian artery), creating the subclavian origin of the definitive vertebral arteries.

NEURAL CREST AND MOLECULAR REGULATION OF AORTIC ARCHES

The neural crest is a transient structure in development with multiple critical roles in the formation of craniofacial structures, the autonomic nervous system, pigmentation, and endocrine function. The cells of the neural crest reside on the lateral margins of the neural plate, and the right- and left-sided populations are brought into apposition by the folding of the neural plate into the neural tube. The cells then disperse and migrate along precise pathways to their multiple destinations. Specific regions of the neural crest seed their cells through specific pathways to specific structures.[72] The neural crest cells that reach the outflow tract of the early heart migrate through the 3rd, 4th, and 6th aortic arch vessels. A role for neural crest in cardiac development was recognized in 1983 through the work of M. L. Kirby; the region of the neural crest contributing to cardiac and 4th aortic arch morphogenesis is sometimes called *cardiac neural crest*.[73] The patterning of the aortic arch arteries is greatly influenced by the migration of neural crest cells into the pharyngeal arches. Studies in animal models have shown that neural crest expression of a receptor for endothelin-1 (ET1) is necessary for interaction with endothelial cells of the arch arteries.[74] Definitive aortic arch formation is the product of complex signaling interactions among neural crest cells, SHF cells, and pharyngeal mesoderm.[54,73,75]

DEVELOPMENT OF THE PULMONARY VEINS

The pulmonary veins develop from coalescence of endothelial networks in the lung parenchyma. The earliest evidence of the formation of the common pulmonary vein in the embryo is the presence of a strand of endothelial cells in the dorsal mesocardium. The endothelial strand forms a lumen and passes through the mesenchyme of the dorsal mesocardium to enter the left atrial myocardium.[23] The common pulmonary vein therefore connects directly to the left atrium in normal development and does not represent an outgrowth of the atrial wall. Despite this, it is now widely recognized that the muscular layer of the proximal portions of the individual pulmonary veins is of a variably myocardial (as opposed to smooth muscle) phenotype that is clinically important in the etiology and management of atrial fibrillation.[76-78]

DEVELOPMENT OF SYSTEMIC VEINS

The embryonic systemic veins are also formed by vasculogenesis. Initially, there are three bilaterally symmetric venous drainages: the vitelline, umbilical, and cardinal venous systems. The vitelline veins drain the embryonic gastrointestinal tract and gut derivatives. The umbilical veins bring oxygenated blood to the heart from the placenta. The cardinal venous system returns blood from the embryonic head, neck, and body wall. All three of these drainages enter into the sinus venosus of the primitive heart tube. The adult venous pattern is established through a complex process of regression, remodeling, and replacement of the embryonic venous systems and their connections to the sinus venosus.[79,80]

The sinus venosus is initially bilaterally symmetric, with right and left "horns" that provide connection for the right and left common cardinal veins, umbilical veins, and vitelline veins. However, the connections of the left-sided cardinal, vitelline, and umbilical venous systems with the left horn of the sinus venosus normally regress. This results in the coronary sinus remaining as the primary structural derivative of the left horn of the sinus venosus in the normal fetal and postnatal heart. When embryonic venous connections with the left venous horn fail to regress, persistence of the left superior vena cava is observed. The right horn of the sinus venosus normally accommodates the entirety of the systemic venous drainage, except the portion from the heart returned through the coronary sinus. In addition, the portion of the mature right atrium between the orifices of the vena cavae is derived from the right horn of the sinus venosus.

The right and left vitelline veins are connected to each other through a plexus of veins that become the liver sinusoids. After the left vitelline vein loses connection with the left horn of the sinus venosus, it regresses. Therefore the entire venous system of the embryonic gut normally drains to the heart through the right vitelline vein. The connection of the right vitelline vein to the right sinus venosus persists into fetal and adult life as the terminal portion of the IVC.

The left umbilical vein also loses its connection with the left horn of the sinus venosus, but it is the right umbilical vein that regresses as a distinct structure. The left umbilical vein forms anastomoses with the ductus venosus (derived from the liver plexus of the vitelline veins). There are no derivatives of the embryonic umbilical venous drainage that connect to the heart or persist after the closure of the ductus venosus in adult life.

The cardinal venous system initially consists of bilateral anterior cardinal veins and bilateral posterior cardinal veins. Fusion of the anterior and posterior cardinal veins at the level of the sinus venosus forms the common cardinal veins. The left anterior cardinal vein loses its connection with the left horn of the sinus venosus, but a small remnant on the surface of the heart normally persists as a passage of coronary venous blood to the coronary sinus and is known as the oblique vein of the left atrium. Another portion of the left anterior cardinal vein persists as the left internal jugular vein. As the left anterior cardinal vein loses connection with the heart, it becomes connected to the right anterior cardinal vein through the intercardinal anastomosis that forms between the thyroid vein and the thymic vein; this connection will persist as the left brachiocephalic vein. The portion of the right anterior cardinal vein between the right atrium and the drainage of the left anterior cardinal vein proximally (through the intercardinal anastomosis) becomes the normal right superior vena cava.

The posterior cardinal veins are the only portion of the embryonic venous drainage that are destined to have a symmetric

fate. Both posterior cardinal veins will regress throughout most of their length and lose their direct connections with the sinus venosus. The posterior cardinal veins originally drain the body wall, gonadal, and renal structures. Their function in venous drainage of the body wall is supplanted by the supracardinal venous plexus, whereas the gonadal and renal venous drainage is captured by the subcardinal venous plexus.

The posterior cardinal, supracardinal, and subcardinal venous beds contribute the segments that form the definitive inferior vena cava (IVC) to the level of the vitelline vein–derived segment connecting to the right atrium. Remnants of the posterior cardinal veins in the fetal and adult circulation are limited to the most distal portion of the IVC (formed by anastomosis of the right and left posterior cardinal veins) and the common iliac veins. The posterior cardinal vein–derived IVC connects to the supracardinal segment of the IVC. The supracardinal venous system is the site of origin of the azygous and hemiazygous veins, which ordinarily connect to the IVC between the renal veins and the common iliac veins. The supracardinal segment of the IVC connects to the subcardinal segment of the IVC, which receives the drainage of the gonadal veins and renal veins before connecting to the vitelline venous channel into the heart.

The molecular pathways differentiating venous development from arterial development are becoming better understood. Key molecular pathways include VEGF and Notch signaling, ephrins and their receptors, and the transcription factor COUP-TF.[81-84] The lymphatic system develops as an outgrowth of the primitive venous circulation, with lymphatic markers that include PROX1, podoplanin, and VEGF-R3.[85-88]

EPICARDIAL CELL MIGRATION AND DEVELOPMENT OF THE CORONARY ARTERIES

Epicardial cells are not present in the tube heart, and an epicardial cell migration is essential for development of the epicardium, the coronary arteries, a major component of the fibrous crux, and the fibroblast population of the myocardium. The epicardium migrates to the surface of the heart from villous projections in the region of the sinus venosus in birds and from the septum transversum in mammals.[89-92] The precursor tissue is histologically and functionally complex and has been called the *proepicardial organ*.[93] It is a transitory embryonic structure that gives rise to the epicardial cell layer and is also a source of fibroblasts and coronary smooth muscle cells of the heart.

In the mouse and rat, villous processes arising from the septum transversum in close proximity to the heart appear to be the source of the epicardial cells. Small aggregates of cells appear on the surface of the ventricles and atria that faces the septum transversum. With time, the cells flatten over the surface of the myocardium and develop morphologic characteristics compatible with primitive epithelial cells. The flattening process also causes cells to occupy a greater surface area, bringing adjacent clusters of cells into contact with each other until a continuous sheet results. These events occur between days 9 and 11 of embryonic life; the villous projections are markedly diminished by day 10.5.[90,93]

As the epicardial cell layer forms, an extensive acellular extracellular matrix layer, similar to the cardiac jelly in the subendocardial space, appears between the epicardium and the myocardium. The mesenchymal cells that subsequently populate this space are derived from an epithelial-to-mesenchymal transformation of the epicardial cells. This process is regulated by expression of transcription factors such as Slug and Snail, as well as growth factors, including transforming growth factor-β.[94] Subepicardial mesenchymal cells are generally accepted to provide the precursors of cardiac fibroblasts, coronary vascular smooth muscle cells, and coronary endothelial cells. The subepicardial extracellular matrix accumulates to its greatest degree in the AV groove. In addition to being a key site for coronary vasculogenesis, the mesenchymal cells that come to populate the AV groove matrix will form the majority of the fibrous insulating ring between the atria and the ventricles (see Figure 63-5).[64]

The generation of subepicardial mesenchyme can be inhibited in chick embryos by perturbing epicardial precursor cell migration from the proepicardial organ, resulting in failure of development of both the epicardium and subepicardial space.[91] The normal development of the epicardium and subepicardial mesenchyme is also dependent on cell-cell interactions with the underlying myocardium. Gene knockout studies in mice show that the absence of expression of genes such as vascular cell adhesion molecule 1 *(Vcam1)* or transcription factor friend of GATA2 *(Fog2)* in the myocardium, or Wilms tumor suppressor 1 *(Wt1)* and α_4 integrin in the epicardium, will produce a similar phenotype of abnormal coronary development and in some models *(Vcam1, Fog2, Wt1)* ventricular myocardium hypoplasia.[46]

All of the cell populations arising from the epicardium are collectively known as epicardium-derived cells (EPDCs).[95] As identified by lineage markers, EPDCs migrate into the sulcus matrix and from there into the AV endocardial cushions. In addition to entering the AV cushions, EPDCs were also noted to migrate individually into the myocardium and subendocardium. Disruption of EPDC migratory contributions to the myocardium and endocardial cushions results in abnormalities of Purkinje fibers, the annulus fibrosis, the compact myocardium, AV cushions, and coronary vasculature.[91,95-97]

The subepicardial space is the site of origin of the vascular plexus of the coronary vessel precursors. Three sequential and overlapping phases of nutrient delivery to the myocardium during embryogenesis of the heart have been described.[98] The first phase is associated with the development of an extensive network of intratrabecular sinusoids lined by endocardial cells, through which nutrient flow to the myocardium is assumed to occur. The second phase is the development of a subepicardial plexus of endothelium-lined channels that penetrate the myocardium. At least some of these channels communicate with the intratrabecular sinusoids. The third stage is the regression and coalescence of the vascular subepicardial network into specific muscular arterial channels. Virtually as soon as the vessels are readily identifiable, they are noted to penetrate into the ventricular and atrial walls, where they establish a mid-myocardial network. The vessels spread to the ventral surface of the heart and follow the sulci (especially the AV sulcus) to the outflow tract, where they form a plexus in the myocardial sheath surrounding the truncus arteriosus. Coalescence of vessels and capillary outgrowth from the peritruncal plexus result in penetration of the wall of the aorta by the definitive proximal coronary arteries.[98,99]

Molecular Determinants of Embryonic Vascular Development

The establishment of the cardiovascular system represents an early, critical event essential for normal embryonic development. Although much of the attention to date has focused on factors involved in key events in cardiac development, such as myocardial differentiation and neural crest migration, the importance of normal vascular morphogenesis has recently become a central focus of cardiovascular research. Considerable new information has accumulated concerning the pivotal role of endothelial differentiation in establishment of the vascular tree. This chapter reviews the general mechanisms of vascular development in light of some of the new information on critical molecular interactions that has recently been delineated. Specific areas of focus include (1) initial differentiation of the endothelium and formation of the primary vascular plexus, (2) vascular heterogeneity and remodeling, and (3) epigenetic factors that play a primary role in vascular ontogeny. Also reviewed is some recent evidence demonstrating how all of these factors are involved in regulation of pulmonary vascular development.

ORIGIN OF ENDOTHELIAL CELLS

Early observers noted the initial formation of blood vessels outside the embryo in the blood islands of the yolk sac, which preceded intraembryonic vascular development. This led to the conclusion that all vessels within the embryo resulted from a direct extension of extraembryonic vessels.[1] This hypothesis was quickly refuted when parts of the embryo, separated from the yolk sac before vascular invasion, were shown subsequently to develop vascular channels.[2] This suggested the possibility of endothelial cell (EC) precursors intrinsic to the embryo. Perhaps the most significant breakthrough in the study of endothelial ontogeny came with the development of monoclonal antibodies that recognized a species-specific epitope on the cell membrane of quail ECs. For the first time, this antibody allowed definitive identification of ECs independent of potentially ambiguous morphologic criteria. Using one of these antibodies, QH1, several investigators have been able to demonstrate that vascular development commences in the embryo proper shortly after gastrulation, as individual presumptive ECs, or angioblasts, differentiate from the mesoderm. These cells soon connect into a vascular plexus that matures into the major vessels of the adult (see later discussion). These studies have documented that most mesodermal tissues contain endothelial precursors and thus have the capacity for vascular formation.[3,4] Similar studies using a battery of endothelium-specific antibodies have defined a similar pattern of endothelial differentiation and vascular development in the mouse.[5]

For more than 70 years, a central question in vascular development has been whether ECs and hematopoietic cells (HCs) share a common origin. In the yolk sac blood islands, and at certain sites within the embryo such as the developing aorta, hematopoiesis and EC differentiation occur side by side. Early observation of simultaneous HC and EC differentiation[6,7] led to the hypothesis that HCs and EC precursors (angioblasts) are derived from the same progenitor cell, the hemangioblast (the subject of several reviews[8-10]). Again, this question has been answered by the

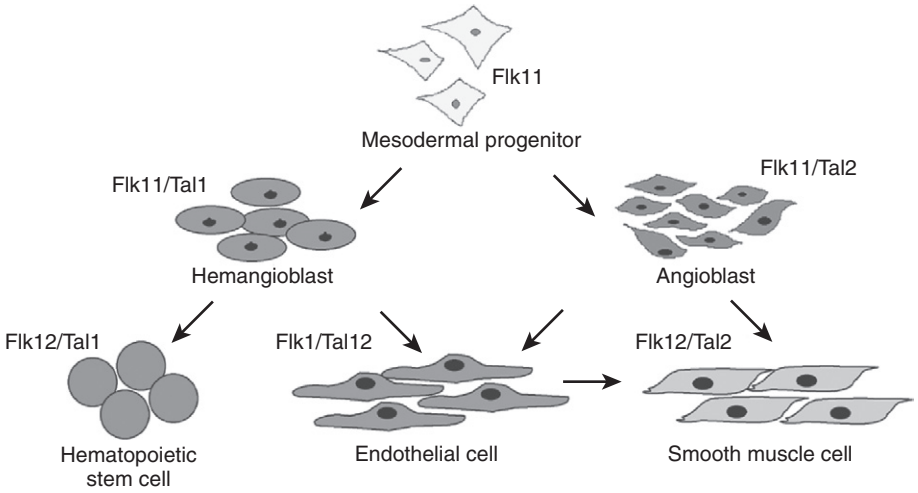

Figure 64-1 The common origins of endothelial and hematopoietic cells. ECs and HCs both derive from mesodermal progenitor cells that express the VEGF receptor VEGFR2 (Flk1). The hemangioblast is a Flk1-positive cell that also expresses the transcription factor TAL1/SCL (Flk1 positive/Tal1 positive) and can give rise to both HCs (down-regulating Flk1) or to ECs (down-regulating Tal1). ECs can also be derived from the angioblast, a precursor cell that, like the ECs themselves, is Flk1 positive but Tal1 negative. An additional cell-fate choice important for blood vessel formation is the production of SMCs versus ECs. Recent data suggest that both angioblasts and mature ECs can give rise to SMCs, which are Flk1 negative/Tal1 negative. *(Modified from Ema M, Faloon P, Zhang WJ, et al: Combinatorial effects of Flk1 and Tal1 on vascular and hematopoietic development in the mouse,* Genes Dev *17:380, 2003.)*

identification of molecular markers that define specific stages of mesodermal differentiation, most notably the vascular endothelial growth factor (VEGF) receptor 2 (VEGFR2). VEGFR2-deficient mice do not develop blood vessels or yolk sac blood islands[11,12] and thus lack both endothelial and hematopoietic components. The combined EC and HC defects are consistent with a common molecular pathway governing EC and HC differentiation and support a direct lineage association between blood and endothelium. However, the combined defects could merely reflect a developmental arrest because loss of VEGFR2 function results in a relatively early embryonic demise.

To separate embryonic survival from the equation, VEGFR2-deficient embryonic stem cells have been used in both chimera and in vitro differentiation studies. These approaches have demonstrated that a single VEGFR2-positive cell can give rise to both endothelial and HCs and further suggest a requirement for VEGF/VEGFR2 signaling in hemangioblast survival, proliferation, or migration, as well as in differentiation.[8,12] Similar knockout, chimera, and in vitro studies suggest that the basic helix-loop-helix transcription factor TAL1/SCL (T-cell acute leukemia/stem cell leukemia) might play a concomitant role in differentiation of both the hematopoietic and EC lineages. TAL1/SCL-deficient animals have defective hematopoiesis, and TAL1/SCL-deficient cells fail to contribute to vascular remodeling. TAL1/SCL deficiency in embryoid bodies (differentiating cultures of embryonic stem cells) leads to defective hematopoiesis, accompanied by an increase in the percentage of cells expressing endothelial markers. Thus it was hypothesized that TAL1/SCL might have a biphasic action, acting in a common precursor to promote formation of HCs, but also acting within the endothelial lineage during angiogenesis.[8] TAL1/SCL is not expressed in VEGFR2-deficient embryos, suggesting a pathway in which expression of this transcription factor is downstream of a VEGF signal through VEGFR2.[13]

In an elegant series of experiments, Ema et al[13] delineated a combinatorial role for VEGFR2 and TAL1/SCL in vascular and hematopoietic development. By knocking-in TAL1/SCL into the VEGFR2 locus, they could separate TAL1/SCL activation from additional downstream effects of VEGFR2 action. They showed that TAL1/SCL partially rescues the in vivo endothelial defects seen in VEGFR2-null mutants but significantly improves hematopoietic differentiation in vitro and in vivo. This study (summarized in Figure 64-1) was able to identify definitively the hemangioblast as expressing TAL1/SCL (Tal1-positive) and the angioblast as nonexpressing (Tal1-negative). It was also able to confirm that angioblasts and definitive ECs could both give rise to smooth muscle cells (SMCs), as had been previously suggested by others.[14] Thus ECs, HCs, and SMCs have a common lineage in which cell-fate choices are governed in part by the combinatorial action of VEGFR2 and TAL1/SCL.

The Two Mechanisms of New Blood Vessel Formation

Following the differentiation and development of the EC populations, as described, a subsequent organization of these ECs into a complex but highly regulated system of arteries, capillaries, and veins occurs. Two different processes are thought to be involved in new blood vessel formation (Figure 64-2): *vasculogenesis*, which is the de novo organization of blood vessels by in situ differentiation of ECs from mesoderm; and *angiogenesis*, the budding and branching of vessels from preexisting vessels.[15-17]

Angiogenesis is the characteristic vascularization process for organs such as the brain and kidney; vasculogenesis is more prominent in the formation of the larger vascular network, including the dorsal aorta, blood islands, endocardium of the heart, and cardinal and vitelline vessels, as well as the liver. In some instances, vascular development may occur by simultaneous angiogenesis and vasculogenesis, which is characteristic of the developing lung.[18,19] Although angiogenesis can occur in both the embryo and the adult (e.g., wound healing, tumor vasculogenesis[20,21]), vasculogenesis is usually considered to be restricted to embryonic development. However, recently identified circulating ECs and EC precursors that can contribute to new blood vessel formation may represent exceptions to this temporal limit on vasculogenesis.[22] Despite this distinction between these two processes, the tasks that ECs subsequently perform in forming a new vessel are similar in both. Thus vasculogenesis and angiogenesis likely share many molecular components involved in cell-cell or cell-matrix signaling or in coordinated cell movement, organization, and adhesion.

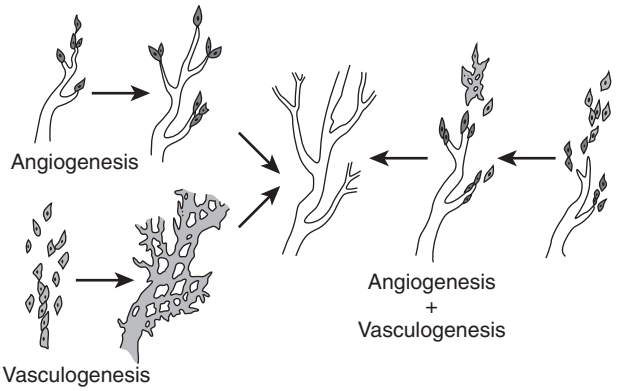

Figure 64-2 The basic mechanisms of vascular development in the embryo. *Angiogenesis* is the sprouting of new vessels from existing vessels, and *vasculogenesis* is the de novo differentiation of angioblasts from mesoderm and organization into a vascular plexus with remodeling into a definitive vessel. A third process may involve congruent angiogenesis and vasculogenesis.

Formation of a Primary Vascular Plexus

In vasculogenesis, ECs first assemble into vessel primordia, which lack a lumen, and then rearrange into endothelial tubes of polarized cells. Many such tubes then are joined into a polygonal array generating the primary vascular network. Recent work has identified key molecules involved in vessel assembly and morphogenesis. An early role for VEGF signaling is revealed by VEGFR1-deficient mice, which form angioblasts but fail to properly assemble ECs into tubes.[23] Inhibition of VEGF signaling using soluble VEGFR1 in quail embryos supports the requirement for VEGF signaling in this phase of vessel assembly.[24] Normally, the polygonal array of vessels is formed through the protrusive behavior of individual ECs, which adopt a bipolar shape and extend processes to link with neighboring ECs. In embryos injected with soluble VEGFR1, normal numbers of ECs are present, but they fail to exhibit protrusive behavior, resulting in a profound deficiency of vessels.[24]

In addition to signaling molecules, cell-cell contact and cell–extracellular matrix (ECM) interactions are important for early vascular morphogenesis. After the formation of vessel primordia, cells rearrange into tubes with lumens. Integrins, the best-characterized group of cell-ECM adhesion molecules, have been implicated in this phase of vasculogenesis, as well as in angiogenesis and vessel maintenance. Integrins are heterodimeric proteins that consist of an α-subunit noncovalently associated with a β-subunit. Currently, 8 different β- and 18 different α-subunits have been identified; however, members of the β1 and β3 family of integrin receptors, together with other cell adhesion family members, are thought to be particularly important in both vasculogenesis and angiogenesis.[25] The combination of specific α- and β-subunits determines ligand-binding specificity. For example, β1 in combination with α5 functions exclusively as a fibronectin receptor, whereas β1 in combination with α6 serves as a laminin receptor. Thus the ability of a cell to modulate adhesive characteristics is determined by both the types of integrins expressed and the absolute number of any given integrin.

Utilizing the monoclonal antibody CSAT, which interferes with ligand binding to the β1 integrins, Drake et al[26] were able to block formation of the lumen of the dorsal aorta in the early chick embryo. It is interesting that in these experiments, the early stages of vasculogenesis were not obviously affected in that angioblast differentiation and spatial organization into cords appeared normal. Only the final stages of tube formation were inhibited, suggesting that although β1 integrins are critical for final development of an endothelial tube, they are not involved in the initial commitment of mesoderm to EC lineage or in initial spatial organization. In results similar to those seen for injection of β_1 antagonists, αvβ3-blocking agents prevented lumen formation but not differentiation or spatial organization of the ECs.[27]

To assign roles in vascular development to specific subunits, integrins, or their ECM ligands requires much additional work, and it should be noted that inhibitor studies and gene inactivation studies have not always produced concordant results. A majority of αv-knockout mouse embryos die by midgestation, probably owing to placental defects, but around one fifth of the embryos survive until birth.[28] These embryos have vascular abnormalities and hemorrhaging that are unexpectedly restricted to intracerebral and intestinal vessels.[28] Similarly, β3-knockout mice are viable and fertile but have defects characteristic of the human bleeding disorder Glanzmann thrombasthenia, including cutaneous and gastrointestinal bleeding.[29] Thus, although both the αv and β3 gene-inactivations in mice have vascular defects, neither recapitulates the defects seen in avians in response to a specific αvβ3 inhibitor.

ANGIOGENESIS, REMODELING, AND VESSEL MATURATION

To generate a fully functional, arborized vascular tree, the primary vascular plexus must be extended and modified, and vessel maturation must occur. Angiogenesis generates new vessels from existing ones, either by a sprouting mechanism or by a nonsprouting (intussusception) mechanism in which columns of interstitial tissue are inserted inside the lumen of an existing vessel, dividing it into two or more new vessels.[30] During angiogenesis, the preexisting network of vessels with relatively uniform diameters is also extensively remodeled to generate a hierarchic arrangement of large and small vessels. These changes are accompanied by vessel maturation and stabilization, which depend upon the recruitment from mesenchyme of periendothelial mural cells, including pericytes and SMCs, as well as on the deposition of basement membrane. Interactions with periendothelial mural cells established during angiogenesis are critical for proper functioning of the vascular network. In particular, blood vessels located in different parts of the vascular tree, such as the elastic vessels, muscular arteries, resistance vessels, veins, and lymphatics, each require different physical properties. Many of these distinctions between vessels stem from local variation in ECM production by the mural cells.

In the last few years, considerable progress has been made in uncovering the molecular signals controlling angiogenesis, vessel remodeling, and maturation. This work has highlighted the involvement of several families of receptor tyrosine kinases (RTKs) and their ligands, shown schematically in Figure 64-3. The functions of selected RTKs and ligands in vascular development are illustrated in Figure 64-4. In addition to functioning during vasculogenesis, signaling by VEGF ligands and VEGF receptors is important for angiogenesis and regulates EC sprouting and survival (reviewed by Carmeliet and Collen[31]). Vascular development is particularly sensitive to VEGF dosage. Heterozygosity for a null mutation in the VEGF gene leads to multiple cardiovascular defects and embryonic lethality.[32,33] Consistent with a role in vessel sprouting, deficiencies occur in intersomitic vessels, in vessel in-growth to the neuroepithelium, and in the sprouting of head mesenchyme vessels. The vitelline vessels fail to fuse with the yolk sac, and an irregular primary plexus within the yolk sac is not remodeled to generate larger vessels.[32,33]

Specific inhibition of VEGF signaling with a soluble receptor and a conditional knockout of VEGF in which the gene is excised only in newborn mice further highlights the dependence on VEGF of vessels that form by angiogenesis.[34] In these animals, there is growth retardation and hypoplasia of multiple organs,

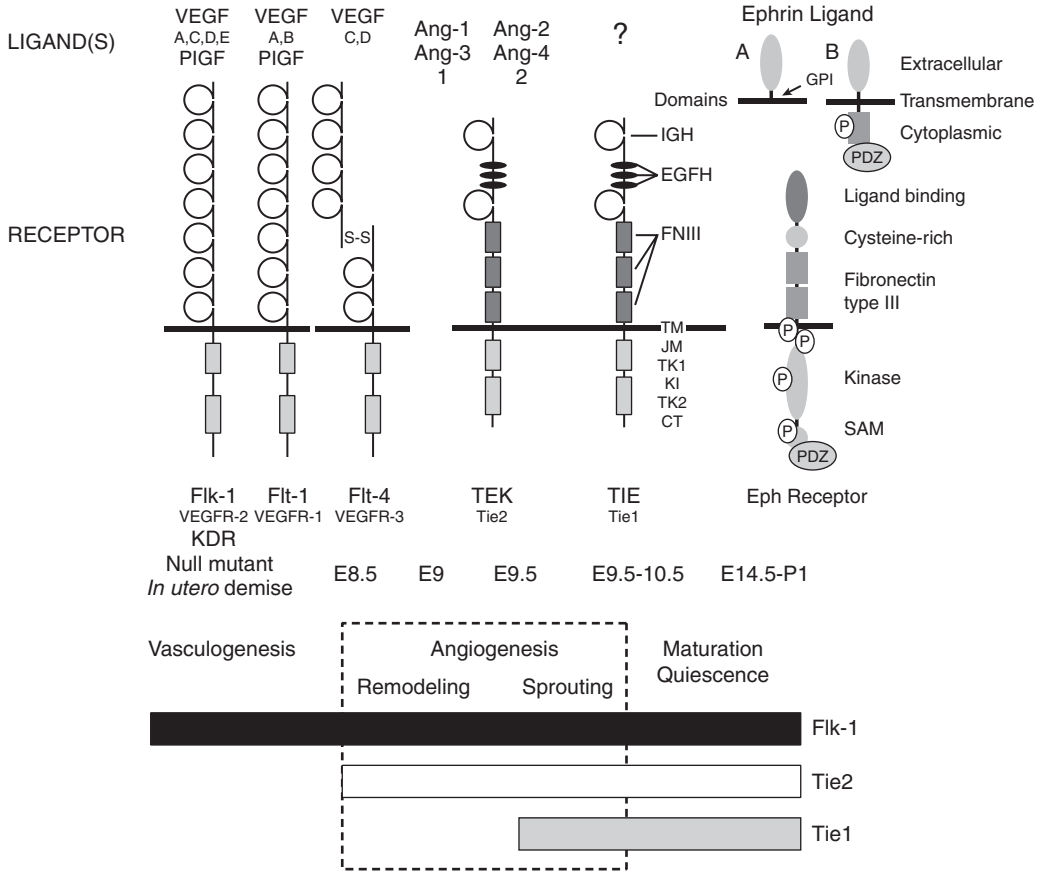

Figure 64-3 Major EC RTKs and growth factor ligands involved in vascular development. The structures of the receptors are shown schematically, and major protein domains have been indicated. (*Ang,* Angiopoietin; *Ang-1, Ang-2, Ang-3, Ang-4,* angiopoietin family of Tie2 ligands; *CT,* carboxyl-terminal tail; *EGFH,* epidermal growth factor homology domain; *FNIII,* fibronectin type III homology domain; *GPI,* glycosylphosphatidyl inositol anchor; *IGH,* immunoglobulin homology domain; *JM,* juxtamembrane domain; *KI,* kinase insert; *P,* phosphorylation site; *PDZ,* site of interaction with the PSD-95/Discs Large/ZO-1 [PDZ] class signaling proteins; *PlGF,* placental growth factor; *SAM,* domain that forms homodimers and may regulate receptor dimerization; *S-S,* disulfide bridge; *TK1* and *TK2,* tyrosine kinase catalytic domains; *TM,* transmembrane domain.) Also shown are the requirements for three RTKs relative to mouse gestation and phases of blood vessel development. Animals deficient in VEGFR2 (Flk1) fail to undergo vasculogenesis, indicating a very early requirement for this receptor. In contrast, Tie2 is not required for vasculogenesis but is necessary for subsequent angiogenesis. Tie1 appears to act later still, mainly in vessel maturation and vessel stability (quiescence).

which is associated with dramatic reductions in organ vascularization. In addition to reducing postnatal angiogenesis, the inhibition of VEGF signaling appears to cause loss of existing vessels because animals treated with soluble receptor exhibit a marked increase in EC apoptosis. Therefore VEGF acts as a survival factor for ECs in immature vessels. This survival function observed in the perinatal period does not appear to extend to mature vessels because treated adult animals did not exhibit organ abnormalities.

Although VEGF receptors such as VEGFR2 are expressed by the earliest EC precursors, other endothelium-specific RTKs are most prominently expressed at later phases of vessel development and are thought to act once initial vessel formation has occurred. Tie1 (tyrosine kinase with immunoglobulin-like loops and epidermal growth factor homology domains) and Tie2 are closely related endothelium-specific RTKs that are involved in angiogenesis and vessel maintenance. Tie2-deficient animals exhibit normal vasculogenesis but fail to remodel the primary vascular plexus correctly and are deficient in vessels that normally form by angiogenic mechanisms. A key defect is in the generation of small vessels from large ones by intussusception. Folds of interstitial tissue that normally invade vessels collapse to produce irregular, abnormally spaced vessel patterns.[35] The failure of proper tissue-fold formation apparently stems from a striking inability of Tie2-null vessels to recruit periendothelial cells to the vessel walls and into the tissue folds. The ECs themselves also exhibit abnormal morphology, being rounder than normal and often projecting into the vessel lumen.[35]

Ang-1 and Ang-2 (see Figure 64-3) are two members of a family of four structurally related Tie2 ligands.[36] Ang-1–null mice have a similar phenotype to Tie2 mutants, suggesting that this molecule is the main agonist ligand. Ang-1 is not expressed in EC cells but rather is produced in tissue adjacent to vessels in areas of angiogenesis, implying that the signals mediated by Ang-1/Tie2 are directed to ECs from their environment. The effect on mural cells indicates a critical place of Ang-1/Tie2 in reciprocal signaling between ECs and their surroundings because it suggests that the loss of Tie2 activity causes a disruption of some further signal produced by the EC cells. Ang-2, identified by its sequence similarity to Ang-1, was found in vitro to antagonize Ang-1 activation of Tie2, a role supported by in vivo overexpression studies that generated a phenotype similar to loss of function of Ang-1 or Tie2.[37] In vitro data and gene knockout experiments suggest a more complex picture, in which the function of Ang-2 is context-dependent and may be modulated by the bioavailability of VEGF.[38-40] Ang-2 appears to induce vessel regression in the absence of VEGF, but it can promote sprouting in the presence

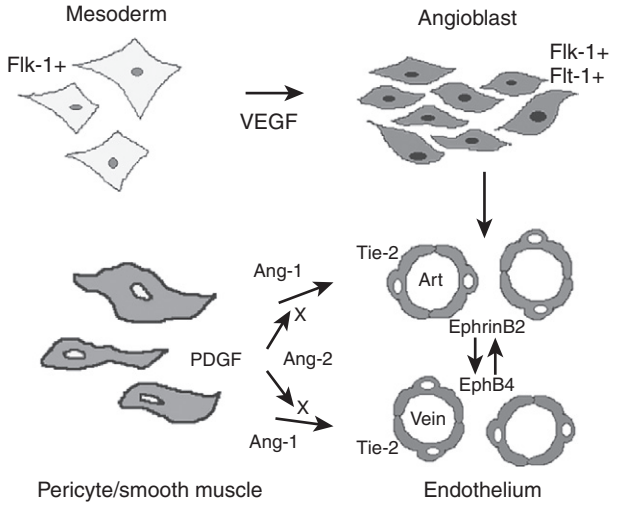

Figure 64-4 Key signals in the production of a vascular tree. Schematic of the cell types contributing to blood vessels, illustrating the action of selected signaling molecules. VEGF signals are involved in the differentiation of endothelial precursor cells (angioblasts) from mesoderm that contains progenitor cells that express VEGFR2 (Flk1). Angioblasts require VEGFR1 (Flt1) to assemble into endothelial tubes. The endothelium is patterned and remodeled. Patterning of vessels includes the expression of ephrin-B2 on arteries and Eph-B4 on veins. The Tie2 receptor, expressed on ECs, and its ligand Ang-1, expressed in adjacent tissues, are required for vessel remodeling and formation of new vessels by angiogenic mechanisms. Ang-2 can act as a negative regulator of these signals. Platelet-derived growth factor B (PDGF-B) is involved in the recruitment of periendothelial mural cells to vessels, which is necessary for vessel maturation and stability. *Art,* Artery.

of VEGF.[41] In blood vessels, Ang-2 functions in vessel regression, as shown by the failure of the normal programmed regression of the hyaloid vasculature of the eye in Ang-2–deficient mice. Conversely, the effect of Ang-2 on intestinal and dermal lymphatic ECs is proangiogenic, and loss of Ang-2 results in hypoplasia of these vessels.[38]

A necessary starting point for vessel regression (pruning of the vascular tree), sprouting (generating new branches), and intussusception (dividing vessels) is the destabilization of existing blood vessels. Work with additional RTKs and their ligands reveals the existence of mechanisms that stabilize ECs and highlights the importance of mural cells in vessel maintenance. Tie1 is an endothelium-specific orphan receptor (a receptor with no known ligand) closely related to Tie2. Tie1 is expressed in ECs and their precursors during development but is also expressed in most nonproliferating adult endothelium. Mice homozygous for null Tie1 mutations exhibit normal vascular development until midgestation. They then appear to suffer a loss of the microvasculature, accompanied by hemorrhage.[42] More detailed analysis of these animals suggests that the vascular density is actually higher than normal in many tissues because intussusception occurs more frequently.[35] This change appears due to the "hyperactive" behavior of Tie1-deficient ECs, which also compromises vessel integrity. Individual Tie1-null ECs project numerous extensions and filopodia and frequently have other defects in morphology, such as frequent intracellular and transcellular holes. Periendothelial mural cells associated with these defective vessels also exhibit a "hyperactive" phenotype.[35] Together these studies suggest that the normal function of Tie1 activity is to suppress the exploratory behavior of EC cells and their associated mural cells, thereby stabilizing vessels and preventing further vessel division.

Recruitment of periendothelial mural cells to new blood vessels is mediated by EC expression of platelet-derived growth factor B (PDGF-B), acting through its receptor PDGFR-β, which is expressed in the adjacent mesenchyme (reviewed by Betsholtz and co-workers[43]). Inactivation of either the PDGF-B or PDGFR-β genes in the mouse results in death in late gestation that is associated with dilation of the heart and blood vessels, rupture of capillaries, and widespread edema and hemorrhage.[44-47] Deficiencies in vascular SMCs and pericytes occur in many tissues, with the extent of deficiency correlating with the occurrence of vessel dilation and microaneurysms.[47] Absence of pericytes is linked to EC hyperplasia, with the walls of dilated vessels containing a higher than normal density of ECs. In the pericyte-deficient vessels of PDGF-B–null mice, ECs exhibit a "hyperactive" morphology that is reminiscent of the Tie1-null phenotype, with the most extreme disorganization of ECs occurring in microaneurysms.[48] Thus the recruitment of periendothelial cells mediated by PDGF-B and PDGFR- β appears to be a critical part of stabilizing both EC number and organization (see Figure 64-4).

Vascular Patterning: Not All Endothelial Cells Are Created Equal

Many differences between classes of vessels involve the vessel wall and stem from differential ECM production by the mural cells. It has long been postulated that the ECs themselves also form very distinct populations, with unique characteristics and perhaps unique origins. However strong molecular evidence for such distinctions has only recently been obtained, when localized expression of regulatory molecules, such as transcription factors, receptors, and ligands, revealed multiple levels of EC heterogeneity. In particular, distinct molecular signatures for ECs are located within arteries, veins, and lymphatic vessels and in the endocardium of the heart.[49-54]

The functional significance of such distinctions is exemplified by differences in the venous and arterial expression patterns of the RTK Eph-B4 and its transmembrane ligand ephrin-B2.[49,51] The Eph receptors, the largest described family of RTKs, bind membrane-bound ephrin family ligands. Members of the ephrin-B family of ligands can autophosphorylate upon receptor binding, thereby allowing bidirectional signaling during cell-cell interactions.[55] During embryogenesis, the Eph-B4 receptor is specifically expressed in ECs almost exclusively in developing veins, whereas its only known specific ligand, ephrin-B2, is expressed in ECs in arteries.[49-51] Homozygosity for null mutations in either ephrin-B2 or Eph-B4 results in defects in angiogenesis, but not in vasculogenesis, both in the yolk sac and in the embryo. In both cases, the primary vascular plexi are established, but there are abnormalities in remodeling that have an impact on both arteries and veins. Although both classes of vessels are disrupted, the venous system is more strongly affected in the Eph-B4–null embryos, and, conversely, the loss of ephrin-B2 has a greater impact on the arterial system.[49,51] The venous and arterial expression of this receptor-ligand pair is suggestive of a role in mediating interactions between the two classes of vessels. Consistent with this idea, normal intercalation between arteries and veins fails to occur in yolk sacs of ephrin-B2–deficient embryos.[49] Together with other data on the expression and function of Eph family members,[50] these results demonstrate that molecular differences between the arterial and venous ECs are established early in development. Moreover, these molecules are essential for the normal development of the vascular tree, likely mediating cell-cell interactions specific for subsets of the endothelium (see Figure 64-4).

The patterns of expression and localized functions of certain transcription factor genes reveal further levels of EC heterogeneity.

Notably the transcription factor gene, nuclear factor of activated T cells-1 (NFATc1), is expressed in the endothelial lining of the heart and the endocardium but not in other EC populations. In valve formation, ECs in the valve-forming region undergo an epithelial-mesenchymal transition, delaminating and entering the underlying endocardial cushion. During development, NFATc1 expression becomes restricted to the valve-forming regions of the endocardium. Thus NFATc1 expression defines an endothelial subpopulation with unique properties. A functional requirement for NFATc1 activity in endocardium is demonstrated by targeted disruption of the *NFATc1* gene. Mouse embryos homozygous for *NFATc1* mutations die in utero with congestive heart failure associated with the absence of aortic and pulmonary valve formation and with ventricular septal defects.[53,54]

The ECs of the lymphatic system are also distinct from other ECs at the molecular level. They exhibit higher levels of expression of several markers, including the transcription factor gene Prox1, the VEGF receptor VEGFR3, and the lymphatic endothelial hyaluronan receptor LYVE-1[52,56,57] (reviews of this subject are available[58,59]). The lymphatic system appears to develop through budding of the preexisting venous system.[60,61] Prox1 is expressed at sites where lymphatic vessels bud from veins, and its expression is subsequently restricted to the lymphatic system.[52] In Prox1-deficient–mice, the early budding of the future lymphatic vessels from the cardinal vein occurs normally, but this process arrests in such a way that the animals lack lymphatic ECs.[52] Failure of budding cells to express high levels of VEGFR3 or LYVE-1 suggests that Prox1 controls a program of lymphatic EC differentiation and is required to maintain the budding process.[52,58]

Our understanding of endothelial heterogeneity is extremely limited, and much remains to be discovered about the extent of such heterogeneity, its significance, and the cellular and molecular mechanisms by which it is acquired. A key question is, "How does such EC heterogeneity arise?" For example, do such differences reflect variation in the origin of ECs, or are they acquired by naive ECs through local environmental cues? Because localized expression of genes within the EC has only recently been described, few experiments have addressed this issue. A recent study of vessels in the skin, however, indicates that the arterial-venous identity of smaller vessels is defined at the time of vessel remodeling through local cues.

It has long been recognized that in peripheral tissues, nerves often run along blood vessels. The vascular system and peripheral nervous system are both complex branched structures, so this intimate association raised the question of whether one branched pattern determined the other, or whether they are independently responding to common cues from their surroundings (as reviewed by Shima and Mailhos[62]). In the embryonic chick skin, only some vessels are co-localized with nerves. Using the arterial and venous markers ephrin-B2 and Eph-B4 (described in an earlier section), Mukouyama et al[63] found that arteries but not veins ran along nerves (Figure 64-5). Mutations that eliminate or alter the patterns of peripheral sensory nerves caused corresponding alterations in arterial patterning, particularly in small-diameter vessels. Thus the pattern of small arteries appears to follow that of the sensory nerves. Expression of the arterial marker ephrin-B2 was found to be acquired during remodeling of the vascular plexus, around the time at which the patterns of vessels and nerves begin to correlate, suggesting that nerves might influence both arterial identity and vessel remodeling. Nerves and their associated Schwann cells are local sources of VEGF, and this factor can account for the ability of both neurons and Schwann cells to induce expression of the ephrin-B2 arterial marker from cultures of ephrin-B2–negative ECs. A specific marker of arterial identity thus appears to be induced by a local VEGF signal from sensory nerves. However, in these experiments the percentage of ECs that could be induced to express ephrin-B2 was never greater than 50%, perhaps also suggesting that only certain ECs are able to respond to this signal.[63]

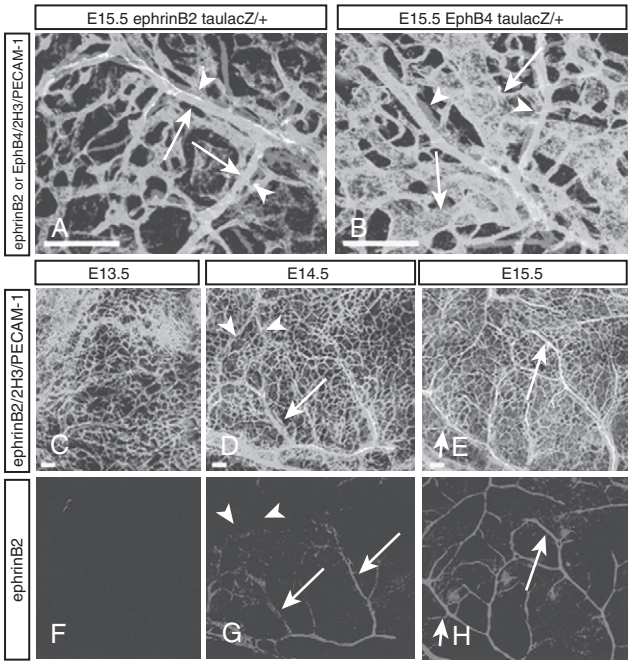

Figure 64-5 Peripheral nerves provide a template for arteriogenesis in the skin. Whole-mount triple immunofluorescence confocal microscopy was used to follow the differentiation of arteries (during embryogenesis; e.g., E15.5 = embryonic day 15.5) by ephrin-B2 in red **(A, C, D),** of veins by Eph-B4 immunolocalization in red **(B),** of nerves with 2H3 localization in green, and of endothelial cells with PECAM11/CD31 localization in blue. Arteries *(arrows)* are specifically aligned with peripheral nerves *(arrowheads)* **(A),** whereas veins *(open arrows)* show a more random distribution **(B).** In **C** to **H,** a time-course from mouse embryonic ages 13.5 days to 15.5 days (E13.5 to E15.5), it is apparent that nerve innervation of the skin *(green)* precedes arterial differentiation *(red)* of the primary vascular plexus *(blue). (Modified from Mukouyama YS, Shin D, Britsch S, et al: Sensory nerves determine the pattern of arterial differentiation and blood vessel branching in the skin,* Cell *109:693, 2002.)*

Epigenetic Factors Driving Vascular Development and Morphogenesis

In the mature vascular system, the extent of vascularization is exquisitely matched to the physiologic needs of the tissue. Moreover at different points in the vascular tree the properties of blood vessels, such as their number, diameter, and wall thickness, are matched to the flows and pressures in that part of the circulatory system. These relationships between vascular system structure and physiology are not the result of a rigid genetic program that predetermines the genesis and final properties of every blood vessel. Instead physiologic (epigenetic) factors exert a major influence over the form of the cardiovascular system. Epigenetic factors help explain some key questions that have arisen from observation of normal blood vessel morphogenesis and play important roles in cardiovascular malformations and disease. As discussed earlier, remodeling results in large vessels being created from a relatively uniform plexus of small vessels. What makes some vessels increase in size while others do not? Extensive vessel regression also occurs, so only a fraction

of the original capillaries within a primary plexus is present in the mature vascular network. What determines which vessels survive? Equally, new vessels are generated in angiogenesis by sprouting and intussusception. Why do new vessels form in one location and not another? What determines how many new vessels should be formed? Two epigenetic factors that play significant roles in vascular development are hemodynamic forces and hypoxia.

Hemodynamic Forces

The forces acting on a blood vessel due to blood flow can be resolved into at least two components (as reviewed by Davies[64]). Blood pressure acts perpendicular to the lumen surface, so changes in pressure stretch all components of the vessel wall (endothelium, smooth muscle, and ECM). Tangential to the lumen surface, the flowing blood generates a frictional force. This produces a shear stress, which mainly has an impact on the endothelium because these are the cells in contact with the fluid.[64] ECs in vivo are aligned in the direction of blood flow, and in vivo and in vitro experiments demonstrate that flow can cause ECs to alter their morphology to adopt this alignment (Figure 64-6). In fact ECs exhibit numerous responses to shear stresses, including alterations in morphology, mechanical properties, and gene expression (reviews are available in the literature[64,65]).

In model organisms, the manipulation of blood flow patterns can have a profound impact on cardiovascular development. For example, the vitelline veins in the avian yolk sac have been ligated to alter the hemodynamics of the developing embryo. Vitelline vein ligation alters the path through the heart adopted by blood flow originating from each region of the yolk sac.[66] Heart rate is also decreased, but there is a compensatory increase in cardiac output.[67] Although the ligation occurs at a site distant from the heart, these altered hemodynamics produce changes in cardiac morphology and disruption of the remodeling of the pharyngeal arch arteries. Typical outcomes include ventricular septal defects, semilunar valve malformations, and pharyngeal arch artery abnormalities.[66,67] Most recently, experiments in the zebrafish[68] further demonstrate that hemodynamic forces are epigenetic factors required for normal heart morphogenesis. Blocking either inflow or outflow to the heart results in similar malformed, hypoplastic hearts with poor differentiation of the valves. The similarity between these phenotypes suggests that shear stress, rather than blood pressure, is the main morphogenetic influence because obstructed inflow and outflow will both result in a reduced flow but are expected to have opposite effects on intracardiac pressure.[68]

During angiogenesis, local variation in hemodynamic forces likely exerts a major influence upon the remodeling of embryonic vessels,[30,69] particularly in determining which vessels are to be enlarged and in controlling the size they attain. For example, it is notable that the large yolk sac vessels develop only after there is significant flow when the connection with the intraembryonic vessels has been established. Defects in this connection are often associated with a failure of subsequent yolk sac remodeling.[32,33,70] Moreover, the vitelline vein ligation experiments described lead to altered remodeling of the capillary plexus, producing a new vein that bypasses the ligation.[66] Thus local changes of blood flow lead to alterations in the pattern of vessel remodeling.

The molecular basis of shear stress responses has yet to be fully characterized, but the wide variety of cellular and molecular responses observed is consistent with multiple structures acting as mechanosensors (see Figure 64-6) and consequently with a diversity of molecules acting in shear stress signal transduction.[64] Because the EC layer provides an "interface" between blood and tissue, it serves as the primary mechanotransducer. Variations

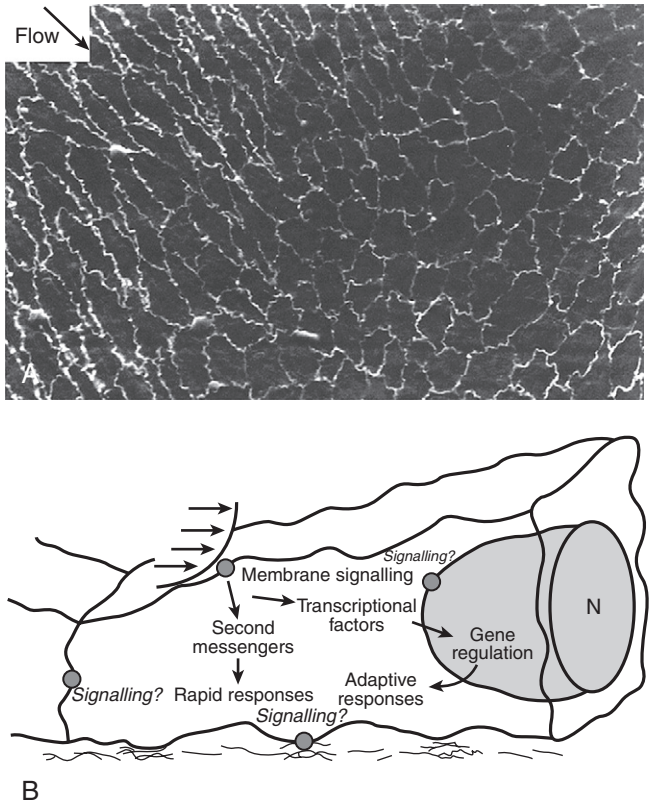

Figure 64-6 Shear stress is a major epigenetic determinant of vascular morphogenesis. **A,** ECs align themselves with direction of flow. **B,** Endothelial response to flow results in numerous alterations at the cell membrane, intercellular junctions, and basal lamina, which result in both primary and secondary alterations in gene regulation. Thus the EC serves as a "mechanotransducer" for flow within the cardiovascular system. *N,* Nucleus. *(Modified from Davies PF: Flow-mediated endothelial mechanotransduction,* Physiol Rev *75:519, 1995.)*

in flow result in altered levels of many vasoconstrictive and vasodilatory factors, including endothelin-1, prostacyclin, and nitric oxide.[64,69] These can certainly modulate vascular tone in response to hemodynamics, but such effects probably play roles late in vascular differentiation.[64,69]

Less is known about flow-responsive pathways in earlier vascular morphogenesis, but some key molecules in vascular development are also implicated in shear stress responses. For example, altered flow changes the EC cytoskeleton and the pattern of focal adhesions, the points of contact between ECs and ECM. Transmembrane integrins are prominent components of focal adhesions, where they bind extracellular adhesion proteins and link the ECM to the actin filaments of the cytoskeleton. New integrin binding to the ECM activates the small guanosine triphosphatase Rac1. Rac1 activation mediates cell alignment and orientation of filamentous actin stress fibers, as well as flow-induced stimulation of the transcription factor nuclear factor kappa B (NF-κB).[71] Thus EC integrins, important for vascular morphogenesis, also play a role in sensing shear stress.

One key transcriptional target of shear stress in ECs is PDGF-B, which is up-regulated by shear stress.[72] The up-regulation of the PDGF-B promoter is mediated by a shear stress–responsive element that is bound by NF-κB.[73] Because PDGF-B mediates recruitment of perivascular mural cells,[47] regulation of its expression by shear stress could link flow to stabilization of vessels during vascular development.

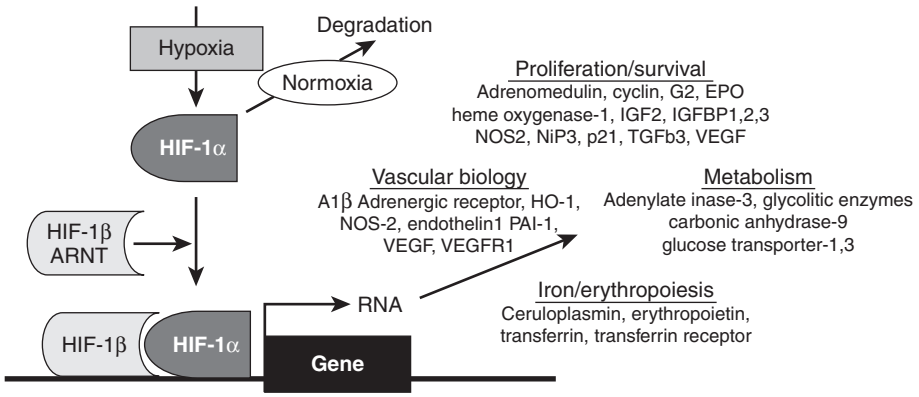

Figure 64-7 Hypoxia-mediated gene regulation through HIF-1α and HIF-1β. The level of HIF-1α is determined by the balance between hypoxia, which drives increased expression, and normoxia, which accentuates expression of signaling cascades, that result in degradation of HIF-1α. Under hypoxic conditions, HIF-1α and HIF-1β dimerize and then bind the hypoxia response element (HRE) in the regulatory region of several genes, resulting in transcription of numerous gene products.

Hypoxia

In healthy adults, angiogenesis is primarily limited to select sites such as the female reproductive system, but extensive angiogenic responses (neovascularization) can accompany disruptions in oxygen homeostasis, such as those that occur during tumor growth or in tissue ischemia.[21] Evidence for oxygen tension governing angiogenic processes in disease states has led to investigation of whether such mechanisms operate during the normal vascular development in utero. Consistent with this idea, multiple components of the signaling systems responsible for normal vascular development are regulated by hypoxia. Notably, VEGF and VEGF receptor 2 are both up-regulated in hypoxic conditions,[74,75] potentially enabling enhanced VEGF signaling to promote new blood vessel formation and/or promote survival of existing vessels. Additional hypoxia-responsive genes important for vascular morphogenesis include those encoding Tie1,[76] the angiopoietins Ang-1 and Ang-2,[77,78] and PDGF-B.[79] Many of these responses occur at the transcriptional level and are mediated by the hypoxia-induced transcription factor HIF-1, discussed in a later section. However, hypoxia also affects expression by other mechanisms, such as specific increases in VEGF messenger RNA stability.[80]

Recently some critical components of the oxygen-sensing pathways have been identified. Central to hypoxia-mediated control of gene expression is HIF-1. HIF-1 target genes up-regulated in hypoxia are involved in increasing O_2 delivery (via erythropoiesis, vascularization, or vasodilation) or are involved in metabolic adaptation to limited O_2 (principally glycolysis) (reviewed by Ikeda and associates[81]). The HIF-1 factor is a heterodimeric complex,[82] consisting of a regulatory α subunit and a constitutive β subunit, both of which are helix-loop-helix PAS domain proteins (Figure 64-7). The α subunits, Hif-1α and Hif-2α, confer the hypoxia responsiveness of the complex. Expression of HIF-1 increases exponentially with decreasing oxygen tension.[83] It is interesting that the major part of this up-regulation is achieved not through an increase in HIF-1α production in response to hypoxia, but rather through increased protein stability of the Hif-α subunits and diversion from the normal pathway of rapid protein degradation.[84,85]

With the exception of structures in direct contact with the atmosphere, such as the respiratory epithelium and outer layers of skin, the normal environment for most mammalian tissues is an O_2 concentration of 3% to 5%, making the tissues "hypoxic" relative to the 20% atmospheric O_2 concentration. The intrauterine environment is likely at a similar low oxygen tension because the optimum O_2 concentration for in vitro culture of early mammalian embryos is 5%, not 20%.[86] Embryonic tissues thus generally are developing at low oxygen tensions but also appear to contain regions of significant hypoxia. Using the hypoxia marker pimonidazole hydrochloride, Lee an colleagues[87] examined the spatiotemporal distribution of tissue hypoxia in the developing mouse embryo. They found multiple domains of local hypoxia that were not only closely correlated with the Hif-1α and VEGF immunoreactivity but also were mapped to locations where angiogenesis is known to occur, including the extraembryonic tissues, neural tissue, intersomitic regions, and ventricles of the heart.[87] These data support the idea that during embryogenesis there is local tissue hypoxia that could modulate blood vessel morphogenesis through induction of VEGF or other HIF-1 responsive genes.

The existence of embryonic tissue hypoxia, together with the oxygen-tension effects on regulators of vascular morphogenesis, has led to the idea that the proper morphogenesis of the vascular system *depends* upon the relatively hypoxic state of tissues in utero. Explant organ-culture models appear to confirm this idea because EC survival and development of the vasculature are sensitive to oxygen tension.[88] Additional evidence supporting an important role for hypoxia in the regulation of vascular development comes from analysis of animals with targeted deficiencies in the HIF-1 regulatory cascade. Mice homozygous for null mutations in the *Hif-1*α gene die at midgestation with pericardial effusion and myocardial hyperplasia. There are vascular malformations, including defects in yolk sac remodeling, interruptions in the intersomitic vessels, and a marked deficiency of cephalic vessels, accompanied by dramatic cephalic vessel dilation.[89,90] It is surprising, however, that the defective remodeling and vascular regression do not appear to be related to a deficiency in VEGF; they may instead by a consequence of extensive cell death in mesenchyme, probably of neural crest origin.[91] These studies also found that glucose deprivation was able to stimulate VEGF expression independently of HIF-1. Therefore, in regions of vascular insufficiency, VEGF up-regulation may be achieved either by a response to inadequate glucose supply or by a response to hypoxia through HIF-1.[91]

Another member of the hypoxia-inducible factor family, Hif-2α (also known as hypoxia-inducible factor-like/endothelial PAS domain protein 1), which is 48% similar to Hif-1α at the amino acid sequence level, can modulate expression of genes important for vascular development, including Tie2.[92] Mice deficient in Hif-2α die in utero and either exhibit a failure of vascular remodeling[93] or exhibit defects of catecholamine homeostasis coupled with heart failure.[94] Mice homozygous for a hypomorphic allele

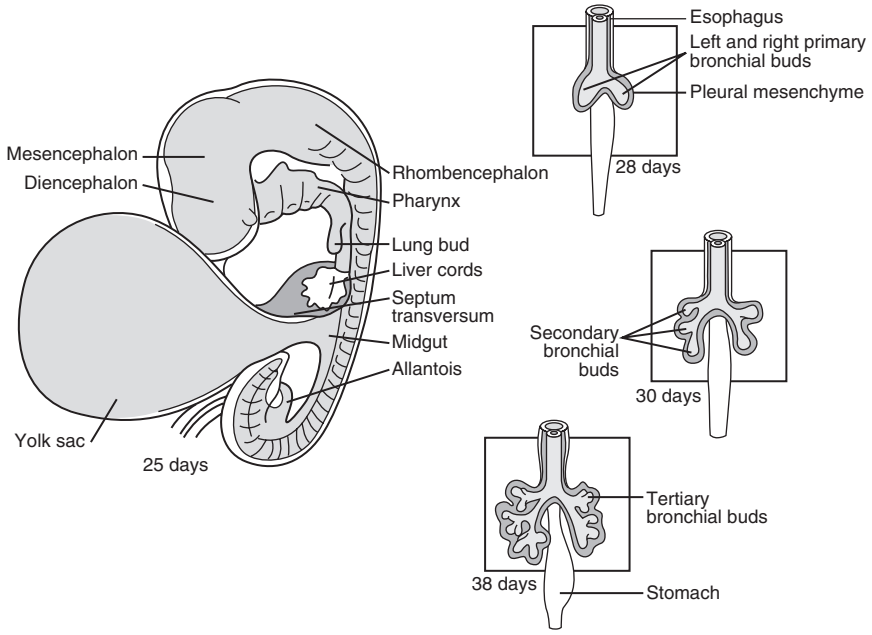
of Hif-2α are viable and apparently develop normally, but they exhibit a diminished response to changes in oxygen tension.[95] In a mouse model of retinopathy of prematurity, exposure of young animals to 75% O_2 for 5 days causes obliteration of retinal vessels, which is followed by neovascularization when the animals are returned to room air and the retina experiences hypoxia owing to vascular insufficiency. After the transfer to room air, Hif-2α expression levels in the eye are approximately 20% of normal in the hypomorphic Hif-2α mutants, and erythropoietin levels are similarly reduced. The retinas of these animals do not undergo neovascularization and instead undergo retinal degeneration. Recombinant erythropoietin restores neovascularization in mutant retinas, suggesting overlap between Hif-2α functions in regulating oxygen delivery and in hypoxia-induced neovascularization.[95]

Two other components of the HIF-1 pathway, Hif-1β (also known as aryl hydrocarbon receptor nuclear translocator) and von Hippel-Lindau syndrome tumor suppressor (VHL), have been studied in the mouse by targeted gene disruption experiments. Deficiencies in these factors have been shown to have profound impacts on vascular development, generating defects that ultimately result in embryonic lethality.[96-100] Animals deficient for Hif-1β also have defective angiogenesis in yolk sac and branchial arch arteries.[97] Defects are also seen in the placenta, where there is a failure of the labyrinth to vascularize.[98,100] The mechanism by which Hif-1β deficiency disrupts placental vascular development has not yet been established, but there has been considerable progress toward identifying the specific cell types and molecules involved.

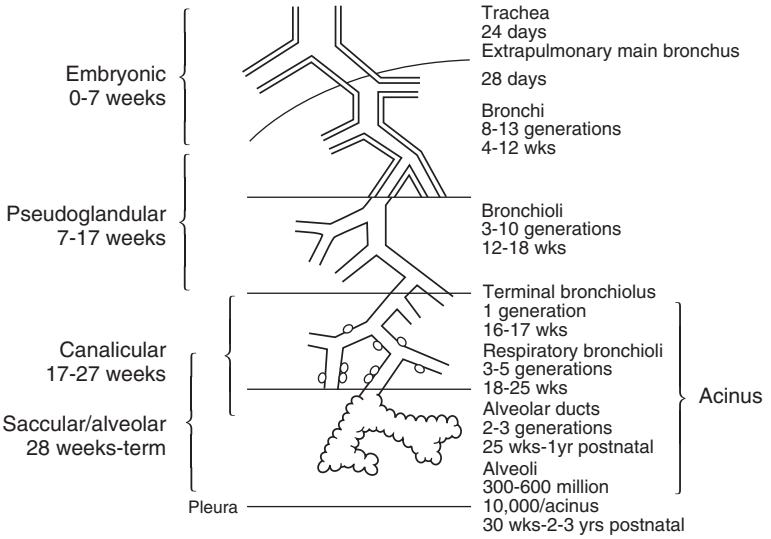
Studies in which Hif-1β–null ES cells are combined with wild-type cells, in chimeric embryos or with tetraploid embryos, demonstrate that Hif-1β function is required in the trophoblast cells rather than in the embryonic endothelial component of the placenta.[100] Placental levels of VEGF are unaltered in Hif-1β–null embryos, but VEGFR2 is significantly lower in the labyrinth endothelial, trophoblast, and giant cells.[99] Deficiency for VHL, which normally serves to "mark" the Hif-1α subunits for degradation, also results in embryonic lethality from defects in the development of the placental vasculature. On the maternal side, the capillary networks of the placenta form by angiogenesis, whereas on the embryonic side, the first capillaries develop in the allantois by vasculogenesis.[101] In VHL-deficient embryos, there is a lack of embryonic blood vessels within the placental labyrinth, which leads to the formation of a severely disrupted, hemorrhagic placental site.[96]

Certainly, VHL and Hif-1β may each have functions besides their contributions to HIF-1 action; nevertheless, the embryonic and placental defects observed in mice with deficiencies in four separate components of the HIF-1 hypoxia-response cascade (Hif-1α, Hif-2α, Hif-1β, and VHL) collectively provide strong genetic evidence for a role for oxygen tension as a regulator of cardiovascular development in utero. For the future, examining how the cellular sensing of oxygen tension is integrated with vascular morphogenesis can be expected to offer significant insight into how the developing vascular system is matched to the metabolic needs of embryonic tissues.

Development of Pulmonary Vessels



Although treatment of airway immaturity in the premature lung is a significant focus of clinical effort in neonatal intensive care units, the pathology associated with abnormal development of the pulmonary vascular bed has been one of the least-studied areas in cardiovascular biology. Establishment of a dual blood supply, considerable development after birth, and an apparent dependence on airway formation combine to make pulmonary vascular ontogeny an extremely challenging area of research. Much of what is known is currently descriptive in nature. Nevertheless, a renewed interest in this vascular bed,[102-106] accompanied by the use of new molecular-genetic tools, cellular markers, and culture models,[103,105,107-109] is beginning to provide answers to some long-standing questions and may provide novel strategies for therapeutic intervention.



Based primarily on epithelial processes, lung development has been divided into four or five stages (Figure 64-8).[110,111] The embryonic stage (26 days to 6 weeks in humans) begins with the first appearance of lung buds as outpocketings of the foregut endoderm, surrounded by splanchnic mesoderm. The pseudoglandular stage (6 to 16 weeks) is characterized by rapid and extensive epithelial branching so that by the end of this stage, all preacinar airways are present. During the canalicular stage (16 to 28 weeks), the airways continue to branch, the mesenchyme thins, capillaries come to underlie the epithelium, and effective blood-gas barriers are first formed. The epithelium differentiates into type I and type II pneumocytes, and surfactant production begins. The saccular stage (26 to 36 weeks) features division of distal air spaces into smooth-walled structures known as saccules. In the alveolar stage (36 weeks onward), the saccules are remodeled into alveoli.

The lung epithelium is closely associated with developing vasculature from the earliest stage. Differentiation of a ventral vascular plexus into which a bud of foregut endoderm protrudes was first described in 1931 by Chang[112] and has since been observed by numerous investigators using a variety of animal models.[113] The arterial system of the lung is ultimately connected through the sixth pharyngeal arch, which becomes the pulmonary artery. The venous system of the lung connects directly to the left atrium. A major issue in past decades has been whether the early vascularization of the lung and its connection to the arterial and venous systems involves vasculogenesis, angiogenesis, or some combination of the two. Incorporated in this question is the origin of the ECs in the pulmonary vessels. Are their precursors endogenous to the lung, or do they immigrate into the lung from elsewhere?

Some of the debate about the relative contributions of angiogenesis or vasculogenesis in pulmonary vascular development may reflect the limitations of the individual techniques employed. Classic histologic analysis and methods that rely on the presence of a patent lumen, such as India ink injections and resin corrosion (Mercox) casts, tend to suggest penetration of the lung primordia by angiogenic mechanisms arising from major pharyngeal arch arteries.[18] On the other hand, using marker gene expression to identify individual ECs or precursors reveals more cell behavior that is not associated with a definitive vessel, behavior characterized as vasculogenesis.[103-105,113] Figure 64-9, *A,* shows a reconstruction[105] of thorax sections from a 34-day-old human embryo, illustrating the early vascular network of the lung primordia in relation to the heart and major vessels. The presumptive pulmonary arteries and pulmonary veins are already present and associate through a capillary plexus. Sections from transgenic mice expressing β-galactosidase in all ECs (Figure 64-9, *B*) reveal a similar continuity between the future arterial, venous, and capillary vessels.[103] In the periphery of the developing pseudoglandular-stage human or mouse lung, ECs assemble into local networks before the anastomosis with the intrapulmonary arteries.[18,106] Thus vasculogenesis is responsible for much of the early lung vascular development.[106]

At this stage, two classes of ECs can already be identified: those associated with smooth muscle actin–positive mural cells, and those that are not.[106] These differences reflect distinctions between capillaries and major vessels, suggesting that extensive differentiation of the lung vasculature begins very early in lung morphogenesis. Allografts of early pseudoglandular-stage mouse lungs under the kidney capsule have been shown to allow for extensive lung development and maturation to the saccular

Stage	Mouse	Human
Embryonic	E9-14.2	3-7 wk
Pseudoglandular	E14.2-16.6	7-17 wk
Canalicular	E16-17.5	17-27 wk
Saccular	E17.5-5d p.c.	24-38 wk
Alveolar	5-30 p.c.	36.5 yrs p.c.

Figure 64-8 The critical stages of lung development, with a comparison of equivalent developmental stages in both mouse and human embryos. These stages are based on branching morphogenesis and relation to alveolar development. Comparative stages in vascular development have not yet been fully defined. *(Modified from Larsen WJ, editor:* Human Embryology, *2nd ed. New York, Churchill Livingstone, 1997, p 138; and Hislop AA: Airway and blood vessel interaction during lung development,* J Anat *201:325, 2002.)*

stage, including formation of appropriate vasculature.[108] Genetic marking of host ECs revealed that all vessels within the lung were derived from the graft. Therefore at the time of grafting the explant contained all the ECs and angioblasts required for production of the complete saccular-stage vascular tree, independent of angiogenic contributions from the extrapulmonary vasculature. Connections with the host circulation were made, but host vessels never penetrated the graft (host to graft), implying that the lung tissue prevents other vessels from entering it while maintaining the intrinsic ability to establish angiogenic connections (graft to host) with the circulatory system.

It was previously thought that the canalicular stage represented a burst of vascular growth/differentiation, but recent studies relating EC number to lung protein content (lung size) refute

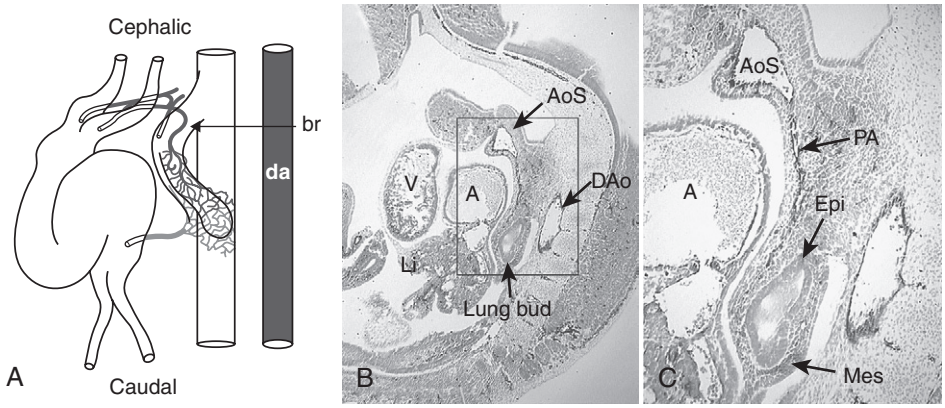


Figure 64-9 A, Diagram produced from a serial reconstruction of a 34-day human embryo, showing continuity of the lung bud capillary network with central vascular structures from the onset of lung development. Low-power **(B)** and high-power **(C)** magnification of a sagittal section through an embryonic day 10.5 mouse embryo of similar gestational age to that of the human embryo in **A.** ECs can be identified by β-galactosidase activity resulting from lacZ inserted into the Flk1 locus. The pulmonary artery *(PA)* can be seen connecting the aortic sac *(AoS)* and lung mesoderm *(Mes).* These examples document that in both human and mouse, development of the pulmonary vascular bed occurs in continuity with the major vascular structures of the embryo. *A,* Atrium of the heart; *br*, bronchus; *da,* dorsal aorta; *DAo,* dorsal aorta; *Epi*, epithelium of the lung bud; *Li,* liver; *V,* ventricle of the heart. *(Modified from Hall SM, Hislop AA, Haworth SG: Origin, differentiation, and maturation of human pulmonary veins,* Am J Respir Cell Mol Biol *26:333, 2002; and Schachtner SK, Wang Y, Scott Baldwin H: Qualitative and quantitative analysis of embryonic pulmonary vessel formation,* Am J Respir Cell Mol Biol *22:157, 2000.)*

this idea. It now appears that the pulmonary vasculature expands smoothly, rather than in a burst, so that the increase in the vasculature with gestation age largely mirrors the total growth of the lung.[103] Of importance in this period, however, is an apparent transition from vasculogenesis to angiogenesis. In particular, although undifferentiated mesenchyme in the early pseudoglandular lung is highly proliferative, the endothelium now exhibits a greater proliferative rate than the remaining mesenchyme, suggesting that the vascular network may be growing by angiogenesis as well.[105]

Lung vasculature development parallels the branching morphogensis of the lung epithelium (as reviewed by Hislop[114]), which suggests that epithelial and vascular development are somehow coordinated. This would likely demand active signaling between epithelium and ECs. Tissue recombination experiments with embryonic lung mesenchyme and epithelium confirm that the lung epithelium produces some factor(s) that promotes or maintains normal vascular development in lung mesenchyme.[109] Separating the lung mesenchyme and epithelium disrupts the normal spatial relationship between epithelium and endothelium, but recombining the separated epithelium and mesenchyme and culturing them together generates new EC patterns in appropriate positions relative to the epithelium. Furthermore, culturing lung mesenchyme in the absence of epithelium results in decreased mesenchymal proliferation and increased apoptosis, as well as a marked reduction in the number of ECs.[109]

The pulmonary ECs express VEGF receptors 1 and 2. These likely mediate signals from the nearby epithelium, which expressed VEGF ligand.[106,115-118] Early lethality of VEGF-null mutations has precluded use of these mice to study the dependence of pulmonary vascular development on VEGF, but other approaches have recently revealed the importance and complexity of VEGF signaling in the lung. Through alternative splicing, the VEGF gene produces multiple protein isoforms that differ in their abilities to bind cell-surface and ECM-associated heparan sulfate proteoglycans and the VEGF receptors (as reviewed by Neufeld and co-workers[119]).

In the mouse, there are at least three such isoforms: $VEGF_{120}$, $VEGF_{164}$, and $VEGF_{188}$, of which only $VEGF_{164}$ and $VEGF_{188}$ can bind heparan sulfate. These heparan sulfate-binding VEGFs are the predominant isoforms expressed in the developing lung.[117,118] Upon synthesis by the epithelium, VEGFs are localized to the subepithelial matrix. Heparin-bound $VEGF_{164}$ on beads implanted into pseudoglandular-stage lung explants induces neovascularization around the bead, suggesting that VEGF localized close to the distal epithelium helps direct the pattern of new blood vessel formation, linking epithelial and vascular morphogenesis.[117] Isoform-specific gene knockout experiments support this idea but also suggest that the heparan-binding VEGF isoforms may be uniquely required only for the microvessels of the pulmonary vascular tree. Mice engineered to produce $VEGF_{120}$, but not $VEGF_{164}$ or $VEGF_{188}$, survive to birth but exhibit pulmonary hypoplasia, with reductions in air spaces and multiple defects in pulmonary vasculature.[120] The diameter and branching patterns of the preacinar vessels are relatively unaffected, but animals producing only $VEGF_{120}$ have dramatically fewer small, but dilated, peripheral vessels (Figure 64-10). Blood-gas barriers are reduced in number, and intervening cells aberrantly separate the capillaries from the air space.[120] These data point to a requirement for epithelium-derived matrix-binding VEGF isoforms in the generation and proper juxtaposition of capillaries with alveolar type I cells.

Pulmonary vascular development depends upon the combinatorial action of multiple signals from the lung epithelium as well as inputs from other cell types, and the repertoire of signals is not limited to the VEGF signaling cascade. During branching morphogenesis, distal lung epithelium expresses high levels of the *Wnt7b* gene,[121] a member of the Wnt family of at least 19 mammalian growth factor genes (as reviewed by Moon[122] and Wodarz[123] and their colleagues). *Wnt7b*-deficient mice die at birth from respiratory failure associated with hypoplastic lungs that exhibit pulmonary hemorrhage. Such mice demonstrate deficiencies in the integrity of the vascular smooth muscle, including both vascular smooth muscle cell (VSMC) hypertrophy and apoptosis.[121] These observations suggest that a *Wnt7b* signal from the lung epithelium promotes mesenchymal proliferation in the early lung and later supports VSMC differentiation and survival. Together, the studies on the actions of VEGFs and *Wnt7b* indicate that the epithelium produces factors controlling

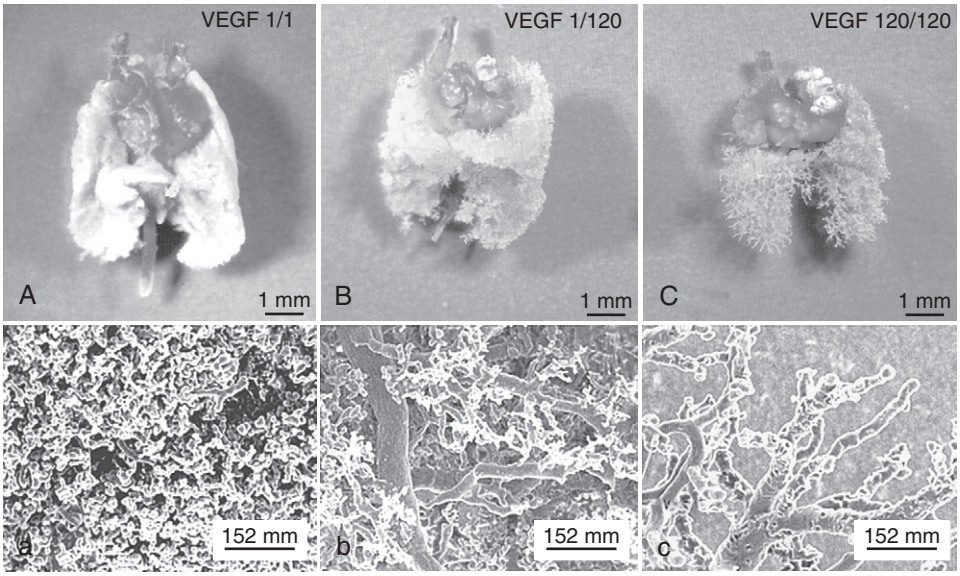

Figure 64-10 The impact of altered VEGF signaling on pulmonary vascular development. Lung resin corrosion (Mercox) casts **(A-C)** and scanning electron micrographs **(a-c)** from E17 wildtype **(A, a),** heterozygous $VEGF_{120/+}$ **(B, b),** or homozygous $VEGF_{120/120}$ mice **(C, c).** Replacement of all VEGF isoforms with $VEGF_{120}$ alone results in a marked, "dose-dependent" reduction in the number of small peripheral vessels without a noticeable impact on the preacinar vessels. *(Modified from Galambos C, Ng YS, Ali A, et al: Defective pulmonary development in the absence of heparin-binding vascular endothelial growth factor isoforms,* Am J Respir Cell Mol Biol 27*:194, 2002.)*

and supporting pulmonary vascular development at many levels that include:

- Promoting and localizing neovascularization
- Regulating vessel size
- Enabling proper association between capillaries and epithelium
- Regulating the behavior of VSMC on larger vessels

Conversely, reciprocal signaling likely occurs from the vessels to the lung epithelium because pulmonary vasculature influences epithelial morphogenesis. Interfering with VEGF signaling in the neonatal animal, normally a time of significant alveolargenesis, is an example of this phenomenon. Mice in which VEGF signaling has been blocked for the first 5 days of life have lungs that appear immature and exhibit a less complex alveolar pattern than normal, establishing that ongoing VEGF-mediated development or function or both of the vasculature is essential for normal alveolar morphogensis.[34]

Epigenetic factors like hypoxia and shear stress are almost certain to be important for pulmonary vascular development. An example from our own work on the role of oxygen tension in pulmonary vascular development is shown in Figure 64-11. Mouse lung explants cultured in 3% O_2 and 19% O_2 exhibit very different patterns of EC localization (revealed by whole-mount immunohistochemisty for the EC-specific adhesion molecule PECAM/CD31). In low-oxygen tension, comparable to that detected in utero, many PECAM-positive cells are present, and an extensive vascular network, including major vessels, is apparent. In contrast, the lungs cultured in 19% O_2 exhibit much lower levels of PECAM immunoreactivity, with most ECs present being located in clusters of small vessels near the periphery of the explant. Thus variation in oxygen tension profoundly alters EC survival and vascular patterning in developing lungs.

The relationship between oxygen tension and lung development has yet to be extensively studied at the molecular level, but recent genetic evidence suggests that the hypoxia-inducible factor Hif-2α regulates VEGF, which in turn is required for proper lung maturation, including the production of surfactant.[124]

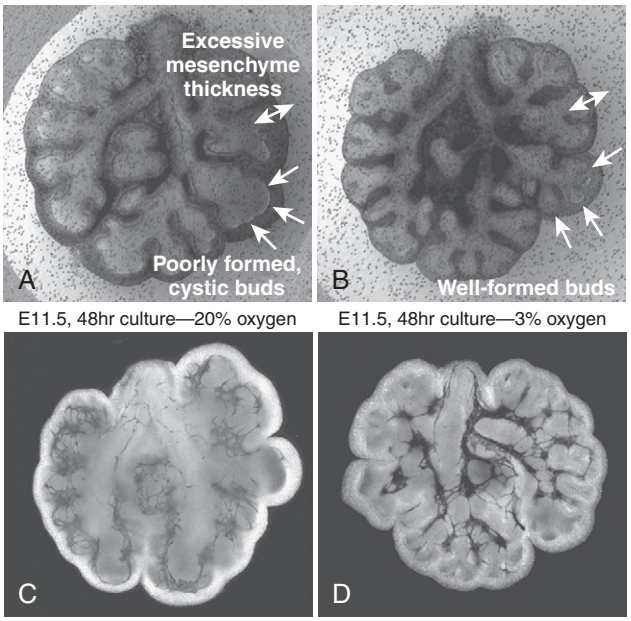

Figure 64-11 A comparison of E11.5 mouse lung buds grown under normoxia **(A, C)** or hypoxia **(B, D).** In normoxia, branching morphogenesis is diminished, with development of poorly formed cystic buds and excessive mesenchymal thickening compared with that seen in hypoxia. **C and D,** Whole-mount immunohistochemical staining with anti-PECAM/CD31 antibody to delineate vascular development. Under hypoxic conditions there is a marked accentuation in larger vessel development (in the regions surrounding the main bronchi) combined with an attenuation of endothelial differentiation surrounding the distal epithelial buds. These data suggest that hypoxia may not only affect endothelial proliferation and survival but also play a critical role in promoting the vascular remodeling required for more proximal large vessel formation.

Hif-2α–deficient animals that do not die in utero breathe irregularly at birth, are cyanotic, and succumb to severe respiratory failure within a few hours. Analysis of lung morphogenesis in these animals reveals that Hif-2α is required both before and after birth to establish an adequate lung microvasculature, to thin the alveolar septa, and to remodel the vessels juxtaposing the endothelium and type 1 pneumocytes. The lung epithelium is immature, and there is abnormally low production of surfactant phospholipids and surfactant proteins A, B, and D. The normal rise in pulmonary VEGF levels during late gestation fails to occur in Hif-2α–deficient animals, which suggests the possible involvement of VEGF in their lung pathology. Consistent with this idea, inhibiting prenatal VEGF signaling by intraamniotic injection of neutralizing antibodies to VEGFR2 results in a comparable level of lung immaturity. Conversely, respiratory distress resulting from premature delivery of mice can be alleviated by in utero or intratracheal administration of VEGF, which results in thinner alveolar septa and increased surfactant production.[124] Studies such as these reveal components of the complex interactions among oxygen tension, lung vascular development, and maturation of the lung epithelium, which may be disrupted by premature birth or oxygen therapy. Understanding such interactions has important clinical implications because disruption of the lung vasculature may contribute to poor outcomes in bronchopulmonary dyplasia, a chronic lung disease in infants that is typically associated with both premature birth and oxygen therapy for acute respiratory failure.[125]

Likewise, flow and resultant shear stress may play a significant role in pulmonary vascular development. Previous work utilizing in utero sheep models suggested that pulmonary blood flow represented only a small percentage of combined cardiac output (3.7% to 7%), with no significant increase in flow despite a dramatic increase in vascular density during the last trimester.[126] Therefore blood flow was not thought to be a primary modulator of pulmonary vascular growth. However, more recent studies on human fetuses suggest that at least 11% of the combined cardiac output from 11 to 41 weeks of gestation is directed to the lung.[127] Additional studies report a gestational increase in pulmonary blood flow from 13% to 25% of combined cardiac output by week 30 of gestation.[128] Similarly, in vitro studies suggest that flow to the pulmonary vascular bed may increase vascular morphogenesis.[129] Although the exact role of flow in pulmonary vascular development remains to be defined, it will likely play a significant role in defining optimal pulmonary development.

CONCLUSION AND FUTURE PROSPECTS

There has been an explosion of new information concerning the molecular regulation of vascular development. However, future efforts to characterize the molecular genetic pathways governing vascular morphogenesis in the lung and elsewhere will need to go beyond molecular characterization and examine the interplay of developmental genetics with shear stress, hypoxia, and other epigenetic phenomena during critical periods of development. This chapter has highlighted just a few of the molecular players that are involved in the production of the vascular system. Many more await discovery. The challenge ahead is not only to identify the interactions among molecules, cells, and environment that govern vessel morphogenesis, but also to build the growing knowledge of these interactions into useful models of vascular development that can help us understand vascular system defects and direct future therapeutic interventions.

65 Cardiomyopathies in Infants and Children

Jeffrey A. Towbin, John Lynn Jefferies, and Matteo Vatta

Cardiomyopathies are major causes of morbidity and mortality, and, over the past 20 years, limited improvements in outcome have been reported.[1-3] However, improvement in the understanding of the major forms of cardiomyopathy has occurred over that time, in large part because of advances in genetics and genomics.[4,5] In addition, new forms of cardiomyopathy have been described and classified over that time frame, in large part because of our improved genetic-based understanding of heart muscle disease. Further, the improved understanding gained in heart muscle disease has led to understanding of similarities and differences in heart and skeletal muscle and their often overlapping clinical presentations.

A new classification scheme was recently developed for the cardiomyopathies in which five forms of disease were formally classified as distinct forms of cardiomyopathy.[6] These forms are dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM), restrictive cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, and left ventricular noncompaction (LVNC). These were further classified into genetic/inherited forms and acquired/noninherited forms.[6] All of these forms of disease occur in childhood, including at birth or in the first weeks of life in many cases, although arrhythmogenic right ventricular cardiomyopathy is almost always identified in young adults, and therefore this disorder will not be discussed herein.

To understand the mechanisms responsible for the development of the clinical phenotypes of cardiomyopathies, an understanding of normal cardiac structure is necessary.

NORMAL CARDIAC STRUCTURE

Cardiac muscle fibers are composed of separate cellular units (myocytes) connected in series.[7] In contrast to skeletal muscle fibers, cardiac fibers do not assemble in parallel arrays but bifurcate and recombine to form a complex three-dimensional network. Cardiac myocytes are joined at each end to adjacent myocytes at the intercalated disk, the specialized area of interdigitating cell membrane (Figure 65-1). The intercalated disk contains gap junctions (containing connexins) and mechanical junctions, composed of adherens junctions (containing N-cadherin, catenins, and vinculin) and desmosomes (containing desmin, desmoplakin, desmocollin, desmoglein). Cardiac myocytes are surrounded by a thin membrane (sarcolemma), and the interior of each myocyte contains bundles of longitudinally arranged myofibrils. The myofibrils are formed by repeating sarcomeres, the basic contractile units of cardiac muscle composed of interdigitating thin (actin) and thick (myosin) filaments (see Figure 65-1), that give the muscle its characteristic striated appearance.[8,9] The thick filaments are composed primarily of myosin but additionally contain myosin-binding proteins C, H, and X. The thin filaments are composed of cardiac actin, α-tropomyosin (α-TM), and troponins T, I, and C (cTnT, cTnI, cTnC). In addition, myofibrils contain a third filament formed by the giant filamentous protein, titin, which extends from the Z disk to the M line and acts as a molecular template for the layout of the sarcomere. The Z disk at the borders of the sarcomere is formed by a lattice

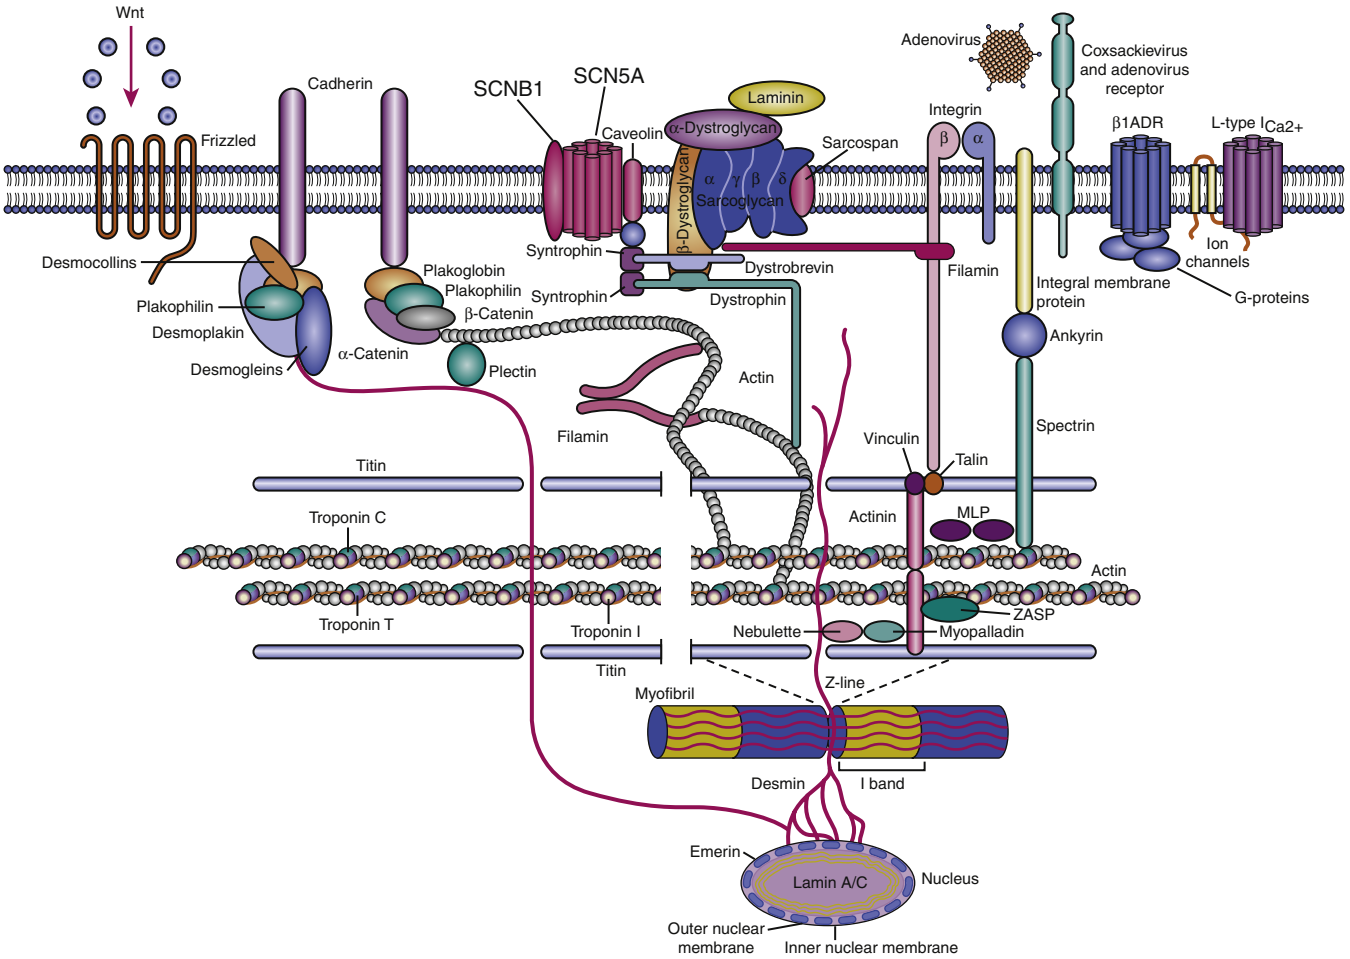

Figure 65-1 Cardiac myocyte cytoarchitecture. Schematic of the interactions between dystrophin and the dystrophin-associated proteins in the sarcolemma and intracellular cytoplasm (dystroglycans, sarcoglycans, syntrophins, dystrobrevin, sarcospan) at the carboxy-terminal end of the dystrophin. The integral membrane proteins interact with the ECM via α-dystroglycan–α_2-laminin connections. The amino-terminus of dystrophin binds actin and connects dystrophin with the sarcomere intracellularly, the sarcolemma, and ECM. Additional sarcolemmal proteins include ion channels, adrenergic receptors, integrins, and the Coxsackie and adenoviral receptor. Cell-cell junctions, including cadherins, the plakin, and other desmosomal family proteins, are also notable. Also shown is the interaction between intermediate filament proteins (i.e., desmin) with the nucleus. *MLP,* Muscle LIM protein.

of interdigitating proteins that maintain myofilament organization by crosslinking antiparallel titin and thin filaments from adjacent sarcomeres (Figure 65-2). Other proteins in the Z disk include α-actinin, nebulette, telethonin/T-cap, capZ, muscle LIM protein (MLP), myopalladin, myotilin, Cypher/ZASP, filamin, and FATZ.[8-10]

Finally, the extrasarcomeric cytoskeleton, a complex network of proteins linking the sarcomere with the sarcolemma and the extracellular matrix (ECM), provides structural support for subcellular structures and transmits mechanical and chemical signals within and between cells. The extrasarcomeric cytoskeleton has intermyofibrillar and subsarcolemmal components, with the intermyofibrillar cytoskeleton composed of intermediate filaments, microfilaments, and microtubules.[11,12] Desmin intermediate filaments form a three-dimensional scaffold throughout the extrasarcomeric cytoskeleton with desmin filaments surrounding the Z disk, allowing for longitudinal connections to adjacent Z disks and lateral connections to subsarcolemmal costameres.[12] Microfilaments composed of nonsarcomeric actin (mainly γ-actin) also form complex networks linking the sarcomere (via α-actinin) to various components of the costameres. Costameres are subsarcolemmal domains located in a periodic, gridlike pattern, flanking the Z disks and overlying the I bands, along the cytoplasmic side of the sarcolemma. These costameres are sites of interconnection between various cytoskeletal networks linking sarcomere and sarcolemma and are thought to function as anchor sites for stabilization of the sarcolemma and for integration of pathways involved in mechanical force transduction. Costameres contain three principal components: the focal adhesion-type complex, the spectrin-based complex, and the dystrophin/dystrophin-associated protein complex (DAPC).[13,14] The focal adhesion-type complex, composed of cytoplasmic proteins (i.e., vinculin, talin, tensin, paxillin, zyxin), connects with cytoskeletal actin filaments and with the transmembrane proteins α- and β-dystroglycan; α-, β-, γ-, and δ-sarcoglycans; dystrobrevin; and syntrophin. Several actin-associated proteins are located at sites of attachment of cytoskeletal actin filaments with costameric complexes, including α-actinin and MLP. The C-terminus of dystrophin binds β-dystroglycan (see Figure 65-1), which in turn interacts with α-dystroglycan to link to the ECM (via α_2-laminin). The N-terminus of dystrophin interacts with actin. Also notable, voltage gated sodium channels colocalize with dystrophin, β-spectrin, ankyrin, and syntrophins, and potassium channels interact with the sarcomeric Z disk and intercalated

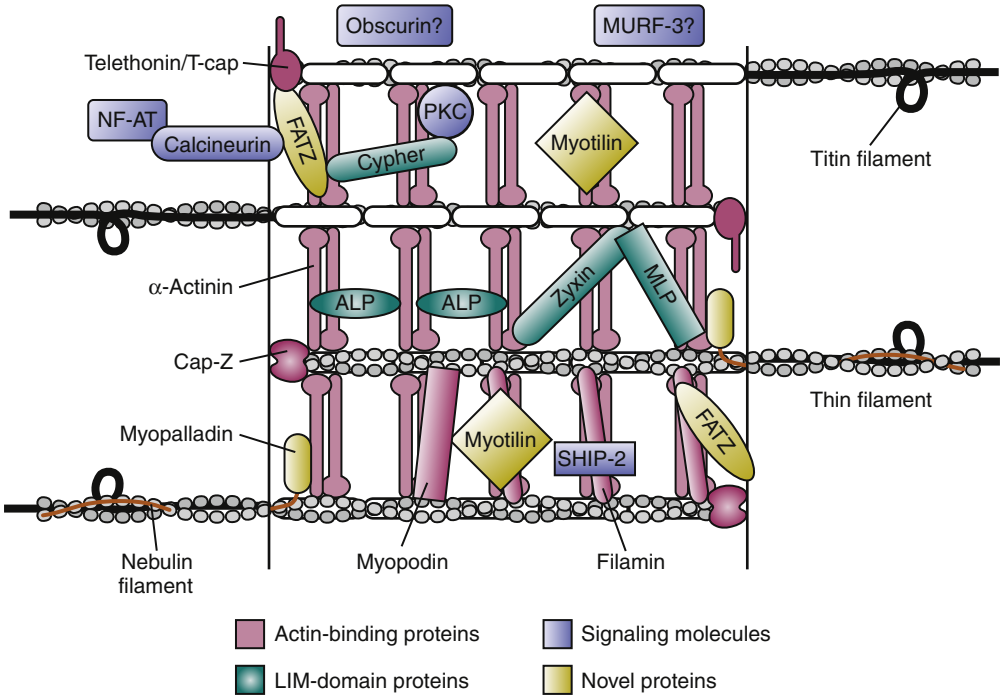

Figure 65-2 Z disk architecture. The Z disk of the sarcomere is composed of multiple interacting proteins that anchor the sarcomere. *(From Clark KA, McElhinny AS, Beckerle MC, Gregorio CC: Striated muscle cytoarchitecture: an intricate web of form and function,* Ann Rev Dev Biol *18:637-706, 2002. With permission.)*

disks.[15,16] Because arrhythmias and conduction system diseases are common in children and adults with DCM, this could play an important role. Hence, disruption of the links from the sarcolemma to ECM at the dystrophin C-terminus and those to the sarcomere and nucleus via N-terminal dystrophin interactions could lead to a "domino effect" disruption of systolic function and development of arrhythmias.

DILATED CARDIOMYOPATHY

DCM, the most common form of cardiomyopathy, is characterized primarily by left ventricular (LV) dilation and systolic dysfunction (Figure 65-3). Increasingly recognized, right ventricular function and diastolic function are also abnormal. In children, the annual incidence of DCM is 0.57 cases per 100,000 per year overall but is higher in boys than in girls (0.66 versus 0.47 cases per 100,000; $p < .001$), in blacks than in whites (0.98 versus 0.46 cases per 100,000; $p < .001$), and in infants (<1 year) than in children (4.40 versus 0.34 cases per 100,000; $p < .001$). The majority of children (66%) are thought to have idiopathic disease.[17] The mortality rate in the United States resulting from cardiomyopathy is greater than 10,000 deaths per annum, with DCM being the major contributor.[1] The total cost of health care in the United States focused on cardiomyopathies is in the billions of dollars, and only limited success has been achieved. To achieve improved care and outcomes in children and adults, understanding of the causes of these disorders has been sought.

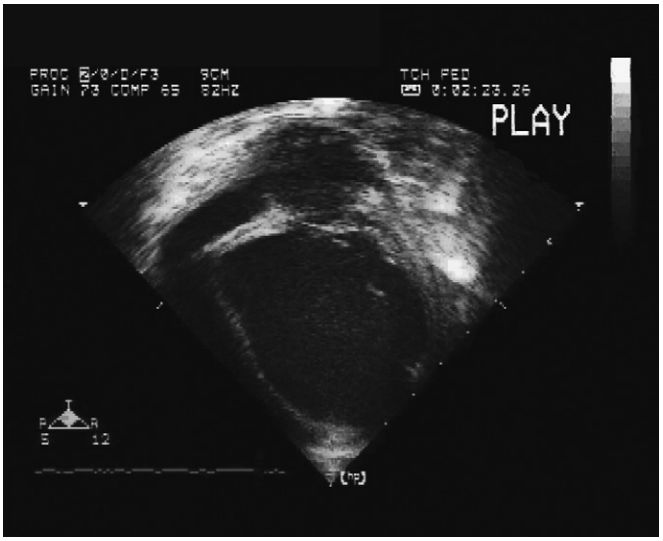

Figure 65-3 Echocardiography in DCM. Apical four-chamber view demonstrating a dilated left ventricle. In real time, the systolic function is depressed.

Etiologies of Dilated Cardiomyopathy

The clinical appearance of DCM, a dilated left ventricle with poor contractile performance, occurs for a variety of causes. These include genetic and acquired etiologies. Acquired forms of disease include myocarditis, usually the result of viral infection; chemotherapy-induced cardiomyopathy; intrauterine disorders such as placental insufficiency and nonimmune hydrops; and acute stress such as hypoxia. In addition, DCM can develop because of genetic-based disease. These genetic disorders include inherited forms of disease, cardioskeletal disease such as muscular dystrophies, and metabolic forms of disease.

Clinical Genetics of Dilated Cardiomyopathy

DCM was initially believed to be inherited in a small percentage of cases until Michels and co-workers[18] showed that approximately 20% of probands had family members with echocardiographic

evidence of DCM when family screening was performed. More recently, inherited, familial DCM has been shown to occur in 30% to 40% of cases[4] with autosomal dominant inheritance being the predominant pattern of transmission; X-linked, autosomal recessive, and mitochondrial inheritance is less common.

Molecular Genetics of Dilated Cardiomyopathy

DCM has become a popular target of research over the past 10 to 15 years, with multiple genes identified during that time period (Table 65-1). These genes appear to encode two major subgroups of proteins, cytoskeletal and sarcomeric proteins.[4] The cytoskeletal proteins identified to date include dystrophin, desmin, lamin A/C, δ-sarcoglycan, β-sarcoglycan, and metavinculin. In the case of sarcomere-encoding genes, the same genes identified for HCM appear to be culprits and include β-myosin heavy chain, myosin binding protein C, actin, α-TM, and cTnT. A new group of sarcomeric genes, those encoding Z-disk proteins, have also been identified and include Cypher/ZASP,[1,3,5] MLP, and α-actinin-2.[1,3,5] In addition, phospholamban and G4.5/tafazzin have also been reported. Another form of DCM, the acquired disorder viral myocarditis, has the same clinical features as DCM including heart failure, arrhythmias, and conduction block.[1,5] The most common causes of myocarditis are viral, including the enteroviruses (coxsackieviruses and echovirus), adenoviruses, and parvovirus B19, among other cardiotropic viruses.[1] Evidence exists that suggests that viral myocarditis and DCM (genetic) have similar mechanisms of disease on the basis of the proteins targeted.

Initial progress was made in understanding the familial forms of DCM by studying families with X-linked forms of DCM. Autosomal dominant forms of DCM began to unravel only over the past few years. In the case of X-linked forms of DCM, three disorders have been well characterized: X-linked cardiomyopathy (XLCM), which presents in adolescence and young adults; Barth syndrome, which is most frequently identified in infancy[19,20]; and Danon disease, which most typically presents with HCM with later-onset DCM, although this presentation can be variable.

X-LINKED CARDIOMYOPATHIES

X-Linked Dilated Cardiomyopathy

First described in 1987 by Berko and Swift[19] as DCM occurring in males in the teen years and early twenties with rapid progression from congestive heart failure (CHF) to death caused by ventricular tachycardia/ventricular fibrillation or transplantation, the condition in these patients is distinguished by elevated serum creatine kinase muscle isoforms (CKMM). Female carriers tend to have development of mild to moderate DCM in the fifth decade, and the disease is slowly progressive. Towbin and colleagues (1993)[21] were the first to identify the disease-causing gene and characterize the functional defect. In this report, the dystrophin gene was shown to be responsible for the clinical abnormalities, and protein analysis by immunoblotting demonstrated severe reduction or absence of dystrophin protein in the heart of these patients. These findings were later confirmed by Muntoni and associates[22] when a mutation in the muscle promoter and exon 1 of dystrophin was identified in another family with XLCM. Subsequently, multiple mutations have been identified in dystrophin in patients with XLCM.

Dystrophin is a cytoskeletal protein that provides structural support to the myocyte by creating a latticelike network to the sarcolemma.[23] In addition, dystrophin plays a major role in linking the sarcomeric contractile apparatus to the sarcolemma and ECM.[23-26] Furthermore, dystrophin is involved in cell signaling, particularly through its interactions with nitric oxide synthase. The dystrophin gene is responsible for Duchenne and Becker muscular dystrophy (DMD and BMD) when mutated as well.[27] These skeletal myopathies present early in life (DMD is diagnosed before age 12 years, and BMD is seen in teenaged males older than 16 years), and the vast majority of patients have DCM before the twenty-fifth birthday. In most patients, CKMM is elevated similar to that seen in XLCM; in addition, manifesting female carriers have disease late in life, similar to XLCM. Furthermore, immunohistochemical analysis demonstrates reduced levels (or absence) of dystrophin, similar to that seen in the hearts of patients with XLCM.

TABLE 65-1

Dilated Cardiomyopathy Genetics

Chromosome locus	Gene	Protein
Xp21.2	DYS	Dystrophin
Xq28	G4.5	Tafazzin
1q21	LMNA	Lamin A/C
1q32	TNNT2	Cardiac troponin T
1q42-43	ACTN	α-Actinin-2
2q31	TTN	Titin
2q35	DES	Desmin
5q33	SGCD	δ-Sarcoglycan
6q22.1	PLN	Phospholamban
10q22.3-23.2	ZASP/Cypher	ZASP
10q22-q23	VCL	Metavinculin
11p11	MYBPC3	Myosin binding protein C
11p15.1	MLP	Muscle LIM protein
14q12	MYH7	β-Myosin heavy chain
15q14	ACTC	Cardiac actin
15q22	TPM1	α-Tropomyosin

Murine models of dystrophin deficiency demonstrate abnormalities of muscle physiology based on membrane structural support abnormalities.[28] In addition to the dysfunction of dystrophin, mutations in dystrophin secondarily affect proteins that interact with dystrophin. At the amino-terminus (N-terminus), dystrophin binds to the sarcomeric protein actin, a member of the thin filament of the contractile apparatus. At the carboxy-terminus (C-terminus), dystrophin interacts with α-dystroglycan, a dystrophin-associated membrane-bound protein that is involved in the function of the DAPC, which includes β-dystroglycan, the sarcoglycan subcomplex (α-, β-, γ-, δ-, and ε-sarcoglycan), syntrophins, and dystrobrevins[29-31] (see Figure 65-1). In turn, this complex interacts with α_2-laminin and the ECM.[32] Like dystrophin, mutations in these genes lead to muscular dystrophies with or without cardiomyopathy, supporting the contention that this group of proteins is important to the normal function of the myocytes of the heart and skeletal muscles.[32,33] In both cases, mechanical stress[28] appears to play a significant role in the age onset–dependent dysfunction of these muscles. The information gained from the studies on XLCM, DMD, and BMD led us to hypothesize that DCM is a disease of the cytoskeleton/sarcolemma that affects the sarcomere,[34] a "final common pathway" of DCM.[35] We also have suggested that dystrophin mutations play a role in idiopathic DCM in males. This is supported when we showed that 3 of 22 boys with DCM had dystrophin mutations, and all were later found to have elevated CKMM as well.[36] In addition, eight families with DCM and possible X-linked inheritance were screened, and in three of eight families dystrophin mutations were noted. Again, CKMM was elevated in all subjects carrying mutations.[37]

Barth Syndrome

Initially described as X-linked cardioskeletal myopathy with abnormal mitochondria and neutropenia by Neustein and colleagues[38] and Barth and co-workers,[39] this disorder typically presents in male infants as CHF associated with neutropenia (cyclic) and 3-methylglutaconic aciduria.[40] Mitochondrial dysfunction

is noted on electron microscopy and electron transport chain biochemical analysis. Recently, abnormalities in cardiolipin have been noted.[41] Echocardiographically these infants typically have LV dysfunction with LV dilation, endocardial fibroelastosis, or a dilated hypertrophic left ventricle. In some cases these infants succumb because of CHF/sudden death, ventricular tachycardia/ventricular fibrillation, or sepsis caused by leukocyte dysfunction. The majority of these children survive through infancy and do well clinically, although DCM usually persists. In some cases, cardiac transplantation has been performed. Histopathologic evaluation typically demonstrates the features of DCM, although endocardial fibroelastosis may be prominent and the mitochondria are abnormal in shape and abundance.

The genetic basis of Barth syndrome was first described by Bione and colleagues,[42] who cloned the disease-causing gene, G4.5. This gene encodes a novel protein called tafazzin, whose gene product is an acyltransferase and results in cardiolipin abnormalities.[41] Mutations in G4.5 result in a wide clinical spectrum, which includes apparent classic DCM, hypertrophic DCM, endocardial fibroelastosis, or LV noncompaction.[4,43]

The final form of X-linked disease, Danon disease, will be discussed in the section on HCM caused by infiltrative disease.

AUTOSOMAL DOMINANT DILATED CARDIOMYOPATHY

The most common form of inherited DCM is the autosomal dominant form of disease.[1,4,5] These patients present as classic "pure" DCM or DCM associated with conduction system disease (CDDC). In the latter case, patients usually present in the third decade of life with mild CDDC that can progress to complete heart block over decades. DCM usually presents late in the course but is out of proportion to the degree of CDDC.[44] The echocardiographic and histologic findings in both subgroups are classic for DCM, although the conduction system may be fibrotic in patients with CDDC. In both groups of patients with DCM, ventricular tachycardia, ventricular fibrillation, and torsades de pointes occur and may result in sudden death.

Genetic heterogeneity exists for autosomal dominant DCM with more than 15 loci mapped for pure DCM and five loci for CDDC.[3] In the case of pure DCM, 10 genes have been identified to date, including three by our group (δ-sarcoglycan, α-actinin-2, ZASP),[4,5,45] as well as actin, desmin, troponin T, β-myosin heavy chain, titin, metavinculin, myosin binding protein C, α-tropomyosin, MLP, β-sarcoglycan, and phospholamban[4,46,47] (see Table 65-1).

The majority of genes identified to date encode either cytoskeletal or sarcomeric proteins. In the case of cytoskeletal proteins (desmin, δ-sarcoglycan, metavinculin, MLP), defects of force transmission are considered to result in the DCM phenotype, whereas defects of force generation have been speculated to cause sarcomeric protein–induced DCM.[4,34]

Cardiac actin is a sarcomeric protein that is a member of the sarcomeric thin filament interacting with tropomyosin and the troponin complex. As previously noted, actin plays a significant role in linking the sarcomere to the sarcolemma via its binding to the N-terminus of dystrophin, and the mutations in actin that resulted in DCM as described by Olson and associates.[48] appear to be directly involved in the binding of dystrophin. The DCM-causing mutations are believed to result by causing force transmission abnormalities. Further, actin interacts in the sarcomere with TnT and β-MHc, two other genes resulting in either DCM or HCM depending on the position of the mutation.[49] In the case of TnT and β-MHC, force generation abnormalities have been speculated as the responsible mechanism.

Desmin is a cytoskeletal protein that forms intermediate filaments specific for muscle.[12] This muscle-specific 53 kDa subunit of class III intermediate filaments forms connections between the nuclear and plasma membranes of cardiac, skeletal, and smooth muscle. Desmin is found at the Z lines and intercalated disk of muscle, and its role in muscle function appears to involve attachment or stabilization of the sarcomere. Mutations in this gene appear to cause abnormalities of force and signal transmission similar to that believed to occur with actin mutations.[50]

Another DCM-causing gene, δ-sarcoglycan is a member of the sarcoglycan subcomplex of the DAPC.[45,51] This gene encodes for a protein involved in stabilization of the myocyte sarcolemma, as well as signal transduction. Mutations identified in familial and sporadic cases resulted in reduction of the protein within the myocardium. In the absence of δ-sarcoglycan, the remaining sarcoglycans (δ, β, γ, Σ) cannot assemble properly in the endoplasmic reticulum.[52] Mouse models of δ-sarcoglycan deficiency demonstrate dilated HCM, sarcolemmal fragility, and disrupted vasculin smooth muscle, which leads to vascular spasm, including coronary spasm.[53,54] In addition, mutations in this gene lead to the phenotype of the cardiomyopathic Syrian hamster.[55] Other human mutations in δ-sarcoglycan cause a form of autosomal recessive limb girdle muscular dystrophy (LGMD2F) that rarely is associated with heart disease.

The final cytoskeletal protein-encoding gene, metavinculin, encodes vinculin and its splice variant metavinculin. Vinculin is ubiquitously expressed, and metavinculin is coexpressed with vinculin in heart, skeletal, and smooth muscle, with this protein complex localized to subsarcolemmal costameres in the heart where they interact with α-actinin, talin, and γ-actin to form a microfilamentous network linking cytoskeleton and sarcolemma. In addition, these proteins are present in adherens junctions in intercalated disks and participate in cell-cell adhesion. Mutations in metavinculin have been shown to disrupt the intercalated disks and alter actin filament crosslinking.[56,57]

Mutations in the sarcomere may produce HCM or DCM. In the latter case, abnormalities in force generation or transmission are thought to contribute to the development of this phenotype.[49] In addition to mutations in the thin filament protein actin, mutations in the thick filament protein-encoding gene β-myosin heavy chain have been shown to cause DCM with associated sudden death in at least one infant, as well as DCM in older children and adults.[49,58] Mutations in this gene are thought to perturb the actin-myosin interaction and force generation or alter cross-bridge movement during contraction. Mutations in cardiac troponin T, a thin filament protein, have been speculated to disrupt calcium-sensitive troponin C binding.[49,58] Mutations in phospholamban[59,60] have also been identified that further support calcium handling as a potentially important mechanism in the development of DCM. Interestingly, Haghihi and co-workers.[60] identified homozygous mutations causing DCM and heart failure, whereas heterozygotes had cardiac hypertrophy. Recessive mutation in troponin I is thought to impair the interaction with troponin T, and α-tropomyosin mutations have also been identified and were predicted to alter the surface charge of the protein leading to impaired interaction with actin.[61,62]

A recent area of interest for evaluation at the molecular level is the Z disk.[63] Knoll and co-workers[64] identified mutations in MLP and demonstrated that this results in defects in the interaction with telethonin.[64] Using mouse models, they also demonstrated that MLP acts as a stretch sensor and that mutant MLP causes defects in this activity. More recently, mutations in MLP in families and sporadic cases were described, and, in addition, abnormalities were identified in the T-tubule system[4] and Z-disk architecture by electron microscopy, which correlates with the histopathology seen in MLP-knockout mice.[65] This was further supported by the finding of reduced expression of MLP in chronic human heart failure.[66,67] In addition, mutations in α-actinin-2, which is involved in crosslinking actin filaments and shares a common actin binding domain with dystrophin, were also identified in familial DCM, which disrupts its binding

to MLP.[5] Vatta and associates[4] identified mutations in the Z band alternatively spliced PDZ-motif protein ZASP, the human homolog of the mouse Cypher gene that when disrupted leads to DCM.[68] Multiple mutations in this gene were identified in families and sporadic cases of DCM and with LVNC. This protein, which interacts with α-actinin-2, disrupts the actin cytoskeleton when mutated. Another gene, titin, which encodes the giant sarcomeric cytoskeletal protein titin that contributes to the maintenance of the sarcomere organization and myofibrillar elasticity, interacts with these proteins at the Z-disk/I-band transition zone.[69] Mutations have been identified in familial DCM as well.[70]

As seen in pure autosomal dominant DCM, genetic heterogeneity also exists for CDDC. To date, CDDC genes have been mapped to chromosomes 1p1-1q1, 2q14-21, 3p25-22, and 6q23. The only gene thus far identified was reported to be lamin A/C on chromosome 1q21, which encodes a nuclear envelope intermediate filament protein.[71,72]

Lamin A/C

The lamins are located in the nuclear lamina at the nucleoplasmic side of the inner nuclear membrane, and lamin A and C are expressed in heart and skeletal muscle.[73] Mutations in this gene were initially reported to cause the autosomal dominant form of Emery-Dreifuss muscular dystrophy,[74,75] which has skeletal myopathy associated with DCM and CDDC. It has also been found to cause a form of autosomal dominant limb girdle muscular dystrophy (LGMD1B), which is also associated with CDDC.[76] Multiple mutations have been identified in patients with CDDC, who, in some cases, had mildly elevated CK. This gene defect appears to be relatively common in patients with CDDC. The mechanism(s) responsible for the development of DCM and conduction system abnormalities and of skeletal myopathy is being determined.[77] Understanding may be aided by understanding how other genes that encode interacting proteins result in disease, such as thymopoietin.[78]

Muscle Is Muscle: Cardiomyopathy and Skeletal Myopathy Genes Overlap

Interestingly, nearly all of the genes identified for inherited DCM are also known to cause skeletal myopathy in humans and/or mouse models. In the case of dystrophin, mutations cause DMD and BMD whereas δ-sarcoglycan mutations cause LGMD2F. Lamin A/C has been shown to cause autosomal dominant Emery-Dreifuss muscular dystrophy and LGMD1B whereas actin mutations are associated with nemaline myopathy. Desmin, G4.5, α-dystrobrevin, Cypher/ZASP, MLP, α-actinin-2, titin, and δ-sarcoglycan mutations also have associated skeletal myopathy, suggesting that cardiac and skeletal muscle function is interrelated and that possibly the skeletal muscle fatigue seen in patients with DCM with and without CHF may be due to primary skeletal muscle disease and not only related to the cardiac dysfunction. It also suggests that the function of these muscles has a final common pathway and that both cardiologists and neurologists should consider evaluation of both sets of muscles.

Further support for this concept comes from studies of animal models. Mutations in δ-sarcoglycan in hamsters result in cardiomyopathy whereas mutations in all sarcoglycan subcomplex genes in mice cause skeletal and cardiac muscle disease. Mutations in other DAPC genes, as well as dystrophin in murine models, also consistently demonstrate abnormalities of skeletal and cardiac muscle function. Arber et al.[65] also produced a mouse deficient in MLP, a structural protein that links the actin cytoskeleton to the contractile apparatus. The resultant mice develop severe DCM, CHF, and disruption of cardiac myocyte cytoskeletal architecture. Murine mutations in titin, Cypher, α-dystrobrevin, desmin, and other all demonstrate cardiac and skeletal muscle disease. Finally, Badorff and colleagues[79] have shown that the DCM that develops after viral myocarditis has a mechanism similar to that of the inherited forms. Using coxsackievirus B3 infection of mice, the authors showed that the coxsackievirus B3 genome encodes for a protease (enteroviral protease 2A) that cleaves dystrophin at the third hinge region of dystrophin, resulting in force transmission abnormalities and DCM. In addition, Xiong and co-workers[80] showed that abnormal dystrophin increases susceptibility to viral infection and resultant myocarditis. Interestingly, a similar dystrophin mutation that affects the first hinge region of dystrophin in patients with XLCM was previously reported by our laboratory, demonstrating a consistent mechanism of DCM development, abnormalities of the cytoskeleton/sarcolemma and sarcomere. In addition, we have shown that N-terminal dystrophin is reduced or absent in hearts of patients with all forms of DCM (ischemic, acquired, genetic, idiopathic) and that reduction of mechanical stress by use of LV assist devices results in reverse remodeling of dystrophin and of the heart itself.[81,82]

HYPERTROPHIC CARDIOMYOPATHY

HCM is characterized by asymmetric or concentric wall thickening (Figure 65-4), hence the term hypertrophic heart disease.[83-85] However, the major impact of this disorder on human health is its predilection to be inherited; its reputation as the most common cause of sudden death in young, healthy, athletic individuals[86-89]; and its potential to develop heart failure.[90-92] In the latter case, heart failure can occur because of diastolic factors or can occur because of the development of systolic dysfunction, so-called burned-out HCM.[90-92] No matter what the cause of untoward clinical features, HCM plays a significant role in our health care monetary burden, as well as the untold price of the tragedies in affected families.

In the pediatric age range, the underlying etiologies responsible for the disease and the variable age range of onset differentiates further the childhood form of disease from the adult counterpart.[93] In very young children (i.e., less than 1 year of age), ventricular hypertrophy associated with systolic dysfunction is more the rule than the exception. In addition, overlap disorders in which HCM coexists with other atypical features are also more common during childhood, further confounding the presentations, treatments, and outcomes compared with adult disease.

Clinical Aspects of Hypertrophic Cardiomyopathy

HCM is a primary myocardial disorder with an autosomal dominant pattern of inheritance that is characterized by hypertrophy of the left (± right) ventricle with histologic features of myocyte hypertrophy, myofibrillar disarray, and interstitial fibrosis.[83-85] HCM is one of the most common inherited cardiac disorders, with a prevalence in young adults of 1 in 500.[85] Various names have been given to this disorder including hypertrophic obstructive cardiomyopathy and idiopathic subaortic stenosis. These names reflect "textbook" features of asymmetric septal hypertrophy and LV outflow tract obstruction. This description of the disease is based primarily on patients with severe symptoms seen in tertiary hospital referral centers. Epidemiologic studies now suggest that a wide spectrum of clinical manifestations of varying severity and prognosis is present in community populations. The first clinical description of HCM was reported in 1869[94] in France, and it was recognized to be a genetic disorder in the late 1950s. Since then, numerous clinical and pathologic studies of HCM have been performed. During the last 15 years, molecular genetic studies have given important insights into the pathogenesis of HCM and have provided a new perspective for the diagnosis and management of patients with this disorder.[95]

Genetics of Familial Hypertrophic Cardiomyopathy

The first gene for familial hypertrophic cardiomyopathy (FHC) was mapped to chromosome 14q11.2-q12 by using genome-wide linkage analysis in a large Canadian family.[96] Soon afterward, FHC locus heterogeneity was reported[97] and subsequently confirmed by the mapping of the second FHC locus to chromosome 1q3 and of the third locus to chromosome 15q2.[98,99] Carrier and associates.[100] mapped the fourth FHC locus to chromosome 11p11.2. Multiple other loci were subsequently reported, including loci on chromosomes[101-108] (Figure 65-5).

Gene Identification in Familial Hypertrophic Cardiomyopathy

The majority of the disease-causing genes identified to date code for proteins that are part of the sarcomere, which is a complex structure with an exact stoichiometry and multiple sites of protein-protein interactions.[95,109,110] These include three myofilament proteins: the β-myosin heavy chain (β-MyHC), the ventricular myosin essential light chain 1 (MLC-1s/v), and the ventricular myosin regulatory light chain 2 (MLC-2s/v); four thin filament proteins: cardiac actin, cTnT, cTnI, and α-TM; and one myosin-binding protein, the cardiac myosin binding protein C (cMyBP-C) (Table 65-2). Each of these proteins is encoded by multigene families that exhibit tissue-specific, developmental, and physiologically regulated patterns of expression.[111] The giant protein titin[105] and its interactive Z-disk protein, MLP, have also been identified.[106] In addition, the gene located on chromosome 7q3 associated with HCM and Wolff-Parkinson-White (WPW) syndrome was identified as AMP kinase (AMPK), which has been suggested to play a role in energy metabolism and cause infiltration of a glycogen-like substance similar to that seen in Pompe disease.[112-114]

Thick Filament Proteins

Myosin Subunits

Myosin is the molecular motor that transduces energy from the hydrolysis of adenosine triphosphate (ATP) into directed movement and that, by doing so, drives sarcomere shortening and muscle contraction. Cardiac myosin consists of two heavy chains (MyHC) and two pairs of light chains (MLC), referred to as essential (or alkali) light chains (MLC-1) and regulatory (or phosphorylatable) light chains (MLC-2), respectively.[111] The myosin molecule is highly asymmetric, consisting of two globular heads joined to a long rodlike tail. The light chains are arranged in tandem in the head-tail junction. Their function is not fully understood. Neither MLC type is required for the adenosine triphosphatase (ATPase) activity of the myosin head, but they probably modulate it in the presence of actin and contribute power stroke. Mutations have been found in the heavy chains and in the two types of ventricular light chains.

Concerning the heavy chains, the β isoform (β-MyHC) is the major isoform of the human ventricle and of slow-twitch skeletal fibers. It is encoded by MYH7. This gene appears to be the most commonly mutated HCM gene, and hot spots for mutations have been identified.[95,109,115] The majority of mutations are missense mutations located either in the head or in the head-rod junction of the molecule. On the basis of their structural location in the myosin head, the majority of mutations are likely to disrupt both mechanical and catalytic components of actin-myosin interactin, resulting in reduced force generation. Sarcomere assembly is also likely to be disrupted. Mutations in the light meromyosin domain have also been identified, and Blair and colleagues[115] speculated that HCM develops in this case because of abnormalities of myosin filament assembly or interactions with thick filament binding proteins.

The MLC isoforms are expressed in the ventricular myocardium and in the slow-twitch muscles and are the so-called ventricular myosin regulatory light chains (MLC-2s/v) encoded by MYL2 and the ventricular myosin essential light chain (MLC-1s/v) encoded by MYL3. The MLCs are thought to influence the mechanical efficiency of cross-bridge cycling and speed of contraction. It is believed that these proteins regulate power output via a calcium-dependent mechanism, and disruption leads to the HCM phenotype.

Myosin-binding Protein C

MyBP-C is part of the thick filaments of the sarcomere, being located at the level of the transverse stripes, 43 nm apart, seen by electron microscopy in the sarcomere A band. Its function is uncertain, but, for more than a decade, evidence has existed to indicate both structural and regulatory roles. Partial extraction of cMyBP-C from rat skinned cardiac myocytes and rabbit skeletal

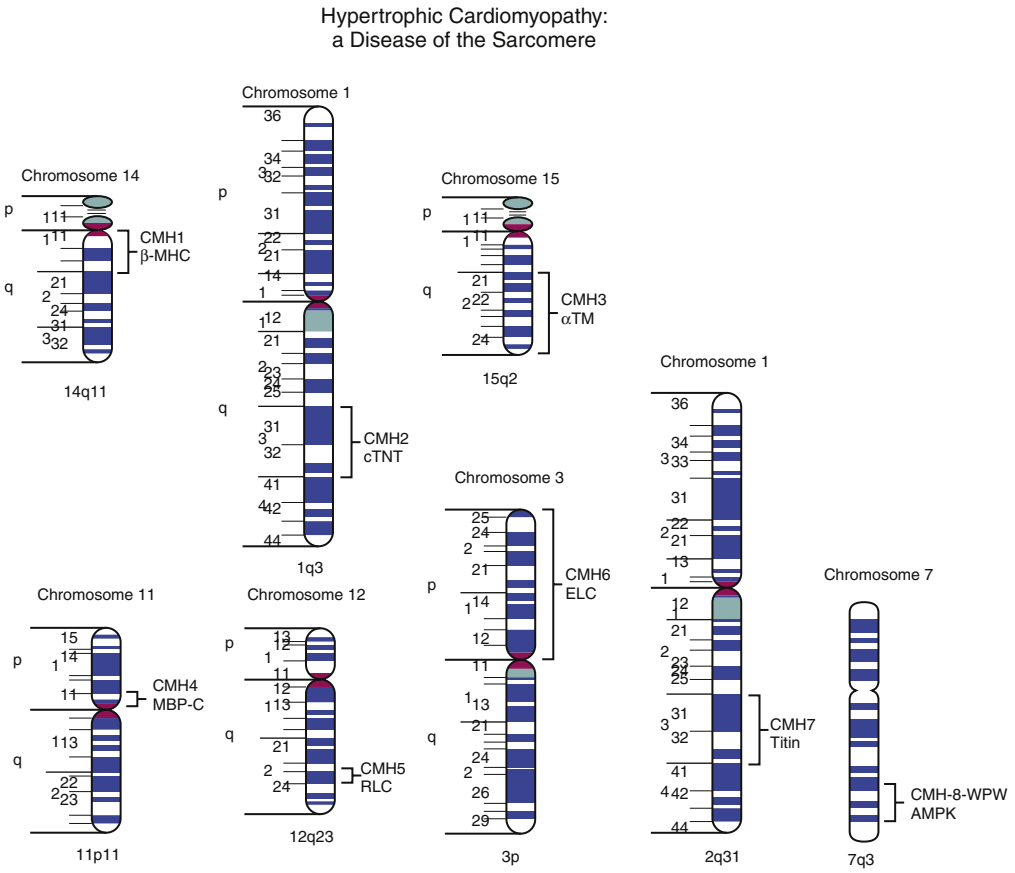

Figure 65-5 Chromosomal locus positions of the original sarcomere-encoding genes responsible for HCM. See Table 65-2 for the complete list of disease-causing genes and their locus positions.

TABLE 65-2

Hypertrophic Cardiomyopathy Genetics

Chromosome locus	Gene	Protein
Xq22	α-Gal	α-Galactosidase
Xq24	LAMP-2	Lysosomal-associated membrane protein 2
Xq28	G4.5	Tafazzin
1q32	TNNT2	Cardiac troponin T
1q42-43	ACTN	α-Actinin-2
2q31	TTN	Titin
3p21.2	MELC	Myosin essential light chain
3p25	CAV3	Caveolin-3
4q26	MYOZ2	Myozenin
6q13	MYO6	Unconventional myosin VI
7q31	AMPK	Adenosine monophosphate–kinase
10q22.3	ZASP/Cypher	ZASP
11p11	MYBPC3	Myosin binding protein C
11p15.1	MLP	Muscle LIM protein
12q23	MRLC	Myosin regulatory light chain
14q12	MYH7	β-Myosin heavy chain
15q14	ACTC	Cardiac actin
15q22	TPM1	α-Tropomyosin
17q12	TCAP	Telethonin
19p13.2	CTNNI	Cardiac troponin I

muscle fibers alters Ca^{2+}-sensitive tension,[116] and it has shown that phosphorylation of cMyBP-C alters myosin cross-bridges in native thick filaments, suggesting that cMyBP-C can modify force production in activated cardiac muscles. The cardiac isoform is encoded by the MYBPC3 gene.

Thin Filament Proteins

The thin filament contains actin, the troponin complex, and tropomyosin. The troponin complex and tropomyosin constitute the Ca^{2+}-sensitive switch that regulates the contraction of cardiac muscle fibers. Mutations have been found in α-TM and in two of the subunits of the troponin complex: cTnI, the inhibitory subunit, and cTnT, the tropomyosin-binding subunit.

α-TM is encoded by TPM1. The cardiac isoform is expressed both in the ventricular myocardium and in fast-twitch skeletal muscles.[117] It shares the overall structure of other tropomyosins that are rodlike proteins that possess a simple dimeric α-coiled-coil structure in parallel orientation along their entire length.[117] It is thought that some mutations in this gene could alter tropomyosin binding to actin.

cTnT is encoded by TNNT2. In human cardiac muscle, multiple isoforms of cTnT have been described that are expressed in the fetal, adult, and diseased heart and that result from alternative splicing of the single gene TNNT2.[118,119] The precise physiologic relevance of these isoforms is currently poorly understood. Mutations in this gene are predicted to influence the inhibitory regulatory effect of the tropomyosin-troponin complex.

cTnI is encoded by TNNI3. The cTnI isoform is expressed only in cardiac muscles.[120] Cooperative binding of cTnI to actin-tropomyosin is a unique property of the cardiac variant; it is thought that mutations disrupt the calcium-sensitive switch mediated by this protein, resulting in increased calcium sensitivity and reduced maximum tension.

α-Cardiac actin (ACTC) mutations also cause FHC. Mogensen et al.[104] identified mutations in a family with heterogeneous phenotypes, ranging from asymptomatic with mild hypertrophy to pronounced septal hypertrophy and LV outflow tract obstruction.

Z-Disk and Other Proteins

Mutations in titin[105] and MLP[106] have been identified as causes of HCM, suggesting the Z disk to be important in the development of HCM (see Figures 65-1 and 65-2). More recently, mutations in ZASP, telethonin (TCAP), α-actinin-2,[121] and myozenin/calsarcin[122] have also been demonstrated to be HCM causing. In addition, disease-causing genes with uncertain mechanisms have been identified including mutations in caveolin-3 and unconventional myosin VI. The functional abnormalities resulting in the clinical phenotype are currently unclear.[107,108]

Genotype-Phenotype Relations in Familial Hypertrophic Cardiomyopathy

The pattern and extent of LV hypertrophy in patients with HCM vary greatly even in first-degree relatives, and a high incidence of sudden death is reported in selected families. An important issue therefore is to determine whether the genotype heterogeneity observed in HCM accounts for the phenotypic diversity of the disease. However, the results must be seen as preliminary, because the available data relate to only a few hundred individuals, and it is obvious that although a given phenotype may be apparent in a small family, examining large or multiple families with the same mutation is required before drawing unambiguous conclusions. Several concepts have been published for mutations in the MYH7, TNNT2, and MYBPC3 genes. For MYH7, the prognosis for patients with different mutations has been shown to vary. For example, the R403Q mutation was thought to be associated with markedly reduced survival,[123] whereas some others, such as V606M, appeared more benign. The disease caused by TNNT2 mutations was reportedly associated with a 20% incidence of nonpenetrance, a relatively mild and sometimes subclinical hypertrophy, but a high incidence of sudden death that occurred even in the absence of significant clinical LV hypertrophy.[124,125] Mutations in MYBPC3, on the other hand, have been characterized by specific clinical features with a mild phenotype in young subjects, a delayed age at the onset of symptoms, and a favorable prognosis before the age of 40 years.[126-129] However, despite these assertions, the notion of mutation-specific clinical outcomes was challenged by Van Driest and colleagues,[130] who demonstrated that "benign" mutations were uncommon (5/253) and that patients with the mutations studied all had severe clinical disease.

Genetic studies have also revealed the presence of clinically healthy individuals carrying the mutant allele, which is associated in first-degree relatives with a typical phenotype of the disease. Several mechanisms could account for the large variability of the phenotypic expression of the mutations: the role of environmental differences and acquired traits (e.g., differences in lifestyle, risk factors, and exercise) and finally the existence of modifier genes and/or polymorphisms that could modulate the phenotypic expression of the disease. Significant results have been obtained thus far regarding the influence of the angiotensin I–converting enzyme (ACE) insertion/deletion polymorphism. Association studies showed that, compared with a control population, the D allele is more common in patients with HCM and in patients with a high incidence of sudden cardiac death.[131,132] It was also shown that the association between the D allele and hypertrophy was seen in the case of MYH7 R403 codon mutations, but not with MYBPC3 mutation carriers,[133] raising the concept of multiple genetic modifiers in HCM.

Therapy in Hypertrophic Cardiomyopathy

The mainstay of therapy in children with HCM has been pharmacologic approaches. The two major medication classes used include β-blockers and calcium channel blockers.[134-136] In small children, we have used propranolol as our drug of choice because of ease of access, liquid formulation, and low side-effect profile. Therapy in these children is monitored by heart rate response, with the goal being approximately 80 to 100 beats per minute. In older children, we typically treat with atenolol; in children with excessive hypertrophy and severe outflow tract obstruction, we occasionally consider use of combination therapy (β-blocker plus calcium channel blocker) although this is not without risk. However, the risk/benefit ratio must be determined for each patient.

When standard pharmacologic therapy fails, there are limited options, although the size of the child plays a role. In small children, myomectomy is the only proved option.[137,138] Again, this is not without risk. In older patients, pacing protocols have been used but are controversial.[139-141] In adults, alcohol septal ablation has been used, but this has not yet been championed in children because of the uncertainties associated with creating an infarct in a young individual regarding long-term outcome.[142-145]

In patients with syncope, ventricular arrhythmias, or other presumed high risk, implantable cardioverter-defibrillator implantation should be considered.[89] In some patients, pacing is necessary as well. Heart failure in HCM occurs because of either diastolic dysfunction or "burned-out" disease with resultant systolic dysfunction. In the latter case, therapy is similar to that used in patients with DCM. This includes use of ACE inhibitor plus β-blocker therapy, with or without diuretic and digoxin.[91] Enalapril and carvedilol are the most common ACE inhibitor/β-blocker combination used. In the case of diastolic dysfunction with heart failure and preserved systolic function, combination therapy with ACE inhibitors, diuretic, with or without angiotensin II–receptor blockers such as candesartan or losartan, is commonly used. In these patients, β-blockers, calcium channel blockers, and pacing are also considered, along with surgical relief.[91]

Finally, in children with metabolic or mitochondrial dysfunction underlying the HCM, metabolic therapies have been successful on occasion. Similar to the therapy in DCM caused by these deficiencies, carnitine, coenzyme Q10, riboflavin, and thiamine may be considered.[93]

Infiltrative Forms of Hypertrophic Cardiomyopathy

A variety of disorders that have apparent LV hypertrophy and features of HCM occur because of infiltrative disorders. The classic form of infiltrative disease in this category is Pompe disease, a disorder presenting in the first weeks of life typically.[93] More recently, other forms of infiltrative disease have been identified with later-onset disease, such as Fabry disease,[146] Danon disease,[147,148] and LV hypertrophy caused by mutations in AMP-activated protein kinase (AMP-K) encoded by the PRKAG2 gene.[112-114] These disorders, along with those caused by mitochondrial abnormalities and genetic dysmorphism syndromes such as Noonan syndrome and LEOPARD syndrome, are caused by abnormalities not primarily affecting the sarcomere.[93] Therapy is similar to that for the sarcomeric form of the disease, unless systolic dysfunction occurs. In this case, heart failure therapy should be instituted.

Pompe Disease (Type II Glycogen Storage Disease)

Genetic deficiency of acid α-1,4-glucosidase, an enzyme involved in the breakdown of glycogen to glucose, results in a wide clinical spectrum ranging from the rapidly fatal infantile onset of type II glycogen storage disease to a slowly progressive adult-onset myopathy. The infantile-onset form (Pompe disease) typically manifests during the first 5 months of life, and patients usually die before their second year.[149] This rare inborn error of glycogen metabolism occurs in fewer than 1 per 100,000 births. Massive glycogen accumulation occurs, leading to the clinical findings of enlarged tongue, striking hepatomegaly, hypotonia with decreased deep tendon reflexes, and cardiomyopathy (usually HCM) with CHF. The glycogen accumulation can be noted

histologically in the skeletal muscles, liver, and heart. Children usually succumb in the first 2 years of life. The diagnosis may be predicted from the pathognomonic electrocardiogram.[93,150] The disease has autosomal recessive inheritance; the gene coding for the lysosomal enzyme was originally mapped to chromosome 17 at subband 17q23-q25.[151]

Allelic variation at the acid α-glucosidase locus is presumed to be the most important factor in diversity of type II glycogen storage disease.[149,152] It has been shown that various combinations of homoallelic and heteroallelic mutant genotypes are the basis for this clinical heterogeneity. Zhong and colleagues[153] identified a missense mutation in one allele of a patient with Pompe disease. This base pair substitution resulted in a loss of restriction endonuclease sites, which allowed them to demonstrate messenger RNA expression deficiency from the second allele using polymerase chain reaction–amplified RNA. This was the first evidence of single–base pair missense mutations in patients with this disease. In addition to molecular analysis, the diagnosis can be made biochemically by analysis of α-glucosidase in blood lymphocytes or skin fibroblasts. Prenatal diagnosis is possible by amniocentesis or chorionic villus sampling by assay of α-glucosidase. Enzyme therapy is now possible and appears to reverse the cardiac phenotype.[154]

Fabry Disease

An X-linked recessive disorder with mild expression occasionally seen in carrier females, this entity is caused by deficiency of the enzyme α-galactosidase (α-Gal) and is found in 1 of 40,000 people. Young adults may be prone to renal failure and myocardial infarctions. Fabry disease usually has its onset in adolescence and usually manifests with sensations of burning pain in the hands and feet.[146,155] These sensations tend to be associated with fever, heat, cold, and exercise. With increasing age, multiple angiokeratoma become noticeable, especially around the umbilicus and genitalia. Corneal opacities are often noted. Progressive renal failure develops with age. Central nervous system manifestations include seizures and headaches, as well as hemiplegia associated with an increased risk of stroke. Primary cardiac manifestations in affected males are HCM and mitral insufficiency, and the diagnosis depends on echocardiography.[156-158] The LV myocardium and mitral valve tend to be areas of greatest storage of lipid material. On electrocardiogram, the PR interval is usually short. Deposition of sphingolipids in the coronary arteries leads to myocardial ischemia and infarction.[157,159]

The disease-causing gene was originally localized to the long arm of the X chromosome in the Xq22 region, and the full-length complementary DNA was isolated and sequenced,[160] demonstrating a 1393–base pair complementary DNA with a 60-nucleotide 5′ untranslated region and encoding a precursor peptide of 429 amino acids. The gene was found to contain seven exons; mutations and phenotypic correlation have been described.[161,162]

Nakao and colleagues[163] studied 1603 men by echocardiography and demonstrated significant LV hypertrophy in 230 subjects (14%), of whom 7 (3%) had proved α-Gal deficiency. These patients had concentric LV hypertrophy. Linhart et al.[164] studied 30 patients with Fabry disease and found 37% had concentric LV hypertrophy, 10% had asymmetric septal hypertrophy, and 3% had an eccentric pattern of hypertrophy. More recently, Sachdev and co-workers[165] identified five patients with HCM diagnosed after age 40 years and one with earlier-onset (younger than 40 years) HCM, all with low α-Gal activity. In five of the six patients, the hypertrophy was concentric whereas one had asymmetric hypertrophy. In one case, LV outflow tract obstruction was noted. Nonsustained ventricular tachycardia occurred in two patients, and another patient had second-degree atrioventricular block initially and then atrial fibrillation. Therefore it appears that these abnormalities in α-Gal activity result in some cases of HCM or "unexplained" LV hypertrophy.

Danon Disease

Danon disease is an X-linked dominant disorder characterized by intracytoplasmic vacuoles containing autophagic material and glycogen in cardiac and skeletal muscle cells, cardiomyopathy, and skeletal myopathy, with or without conduction defect, WPW syndrome, or mental retardation.[166] The underlying abnormality affects lysosomal function and is due to mutations in the lysosomal-associated membrane protein 2 (LAMP2).[167] The clinical phenotypic expression of Danon disease is variable. Charron et al.[168] screened 50 cases of HCM for LAMP2 mutations and identified mutations in two patients with HCM and skeletal myopathy. Both of these individuals presented during their teenage years, and other younger affected individuals in the family were also identified as young as 7 years of age. WPW syndrome and high-voltage QRS complexes on electrocardiogram were notable along with high creatine kinase plasma levels. In addition, late LV dilation and dysfunction occurred with symptoms of heart failure. Atrial and ventricular arrhythmias and conduction disease was notable along with death during their twenties. Visual acuity abnormality was also common, because of choriocapillary ocular atrophy. This disease appears to be underrecognized and may play a significant role in pediatric heart failure.

Adenosine Monophosphate–Activated Protein Kinase

AMP-K, encoded by the γ2 regulatory subunit of the PRKAG2 gene on chromosome 7q31,[101] is an enzyme that modulates glucose uptake and glycolysis.[169,170] Dominant mutations in this gene were first identified by Gollob and associates[112] and Blair and colleagues[113] in 2001 in subjects with HCM, WPW preexcitation, and atrioventricular block. The genetic locus on chromosome 7q3 was first described by MacRae and colleagues[101] in 1995 in families with HCM and WPW and was thought to be clinically different than in the patients with other forms of adult HCM. Blair and colleagues[113] made the case that mutations in AMP-K resulted in HCM because of compromise of energy production and utilization, but Arad and colleagues[114] provided evidence that this disorder is a form of glycogen storage disease. Cardiac pathology differed from that in other forms of HCM, with no myocyte and myofibrillar disarray seen but instead pronounced formation of vacuoles that were filled with glycogen-associated granules. The myocytes were enlarged, and interstitial fibrosis was minimal. Using a yeast system in which a similar enzyme is functional, Arad and co-workers[114] introduced the same mutations found in the patients and showed that the enzyme activity is persistent (i.e., does not turn off), leading to glycogen accumulation. The authors confirmed these findings by developing a murine model that mimics the human disorder.[171]

Energy-Dependent Forms of Hypertrophic Cardiomyopathy

Mitochondrial Cardiomyopathies

The human mitochondrial genome[172] is a small, circular DNA molecule that is maternally inherited. Mitochondrial DNA (mtDNA) encodes 13 of the 69 proteins required for oxidative metabolism and 22 transfer RNAs (tRNAs) and two ribosomal RNAs required for their translation. Because mtDNA has much less redundancy than the nuclear genome (in which essentially identical information is received from both parents), and tRNAs and ribosomal RNAs are present in multiple copies, the mitochondrial genome is an excellent target for mutations giving rise to human disease.[173-175] Mitochondria enjoy a symbiotic relationship with the cell. These subcellular organelles are dependent on nucleocytoplasmic mechanisms for most structural components but do contribute vital peptides that are central to cellular respiration. Mitochondria contain a permeable outer membrane and a highly restrictive inner membrane that guards the chemical

microenvironment of the matrix compartment. Adaptive mechanisms exist for the passage of large and small molecules across the inner membrane. Translocases shuttle monocarboxylic acids, amino acids, acyl-carnitine conjugates, small ions, and other metabolites in and out of the mitochondrial matrix. Energy is required for importation of proteins into the mitochondria because the nuclear gene-synthesized mitochondrial proteins are precursor molecules that require presequence cleavage. The 13 mtDNA genes are located in the respiratory chain[175-177] and include seven complex I subunits (ND1, 2, 3, 4L, 4, 5, and 6), one complex III subunit (cytochrome b), three complex IV subunits (COI, II, III), and two complex V subunits (ATPase 6 and 8). Coordination must exist between nuclear and mitochondrial genomes to permit assembly of the complex holoenzymes. Each cell contains numerous mitochondria, and each mitochondrion contains multiple copies of mtDNA. This genetic material derives exclusively from the female gamete, and any mutation must be passed from female parent to all progeny, male and female. The replicative segregation of mutant mtDNA copies within the cell determines whether this biologic disadvantage is expressed. In most mitochondrial disorders, patients carry a mix of mutant and normal mitochondria, a condition known as heteroplasmy, with the proportions varying from tissue to tissue and individual to individual within a pedigree in a manner correlating with severity of phenotype.[174,175]

Mitochondrial diseases often produce disturbances of brain and muscle function, presumably because these two organs are so metabolically active, and therefore the metabolic demand is high during growth and development.[178] Cardiac disease is most commonly seen with respiratory chain defects.[179,180] Ragged red fibers are present in muscle biopsy specimens almost invariably when the molecular defect involves mtDNA (except in infants).[173] These defects represent the genetics of ATP production. The diverse clinical syndromes associated with various respiratory chain complexes are thought to result from involvement of tissue-nonspecific (generalized) subunits in other cases and the residual enzyme activity in affected tissues.[181] The cardiac diseases associated with mitochondrial defects include both HCM and DCM, and LVNC.[182,183] No theory has thus far been advanced to explain the cause of these phenotypically different cardiac abnormalities. It is possible, however, that the dilated form occurs after an initial hypertrophic response (i.e., it is a burned-out dilated form of HCM).

Kearns-Sayre Syndrome

This mitochondrial myopathy is characterized by ptosis, chronic progressive external ophthalmoplegia, abnormal retinal pigmentation, and cardiac conduction defects, as well as DCM. Channer and associates[184] reported a case of rapidly developing progressive CHF and DCM requiring transplantation in a patient with Kearns-Sayre syndrome. Approximately 20% of patients with Kearns-Sayre syndrome have cardiac involvement, and the majority usually have conduction defects causing progressive heart block. These patients generally have large, heterogeneous deletions in the mitochondrial chromosome. Poulton and associates[185] showed germ line deletions of mtDNA in a family with Kearns-Sayre syndrome using polymerase chain reaction to amplify across the deletion, with primers flanking these deletions. The patient was shown to have a deletion in muscle mtDNA and at low levels in blood that was identical to that found in the mother and sister. The probands, however, had more deleted DNA, correlating with more severe symptoms. Other mutations have also been described.[186,187]

MERRF Syndrome

This syndrome is characterized by myoclonic epilepsy with ragged red muscle fibers (MERRF) and is caused by a single nucleotide substitution in tRNA LYS that apparently interferes with mitochondrial translation.[188,189] Shoffner and colleagues[190] showed an A to G transition mutation as the cause of the disease associated with defects in complexes I and IV. This abnormality causes decline in ATP-generating capacity, with onset of disease that includes cardiomyopathy. Other reports outline various disease-causing mutations.[191-193]

OVERLAP DISORDERS

Left Ventricular Noncompaction

This disorder has previously been considered to be a rare disease and has been identified by a variety of names including spongy myocardium, fetal myocardium, and noncompaction of the LV myocardium.[194-198] The abnormality is believed to represent an arrest in the normal process of myocardial compaction, the final stage of myocardial morphogenesis, resulting in persistence of multiple prominent ventricular trabeculations and deep intertrabecular recesses (Figure 65-6). This cardiomyopathy is somewhat difficult to diagnose unless the physician has a high level of suspicion during echocardiographic evaluation. In fact, on careful review of echocardiograms and other clinical data, it appears that LVNC is relatively common in children and is also seen in adults.[194,197] In the most recent American Heart Association/American College of Cardiology Cardiomyopathy Classification, LVNC for the first time was recognized as a formal form of classified cardiomyopathy.

Two forms of LVNC occur: (1) isolated noncompaction and (2) noncompaction associated with congenital heart disease such as septal defects (ventricular and/or atrial septal defect), pulmonic stenosis, and hypoplastic left heart syndrome, among others.[110,195-199] In the isolated form and the form associated with congenital heart disease, metabolic derangements may be notable.[183,196]

Clinical Features

LVNC most commonly presents in infancy with signs and symptoms of heart failure, but some patients are identified during later childhood, adolescence, or adulthood. Pignatelli and associates[194] recently reported the findings in 36 children identified over a 5-year period, with the median age at presentation being 90 days (range 1 day to 17 years). In this study, 40% of the children presented with low cardiac output or CHF, and only one child (3%) presented with syncope. The most common presenting symptom other than heart failure was asymptomatic electrocardiographic or radiographic abnormalities, with 42% being asymptomatic. In addition, 14% of children had associated dysmorphic features, and 19% of affected children had first-degree relatives with cardiomyopathy. Among the children with dysmorphic features, DiGeorge syndrome was diagnosed in one child and one child had congenital adrenal hyperplasia.

Genetics

When LVNC is inherited, it can be transmitted as an X-linked, mitochondrial, autosomal recessive, or autosomal dominant trait.[110] In approximately 20% to 30% of cases, familial inheritance has been identified. The X-linked form usually is associated with isolated noncompaction and a mutation in the G4.5 (tafazzin) gene located on chromosome Xq28.[199] This gene has also been identified in patients with Barth syndrome.

In autosomal dominant inherited cases, mutations in the Z-line protein encoding ZASP, located on chromosome 10q22, have been identified in isolated noncompaction,[200] and mutations in the gene encoding α-dystrobrevin, a cytoskeletal protein located on chromosome 18q12, have been identified in patients with noncompaction associated with congenital heart disease.[199] No genes have been identified thus far for autosomal recessive–inherited noncompaction whereas mutations in mtDNA have been seen in patients with noncompaction.[183,196]

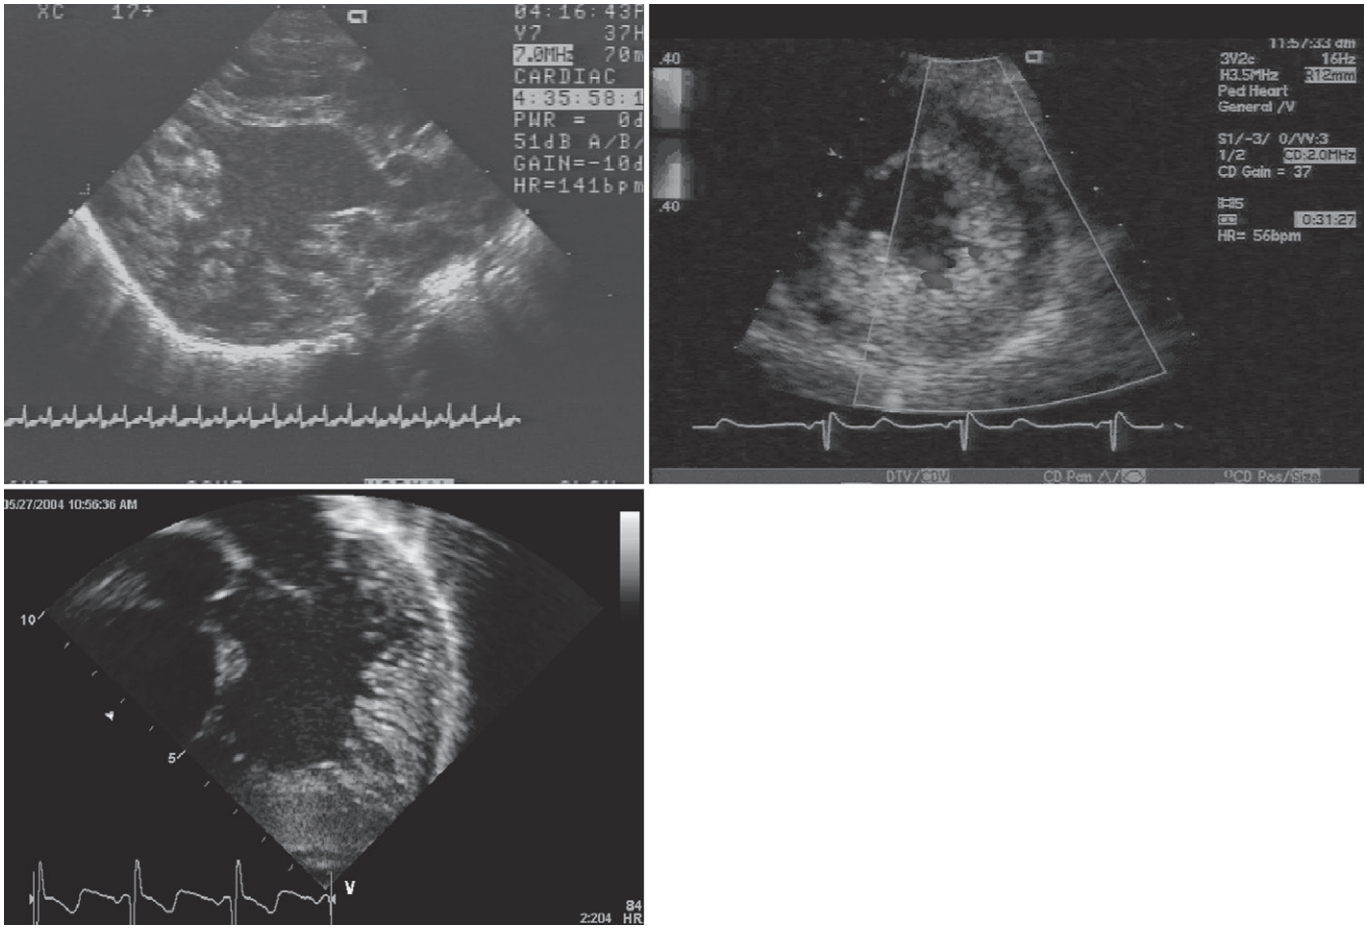

Figure 65-6 Echocardiographic features of left ventricular noncompaction (LVNC). *Top left panel,* A parasternal long-axis view demonstrates a hypertrophic posterior left ventricular (LV) wall with a moth-eaten pattern. The LV chamber is small. *Top right panel,* A parasternal short-axis view with color Doppler demonstrates hypertrophy of the LV apex with deep trabeculations filled with blood.

Therapy and Outcome

The specific therapy depends on the clinical and echocardiographic findings. In patients with systolic dysfunction and heart failure, anticongestive therapy identical to that used in patients with DCM is appropriate. In particular, ACE inhibitors such as captopril and enalapril, as well as β-adrenergic blocking agents such as metoprolol or carvedilol, are useful. Diuretics may also be needed. However, in those patients exhibiting findings more consistent with a HCM or diastolic dysfunction physiologic phenotype, β-blocker therapy alone with propranolol or atenolol is more appropriate. In patients with either of these forms of noncompaction with associated mitochondrial or metabolic dysfunction some investigators add a "vitamin cocktail" to the cardiac therapy with coenzyme Q10, carnitine, riboflavin, and thiamine commonly used alone or in combination.

In patients having associated congenital heart disease, appropriate therapeutic approaches may include simple pharmacologic therapy with diuretics for volume overload associated with left-to-right shunts, more complex pharmacologic therapy for patients with restrictive physiology and pulmonary hypertension, or invasive therapy with catheter intervention or surgical repairs, depending on the lesions. Intimate understanding of the cardiac function abnormalities, evidence of thrombi (which should be treated with anticoagulation), and the metabolic status of the patient must be attended to by the interventional cardiologist, cardiac anesthesiologist, and surgeon in approaching these patients invasively. In addition, cardiac rhythm disturbances need to be identified and therapies such as pacemakers, implantable defibrillators, and intracardiac ablations considered.

The clinical outcome of patients with noncompaction has been reported to be poor with death occurring because of heart failure or sudden death presumably arrhythmia related or stroke related because of embolization of LV thrombi.[195,198] However, Pignatelli and colleagues.[194] demonstrated a 5-year survival rate of 86%; when patients who had transplants were added, the 5-year survival free of death or transplantation was 75%.

CONCLUSION

The cardiomyopathies appear to occur because of disruption of "final common pathways." These disruptions may be due to purely genetic causes, such as mutations in a single gene that result in a dysfunctional protein, which leads to a domino effect of downstream protein interaction abnormalities and ultimately a phenotype. In other situations, multiple mutations in the same gene (compound heterozygosity) or in different genes (digenic heterozygosity) may lead to a phenotype that may be classic, more severe, or even overlapping with other disease forms. In some cases, different intersecting pathways may become disturbed, resulting in complex phenotypes. Further, acquired causes may play a role by causing disruption of these functional pathways. For instance, DCM results from disruption in the final common pathway linking the sarcomere and sarcolemma, and mutations in the affected genes are responsible for cardiac and

skeletal muscle dysfunction. The mechanisms of disease, which include disruption of the linkage caused by protein-protein interaction abnormalities that occur from dysfunctional proteins, as well as the interplay of other factors such as mechanical stress and stretch, are being elucidated in detail with the development of animal models of the human disease. Many of the genes identified are now clinically available in fee-for-service laboratories. Novel therapies have resulted from the improved understanding of this clinical phenotype, as noted earlier. Similarly, the genetic basis and mechanistic understanding of HCM as a disturbance of sarcomeric function have occurred over the past two decades, and genetic tests are clinically available. The development of novel targeted therapies has been somewhat slow in coming but is expected to develop in the near future. In the case of LVNC, the "new kid on the block," genetic understanding is in the early phases. The future of cardiomyopathy care is poised to shift in the next decade because of these new developments, as well as the growing science of stem cell therapy. Because children have "pure" disease states, unfettered by comorbidities, the dream of "cures" of muscle disease (cardiac, skeletal muscle) will likely be realized more fully in this population. We must move toward that goal.

Arthur S. Pickoff

Developmental Electrophysiology in the Fetus and Neonate

In this chapter, the physiology of both impulse formation and conduction within the developing heart is discussed. It is now clear that there are significant age-related changes in the ionic currents responsible for the generation of the cardiac action potential as well as changes in the microscopic and macroscopic anatomic and neural substrates that govern the physiology of intracardiac conduction.

CARDIAC ACTION POTENTIAL

The cardiac action potential is the electrical event responsible for the generation of the cardiac impulse and conduction of the electrical impulse through the myocardium and specialized cardiac conduction system. It is based on a complex series of transmembrane ion fluxes that result in a net flow of electrical current across the cell membrane.[1,2] The cell membrane is a lipid bilayer and is thus highly impermeable to charged ions. The cardiac action potential is generated as a result of two important conditions. The first is an unequal distribution of electrically charged ions, most importantly sodium, potassium, and calcium ions, across the cell membrane (Table 66-1). These ion gradients are established and maintained largely as a result of the activity of energy-expending membrane ion pumps (sodium-potassium adenosine triphosphatase [ATPase]) and ion exchange complexes (the sodium-calcium exchanger). The second critical factor in the generation of the action potential is that under appropriate biophysical conditions, complex polypeptide pores known as *ion channels*, embedded within the cell membrane, are open, thereby allowing the passage of charged ions through the cell membrane. The detailed molecular structure of many of these ion channels is now understood (Figure 66-1, *A* to *C*).[3,4] The direction and magnitude of ion flow through these channels are determined by both ion concentration and electrical gradients, and also, in part, by physical properties inherent to the specific ion channel.

It is useful to consider the ionic events that determine the cardiac action potential before considering the influence of development on this process. The descriptions that follow are derived in part from intracellular microelectrode recordings of changes in the cellular transmembrane potential and also from voltage-clamp studies. At rest, the interior of the typical cardiac cell exhibits a negative electrical potential with respect to the extracellular space. For Purkinje fibers and atrial and ventricular myocytes, this transmembrane potential is approximately −90 mV. In the sinoatrial and atrioventricular (AV) nodes, the interior of the cell is somewhat less negative, approximately −60 mV (Table 66-2). This negative resting membrane potential is generated in part by the activity of the sodium-potassium ATPase pump. This

TABLE 66-1

Intracellular and Extracellular Ion Distribution in the Cardiac Cell

	Na^+,K^+	Cl^-	Ca^{2+}	
Extracellular	145 mM	4 mM	120 mM	2 mM
		cell membrane		
Intracellular	15 mM	145 mM	5 mM	10^{-4} mM

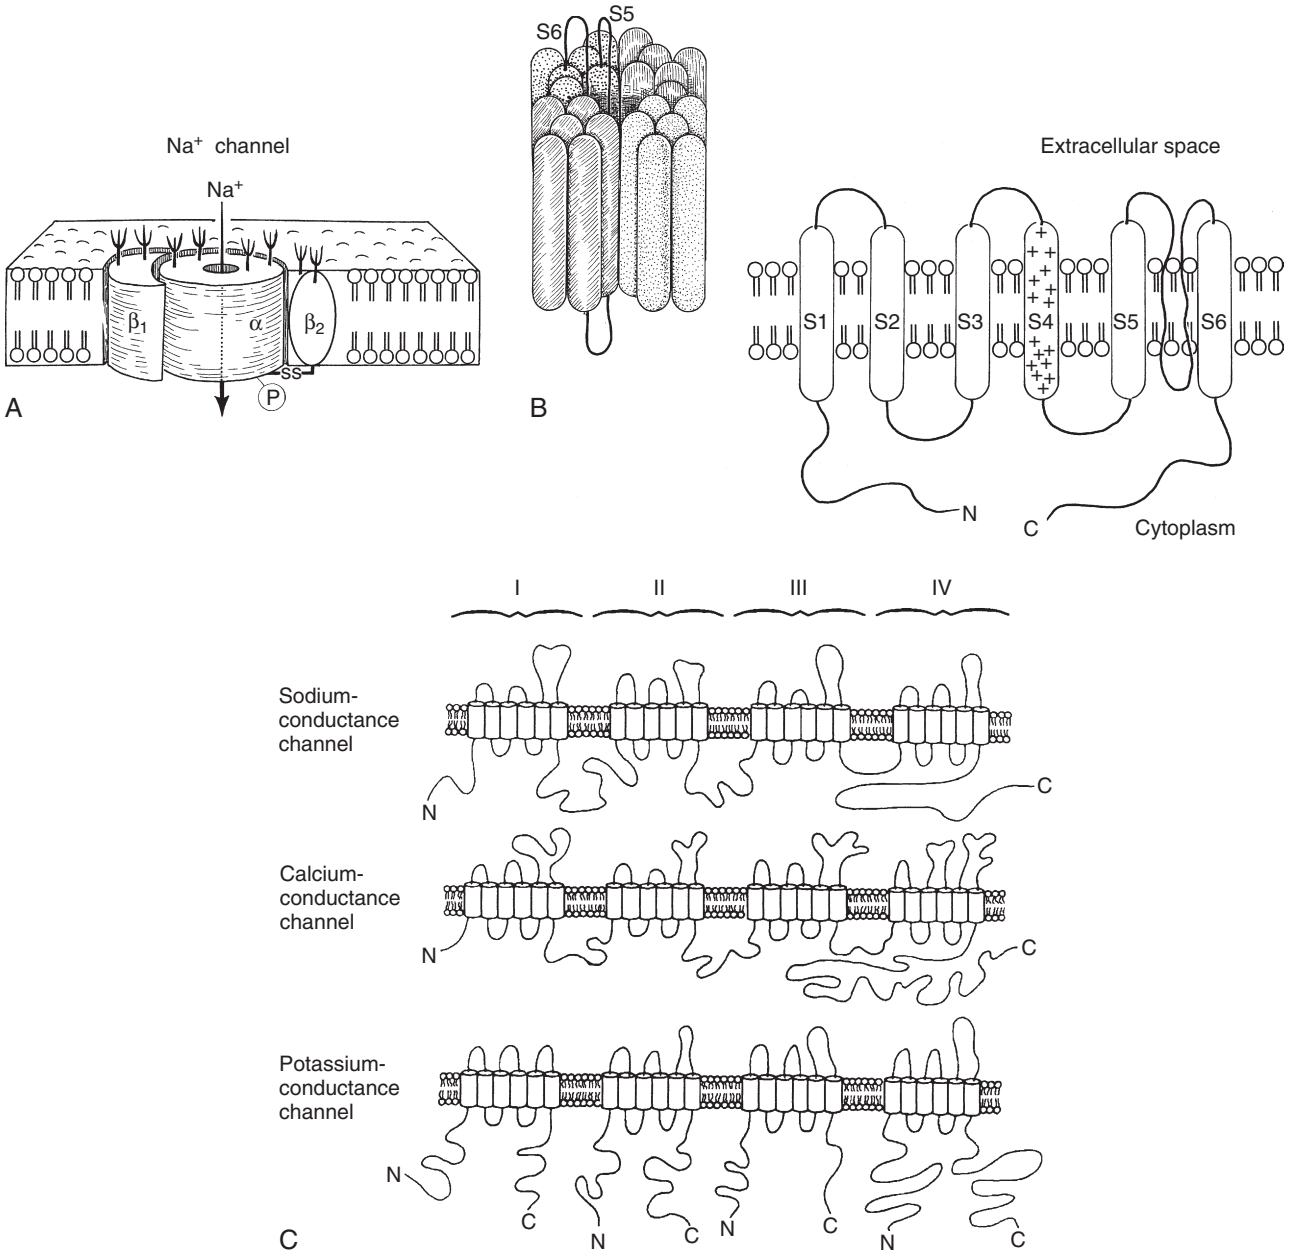

Figure 66-1 **A,** Three-dimensional representation of a sodium channel from mammalian brain. The ion channel consists of the α subunit, with two smaller protein subunits (β_1 and β_2) associated with the main channel. The β_1 subunit is found only in cardiac sodium channels and is thought to stabilize the channel. The treelike (cactus-like) structures are glycosylation sites. *P,* Phosphorylation sites; *SS,* disulfide bond; **B,** The ion channel is composed of four domains of a protein complex that consists of six separate transmembrane segments (S1 to S6). The topographic arrangement of one such domain is shown on the left. The peptide loops between S5 and S6 are thought to represent the central pore of the channel. Subunit S4 is a highly charged protein segment that is thought to serve as the voltage sensor of the ion channel. **C,** Diagrammatic representation of the sodium channel, calcium channel, and potassium channel. In sodium and calcium channels, there is covalent linkage of the four domains (I to IV). (Each domain consists of the six transmembrane segments S1 to S6 already described.) Potassium channels consist of single domains. There is no covalent linkage between domains. *(***A,** *Modified from Shib H-T. Anatomy of the action potential in the heart,* Tex Heart Inst J *21:30, 1994.* **B,** *From Brown AM: Ion channels in action potential generation.* Hosp Pract [Off Ed] *27:129, 1992. energy-requiring pump maintains a high intracellular concentration of potassium ions and low intracellular sodium concentration relative to the extracellular space, by pumping two potassium ions into the cell for every three sodium ions extruded into the extracellular space. This unequal exchange rate of positive ions results in a net negative charge of the intracellular space. The most important factor responsible for the negative resting membrane potential of the cardiac cell is the relatively high permeability of the resting cell membrane to the potassium ion. This high permeability permits the movement of potassium

TABLE 66-2

Action Potential Characteristics in Cardiac Cells

	SA Node	Atrium	AV Node	His-Purkinje	Ventricle
Resting potential (mV)					
Action potential	250-260	280-290	260-270	290-295	280-290
Amplitude (mV)	60-70	110-120	70-80	120	110-120
Overshoot (mV)	0-10	30	5-15	30	30
Duration (msec)	100-300	100-300	100-300	300-500	100-200
$\dot{V}_{max}$ (V/sec)	1-10	100-200	5-15	500-700	100-200
Conduction velocity (m/sec)	<0.05	0.3-0.4	0.1	2-3	0.3-0.4

AV, Atrioventricular; mV, millivolts; msec, milliseconds; m/sec, meters per second SA, sinoatrial; $\dot{V}_{max}$, maximum rate of rise of the action potential phase 0 in volts per second (V/sec).

(Modified from Sperelakis N. Origin of the cardiac resting potential. In Berne RM, Sperelakis N (eds): *Handbook of Physiology, Vol 1. The Cardiovascular System*. Bethesda, MD, American Physiological Society, 1979, pp 187-267.)

ions down their concentration gradient (from the intracellular space into the extracellular space), thereby rendering the interior of the cell more negative with respect to the exterior. The relationship of resting membrane potential to the intracellular-extracellular potassium concentration gradient is described by the Nernst equation:

$$E = (RT/F) \log \left(K^+_{in} / K^+_{out} \right)$$

where E is the membrane potential, R is the gas constant, T is the temperature, F is the Faraday constant, and K^+_{in} and K^+_{out} represent the concentrations of potassium ion inside and outside of the cell.

When the resting potential of the cardiac cell is made less negative, either as a result of the cell's exhibiting spontaneous depolarization (automaticity) or as a result of an advancing wave of electrical current, the cell reaches a level of depolarization, called the *activation potential*. At that point, there is a sudden and rapid influx of positively charged sodium ions (in the case of atrial and ventricular myocytes and Purkinje fibers). This rapid influx of positively charged sodium ions rapidly depolarizes the cell to potentials close to +20 to +30 mV. This rapid phase of depolarization is commonly referred to as *Phase 0 of the action potential* (Figure 66-2). The maximal rate of rise of the action potential phase 0, $\dot{V}_{max}$, in ventricular and atrial muscle approaches 200 volts (V)/second; in Purkinje fibers, even higher rates of change in membrane potential are observed ($\dot{V}_{max}$ of approximately 500 V/second) (see Table 66-2). The amplitude and rate of rise of phase 0 of the action potential are key determinants of conduction velocity in the myocardium and specialized conduction system, with greater conduction velocities resulting from action potentials of greater amplitude and greater $\dot{V}_{max}$. The sudden influx of sodium ions, triggered by the change in membrane potential, results from the sodium channel's changing from a conformationally specific "rested" state to an active or "open" channel configuration[3] (Figure 66-3). A highly charged protein subunit (subunit S4; see Figure 66-1, *B*) of the sodium channel serves as the so-called voltage sensor. After the activation potential has been reached, the voltage sensor moves within the membrane, inducing a conformational change in the sodium channel and resulting in the opening of an "m" or activation gate. This, in turn, allows free passage of sodium ions. As the membrane potential becomes more positive, the sodium channel enters into a third distinct conformational state, the inactivated state, which results from closure of an "h," or inactivation, gate (see Figure 66-3). This inactivation gate may correspond to one of the intracellular peptide loops of the cardiac ion channel.[5,6] Activation and inactivation of the sodium channel occur rapidly, within a time course of a few milliseconds. Allowing for significant differences in the kinetics of channel activation and inactivation, other voltage-gated ion channels, such as calcium and potassium channels, are believed to function in a similar state-dependent fashion (Table 66-3).

After the completion of phase 0, there is often a short, rapid repolarization phase, which creates a notch in the action potential. This notch, which represents phase 1 of the action potential, and the resulting spike-and-dome appearance of the initial portion of the action potential plateau are most notable in epicardial ventricular muscle cells and in Purkinje fibers (Figure 66-4, *A*). There are two principal charge carriers responsible for this phase 1 notch. One is a transiently activated outward potassium current, referred to as I_{to}, and the second is an inward chloride current (I_{to2}).[7] The transient outward current is markedly reduced or absent in ventricular endocardium. It exhibits significant rate-dependent behavior (except possibly in humans) (see Figure 66-4, *B*).

The plateau of the action potential, phase 2 (see Figure 66-2), can persist for hundreds of milliseconds and reflects the delicate balance of both inward and outward currents on a high-resistance membrane. The most important of the inward currents during the action potential plateau is the inward calcium current. L-type ("long-lasting," "large"), and T-type ("tiny," "transient") calcium channels predominate in the heart.[8] The L-type calcium current ($I_{Ca\text{-}L}$) activates at membrane potentials of −55 to −30 mV and is the main charge carrier responsible for maintaining the action potential plateau during phase 2. Activation of $I_{Ca\text{-}L}$ is also highly dependent on intracellular calcium concentration.[9] T-type calcium channels, which activate at potentials more negative than those of the L-type channels, may primarily contribute to pacemaker activity in the heart.[8] The magnitude of $I_{Ca\text{-}L}$ is nearly 10-fold less than that of the sodium current. Activation and inactivation kinetics of $I_{Ca\text{-}L}$ are also an order of magnitude slower than those of the sodium channel (see Table 66-3).[10] The slow inward current, $I_{Ca\text{-}L}$, also represents the major current responsible for phase 0 of the action potential in the sinus and AV nodes (see Figure 66-2, *right side*) and is characterized by a very slow $\dot{V}_{max}$ of approximately 10 V/second. The action potentials recorded from these regions are, therefore, referred to as *slow response* action potentials. A small inward sodium current is also present during phase 2 of the action potential, termed the *window current*.

Balancing the inward depolarizing plateau currents is a family of repolarization currents, largely outward potassium currents, that drive the membrane potential back toward the resting potential (see Figure 66-2). Experiments with cloned pore-forming (α) and accessory (β) subunits of potassium channels have provided new insights into the relationships between molecular assembly and the functional expression of the major repolarization currents (I_K, I_{Kr}, I_{Ks}, I_{Kur}) in the mammalian heart.[11] The first major repolarizing current is referred to as the *delayed rectifier*, I_K. This large outward potassium current is termed *delayed* because of its slow time course of activation. I_K begins to activate relatively late during the action potential plateau, as the time-dependent slow calcium current $I_{Ca\text{-}L}$ begins to inactivate. In some species, including the human, there are two principal components of the delayed rectifier potassium current, a fast (I_{Kr}) and a slow (I_{Ks}) component.[12] Phase 3 of the action potential represents the phase of rapid repolarization of the cell toward the resting membrane potential. Phase 3 occurs as the result of decay in the inward calcium current and the activation of (several) outward potassium currents. The ion current responsible for the terminal portion of this phase of the action potential, as well as the current responsible for maintaining the resting potential, is an outward potassium current activated at negative membrane potentials, referred to as the *inward rectifier*, or I_{K1}.[13] An additional outward potassium

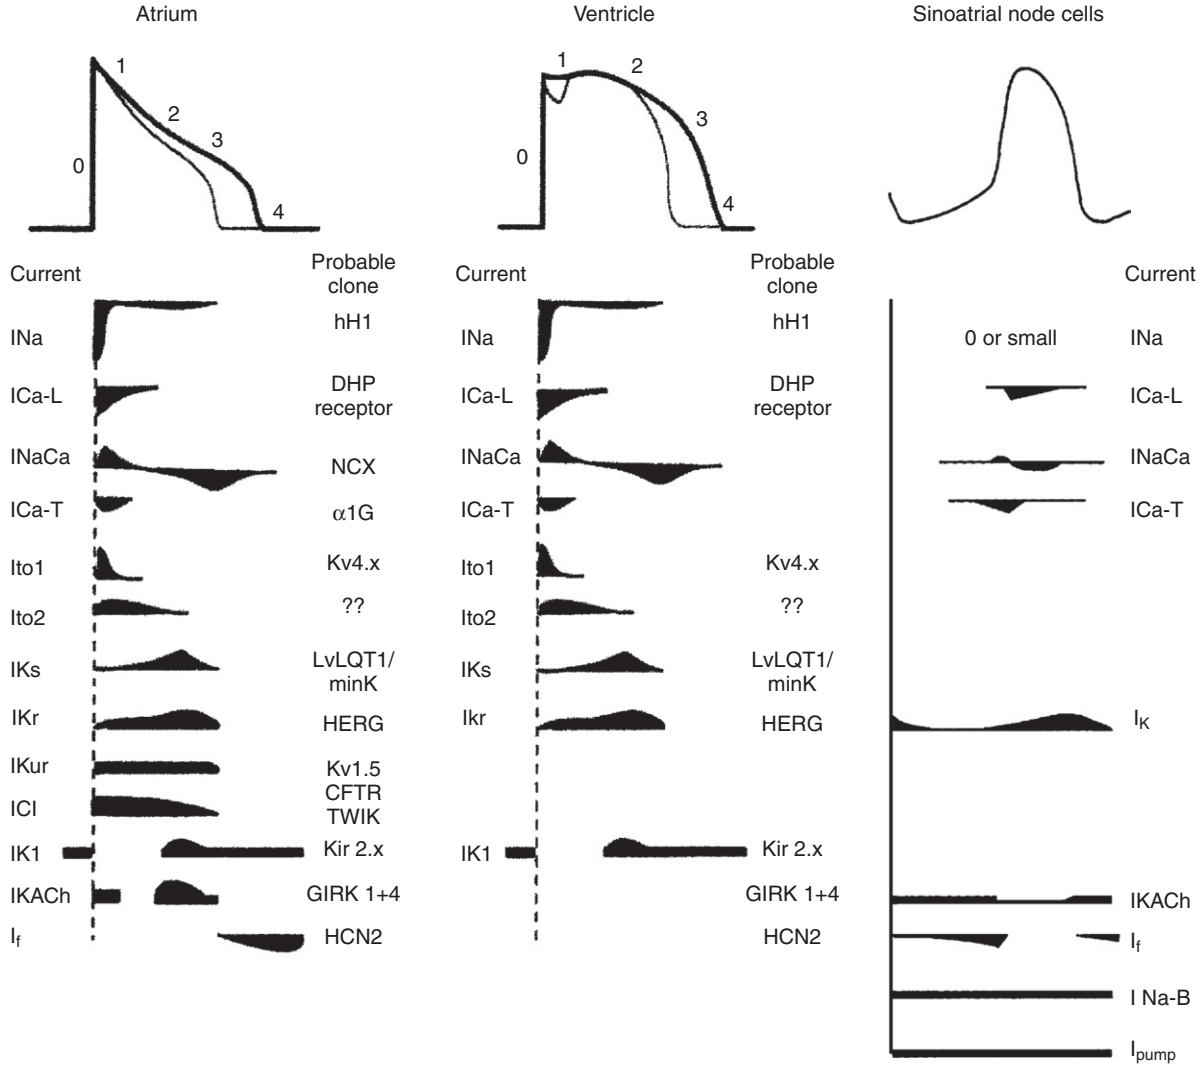

Figure 66-2 Diagrammatic representation of the atrial, ventricular, and sinus node action potential. (For atrial and ventricular action potentials, the bolded action potentials depict changes in action potential morphology that have been associated with the failing heart.) The major ion currents and ion pumps involved in the generation of the action potentials are depicted. For each of the currents, the direction of current flow is indicated (downward indicating an inward current, upward indicating an outward current) as well as the approximate time course of activation and inactivation. Gene products (Probable Clone) that are associated with each current are shown. Relative current amplitudes are *not* depicted. I_{Na} represents the inward sodium current; $I_{Ca\text{-}L}$, the large, long-lasting slow inward calcium current; $I_{Ca\text{-}T}$, the tiny, transient calcium current; and $I_{Na/Ca}$, the current generated by the action of the sodium-calcium exchanger. Outward potassium currents depicted include I_{K1}, the inward rectifier current; I_K, the delayed rectifier current; I_{to}, the transient outward current (of which there are two components); and, limited to the atrium, I_{Kur}. $I_{K(ACh)}$ represents the receptor-activated potassium channel (activated by acetylcholine and adenosine). I_f represents the "funny" pacemaker current, a current carried by both sodium and potassium. All these currents are discussed further in the text. Not discussed but presented here for completeness are I_{Cl}, a chloride current; I_{ump}, an ion pump current; and $I_{Na\text{-}B}$, an inward background current thought to be present in sinus node cells. *(Modified from Task Force of the Working Group on Arrhythmias of the European Society of Cardiology: The Sicilian gambit: A new approach to the classification of antiarrhythmic drugs based on their actions on arrhythmogenic mechanisms,* Circulation *84:1831, 1991, by permission of the American Heart Association; and from Fuster V, Alexander RW, O'Rourke RA:* Hurst's the Heart, *11th ed. New York, McGraw-Hill, 2004.)*

repolarization current called I_{Kur} ("ur" for "ultrarapid") is identified in the human atrium. This atrial current is a rapidly activating, non-inactivating potassium current.[14]

The repolarizing outward potassium currents described are the *major* currents involved in cardiac repolarization. There are other outward potassium currents that have been described that can become important under specific conditions. For example, the ATP-dependent potassium current, $I_{K(ATP)}$, is an outward current that is small under normal conditions; however, it activates strongly under conditions of depleted intracellular stores of ATP.[15] This outward current may become important under hypoxic conditions. The receptor-activated potassium channel, $I_{K(ACh)}$, is activated by exposure to either the parasympathetic agonist acetylcholine or to adenosine.[13] Other potassium channels that have been described include one that activates in response to elevated intracellular calcium concentrations ($I_{K(Ca)}$) and another that activates in response to increased intracellular sodium concentrations ($I_{K(Na)}$).[2]

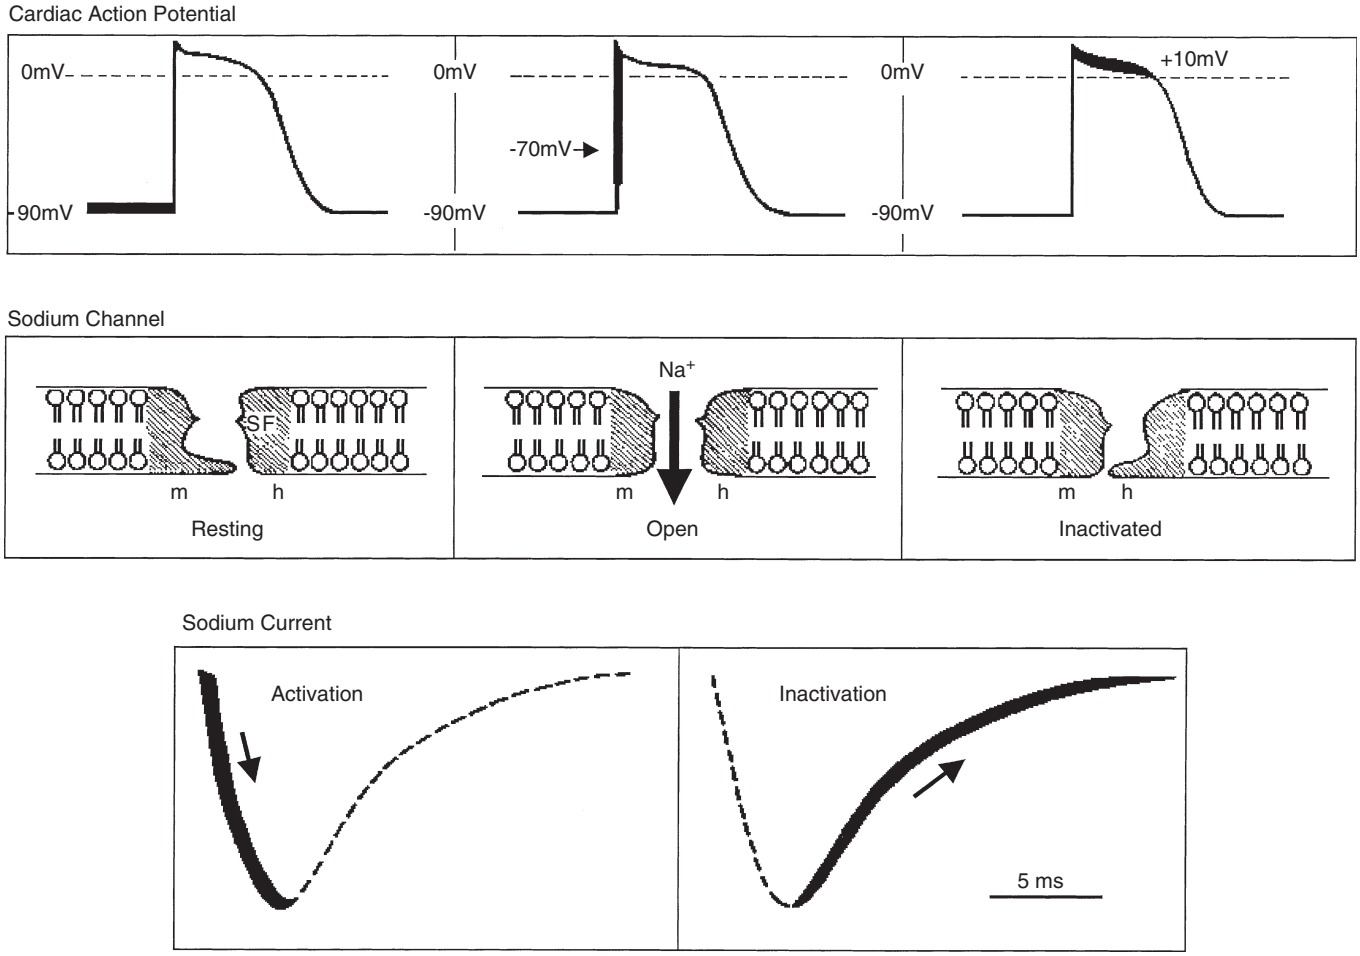

Figure 66-3 Three conformation states of the sodium channel. Illustration of the changes in transmembrane action potential *(top three diagrams),* changes in the conformational state of the sodium channel *(middle diagrams),* and corresponding activation and inactivation of the sodium current *(lower diagrams).* At rest, the membrane potential is approximately −90 mV *(left).* At this membrane potential, the sodium channel exists primarily in the rested state. The *m* gate of the sodium channel is closed. (*SF* denotes the selectivity filter of the ion channel.) As the cell membrane depolarizes (phase 0 of the action potential), the sodium channel changes to the open conformation, associated with opening of the *m* gate *(middle).* The sodium current rapidly activates because sodium ions can now pass through the ion channel. As the membrane potential becomes more positive, the sodium channel enters into its third conformational state, the inactivated state. This occurs as a result of closure of the inactivation gate *h (right).* The sodium current rapidly inactivates, or decays, back toward zero current.

$I_{Ca\text{-}L}$, L-type calcium channel; I_K, delayed rectifier current (the "s" or slow component); I_{Na}, sodium channel; mA/cm^2, milliamperes per squared centimeter; msec, milliseconds; mV, millivolts.

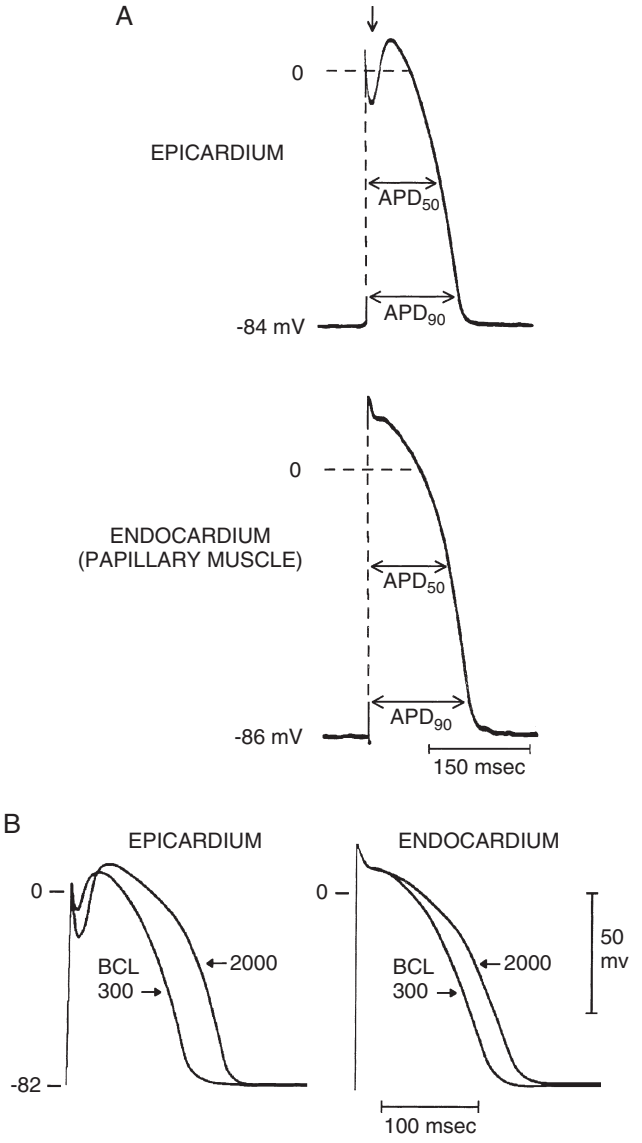

Figure 66-4 **A,** Representative action potentials from ventricular endocardium and epicardium. In the epicardium, there is a prominent spike-and-dome appearance of the action potential plateau *(arrow).* This spike-and-dome appearance is the result of a prominent transient outward current, carried by potassium, which is present in the epicardium and separates phases 1 and 2 of the action potential. This is much less pronounced in action potentials recorded from the endocardium. **B,** Demonstration of the rate-dependent behavior of the transient outward current in canine ventricular myocardium. In epicardium, decreasing basic cycle length (BCL) (i.e., increasing heart rate) from 2000 to 300 msec markedly diminishes the spike-and-dome appearance of the action potential plateau and causes marked shortening of action potential duration. This is due to rate-dependent reduction of the transient outward current at faster heart rates (due to incomplete recovery from inactivation). This is not seen in endocardium, where I_{to} is negligible, resulting in little or no change in action potential duration in response to increases in heart rate. (*Note:* The effects of the rate-dependent decreases in I_{to} on action potential duration are variable. In some species and preparations, action potential duration increases; in others, it decreases.) *(**A,** Modified from Litovsky SH, Antzelevitch C: Transient outward current prominent in canine ventricular epicardium but not endocardium,* Circ Res *62:116, 1988, by permission of the American Heart Association.* **B,** *From Litovsky SH, Antzelevitch C: Rate dependence of action potential duration and refractoriness in canine ventricular endocardium differs from that of epicardium: role of the transient outward current,* J Am Coll Cardiol *14:1053, 1989. Reprinted with permission from the American College of Cardiology.)*

Under normal conditions, spontaneous automaticity is generally confined to the pacemaker cells of the sinus node. In these cells, microelectrode recordings reveal a slow depolarization of the membrane potential during phase 4 of the action potential, from the maximal diastolic potential (MDP) toward the activation, or threshold potential (Figure 66-5). Atrial myocytes, AV junctional cells, and His-Purkinje cells can all exhibit spontaneous diastolic depolarization, although at significantly slower rates than the sinus node. The precise currents responsible for pacemaker activity are still not completely delineated and may vary from site to site. A decline in an outward potassium current (referred to originally as I_{K2}) was initially proposed as the major depolarizing force resulting in spontaneous automaticity. It is now believed that spontaneous automaticity may result from a combination of factors, including a decline in an outward potassium current (possibly a decline in I_K or in AV nodal cells, I_{K1}), increases in both L- and T-type calcium currents, and a transient background Na^+ current.[16,17] Another inward current, carried partly by potassium and partly by sodium and termed I_f ("f" for "funny"), has been described and is believed to be an important pacemaker current in relatively hyperpolarized cells.[18] It is not clear whether I_f has a significant role in mediating pacemaker automaticity under normal conditions in the sinus node, where MDPs of only −50 to −60 mV are achieved.

DEVELOPMENTAL CHANGES IN ACTION POTENTIAL MORPHOLOGY AND TRANSMEMBRANE ION CURRENTS

Changes in action potential morphology and corresponding changes in ion current physiology occur throughout the course of development, beginning in early embryonic life, in both mammalian and nonmammalian species. Although important species-related differences do exist, increases in membrane resting potential, action potential amplitude, $\dot{V}_{max}$, and action potential duration are most often noted during the course of development.

Resting Membrane Potential

Increases in the resting membrane potential during development have been reported in several species. The resting membrane potential in the chick embryo doubles from −35 mV to approximately −70 mV from day 2 to day 18.[19] Similar increases in resting membrane potential have been reported in fetal rat, dog, and guinea pig hearts.[20-22] In rat and dog hearts, further increases in the resting membrane potential occur postnatally. There are several likely mechanisms responsible for the increasing resting membrane potential noted with development. Increases in activity of the sodium-potassium ATPase pump have been reported with maturation. In the chick heart, a threefold increase in the activity of sodium-potassium ATPase has been reported between day 6 and day 20 of incubation.[23] Similar increases in sodium-potassium ATPase have been observed in guinea pig myocardium from fetal day 45 to neonatal days 21 to 25.[24] The increase in sodium-potassium ATPase activity noted during development may in part result from expression of different isoforms of the sodium-potassium ATPase pump.[25] Increased activity of the

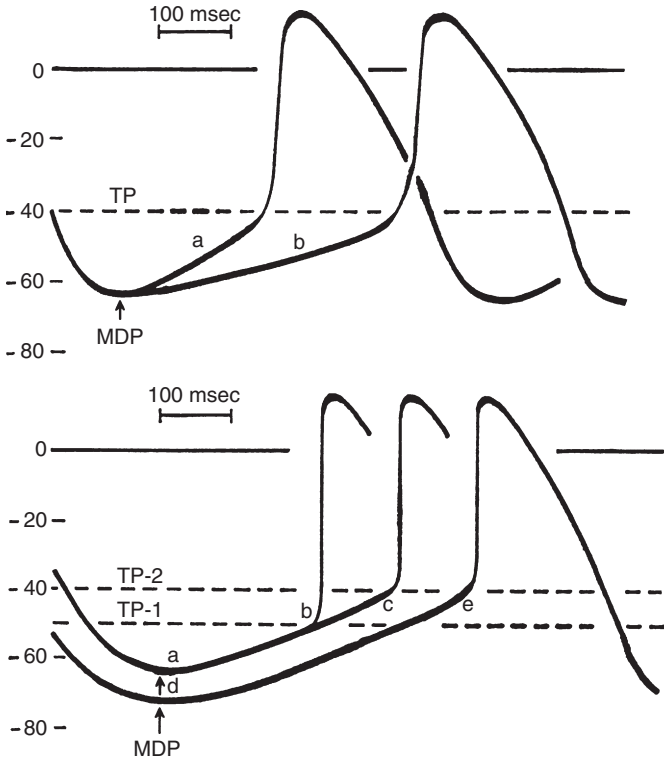

Figure 66-5 Mechanisms of modulation of cardiac pacemaker rate. *Top panel*, Two sinus node action potentials are illustrated. The threshold potential (TP) for both action potentials is −40 mV. The maximum diastolic potential (MDP) is approximately −60 mV. If the slope of spontaneous depolarization decreases (*b*), pacemaker firing rate is delayed. *Bottom panel*, Three sinus node action potentials are shown. A decrease in the threshold potential (i.e., less negative, TP-1 to TP-2) results in a delay in firing rate (*c* versus *b*). Pacemaker firing rate can also be delayed (*e* versus *c*) by an increase in the MDP (i.e., a more negative diastolic potential) (*a* versus *d*), with the slope of spontaneous depolarization and the threshold potential remaining constant. *(From Hoffman BF, Cranefield PF.* Electrophysiology of the Heart. *New York, McGraw-Hill, 1960, p 109.)*

sodium-potassium ATPase pump increases the concentration of potassium intracellularly and decreases the concentration of sodium. This results in a more strongly negative resting membrane potential, as discussed earlier in this chapter.

An increase in membrane permeability to potassium with development also contributes to the more negative resting potential observed with maturation. Specific increases in the current density of the inward rectifier current, I_{K1}, the main outward potassium current responsible for maintenance of the resting membrane potential, have been reported in the chick embryo, and in fetal and newborn rat and rabbit ventricular myocytes.[26-31] In the rat, the increase in I_{K1} may occur as a result of acquisition of a high-conductance potassium channel, one that is absent in the neonate.[31] In the human fetus, resting membrane potentials at midgestation (about 20 weeks) are similar to values reported in adult mammalian tissue.[32] In studies performed in atrial myocytes isolated from young infants (more than 2 months) undergoing heart surgery, the resting membrane potential is similar to that of the adult.[33] These studies suggest that in the human, developmental increases in resting membrane potential are not evident after midterm gestation. This does not preclude the possibility that increases in resting membrane potential might occur earlier in gestation.

Action Potential Upstroke, Phase 0

An increase in action potential phase 0 amplitude and $\dot{V}_{max}$ with maturation has been documented in several species. In the chick heart, $\dot{V}_{max}$ increases from 20 V/second at day 2 to more than 250 V/second at day 18.[19] In the rat, $\dot{V}_{max}$ increases 10-fold from day 10 of gestation to day 21 (term).[20] A threefold increase in $\dot{V}_{max}$ (200-550 V/second) occurs in the canine fetus Purkinje fiber action potential, from early fetal life to near term.[21] Similar trends are noted in guinea pig atrium and ventricle.[22] These increases in action potential amplitude and $\dot{V}_{max}$ are only partly the result of the increases in the resting membrane potential already described. Developmental changes in the structure or function of the ion channel or channels responsible for the upstroke of the action potential appear to contribute importantly to the developmental changes noted in the rate of rise of phase 0 of the action potential in the young embryo and fetus. In the early embryonic chick heart (before day 5), phase 0 of the action potential appears to depend on an ion channel that is not sensitive to the potent sodium channel blocker tetrodotoxin. Through day 8 of incubation, as $\dot{V}_{max}$ increases, a marked increase is noted in the sensitivity of phase 0 of the action potential to tetrodotoxin.[19] This suggests that in the early embryonic phase, the current responsible for the upstroke of the action potential is an embryonic sodium channel, one with slow kinetics, and one that is insensitive to tetrodotoxin. With maturation, an apparent switch occurs, with increased expression of a fast, tetrodotoxin-sensitive sodium channel. (Phase 0 of the action potential in the early chick embryonic heart is inhibited by calcium channel blockers, but sodium is still believed to be the dominant charge carrier.) An increasing sensitivity with maturation of phase 0 of the action potential to tetrodotoxin has also been reported in the fetal rat heart.[20] In the fetal mouse heart (fewer than 13 days' gestation), L-type calcium currents appear to play the dominant role in cardiac excitation, with sodium channel expression increasing only just before birth.[34] In contrast, in the canine heart, although increases in action potential amplitude and $\dot{V}_{max}$ also occur during fetal life, there appears to be no change in the apparent sensitivity of phase 0 to tetrodotoxin.[21] In summary, substantial increases in the amplitude and rate of rise of phase 0 of the action potential occur during avian embryonic and mammalian fetal life. Although increases in resting membrane potential undoubtedly contribute to this increase, developmental changes in the structure and function of cardiac ion channels, including the expression or function of accessory protein subunits, or changes in posttranslational modification of channel function, also likely contribute to the observed differences.

Phase 1 of the Action Potential

Developmental increases in the transient outward current, the outward current responsible for the spike-and-dome appearance of the action potential, have been described in several species. In rabbit ventricular cells, the current density of I_{to} in the neonate is about half that recorded in adult tissue.[29] The rate of inactivation and the rate of recovery from inactivation of I_{to} are both significantly faster (5 to 10 times) in neonatal cells. Because I_{to} displays rate-dependent behavior (decreasing as rate increases), developmental changes are observed in the response of action potential duration to pacing. In the adult rabbit, action potential duration increases, whereas in neonatal cells, little change in action potential duration is observed.[29,35] In rat ventricular myocytes, I_{to} appears to be absent in newborn myocytes and increases slightly between days 1 and 8. The most significant increases occur between 1 week of age and adulthood.[36] In canine ventricular myocytes, neither a notch nor spike-and-dome appearance in the action potential plateau is observed in epicardial myocytes until 2 months of age.[37] The spike-and-dome evolves with increasing postnatal age, reaching its full phenotypic expression only in adulthood. Maturation

of the spike-and-dome appearance correlates with the messenger RNA (mRNA) expression of genes associated with the transient outward current, specifically *KCNIP2* and *Kv4.3* (encoded by *KCND3*).[38] The maturation of the transient outward current also is associated with the development of the phenomenon of "cardiac memory," which refers to changes in repolarization that occur with and that persist after a period of chronic pacing, thought to represent a form of electrophysiologic remodeling. In human atrial cells, an absence of the typical spike-and-dome shape of the action potential has been reported in infant tissue, believed to reflect an absence of the transient outward current (Figure 66-6, *A*).[33] Although I_{to} has subsequently been identified in some cells isolated from young infants undergoing heart surgery,[39,40] significant changes in current density and in recovery kinetics have been reported with maturation (see Figure 66-6, *B*).[40] Most recently, changes that include a larger current density, faster inactivation, and slower recovery from inactivation in the neonate have been described and are believed to be a function of the differences in the relative expression of *KCNIP2* and *Kv4.3* (encoded by *KCND3*) in the neonate compared with the adult heart.[41] Thus, there appear to be consistent age-related increases in I_{to}, the transient outward current. The functional significance of the increase in the transient outward current is not fully understood, nor are the mechanisms that lead to the increased expression of the transient outward current in postnatal life, although augmentation of I_{to} may be linked to postnatal increases in oxygen tension.[42]

Action Potential Plateau and Repolarization, Phases 2 and 3

The slow inward calcium current ($I_{Ca\text{-}L}$) contributes importantly to the sustained depolarization that constitutes the action potential plateau. In the chick heart, nitrendipine (a calcium channel blocker) binding sites increase in number, beginning from day 3 of incubation, but channel affinity appears to be similar throughout development.[43] In day 11 chick embryos, calcium channels detected by nitrendipine binding studies are 100-fold more numerous than calcium channels determined by voltage-clamp studies.[44] These so-called silent calcium channels (present in ligand binding studies, absent from electrophysiologic studies) appear to become electrically active with further development. Kinetic changes in the behavior of the calcium channel have also been described in the chick heart with maturation. In voltage-clamp studies of very young (i.e., 3-day-old) chick embryos, the L-type calcium channel exhibits two distinct modes of firing: a bursting, transient mode and a long-lasting mode. With maturation, a significant decrease occurs in the long-lasting firing mode, and there is an increase in the bursting mode.[45] This *loss* of the long-lasting firing mode may contribute to the decrease in calcium current density that has been observed during chick embryonic development, despite an increasing number of calcium channels.[45,46] Furthermore, shifts occur in the relative contributions of L-type and T-type calcium channels to the calcium transient in early embryonic development. At embryonic day 5 in the chick heart, the relative contribution of the T-type current to the calcium transient is greatest. This dominant T-type current likely plays a significant role in excitation-contraction coupling in the very early ventricular myocardium (through Ca^{2+}-induced Ca^{2+} release from the sarcoplasmic reticulum).[47] In the 10-day-old chick embryo (and 18-week human fetus), angiotensin II can be shown to differentially modulate the relative contribution of the T- and L-type calcium current, acting to increase the T-type and decrease the L-type current.[48] The relative contribution of the T-type current then declines, such that by embryonic day 11 to day 15, it is the L-type current that becomes dominant.[47]

In mammalian hearts, increases in nitrendipine binding sites have been described in fetal rat and mouse hearts.[49,50] In the fetal rat heart (18 days), novel non-L-type, non-T-type calcium channels have been described.[51] These novel channels inactivate faster than the typical L-type calcium channel, and they have a different steady-state inactivation curve (percentage of channels inactivated as a function of membrane potential). Thus, as in the chick heart, there appears to be a functionally different calcium channel present in the rat fetus, one that is less expressed with further development. Postnatal increases in the L-type calcium current has been described in the mouse heart and is believed to be dependent on postnatal completion of sympathetic innervation and the action of the sympathetic cotransmitter, neuropeptide Y.[52] Calcium current density in the rat heart is fivefold larger in cells isolated from neonates compared with those from adults.[53] In addition to the inward calcium current, an inward sodium current (the window current) appears to play a relatively greater role in maintaining the action potential plateau in the fetal rat myocyte.[54]

In contrast to the developing chick and rat heart, in which calcium current densities tend to decrease with maturation, in the rabbit progressive increases in myocardial calcium current

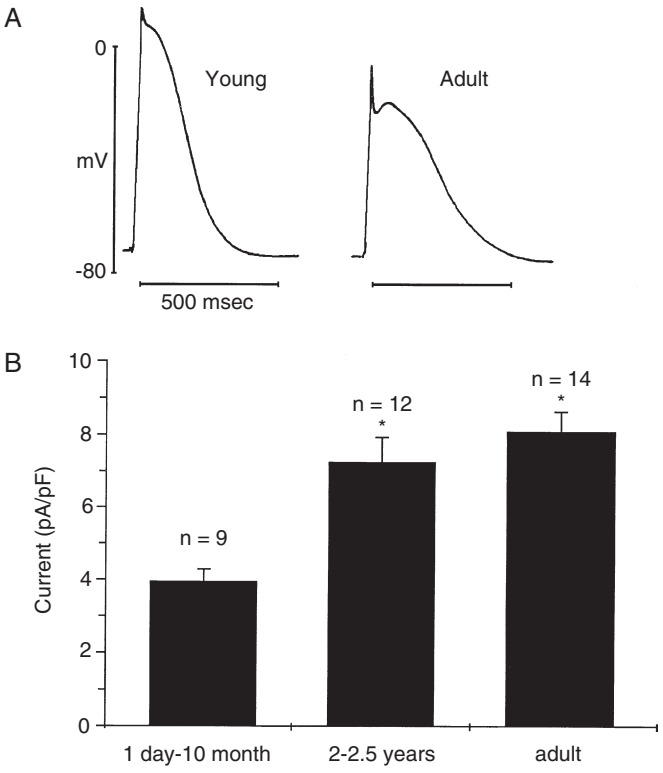

Figure 66-6 A, Comparison of human atrial action potentials. Note that in the adult atrial action potential, there is a prominent spike-and-dome appearance to the plateau phase of the action potential. This is presumed to reflect a prominent transient outward current (I_{to}) in the adult. This spike-and-dome shape of the atrial action potential is absent in the recording from a young infant. **B,** Relationship between age and transient outward current amplitude (I_{to}) in human atrial myocytes. Note that the transient outward current amplitude (pA/pF) is significantly less (*P <.05) in atrial cells isolated from infants less than 2 years of age. *(**A,** From Escande D, Loisance D, Planche C, et al: Age-related changes of action potential plateau shape in isolated human atrial fibers.* Am J Physiol *249:H843, 1985.* **B,** *From Crumb WJ Jr, Pigott JD, Clarkson CW: Comparison of I_{to} in young and adult human atrial myocytes: evidence for developmental changes,* Am J Physiol *268:H1335, 1995.)*

density have been described from fetal to adult life.[27] In addition to an increase in current density, significant changes in calcium channel kinetics also occur during development in the rabbit.[55] Inactivation of the calcium current occurs at less-negative membrane potentials in fetal myocytes compared with adult myocytes. In addition, recovery from inactivation occurs over a longer time course in immature cells. Because of the more prolonged time course of recovery from inactivation in immature cells, the calcium current becomes inhibited to a greater extent at faster stimulation frequencies in the fetus and newborn. This inhibition of the calcium current at faster heart rates may place the immature heart at a potential disadvantage for excitation-contraction coupling (a process that is dependent on transsarcolemmal calcium transport predominantly through the Na^+-Ca^{2+} exchanger but also to some extent through the L-type calcium channel).[56,57] Finally, it has been reported that calcium current density is equivalent in atrial myocytes of newborn and adult humans.[58]

Repolarization is the gradual activation of outward potassium currents during phases 2 and 3 that initiates and then drives the repolarization process. Marked developmental changes have been reported in the densities and distribution of the various K^+ repolarization currents over the course of development (Table 66-4).[11,59] In the rat, rabbit, and mouse, significant increases in I_K have been described from the fetal to neonatal period. In the rabbit, current density of I_K doubles postnatally through adulthood.[29] Interestingly, functional expression of I_{Kr} and I_{Ks}, the two main components of I_K, are only detectable in fetal or neonatal mouse hearts, and not in those of the adult.[60] In the canine heart, I_{Kr} but not I_{Ks} is expressed in the first 30 days of life, with both currents being observed in the adult myocardium.[61] I_{Kr} blockers, such as dofetilide, thus cause the greatest prolongation in action potential duration in the neonatal canine heart.

I_{Kur}, the ultrarapid component of the delayed rectifier I_K, which is detected only in the atrium of the adult dog, rat, and human heart, is also detected in neonatal rat ventricular myocytes.[62] I_{Kur} is absent in the immature mouse atrium.[63] Finally, an outward repolarization current unique to the newborn heart has been described in canine epicardial ventricular myocytes.[37] In neonatal myocytes, but not adult myocytes, an outward current is present (probably a potassium current) that rapidly activates with depolarization and shows little decay as a function of time, features qualitatively similar to I_{Kur} (Figure 66-7).

In summary, substantial changes have been described with maturation in action potential morphology and in the kinetics and densities of the individual ion currents that constitute the action potential. Allowing for some significant species-related and tissue site differences, increases in (1) the resting membrane potential, (2) the major inward cationic currents responsible for the upstroke of the action potential, (3) the plateau currents, and (4) many outward repolarization currents have been observed from early embryonic or fetal life. These maturational changes undoubtedly contribute to some important functional differences in impulse formation, conduction, and myocardial refractoriness that have been noted with development.

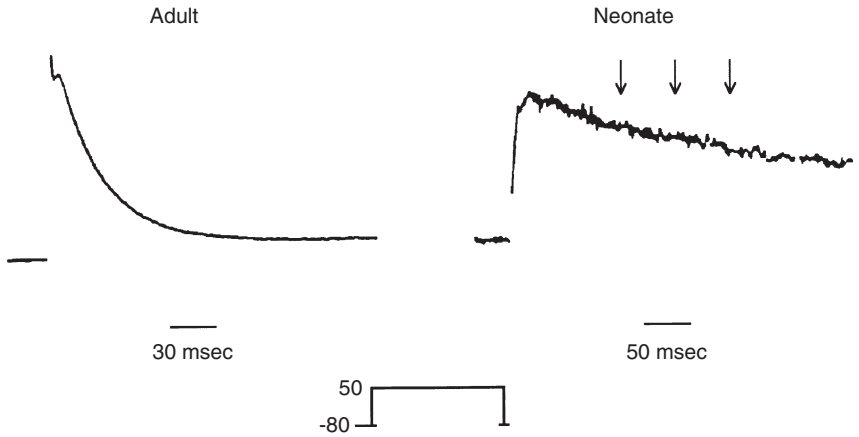

Figure 66-7 Comparison of outward currents recorded from ventricular myocytes isolated from adult and neonatal dogs. On the left, the transient outward current (I_{to}) is elicited in the adult myocyte in response to changing membrane voltage from −80 mV to +50 mV. The transient outward current is not recorded in neonatal cells. In the neonate, a unique outward current is elicited that rapidly activates and shows little decay over time. This current is not observed in adult myocytes. *(Modified from Jeck CD, Boyden PA. Age-related appearance of outward currents may contribute to developmental differences in ventricular repolarization,* Circ Res *71:1390, 1992, by permission of the American Heart Association.)*

IMPULSE FORMATION AND INTRAATRIAL AND ATRIOVENTRICULAR CONDUCTION IN THE EMBRYO, FETUS, AND NEONATE: MORPHOLOGIC AND PHYSIOLOGIC CONSIDERATIONS

In the chick embryo, spontaneous cardiac electrical depolarizations can be detected by voltage-sensitive dyes at about the seventh somite stage, well before contractions become evident.[64] These studies, as well as direct microelectrode recordings,[65] have demonstrated that, although contraction is first noted in the primitive ventricle of the chick embryo (somite stage 10), pacemaker activity evolves simultaneously in both atrial and ventricular sites. With subsequent development, pacemaker activity becomes confined to atrial sites. There is little information concerning the specific ion currents responsible for cardiac automaticity during development. Very early in embryonic life, before the development of true pacemaker ionic currents, "shuttling" of calcium in and out of the sarcoplasmic reticulum, through an inositol triphosphate–dependent mechanism, may be responsible for pacemaker activity at the earliest stages of development.[66] Embryonic stem cell–derived cardiomyocytes depend on a functional ryanodine receptor to differentiate into contracting myocytes with a progressively increasing beating rate.[67] Clusters of murine embryonic stem cells that in vitro demonstrate spontaneous depolarization ("pacemaker nodes") emit calcium signals to adjacent contractile cells. These "pacemaker nodes" are characterized by the expression of the genetic molecular marker *GATA6*.[68] It has been suggested that the so-called funny inward pacemaker current, I_f, which normally activates at hyperpolarized membrane potentials, may also contribute importantly to cardiac automaticity in very early embryonic life.[69] I_f is prominent in ventricular cells of 3-day-old chick embryos and is virtually absent from cells isolated from 17-day-old embryos. In the mouse heart, expression of I_f is also very high in ventricular cells early in development (10.5 days postcoitus) and diminishes in later developmental stages (13 to 16 days postcoitus).[70] In the newborn rabbit, sinus node automaticity can be shown to be due in part to a small, slowly inactivating, tetrodotoxin-sensitive inward sodium current. This current completely disappears shortly after birth.[71,72] Postnatal differences in sinus node L-type (but not T-type) calcium current density and kinetics have also been identified in rabbit sinus node.[73]

The genetic and environmental factors that contribute to pacemaker formation are largely unknown. It is known that cardiac mesenchymal tissues that are destined to form specific regions of the embryonic heart beat at predetermined, characteristic rates.[74] Tissue explanted from regions destined to form the sinoatrial region beats at a faster intrinsic rate than tissue destined to form the primitive ventricle.[75] Genetically determined differences in ion channel populations and kinetics of ion channel function are believed to be important in determining these programmed beating rates. That environmental cues can also modulate pacemaker development and function is demonstrable, in that transplanting mesenchymal tissue from "fast" sinoatrial regions into "slow" regions results in a gradual decrease in the rate of spontaneous firing of the transplanted tissue.[76] Physical contact between myocardial cells and nonmyocardial elements also may contribute to the induction of pacemaker cell aggregates.[77] In vivo, looping of the heart may bring the sinoatrial region of the heart into close contact with nonmyocardial mesenchyme and thereby induce formation of the sinoatrial pacemaker. In the human embryo, a sinus node is first identified shortly after the looping process is completed. The sinus node is an epicardial structure; it is positioned at the junction of the superior vena cava and the right atrium. It is relatively larger in the fetus than in the adult and is horseshoe shaped rather than having the spindle shape observed in the adult.[78]

Conduction of the Impulse From Sinus Node to Atrioventricular Node

The existence of specialized "internodal" conduction pathways within the right atrium, linking the sinus and AV nodes, has been proposed.[79] These putative specialized conduction pathways are located laterally, along the terminal crest of the right atrium, and medially, along the posterior and anterior rims of the fossa ovalis. Although such internodal pathways have been demonstrated histologically and by immunochemistry (including in the developing heart[80,81]), a lack of true specialized cell types and lack of insulation from surrounding myocardium have been cited by some researchers as evidence against true specialized internodal conduction pathways.[82] Studies of HNK-1 (Leu-7) antigen expression patterns in the embryonic rat heart provide evidence that connections between the sinus and AV nodes do exist and that they are derived from the embryonic sinoatrial junction. These connections will, by necessity, join the sinus and AV nodes and are in anatomic proximity to the putative special internodal tracks.[83] More recently, in the developing human heart, three internodal pathways have been identified connecting the sinus node and AV node after incorporation of the sinus venosus into the atrium. These studies, which also employed the HNK-1 antibody to track development of the cardiac conduction system, suggest that these internodal tracks (as well as portions of the posterior left atrial wall surrounding the pulmonary veins) are derivatives of the embryonic sinoatrial ring.[84]

Electrophysiologic studies of intraatrial conduction have also yielded conflicting results. In the dog and rabbit atrium, Spach and colleagues[85] were unable to find electrophysiologic evidence of specialized internodal conduction pathways. Other studies of the canine atrium, however, have reported the identification of three distinct bundles of myocardium that appear to serve as specialized inputs to the canine AV node. These myocardial fibers are electrically active even when atrial contractility is abolished by exposure to high levels of extracellular potassium, and they fire at the same rate as the sinus node.[86]

Whether or not true specialized internodal pathways exist, intraatrial conduction tends to propagate as waves of excitation within the atrium along directions that roughly follow the anatomic courses of the putative internodal pathways. This preferential conduction, along the terminal crest and the anterior and posterior interatrial septum, may be the result of a more uniform, longitudinal alignment of atrial myocytes in these anatomic locations, rather than being the result of specialized conduction pathways.[87]

Electrophysiologic differences in atrial action potential morphology and intraatrial conduction have been described during the course of development. In the adult dog, atrial action potential durations tend to decrease as recordings are made at sites more distal to the sinus node. Action potential durations in the newborn, in contrast, tend to be much more uniform throughout the atrium.[88] Atrial action potential durations also tend to be significantly shorter in the newborn rat, dog, and human compared with the adult (Figure 66-8, *A*).[33,88,89] In the mouse atrium, action potential durations are dramatically shorter in the neonate, a result of postnatal upregulation of outward K^+ currents (other than IKur, which as previously stated is absent in the newborn atrium).[63] Shorter action potential durations result in shorter refractory periods in the neonatal atrium compared with in the adult, which may facilitate the development of intraatrial reentry (see Figure 66-8, *B*).[90,91] It is possible that the occurrence of "benign" atrial flutter, observed at times in the fetus and newborn with an otherwise structurally normal heart, results in part from these shorter atrial refractory periods.[90,92] Finally, in addition to developmental changes in the electrophysiology of the developing atrial myocyte, growth of nonmyocardial elements within the atrium is believed to contribute to developmental differences

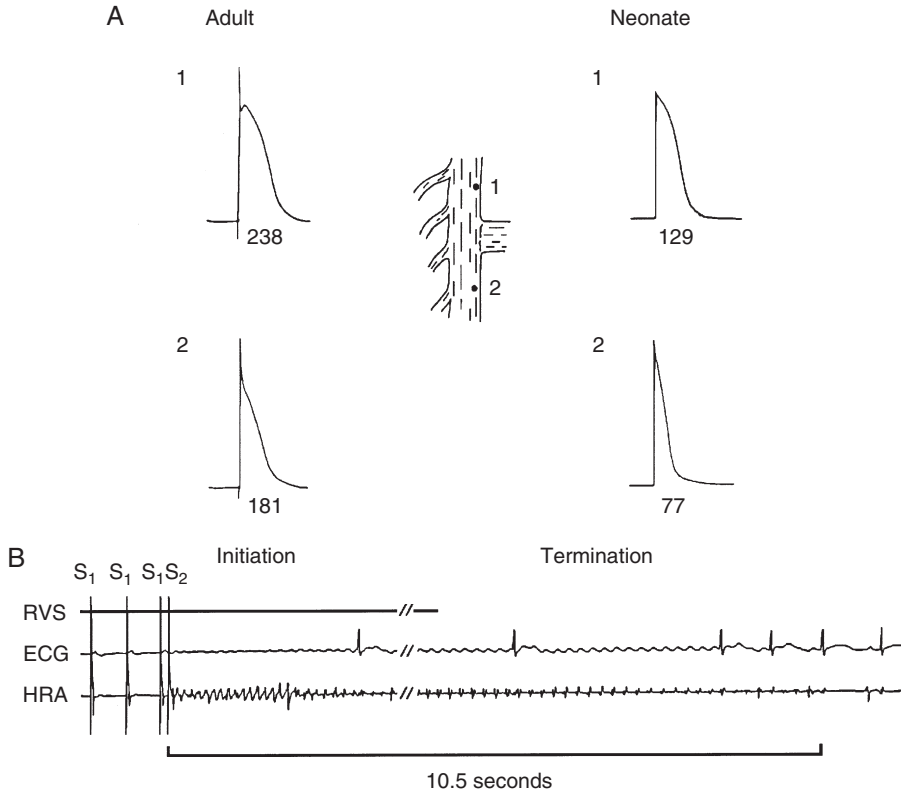

Figure 66-8 A, Atrial action potentials recorded from roughly similar locations along the terminal crest in adult and newborn dogs. Note that neonatal action potentials are characterized by little or no action potential plateau and shorter action potential durations (indicated beneath each action potential, in milliseconds) compared with the adult. **B,** The effect of premature atrial simulation during vagal stimulation in the newborn dog. RVS indicates the period of stimulation of the right vagus nerve; S_1 refers to a basic paced drive train; S_2 refers to a single premature atrial paced beat. Surface electrocardiogram lead II and intracardiac recordings of atrial activity from the right atrium (HRA) are shown. Note that with the introduction of the premature beat (S_2), a long train of atrial fibrillation-flutter is induced. (Similar but shorter runs of atrial fibrillation-flutter are induced in the atrium of the newborn in the absence of vagal stimulation.) *(**A,** Modified from Spach MS, Dolber PC, Anderson PA: Multiple regional differences in cellular properties that regulate repolarization and contraction in the right atrium of adult and newborn dogs.* Circ Res *65:1594, 1989, by permission of the American Heart Association.* **B,** *Modified from Pickoff AS, Stolfi A: Modulation of electrophysiological properties of neonatal canine heart by tonic parasympathetic stimulation,* Am J Physiol *258:H38, 1990.)*

noted in propagation patterns within the atrium. For example, in the neonatal heart, impulses conduct directly from the superior rim of the terminal crest to the adjacent atrial myocardium, whereas in the adult, atrial conduction proceeds inferiorly first, before activation of the myocardium adjacent to the superior terminal crest.[88]

Atrioventricular Conduction *Before* the Formation of the Specialized Atrioventricular Conduction System

Delay between contraction of the chick atrium and contraction of the ventricle is first noted 50 hours after conception (20th somite stage).[93,94] This emulation of AV nodal function occurs before the development of the AV conduction system. Microcellular recordings from the AV canal region at this stage of development demonstrate the presence of slow response-type action potentials. The slow rate of rise of the action potential upstroke functionally corresponds to this zone of slow conduction. It is likely that AV canal cells are the mediators of AV delay in the early chick embryo.[95] These cells, however, can be shown *not* to contribute to the formation of the definitive AV node in later development.[96] Similar findings have been reported in mammalian hearts. In the prelooped, preinnervated rat heart, AV delay also appears to originate in cell populations corresponding to the endocardial cushions or AV canal.[97] Although the endocardial cushions stain positive for acetylcholinesterase in these preinnervated hearts (and adjacent myocardium lacks this cholinergic enzyme),[98] it is not clear that this intrinsic cholinergic system contributes to the observed AV delay. Finally, in the rat embryo, simulation of His-Purkinje system function is also observed before formation of the true AV conduction system. Shortly after looping, a synchronization of ventricular wall motion is observed, coupled with a 10-fold increase in conduction velocity.[97] These changes are highly correlated with expression of the major gap junction protein, connexin 43.[99] Gap junctions are the specialized protein channels that connect adjacent myocytes (Figure 66-9, *A* to *C*).[100] These channels allow not only the passage of electrical current through a low-resistance pathway from cell to cell but also the exchange of larger molecules between cells. The expression of different isoforms of the connexin proteins form gap junctions with different functional characteristics. Expression of connexin isoforms is highly regulated throughout cardiac development.[101] In the mouse heart, connexin 40 is diffusely up-regulated through embryonic day 14, at which time its expression becomes largely confined to the atrium, whereas connexin 43 becomes the dominant isoform expressed in the ventricular myocardium.[99,102] Expression of a third isoform, connexin 45, is largely confined to the specialized cardiac conduction system (see Figure 66-9, *D*). A similar pattern of differential connexin expression is observed in the human

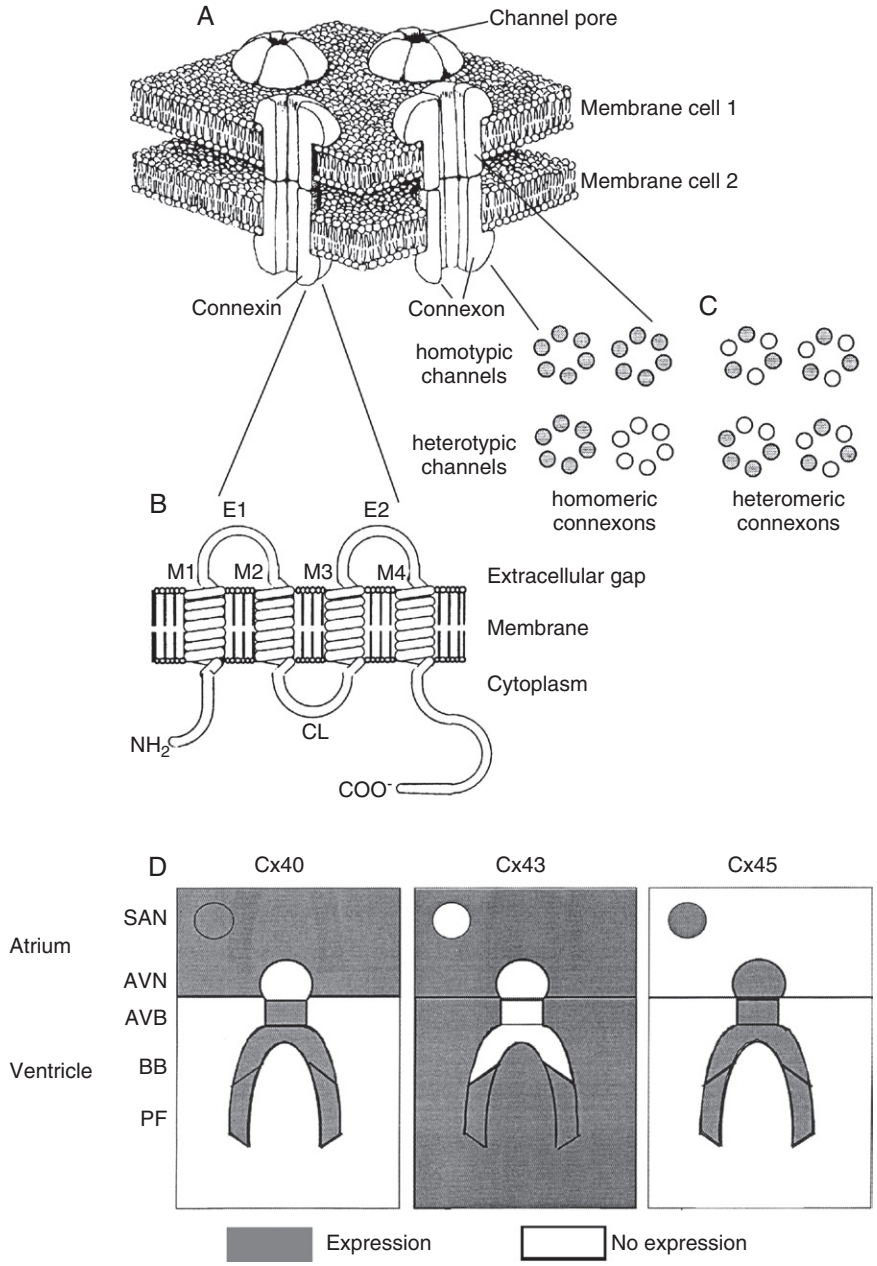

Figure 66-9 Ultrastructure of cardiac gap junctions. Gap junctions occur as "plaques" of multiple intercellular channels. **A,** Portion of a gap junction plaque demonstrating the structure of the intercellular channels, which join cell membranes from two adjacent cardiac myocytes (membrane cell 1, membrane cell 2). Each cell membrane contributes half of the channel structure, called a *connexon*. Each connexon consists of six connexin proteins. **B,** Secondary structure of a single connexin protein. **C,** Connexons formed from identical sets of connexins are termed *homomeric connexons*. Those formed from dissimilar connexin isoforms are termed *heteromeric connexons*. These then combine to form either homotypic or heterotypic intercellular channels. **D,** Expression of the major connexin isoforms, Cx40, Cx43, and Cx45, in the mammalian myocardium and specialized conduction system. AVB, His bundle; BB, bundle branches; AVN, atrioventricular node; PF, Purkinje fibers; SAN, sinoatrial node. *(From van Veen TA, van Rijen HVM, Opthof T: Cardiac gap junction channels: Modulation of expression and channel properties,* Cardiovasc Res *51:217, 2001.)*

fetal heart.[103] The differential regulation of expression of connexins within the developing heart may be altered by factors such as exposure to hypoxia and tumor necrosis factor-α.[104,105] The critical role of connexins for normal cardiac conduction, as well as normal cardiac development, is demonstrated by reports of abnormal, sometimes lethal, intracardiac conduction abnormalities, and of abnormal anatomic development, in hearts of mice with absent or diminished expression of specific connexins.[106,107]

In the developing embryo, the newer regions of fast conduction remain flanked by persisting zones of slow conduction, including the AV canal region and the outflow tract. These regions are characterized by continued expression of both atrial and ventricular myosin heavy chain isoforms and very scarce gap junctional protein.[108] With completion of septation, ventricular activation in the chick embryo switches from an "immature" base-to-apex activation pattern to the "mature" apex-to-base activation pattern.[109] This switch in activation pattern occurs gradually, rather than

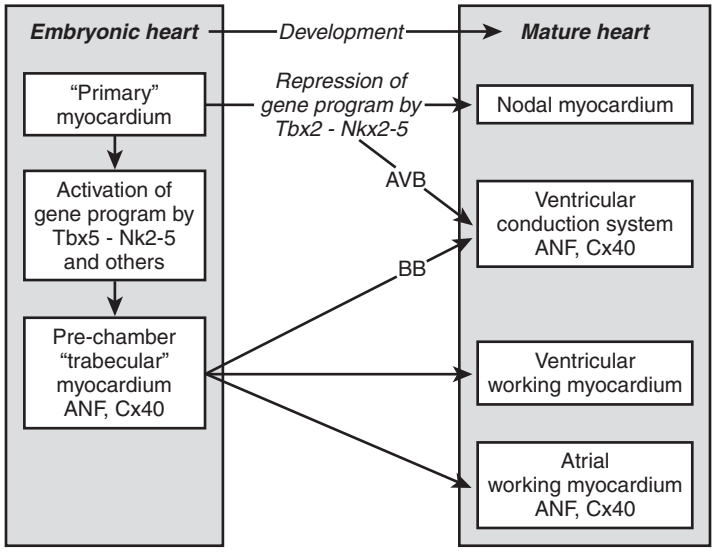

Figure 66-10 The primary myocardium of the heart tube is of a nodal phenotype. The SA node, AV node, and His bundle are derived from this embryonic primary myocardium. The ventricular conduction system (i.e., the bundle branches) and myocardium of the ventricles are derived from the prechamber trabecular myocardium of the embryo. ANF and Cx40 are expressed in those elements of the conduction system that are formed through the trabecular, or secondary, myocardium, whereas ANF and Cx40 expression is repressed by Tbx and Nkx2.5 in components derived from the primary myocardium. See text for further discussion. *(From Moorman AFM. Christoffels VM. Development of the cardiac conduction system: A matter of chamber development. In Chadwick DJ, Goode J (eds):* Novartis Foundation Symposium 250. Development of the Cardiac Conduction System. *Chichester, UK, Wiley and Sons, 2003, pp 25-43.)*

abruptly.[110,111] Two-dimensional optical mapping has permitted the elucidation of "breakthrough" foci in ventricular activation in the course of development. These foci roughly correspond to regions of precursors of the cardiac conduction system.[111,112] In contrast, in the mammalian heart, completion of septation may not be associated with such a switch in ventricular activation sequence.[113]

Formation of the Specialized Atrioventricular Conduction System

The true specialized AV conduction system, including the AV node, bundle of His, and right and left bundle branches, forms after the looping process is completed. Multiple immunohistochemical markers have been employed to delineate and track the development of the specialized conduction system, including in the human heart. Although many of these molecular markers are also markers of neural tissue (e.g., ganglion nodosum [GLN], HNK-1), the conduction system is *not* derived from neural (i.e., ectodermal) precursors. Rather, the conduction system is derived from multipotential mesenchymal precursors. The sinus node, AV node, and bundle of His are derivatives of the embryonic primary myocardium, whereas the more distal ramifications of the conduction system, or bundle branches, are formed from derivatives of embryonic secondary myocardium, specifically, the "prechamber" trabecular myocardium, a domain that is genetically distinct from the adjacent embryonic compact myocardium (Figure 66-10).[108,114] Derivatives of the secondary myocardium are characterized by the expression of atrial natriuretic factor (ANF), connexin 40 and connexin 43, a genetic program not present in derivatives of the embryonic primary myocardium.[114] Cardiomyogenic precursor cells may be induced by regional cues to express genetic programs that promote differentiation into cells of the specialized cardiac conduction system. These regional cues, or inducers, may include neural crest cells, which migrate during development into the region of the central cardiac conduction system, and epicardium-derived cells, which may influence the differentiation of the more distal ramifications of the Purkinje network.[115,116] Neural crest cells entering the heart through the arterial poles may contribute to the differentiation of the bundle branches, whereas neural crest cells entering through the venous pole may have a role in the induction of sinus node and AV nodal cell development.[117] Recruitment of mesenchymal tissue into the specialized cardiac conduction system may also involve induction by cues originating from nearby developing coronary vasculature.[118] Mounting evidence points to endothelin-1 as a crucial signaling molecule governing the transformation of cardiomyogenic precursor cells into cells of the specialized cardiac conduction system.[115,119]

The transcriptional regulation of the differentiation of cardiomyogenic precursor cells into cells of the specialized cardiac conduction system is the subject of intense investigation. Several transcription factors, including the homeodomain transcription factor *Nkx2.5,* the zinc finger factor GATA6, members of the T-Box family (*Tbx2, Tbx 3,* and *Tbx5*), and Hop (homeodomain only protein, acting downstream from *Nkx2.5*) appear to be critical in the differentiation, formation, and function of the specialized cardiac conduction system.[120-122] *Nkx2.5* is preferentially expressed in the developing cardiac conduction system. Precise regulation of *Nkx2.5* expression is essential for normal development of Purkinje fibers in the developing chick embryo.[123] Mutations of this critical transcription factor in humans result in congenital heart defects as well as conduction disturbances and arrhythmias.[124,125] In some patients, mutations of *Nkx2.5* are also associated with a cardiomyopathy, characterized by overgrowth of trabecular ventricular muscle.[126] In transgenic mouse models, *Nkx2.5* insufficient mice develop conduction and electrophysiologic abnormalities that are in part the result of the marked hypoplasia of the AV node and His-Purkinje system.[127] How the aforementioned transcription factors direct the differentiation of the heart and cardiac conduction system is illustrated in Figure 66-10. ANF is a highly specific marker for the developing working myocardium. Furthermore, the promotor region of

the *ANF* gene contains multiple binding sites for several cardiac transcription factors important in the development and function of the cardiac conduction system, including *Nkx2.5, GATA,* and *Tbx.*[127] It is hypothesized that chamber-specific, working myocardium gene expression is repressed in the nodal myocardium (sinus node, AV node, and His bundle) secondary to an inhibition of ANF expression, as a result of the binding of *Tbx2* and *Nkx2.5* to the ANF promotor region.[124,128] Elements of the cardiac conduction system derived from the prechamber trabecular myocardium (the bundle branches) do express ANF as well as connexin 40 *(Cx40).* The result is that with differentiation, the specialized conduction system expresses a molecular pattern that is distinct from the surrounding atrial or ventricular myocardium.[117,129,130]

In humans, recent immunohistochemical studies have demonstrated that the entire AV conduction system forms from a single ring of specialized tissue. This ring of tissue can be identified by its binding of a specific monoclonal antibody raised against chicken GLN antigen (Figure 66-11, *A*). The region can be tracked throughout the development of the AV conduction system.[131] In the human embryo (Carnegie stage 14), the original GLN ring surrounds the interventricular foramen, which connects the primitive left and right ventricles (see Figure 66-11, *B*). At this early stage of development, just after looping of the heart has occurred, the atrium is connected only with the left ventricle. With further development (Carnegie stages 15 to 17), rightward expansion of the GLN ring is observed, as the atrium expands rightward to form the tricuspid orifice (see Figure 66-11, *C*). Thus, the GLN ring always outlines the pathways of blood that flow into the primitive right ventricle. As development of the interventricular septum proceeds (Carnegie stages 18 to 23), the lower rim of the original GLN ring is raised superiorly. After contact between the rising interventricular septum and the lesser curve of the looped heart, the AV node and proximal bundle of His are formed at the medial posterior aspect of the rightward expansion of the GLN ring, with the bundle of His in continuity with the right and left bundle branches (see Figure 66-11, *D*).

In the normal heart, the AV node is positioned anatomically within the triangle of Koch. This triangle is formed by the septal leaflet of the tricuspid valve and the tendon of Todoro, forming two arms of the triangle, and the coronary sinus orifice, defining

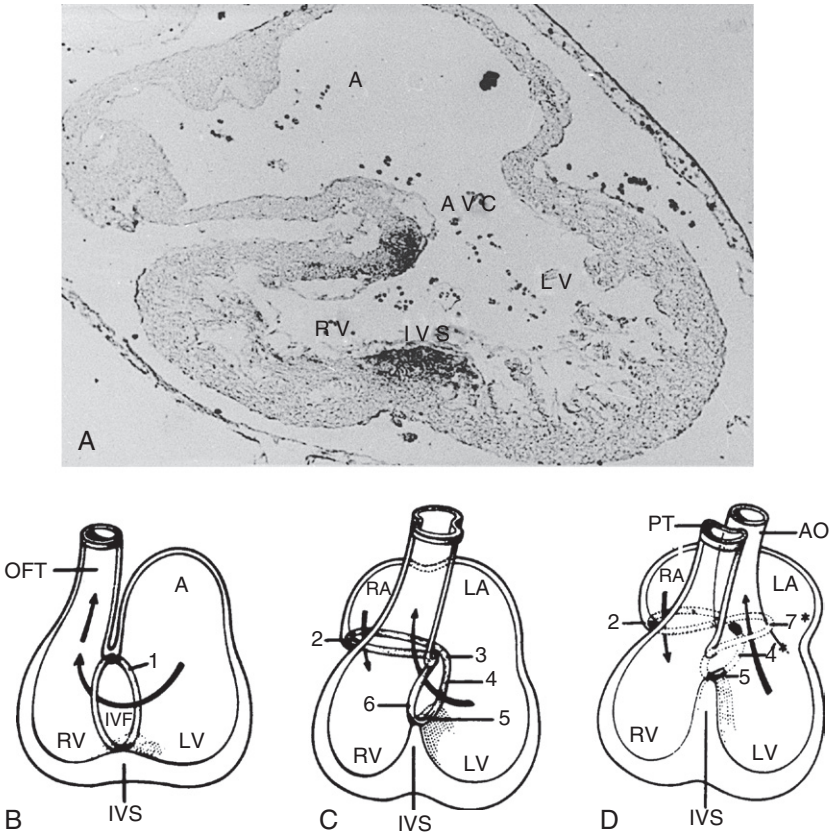

Figure 66-11 **A,** Immunohistochemical staining of the embryonic precursor of the atrioventricular (AV) conduction system in the human heart (Carnegie stage 14). A single ring of tissue, stained for the ganglion nodosum (GLN) antigen, is seen surrounding the interventricular foramen. It is from this single ring of tissue that the entire AV conduction system forms. This includes the AV node, His bundle, and right and left bundle branches. AVC, atrioventricular canal. **B-D,** Formation of the AV conduction system. **B,** The single GLN ring surrounds the interventricular foramen (IVF) in the looped heart (Carnegie stage 14). At this stage of development, the primitive atrium connects solely with the left ventricle (LV). **C,** At Carnegie stages 15 to 17, there is rightward expansion of the GLN ring, as the right atrium (RA) and tricuspid orifice form over the right ventricle (RV). Note the interventricular septum (IVS) rising from the floor of the ventricles. The AV node forms at position 3, the His bundle at position 4, and the bundle branches at position 5. **D,** At Carnegie stages 18 to 23, there is further development of the IVS. Involution of much of the original GLN ring now occurs, leaving the newly formed AV conduction system. *(From Wessels A, Vermeulen JLM, Verbeek FJ, et al: Spatial distribution of "tissue-specific" antigens in the developing human heart and skeletal muscle. III. An immunohistochemical analysis of the distribution of the neural tissue antigen G1N2 in the embryonic heart; implications for the development of the atrioventricular conduction system.* Anat Rec *232:97, 1992, by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons.)*

the base of the triangle. The AV node is positioned at the apex of the triangle. Histologically, the node consists of a loose or transitional zone and a compact region.[132] In hearts from some neonates, extensions from the compact zone of the AV node have been observed and in the past have been considered by some as possible substrates of electrical instability and a possible cause of sudden death.[133] These extensions are now believed to more likely represent normal variants.[134] From the compact node, the AV bundle arises, piercing the central fibrous body of the heart and branching into the right and left bundle branches. The left bundle branch is located in a subendocardial position and spreads in a fanlike fashion over the left ventricular septal surface. The right bundle branch runs an intramyocardial course within the right septal surface, is more cordlike, and emerges onto the endocardial surface of the right ventricle beneath the medial papillary muscle, descending to the apex of the right ventricle along the moderator band.

Physiology of Atrioventricular Conduction

Earlier studies of AV conduction in the developing mammal suggested that the AV node and specialized conduction system of the younger animal offered little or no protection of the ventricles against rapid atrial rates. In young goats, pigs, and puppies, it was reported that the refractory period of the AV conduction system (which determines how closely two impulses can be conducted) was shorter than the refractory period of the ventricle. Thus, rapid atrial rates were reported to conduct down the specialized conduction system to the ventricles, causing ventricular fibrillation in young goats and pigs.[135,136] In newborn calves, little or no increase in AV nodal conduction time was noted during closely coupled electrical stimulation of the atrium.[137] Collectively, these studies suggested that the neonatal AV node was ineffective as a filter.

More recent studies have challenged these conclusions. In the intact, anesthetized newborn dog, intracardiac electrographic recordings have demonstrated that, when corrected for inherent differences in heart rate, the neonatal AV node does in fact act as an effective filter.[138] The refractory period of the AV node in the neonate is significantly longer than the ventricular refractory period, and the AV node serves as the primary site of conduction slowing in both neonates and adult animals. Microelectrode recordings within the neonatal and adult rabbit AV node have also demonstrated little developmental difference in the electrophysiologic characteristics of the AV node.[139] Normal AV conduction delay has been demonstrated by magnetocardiography and fetal echocardiography in fetal sheep and in human fetuses at about 20 weeks of gestation.[140-143] In humans, there are few differences in the AV nodal conduction times of young infants and adults.[144] Thus, the neonatal AV node may act as more of an effective filter than was suggested by earlier studies.

In the dog, the electrophysiology of the specialized conduction system has been studied from the time of implantation to birth.[21] Conduction velocities increase during the course of development. This increase in conduction velocity is due in part to maturational changes in Purkinje fiber action potential characteristics (increases in resting membrane potential and increases in amplitude and $\dot{V}_{max}$). Changes in the architecture of the developing Purkinje fiber, however, likely contribute to the increase in conduction velocity as well. Increases in Purkinje fiber diameter and cell-to-cell contacts have been described in the developing canine conduction system.[145] In addition to an increase in cell size, gap junctions "redistribute" with maturation. In newborn ventricular myocytes, gap junctions are located over the entire cell surface (ends and sides), whereas in the adult, an end-to-end arrangement is observed (Figure 66-12). Both the increase in cell size and the redistribution of gap junctions contribute to the significant increase in $\dot{V}_{max}$ observed in conduction along the transverse (but not longitudinal) direction in the adult heart.[146]

Maturational changes in His-Purkinje conduction characteristics other than conduction velocity have also been described in the canine conduction system. In the newborn dog, the initial site of activation of the ventricles appears to be a right ventricular site rather than the left aspect of the interventricular septum, as in the adult.[147] Retrograde conduction, the ability to conduct an impulse from the ventricle to the atrium, appears more common in the neonatal heart.[148] Finally, action potential durations along the His-Purkinje system are more uniform in the neonate than in the adult, in whom there is an abrupt increase distally in the action potential duration of the Purkinje fiber, at the level of the distal false tendon.[149] This abrupt increase in action potential duration at the site of insertion of the Purkinje fiber into the ventricular muscle has been interpreted as functioning as a "physiologic gate," serving as a protector against closely coupled, rapid impulses.[149,150] This physiologic gate appears to be absent in the neonatal heart, rendering the neonatal ventricle *potentially* susceptible to the rapid conduction of supraventricular impulses (Figure 66-13).

Autonomic Innervation-Modulation of Cardiac Automaticity and Conduction

In considering developmental cardiac electrophysiology, it is also necessary to consider maturation of the autonomic nervous system and its effect on the electrophysiologic properties of the heart. Changes in autonomic tone profoundly affect pacemaker impulse generation as well as AV conduction and myocardial refractoriness.

Parasympathetic Nervous System

In the chick heart, evidence of cholinergic innervation, assessed by the histochemical detection of choline acetyltransferase (CAT) (the enzyme responsible for the synthesis of acetylcholine), is first noted about 3 days after fertilization. Progressive increases in CAT, and in the uptake of the parasympathetic neurotransmitter precursor choline, occur with further development. Choline uptake peaks about10 days after fertilization, just before the onset of ganglionic transmission.[151] In the mammalian heart, muscarinic receptors are present before actual innervation of the heart. Acetylcholinesterase is also demonstrable before innervation in the developing rat, rabbit, and human heart.[152] Progressive age-related increases in acetylcholine synthesis are demonstrable in the atria of rats. Cholinergic innervation of the heart becomes denser in the regions of the sinus and AV nodes and throughout the atria. In the human newborn, moderate cholinesterase activity is found in association with the conduction system, mostly in association with the sinus and AV nodes.[153] Little or no cholinesterase staining of the bundle branches is observed in the newborn infant. Postnatal maturation of innervation to include the remainder of the conduction system occurs, reaching a maximal density in childhood.[154,155] Intracardiac ganglia undergo significant postnatal morphologic changes in the human, with increases in the area occupied by both intracardiac ganglia and neurons occurring with age.[156] Furthermore, developmental changes in the expression and function of ion channels of intracardiac neurons have been described, with an inwardly rectifying potassium channel being identified in adult, but not neonatal, rat intrinsic cardiac neurons.[157]

Muscarinic receptor density has been found to be significantly higher in the myocardium of fetal rat and sheep hearts compared with in the adult. The production of phosphoinositol (a secondary muscarinic messenger) is also greater after muscarinic receptor activation in the immature heart.[158] Muscarinic receptor subtypes may differ in the immature heart. In addition to the dominant cardiac cholinergic M2 receptor found in the adult heart, M1 subtypes may be found in the neonatal heart. These receptors may subserve different physiologic responses to

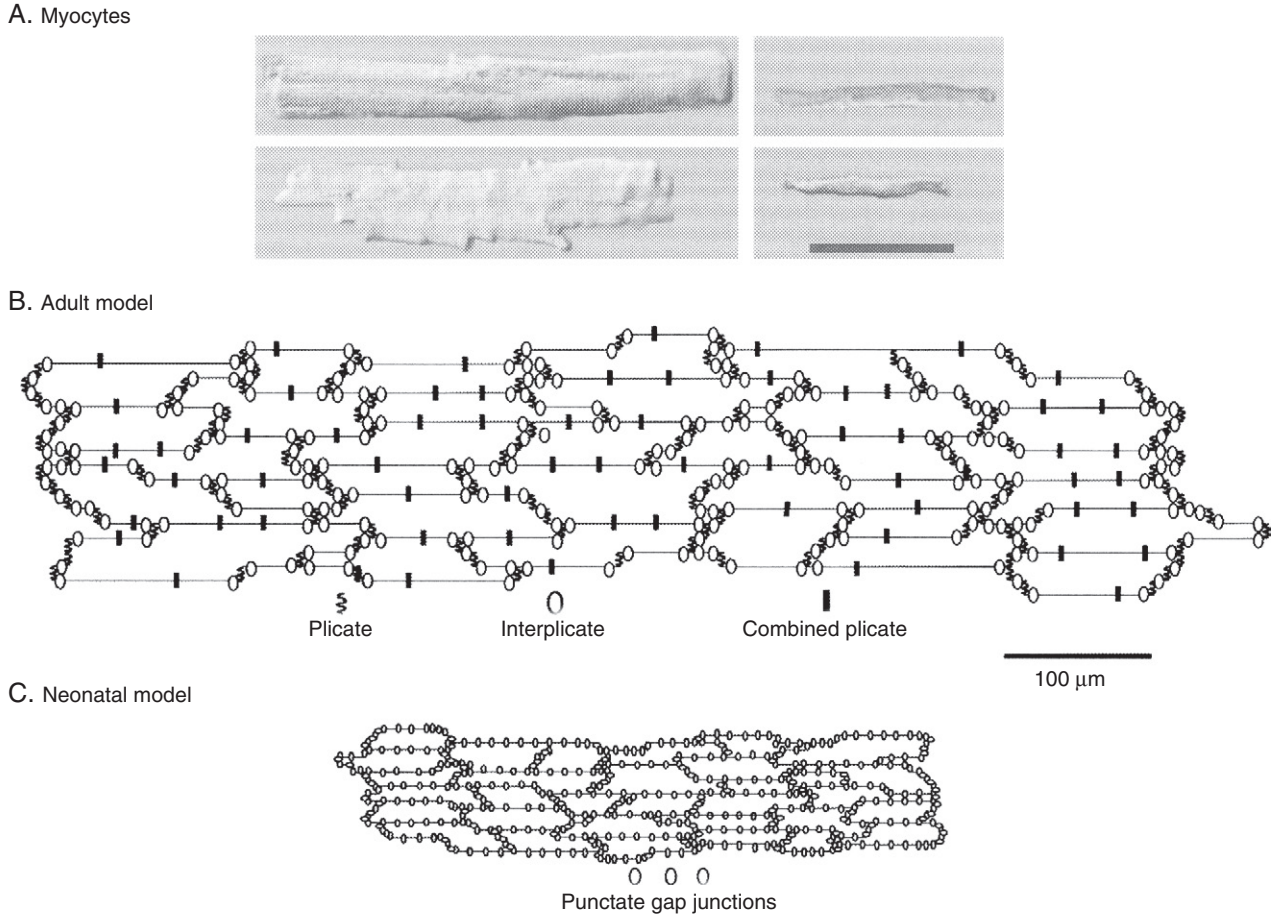

Figure 66-12 Ventricular myocyte dimensions and gap junction distributions in the adult and newborn dog. **A,** Relative size of adult compared with newborn ventricular myocytes. Adult myocytes are significantly larger than newborn myocytes. (Bar measurement = 50 μm). **B,** Two-dimensional multicellular model of adult ventricular myocytes. Three different gap junction morphologies are illustrated (plicate, interplicate, and combined plicate). Note that the location of most gap junctions in the adult (all of the plicate and interplicate types) are confined to the ends of the ventricular myocytes. **C,** Two-dimensional multicellular model of neonatal ventricular myocytes. A diffuse end and side distribution of gap junctions is illustrated. *(From Spach MS, Heidlage JF, Dolber PC, Barr RC. Electrophysiological effects of remodeling cardiac gap junctions and cell size,* Circ Res *86:302, 2000, by permission of the American Heart Association.)*

acetylcholine stimulation. The presence of a different subpopulation of muscarinic receptors in the neonate may explain the paradoxical increase in automaticity observed in neonatal ventricular cells in response to low concentrations of acetylcholine, a response not seen in adult cells.[159]

The primary actions of acetylcholine on cardiac ion channels include an increase in outward potassium currents ($I_{K(ACh)}$ and I_{K1}) and an inhibition of the inward calcium current, $I_{Ca\text{-}L}$.[159-162] These primary effects are mediated through a membrane-bound, pertussis toxin–sensitive, inhibitory G_i protein and a pertussis toxin–insensitive protein, G_q (Figure 66-14, *A*). In sinus and AV nodal tissue, increases in outward potassium currents result in hyperpolarization of the cell. This increase in membrane potential, coupled with muscarinic inhibition of the inward calcium current, accounts for the slowing of the cardiac pacemaker rate that is characteristic of muscarinic stimulation. It has also been shown that acetylcholine inhibits I_f, the funny pacemaker current, which also contributes to cardiac pacemaker slowing by acetylcholine.[163] Increases in outward potassium currents account for the marked shortening of atrial action potential duration and the marked shortening of atrial refractoriness observed with muscarinic stimulation in atrial tissue. In the rat atrium, acetylcholine-induced outward potassium current density progressively increases from 12 days gestation to 20 days postnatally (and then decreases in adulthood as cell capacitance [i.e., cell size] increases).[164] Inhibition of the inward calcium current, primarily within the nodal or N region of the AV node, reduces the amplitude and rate of rise of the slow-response AV nodal action potential. This accounts for the slowing of conduction through the AV node. The refractoriness of the AV node is also markedly increased by muscarinic stimulation. In ventricular myocardium, a slight but significant increase in ventricular refractory periods occurs with vagal stimulation. Evidence is increasing that this is a direct effect of acetylcholine.[165] The precise ionic basis for this effect is not well understood.

Maturation of parasympathetic control of cardiac electrophysiology is evident from studies of heart rate variability, as well as the effects of muscarinic blockade, vagus nerve transection, and vagal nerve stimulation in the course of development. In the human fetus, the increase in heart rate observed in response to a maternal dose of atropine increases with advancing gestation.[166] In the premature infant (32.3 ± 1.3 weeks), analyses of the respiratory component of heart rate variability, a surrogate of vagal activity, suggest that respiratory vagal activity increases over the first postnatal month.[167] In the fetal rabbit, cutting the vagus nerve causes a smaller increase in heart rate than is observed in the adult.[168] In the fetal lamb, vagal stimulation causes a greater slowing of the heart rate as gestation progresses.[169] Continued maturation

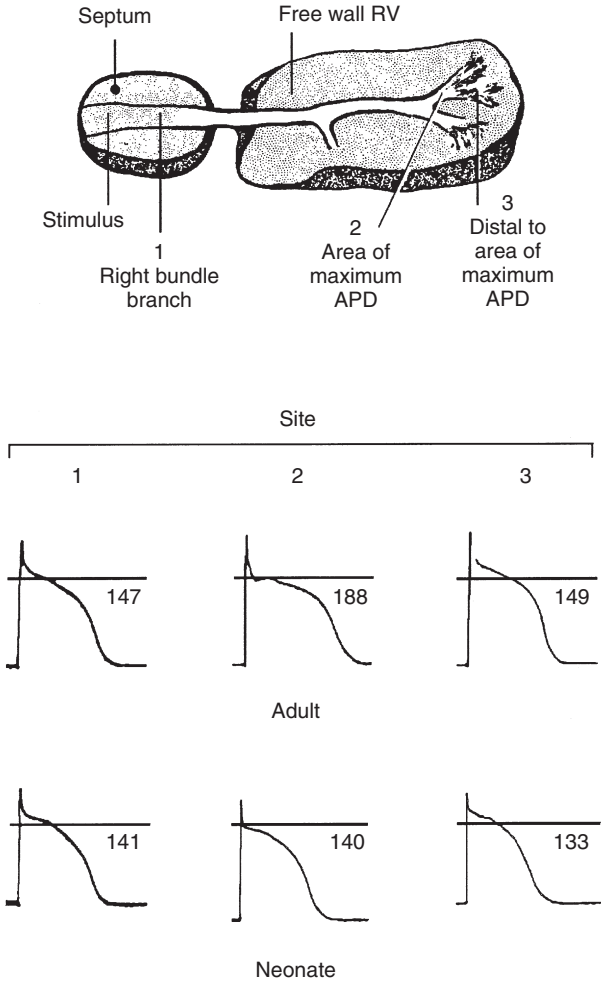

Figure 66-13 Physiology of the specialized ventricular conduction system in the neonatal and adult dog. Intracellular microelectrode recordings of transmembrane action potentials are shown along the length of the right bundle branch, including distal ramifications. Site 1 corresponds to the proximal right bundle branch, site 2 just proximal to distal ramifications, and site 3 distal ramifications. In the adult dog, there is an abrupt increase in action potential duration (APD) noted at site 2 (increase from 147 to 188 msec, site 1 to site 2). This abrupt increase in action potential duration functions as a physiologic gate, blocking the conduction of closely coupled impulses to the ventricle. This abrupt increase in action potential duration is not present in the neonate. Therefore the physiologic gate is inoperative in the neonate. *(Diagram of right bundle branch and right ventricle free wall is from Myerburg RJ, Stewart JW, Hoffman BF. Electrophysiological properties of the canine peripheral A-V conducting system.* Circ Res *26:361, 1970, by permission of the American Heart Association. Action potentials are modified from Untereker WJ, Danilo P Jr, Rosen MR. Developmental changes in action potential duration, refractoriness, and conduction in the canine ventricular conducting system,* Pediatr Res *18:53, 1984.)*

of parasympathetic responses is evident in many species postnatally. In the puppy, the magnitude of the response of heart rate to long trains of vagal nerve stimulation increases postnatally.[170] The response to brief trains of vagal stimuli, which experimentally mimics how the vagus actually fires in vivo, also changes with development. In the adult, the degree of prolongation of sinus cycle length (as well as the degree of prolongation of AV nodal conduction) progressively *increases* as a brief vagal train is delivered progressively later in the cardiac cycle. This typical phase-response relationship is not observed in the newborn (Figure 66-15). Full maturation of the response to brief vagal stimuli is not observed until about 1 to 2 months of age.[171,172] Thus, although parasympathetic responses and reflexes are clearly present in utero and in the preterm infant, it is incorrect to consider the parasympathetic nervous system as being fully mature at birth. Significant maturation occurs in both the magnitude and type of responses elicited by parasympathetic stimulation in postnatal life.

Sympathetic Nervous System

Evidence of functional β-adrenergic receptor modulation of calcium channel currents is observed in the early mammalian heart, before the time of sympathetic innervation.[173] However, in many mammalian species, including the human, rat, and dog, it is believed that the sympathetic nervous system is not as well developed as the parasympathetic nervous system at the time of birth. Rapid maturation occurs within the first postnatal months. Immunohistochemical studies of the specialized cardiac conduction system of the newborn human and dog heart have demonstrated nerve fibers reactive to dopamine β-hydroxylase (putative sympathetic neurons) mostly in the sinus and AV nodes, principally in association with small blood vessels, and only in small numbers.[153,174] Evidence of sympathetic innervation of the atrium, sinus, and AV nodes, as well as the ventricular epicardium, is first observed at midgestation and progressively increases, reaching full maturity only after 2 months of age. In the dog, there is no sympathetic innervation of the AV bundle noted at birth, but this region also is fully innervated by 2 months of age. These histochemical studies of the mammalian cardiac conduction system complement earlier reports of increasing catecholamine content with maturation in the hearts of fetal and newborn dogs, as well as other mammalian species.[175-177]

Maturation of sympathetic innervation is associated with profound changes in the electrophysiologic responses of the developing heart to catecholamine stimulation. In Purkinje fibers of neonatal dogs, exposure to the α-adrenergic agonist phenylephrine increases the rate of spontaneous firing in a dose-dependent fashion.[178] This α-adrenergic-mediated *increase* in automaticity is not observed in Purkinje fibers from adult animals in whom α-adrenergic stimulation *decreases* automaticity. It has been shown that the conversion of the chronotropic response to α-adrenergic stimulation from the neonatal response (increase in automaticity) to the adult response (decrease in automaticity) is contingent on the process of sympathetic innervation. In rat myocytes that are cocultured with sympathetic nerves, it can be shown that a specific pertussis toxin–sensitive 41-kDa guanosine triphosphate-binding protein is acquired that links the α-adrenergic receptor to the sodium-potassium pump, increasing MDP and thus causing a corresponding decrease in automaticity.[179,180] Two separate subtypes of α_1-adrenergic receptors appear to mediate the positive and negative chronotropic responses. One subtype is antagonized by an analogue of clonidine and is linked to the neonatal positive chronotropic response. The other subtype is linked to the adult negative chronotropic response.[181] In the neonatal rat, α_1-adrenergic activation increases the L-type calcium current, $I_{Ca\text{-}L}$, one of the currents responsible for automaticity. This α_1-adrenergic-mediated increase in calcium current is not observed in the adult heart. This suggests that there is also a developmentally determined switching of the coupling of α_1-adrenergic receptors with respect to calcium channels during development.[182]

In contrast to the cardiac electrophysiologic effects of parasympathetic stimulation, which exhibit rapid kinetics, the kinetics of sympathetic stimulation are more prolonged. The maximal effects of adrenergic stimulation on heart rate, myocardial refractoriness, and conduction tend to develop over several seconds, in

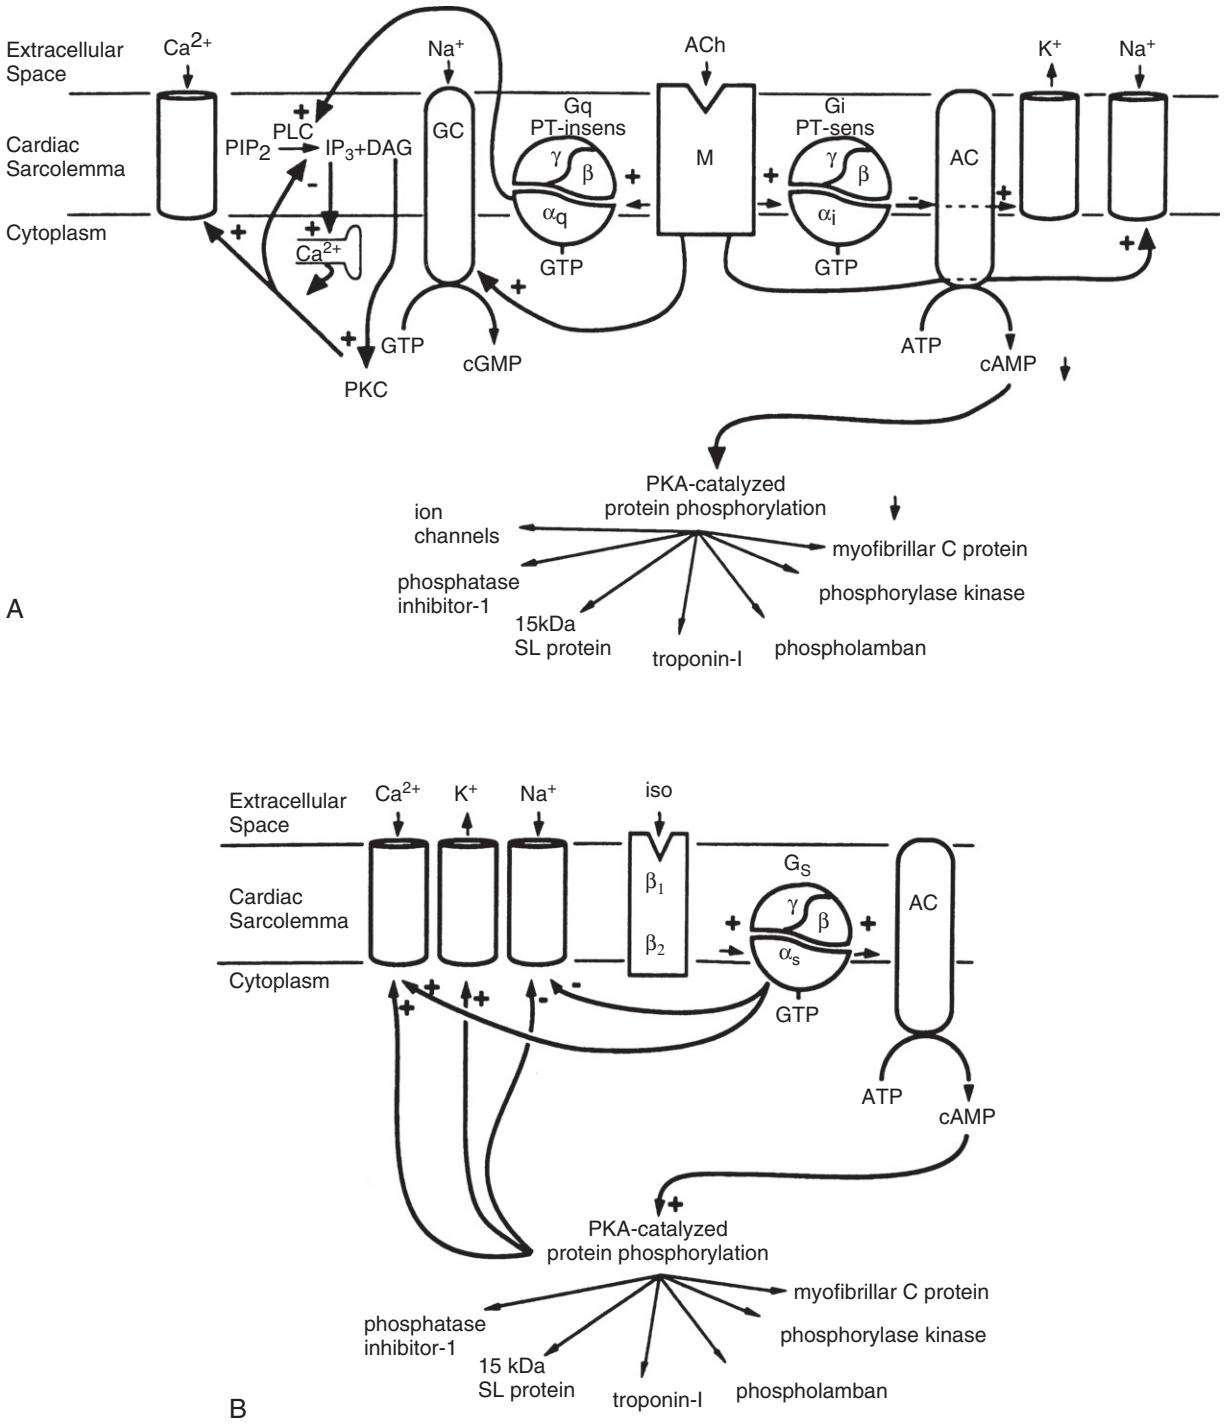

Figure 66-14 A, Schematic of cholinergic receptor-effector coupling. The muscarinic receptor is coupled to a pertussis toxin–sensitive inhibitory G protein (G_i). When activated, the α_i-subunit of the G protein dissociates and causes an inhibition of adenylate cyclase (AC) and a fall in intracellular cyclic adenosine monophosphate (cAMP) levels, with a resultant decrease in protein kinase A (PKA) phosphorylation of cellular proteins, including cardiac ion channels. It is by this mechanism that muscarinic stimulation decreases the inward calcium current. Direct activation of potassium channels by the G protein is also known to occur. There is also a pertussis toxin-insensitive G protein (G_q) that is linked to the muscarinic receptor. This G protein stimulates phospholipase C production, which stimulates the production of diacylglycerol (DAG) and 1,4,5-trisphosphate (IP_3). DAG stimulates protein kinase C (PKC), which phosphorylates and stimulates sarcoplasmic reticulum receptors, causing intracellular release of calcium. IP_3 directly stimulates release of calcium from the sarcoplasmic reticulum. **B,** Schematic of β-adrenergic receptor-effector coupling. The β -adrenergic receptor is coupled to the stimulatory trimeric G protein, G_s. In the presence of guanosine triphosphate (GTP), this G protein dissociates, and the α_s subunit results in direct activation of adenylate cyclase (AC). This increases intracellular cAMP and stimulates protein kinase A. This enhances phosphorylation of cellular proteins, including cardiac ion channels. *(From Fleming JW, Wisler PL, Wantanabe AM. Signal transduction by G proteins in cardiac tissues,* Circulation *85:420, 1992, by permission of the American Heart Association.)*

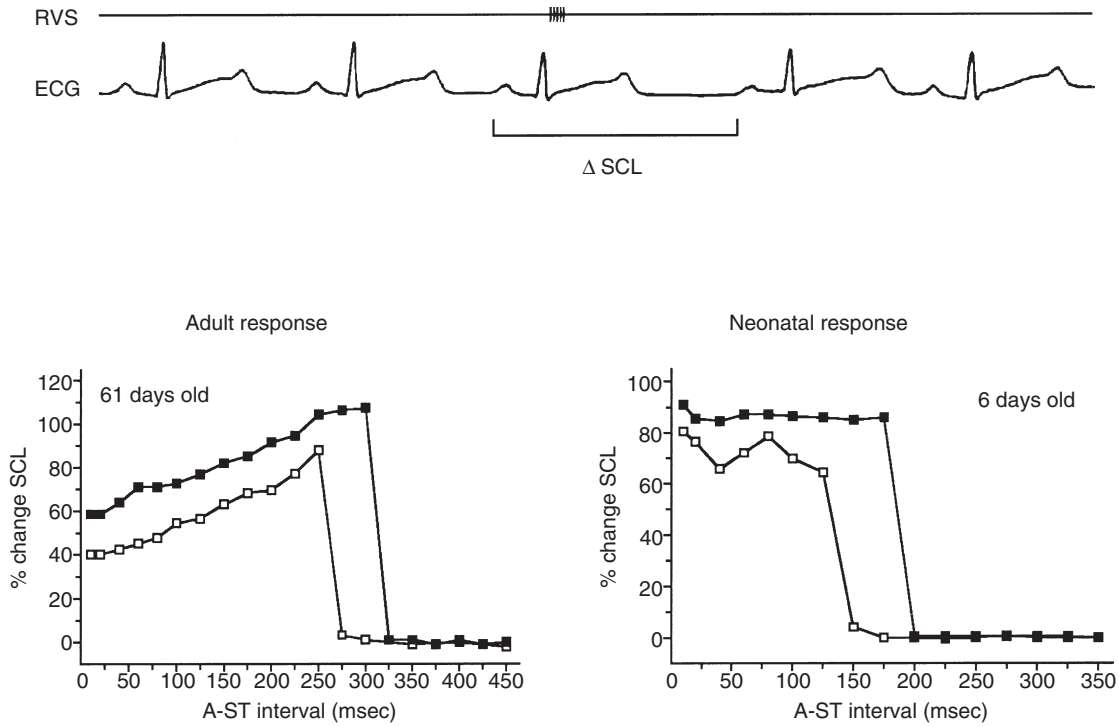

Figure 66-15 The response of heart rate to brief vagal stimulation. A short train of vagal stimulation is delivered once, at varying times, within the cardiac cycle. The effect of each brief, critically timed vagal train on sinus cycle length is determined, and a phase-response curve is generated. On the left, a typical adult-type vagal phase response curve is shown, obtained in experiments performed on a 2-month-old puppy. As the vagal train is delivered at progressively later times after the last atrial depolarization (A-ST interval), the change in sinus cycle length (percentage change of sinus cycle length [SCL]) evoked by that vagal stimulation train progressively increases. Eventually the vagal train is delivered too late in the cardiac cycle to affect sinus cycle length. On the right, a typical phase-response curve in a newborn is shown. In contrast to in the older puppy, in the neonate, the vagal response remains flat as the vagal train is advanced through the cardiac cycle. *Closed squares* indicate right vagal stimulation (RVS); *open squares* are left vagal stimulation (LVS). *(Phase response curves are from Pickoff AS, Rios R, Stolfi A, Wang SN. Pickoff AS, et al. Postnatal maturation of the response of the canine sinus node to critically timed, brief vagal stimulation,* Pediatr Res *35:55, 1994.)*

contrast to the nearly instantaneous effects of vagal stimulation. The dominant electrophysiologic actions of sympathetic stimulation in the heart are mediated by the β_1 receptor, although β_2 receptors do coexist on the cardiac myocyte. The main electrophysiologic effects of β-adrenergic stimulation include an increase in sinus node automaticity, which is in part mediated by an increase in the rate of diastolic depolarization (phase 4 of the action potential). There is also an increase in the MDP of the sinus node, which serves to increase the activity of the I_f pacemaker current. In the AV node, conduction velocities are increased and refractory periods are shortened; the increases in AV nodal action potential amplitude and $\dot{V}_{max}$ account for the increase in conduction velocity. In the myocardium, β-adrenergic stimulation increases the height of the action potential plateau by increasing the inward calcium current; it also increases the speed of repolarization by increasing outward potassium currents. Overall, these effects tend to shorten myocardial refractoriness. The increase in MDP, observed in the sinus node and in the working myocardium, is likely caused by an adrenergic-mediated increase in the activity of the sodium-potassium pump. These primary effects of β-adrenergic stimulation are mediated through a membrane-bound stimulatory guanine nucleotide binding protein, G_s (see Figure 66-14, *B*). The effects of sympathetic stimulation on the heart of the newborn and young infant are qualitatively similar to those in the adult. The degree of change in heart rate with sympathetic stimulation, however, is considerably less in the young puppy compared with the adult.[170] The increase in response to sympathetic stimulation with maturation is probably multifactorial. As was mentioned previously, the density of sympathetic innervation continues to increase in many species postnatally. Furthermore, the stimulatory effect of β-agonists on adenylate cyclase increases postnatally in many mammalian species.[183-186] In rabbit ventricular cells, it has been reported that the postnatal increase in β-adrenergic-stimulated cyclic adenosine monophosphate is more related to a reduction in inhibition of adenylate cyclase by the inhibitory G protein, G_i, with maturation, rather than to a change in the β receptor–adenylate cyclase complex.[186]

Several complex interactions between the two branches of the autonomic nervous system have been described.[187] These interactions involve complex presynaptic and postsynaptic mechanisms that allow for fine regulation of autonomic modulation of the electrophysiologic and mechanical properties of the heart. One classic interaction is the "accentuated antagonism" interaction between the sympathetic and parasympathetic nervous systems. With respect to heart rate and contractility, the effect of a given vagal stimulus becomes progressively greater as the level of background sympathetic tone increases.[187,188] At the presynaptic level, it is believed that a cholinergic inhibition of norepinephrine release from sympathetic nerve endings contributes to the antagonism of sympathetic effects. At the postsynaptic level, the precise basis for interaction between the sympathetic and parasympathetic nervous systems is still somewhat speculative but may involve a muscarinic-mediated stimulation of phosphatases (enzymes), which results in a reversal of the adrenergic-stimulated phosphorylation of key intracellular proteins, such as the calcium channel.[189] Nitric oxide, a derivative of L-arginine, has also been implicated as a mediator of the cholinergic inhibition of β-adrenergic responses.[190,191]

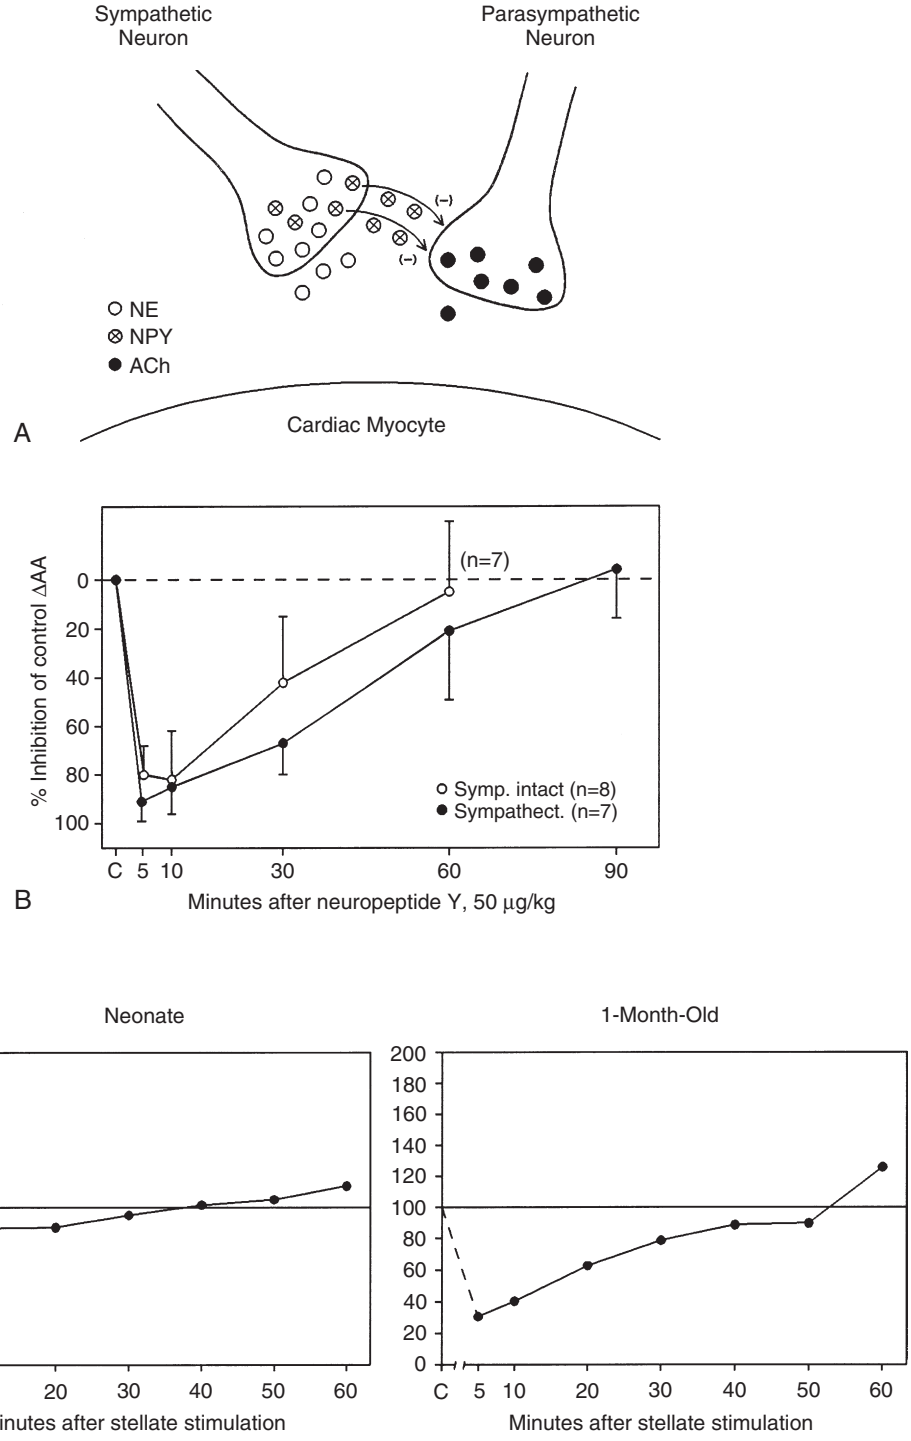

Figure 66-16 **A,** Illustration of the neuropeptide Y (NPY)-mediated sympathetic-parasympathetic interaction. NPY is stored within neuronal vesicles, along with norepinephrine (NE), in sympathetic nerve endings. When released, NPY can bind to receptors on the parasympathetic nerve terminals and inhibit the release of acetylcholine (ACh). **B,** The effects of an intravenous injection of NPY (50 μg/kg) on the vagal response of heart rate to vagal stimulation in sympathetically intact and sympathectomized newborn dogs. In both groups, NPY causes a profound (nearly 100%) and long-lasting (nearly 60 minutes) inhibition of the change in sinus cycle length caused by vagal stimulation (percentage inhibition of control ΔAA). C, control (pre-NPY administration). **C,** The effects of right stellate ganglion stimulation (10 Hz, 5 minutes) on cardiac vagal chronotropic responses in young puppies. In these graphs, 100% represents the control (i.e., prestellate stimulation) vagal response. In the neonate *(left),* stellate stimulation causes little change in the magnitude of elicited vagal responses. In contrast, in the 1-month-old puppy *(right),* 5 minutes of stellate stimulation causes a profound, long-lasting inhibition of the cardiac vagal response. This occurs, presumably, as a result of the release of NPY during stellate stimulation. *(***A** *and* **C,** *From Rios R, Stolfi A, Campbell PH, Pickoff AS.* Cardiovasc Res *31:E96, 1996, with permission of Elsevier Science-NL.* **B,** *From Yamasaki S, Stolfi A, Mas MS et al. Rapid attenuation ("fade") of the chronotropic response during vagal stimulation in the canine newborn: Evidence for a prominent neuropeptide Y effect,* Circ Res *69:406, 1991, by permission of the American Heart Association.)*

There have been few studies of interactions between the two branches of the autonomic nervous system during development. In isolated canine Purkinje fibers, Moak and colleagues[192] reported that acetylcholine attenuated the isoproterenol-induced shortening of action potential duration in adult cells. In neonatal (i.e., 1 to 10 days old) Purkinje cells, in contrast, action potential duration lengthened after exposure to isoproterenol. Furthermore, this effect was not modified by exposure to acetylcholine. This was interpreted to indicate that accentuated antagonism is not present in the neonate. In somewhat older (e.g., 35 days) animals, however, prominent sympathetic-vagal interactions in the control of heart rate can be demonstrated, with sympathetic effects becoming more attenuated with higher levels of background vagal stimulation.[193] With respect to AV nodal conduction, an interaction between the sympathetic and parasympathetic nervous systems has been demonstrated in young puppies, but one with dominance of the sympathetic, not parasympathetic, nervous system.[194] Recent studies of beat-to-beat variability in AV nodal conduction in the premature infant during the first postnatal month (measured as variability in the PR interval of the surface electrocardiogram) also provide evidence for accentuated sympathetic modulation of AV nodal conduction.[167] Further studies characterizing interactions between the branches of the autonomic nervous system in the developing heart are needed.

It is known that in addition to the classic autonomic neurotransmitters, acetylcholine and norepinephrine, a family of "neuropeptides" also appears to innervate the human heart. These peptides include neuropeptide Y, vasoactive intestinal peptide, calcitonin gene–related peptide, somatostatin, and substance P.[195] These neuropeptides exist, either colocalized with the classic neurotransmitters within neurons of the sympathetic or parasympathetic nervous system or confined to neurons that appear to be separate from the two major branches of the autonomic nervous system. In the fetal heart, peptide immunoreactive nerves first appear at about 10 weeks gestation, or 3 weeks after the appearance of cardiac ganglia and nerves.[196] Neuropeptide Y–containing nerves are the dominant peptide-containing nerves in the heart.[197] In the early fetal heart, neuropeptide Y is initially localized within the atria. With further development, innervation of the ventricles becomes evident. Vasoactive intestinal peptide and somatostatin appear localized primarily within the atrium and are first observed at 10 to 12 weeks gestation. Substance P and calcitonin gene–related peptide do not appear in the fetal heart until somewhat later, at 18 to 24 weeks of gestation. In the newborn canine heart, neuropeptide Y and vasoactive intestinal peptide are both found in higher concentrations in the atria than ventricles, and for both peptides, concentrations in the first weeks after birth are higher than in the adult.[198]

Although the precise function and mechanisms of action of this peptidergic neurotransmission system remain to be fully elucidated, it is clear that at least two of these peptides, vasoactive intestinal peptide and neuropeptide Y, may exert significant direct or indirect (or combined) effects on cardiac automaticity and conduction. Vasoactive intestinal peptide can be shown to increase sinus node automaticity directly and to enhance AV nodal conduction in both the adult dog[199,200] and the newborn.[201] In the adult dog, vasoactive intestinal peptide shortens atrial refractoriness,[200] an effect not observed in the neonatal atrium.[201] Vasoactive intestinal peptide may be responsible for the acceleration in heart rate observed with vagal stimulation in the presence of autonomic blockade.[202] Neuropeptide Y appears to function as a sympathetic cotransmitter, being localized with norepinephrine within adrenergic neurons.[203,204] Neuropeptide Y release from sympathetic nerves inhibits release of acetylcholine from adjacent parasympathetic nerve endings, thus representing another type of autonomic sympathetic-parasympathetic interaction (Figure 66-16, *A*). This interaction explains the profound and prolonged attenuation of vagal responses that is observed after a period of antecedent stellate ganglion stimulation in the adult dog.[205] In the neonatal dog, intravenous neuropeptide Y causes a profound and long-lasting inhibition of cardiac vagal response (see Figure 66-16, *B*).[206] Stellate stimulation, however, causes only a small inhibition of cardiac vagal response in the neonate, suggesting that the neuropeptide Y–sympathetic–parasympathetic autonomic interaction is immature at birth. The magnitude of the neuropeptide Y–autonomic interaction increases dramatically within the first postnatal month, probably as a result of the general postnatal maturation of adrenergic innervation (see Figure 66-16, *C*).[207] Further research is warranted to elucidate the role of peptidergic transmission in the modulation of cardiac electrophysiology throughout development.

Developmental Biology of the Pulmonary Vasculature

This chapter discusses the fetal, neonatal, and postnatal changing morphology of the developing pulmonary vascular bed. Studies have focused on structural and functional alterations in endothelial cells during postnatal development and have addressed the phenotypic heterogeneity of the vascular smooth muscle cells in the perinatal period.There are new insights into mechanisms regulating endothelial migration and angiogenesis, smooth muscle cell proliferation, hypertrophy, and migration.These studies have also provided novel therapeutic targets whereby progression of pulmonary vascular disease may be retarded or prevented and regression induced.

MORPHOLOGY OF THE DEVELOPING PULMONARY CIRCULATION IN THE FETUS

Early embryologic studies have shown primitive pulmonary vessels from the sixth aortic arch in the 5-week human embryo. These vessels supply the upper poles of the right and left lung. The lower poles are supplied by a pair of intersegmental arteries arising from the dorsal aorta that penetrate upward through the diaphragm.At this stage the developing lung parenchymal blood vessels are largely localized to the interlobular septa. Between 5 and 8 weeks gestation it is likely that numerous paired dorsal intersegmental arteries supply the emerging blood vessels that are developing alongside the branching bronchi in the lung parenchyma. As the true central pulmonary arteries form from the aortopulmonary trunk and anastomose with the intrapulmonary arteries, the primitive pulmonary arteries arising from the aorta as well as the primitive intersegmental arteries involute. By 9 weeks gestation the bronchial system has formed. With each airway generation is an accompanying artery, in addition to numerous supernumerary arteries that are also produced. By 16 weeks gestation the number of preacinar airways and accompanying arteries is complete. Thereafter, as the acini develop (terminal bronchioli, respiratory bronchioli, alveolar ducts, and alveoli), so do the accompanying and supernumerary arteries.[1,2]

Abnormal maturation or maturational arrest in pulmonary arterial development is reflected in functional derangement that can appear in the newborn period. For example, persistent pulmonary hypertension of the neonate has been reported in association with pulmonary arterial maturational arrest at the fifth week gestation (Figure 67-1).[3] Infants with pulmonary atresia and ventricular septal defect frequently have persistence of the intersegmental arteries (aortopulmonary collaterals) (Figure 67-2).[4] These vessels can serve as the sole source of blood supply to a lobe or lobar segment.Alternatively, a dual circulation with intersegmental arteries anastomosing to arteries can be traced back to a central pulmonary artery origin. In these infants there can

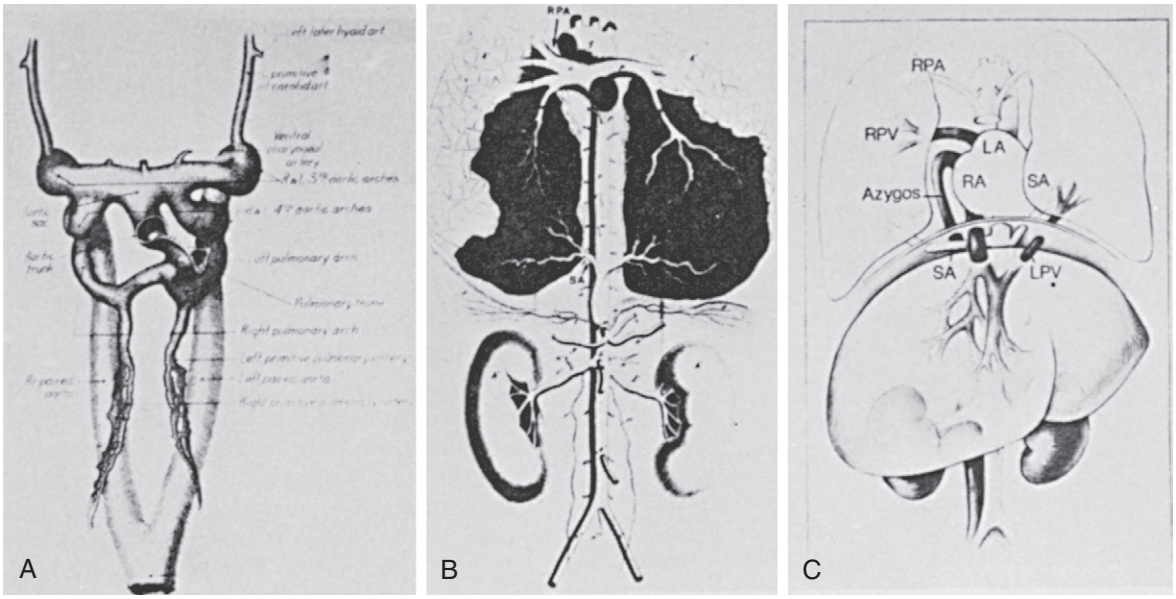

Figure 67-1 A, Early embryologic development shows normal disparity between the large main pulmonary artery and narrow right and left branch pulmonary arteries at 5 weeks. **B,** Only the arterial system is shown.The bilateral systemic arteries arising from a single trunk supply the lower lobes. **C,** An infant with persistent pulmonary hypertension and developmental arrest at 5 weeks gestation. *LA,* Left atrium; *LPV,* left pulmonary vein; *RA,* right atrium; *RPA,* right pulmonary artery; *RPV,* right pulmonary vein; *SA,* systemic arteries. *(***A,** *From Congdon ED:Transformation of the aortic-arch system during the development of the human embryo,* Contrib Embryol *14:47, 1922;* **B,** *from Maugars A:* J Med Chir Pharm Paris *3:453, 1802;* **C,** *reprinted by permission of the publisher from Goldstein JD, Rabinovitch M, Van Praagh R, et al: Unusual vascular anomalies causing persistent pulmonary hypertension in a newborn,* Am J Cardiol *43(5):962, 1979. Copyright 1979 by Excerpta Medica, Inc.)*

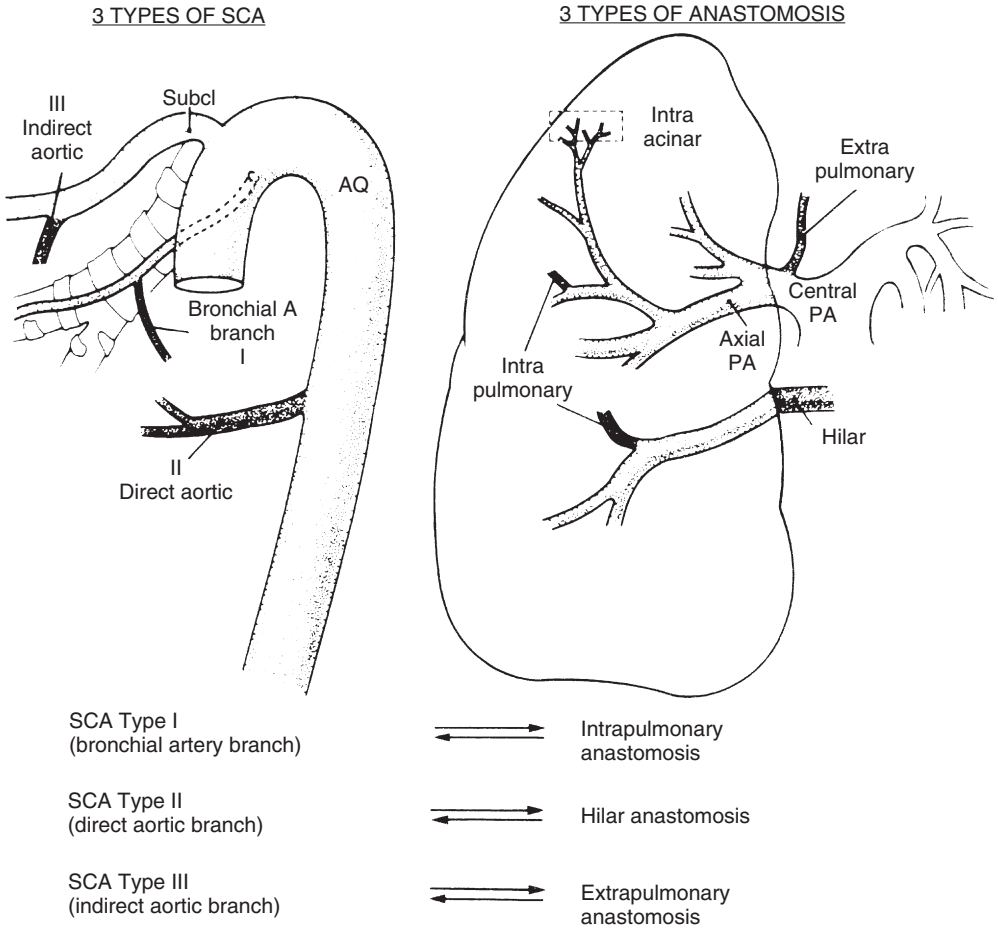

Figure 67-2 The three types of systemic collateral artery (SCA) and the three types of anastomosis with the pulmonary artery (PA). The characteristic pattern of anastomosis for each type of SCA is given. *AO,* Aorta; *SUBCL,* subclavian. *(From Rabinovitch M, Herrera-deLeon V, Castaneda AR, et al: Growth and development of the pulmonary vascular bed in patients with tetralogy of Fallot with or without pulmonary atresia,* Circulation *64(6):1234, 1981.)*

also be multiple indirect aortopulmonary collaterals arising from branches of aortic branches (e.g., from subclavian, intercostals, and coronary arteries). Because these indirect collaterals can be observed in the absence of direct collaterals, they probably represent the sequelae of pulmonary atresia when it occurs later in development. Finally, in some cases of pulmonary atresia, there is supply by anastomotic vessels, which arise from true bronchial arteries.

Another morphologic pulmonary vascular abnormality is observed with absence of the pulmonary valve.[5] In those patients who present with severe respiratory problems from birth, abnormal branching of the vessels has been observed. Tufts of intersegmental pulmonary arteries are seen arising in weeping willow or squidlike fashion, encircling and compressing the intrapulmonary airways (Figure 67-3).

Experimental evidence shows that branching morphogenesis of the large preacinar airways provides cues to regulate branching morphogenesis of the preacinar arterial tree, whereas the intra-acinar vessels regulate the development of the alveoli (this is discussed later).

Microscopic Features

The normal morphologic development of the pulmonary circulation has also been studied at the microscopic level. In the fetus, the preacinar arteries and those at the terminal bronchiolus level are muscular, whereas the intra-acinar arteries (i.e., those accompanying respiratory bronchioli) are partially muscular (surrounded by a spiral of muscle) or nonmuscular. Arteries at alveolar duct and alveolar wall levels are nonmuscular. The preacinar arteries are thick walled and change little in wall thickness relative to external diameter throughout the fetal period. Experimental studies[6] suggest that the immediate postnatal period is characterized by rapid recruitment of small alveolar duct and wall vessels that appear to be functionally and structurally closed in the prenatal period. There is also progressive dilation of muscular arteries. Within a few days the smallest muscular arteries (<250 μm) dilate, and their walls thin to adult levels; by 4 months of age this process has included the largest pulmonary arteries at the hilum. As intra-acinar arteries at the various airway levels increase in external diameter, muscle is said to extend peripherally (i.e., it is observed in arteries located more peripherally within the acinus). At first nonmuscular arteries become partially muscular and later they become fully muscularized. For example, in infancy, vessels at alveolar duct level are still largely nonmuscular, but in childhood they become partially muscularized and in the adult they are fully muscularized.[7] Alveolar wall arteries remain largely nonmuscular, even in the adult.

Clinical as well as experimental studies have suggested that the muscularization of these peripheral pulmonary arteries may be related to the differentiation of pericytes as well as to the recruitment of fibroblasts.[8,9] Arteries proliferate through the neonatal period and early infancy, accompanying the proliferation of alveoli; the alveoli-arteries ratio can therefore be used

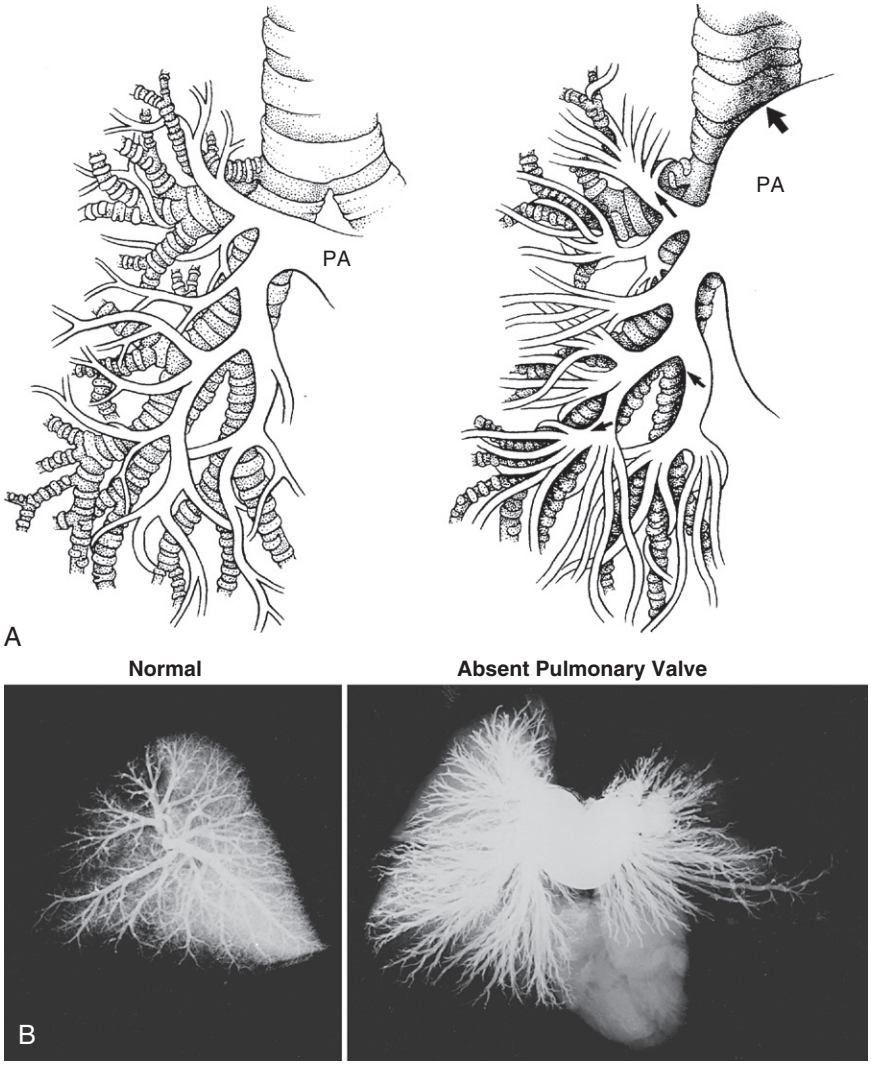

Figure 67-3 A, Diagrammatic representation of normal pulmonary artery (PA) branching and the abnormal pattern seen in cases of absent pulmonary valve syndrome—tufts of vessels emerging at the segmental artery level that entwine the bronchi. *Arrows* denote large right pulmonary artery compressing right mainstem bronchus. **B,** Postmortem arteriograms from a 4-day-old normal infant *(left)* and from a 4-day-old patient with absent pulmonary valve syndrome associated with a ventricular septal defect and D-transposition of the great arteries *(right),* showing tufts of vessels in both lungs. *(Reprinted by permission of the publisher from Rabinovitch M, Grady S, David I, et al: Compression of intrapulmonary bronchi by abnormally branching pulmonary arteries associated with absent pulmonary valves,* Am J Cardiol *50(4):804, 1982. Copyright 1982 by Excerpta Medica, Inc.)*

as a measure of numerical arterial growth. The alveoli-arteries ratio actually decreases from the newborn value of 20:1 to the value of 8:1, which is achieved first in early childhood and persists (Figure 67-4). The growth and development of the pulmonary circulation are also likely influenced by the trophic effects of neuropeptides[10] released from nerve endings, as well as from neuroendocrine bodies[11] associated with accompanying airways (Figure 67-5).

Experimental studies have indicated how changes in connective tissue, especially elastin and collagen,[12,13] and cellular arrangement[14] govern the normal adaptation to postnatal life. The endothelial cells begin to flatten because of increased deposition of elastin in peripheral arteries, forming an intact elastic lamina. In the central pulmonary arteries similar changes occur, and elastin remodeling is prominent in the subendothelium in the early neonatal period,[13] whereas elastin synthesis, as judged by messenger RNA (mRNA) levels, appears to be less prominent in the outer media and adventitia (Figure 67-6). It has also been shown experimentally that there are smooth muscle cells with differing proliferative potentials and that, in the neonatal period, the specialized functions of selective subgroups of smooth muscle cells, characterized by expression of cytoskeletal proteins, become even better defined.[15] The metavinculin-positive smooth muscle cells are relatively resistant to proliferation. Moreover, the high proliferative potential demonstrated in neonatal bovine pulmonary artery smooth muscle cells is reflective of a difference in activation of protein kinase C.[16]

Cellular Mechanisms

The cellular and molecular mechanisms that regulate fetal growth and development of the vasculature are being studied by a number of groups,[17] with extensive investigation into the expression in early vascular development of cell adhesion molecules, such as vascular cell adhesion molecule 1 (V-CAM-1)[18] and platelet cell adhesion molecule (PECAM)[19] (Figure 67-7) in addition to the β_1[20] and β_3 family of integrin receptors, especially $\alpha_v\beta b_3$.[21] These molecules appear to direct interactions between endothelial and

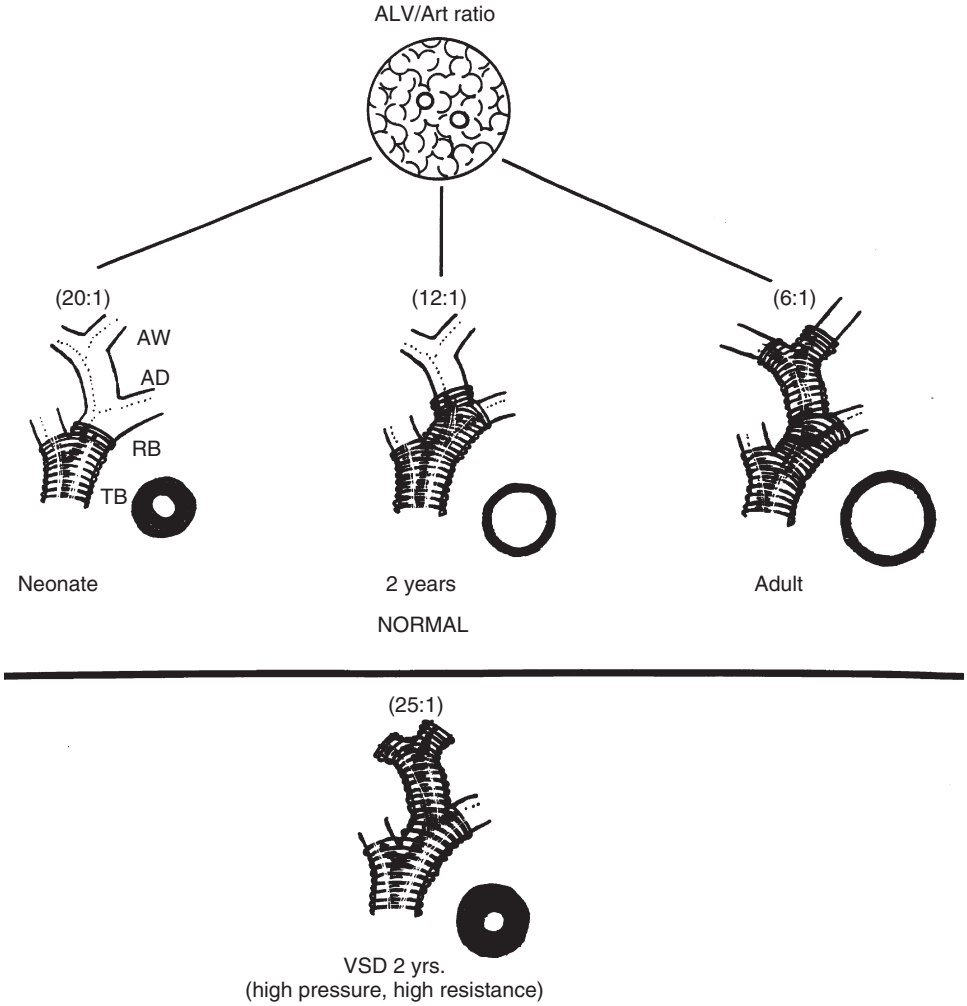

Figure 67-4 Schema showing peripheral pulmonary arterial development through morphometric changes: extension of muscle into peripheral arteries, percent wall thickness, and artery number (alveolar/arterial ratio), as they relate to age. *Upper panel*, Normal development. *Bottom panel*, Abnormalities in all three features in a 2-year-old child with a hypertensive ventricular septal defect (VSD). *ALV/Art,* Alveolar-arterial; *AD,* artery accompanying an alveolar duct; *AW,* artery accompanying an alveolar wall; *RB,* artery accompanying a respiratory bronchiolus; *TB,* artery accompanying a terminal bronchiolus. *(From Rabinovitch M, Haworth SG, Castaneda AR, et al: Lung biopsy in congenital heart disease: a morphometric approach to pulmonary vascular disease,* Circulation *58:1107, 1978.)*

smooth muscle cells, and the extracellular matrix and perturbations of these interactions lead to malformation of the pulmonary and systemic arteries. The β_1 family of integrins bind fibronectin; the β_3 family binds fibronectin as well as a host of matrix molecules, but especially tenascin, osteopontin, and vitronectin, some of which have been shown to govern vascular cell migration (e.g., fibronectin)[22-25] and proliferation (e.g., tenascin).[26] In addition, a variety of growth factors also appear to be responsible for the orderly growth and branching morphogenesis of blood vessels. These include vascular endothelial growth factor (VEGF),[27] particularly VEGF A and D,[28] and angiopoietin,[29] as well as acidic and basic fibroblast growth factor (FGF-1 and FGF-2).[30] Evidence shows that VEGF production by epithelial cells is necessary for angiogenesis but that blockade of VEGF A induction of angiogenesis represses epithelial proliferation, suggesting that blood vessel formation regulates alveolar formation.[31-33] More studies have characterized the endothelial contribution to alveolar septae as being regulated by hepatocyte growth factor[34] (Figure 67-8). In addition, endothelial nitric oxide synthase (eNOS) also appears to regulate distal vascular and alveolar growth based on studies in transgenic mice with eNOS deleted.[35]

It has also been suggested that growth factors promote the induction of stromal derived factor-1,[36] a chemokine for endothelial cells bearing the receptor CXCR4, which is also induced. The functions and interactions between members of the Wingless family (Wnts) and bone morphogenetic proteins (BMPs) in regulating lung branching morphogenesis have been studied by a number of groups.[37-40] Our work in endothelial and smooth muscle cells indicates that signaling interactions downstream of the receptors for these ligands may be critical in regulating endothelial and smooth muscle cell survival, proliferation, and migration. Wnt7b,[41] has specifically been implicated in vascular development, particularly those features that regulate investment of smooth muscle cells around the endothelial framework (Figure 67-9).

Growth factors are regulated in their function by specific tyrosine kinase receptors, such as flt-1 and flk-1, tek, and tie,[42-44] as well as the activin receptor–like kinase (Alk)-1[45] and bone morphogenetic protein receptors. Alk-1 has been implicated in the later stages of vasculogenesis, and a mutation is associated with hereditary hemorrhagic telangiectasia,[46] whereas bone morphogenetic protein receptor (BMPR) II mutations are found in primary pulmonary hypertension.[47] Using a flk-1 reporter construct,

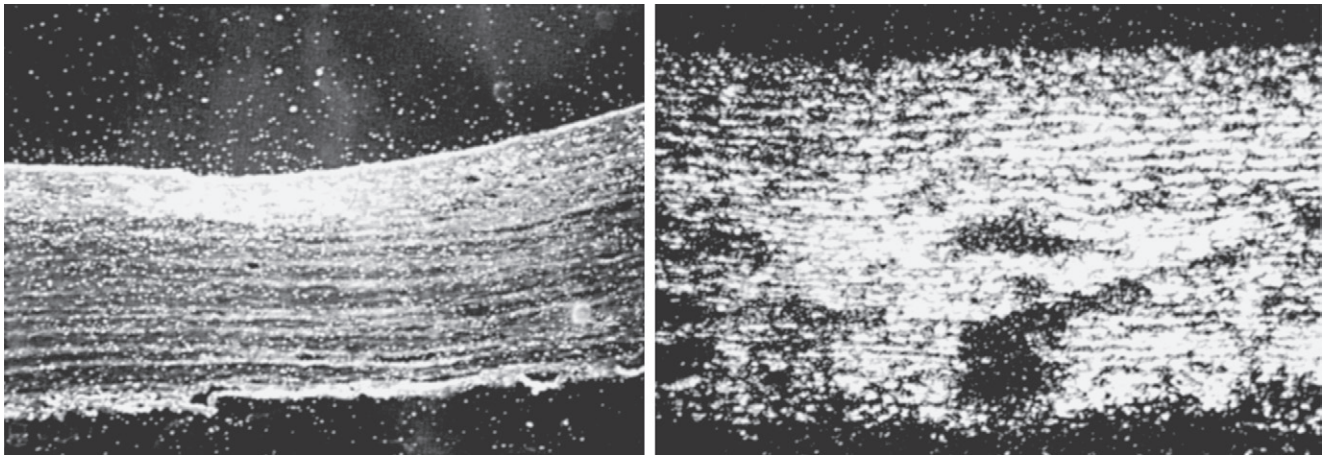

Figure 67-6 In situ hybridization localization of tropoelastin messenger RNA (mRNA) in control and hypertensive vessels from neonatal calves. White staining over areas indicates tropoelastin mRNA labeling. In normotensive vessels *(left),* labeled cells (^{35}S-labeled T66-T7) were confined to the inner media. Minimal signal is noted in the outer vessel wall. In vessels from hypertensive animals (14 days of hypoxia) *(right),* intense autoradiographic signal was observed throughout the media, albeit in a patchy distribution. *(From Prosser IW, Stenmark KR, Suthar M, et al: Regional heterogeneity of elastin and collagen gene expression in intralobar arteries in response to hypoxic pulmonary hypertension as demonstrated by in situ hybridization,* Am J Pathol *135:1073, 1989.)*

Schachtner and colleagues[48] found lung vascular development at all stages of lung growth. Notch and Jagged1 interaction are associated with early stages of lung vascular development.[49] The transcription factors TAL1[50] and Foxp,[51] are implicated in vasculogenesis from precursor cells of the hematopoietic lineage.

Matrix components (especially elastin and collagen) are regulated by insulin-like growth factor-1[52,53] and transforming growth factor-β (TGF-β).[54] Insulin-like growth factor-1 and its receptor act in concert with VEGF to stimulate fetal vascular growth through the same intracellular signaling pathways.[53] Lack of elastin leads to extensive proliferation of smooth muscle cells in pulmonary arteries. The regulation of growth factor interaction with cell surface molecules is also determined by the balance between proteases and antiproteinases. Plasmin, thrombin,[55,56] and elastases, including leukocyte and endogenous vascular elastase,[57] have been shown to release growth factors from storage

sites in the extracellular matrix in an active form. In addition, a variety of endogenously expressed inhibitors of proteinases and elastases, such as plasminogen activator inhibitor[58] and elafin,[59] control growth and development, and other classes of molecules are known to control angiogenesis, such as angiostatin, a molecule derived from plasminogen.[60]

The expression of vasoactive peptides in the lung during development also may play a role in the development of the pulmonary vasculature. Endothelin has been associated with cell proliferation and NO with the suppression of smooth muscle cell growth,[61] and the early expression of NOS,[62] and it likely regulates vasculogenesis in addition to vascular tone.

ABNORMAL LUNG GROWTH

Underdevelopment of the lung parenchyma and associated pulmonary vasculature[1] is associated with congenital diaphragmatic hernia,[63] hypoplastic or dysplastic lungs, scimitar syndrome, and oligohydramnios secondary to renal agenesis and dysplasia. Pulmonary hypoplasia is also a feature of prematurity, absence of the phrenic nerve, asphyxiating thoracic dystrophy, rhesus isoimmunization, and, experimentally, amniocentesis[64] and smoking.[65]

Reversible or irreversible pulmonary artery hypertension and right-to-left shunting from birth can be a direct result of derangement or hypoplasia of the pulmonary vascular bed, or both. In addition to the structural changes in the vessels, heightened pulmonary vascular resistance also can be attributed to impaired gas exchange (hypoxia, hypercapnia). In infants with congenital diaphragmatic hernia, reversal of pulmonary hypertension has been achieved with the use of vasodilators,[66] extracorporeal membrane oxygenation (ECMO) (or high-frequency oscillation),[67] and NO alone or in combination with phosphodiesterase inhibitors.[68] Infants with hypoplastic lungs that had been refractory to nitric oxide before ECMO have demonstrated a beneficial effect from NO after ECMO. The expectation is that the reduction in pulmonary artery resistance will stimulate regression of vascular changes and maturation in growth of the pulmonary arteries.

Although the degree of arterial muscularity may predict whether the pulmonary vascular bed is reactive, in studies of infants who succumbed after attempt at repair of congenital diaphragmatic hernia, a striking decrease in the number of alveoli and associated arteries was the major determinant of mortality (Figure 67-10). This is probably why attempts to reverse severe pulmonary hypertension with NO have been less successful in this group of patients. Studies in experimental models of diaphragmatic hernia in lambs have indicated that endothelin A receptor blockade and endothelin B receptor–stimulated might reverse pulmonary hypertension[69] and that soluble guanylate cyclase activity is reduced.[70] It was also shown that vitamin A might stimulate lung maturation in a nitrogen-induced model of congenital diaphragmatic hernia.[71] Inflation of the lungs in utero via occlusion of the trachea has been proposed to help mature the lung.[72,73] Platelet-derived growth factor (PDGF) when dysregulated (e.g., increased in response to hypoxia) may contribute to aberrant vascular development.[74]

Future strategies to improve lung growth may come from understanding underlying transcription factor pathways that are repressed, such as the Sonic hedgehog pathway.[75] Studies

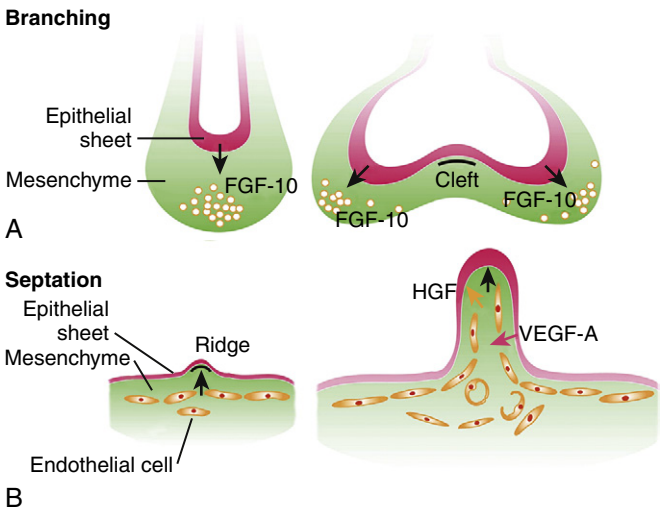

Figure 67-8 Model for septation in comparison to branching morphogenesis. **A,** During branching morphogenesis, epithelial tubes grow toward a chemoattractive source such as fibroblast growth factor (FGF)-10 in the mesenchyme. On redistribution of the chemoattractive source, the epithelial tube bifurcates to grow toward the new sources and a cleft is formed at the previous tip, causing branching. **B,** During septation, the epithelial sheet is pushed up to form a ridge or crest by underlying endothelial cells. Capillary angiogenesis stimulated by epithelium-derived vascular endothelial growth factor-A (VEGF-A) coupled with growth of epithelial cells induced by endothelium-derived paracrine factors such as hematocyte growth factor (HGF) causes formation and growth of the septae. *(From Yamamoto H, Jun Yun E, Gerber HP, et al: Epithelial-vascular cross talk mediated by VEGF-A and HGF signaling directs primary septae formation during distal lung morphogenesis,* Dev Biol *308(1):44-53, 2007.)*

have also focused on the possible contribution of resident, bone marrow–derived, or engineered stem cells.[76,77] The expansion of these cells is repressed by hyperoxia as is the expansion of endothelial progenitor cells.[78,79]

In lungs studied postmortem from infants with pulmonary hypoplasia or dysplasia, a reduced number of arteries is observed, appropriate to the reduced number of airways (see Figure 67-10). The arteries are also generally small but not incompatible with the size of the lung. Also, although the arteries, both centrally and peripherally, may be more muscular than normal, as in congenital diaphragmatic hernia, there may be hypoplasia of the pulmonary musculature, as in renal agenesis. Dysplasias of the lung associated with persistent pulmonary hypertension of the newborn (e.g., alveolar capillary dysplasia) (Figure 67-11)[80] are so refractory to treatment that a biopsy should probably be done to guide clinical management. That having been said, the pathology is similar to that seen in transgenic mice with deletion of endothelial NOS.[35] In unpublished studies Stewart and colleagues have injected progenitor cells producing eNOS into the lungs of the embryonic mice that lack eNOS with the expectation that this might lead to normal realignment of arteries, veins, and capillaries. Experimental studies carried out in newborn lambs and rabbits have shown that heparin can stimulate remodeling of the pulmonary circulation.[81] Accelerated maturation of the pulmonary circulation was achieved by inducing an increase in the number of peripheral pulmonary arteries relative to alveoli. This therapeutic strategy might prove clinically useful in inducing the growth of peripheral arteries and thereby reducing pulmonary vascular resistance.

Another factor that contributes to arrest in arterial and subsequently alveolar development is mechanical ventilation as studied in the fetal lamb[82] and more recently in the neonatal mouse.[83] In the latter study it was shown that those genes that regulate arterial and alveolar growth are suppressed by mechanical ventilation. It is interesting that dysregulaton of elastin with mechanical ventilation appears to play a critical role in impairing the formation of the distal lung vasculature and alveoli.

FAILURE TO REVERSE ELEVATED PULMONARY VASCULAR RESISTANCE

Perinatal stress (e.g., hemorrhage, hypoglycemia, aspiration, or hypoxia) may result in failure of dilation of normally muscular vessels and left ventricular dysfunction, both contributing to persistent pulmonary hypertension. The use of inhaled NO in clinical studies,[84] L-arginine in experimental studies,[85] gene transfer of endothelial NOS,[86] and inhibition of phosphodiesterases[87] have proved effective in lowering pulmonary artery pressure.

Because increased production of endothelin may underlie the pathophysiology of persistent pulmonary hypertension of the newborn,[88] the use of endothelin receptor blockade or endothelial-converting enzyme inhibition[89] may prove beneficial.[90]

INDUCTION OF VASCULAR ABNORMALITIES

In Utero

Structural studies of the lung at postmortem in fatal cases of meconium aspiration suggest that antecedent pulmonary vascular abnormalities exacerbated the postnatal pulmonary hypertension.[91] The most striking feature is the presence of muscle in arteries, small and peripheral in location and normally nonmuscular. The muscle cells are surrounded by darkly stained elastic laminae, suggesting that they formed several weeks before death and therefore in utero. Clinical studies have suggested a relationship between maternal ingestion of prostaglandin synthetase inhibitors and subsequent persistent pulmonary hypertension.[92] However, a large population of women take aspirin or indomethacin during pregnancy, and a low incidence of persistent pulmonary hypertension occurs in their newborn infants. Conversely, in the majority of infants with persistent pulmonary hypertension, no history of maternal ingestion of these compounds can be documented. Experimental studies in lambs have shown that prostaglandin synthetase inhibitors constrict the ductus arteriosus in utero. Chronic indomethacin treatment in pregnant rats produces structural changes in the pulmonary vascular bed of the newborn.[93] Thus it seems likely that, in an occasional susceptible human fetus, there may be a relationship between prostaglandin synthetase inhibitors and persistent pulmonary hypertension.

Chronic maternal hypoxemia in experimental guinea pigs has not reproduced the structural and physiologic changes of pulmonary hypertension.[94] In lambs the clinical syndrome has been produced by administration of a cytokine associated with inflammation (i.e., tumor necrosis factor-α).[95] Relatively short periods of hypoxia in the fetal lamb result in sustained elevation of pulmonary artery pressure and structural changes in the pulmonary arteries. In utero closure or constriction of the ductus arteriosus has proved to simulate the structural changes and the initial hemodynamic profile of persistent pulmonary hypertension.[96,97] An intriguing observation between increased superoxide generation and pulmonary hypertension has been established in this model,[98] suggesting a potential for treatment with superoxide dismutase.[99] This also helps explain the refractoriness of this particular group of patients to NO[100] and is in keeping with the elevated levels of soluble guanylate cyclase and phosphodiesterase.[101]

Although the mechanism is not established, changes in the regulation of production of vasodilators and vasoconstrictors may be

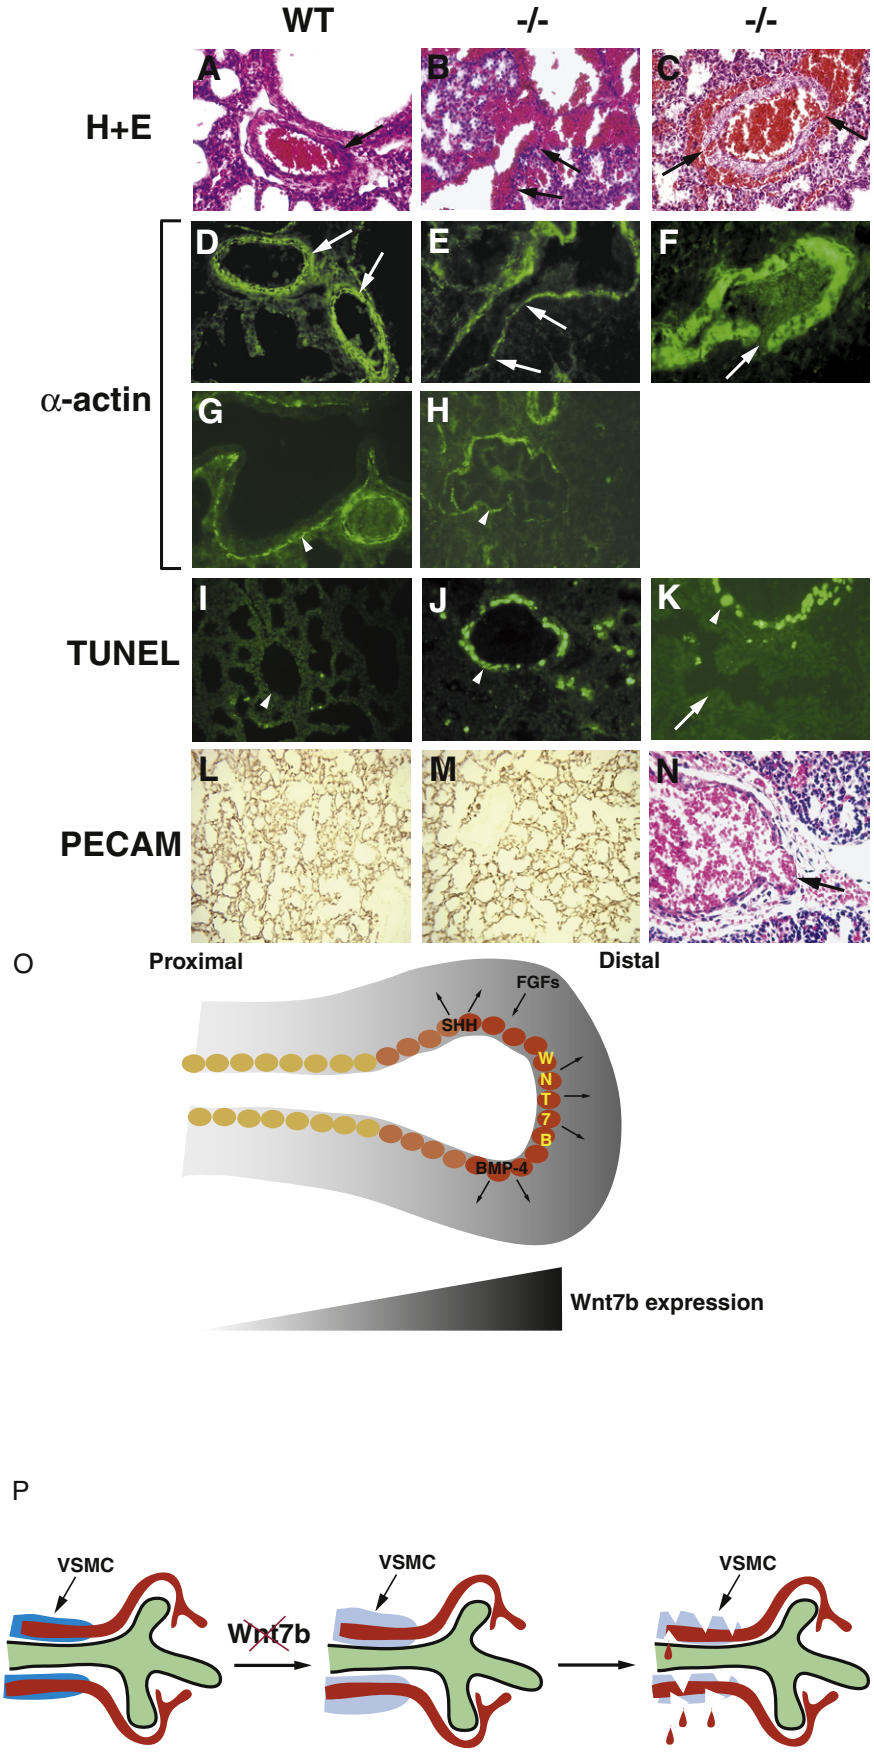

Figure 67-9 Defective smooth muscle integrity in Wnt7b$^{lacZ-/-}$ embryos and mice. Close examination of blood vessels in wild-type (**A,** *arrow*) and Wnt7b$^{lacZ-/-}$ P0 neonates (**B** and **C**) reveals several breaches in the vessel wall in Wnt7b$^{lacZ-/-}$ mice. In some instances, very little of the structure of the wall is left (**B,** *arrows*), whereas in others a thicker vessel wall with several ruptures is observed (**C,** *arrows*). Staining of sections with an antibody against smooth muscle α-actin shows robust staining surrounding blood vessels in wild-type neonates (**D,** *arrows*). Smooth muscle α-actin staining shows reduced staining, suggesting degradation of smooth muscle surrounding some vessels in Wnt7b$^{lacZ-/-}$neonates (**E,** *arrows*), whereas other vessels show frank breaches in the hypertrophic vessel wall **(F).** Bronchial smooth muscle appears normal in both wild-type (**G,** *arrowhead*) and Wnt7b$^{lacZ-/-}$neonates (**H,** *arrowhead*).TUNEL staining shows an increase in TUNEL-positive cells in the smooth muscle of the blood vessel wall in Wnt7b$^{lacZ-/-}$neonates (**J,** *arrowhead*) but not in bronchial smooth muscle (**K,** *arrow*).This is not observed in wild-type littermates (**I,** *arrow*). PECAM staining reveals a normal endothelial network in wild-type **(L)** and Wnt7b$^{lacZ-/-}$ neonates **(M).** Many large blood vessels showed rupture of the smooth muscle layer, with herniation of the intact endothelial cell layer (**N,** *arrow*). **O,** A model for the role of Wnt7b in lung development. Wnt7b is expressed at the distal tips of the airway epithelium in a pattern similar to that observed with BMP4 and overlapping that of SHH. In addition,Wnt7b is expressed in an increasing gradient from the proximal-to-distal airway epithelium. FGFs are expressed in the mesenchyme and are known to regulate epithelial branching and proliferation. However, because BMP-4 and SHH expression are unchanged in Wnt7b$^{lacZ-/-}$ embryos and Wnt7b expression is unchanged in *Shh*-null mice,Wnt7b regulates mesenchymal proliferation and differentiation through a unique pathway. **P,** Lung vasculature is composed of both endothelium *(red)* and vascular smooth muscle (VSMC, *blue*), and develops in parallel with the airways *(green)*. Loss of Wnt7b function results in defects in vascular smooth muscle differentiation and/or survival, leading to a hypertrophic response (change from *dark blue* to *light blue*), degradation of the vessel wall, and eventual rupture of the weakened vessels. *BMP,* Bone morphogenetic protein; *FGFs,* fibroblast growth factors; *H+E,* hematoxylin and eosin (stain); *PECAM,* platelet cell adhesion molecule; *TUNEL,* terminal deoxynucleotidyl transferase dUTP nick end labeling. *(From Shu W, Jiang YQ, Lu MM, et al:Wnt7b regulates mesenchymal proliferation and vascular development in the lung,* Development *129(20):4831, 2002.)*

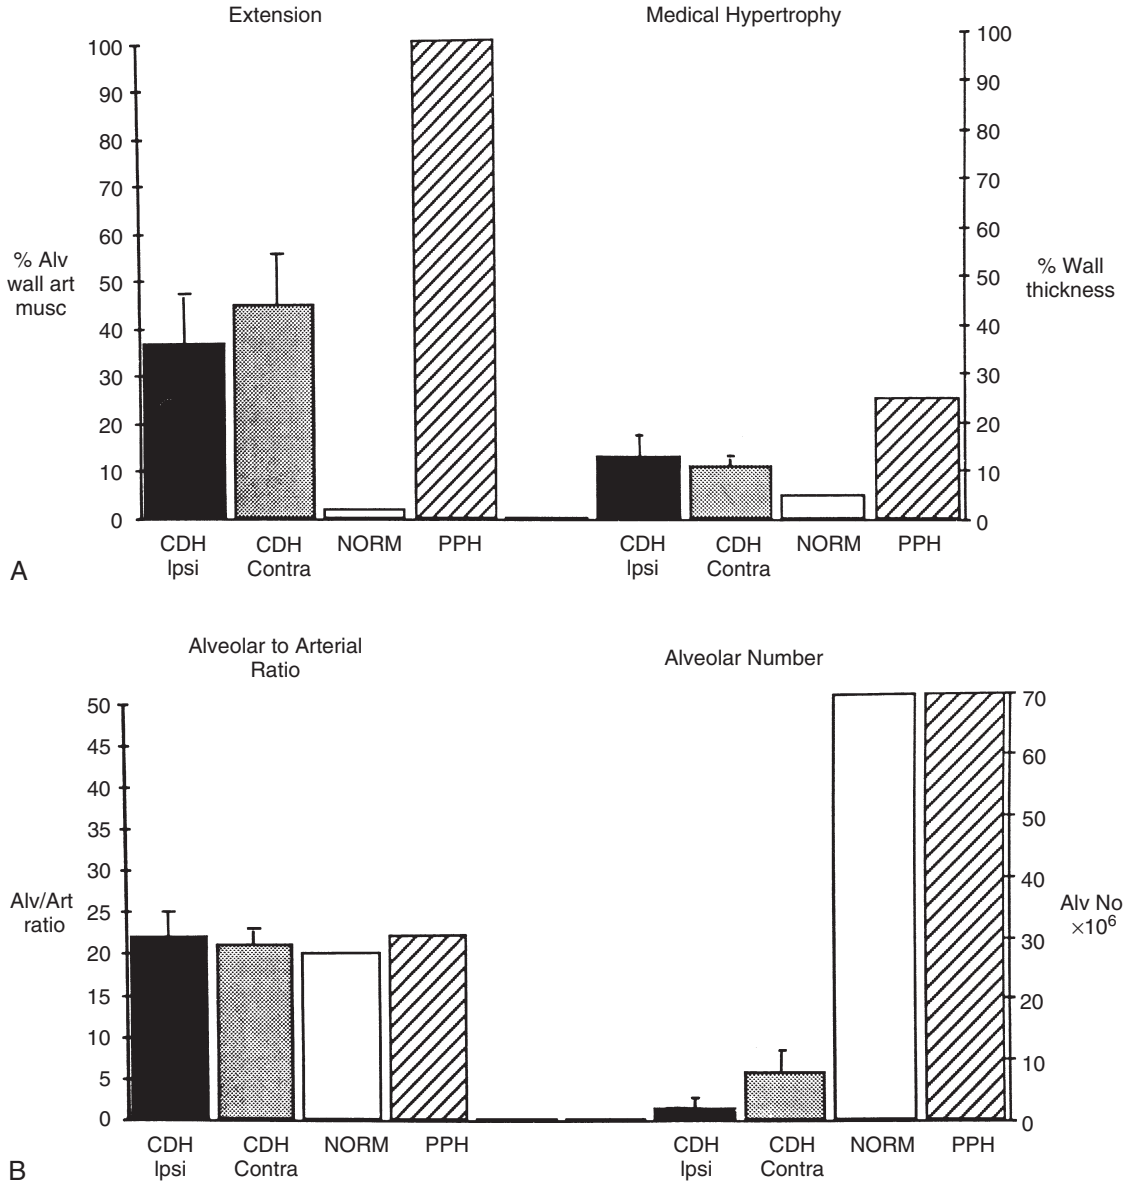

Figure 67-10 A, Morphometric data from nine patients with congenital diaphragmatic hernia (CDH), compared with published values in normal neonates and in infants with idiopathic persistent pulmonary hypertension of the newborn (PPH). Infants with CDH had greater smooth muscle extension into peripheral arteries and increased medial hypertrophy than normal infants but less than infants with PPH. **B,** Morphometric data from 6 infants with CDH compared with normal neonates and infants with PPH. Alveolar/arterial ratio was similar to that in normal infants, but total alveolar number was severely reduced in both ipsilateral and contralateral lungs. *(From Bohn D, Tamura M, Perrin D, et al: Ventilatory predictors of pulmonary hypoplasia in congenital diaphragmatic hernia, confirmed by morphologic assessment,* J Pediatr *111(3):423, 1987.)*

pertinent. That is, because NO can induce angiogenesis and endothelin may be a mitogen for smooth muscle cells, one might speculate that increased production of endothelin or reduced production of nitric oxide in utero might lead to an increase in muscularity of peripheral pulmonary arteries and a reduction in their number.

As previously discussed, smooth muscle cells with differences in potential for proliferation and for production and accumulation of extracellular matrix components may also be differentially responsive to stimuli that perturb the pulmonary vasculature. Conversely, structural remodeling of the pulmonary circulation affects the responsivity to vasodilator stimuli. For example, increased adventitial thickening, as observed in hypoxia-induced neonatal pulmonary hypertension, may prevent the access of NO to the vascular smooth muscle cells.[102] An alternative pathway that might be equally important in reducing vascular tone as well as in suppressing the propensity to vascular inflammation is the heme oxygenase pathway.[103]

ALTERED POSTNATAL PULMONARY VASCULAR DEVELOPMENT

Hypoxia, hyperoxia, toxins, or alterations in pulmonary blood flow also affect the postnatal structural development of the pulmonary vascular bed in infancy and childhood. We have shown in clinical studies that high flow and pressure induce increasing pulmonary hypertension in association with progressive vascular abnormalities.[104] First, there is extension of muscle into peripheral, normally nonmuscular arteries (morphometric grade A). This is followed by

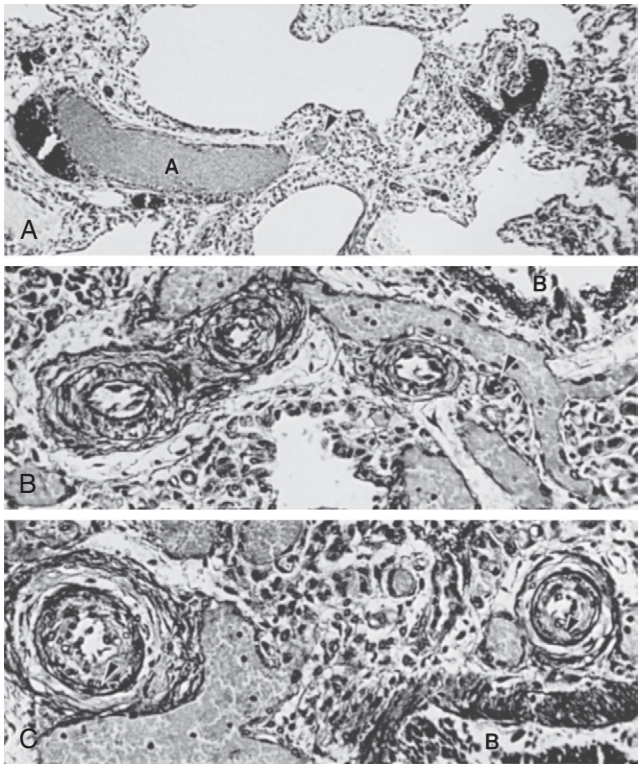

Figure 67-11 Lung micrographs from the left **(A)** and right **(B, C)** lungs of a patient with alveolar capillary dysplasia. **A,** Barium distends the lumen of a preacinar artery *(A)* but does not enter the anomalous vein to the left of the artery. Intra-acinar arterial branches that contain barium are identified *(arrowheads),* but intra-acinar veins and venules are distended with red blood cells, presumably forced ahead of the barium by the postmortem angiogram. Air spaces are lined by cuboidal epithelium, and no luminal capillaries are seen, all vessels lying centrally in the air space walls. (Hematoxylin-eosin, ×90.) **B,** Intra-acinar pulmonary arteries showing medial muscular thickening that forms a continuous layer even in the smallest branch *(arrowhead),* which is 20 μm in external diameter. Media is demarcated by external and internal elastic laminae, stained black in this elastic stain. A bronchiole is identified *(B).* (Elastic–van Gieson, ×220.) **C,** Intra-acinar arteries, the smaller measuring 60 μm in external diameter, with concentric intimal fibrosis; the latter is overlaid by *arrowheads* that mark the internal elastic laminae. The media is narrow in these branches, but note that the lumen (containing festooned endothelial cells) is the same size as in the similar-sized arteries seen in *B.* (Elastic–van Gieson, ×220.) *(From Cullinane C, Cox PN, Silver MM, et al: Persistent pulmonary hypertension of the newborn due to alveolar capillary dysplasia,* Pediatr Pathol *12:499, 1992. Reproduced with permission. All rights reserved.)*

medial hypertrophy of muscular arteries (grade B = Heath-Edwards grade I)[105] and reduced arterial concentration (morphometric grade C), associated with increased pulmonary artery pressure and resistance.[104] There is also the concomitant development of neointimal formation. This is initiated by cellular changes (Heath-Edwards grade II), which further progress to occlusive fibroproliferative lesions (grade III) and culminate in plexiform networks of obstructed and dilated vessels (grade IV). The potential for reversibility of these changes is dictated by their severity; for example, grade I-B almost always regresses following removal of the abnormal hemodynamic stimulus, whereas the loss of arteries (grade C) and the higher Heath-Edwards grades generally regress or remain functionally insignificant only if the hemodynamic insult is relieved in early infancy (first 8 months of life).[106]

To investigate the cellular mechanisms that control the pulmonary vascular abnormalities in congenital heart defects, we applied electron microscopy to the study of lung biopsy tissue. Endothelial changes were observed on scanning and transmission electron microscopy, suggesting a potential for altered interaction with circulating blood elements, such as platelets and leukocytes.[107] Functional abnormalities also were reflected in increased production of von Willebrand factor.[108,109] In addition, alterations in the subendothelium, reflected in fragmentation of elastin, suggested that an elastolytic enzyme might be stimulating the remodeling process.[107]

EXPERIMENTAL PATHOPHYSIOLOGY OF PULMONARY HYPERTENSION

We have shown experimentally in infant rats that exposure to low oxygen (equivalent to 10% Fio_2) or hyperoxia (80% to 100% Fio_2), or to the toxin monocrotaline induces abnormal muscularization of peripheral arteries, medial hypertrophy of muscular arteries, and reduced arterial relative to alveolar density.[1] Although the pulmonary vascular abnormalities induced by changes in ambient oxygen may be largely reversible, monocrotaline-induced changes progress in the adult animal but not in the infant. Hyperoxia is especially associated with a failure of normal lung compliance and growth, whereas monocrotaline induces only alveolar abnormalities when given to neonatal rats.

Experimentally we have related the induction of structural changes in pulmonary arteries to the increased activity of the endogenous vascular elastase (EVE).[110,111] Increased EVE is observed in rat pulmonary arteries several days after exposure to hypoxia or injection of monocrotaline. A second increase in elastase activity is seen in adult animals injected with monocrotaline but not in infant rats or adult or infant hypoxic rats in which there is potential for regression. A cause-and-effect relationship between elastase and the pathophysiology of pulmonary arterial changes and hypertension is further demonstrated in studies in which a variety of serine elastase inhibitors proved effective in preventing development or progression of pulmonary vascular changes and pulmonary hypertension.[110,112]

The induction of elastase activity appears to be related to the functional changes associated with the perturbed endothelium, which results in loss of the barrier function. We speculated and subsequently showed in vitro that serum factors or endothelial factors that might gain access to the subendothelium when the barrier is lost can induce release of a serine elastase from pulmonary vascular smooth muscle cells.[113] This elastase can liberate biologically active smooth muscle cell mitogens, such as basic fibroblast growth factor (FGF) (FGF-2), from extracellular matrix stores.[57]

The resulting smooth muscle cell hyperplasia contributes to the hypertrophy of the arterial wall. Release of other growth factors, such as TGF-β, which can induce increased synthesis of elastin and collagen, might also add to the thickening. We have shown further that there is also induction of the matrix glycoprotein tenascin, which interacts cooperatively with growth factors, such as epidermal growth factor and basic FGF, in inducing the proliferative response in the vessel wall[114] (Figure 67-12). Having shown that hyperoxia-induced pulmonary hypertension and altered lung compliance in newborn rats could also be largely prevented with the use of elastase inhibitors,[115] we initiated a clinical trial with promising results in preventing and reducing the severity of bronchopulmonary dysplasia in premature infants.[116] Experimental studies by our group have also shown that elastase inhibitors can reverse established pulmonary vascular disease produced by the toxin monocrotaline, including muscularization of distal arteries, medial hypertrophy of muscular arteries, and loss of small vessels (Figure 67-13).

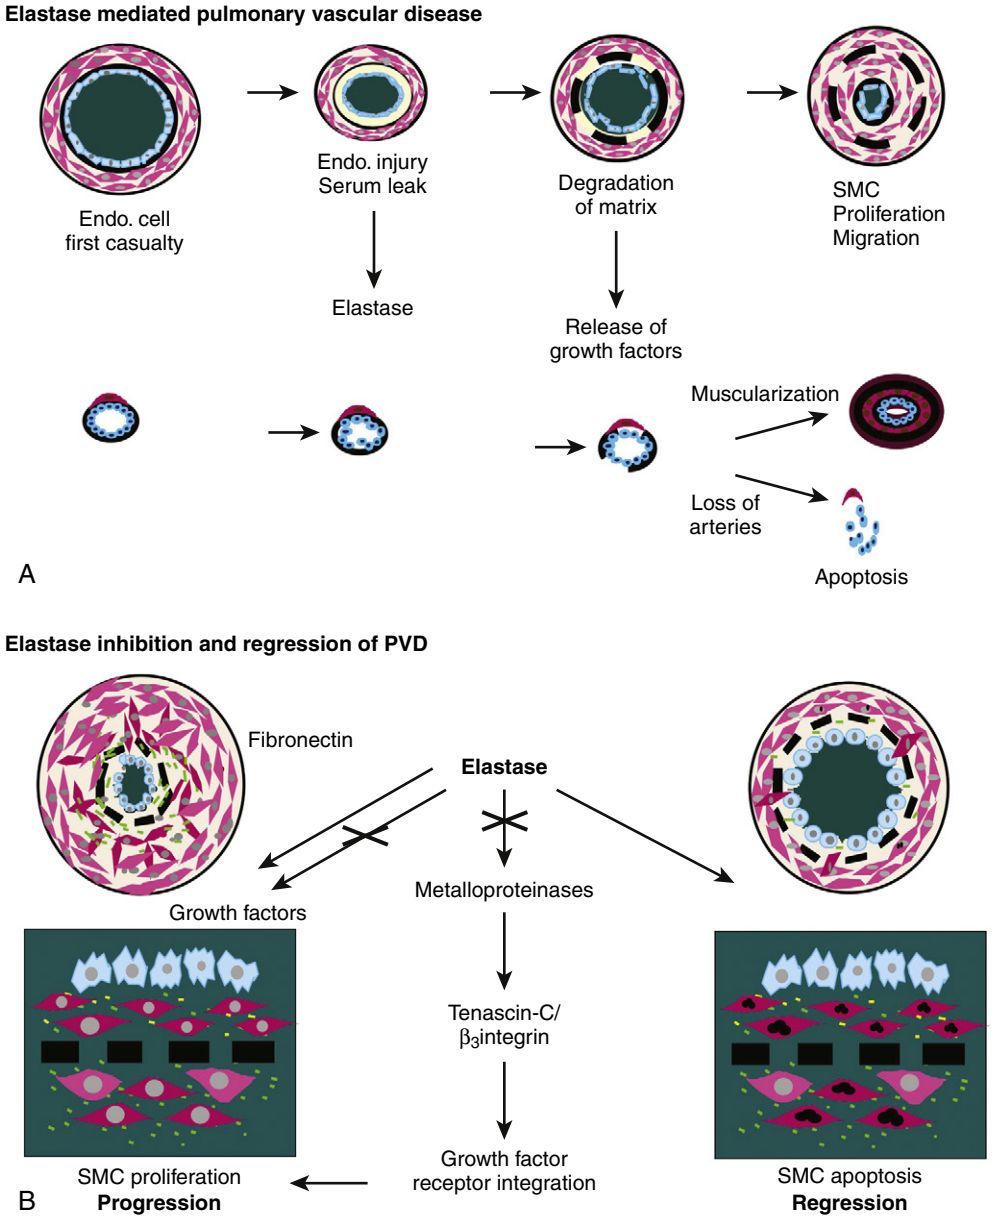

Figure 67-12 Schema describing relationship of elastase to pulmonary vascular disease. We speculated, based on our studies in cultured cells and in experimental animals, as to how a stimulus could induce activity of an elastolytic enzyme and how this might stimulate the remodeling process. In response to an injurious stimulus, the first "casualty" is the endothelial cell. As a result of structural and functional alterations in endothelial cells, some of the barrier function would be lost, allowing a leak into the subendothelium of a serum factor normally excluded from this region. The serum factor could induce activity of an endogenous vascular elastase (EVE). This enzyme released from precursor or mature SMCs would activate growth factors normally stored in the extracellular matrix in an inactive form, which are known to induce smooth muscle hypertrophy and proliferation and increases in connective tissue (CT) protein (e.g., collagen and elastin) synthesis. The growth factors could also result in the differentiation of precursor cells to mature smooth muscle related to the muscularization of normally nonmuscular small peripheral arteries. Elastase activity could also contribute to the loss of small arteries. **B,** As a result of elastase activity, a proteolytic cascade could be amplified through the activation of matrix metalloproteinases. We have shown that proteolysis of the matrix leads to the induction of tenascin-C, which in clustering to β_3 integrins results in the clustering and activation of growth factor receptors that send important survival as well as growth signals to the cells. Continued elastase activity causes migration of SMCs in several ways. The elastin peptides or degradation products of elastin can stimulate fibronectin, a glycoprotein that is pivotal in altering smooth muscle cell shape and in switching them to the motile phenotype. Inhibition of elastase activity could lead to smooth muscle cell apoptosis and regression of vascular disease. *(From Rabinovitch, M: Pathobiology of pulmonary hypertension,* Annu Rev Pathol Mech Dis *2:369-99, 2007.)*

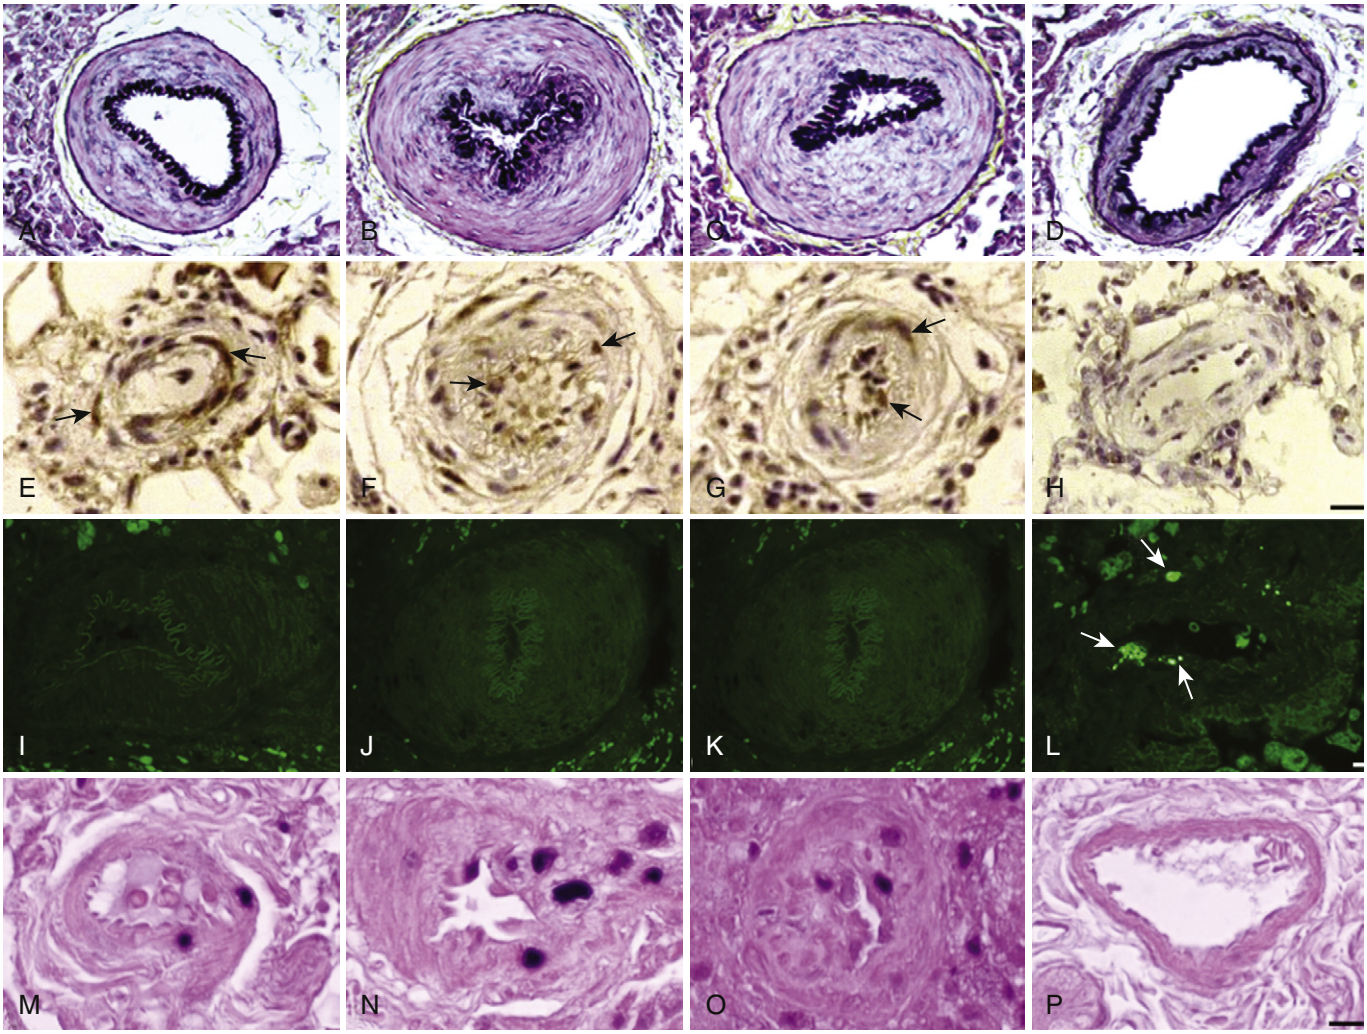

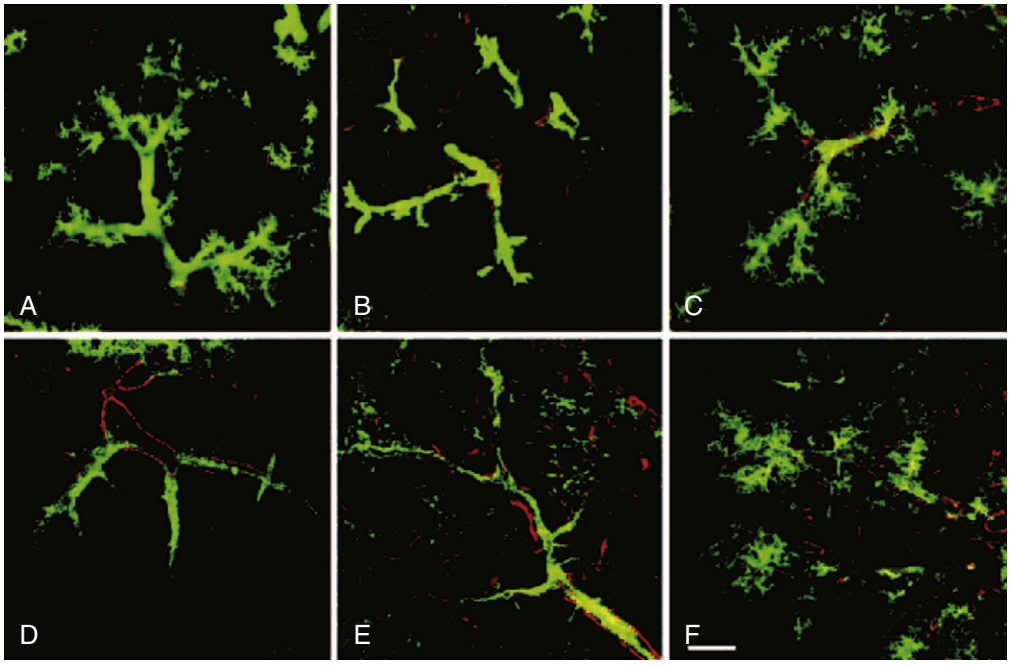

Figure 67-13 Cellular mechanism responsible for reversal of pulmonary artery muscularity. Elastase inhibition arrests tenascin-C accumulation and proliferation and induces apoptosis and loss of extracellular matrix (such as elastin). **A–P,** Days refer to time after injection of monocrotaline: A,E,I,M, day 21; B,F,J,N, day 28; C,G,K,O, day 28; D,H,L,P, day 28. **A–D,** Saline-perfused pulmonary arteries stained with Movat pentachrome stain. **E–H,** Pulmonary arteries after tenascin-C immunohistochemistry. *Arrows* indicate positive brown peroxidase staining. **I–L,** In situ TUNEL assays identifying apoptosis. *Arrows* indicate TUNEL-positive vascular cells. **M–P,** Proliferating vascular cells, shown by immunohistochemistry for proliferating cell nuclear antigen (PCNA); dark nuclei are PCNA-positive cells. *(From Cowan KN, Heilbut A, Humpl T, et al: Complete reversal of fatal pulmonary hypertension in rats by a serine elastase inhibitor,* Nat Med *6:698-702, 2000)*

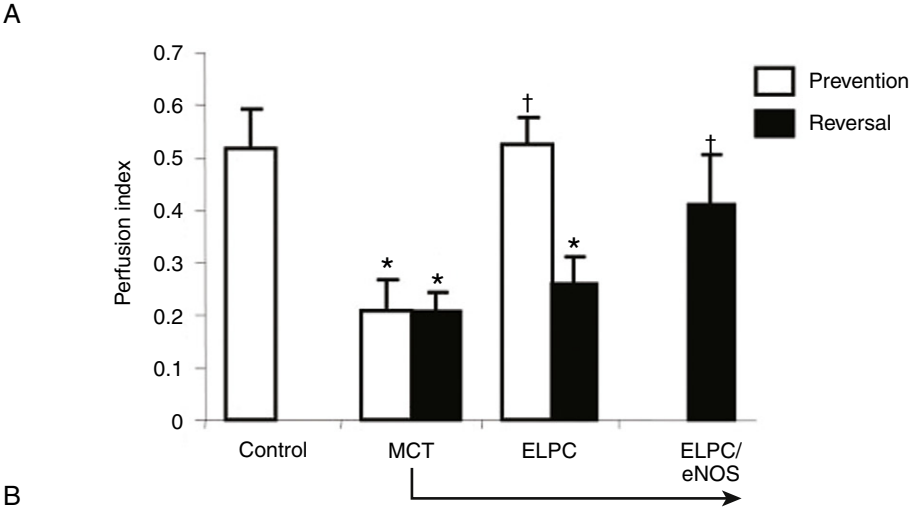

Based on subsequent knowledge that the effect of elastase was critical in maintaining survival signals through epidermal growth factor receptors (EGFRs), we blocked EGFR.[117] In these studies we were able to show reversal of progressive pulmonary arterial hypertension (PAH) that was sustained even 1 month after cessation of treatment. More recently, the use of a PDGF receptor blocker to reverse PAH in this experimental model[118] has prompted a case report showing the successful use of the tyrosine kinase inhibitor Imatinib (Gleevec) in a patient with advanced pulmonary vascular disease.[119] This report has prompted several clinical trials. Others have used simvastatin to reverse PAH in a monocrotaline-pneumonectomy model[120] or endothelial eNOS gene therapy in association with endothelial progenitor cell administration (Figure 67-14).[32,121] This study is important in showing recovery of the distal vasculature using this strategy.

Gene therapy with survivin[122] or angiopoietin-1,[123] as well as inhibition of the serotonin transporter (SERT),[124] and administration of adrenomedullin[125] and the rho kinase inhibitor, fasudil[126] have been used to reverse experimental pulmonary vascular disease. Potassium channel dysfunction is implicated in the pathogenesis of pulmonary vascular disease,[127] and gene therapy restoring K channel function has been used effectively to suppress[128] and reverse experimentally induced pulmonary vascular abnormalities. Our ability to prevent progression or reverse advanced pulmonary vascular disease in patients and restore the normal growth of blood vessels may require further identification of the cause of the smooth muscle cell and fibroblast proliferative response and the initial endothelial cell susceptibility to apoptosis.[129-132]

DECREASED GROWTH OF THE PULMONARY VASCULAR BED

Reduced pulmonary blood flow and pressure may also result in reduced growth of the pulmonary vascular bed with relative hypomuscularity of vessels that are decreased in size and number. This can be further aggravated by suppressed growth of the

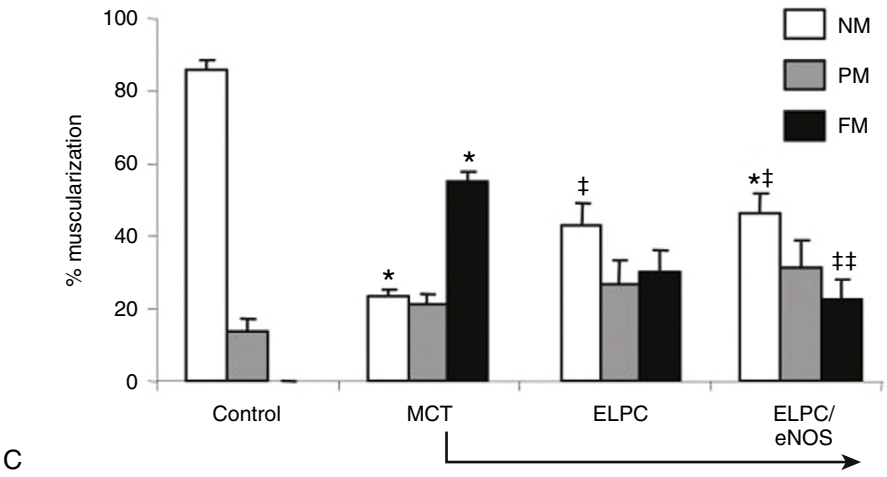

Figure 67-14 **A,** Representative confocal projection images of lung sections perfused with fluorescent microspheres *(green)* suspended in agarose (i.e., fluorescent microangiography) and immunostained for α-smooth muscle actin *(red)*. Normal filling of the microvasculature was observed in control rats *(A),* whereas rats treated with MCT showed a marked loss of microvascular perfusion and widespread precapillary occlusion 21 days *(B)* and 35 *(D)* days after MCT injection. In the prevention model, animals receiving ELPCs displayed improved microvascular perfusion and preserved continuity of the distal vasculature *(C).* In the reversal model, eNOS-transduced ELPCs dramatically improved the appearance of the pulmonary microvasculature *(F),* whereas progenitor cells alone resulted in more modest increases in perfusion and little noticeable reduction in arteriolar muscularization *(E).* Summary data for pulmonary microvasculature perfusion **(B)** for animals treated in the prevention *(white bars)* and reversal *(shaded bars)* protocol. **C,** Proportion of small pulmonary arterioles that are nonmuscularized *(NM),* partially muscularized *(PM),* or full muscularized *(FM)* in the various treatment groups of the reversal protocol. *(From Zhao YD, Courtman DW, Deng Y, et al: Rescue of monocrotaline-induced pulmonary arterial hypertension using bone marrow-derived endothelial-like progenitor cells: efficacy of combined cell and eNOS gene therapy in established disease,* Circ Res *96(4): 442-50, 2005.)*

lung parenchyma, which can also be a feature of low pulmonary blood supply.[4]

PULMONARY VENOUS ABNORMALITIES

The pulmonary vascular abnormalities that are caused by pulmonary venous hypertension are the result of mitral valve or left ventricular dysfunction and anomalous pulmonary venous return. They largely regress following correction of the anatomic or physiologic abnormality, although in the initial postoperative period the abnormally muscularized vasculature[133,134] may be reactive. Individual stenoses of the extraparenchymal and particularly of the intraparenchymal pulmonary veins are difficult to correct with current surgical or interventional cardiologic approaches. We created a neonatal piglet model of progressive pulmonary venous obstruction and showed that there was altered compliance of the veins, which was reflected in an increase in pulmonary arterial pressure.[135] This preceded the elevation in pulmonary venous pressure, which occurred later when there was evidence of some compromise of the vessel lumen by the intimal lesion. At this stage, there was a disproportionate increase in collagen in the vessel wall, which likely further contributes to the hemodynamic abnormality and the resistance to successful intervention.

CLINICAL IMPLICATIONS

The reduced growth of the pulmonary circulation may pose a contraindication for surgery using the Fontan principle.[133] Also, consideration of patients for cavopulmonary anastomoses in preparation for a final-stage Norwood operation must take into account evidence of regression of the left-sided obstructive lesion–induced vascular changes, that is, the increased muscularity of pulmonary arteries and veins that are associated with heightened pulmonary vascular reactivity. Future studies aimed at accelerating the structural maturation of the lung to induce both dilation and recruitment of small vessels may prove of benefit in allowing surgical correction of even complex congenital heart disease in the newborn infant.

CONCLUSION

Increasing knowledge of the genes that control vascular cell phenotype and differentiation and their regulation in development will lead to new and fruitful directions in preventing or reversing abnormal structural development of the lung.

Development of the Gastrointestinal Circulation in the Fetus and Newborn

The rapid cellular growth of the intestine in fetal life requires sufficient substrate for energy and a means for clearance of metabolic waste. This is accomplished by a rapid and proportionate growth of the intestinal circulation. Although anatomic and histologic studies have been performed on salvaged human fetal intestines, lack of availability of samples and autolysis has precluded detailed and systematic studies of the physiology of the developing gastrointestinal circulation. Therefore much of the information presented in this chapter is derived from controlled studies in animals. In addition, the most reliable data involve only that portion of the alimentary tract below the diaphragm, namely, the gastrointestinal and colonic circulation.

Several principles of gut development have an impact on intestinal blood flow. The cephalic portion of the embryonic intestinal tract develops and matures more rapidly than do caudal areas.[1] As the gut intestinal lining rapidly multiplies, the embryonic ileum is obliterated and eventually recanalizes. Although the intestine begins as a straight tube, differential growth rates result in the contrasting calibers of various gut segments and in the rotation and final positioning of various components.[2]

The arterial supply to the intestine does not develop in isolation but forms in response to the rapid growth of this organ. The majority of the intestinal tract mucosa, along with the liver parenchyma and pancreas, is derived from endoderm. However, the connective tissue and muscular components are derived from splanchnopleuric mesoderm. Oral and anal epithelium is derived from the ectoderm of the stomatodeum and proctodeum, respectively. Progressing from the germ cell stage, the intestine is divided into three primary portions: the foregut, midgut, and hindgut.[2-4] The foregut includes all structures distal to the tracheal diverticulum from the esophagus through the first half of the duodenum. The midgut is composed of structures distal to the second portion of the duodenum, including the jejunum, ileum, and proximal two thirds of the transverse colon. The hindgut consists of the distal transverse colon and the proximal two thirds of the anal canal.

DEVELOPMENT OF INTESTINAL CIRCULATION

Early somite embryos have an extensive vascular network on the yolk sac. In the process of vasculogenesis, vascular endothelial precursor cells (angioblasts) migrate to the location of future vessels, coalesce into cords, differentiate into endothelial cells and ultimately form patent vessels. Vascular endothelial growth factors and their receptors have been identified. Erythropoietin has been shown to stimulate vasculogenesis in neonatal rat mesenteric microvascular endothelial cells.[5] Unpaired ventral branches of the dorsal aorta (vitelline arteries) pass to the yolk sac, allantois, and chorion. The network drains by way of the vitelline veins to the heart. During the fourth week the primitive gut is formed as the dorsal portion of the yolk sac is incorporated into the embryo. Three vitelline arteries persist to supply the foregut (celiac artery), midgut (superior mesenteric artery), and hindgut (inferior mesenteric artery).[2]

The vessels distributed to the foregut fuse and form a single vessel, the celiac artery. With a downward migration of the viscera, the aortic attachment of the celiac artery moves caudally. It divides into the hepatic artery, splenic artery, and left gastric branches to supply the stomach and duodenum. The liver, pancreas, and related mesodermal spleen receive their blood supply from these branches. At the vascular division between the foregut and midgut is the anastomosis between the superior pancreaticoduodenal and the inferior pancreaticoduodenal arteries.[4]

The embryonic vitelline arteries fuse and form a superior mesenteric trunk, which reaches the midgut by passing through the mesentery. Terminal branches of this trunk supply the yolk sac. The various branches distal to the intestine are obliterated when the ileum separates from the yolk sac and vitelline stalk. However, the superior mesenteric artery remains and supplies the intestinal circulation from the second part of the duodenum through the proximal two thirds of the transverse colon.[3,4]

The ventral branches of the aorta supplying the hindgut fuse to form a single inferior mesenteric trunk. Its final distribution includes the distal one third of the transverse colon and the entire descending colon and sigmoid. The inferior mesenteric trunk anastomoses with the middle colic artery, which is a branch of the superior mesenteric artery. Furthermore distal to this is an anastomosis to branches of the inferior and middle rectal arteries from the internal iliac trunk.[2,3]

VENOUS DRAINAGE OF THE GASTROINTESTINAL TRACT

The venous drainage of the intestine is much more variable than is the arterial blood supply. The low pressure venous drainage in the embryo is plexiform, and therefore patency is based somewhat on blood flow. In addition, blood has a tendency to seek the most direct route of flow because of hydrodynamic factors.

The vitelline veins initially pass along each side of the anterior intestinal portal vein. They form an anastomosing plexus around the developing duodenal loop in the substance of the septum transversum. Cords of liver cells extend into the septum transversum and divide the vitelline plexus into the primitive hepatic sinusoids. Anterior stems of the vitelline veins enter the primitive sinus venosus. As the stomach, duodenum, and small intestine elongate and rotate from their original midsagittal position to the adult position, blood flow develops along the most direct route to the liver cutting from one vitelline vein to another through the connecting plexus. Thus the portal venous system does not develop in a spiral fashion around the developing intestine but instead evolves short and straight with the duodenum and intestine around it.[2,3]

In embryos of less than 5-mm crown-rump length (<5 weeks), blood from the paired umbilical veins passes into the liver, at which point it communicates with the vitelline sinusoids. At a 7-mm crown-rump length (33 to 34 days), the right umbilical vein atrophies and disappears.[2] As a result, all the placental blood entering the embryo enters through the left umbilical vein and

empties into the hepatic sinusoids. As the right side of the sinus venosus elaborates, an enlargement of the hepatic sinusoidal communication occurs between the right hepatocardiac channel and the left umbilical vein forming the ductus venosus.[4] Thus blood entering from either the umbilical or vitelline systems can pass by way of the ductus venosus to the right atrium or into the liver sinusoids. The venae advehentes, connecting the umbilical and vitelline systems to the hepatic sinusoids, become the branches of the portal vein in the liver. In addition, the venae revehentes connecting the sinusoids to the right hepatocardiac channel become the tributaries to the hepatic veins. After birth the left umbilical vein and the ductus venosus are obliterated and become the ligamentum teres and the ligamentum venosum, respectively.[3]

THE INTESTINAL MICROCIRCULATION

The microscopic anatomy of the intestinal circulation varies from species to species. In rabbits and humans, villus arterioles ascend from the submucosal arterioles into the villus. As the arteriole reaches the villus tip, it divides into a diffused capillary network, which then drains into a centrally located villus venule originating in the distal one third of the villus.[6] In most mammals, the capillaries of the intestinal villus are fenestrated. Just as the villus and the microvillus are exposed to a large solute and water load, so the villus capillaries must be capable of handling the absorbed materials. The endothelium of the capillary facing the epithelium is very thin and usually contains fenestrae, with the greatest number at the villus tips and in the crypts.

Water and solutes are transported into the capillary by a number of different pathways (Figure 68-1). Low-molecular-weight nonpolar substances and lipid-soluble substances such as oxygen and carbon dioxide may cross directly through the cell membrane. The bulk of absorbed materials passes through fenestrae, which are numerous circular openings of up to 30 nm in the capillary endothelium and may be either opened or diaphragmed.[6] At least 60% of the fenestrae have a diaphragm. Although the porosity is not known, these diaphragms limit the movement of molecules. Much less commonly, water and solutes move slowly by pinocytosis. In this process, vesicles are formed that move through the cell to the opposing side before releasing their contents. On rare occasions, transendothelial channels may be formed when several vesicles simultaneously open and bridge the cell. These occurrences are relatively infrequent and do not have a major impact on total absorptive capacity. Intercellular junctions are impermeable to solutes of 2-nm diameter in the arteriole and capillary but may play a limited role in venule absorption.

CONTROL OF BLOOD FLOW

Numerous factors impinge on the maintenance of intestinal blood flow. They can be grouped into at least four major categories: cardiovascular status, neural control, humoral substances, and local control.[7-9] Although not much data are available specifically regarding the fetal intestine in these areas, certain principles can be inferred to be operative in the fetus.

Cardiovascular Function

Adequate perfusion of any tissue in the body is dependent on the maintenance of sufficient cardiac output and mean arterial pressure. Reduction in cardiac output or systemic arterial pressure within physiological range leads to compensatory vasodilation of the regional circulation to maintain the tissue blood flow relatively constant, the process termed as pressure-flow autoregulation. The autoregulation of intestinal blood flow guarantees the preservation of continuous blood flow to the intestine while large fluctuations are occurring in the arterial perfusion pressure.[8,10] Although superior mesenteric circulation autoregulation has been well established in canine, porcine, and feline circulations, the mechanism for this regulation is controversial.[11] The capacity to autoregulate the intestinal blood flow is a function of gestational maturation: however, in the presence of profound hypotension, net vasoconstriction occurs and intestinal blood flow decreases. In newborn swine, moderate systemic arterial hypoxemia causes vasodilation and increase in gut perfusion, whereas severe hypoxemia (PO_2 <40 mm Hg) causes vasoconstriction and gut ischemia.[12] Intestinal perfusion and oxygenation is profoundly reduced in puppies made polycythemic by exchange transfusion. Fortunately few infants have polycythemia and most escape intestinal damage. Both of these factors are influenced by blood volume. The proportion of cardiac output destined for the intestine is altered in newborns with cyanotic congenital heart disease and vascular malformations, such as coarctation of the aorta, which limits blood flow to the intestinal tract. In the fetus, systemic circulatory needs are maintained even with severe left ventricular obstruction. However, fetal asphyxia and other fetal problems can be associated with reduced myocardial contractility and tricuspid regurgitation, limiting cardiac output and consequently reducing intestinal flow.

Intestinal oxygen uptake and blood flow increase dramatically after birth to sustain rapid growth of the mucosa and oxidative demands of enteral nutrition (secretion, absorption, motility).[11] Postnatally, the splanchnic circulation accounts for 20% of cardiac output; however, splanchnic blood flow increases 30% to

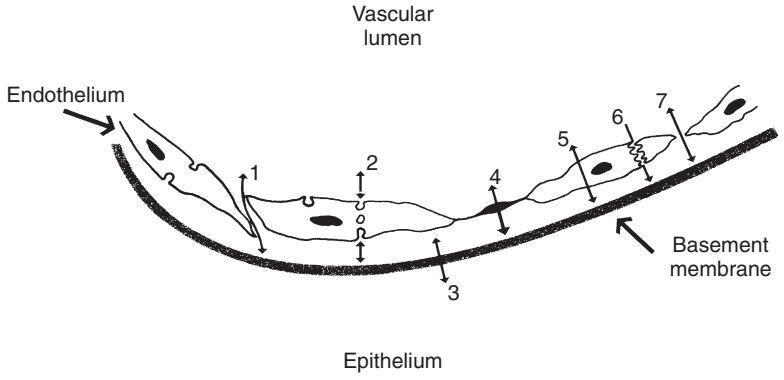

Figure 68-1 Transport pathways in intestinal capillaries. *Arrow* represents potential direction of movement of fluid and solids. (1) Intercellular junction, (2) pinocytosis, (3) basement membrane, (4) fenestrae with diaphragms, (5) cell membrane, (6) transendothelial channel, and (7) open fenestrae.

130% after a meal, known as *postprandial hyperemia*.[10] Glucose and solubilized long-chain fatty acids increase jejunal blood flow. In preterm infants, dietary mixed nucleotides increased the superior mesenteric artery blood flow velocity, peaking at 30 minutes postprandial and having a sustained effect for 90 minutes.[13] Bile and bile salts may double ileal blood flow. Volatile fatty acids (acetic, butyric, propionic) derived from fermentation of undigested carbohydrates by microflora increase colonic blood flow and serve as a metabolic substrate for colonic enterocytes.[8]

Neural Controls

The gastrointestinal tract is extensively innervated by the autonomic and enteric nervous system.[7,11] Enhanced sympathetic tone elicits arterial smooth muscle contraction, thereby raising intestinal vascular resistance and decreasing blood flow. This effect is mediated through the α-adrenergic receptors in the vascular smooth muscle. However, this vasoconstrictor response is short lived, and decreased vascular resistance and improved blood flow rapidly return by stimulation of α-adrenergic receptors.[9,12,14] Thus sympathetic stimulation may produce a variable response (Box 68-1). Although acetylcholine causes vasodilation through an endothelium-dependent mechanism,[14-16] the effects of acetylcholine on intestinal blood flow are also variable. Acetylcholine has the ability to initiate intestinal smooth muscle contraction, which can impede blood flow by increasing transmural pressure.

Marginal tissue oxygenation antagonizes the sympathetic response by inducing vasodilation. Furthermore, intestinal wall relaxation resulting from sympathetic stimulation decreases the resistance of the vessels and allows increased blood flow to the stomach and intestines. The adrenal medullary catecholamines and angiotensin II, formed locally in response to renal renin, constrict vascular smooth muscle in the gastrointestinal circulation and therefore decrease local blood flow.[17,18] This effect may be temporary, however, and can be readily overridden by local metabolic control.

The majority of extrinsic nerves innervating the intestine are afferents. They contain two important polypeptides, substance P and calcitonin gene-related peptide (CGRP), which are released by noxious chemical and mechanical stimulation. These agents induce local vasodilation and contribute to neurogenic inflammation by mast cell degranulation and altering vascular permeability.[19]

BOX 68-1

Agents That Increase Intestinal Blood Flow

Acetylcholine[14,17,19,41]; motlin[8,10,20]
Adenosine[8]; neurotensin[10]
Adrenergics[16]; nitric oxide[24,25,27,42]
Isoproterenol
Salbutamol peptide hormones
Cholecystokinin[19-21]
Aminophylline[1]; gastrin[19-21]
Glucagon[43,44]
Bradykinin[21,45]; vasoactive intestinal polypeptide[46]
Calcium antagonists[47]; platelet-activating factor (directly)[15,40]
Carbon dioxide[14]; potassium low dose[16,20,23]
Dietary nucleotides[13]; prostaglandins[8,45,48]
PGD2, PGE1, PGE2
Histamine[17,43]
Serotonin[8]
Magnesium[16,22]
Methionine-enkephalin[46]; substance P[18]

Humoral Controls

Numerous humoral substances have been demonstrated to alter gastrointestinal blood flow in experimental animals. Some are circulating substances, whereas others are released locally. Boxes 68-1 and 68-2 summarize the agents that have been well demonstrated to increase or decrease intestinal blood flow. Gastrointestinal hormones released during various phases of digestion may dilate the gastrointestinal circulation. Glucagon and cholecystokinin increase both intestinal blood flow and pancreatic flow.[19-21] Gastrin specifically increases blood flow to the gastric mucosa.[19,21]

Local Controls

The local extracellular environment is altered by the increased metabolic activity of the gastrointestinal parenchymal cells, for example, during digestion.[10] An increased metabolic demand may lead to relative tissue hypoxia and consequently the release of many vasodilators, for example, K^+, Mg^{2+}, histamine, polypeptides (bradykinin, vasoactive intestinal polypeptide), prostaglandins, carbon dioxide, and adenosine.[8,14-16,22,23] Cells with an increased metabolic rate are likely to produce greater quantities of dilator metabolites, which ensure the provision of more substrate by increasing blood flow.

Role of Nitric Oxide

Basal vascular resistance, which determines the regional gastrointestinal blood flow, depends upon the delicate balance between the constrictor and dilator forces which are acting upon the vascular smooth muscle. Nitric oxide is the major dilator which counterbalances the constrictive effect of the endothelin 1 and the intrinsic contractile response of smooth vascular muscle. Under basal conditions, nitric oxide is continuously produced by endothelial cell in presence of nitric oxide synthase (constitutive isoform) from L-arginine. It relaxes vascular smooth muscle by decreasing cytosolic free calcium via increased cGMP.[24,25] In rats, acute administration of a nitric oxide synthase inhibitor (L-NNA) reduces basal intestinal blood flow.[26] Rate of nitric oxide production can increase markedly following chemical or mechanical stimulation of nitric oxide synthase (induced or stimulated isoform). Methylene blue, a guanylate cyclase inhibitor, abolishes intestinal vasodilation resulting from administration of sodium nitroprusside, a nitric oxide donor.[27] After ischemia with reperfusion, exogenous nitric oxide sources (SIN-1, CAS-754, and nitroprusside) and L-arginine reduce mucosal barrier dysfunction without improving intestinal blood flow, suggesting that nitric oxide may have modulating effect on microvascular permeability.[28]

The fetal circulation has an increased basal production of nitric oxide compared with the adult.[29] In late gestation sheep fetus,

BOX 68-2

Agents That Decrease Intestinal Blood Flow

Adrenergics[8,16]; peptide hormones
Dopamine angiotensin II[8]
Epinehprine vasopressin[21,49]
Methoxamine
Norepinephrine physostigmine[8]
Phenylephrine
Potassium high dose[16,21]
Calcium[16,23,47]
Endothelin[35,36]; prostaglandin F2a[41]
5-Hydroxytryptamine[1]; somatostatin[50]
Leukoterine D4[38,39]; thromboxane A2[48]
Methacholine[44]; tyramine[1]

nitric oxide was shown to play important role in contributing to low vascular resistance and increased blood flow throughout the gastrointestinal tract, as well as in redistribution of intestinal blood flow between intestinal segments.[30] Inhibition of endogenous nitric oxide in midgestation fetal sheep results in substantial blood flow reduction across all segments of gastrointestinal tract, implying that nitric oxide plays a major vasodilator role at such an early stage of development of gastrointestinal circulation.[31] Sustained inhibition of nitric oxide synthase in utero results in vasoconstriction of fetal blood vessels, but no evidence of injury to the gastrointestinal tract exists.[32] A lack of nitric oxide synthesis appears to be causative in neonatal hypertrophic pyloric stenosis,[33] but this effect is mediated by the neuronal not the endothelial isoform of nitric oxide synthase based on gene knockout studies.[34]

Endothelin 1

Endothelin 1 is a vasoactive and mitogenic polypeptide synthesized and secreted by endothelial cells.[15] It acts on specific receptor ET_A on vascular smooth muscle, causing sustained powerful vasoconstriction, whereas binding to ET_B receptor on endothelial cell causes release of nitric oxide with resultant vascular relaxation. Although cord blood levels are higher than any other values reported in humans, little information is available about its role in the splanchnic circulation of the fetus and newborn.[35] Hypoxia and shear stress stimulates endothelin 1 secretion.[36] Preterm neonates born to mothers with pre-eclampsia have increased circulating levels of endothelin 1 and reduced superior mesenteric artery blood flow velocity, possibly due to fetal hypoxia.[37]

Local inflammatory mediators

Systemic or local activation of polymorphonuclear cells has been demonstrated to be a component of the pathophysiology of a variety of altered blood flow states. Activated neutrophils adhere to vascular endothelium and may damage or occlude them. Secondary release of vasoconstrictors (leukotrienes) and substances that increase permeability (platelet-activating factor, leukotrienes) may further compromise tissue perfusion.[38,39]

Platelet-activating factor (PAF) is a phospholipid synthesized by many types of cells including endothelium, macrophages, and granulocytes.[27] Although PAF is a vasodilator, it may cause paradoxical vasoconstriction and ischemic injury to the intestine as a consequence of its ability to activate leukocytes. PAF-activated leukocytes may plug postcapillary venules and release vasoconstrictors, for example, leukotriene C_4.[39]

CLINICAL CONSIDERATIONS

Virtually no study has examined the human fetal and neonatal intestinal blood flow in vivo. It may be inferred from various animal models that some of the clinical conditions encountered in critically ill neonates may result from compromise of the gastrointestinal circulation.[6] Limitation of blood flow as local tissue metabolism increases may result in malabsorption. The early-onset form of necrotizing enterocolitis (in the first week of life) is often associated with perinatal asphyxia, arterial catheterization, or the polycythemia-hyperviscosity syndrome.[40] In each of these conditions, poor tissue perfusion may result in ischemic necrosis of the intestine.

With gene expression techniques it may be possible to trace the ontogeny of systems regulating the gastrointestinal circulation (neural and humoral) in the developing human and experimental animals. These approaches may circumvent the technical problems of directly assessing the splanchnic circulation in the perinatal period. Insights drawn from these molecular approaches may guide improvements in the therapeutic management of the fetus and newborn.

69 Physiology of Congenital Heart Disease in the Neonate

Thomas J. Kulik

If one juxtaposes a drawing of the heart and great arteries—four chambers and a few large blood vessels—with a depiction of the cascade of biochemical events that follow, say, a growth factor binding to its receptor, it may seem that the physiology of congenital heart disease ought to be child's play. It is not, for several reasons key to understanding the physiologic responses to congenital heart lesions.

A comprehensive understanding of the cardiovascular physiology of a neonate with a cardiac lesion requires consideration of *many factors.* The first factor pertains to key variables (myocardial function; intravascular volume; cardiac and vascular transmural pressures, flows, and compliances; and pulmonary venous oxygen [O_2] content)[1] needed to describe the physiology of a neonate with a cardiac lesion. However, any description taking into account only these variables, although complex, would be incomplete because cardiac lesions affect somatic physiology in various ways (e.g., sympathetic nervous system activation) that cannot be specified from these variables alone. Indeed, alterations in somatic physiology linked to altered hemodynamics account for many of the clinical manifestations of cardiac lesions.[2,3] Hence, the net physiology observed is a result of the interaction of many elements: (1) cardiac and vascular anatomy; (2) hemodynamic variables related to cardiovascular function; (3) pulmonary function; (4) O_2 carrying capacity and O_2 release from the blood; and (5) myriad other factors, such as O_2 consumption (Vo_2), autonomic nervous system, and endocrine, lymphatic, and other organ system function.

The physiology of such lesions is complex for other reasons as well. With cardiac structural anomalies, *more than one type* of physiologic derangement will often be operative. For example, with a large patent ductus arteriosus (PDA) the left ventricle (LV) may have both an increased volume load and reduced myocardial perfusion, the latter resulting from decreased aortic diastolic pressure. In addition, the consequences of multiple anatomic cardiac abnormalities may be *additive, or,* conversely, *they may balance each other*. Finally, subtle differences in physiology may result in very different clinical phenotypes in anatomically identical patients. For example, the arterial O_2 saturation in neonates with D-transposition of the great arteries after balloon atrial septostomy is variable and unpredictable, related to subtle differences in physiology.[4]

Second, physiologic variables change. Some factors that affect cardiovascular physiology may vary over months (especially those related to anatomic changes, e.g., pressure-related remodeling of pulmonary blood vessels), whereas others may change significantly over seconds or minutes (e.g., alterations in pulmonary vascular tone). The physiology that attends a given cardiac defect may actually be a spectrum of physiologies.

Finally, the precise elucidation of a given patient's hemodynamics may be difficult or impossible, even with "simple" anatomic lesions. Measurement of relevant pressures, blood flows, and ventricular function is often not feasible, especially when invasive studies are not warranted. Although information derived from noninvasive evaluation is usually sufficient for design of therapy, situations exist in which important information is difficult or impossible to obtain. For example, in patients with reduced pulmonary blood flow (Qp) and an anatomic restriction to flow, it can be difficult to determine to what extent flow is limited by the anatomic restriction versus increased pulmonary vascular resistance (PVR).

This chapter focuses on congenital cardiovascular *anatomic* lesions; nonanatomic abnormalities (e.g., arrhythmia, intrinsic myocardial muscle dysfunction) are not discussed. It is also beyond the scope of this chapter to examine the biology of specific elements related to cardiovascular function (e.g., cardiac mechanics) or to discuss structural alterations caused by cardiac lesions (e.g., ventricular hypertrophy with pressure overload). Essential to understanding of congenital cardiac malformations is an appreciation of normal fetal and neonatal physiology,[5,6] the physiology and pharmacology of the pulmonary circulation,[7-9] the general principles of cardiac hemodynamics,[10] and the anatomy of congenital cardiac lesions.

HOW CONGENITAL HEART LESIONS ALTER THE CLINICAL PHENOTYPE OF THE NEONATE

A description of the hemodynamic characteristics of an anatomic cardiac lesion is only characters on a page unless the impact of the abnormal hemodynamics on the greater physiology of the organism is considered. Leaving aside that a congenital heart

lesion may occasion the need for neonatal surgery, and ignoring the important issue of the impact of abnormal hemodynamics on cardiovascular growth and remodeling, a congenital anatomic lesion may affect a neonate in three ways.

No Appreciable Effect

An anatomic lesion may be such a minor perturbation of normal structure (e.g., a small ventricular septal defect [VSD]) that it may *never* have any appreciable physiologic consequences. In other cases, a lesion destined to later have significant impact may have few manifestations in the neonate because of the physiologic characteristics of the newborn. The classic example is that of a large VSD, which may have little effect initially but causes congestive heart failure (CHF) at a few weeks of age. The clinical phenotype changes partly because the relatively high neonatal PVR falls over time, increasing left-to-right shunting and hence the LV volume pumped,[11] and partly because of other changes, such as the normal postnatal decline in hematocrit.[12] Lesions that cause higher than normal right ventricular (RV) pressure (as long as the pressure is no higher than roughly systemic), for example, pulmonary stenosis, usually have little impact on ventricular function in the newborn because the neonate's RV is well adapted to pumping at systemic pressure.[6] Ductal-dependent left-sided obstructive lesions (e.g., severe coarctation of the aorta) may also have only subtle clinical manifestations in the first few days of life if the ductus remains widely patent.

Reduction of Systemic Oxygen Transport

Congenital cardiac lesions may reduce systemic arterial blood O_2 tension *(hypoxemia)* or *systemic blood flow* (Qs) and thus decrease systemic O_2 transport (Systemic O_2 transport [SOT] = Arterial O_2 content × Qs).[13]

Reduction of Systemic Oxygen Transport Resulting From Hypoxemia

Hypoxemia may be the only manifestation of some lesions (e.g., tetralogy of Fallot), or it may be present with defects that also cause reduced Qs (e.g., severe Ebstein anomaly). It appears that the neonate can tolerate a low P_{O_2} better than the mature organism,[14] and moderate hypoxemia, as an isolated abnormality, generally has little obvious effect on the neonate. Increased O_2 extraction, redistribution of blood flow to organs of high O_2 need, and perhaps increased Qs help to maintain systemic V_{O_2} with hypoxemia.[15,16] For example, when conscious lambs less than 1 week old were subjected to acute alveolar hypoxia (fraction of inspired O_2 [F_{IO_2}] = 0.12; arterial P_{O_2} = 35 mm Hg) no fall in V_{O_2} or acidosis occurred.[16] More severe hypoxia (F_{IO_2} <0.10; arterial P_{O_2} approximately 25 mm Hg) caused V_{O_2} to fall, but it was not associated with much acidosis in conscious newborn lambs.[15,16] Multiple variables (e.g., hematocrit, half-saturation O_2 pressure [P_{50}] of hemoglobin, environmental temperature, Qs, V_{O_2}, and whether the organism is spontaneously ventilating) determine the physiologic impact of hypoxemia.[13-16]

The quantitative relationship between hypoxemia and organ dysfunction or damage in the *human* neonate is unknown. One study found an F_{IO_2} of 0.15 to cause V_{O_2} to fall significantly in human infants, albeit without obvious detrimental effect.[17] Perhaps the clearest evidence that neonates can tolerate substantial hypoxemia with modest or no long-term consequences comes from experience treating infants with D-transposition of the great arteries, a lesion that almost always causes considerable hypoxemia, especially before balloon septostomy is performed. One hundred twenty-nine neonates with this lesion were operated on in the first week of life at the Children's Hospital in Boston; the mean lowest preoperative arterial P_{O_2} was approximately 24 mm Hg. Even though these infants had undergone a period of substantial hypoxemia (before operation), the hospital survival rate for these patients was more than 98%.[18] Neurologic evaluation at 4 years of age revealed that only 4% of these patients had moderate or severe neurologic abnormalities; average intelligence quotient scores were lower than average, but not much (94 vs. 100).[19] Furthermore, it is likely that some or all of the observed decrement in neurologic function was related to aspects of the patient's treatment and clinical course distinct from the hypoxemia.

Reduction of Systemic Oxygen Transport Resulting From Reduction of Systemic Blood Flow

Congenital heart lesions may also decrease SOT by decreasing Qs. As is the case for hypoxemia, modest reductions of Qs may not affect tissue oxygenation. For example, Fahey and Lister[20] found that Qs could be reduced to approximately 42% of the resting value before V_{O_2} fell in the conscious 2-week-old lamb; increased fractional extraction of O_2 from the blood maintained O_2 delivery with decreased Qs. Most congenital cardiac lesions that reduce Qs do so by one or more of three mechanisms: (1) abnormally low systemic ventricular output, (2) abnormal arterial connection between the heart and peripheral tissues, and (3) recirculation of previously oxygenated blood to the lungs (see later). Few quantitative data regarding Qs in the neonate with heart disease are available, in part because of the difficulty in measuring this variable.

Neurohumoral Effects of Abnormal Hemodynamics

Symptoms can occur in infants with a heart lesion not attended by a reduction in SOT. For example, infants with CHF resulting from a large VSD generally have Qs within the normal range[11,21,22] (but see references 12 and 23). The symptoms of "CHF" are a consequence of *neurohumoral alterations* related to the physiologic abnormality, not altered SOT.[2,3,24] These alterations help to maintain adequate blood pressure and tissue perfusion in part by augmenting myocardial contractility (sympathetic nervous system activation)[25,26] and by increasing systemic vascular resistance (SVR; activation of the sympathetic nervous system, the renin-angiotensin-aldosterone system,[24,27,28] and release of vasopressin). Ventricular output is also increased (via the Frank-Starling principle) through fluid retention (and therefore increased ventricular filling) caused by activation of the renin-angiotensin-aldosterone system and other mechanisms.[2,3,24]

These factors help to maintain adequate SOT, but they also have *unfavorable consequences*. For example, vasoconstrictors increase SVR and therefore ventricular afterload; the clinical result is decreased peripheral perfusion. Increased catecholamines also contribute to failure to thrive by increasing V_{O_2}.[29] Fluid retention causes edema,[30] and it increases lung water and the work of breathing. It is often these secondary manifestations of abnormal cardiovascular function, caused by the attendant neurohumoral activation, rather than critically reduced SOT per se, that affect infants with congenital cardiac lesions.

PHYSIOLOGY OF SHUNTING AND SINGLE-VENTRICLE PHYSIOLOGY

Multiple formulas are useful for calculating flows and resistances relevant to understanding intracardiac shunting, but because space constraints prohibit delineation and derivation of most of them here the reader is referred to the literature.[10] However, a few concepts are especially important and are briefly covered.

Pulmonary Vascular Resistance

The *resistance to blood flow through the lungs* is an important determinant of the physiologic effects (ventricular work and systemic O_2 saturation) of many cardiac lesions with

shunting. A useful, albeit simplified[31] way to conceive of PVR is PVR = (PAP − LAP)/Qp, where PAP is mean pulmonary arterial pressure (millimeters of mercury), LAP is mean left atrial pressure (millimeters of mercury), and Qp is pulmonary blood flow (which, for pediatric patients, is usually indexed—liters per minute per square meter). SVR is calculated in an analogous way. Because PVR is primarily a reflection of resistance to flow through the pulmonary microcirculation, it is sometimes referred to as pulmonary *arteriolar* resistance. The calculated PVR can be low, but total resistance to flow through the lungs and into the heart can be high, if the patient has obstruction to systemic ventricular inflow (e.g., because of mitral stenosis) or poor systemic ventricular compliance. The concept of *total pulmonary resistance* (Total pulmonary resistance = Mean PAP/Qp) takes into account all resistance to flow from the central pulmonary arteries to the ventricle, although the term is misleading because some of the resistance to flow resides outside the lungs.

PVR is much higher than SVR in the fetus,[8,32] but PAP normally decreases to approximately one-half systemic arterial pressure in the first 24 hours of life (presuming the ductus does not remain widely patent), and it is at essentially mature levels by 1 to 2 weeks after birth.[33] The postnatal decline in PVR is considerably slower with cardiac lesions that maintain elevated PAP (e.g., a large VSD or PDA).

Ratio of Pulmonary to Systemic Blood Flow

The *Qp/Qs ratio* provides an estimate of the volume pumped by the ventricles and an estimate of the Qp (and hence of PVR if the PAP is known). It can be calculated by using blood oximetry values: $Qp/Qs = (Sao_2 - Mvo_2)/(Pvo_2 - Pao_2)$, where Sao_2 is the systemic arterial O_2 saturation, Mvo_2 is the mixed venous O_2 saturation, Pvo_2 is the pulmonary venous O_2 saturation, and Pao_2 is the pulmonary arterial O_2 saturation. The superior vena caval O_2 saturation is generally taken as representative of the Mvo_2 when there is left-to-right intracardiac shunting. This formula can be used to calculate Qp/Qs with any sort of lesion, presuming that the relevant O_2 saturations can be measured. This calculation can be simplified in certain situations; for example, if there is no right-to-left shunt, then $Pvo_2 = Sao_2$. Likewise, if there is no left-to-right shunt, then $Pao_2 = Mvo_2$. It cannot be used when multiple sources of pulmonary or systemic flow are present, with each source having a different O_2 saturation. For example, with right-to-left ductal shunting, O_2 saturations in the ascending aorta or transverse arch and descending aorta will differ, making the calculation of Qp/Qs virtually impossible.

Effective Versus Ineffective Blood Flow

Left-to-right shunting occurs when blood that has traversed the lungs is recirculated to them without having first crossed the systemic capillary bed. Such pulmonary flow is sometimes termed *ineffective,* because little additional O_2 is picked up with more than one passage through the lungs. (Pulmonary flow composed of systemic venous blood is *effective* pulmonary flow.) Ineffective Qp represents volume pumped by the heart to no useful end, at least as far as systemic O_2 transport is concerned (see later). In an analogous fashion, blood that has traversed the lungs before being pumped to the systemic circulation is considered *effective* Qs, whereas systemic venous blood that enters the systemic arterial circulation without passage through the lungs (right-to-left shunting) is *ineffective* Qs. The concepts of effective and ineffective blood flow are useful because they help in thinking about complex cardiac physiology, such as that observed with D-transposition of the great arteries (see later).

Left-to-Right Shunting at the Ventricular or Great Artery Level

Because the ventricle pumps only blood that enters it during diastole, left-to-right shunting at the ventricular or great artery level imposes a volume load on the *systemic* ventricle (LV in an otherwise normal heart). (Actually, with a large VSD, because some pulmonary venous blood enters the RV during diastole, the RV volume pumped is also somewhat increased.[34,35])

If the connection between the systemic and pulmonary circulations (e.g., VSD or PDA) is large enough so that the systolic pressure in the two circuits is equal, the communication is said to be *unrestrictive*. With an unrestrictive defect, the *Qp/Qs is primarily determined by the ratio of total pulmonary resistance to SVR*. (With a small defect, the pressure difference between the two ventricles and the size of the communication are usually the primary determinants of the shunt magnitude.) However, not only PVR but also *all* resistances to flow affect Qp/Qs; that is, relevant variables include not only the cross-sectional area of the pulmonary microcirculation but also the size of the central pulmonary arteries and large pulmonary veins, any impediment to ventricular filling (such as obstruction to ventricular inflow), and the compliance of the ventricle. Because the systemic and pulmonary microvascular resistance can change substantially with physiologic, pharmacologic, and other perturbations,[8,36] the Qp/Qs can vary considerably.

As a relevant aside: in an anatomically normal heart, PAP is a function of Qp and total pulmonary resistance. However, the *systolic PAP will always be essentially the same as the ventricle or artery to which it is connected* (assuming that the connection is unobstructed), regardless of the volume of flow through the lungs or the resistance to flow. Therefore, with an unrestrictive VSD or PDA, systolic PAP will be essentially the same as aortic pressure regardless of the magnitude of flow or PVR. In neonates with unrestrictive ventricular or great vessel communications large shunts generally develop as their PVR falls after birth, but the systolic PA pressure remains elevated. High PVR with unrestrictive communications is reflected by a low Qp/Qs, not the pulmonary arterial systolic pressure per se. (Pulmonary arterial *diastolic* pressure is, however, a reflection of PVR with an unrestrictive VSD.) Thus pulmonary arterial systolic hypertension and increased PVR are related but distinct concepts (see Figure 69-1).

Other factors besides PVR and SVR also influence cardiovascular physiology with ventricular or great artery–level shunting lesions. For example, Jarmakani and colleagues[37] demonstrated that infants younger than 2 years old with a PDA had greater LV end-diastolic pressure and end-diastolic wall stress than patients with a VSD and comparable magnitude of shunt. The reason for this is unclear, but it may be related to differences in LV stroke work with the two lesions.[37] *Diastolic runoff* into the pulmonary arteries with connections between the aorta and pulmonary artery may decrease aortic diastolic pressure and hence may reduce coronary perfusion.[38] *Streaming* of blood can affect whether pulmonary venous blood ends up in the aorta or in the pulmonary artery. For example, with double-outlet RV, the location of the VSD (subpulmonary vs. subaortic) will influence the volume of *effective* Qp (with a subpulmonary VSD, pulmonary venous blood tends to be recirculated to the lungs rather than find its way into the aorta).[39] Left-to-right shunting from the *LV to the right atrium* can occur, mostly with atrioventricular canal defects. The magnitude of an LV-to-RA shunt is primarily determined by the effective size of the LV–right atrial communication; PVR and right atrial pressure have no appreciable role.

Left-to-Right Shunting at the Atrial Level

Left-to-right shunts across an atrial septal opening increase the volume of blood pumped by the pulmonary ventricle (the RV in an otherwise normal heart). With a small defect, left atrial mean

pressure is usually substantially different from that of the right atrium, and shunting is primarily the result of this pressure difference. Given a large defect (in which the mean atrial pressures are essentially the same), the magnitude of shunting is generally ascribed to the relative compliances of the left atrium–pulmonary veins–LV and the right atrium–vena cava–RV: blood tends to flow into the venous chamber or ventricle that most readily accepts it (see Figure 69-1).[40] This finding explains the presence of left-to-right shunting in older patients, because the RV is thinner than the LV and is more compliant. Because substantial atrial shunting can occur in the neonate,[41,42] whose RV and LV presumably have similar compliances, Rudolph[43] proposed that such shunting may be a function of *differential ejection* of blood from the two ventricles, given that RV afterload is less than that of the LV. Left-to-right atrial shunting also occurs *with partial anomalous pulmonary venous connection* to the right side of the circulation. Assuming that there is no defect in the atrial septum, the shunt magnitude is determined by the fraction of Qp that goes to the lobes of the lungs drained by the anomalously connected veins, which is a function of the total resistance to blood flow through those lobes relative to lobes with normal venous connection to the heart. It is unusual for atrial level shunts in *children*—even if the Qp is very large—to be associated with significant pulmonary hypertension. However, in the neonate, the capacity for flow-related dilation or recruitment in the pulmonary vascular bed is apparently limited, and large *atrial* level shunts (e.g., unobstructed total anomalous pulmonary venous connection) are often accompanied by considerably increased PAP.[44-47]

Right-to-Left Shunting

Right-to-left shunting occurs when systemic venous blood enters the systemic arterial circulation without having passed through the pulmonary microcirculation. Isolated right-to-left shunting is unusual (tetralogy of Fallot being the obvious exception), and in most congenital heart defects with right-to-left shunting (especially if the ductus is patent) a left-to-right shunt is also present.

Determinants of Systemic Arterial Oxygen Saturation With Right-to-Left Shunting

Whenever there is right-to-left shunting, *systemic arterial O_2 saturation* is primarily a function of four variables:

1. The *fraction of systemic arterial blood composed of systemic venous blood.* No matter how complex the pattern of intracardiac shunting is, with right-to-left shunting a certain fraction of the aortic blood will not have crossed the lungs, and this results in a reduced systemic O_2 saturation. The greater the fraction of systemic arterial blood that did not pass through the lungs, the lower the arterial O_2 saturation.
2. *Mixed venous O_2 saturation*. The O_2 saturation of venous blood that reaches the aorta will obviously affect the O_2 saturation of the aortic blood. Because the mixed venous O_2 saturation reflects what O_2 is left in the blood after it has crossed the systemic capillary bed, this value is influenced by the following:
   a. Hematocrit. The greater the O_2 carrying capacity of the blood, the greater the SOT will be, and, given a fixed quantity of O_2 unloaded to the tissue, the greater the venous O_2 saturation.
   b. Qs. Given a fixed amount of O_2 unloaded into the tissues, the greater the quantity of O_2 transported, the greater the venous O_2 saturation will be.
   c. V_{O_2}. The greater the quantity of O_2 consumed, given a fixed amount transported, the lower the venous O_2 saturation will be.
3. *Pulmonary venous O_2 saturation*. For obvious reasons, the lower the pulmonary venous O_2 saturation, the lower the systemic arterial O_2 saturation will be.
4. *The O_2 dissociation characteristics of hemoglobin*. With a leftward shift of the O_2 dissociation curve, *less* O_2 is unloaded from hemoglobin at any given P_{O_2}. Therefore, for any given end-capillary P_{O_2}, the mixed venous saturation will be a function of the P_{50} of the hemoglobin. With a right-to-left shunt, a leftward shift of the curve will increase the mixed venous O_2 saturation and therefore will *increase* the systemic arterial saturation.

Systemic Oxygen Transport With Right-to-Left Shunting

SOT and O_2 delivery to the tissues are not necessarily proportional to arterial O_2 saturation with *right-to-left* shunting lesions. For example, a leftward shift in the hemoglobin O_2 dissociation curve will increase the arterial O_2 saturation with right-to-left shunting lesions; however, this increase in saturation does not imply an increase in O_2 delivery to the tissue, because less O_2 is released at any given tissue P_{O_2}. In addition, with admixture lesions, systemic O_2 transport actually *declines* as arterial O_2 saturation increases beyond a certain point (see later). *Maximum* V_{O_2} = maximum O_2 uptake in the lungs, which is a function of effective Qp, the gas exchange properties of the lung, and the O_2 capacity of the blood. Hence, if effective Qp is severely reduced, SOT will be compromised, regardless of Qs or any other factors.

Isolated Right-to-Left Shunting

Isolated right-to-left shunting occurs at the *ventricular level* when a VSD is present and resistance to Qp (resulting from obstruction at the level of the RV outflow tract or points beyond) is greater than resistance to flow into the systemic vascular bed, thus causing a shunt of desaturated (RV) blood into the aorta. Right-to-left *ductal* shunting occurs when total pulmonary resistance is greater than SVR, which is most often the result of increased PVR but can also be caused by pulmonary venous or left atrial hypertension. There is also right-to-left ductal shunting when the descending aorta is mostly or entirely supplied by the RV, such as severe coarctation of the aorta. In such cases, however, there is almost always a component of left-to-right shunting—at the atrial or ventricular level—as well. The magnitude of right-to-left shunting with ventricular or arterial communications is determined by the ratio of resistance to flow into and through the pulmonary circuit relative to the systemic circuit. Because SVR and PVR (and sometimes even the degree of RV outflow tract obstruction, as in tetralogy of Fallot) may fluctuate with time, the magnitude of right-to-left shunting is variable. Right-to-left shunting across an atrial defect most commonly results from a reduction in RV compliance, usually because of RV hypertrophy or hypertension (Figure 69-1).

Bidirectional Shunting

Both left-to-right shunting and right-to-left shunting are present in various cardiac lesions. For example, a patient with severe aortic stenosis (and severely reduced LV ejection) with an open ductus arteriosus will often have a left-to-right atrial shunt, as well as a right-to-left shunt across the ductus to the aorta. Right-to-left atrial shunting can also occur simultaneously with a left-to-right ventricular shunt (e.g., with an atrioventricular septal defect).

With total anomalous connection of the pulmonary veins, all pulmonary veins connect to the systemic veins, coronary sinus, or right atrium; thus a fraction of both the pulmonary and systemic venous return crosses the atrial septum to supply the LV. The variables that influence Qp (the mixture of systemic and pulmonary venous blood that finds its way into the RV) and Qs (the mixture of systemic and pulmonary venous blood entering the LV) likely include the size of the atrial opening,[47] the relative ventricular compliances, and possibly any preferential streaming of venous

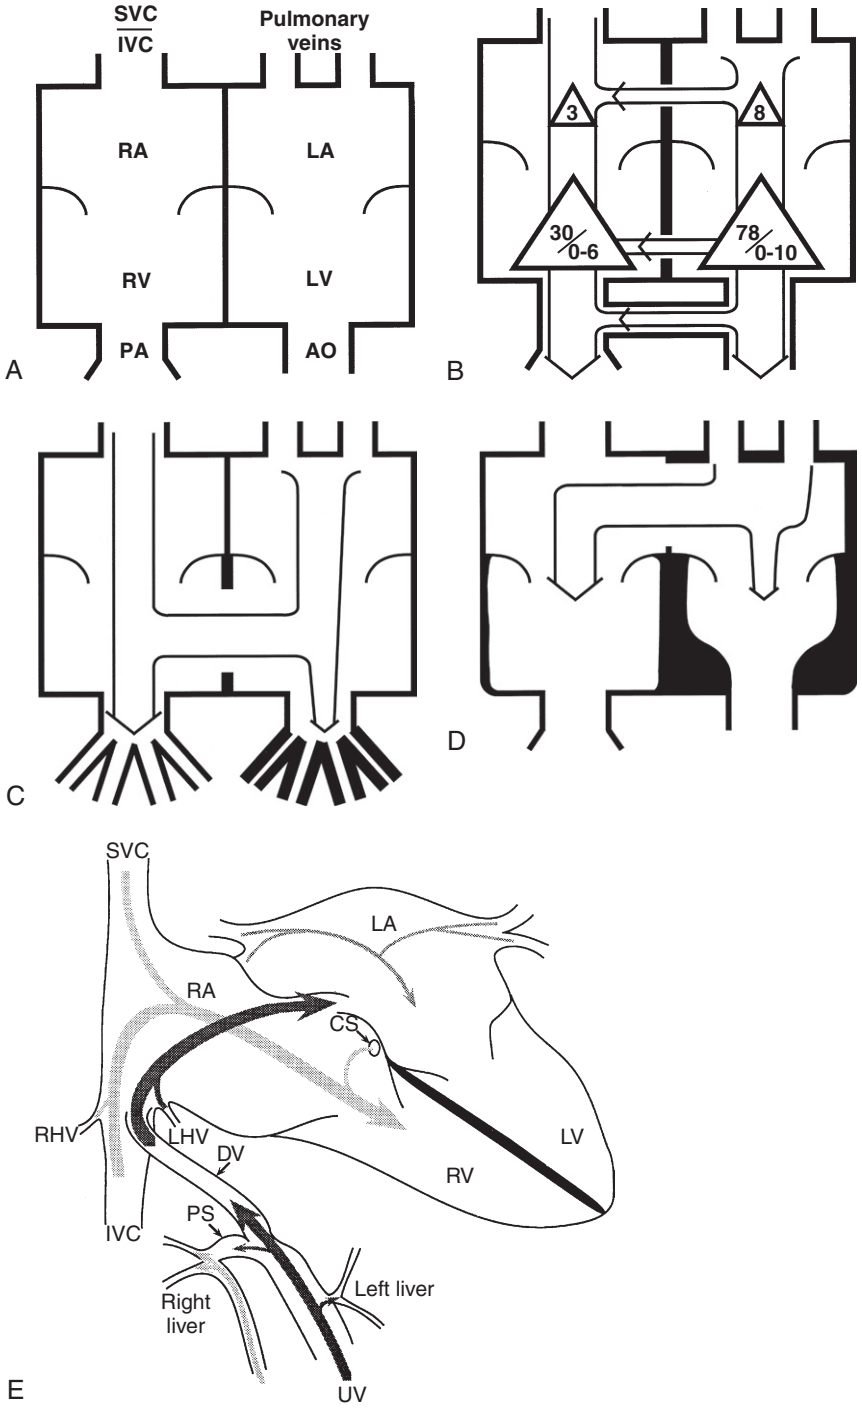

Figure 69-1 Factors that influence where blood goes with structural heart lesions. A, General scheme of box diagrams. **B,** Blood moves from high pressure to low. With relatively small communications, shunting at the atrial, ventricular, and great vessel levels can result from a pressure gradient between communicating structures. **C,** When two vascular beds differing in resistance to flow are connected to a source of flow, more blood finds its way into the lower- than into the higher-resistance circuit. With an unrestrictive VSD and low PVR, systolic pressures are essentially the same in both the aorta and the pulmonary artery, yet there is more flow to the pulmonary artery. **D,** When two chambers differing in resistance to filling (compliance) are connected to a source of flow, more blood finds its way into the chamber with the greater compliance. **E,** Streaming can influence the chamber or vessel to which the blood flows. As depicted here, in the fetus umbilical venous blood preferentially crosses the foramen ovale, and therefore the most highly oxygenated blood tends to go to the organs of greatest need. Streaming can also take place at the ventricular and great vessel level. *AO,* Aorta; *CS,* coronary sinus; *DV,* ductus venosus; *IVC,* inferior vena cava; *LA,* left atrium; *LHV,* left hepatic vein; *LV,* left ventricle; *PA,* pulmonary artery; *PS,* portal sinus; *RA,* right atrium; *RHV,* right hepatic vein; *RV,* right ventricle; *SVC,* superior vena cava; *UV,* umbilical vein. Numbers in *triangles* indicate pressure. *(***E,** *From Teitel DF, Cassidy SC:* Moss and Adams' Heart Disease in Infants, Children, and Adolescents*, vol 1, ed 5, Baltimore, 1995, Williams & Wilkins, 1995, p 49.)*

blood. Whether streaming of venous blood actually affects Qp per se is unclear, but it can affect the arterial O_2 saturation[44,47] because pulmonary venous return from the inferior vena cava (with infradiaphragmatic total anomalous pulmonary venous connection) can preferentially stream across the foramen ovale into the left atrium. With a total anomalous pulmonary venous connection (assuming no other communication between the pulmonary and systemic arterial circuits), PVR only affects the pattern of intracardiac shunting insofar as it influences RV pressure and therefore RV compliance and systolic function. (Another physiologic consequence of obstructed pulmonary venous connection is pulmonary edema, which interferes with gas exchange and reduces lung compliance.) The shunting physiology with cerebral arteriovenous malformations is similar in many ways[46] (see Figure 69-2).

Admixture Lesions

Cardiac lesions that cause complete mixing of systemic and pulmonary venous blood are sometimes termed *admixture lesions*. All malformations with a single functional ventricle (e.g., hypoplastic left heart syndrome, tricuspid atresia) have this physiology, as well as some two-ventricle defects (e.g., tetralogy of Fallot with pulmonary atresia). Actually, there can be preferential streaming of pulmonary or systemic venous blood into one or the other great artery in some lesions with substantial mixing of pulmonary and systemic venous blood (e.g., truncus arteriosus), but, unless the quantity of "streamed" blood is significant, the physiology is best understood as admixture.

Determinants of Systemic Arterial Oxygen Saturation With Admixture Lesions

With admixture lesions, systemic arterial O_2 saturation is a function of all the variables outlined earlier. The fraction of aortic blood composed of pulmonary venous blood is determined by the *Qp/Qs:* because all the pulmonary venous blood mixes with all the systemic venous blood, the ratio of "blue" and "pink" blood will influence aortic O_2 saturation. For lesions in which the systemic and pulmonary arterial circuits are in unrestricted communication, the Qp/Qs is primarily determined by the ratio of total pulmonary resistance to SVR. When mixing of venous blood occurs at the atrial level and systemic and pulmonary arterial circulations are separate (e.g., total anomalous pulmonary venous connection), Qp/Qs may be largely determined by other factors (see earlier) (see Figure 69-2).

Systemic Arterial Oxygen Saturation Versus Systemic Oxygen Transport in Admixture Lesions

The variables that determine systemic arterial O_2 *transport* in admixture lesions (usually more relevant to tissue oxygenation than arterial O_2 saturation per se) are more complex. At any given ventricular output, every milliliter of blood pumped to the lungs is one less milliliter that goes to the systemic circulation. Therefore, as the Qp/Qs (and systemic arterial O_2 saturation) *increases*, Qs *falls*. Systemic O_2 transport is therefore a function of total ventricular output, hematocrit, pulmonary venous O_2 saturation, Vo_2, and Qp/Qs; the relationship between Qp/Qs and systemic O_2 transport is sigmoidal[48–50] (Figure 69-3).

Transposition Physiology

With D-transposition of the great arteries, the aorta arises from the RV and the pulmonary artery from the LV. Because systemic and pulmonary venous blood enters the right and left atria, respectively, the systemic and pulmonary circulations function in parallel rather than in series. Systemic venous blood, largely depleted of O_2, entering the RV is pumped out again to the body, whereas oxygenated pulmonary venous blood is ejected into the lungs.[51] Without any communication between the two circuits, all blood flow would be ineffective, and life would cease shortly after the placenta was disconnected from the systemic circulation. As it happens, communications between the systemic and pulmonary circuits usually exist at one or more levels (atrial septum, ventricular septum, ductus arteriosus) and, if of sufficient size, usually allow for enough *mixing* of systemic and pulmonary venous blood for adequate systemic arterial O_2 saturation (Figure 69-4). (Note, however, that rarely is a communication at the ductal or ventricular level alone sufficient—atrial level mixing is almost always required for adequate arterial O_2 saturation.)

The essence of mixing is (in a steady-state system) that for every milliliter of systemic venous blood that crosses from the right side of the heart, or the aorta, into the left side of the heart or pulmonary artery (and then into the lungs, constituting effective Qp), 1 mL of pulmonary venous blood must cross from the left side of the heart into the right side of the heart and into the aorta (becoming effective Qs). Were more blood to flow in one direction than the other, one of the two circulations would become depleted of blood. That is not to say that the volumes of blood pumped by the LV and RV need be equal, just that the average amount of blood crossing from left to right must equal the amount moving from right to left.[51] Indeed, whereas in the neonate with this lesion the LV volume pumped is similar to that of a normal neonate, by approximately 6 months of age it is considerably greater than normal.[52,53]

Echocardiographic studies have shown that infants with D-transposition and an atrial septal opening have shunting from the left atrium to the right atrium during systole and right-to-left blood flow during diastole.[54] The factors determining mixing have not been precisely determined, although it is clear that Qp is strongly positively related to the aortic O_2 saturation.[55] Thus the presence of a PDA increases mixing by increasing Qp.[56] Conversely, increased PVR in neonates with D-transposition can markedly reduce the aortic saturation.[57] The number of sites of mixing also plays a role, with arterial O_2 saturation increasing with the number of mixing sites.[55]

Whereas cyanosis is usually the key physiologic feature of the newborn with this lesion (although some neonates with D-transposition and a large VSD may be pink), CHF can develop in the neonate with D-transposition and a large PDA or VSD.[56,58] With a large VSD, the pattern of blood flow has not been fully elucidated, but there appears to be increased volume pumped by both ventricles,[59] and the Qp/Qs can be quite large.

Single-Ventricle Physiology

Multiple factors affect the physiology of neonates with complete mixing of systemic and pulmonary venous blood and communication at the level of the ventricle or great arteries (sometimes referred to as *single-ventricle physiology*). This physiology actually pertains to some lesions with two ventricles (e.g., truncus arteriosus or tetralogy of Fallot with pulmonary atresia), as well as with as the single ventricle. (With single-ventricle physiology, it is unclear whether the number of ventricles materially affects the hemodynamics, at least in the neonate. It may seem that two separate pumping chambers would be better than one at providing SOT in this context, but I am aware of no relevant data in this regard.)

1. With single-ventricle physiology (and therefore some fraction of Qp is ineffective), *volume work is increased for the ventricle* and can be considerable (see later and Figure 69-2).
2. In patients with a left-sided obstructive lesion and an unrestrictive PDA (e.g., hypoplastic left heart syndrome), the Qp tends to be very large, especially as PVR falls in the perinatal period, and hence for *Qs tends to be reduced*, as discussed earlier. This is less the case for right-sided obstructive ductal-dependent lesions (e.g., pulmonary atresia with intact ventricular septum) because the ductus is usually restrictive.

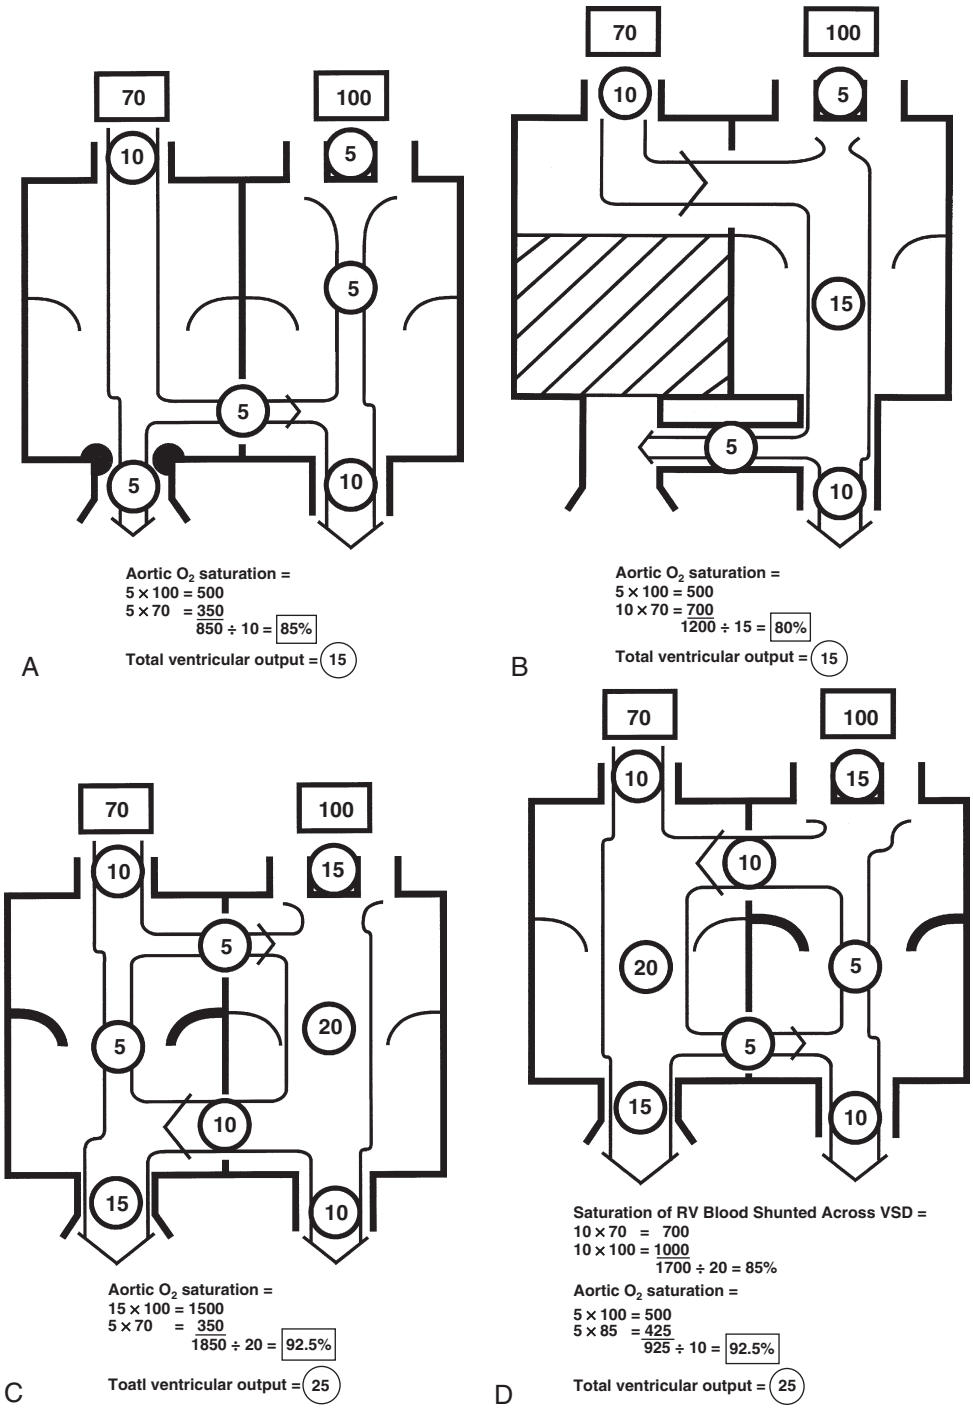

Figure 69-2 Patterns of intracardiac blood flow and ventricular output with right-to-left shunting. This illustration aims to provide a conceptual understanding of the relationship among intracardiac shunting, ventricular output, and oxygen saturation, but it is a simplified view relative to cardiac physiology; for example, given a fixed oxygen consumption, it would be unrealistic to expect systemic venous saturation to remain constant as SOT varies. Numbers in *boxes* indicate blood O_2 saturation; numbers in *circles* indicate the relative amount of blood flow. **A,** With an isolated right-to-left shunt (e.g., tetralogy of Fallot), all pulmonary blood flow is effective, and combined ventricular output is normal. **B,** With admixture physiology, there is ineffective pulmonary blood flow, and therefore systemic arterial saturation is less, for a given amount of ventricular output, than for a lesion with isolated right-to-left shunting. **C** and **D,** With bidirectional shunting, equal volumes of right-to-left shunting at either the atrial or ventricular level will result in equal systemic arterial oxygen saturation and equal ventricular output. The relationship between systemic arterial oxygen saturation and ventricular output depends on the volume of ineffective pulmonary blood flow (left-to-right shunt). *RV,* Right ventricular; *VSD,* ventricular septal defect.

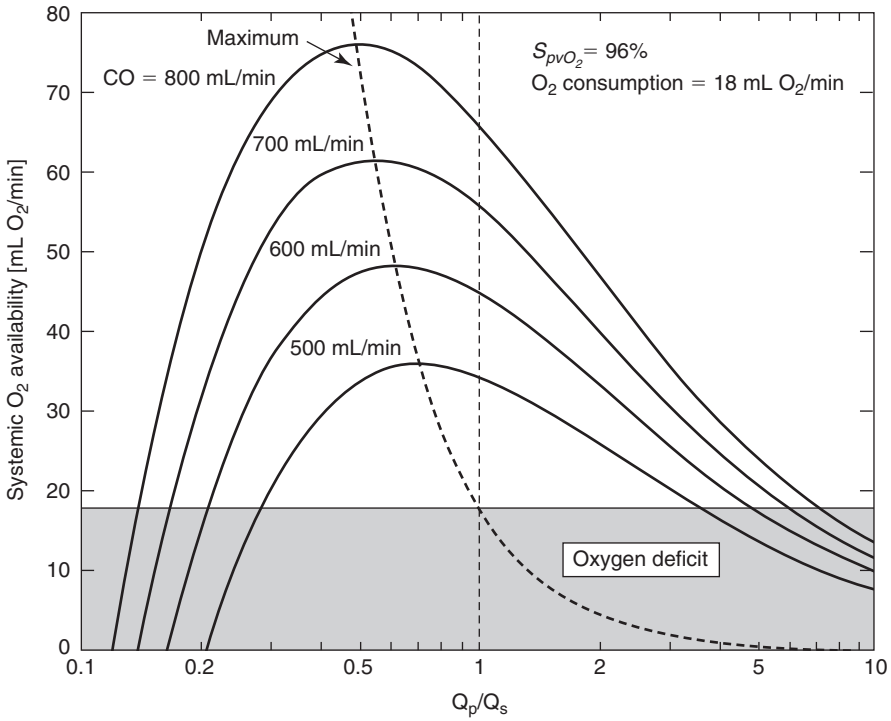

Figure 69-3 The relationship between systemic oxygen availability (transport) and the ratio of pulmonary to systemic blood flow (Qp/Qs) with cardiac admixture lesions. Barnea and colleagues[48] used a mathematical model to determine SOT for a patient with a single ventricle, with the aorta and pulmonary artery in communication, assuming the oxygen capacity of the blood to be 22 mL oxygen per deciliter, pulmonary venous oxygen saturation ($Spvo_2$) to be 96%, and oxygen consumption to be 18 mL oxygen per minute (the normal mean value for a 3-kg neonate). SOT is a function of both cardiac output and the ratio of pulmonary to systemic blood flow. Maximum SOT occurs with a Qp/Qs of <1, a value lower than that typical of most patients with hypoplastic left heart syndrome[86] and probably most patients with a "single-ventricle" lesion. *(From Barnea O, Austin EH, Richman B, et al: Balancing the circulation: theoretic optimization of pulmonary/systemic flow ratio in hypoplastic left heart syndrome,* J Am Coll Cardiol *24:1376, 1994.)*

3. With single-ventricle physiology, *arterial O_2 saturation is less* than normal, also contributing to a tendency to reduced SOT.
4. Lesions with aortic diastolic runoff into the pulmonary circuit can have *decreased diastolic perfusion pressure* and therefore decreased myocardial perfusion.[38] Diastolic retrograde flow away from the mesenteric arteries, perhaps in combination with reduced SOT for the reasons noted earlier, also appears to increase the risk for necrotizing enterocolitis.[60]

The concurrence of these factors, especially in infants with high Qp, often leads to CHF and sometimes even substantially reduced SOT. For example, many babies with truncus arteriosus have severe CHF and even die in the neonatal period,[61] presumably because of the combination of large ventricular volume load, cyanosis, and reduced myocardial perfusion.

HOW CONGENITAL HEART LESIONS AFFECT CARDIOVASCULAR PHYSIOLOGY IN THE NEONATE: GENERAL MECHANISMS

Because one's ultimate aim is to understand not general principles of physiology but rather individual patients, it is necessary to link these general principles with specific cardiac lesions. However, given the large number of distinct malformations, it is not feasible to describe the physiologic characteristics of each one. Even describing various classes of lesions (e.g., defects with left-to-right shunting) is unsatisfactory, because lesions within a class vary significantly in physiologic detail. The approach taken here is to describe several *characteristics of the efficient cardiovascular system,* to indicate how a heart with a given malformation *lacks* one or more of these characteristics, and the resulting physiologic consequences.

Adequate Capacity to Pump Blood to the Lungs and Body

The capacity to supply blood requires one or two pumping chambers of adequate size, with acceptable rhythm and systolic and diastolic function, in communication with the greater and lesser circulations. Only one ventricle is required for fetal development and postnatal survival, and inadequate pumping capacity resulting from a lack of ventricular capacity is rare in neonates with congenital heart disease. Far more commonly, an adequate pump is not connected to the systemic (e.g., the RV in hypoplastic left heart syndrome with ductal closure) or pulmonary circulation (e.g., the LV in pulmonary atresia with intact ventricular septum with ductal closure). Whereas modest degrees of ventricular dysfunction are not uncommon in neonates with cardiac lesions (especially those who have severe hypoxia or ischemia), frankly inadequate systolic or diastolic ventricular function resulting from intrinsic abnormality of the myocardium is rare. The infant with a coronary artery anomaly, such as anomalous origin of the left coronary artery[62] or pulmonary atresia with intact ventricular septum and coronary artery stenoses,[63] can have ventricular dysfunction resulting from myocardial ischemia, but these patients are very uncommon.

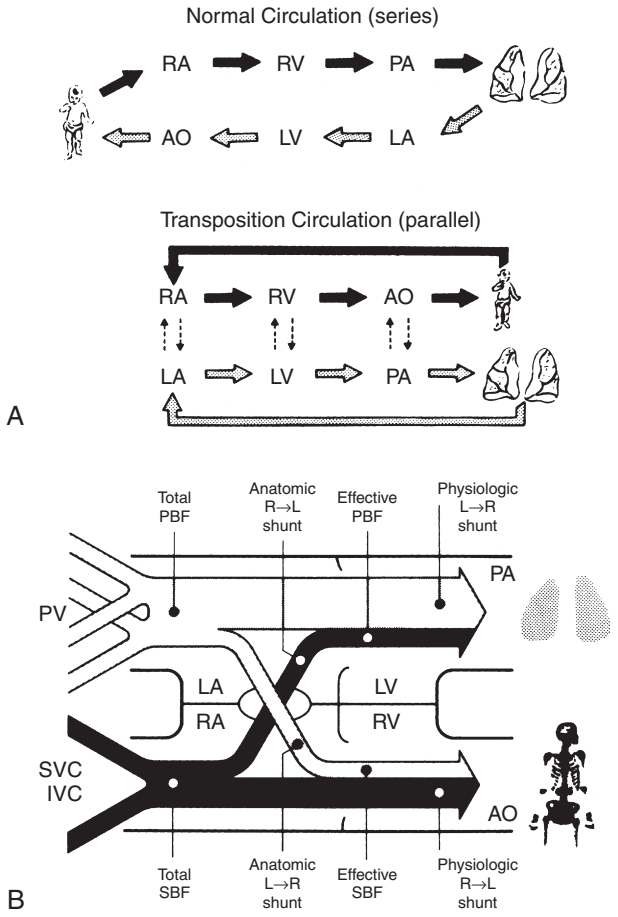

Figure 69-4 A and **B,** Intracardiac blood flow with D-transposition of the great arteries. Most pulmonary and systemic blood flow is ineffective. Systemic oxygen delivery depends on the passage of blood from the right side of the heart into the lungs (effective pulmonary blood flow) and the passage of an equal amount from the left side of the heart to the aorta (effective systemic blood flow). *AO,* Aorta; *IVC,* inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *PV,* pulmonary vein; *RA,* right atrium; *RV,* right ventricle; *SBF,* systemic blood flow; *SVC,* superior vena cava. *(From Paul MH, Wernovsky G: Transposition of the great arteries.* Moss and Adams' Heart Disease in Infants, Children, and Adolescents, *vol 2, ed 5, Baltimore, 1995, Williams & Wilkins, 1995, pp 1166-1170.)*

Appropriate Afterload

The term *afterload* is used here to denote the resistance against which the heart pumps. Although convenient, this is, for a variety of reasons, a crude way to think of afterload (e.g., resistance to ventricular ejection imposed by small blood vessels has a different physiologic effect than that caused by semilunar valve stenosis).

Effect of Increased Afterload on Cardiovascular Physiology

The amount of blood ejected by the ventricle is inversely related to the magnitude of afterload against which it ejects.[64,65] Although the normal heart can to some extent maintain its output in the presence of *acutely* increased afterload,[65,66] this reserve is limited, especially for a dysfunctional ventricle. Because the neonatal heart has less contractile reserve than the more mature one,[67] this is especially pertinent. Furthermore, because the major determinant of myocardial V_{O_2} is pressure work,[68,69] the ventricle's ability to respond to an increase in afterload is crucially dependent on coronary perfusion pressure[70]; when increased afterload occurs with normal or decreased aortic pressure (e.g., severe valvar aortic stenosis), myocardial O_2 supply is especially likely to be inadequate.

Chronically increased afterload causes myocardial hypertrophy, which is usually adequate to maintain ventricular systolic function. Whereas hypertrophy is an adaptive response insofar as it normalizes wall stress,[71] *ventricular compliance* is reduced by hypertrophy, manifested in *increased atrial pressure*. Left atrial hypertension can cause pulmonary edema, or left-to-right shunting if there is an atrial opening, and "reflex" pulmonary vasoconstriction,[72,73] thereby increasing PAP beyond that accounted for by the elevation in LAP alone. Pressure overload of the RV can also cause increased right atrial pressure and systemic venous congestion. However, because the foramen ovale is usually nonrestrictive to right-to-left flow in the neonate, a reduction in RV filling is usually reflected by a right-to-left atrial shunt, rather than by systemic venous hypertension. Finally, *subendocardial ischemia* from severe chronic pressure overload can lead to endocardial fibrosis and to papillary muscle dysfunction or infarction and hence mitral regurgitation.[74]

Congenital Cardiac Lesions Causing Increased Afterload

The effects of increased afterload are clearly manifest in neonates with severe valvar *aortic stenosis*.[74] LV output is reduced,[75] sometimes so much so that adequate systemic perfusion requires maintaining patency of the ductus to allow the RV to contribute to Qs. Left atrial hypertension often causes a considerable left-to-right atrial shunt through the foramen ovale, pulmonary edema, and pulmonary arterial hypertension. Whereas relief of the increased afterload by balloon dilation of the aortic valve results in an immediate decrease in (but not normalization of) LAP,[76,77] LV systolic function remains abnormal for some time—at least days and probably weeks—after dilation.[78] *Severe coarctation of the aorta* in the neonate also causes reduction in LV systolic and diastolic function and output, as well as left-to-right atrial shunting. PAP is markedly increased, largely resulting from left atrial hypertension.[79]

Because the fetal RV operated at (and is therefore well adapted to) systemic pressure,[6] *increased RV pressure* does not appear to have a measurable impact on RV systolic performance in a neonate, as long as it is approximately at or lower than systemic blood pressure. However, neonates with *severe valvar pulmonary stenosis* with suprasystemic RV pressure will have reduced RV output and an atrial right-to-left shunt.[80] Right-to-left atrial shunting, often enough to cause substantial arterial desaturation, may persist for weeks after reduction of RV afterload by balloon dilation, a reflection of the relatively slow pace of normalization of RV compliance.[81]

Effect of Decreased Afterload on Cardiovascular Physiology

Because pressure is a function of vascular resistance and flow, inappropriately *low* SVR will cause hypotension unless Qs is increased. Lower-than-normal SVR (resulting from dilation of systemic arterioles) occurs in some settings (e.g., with sepsis), but it does not seem to be an inherent feature of congenital cardiac malformations. In lesions in which the systemic circulation is in unrestricted communication with the venous (e.g., arteriovenous malformation)[46] or pulmonary (e.g., large VSD or PDA) circulation, outflow resistance to systemic ventricular ejection is reduced (at least if PVR is lower than SVR, in the case of the latter). This does not generally have a clinically significant impact on blood pressure because total blood flow into the systemic and pulmonary circuits is usually sufficient to maintain normal blood pressure. However, the relatively low blood pressure associated with a large PDA in the premature infant[82,83] suggests that in these cases total (systemic plus pulmonary) flow is insufficient to compensate for the low total vascular resistance, resulting from inclusion of the pulmonary circuit (see later).

All the Blood Pumped by the Heart Moves Toward the Systemic Capillaries

In other words, the valves do not leak, and there is no left-to-right shunt. Valvar regurgitation and left-to-right shunting result in an inefficient circulation because the heart pumps volume that does not participate in gas exchange or SOT. Lumping together these multiple causes of volume overload is in one sense a crude approach, because these lesions perturb cardiac mechanics and biology differently. For example, acute mitral regurgitation increases LV systolic and diastolic wall tension much less than aortic regurgitation does.[84] Furthermore, as noted previously, left-to-right shunting at the ventricular level affects the LV differently than ductal level shunting does. The virtue of considering these defects together is that their physiologic impact is in many ways very similar (increased ventricular volume load, ventricular dilation, CHF).

Effect of Valve Regurgitation on Cardiovascular Physiology

Regurgitation of either the semilunar or the atrioventricular valves increases the volume pumped by the relevant ventricle. The magnitude of semilunar valve regurgitation is influenced by the degree of valve deformity, the heart rate, and the vascular resistance of the relevant circulation. Mild regurgitation has minimal effects on patient physiology, but more severe volume overload may be attended by symptoms of CHF, increased atrial pressure, and even reduced Qs. *Aortic valve regurgitation,* by reducing coronary perfusion pressure, may also compromise myocardial perfusion.[38] *Pulmonary valve* regurgitation may be more pernicious in the neonate relative to the older patient because PVR is likely to be higher in the newborn.

Effect of Left-to-Right Shunting on Cardiovascular Physiology

As with valve regurgitation, left-to-right shunts of sufficient size cause symptoms of CHF. Profound reduction in Qs, as may be seen with severe aortic stenosis, is unusual with left-to-right shunting lesions. More modest compromise in Qs may occur with a large left-to-right shunt, although there are few quantitative data regarding neonates.

Other physiologic perturbations, although not a direct consequence of the shunting per se, may attend lesions that cause left-to-right shunting: (1) with a large communication between the aorta and pulmonary artery, diastolic pressure and hence myocardial perfusion may be reduced[38]; and (2) shunting lesions attended by increased PAP are associated with decreased lung compliance.[85]

How Much Volume Reserve Does the Neonatal Heart Have?

The neonatal ventricle is capable of pumping considerably more blood than normal under certain circumstances. For example, Tabbutt and co-workers[86] measured the Qp/Qs in 10 anesthetized and hemodynamically stable neonates with hypoplastic left heart syndrome; they found that the mean Qp/Qs was approximately 3.4:1. Because neither actual Qp nor actual Qs was measured, the output from the (single) RV could not be determined. However, if one assumes that Qs was only 50% of usual (likely an underestimate), the single ventricle (RV) in these patients pumped 2.2 times as much blood as normal.

Data from animals are conflicting regarding how much extra volume can be pumped without significantly compromising Qs. In one study of mechanically ventilated preterm newborn lambs, relevant blood flows were measured with the ductus arteriosus open and closed; an approximately 60% increase in LV output resulting from opening the ductus was associated with a significant fall in Qs.[87] A similar study, however, showed no significant fall in Qs even with a 100% increase in LV output with opening of the ductus arteriosus.[88] Both studies were conducted over an hour or two and may not be reflective of long-term physiology. The newborn *human* with a PDA can have an LV output greater than 150% of normal,[89-92] but information regarding Qs in these neonates is very limited. Data from a few neonates with a PDA suggest that LV output of more than three times normal may be generated with Qs greater than 3 L/m^2/minute,[89,91] although accurate measurement of Qp in this setting is very difficult. Infants (generally >1 month old) with a VSD may have an LV output of three to four times normal, assuming that normal cardiac output = 4.2 ± 1.2 L/m^2/minute,[93] while still maintaining Qs greater than 3 L/m^2/minute.[11,21,22]

Congenital Cardiac Lesions With Valve Regurgitation

Atrioventricular valve regurgitation is uncommon in the neonate, although it can occur as an isolated lesion, with cardiac malformations,[74,94,95] or in association with papillary muscle dysfunction resulting from neonatal asphyxia.[96] Aortic regurgitation is exceedingly unusual (absent surgical intervention on the aortic valve). With absent pulmonary valve syndrome (tetralogy of Fallot with absent pulmonary valve), there is severe pulmonary regurgitation, but it is unclear precisely how this affects cardiac physiology because these patients also have a large VSD and RV outflow tract obstruction. With this condition, clinical phenotype is usually primarily determined by large airway abnormalities.[97]

Congenital Cardiac Lesions With Left-to-Right Shunting

Most cardiac lesions in the neonate have at least a component of left-to-right shunting. An isolated *VSD* causes left-to-right shunting, although, for the reasons noted earlier, symptoms of CHF usually do not develop for a few weeks. However, premature babies with a large VSD can have symptoms within 1 to 2 weeks of age, perhaps in part because PVR declines more rapidly than in the term infant.[32] A large PDA is usually associated with a large left-to-right shunt, especially in the premature infant.

It is also very unusual, but well described,[42] for left-to-right atrial level shunting through an isolated *atrial septal defect* to cause symptoms in infants. Left-to-right atrial shunting across the foramen ovale may be substantial in neonates with left-sided obstructive lesions (e.g., aortic stenosis, coarctation).[98] (This shunting is actually very helpful, because the left ventricle may have a limited capacity to accept pulmonary venous return in these lesions—especially with critical aortic stenosis and hypoplastic left heart syndrome—and without an atrial opening pulmonary venous pressures are therefore high and pulmonary blood flow limited.)

All Systemic Venous Blood Passes Through the Lungs Before Being Pumped to the Systemic Circulation

In other words, there is no right-to-left shunting. Actually, in the neonate, mildly to moderately reduced systemic arterial O_2 saturation may have little detectable impact on physiology; the unfavorable effects of chronic hypoxia (e.g., reduced exercise capacity, polycythemia, brain abscess, stroke, and other neurologic symptoms) are rarely manifest in the neonate. However, it is unclear where to draw the line between moderate hypoxemia (with little or no physiologic impact) and severe hypoxemia (which impairs organ function) in the neonate. As previously noted, other determinants of SOT (especially Qs and hematocrit) and Vo_2 undoubtedly influence what level of hypoxemia is compatible with aerobic metabolism, and there must be intraindividual variation as well. It seems clear that an arterial Po_2 in the mid-20 mm Hg range (and probably even somewhat lower) can be tolerated for at least hours or days in most patients, presuming that other factors influencing SOT are acceptable. A lack of metabolic acidosis is often taken as an indication that SOT (and hence Po_2)

is acceptable, but whether a lack of acidosis with hypoxemia correlates with a lack of long-term sequelae (especially central nervous system dysfunction) has not been clearly established.

Congenital Cardiac Lesions With Right-to-Left Shunting

Hypoxemia is usually the primary or sole physiologic manifestation of most lesions with *reduced Qp* (e.g., tetralogy of Fallot or severe valvar pulmonary stenosis). When some or all Qp is provided by a ductus in a patient with a right-sided obstructive lesion, there will be ineffective Qp and therefore increased volume pumped by the ventricle, but this volume load is usually modest, presumably because the ductus is somewhat restrictive with those lesions. Patients with lesions with *admixture physiology* and an unrestrictive communication between the systemic and pulmonary circulations (e.g., single-ventricle lesions without significant pulmonary stenosis) usually have only mild hypoxemia (presuming that PVR falls normally in the postnatal period), but they commonly manifest CHF resulting from increased ventricular volume load. Single-ventricle lesions with some limitation of Qp resulting from increased PVR or anatomic restriction (e.g., tricuspid atresia with a restrictive VSD) can be well balanced and may have adequate arterial O_2 saturation without CHF.

Systemic and Pulmonary Venous Blood Readily Enters the Ventricles

In other words, there is no anatomic obstruction to ventricular filling. The heart can eject only what it receives, and ventricular filling is largely a function of transmural filling pressure. Abnormalities that impair flow into the heart may reduce ventricular output, but more commonly adequate output is maintained at the expense of venous hypertension, which causes third spacing of fluid (edema, effusions). This is a serious liability, especially in neonates, and tends to beget more of the same: edema and effusions increase mean airway pressure, compress abdominal venous return, or directly compress the heart, leading to the accumulation of yet more fluid.

Congenital Cardiac Lesions With Restriction of Ventricular Filling

Isolated obstruction to ventricular inflow is very unusual in the neonate; when the tricuspid or mitral valve is small, the corresponding ventricle is usually reduced in volume. When filling of the RV is impeded (e.g., pulmonary atresia with intact ventricular septum), right-to-left flow across the foramen ovale is rarely obstructed; hence, right atrial pressure is usually normal. With mitral stenosis or atresia and hypoplasia of the LV (hypoplastic left heart syndrome), the atrial septal opening is usually large enough so that pulmonary venous return is not significantly obstructed, although the size of the opening often becomes smaller over the first few weeks of life. Occasionally, the atrial septal opening is small, with the resulting left atrial hypertension and increased total pulmonary resistance, causing a reduction in Qp. Pulmonary edema further reduces systemic arterial saturation by interfering with gas exchange and by reducing lung compliance. Qs, however, may actually be increased, because systemic venous return to the RV is not obstructed, and the increased total PVR reduces the fraction of RV output that goes to the lungs.

Isolated mitral stenosis with adequate LV size is rare in the neonate.[99] Obstruction to pulmonary venous return can occur with *total anomalous pulmonary venous connection,* cor triatriatum, and stenosis of the individual pulmonary veins, the latter two being very rare. Pulmonary arterial hypertension, a reduction of RV compliance and output, and pulmonary edema are the primary physiologic manifestations.

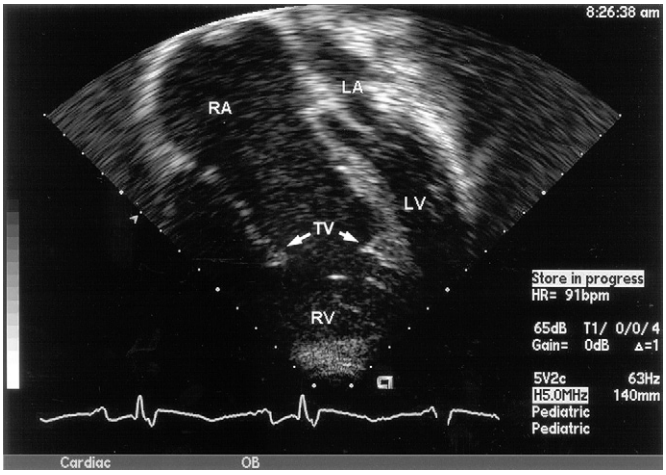

Figure 69-5 A cardiac ultrasound scan of a patient with Ebstein anomaly. The dilated right-sided structures impinge on the much smaller left ventricle *(LV). LA,* Left atrium; *RA,* right atrium; *RV,* right ventricle; *TV,* tricuspid valve.

Rarely, one massively enlarged ventricle encroaches on the other and inhibits ventricular filling, such as LV encroachment by the right atrium or RV with a severe Ebstein anomaly[95] (Figure 69-5). Other impediments to ventricular filling exist, such as pericardial effusion, that are not congenital malformations per se.

Neural Regulation of Blood Pressure During Fetal and Newborn Life

Control of circulatory function is mediated through interacting neural, hormonal, and metabolic mechanisms acting at both central and local levels. The central nervous system in particular is critical for cardiovascular homeostasis including the maintenance of blood pressure within normal limits.[1,2] Autonomic tone to the heart and blood vessels is continuously modulated by an array of peripheral sensors, including arterial baroreceptors and chemoreceptors located in the aortic arch and carotid sinus, as well as mechanoreceptors located in the heart and lungs.[3] Brain cardiovascular centers, located between afferent and efferent pathways of the reflex arc, integrate a variety of visceral and behavioral sensations allowing for a wide range of modulation of specific autonomic, cardiovascular, and endocrine responses. While these basic mechanisms exist in the fetus and newborn, differential rates of maturation of these systems influence the ability of the developing animal to maintain adequate blood pressure and organ blood flow.

Arterial pressure displays natural oscillations within a physiologic range, the degree of which is similar in fetal and postnatal life.[4-7] In the adult, ganglionic blockade increases arterial pressure variability,[4,8] suggesting that a component of arterial pressure lability is peripheral or humoral in origin and is buffered by autonomic functions. In contrast, ganglionic blockade in term fetal sheep significantly attenuates heart rate and arterial pressure variability.[6] Changes in sympathetic tone as recorded from the renal sympathetic nerve have been shown to correlate positively with the fluctuations in heart rate and arterial pressure.[6] Oscillations in basal sympathetic tone appear to be related to changes in the behavioral state of the fetus.[9-11] Although fetal electrocortical and sympathetic activity have not been recorded simultaneously, heart rate, arterial pressure, and catecholamine levels are highest during periods of high-voltage, low-frequency electrocortical activity.[10-15] Other physiologic parameters, including organ blood flows, regional vascular resistances, and cerebral oxygen consumption are also dependent on electrocortical state and likely reflect changes in autonomic activity.[12,16,17]

Tonic discharge of spinal vasoconstrictor neurons is an important regulator of vasomotor tone early in development. However, the contribution of the autonomic nervous system on cardiovascular homeostasis changes with maturation. Both α-adrenergic and ganglionic blockade produce greater decreases in blood pressure in term fetal lambs than in preterm fetal lambs.[18,19] The hypotensive effect following α-adrenergic and ganglionic blockade is less in newborn lambs than in term fetuses and continues to decline with postnatal development.[20] These findings suggest that sympathetic tone is high late in fetal life and is important in the maintenance of fetal arterial pressure. The influence of the parasympathetic system on resting heart rate appears to increase with maturation.[21] There is evidence of choline acetyltransferase and muscarinic acetylcholine receptors in the human heart early during development.[22] In utero fetal tachycardic responses to atropine have been demonstrated at 15 to 17 weeks gestation, before the bradycardic responses from β-blockers.[22] Cholinergic blockade produces no consistent effect on heart rate in premature fetal sheep, a slight increase in heart rate in term fetuses, and the greatest effect in lambs beyond the first week of life.[19,20] Central cholinergic modulation of cardiovascular function also appears during fetal development. Acetylcholine receptors are present in the brain during the first trimester,[23] and intracerebroventricular administration of carbachol increases blood pressure in fetal sheep associated with increased neuronal c-fos expression in central cardiovascular centers.[24]

THE ARTERIAL BAROREFLEX

Arterial baroreceptors are major sensing elements of the cardiovascular system.[1,2] Acute changes in vascular stretch related to arterial pressure modify the discharge of afferent baroreceptors fibers located in the carotid sinus and aortic arch.[2] Afferent fibers located in the vagus and glossopharyngeal nerves carry signals to the lower brain stem, primarily to the nucleus of the solitary tract. Secondary fibers project to the midbrain and other regions

of the brain stem. From these centers, efferent parasympathetic and sympathetic activity is modulated. This, in turn, influences outflow, heart rate, myocardial contractility, and peripheral vascular resistance, and it buffers changes in arterial pressure.[25,26] Studies in sheep, which to date serve as the most common model for studying integrative developmental cardiovascular physiology, demonstrate that the arterial baroreflex is functional during fetal and postnatal life.[7,21,27,28] Investigators disagree, however, about the magnitude of the influence of these reflexes on controlling heart rate and arterial pressure early in development. Early studies indicate that the threshold for baroreceptor activity is above the normal range of arterial pressure during fetal and neonatal life and that baroreceptors may not be loaded during fetal life.[29,30] However, studies demonstrating that sinoaortic denervation produces marked fluctuations in fetal arterial pressure and heart rate[7,28] suggest that the arterial baroreflex plays an important role in maintaining cardiovascular homeostasis. Single fiber recordings of carotid sinus and aortic depressor nerve baroreceptor afferents in fetal and newborn animals demonstrate carotid sinus nerve activity is phasic and pulse synchronous and that activity increases with a rise in arterial or carotid sinus pressure.[31-33] Basal discharge of baroreceptor afferents does not change during fetal and postnatal maturation despite a considerable increase in mean arterial pressure during this time,[31] indicating that baroreceptors reset during development and continue to function within the physiologic range for arterial pressure.[34] The sensitivity of carotid baroreceptors to increases in carotid sinus pressure is greater in fetal than in newborn and 1-month-old lambs[31] and in newborn compared with adult rabbits.[34] These finding suggest that reduced heart rate responses to changes in arterial pressure during fetal life are not due to underdeveloped afferent activity of baroreceptors but to differences in central integration, efferent parasympathetic nerve activity, or end organ responsiveness.

The mechanisms regulating the changes in sensitivity of the baroreceptors early in development have not been investigated, but may be similar to those proposed in the adult.[35-37] In younger animals, the carotid sinus is more distensible, resulting in an increase in the degree of mechanical deformation of nerve endings and ultimately in a greater strain sensitivity.[35] Alternatively, mechanosensitive ion channels[36,38]—such as the degenerin/epithelial sodium channel (DEG/ENaC) that may operate at the receptor membrane to cause hyperpolarization of the endings—and substances released from the endothelium including prostacyclin[39] and nitric oxide[40-42] may modulate baroreceptor activity during development. Blockade of cyclooxygenase with indomethacin reduces carotid baroreceptor sensitivity in newborn but not adult sheep.[43] Along these lines, prostaglandin E_2 and I_2 levels within carotid sinus tissues are six-fold higher in newborn than adult sheep.[43] Whether such influences on baroreceptor activity are present during fetal development has not been investigated.

The arterial baroreflex during fetal and postnatal maturation has been investigated primarily by examining the relationship between the increase in arterial pressure and the fall in heart rate.[28,30,44-46] Baroreflex control of fetal heart rate is dominated by changes in cardiac vagal tone, although integrity of the reflex is dependent upon both sympathetic and parasympathetic pathways.[47] Several studies describe a relatively reduced heart rate response to alterations in arterial pressure in fetal and newborn animals and in human infants.[30,48-50] Using reflex bradycardia in response to increased blood pressure by balloon inflation, Shinebourne and colleagues[48] found that baroreflex activity is present as early as 60% of completed gestation in fetal lambs and that the sensitivity of the reflex increased up to term. Additional studies in sheep[49] and other species[51,52] have similarly found increasing baroreflex sensitivity with postnatal age. For example, reflex bradycardia in response to carotid sinus stimulation is absent during the first week of life in the piglet although vagal efferents exert a tonic action on the heart at this stage of development.[51] Age-related changes in heart rate in response to phenylephrine are also greater in 2-month-old piglets than in 1-day-old animals.[52]

Other studies suggest that the sensitivity of the cardiac baroreflex is in fact greater in the fetus than in the newborn and that it decreases with maturation.[46,53] Recent studies in the equine fetus at 60% and 90% of completed gestation demonstrate that cardiac baroreflex sensitivity decreased with advancing gestational age.[54] Recordings of heart rate and efferent renal sympathetic nerve activity (RSNA) in response to increases and decreases in blood pressure in fetal, newborn, and 4- to 6-week-old sheep demonstrate that baroreceptor activity regulates sympathetic outflow as well as heart rate during fetal life; that functional baroreflex control of RSNA and heart rate shifts toward higher pressures during development; and that the sensitivity of the RSNA baroreflex function curve is greater early in development and decreases following the transition from fetal to newborn life.[55] Interestingly, studies during postnatal life have shown that baroreflex controls heart rate and that sympathetic nerve activity is impaired with senescence,[56] an effect that may contribute to the development of hypertension.

Several reasons for reported differences in the sensitivity of baroreflex function early in development are apparent. Interspecies variability exists in the maturation and functional innervation of sympathetic and parasympathetic function, including maturity of the central and efferent components of the reflex.[49,52,57] Differences in methodologies, including the use of anesthesia, may also contribute to variances in results.[28,46,58] Some investigators looked at the heart rate response to a rise in blood pressure using either phenylephrine[28,46] or aortic balloon inflation.[46,48] Others derived complete sigmoidal baroreflex curves for heart rate and efferent sympathetic activity.[55] The use of anesthesia in several studies might also have altered baroreflex mediated responses in adults.[58]

Resetting the Arterial Baroreflex

Resetting the arterial baroreflex is defined as a change in the relationship between arterial pressure and heart rate or between pressure and sympathetic and parasympathetic nerve activities.[36,37] A number of studies demonstrate that the sensitivity of the baroreflex changes with maturation, and shifts—or resets—toward higher pressures.[55,56,59] This shift occurs during fetal life, is present immediately after birth, and continues with postnatal maturation, paralleling the naturally occurring increase in blood pressure.[60] The mechanisms regulating developmental changes in baroreflex sensitivity and controlling the resetting of the baroreflex are poorly understood. Changes in the relationship between arterial pressure and sympathetic activity or heart rate occur at the level of the baroreceptor itself (peripheral resetting) and from altered coupling within the central nervous system of afferent impulses from baroreceptors to efferent sympathetic or parasympathetic activities (central resetting).[36] Other factors that may modulate changes in arterial baroreflex during development are (1) changes in the levels of locally produced factors such as nitric oxide, (2) circulating hormones and neuropeptides such as angiotensin II (ANG II), vasopressin (AVP), and serotonin, and (3) activation of additional neural reflex pathways.[36,42,61,62]

In adults, adaptation or resetting of the baroreflex during acute or chronic increases in arterial pressure is modulated by both peripheral and central mechanisms.[36] Early in development, however, short-term increases in blood pressure do not alter the arterial baroreflex.[55] Based on observation, this failure of resetting seems to result in part from the absence of the arterial pressure-baroreceptor activity relation to adapt to increased pressure. With a sustained increase in arterial pressure, activity of the aortic depressor nerve, which contains afferent fibers from aortic arch

baroreceptors, remains elevated and fails to decrease, or escape, from constant baroreceptor stimulation. These findings suggest that factors other than the maturational increase in blood pressure influence the ontogenic changes in the arterial baroreflex.

Baroreflex Function in the Human Neonate

Information regarding the ontogeny of baroreflex function in the human infant is limited. Most commonly, the head-up tilt test has been used to unload arterial baroreceptors and measure heart rate and blood flow responses. Several investigators report the ability of the healthy term or preterm infant to demonstrate a consistent response of the heart rate to tilting, although reports have been conflicting.[63-65] Using venous occlusion plethysmography, Waldman and colleagues[65] found in healthy preterm and term infants that 45-degree head-up tilting produced on average a 25% decrease in limb blood flow, suggestive of an increase in peripheral vascular resistance, although no significant tachycardia was observed. A longitudinal study in preterm infants of spontaneous baroreflex sequences (hypertension/bradycardia and hypotension/tachycardia) found the baroreflex to be functional in premature infants (less than 30 weeks gestation) and that the sensitivity of baroreflex increases with postnatal age.[66] Baroreflex sensitivity values of premature infants upon reaching term postmenstrual age were less than that observed in term infants, suggesting ex utero maturation delays development of the reflex. A study of term infants at birth and again at 2 to 4 months of age demonstrates the sensitivity of the heart rate response to head tilt is lost at the later time point.[67] Loss of the heart rate response to tilt may reflect changes in autonomic input to the heart or increased capacity of vascular responsiveness to postural challenge and hypotension. Findings of Galland and colleagues[68] suggest that term, small-for-gestational–age infants exhibit higher resting sympathetic tone than appropriately grown term infants but relatively immature autonomic control of heart rate.

Spectral analysis, which offers the ability to quantify and characterize small spontaneous beat-by-beat variations in heart rate has been used in human adults,[69] infants,[70-72] and fetuses[73] to evaluate the contribution of the autonomic nervous system in maintaining cardiovascular homeostasis. Fetal electrocardiogram tracings have shown that younger fetuses have a greater total energy of the power spectrum compared with more mature fetuses, consistent with the evolution of a stable and mature autonomic nervous system.[73] Maturational changes in the power spectra of heart rate variability have also been shown by comparing preterm to term infants.[70-72] There is a progressive decline in the low-frequency/high-frequency power ratio associated with both increasing postnatal and gestational age, indicating an increase in parasympathetic contribution to control of resting heart rate with maturation. Clairembault and colleagues[72] found that changes in the high-frequency component of the spectrum were greater at 37 to 38 weeks, suggesting a steep increase in vagal tone at this age. In a cross-sectional study of infants between 28 and 42 weeks postmenstrual age (approximately 3 to 4 days postnatal age), Andriessen and colleagues[70] found increases in R-R interval fluctuations and baroreflex sensitivity (using low-frequency transfer gain) with advancing postmenstrual age. Using atropine to block muscarinic receptors, this same group demonstrated in preterm infants that vagal tone is present at birth and parasympathetic influence on baroreflex control of heart rate is significant.[74]

We performed a longitudinal study using power spectral analysis to characterize developmental changes in sympathovagal balance in response to arterial baroreceptor unloading in preterm infants beginning at 28 to 30 weeks postconceptional age.[75] The low-frequency/high-frequency ratio did not change with head-up postural change in infants at 28 to 30 weeks post conceptional age, although the low-frequency component of the spectrum increased with head-up tilt with increasing postnatal age. These findings support maturational changes in neural regulation of cardiac function occurring in the early postnatal period.

The Cardiopulmonary Reflex

In older children and adults, extracellular fluid volume remains remarkably constant despite day-to-day variations in dietary intake of salt and water.[76] The integrity of this system is essential to preserve circulatory performance and to ensure appropriate fluid and electrolyte homeostasis. Contrary to the steady-state condition of extracellular fluid volume in the adult, significant changes in total body water and in the partition of body water between intracellular and extracellular compartments occur during fetal and postnatal development.[77,78] It is likely that the changes in body water during development are, in part, linked to ontogenic changes in the sensing and effector mechanisms regulating extracellular fluid volume, including the cardiopulmonary baroreflex. Cardiopulmonary receptors are sensory endings located in the four cardiac chambers, in the great veins, and in the lungs.[79] The volume sensors mediating reflex changes in cardiovascular and renal function are believed to be primarily those residing in the atria[80,81] and the ventricles,[79] with the ventricular receptors being of utmost importance during decreases in cardiopulmonary pressures.[79,82,83] The majority of ventricular receptor vagal afferents are unmyelinated C-fibers that can be activated by exposure to chemical irritants (chemosensitive) and changes in pressure or strength (mechanosensitive receptors).[84,85] These receptors have a low basal discharge rate, which exerts a tonic inhibitory influence on sympathetic outflow and vascular resistance[79] and regulates plasma AVP concentration.[86] Interruption of this basal activity results in increases in heart rate, blood pressure, and sympathetic nerve activity, whereas activation of cardiopulmonary receptors results in reflex bradycardia, vasodilation, and sympathoinhibition.[79]

Initial characterization of the cardiopulmonary reflex during the perinatal and neonatal periods was performed by chemostimulation of cardiopulmonary receptors.[52,87,88] These studies demonstrated that the heart rate, blood pressure, and regional blood flow responses to stimulation of chemosensitive cardiac receptors were smaller during early development than later in life and absent in premature fetal lambs[87] and in piglets less than 1-week old.[88] Stimulation of cardiopulmonary receptors with volume expansion had no effect on basal renal nerve activity in the fetus, but significantly reduced RSNA in newborn and 8-week-old sheep.[89,90] However, the decrease in RSNA in response to volume expansion was totally abolished in sinoaortic denervated newborn lambs but was not affected by sinoaortic denervation in 6- to 8-week-old sheep.[91] These results suggest that cardiopulmonary reflexes are immature early in life and that stimulation of sinoaortic baroreceptors plays a greater role than cardiopulmonary mechanoreceptors in regulating changes in sympathetic activity in response to expansion of vascular volume.

Cardiopulmonary mechanoreceptors also respond to reductions in blood volume by eliciting reflexes that influence systemic hemodynamics, although these effects are developmentally regulated. Hemorrhage produces a significant decrease in arterial blood pressure without accompanying changes in heart rate in fetal sheep at less than 120 days gestation, whereas blood pressure remains stable and heart rate increases in near-term fetuses.[92] However, other investigators[93,94] found the hemodynamic response to hemorrhage to be similar in immature and near-term fetuses, with reductions in both heart rate and blood pressure. Inhibition of vagal afferents during slow and non-hypotensive hemorrhage blocks the normal rise in plasma AVP but does not alter the rise in plasma renin activity in near-term fetal sheep.[93]

When input from cardiopulmonary receptors is removed by section of the cervical vagosympathetic trunks, the decrease in

fetal blood pressure in response to hemorrhage is similar to that in intact fetuses,[95] whereas vagotomy with sinoaortic denervation enhances the decrease in blood pressure.[93] Therefore it is likely that activation of fibers from the carotid sinus (arterial baroreceptors and chemoreceptors), but not vagal afferents (cardiopulmonary baroreceptors and chemoreceptors), are involved in the maintenance of blood pressure homeostasis during fetal hemorrhage. Cardiopulmonary receptors also appear to have a diminished role in early postnatal life as reflex changes in newborn lamb RSNA during non-hypotensive and hypotensive hemorrhage are dependent upon the integrity of arterial baroreceptors but not cardiopulmonary receptors.[96]

The RSNA responses to vagal afferent nerve stimulation are similar in sinoaortic denervated fetal and postnatal lambs,[97] suggesting that delayed maturation of the cardiopulmonary reflex is not secondary to incomplete central integration of vagal afferent input. On the other hand, the decreased sensitivity of the cardiopulmonary reflex early in development in the face of a sensitive arterial baroreflex response (as outlined above) is intriguing. One may suggest that there is a competing interaction between these two reflexes during development. In support of this hypothesis, studies in adults[98,99] have shown that activation of arterial baroreceptors may impair the reflex responses to activation of cardiopulmonary receptors.

Peripheral Chemoreflex Responses

Acute hypoxemia is a physiologic stressor that evokes integrated cardiovascular, metabolic, and endocrine responses. These responses, mediated by peripheral chemoreceptors located in the aortic arch and carotid bodies are developmentally regulated during fetal life.[100-102] In fetal lambs, the cardiovascular response to acute hypoxemia is eliminated by carotid but not aortic chemodenervation.[103] The fetal cardiovascular responses to acute hypoxemia include transient bradycardia, an increase in arterial blood pressure resulting from increase in peripheral vascular resistance, and a redistribution of blood flow in favor of the cerebral, myocardial, and adrenal circulations.[104,105] The bradycardia is mediated by parasympathetic efferents while the initial vasoconstriction results from increased sympathetic tone.[102,106] The release of circulating factors such as AVP, neuropeptide Y (NPY) and catecholamines serve to maintain peripheral vasoconstriction while heart rate returns toward basal levels.[102,107] Fletcher and colleagues[108] examined cardiovascular responses to transient (1 hour) hypoxia in fetal sheep at three distinct ages (125 to 130, 135 to 140, more than 140 days of gestation, and term [145 days]). Close to term, there was an increase in the magnitude and persistence of bradycardia and the magnitude of the femoral constrictor response to hypoxemia, associated with greater increases in neuropeptide Y (NPY) and AVP levels. Irrespective of gestational age, the responses positively correlated to basal cortisol concentrations, suggesting the normal prepartum increase in fetal serum cortisol levels may mediate the gain of the neural and endocrine responses to hypoxemia.

Although chemoreceptors are active and responsive in the fetus and newborn, studies in sheep and human infants suggest that chemoreceptor sensitivity and activity is reduced immediately after birth.[100,109] This decreased sensitivity persists for several days until the chemoreceptors adapt and reset their sensitivity from the low oxygen tension of the fetus to the higher levels seen postnatally.[100,109] The mechanisms involved with this resetting are not known, although the postnatal rise in PaO_2 appears crucial because raising fetal PaO_2 produces a rightward shift in the response curve of carotid baroreceptors to differing oxygen tension.[110] Holgert and colleagues[111] hypothesized that developmental changes in dopamine turnover within the carotid body contribute the postnatal resetting of the arterial chemoreceptors, whereas others suggest differences in intracellular calcium mobilization during hypoxia may be an important component of chemoreceptor maturation.[112]

The cardiovascular responses to acute fetal hypoxemia undergo adaptation and depend on the prevailing intrauterine condition.[104,113] Chronically hypoxic fetuses (baseline $Pa\text{-}O_2$ 17.3 ± 0.5 mm Hg) displayed greater increases in arterial blood pressure and femoral vascular resistance than control fetuses (baseline PaO_2 22.9 ±1.0 mm Hg) in response to acute hypoxia.[104] Exposure to hypoxia for a limited period of time (hours to days) may have a sensitizing effect on the chemoreflex, whereas sustained hypoxia (days to weeks) appears to have a desensitizing effect.[113] The degree of preexisting hypoxia may also affect whether chemoreflex responses are attenuated or enhanced.[114] The mechanisms or factors regulating these adaptations are unclear. In the chick embryo, hypoxia increases sympathetic nerve fiber density and neuronal capacity for norepinephrine synthesis.[115] Thus, augmented efferent pathways may contribute to the enhanced responses. On the other hand, recordings from carotid chemoreceptors in chronically hypoxic kittens demonstrate blunted responses to acute decreases in PaO_2 relative to control animals.[116] It is therefore possible that with prolonged hypoxia, blunting of the chemoreflex responses may be related to afferent mechanisms.

Developmental changes in the chemoreflex responses are likely related to carotid body sensor mechanisms as well and end-organ responsiveness. The sensitivity of carotid body glomus cells from 1- to 3-day-old rats to hypoxia is decreased compared to that in 11- to 14-day-old rats.[117] Carotid body afferent discharge is also regulated by a large number factors other than arterial PaO_2, including hypercapnia, acidosis, hyperkalemia, hypoperfusion, and circulating hormones.[118] The purine nucleoside adenosine appears to play an important role in chemoreceptor mediated responses as adenosine receptor blockade abolishes hypoxia-induced bradycardia and hypertension in fetal sheep.[119,120] Treatment with an adenosine receptor antagonist or carotid sinus denervation prior to acute fetal hypoxemia also prevents an increase in plasma epinephrine and markedly reduces the increase in plasma norepinephrine.[121,122] Thus adenosine receptor blockade may act via chemoreceptor-dependent mechanisms to abolish circulatory and adrenergic responses to acute hypoxemia in fetal sheep, although chemoreflex-independent mechanisms also likely exist. In postnatal animals, adenosine increases carotid body afferent discharge, whereas hypoxia-induced increases in afferent activity are attenuated by adenosine receptor antagonists.[123]

Sympathetic Activity at Birth

Activation of the sympathetic nervous system plays an important role in the hemodynamic adjustments at birth, including changes in heart rate, peripheral vascular resistance, and a redistribution of blood flow.[124,125] Marked increases in circulating catecholamine levels occur with birth,[126,127] and sympathetic ganglionic blockade depresses arterial pressure and cardiac function, including heart rate and cardiac output, in newborn (1- to 3-day-old) lambs.[128] Renal sympathetic nerve activity increases nearly 250% following delivery of term fetal sheep by cesarean section and parallels the rise in arterial pressure and heart rate.[60] Delivery appears to produce near maximal stimulation of renal sympathetic outflow since further increases cannot be elicited by unloading of arterial baroreceptors.[60] Reflex inhibition of this increase in RSNA could not be achieved by arterial baroreceptor stimulation, as seen in fetal and 3- to 7-day-old lambs,[55] suggesting that central influences exist that override the arterial baroreflex and that the maintenance of a high sympathetic tone is vital during this transition period. A similar pattern of baroreceptor reflex inhibition has been well described in adult animals as part of the defense reaction.[129]

Factors mediating the large increase in sympathetic outflow at birth are unclear. In utero ventilation studies of fetal sheep have shown that rhythmic lung inflation increases plasma catecholamine concentrations although there are no consistent effects on blood pressure or heart rate.[130,131] Fetal RSNA increases only 50% during in utero ventilation, while in utero oxygenation and removal of the placental circulation by umbilical cord occlusion produces no additional effect.[132] Thus lung inflation and increased arterial oxygen tension appear to contribute little to the sympathoexcitation process at birth. The increases in heart rate, mean arterial blood pressure, and RSNA following delivery are similar in intact and sinoaortic denervated plus vagotomized fetal lambs,[133] suggesting that afferent input from peripheral chemoreceptors and mechanoreceptors contribute little to the hemodynamic and sympathetic responses at delivery.

On the other hand, change in environmental temperature at birth may play an important role in the sympathoexcitatory response at birth. Cooling of the near-term fetus both in utero and in exteriorized preparations results in an increase in heart rate, blood pressure, and norepinephrine concentrations, consistent with sympathoexcitation.[134,135] In contrast, exteriorization of the near-term lamb fetus into a warm water bath does not produce the alterations in systemic hemodynamics or catecholamine values typically seen at birth.[135] Fetal cooling, but not ventilation or umbilical cord occlusion, also initiates nonshivering thermogenesis via neurally mediated sympathetic stimulation of brown adipose tissue.[136] In utero cooling of fetal lambs produces an increase in RSNA of similar magnitude to that seen at delivery by cesarean section,[65] suggesting that cold stress plays an important role in the activation of the sympathetic nervous system at birth. These changes occur before a decrease in core temperature and are reversible with rewarming, suggesting that sensory input from cutaneous cold-sensitive thermoreceptors rather than a response to a change in core temperature is mediating the response.

Multiple brain centers are involved in autonomic control of the systemic circulation in adults. Sympathetic outflow is controlled not only by the medulla oblongata,[137] but also by higher centers, especially the hypothalamus,[138, 139] allowing for a wide range of modulation. In fetal sheep, electrical stimulation of the hypothalamus evokes tachycardia and a pressor response, which are attenuated by α-adrenoreceptor blockade.[140] Stimulation of the dorsolateral medulla and lateral hypothalamus in the newborn piglet similarly increases blood pressure and femoral blood flow.[52] Because the responses to hypothalamic stimulation are lost during stress (hypoxia, hypercapnia, hemorrhage), whereas those elicited from the medulla are not, some investigators have proposed that the hypothalamus exerts little influence of cardiovascular function until later in postnatal development.[52] However, other studies suggest forebrain structures are vital for normal physiological adaptation following the transition from fetal to newborn life.[132] Increases in heart rate, mean arterial blood pressure, and RSNA, which normally occur at birth, are absent in animals subjected to transection of the brain stem at the level of the rostral pons before delivery. These data suggest that supramedullary structures are involved in mediating the sympathoexcitation seen at birth. Ablation of the paraventricular nucleus of the hypothalamus also attenuates the postnatal increase in sympathetic outflow and alters baroreflex function.[141] Thus hypothalamic structures appear intimately involved in the regulation of circulatory and autonomic functions during the transition from fetal to newborn life.

The hemodynamic and sympathetic responses at birth are markedly different in prematurely delivered lambs (85% of completed gestation) compared to those delivered at term.[142] Postnatal increases in heart rate and blood pressure are attenuated, whereas the sympathoexcitatory response, as measured by RSNA, is absent.[142] This impaired response occurs despite the fact the descending pathways of the sympathetic nervous system are intact and functional at this stage of development, as demonstrated by a large pressor and sympathoexcitatory response to in utero cooling.[142] Antenatal administration of glucocorticoids augments sympathetic activity at birth in premature lambs and decreases the sensitivity of the cardiac baroreflex.[142] The mechanisms for antenatal glucocorticoid administration augmenting cardiovascular and sympathetic responses at birth are unclear, although stimulation of the peripheral renin-angiotensin system and activation of systemically accessible AT_1 receptors are not involved.[143]

Humoral Influences

Angiotensin II

The renin-angiotensin system is active in the fetal and perinatal periods.[144-146] During embryonic and early fetal life, the primary function of the renin-angiotensin system may be to regulate organ growth and development.[147,148] Only later during fetal development does the renin-angiotensin system become involved in modulating cardiovascular function and renal hemodynamics. In sheep, fetal plasma levels of renin are elevated when compared with adults.[149,150] In healthy children, plasma renin activity is elevated during the newborn period, declines rapidly in the first year of life, and continues to gradually decline until adulthood.[151-153] In preterm infants, plasma renin activity is markedly elevated and has close inverse relationship to postconceptual age.[154]

A large number of studies also report that administration of inhibitors of ANG II, including angiotensin converting enzyme inhibitors and ANG II subtype 1 receptor blockers, decrease fetal and newborn arterial blood pressure.[13,59,146,155-157] Fetal plasma renin activity and plasma ANG II concentration increase after aortic constriction, hypotension, and blood volume reduction.[144,158] Conversely, a rise in arterial blood pressure and volume expansion reduces plasma renin activity in fetal and newborn animals.[159,160] The vasopressor response and renal vascular reactivity to exogenous ANG II are less in fetal lambs than in adult sheep.[161,162] Factors explaining the higher activity of the renin-angiotensin system early in development and the decreased sensitivity to ANG II have not been explored in detail, although differences in localization and expression of the ANG II receptor subtypes or activation of second messenger systems contribute to this effect.

In addition to their direct effects on neural function, baroreceptors and chemoreceptors regulate the release of vasoactive hormones, including ANG II.[61,163] Changes in the levels of circulating hormones, in turn, influence neural regulation of cardiovascular function. For example, in the sheep fetus, a rise in arterial blood pressure produced by ANG II administration produces either attenuated or no reflex cardiac slowing.[161,164] The bradycardic and sympathoinhibitory responses to a given increase in blood pressure are less for ANG II than for other vasoconstrictor agents.[62] The site of action of ANG II in regulating baroreflex function in the fetus is not known. In the adult, ANG II facilitates activation of sympathetic ganglia and enhances the release of norepinephrine at the neuroeffector junction.[165] Within the central nervous system, ANG II stimulates sympathetic outflow and alters baroreceptor reflexes by acting on ANG II type 1 (AT_1) receptors located within the hypothalamus, medulla, and circumventricular organs.[166,167]

Endogenous ANG II participates in regulating arterial baroreflex responses early during development. The absence of rebound tachycardia after reduction in blood pressure by angiotensin converting enzyme (ACE) inhibitors is well described in fetal and postnatal animals,[155] as well in human adults and infants.[168] In the newborn lamb, angiotensin converting enzyme inhibition or ANG II type 1 (AT_1) receptor blockade decreases RSNA and heart rate and resets the baroreflex toward lower pressure.[62,169]

Resetting of the reflex is independent of changes in prevailing blood pressure. Lateral ventricle administration of an ANG II type 1 (AT_1) but not AT_2 receptor antagonist also lowers blood pressure and resets the baroreflex toward lower pressure in newborn and 8-week-old sheep at doses that have no effect when given systemically.[169]

Arginine Vasopressin

In addition to ANG II, arginine AVP plays an important role in maintaining cardiovascular homeostasis during fetal and postnatal development. Plasma AVP concentrations in the fetus are increased by multiple stimuli, including hypotension, hemorrhage, hypoxemia, acidemia, and hyperosmolality.[163,170-173] Graded infusions of AVP increase fetal blood pressure and decrease fetal heart rate in a dose-dependent manner.[174-176] AVP responses to hypotension are partially mediated by arterial baroreceptors, whereas the contribution of carotid or aortic chemoreceptors to the AVP response to hypoxia is limited.[122,177-179] Although AVP provides an important component of the cardiovascular response to acute stress, it appears to have little impact on basal fetal circulatory regulation. Blockade of AVP receptors in fetal sheep has no measurable effects on arterial blood pressure, heart rate, or renal sympathetic nerve activity in fetal sheep or newborn lambs.[43,180-182] However, AVP receptor inhibition impairs the ability of the fetus to maintain blood pressure during hypotensive hemorrhage and reduces the catecholamine response.[183]

In several adult species, AVP modulates parasympathetic and sympathetic tone and baroreflex function.[61,181,182] Administration of AVP evokes a greater sympathoinhibition and bradycardia than other vasoconstrictors for a comparable increase in blood pressure.[61,184] This modulation of the baroreflex has been attributed to AVP enhancing the gain of the reflex as well as resetting the reflex to a lower pressure.[61,184] While AVP increases fetal arterial pressure and decreases heart rate in a dose-dependent manner,[175,185] sequential increases in plasma AVP in fetal and newborn sheep does not alter baroreflex control of RSNA and heart rate in response to acute changes in blood pressure.[43] Endogenous AVP also appears to have little effect on baroreflex function early during development. Peripheral administration of a V_1-receptor antagonist has no measurable effects on resting hemodynamics in fetal sheep or on basal arterial blood pressure, heart rate, RSNA, or baroreflex response in newborn lambs.[43,180] This lack of baroreflex modulation by AVP may facilitate the pressor response to AVP in fetuses and newborns during stressful situations such as hypoxia and hemorrhage. In this way, AVP could play a particularly important role in maintaining arterial pressures during these states early in development.

The role of central AVP in maintaining hemodynamic homeostasis in the developing animal has not been extensively studied. Under basal conditions, fetal AVP levels are tenfold higher in the cerebrospinal fluid than in plasma, suggesting AVP contributes to central regulation of autonomic function.[186] Intracerebroventricular infusion of AVP produces significant decreases in mean arterial blood pressure and heart rate in newborn lambs although no reflex changes in RSNA are seen.[187] Interestingly, intracerebroventricular administration of AVP increases RSNA in 8-week-old sheep, demonstrating that the role of AVP receptors within the CNS in regulation autonomic function is developmentally regulated.[187] The changes in blood pressure and heart rate are completely inhibited by administration of a V_1 antagonist, suggesting the central cardiovascular effects of AVP are mediated by V_1 receptors, as has been reported in mature animals.[188]

Corticosteroids

Adrenal steroids are vital for normal physiological development. Fetal adrenalectomy attenuates the normal gestational age-dependent increase in blood pressure that occurs in late gestation, while cortisol replacement produces a sustained increase in fetal blood pressure.[153,189,190] Antenatal exposure to exogenous glucocorticoids increases fetal postnatal arterial blood pressure by enhancing peripheral vascular resistance and cardiac output without altering heart rate.[191-193] The mechanisms accounting for the increase in fetal vascular resistance are not clear. Although direct effects of glucocorticoids on vascular reactivity likely exist, antenatal glucocorticoids also modify autonomic and endocrine functions. Increases in fetal blood pressure and vascular resistance following betamethasone treatment occur despite marked suppression of circulating vasoconstrictors, including catecholamines, ANG II, and AVP.[142,178,192,194-196] Circulating neuropeptide Y concentration, which may provide an index of peripheral sympathetic activity, is increased following fetal exposure to dexamethasone.[197] Glucocorticoid treatment accelerates postnatal maturation of brain catecholaminergic-signaling pathways in rats and enhances renal sympathetic nerve activity in prematurely delivered lambs.[142,198-202]

Endogenous production of cortisol is important for normal maturational changes in autonomic and baroreflex function. Adrenalectomized sheep fail to display the normal postnatal increase in RSNA, but the response is restored by cortisol replacement.[116,203] Restoring circulating cortisol levels to the prepartum physiological range shifts the fetal and immediate postnatal heart rate and RSNA baroreflex curves toward higher pressure without altering the slope of the curves.[203] Antenatal administration of betamethasone decreases the sensitivity of baroreflex-mediated changes in heart rate in fetuses and lambs while resetting baroreflex control of heart rate and RSNA toward higher pressures.[142,197,200,204] In response to acute hypoxia, fetuses exposed to glucocorticoids display prolonged bradycardia and attenuated plasma catecholamine and AVP responses.[197] Taken together, these findings indicate that glucocorticoids modify autonomic and endocrine control of cardiovascular function during development. These effects may even persist well after cessation of exposure.[197]

Nitric Oxide

Endogenous NO contributes to regulation of fetal blood pressure and organ specific vascular resistance as acute blockade of NO production causes an immediate rise in blood pressure and umbilico-placental resistance, and it decreases heart rate, renal blood flow velocity, and plasma renin concentration.[205,206] In addition to its direct effect on vascular tone, there is evidence to suggest NO affects vascular function through interactions with central and peripheral autonomic function.[207] Studies in adult animals demonstrate that NO modulates sympathetic activity via its inhibitory actions on baroreceptor afferents and brain regions involved in regulating sympathetic activity.[207] NO also appears to function as a central neurotransmitter and acts within the brain to regulate fetal arterial blood pressure. Administration of the NO donor nitroglycerin into the fourth cerebral ventricle of the ovine fetus decreases mean arterial pressure, whereas blocking NO synthase in the fourth ventricle increases fetal blood pressure.[208] Inhibition of endogenously produced NO increases blood pressure in 1- and 6-week-old lambs to similar extents although the concomitant decreases in heart rate are greater in the young lamb, suggesting NO[42] may contribute to maturation changes in baroreflex function during this period. Developmentally regulated changes in the expression of NO synthase isoforms in the brain stem, which is known to occur in the fetus, may play a role in baroreflex function during fetal and early postnatal development.[42,209]

Conclusion

Understanding the mechanisms regulating cardiovascular function in the fetus and newborn is of great importance, particularly as these mechanisms relate to the physiologic adaptations

occurring with the transition from fetal to newborn life. Failure to regulate arterial pressure, peripheral resistance, and blood volume may lead to significant variations in organ blood flow and substrate delivery, resulting in ischemic or hemorrhagic injury. There is abundant evidence to suggest that autonomic regulatory mechanisms, including baroreceptors and chemoreceptors, are important modulators of blood pressure and circulatory function in the developing fetus and newborn. Humoral and endocrine factors also act directly and indirectly to regulate vascular tone and cardiac function. A large number of other cardiovascular regulatory factors, including opioids, natriuretic peptides, and prostenoids act centrally and peripherally to regulate systemic hemodynamics, and these have not been addressed. Further work is needed to determine the role of these factors and their interactions during relevant pathophysiological conditions. A more complete understanding of neurohumoral control of cardiovascular function early in life will result in the development of new therapeutic strategies to prevent complications during the perinatal period.

Developmental Effects on Fetal Circulation

The fetus depends on its cardiovascular system for growth and development. Vascular growth is closely linked to tissue growth, and the fetal heart must develop in relation to the venous return (preload), primarily from the umbilical vein, and the similar arterial pressures in the pulmonary trunk and the aortic arch (afterload). This matching of cardiovascular function to growth is known to be particularly important in late gestation, when cardiovascular redistribution and changes in tissue metabolism occur in response to placental insufficiency (reviewed in References 1 and 2). Whether such processes operate in early gestation is not known.

Current knowledge of late gestation fetal cardiovascular control is based on the concept that the mechanisms of such control will be best revealed when the system is challenged with a stimulus and the resulting response measured. The stimulus most widely employed is hypoxia, which has permitted a fairly complete picture of a temporal and functional hierarchy of reflex, endocrine, and local mechanisms operating during acute hypoxia.[3] Such mechanisms change in the course of gestation,[4,5] in the face of repeated acute or sustained hypoxia,[6-8] and in species adapted to life in the hypoxia of altitude.[9-12] However, whether such mechanisms operate in response to changes in fetal nutrition (e.g., glucose, amino acid, or micronutrient provision) is now beginning to be understood. This chapter addresses this question in the context of what is known of the programming effects of prenatal nutrition on cardiovascular development and fetal circulatory control mechanisms.

EPIDEMIOLOGIC OBSERVATIONS

Considerable evidence has now accumulated from a variety of studies that small or disproportionate size at birth is associated with increased risk of cardiovascular disease. The studies of Barker and colleagues[13] in adult men and women showed that the standardized mortality ratio for cardiovascular disease (CVD) decreased in a graded manner across the normal birth weight range. Numerous studies have linked low birth weight to the metabolic syndrome[14] or to components of the syndrome (defined as fasting plasma glucose more than 6 mmol/L; blood pressure more than 130/85 mm Hg; fasting plasma triglycerides greater than

1.7 mmol/L; plasma high-density lipoprotein cholesterol less than 1.1 mmol/L; (in men) waist measurement greater than 102 cm). A metaanalysis of the blood pressure effect suggests that a 1-kg increase in birth weight is associated with a decrease of 2 mm Hg in systolic blood pressure in later life.[15] Inevitably, the size and nature of these studies vary enormously and the effect of study size has been questioned[16] because larger studies (where birth weight is more likely to have been self-reported than actually measured) show weaker associations between birth weight and blood pressure than smaller studies. Nonetheless, the direction of the effect (small size at birth predicting higher blood pressure in later life) is not under question even if the magnitude of the effect is debated. Thus a major part of an individual's predisposition to cardiovascular disease appears to be established during development.

Birth weight is a poor proxy for fetal growth, and of course, blood pressure is a poor proxy for cardiovascular function or tissue perfusion. For these reasons it is vital that physiologic studies are conducted to understand the mechanisms underlying programming of cardiovascular function by life events in utero. Moreover it is highly unlikely that appropriate intervention measures to prevent the progression to disease (i.e., the metabolic syndrome) in susceptible individuals can be developed without an understanding of the mechanisms underlying the development of the disease. This may have enormous implications for public health; calculations based on the epidemiologic studies conducted in Finland[17] suggest that if all male offspring could be prevented from being thin at birth and thin and short at 1 year of age, the incidence of coronary heart disease (CHD) would have been halved. The phenomenon exists in developing societies across the normal birth weight range, which averages 1 kg less than in developed societies. Probably those at greatest risk throughout the world belong to transitional societies, in which, for example, children from agrarian societies in the developing world move to cities as adolescents. These considerations may explain the epidemic in CHD and in type 2 diabetes that is developing, for example, in the Indian subcontinent.[19] It has been proposed that developmental responses (e.g., of the fetus) might give offspring a survival advantage in the postnatal environment in which it predicts that it will live. By definition such predictive adaptive responses occur within the normal range of fetal growth and development, and they must use processes by which development is influenced by the prenatal environment in all pregnancies (e.g., maternal constraint).[20] A greater risk for disease may result when the postnatal environment does not match that which was predicted prenatally.[21]

GENES VERSUS ENVIRONMENT

Many reasons exist for believing that the effects just described are not purely genetic in origin; the most obvious is that changes in the incidence of the metabolic syndrome within a generation cannot be due purely to genetic (heritable) traits. Moreover, the maternal and paternal genetic contributions to fetal growth (see later discussion) and to outcome measures such as systolic blood pressure in adulthood, are highly dissimilar; in a study of adults in Preston, United Kingdom, systolic pressure was inversely related to maternal but not to paternal birth weight.[22] In pursuing the mechanisms underlying programming of cardiovascular function in relation to growth, it is therefore important to consider the interaction between the genome and the early environment in determining a phenotype that is susceptible to disease. This argument is substantiated by the discovery of numerous processes that modify genomic DNA, gene expression, and thus the production of the proteins that confer the phenotype. These include not only single-nucleotide polymorphisms, DNA methylation, and changes in histone structure that alter gene expression but also the many transcription factors that act to modify gene transcription and the processes that control the half-life of mRNA.

A good example of the interaction between genotype and the early environment is provided by studying peroxisome proliferator-activated receptor-gamma (PPAR-γ), a nuclear hormone receptor that mediates the effect of synthetic and endogenous ligands on the modulation of gene expression. Polymorphisms in the PPAR-γ2 gene are associated with type 2 diabetes. Moreover, the well-documented link between low birth weight and insulin resistance is seen only in subjects with PPAR-γ gene polymorphism.[23] Dennison and colleagues[24] have shown a similar relationship between the programming of osteoporosis, known to be inversely related to birth weight, and a polymorphism in the vitamin D receptor gene.

The processes most likely to be involved in mediating the maternal versus paternal genomic effects on development involve imprinting. Of the range of genes that are imprinted, the *H19/IGF2* cluster has received particular attention.[25] The insulin-like growth factor II (IGF-II) peptide, which is paternally expressed, is a potent stimulator of fetal cell division and differentiation—showing how the paternal genome drives growth in various key tissues, such as the fetal liver and growth and nutrient transport in the placenta.[26] The type II IGF receptor, which is maternally expressed, serves as a clearance receptor that modulates IGF-II peptide action in the tissues—showing how the maternal genome can down-regulate growth in accordance with the maternal body habitus. This observation is consistent with the concept of maternal constraint of fetal growth, which was highlighted by the pioneering studies of Walton and Hammond in which Shire horses were crossed with Shetland ponies.[27] It is therefore clear that the trajectory of growth in early life is determined by maternal and environmental factors acting to regulate the gene expression of the early embryo. First trimester growth in the human sets the trajectory for later fetal growth and predicts risk of low birth weight.[28] Similar epigenetic processes are now believed to provide a mechanism whereby undernutrition during development can influence gene expression and cardiovascular or metabolic phenotype into mature adulthood (see "Mechanisms").[29] Of importance, these processes involve not simply imprinted genes but a much wider range of the genome, which appears to be under graded epigenetic control throughout development.[30]

ENVIRONMENTAL STIMULI

In investigating the interaction between gene and environment it is important to take a lifespan perspective in considering the influence of maternal diet, body composition, social status, smoking, the effect of the tubal and uterine fluid environment on the early embryo, the development of the placenta, fetal adaptations, and postnatal effects which may exacerbate the problem.

Timing

Each organ has a timetable for development, so it is not surprising that the timing of environmental stimuli will influence the effects on offspring phenotype. In adults who were in utero at the time of the Dutch Winter Famine (an abrupt onset 5-month period of malnutrition in 1944 to 1945), exposure during early gestation was associated with increased incidence of CHD[31,32] and increased blood pressure response to stress,[33] and exposure to famine in midgestation was associated with microalbinuria in adults, possibly indicative of hyperfiltration injury as a result of fewer nephrons.[34] Mid- to late gestation undernutrition was associated with reduced glucose tolerance in adulthood.[35] Sheep are widely used as an animal model for studying the programming phenomenon, not least because they share similarities with humans in that the full complement of cardiomyocytes and renal glomeruli are formed prenatally. Studies support the concept that the early gestation

nutrient environment is important in determining later cardiovascular control,[36-39] whereas nutrition in the late gestation period may be important in determining later metabolic function and endocrine control.[40-42] The rat model has been widely used for studying programming phenomena (reviewed by Brawley[43] and Armitage[44] and their associates). Most previous studies with this model involved administration of the diet for the whole of pregnancy (approximately 21 days), and now a range of studies shows that offspring of rats fed a low-protein diet during pregnancy have altered endothelial function (e.g., the degree of relaxation to the endothelium dependent vasodilator acetylcholine). However Kwong and colleagues[45] have also shown that administration of a low-protein diet to rat dams in the first 4 days of gestation (i.e., preimplantation) produces blastocysts that have altered allocation of cells to the trophectoderm and inner-cell mass and to offspring with permanently increased blood pressure in adult life. Recent work suggests that feeding rat dams this low-protein diet exclusively during oocyte maturation leads to altered behavior and cardiovascular control in postnatal life.[46] Further observations in the mouse have shown that embryos transferred to recipient females mice developed elevated blood pressure in adult life.[47] Apart from demonstrating the importance of the early preimplantation embryonic environment in the programming of subsequent phenotype, these studies raise important questions about the long-term effects of reproductive technologies increasingly used in humans.[48] Additional evidence suggests that even prepregnancy maternal nutrient environment can influence cardiovascular function.[49,50]

Nutrients

The relative contribution of specific macro- or micronutrients in determining the balance between supply and demand during fetal growth has not yet been resolved. The fetal requirements in late gestation for the amino acid glycine are greater than any other amino acid, even though this amino acid is not normally considered to be essential. Glycine provision, with the availability of the micronutrient cofactor folate, is important in a range of biological processes that may alter cardiovascular function (Figure 71-1). It is involved in the synthesis of DNA and RNA that is important for cell growth and differentiation. It provides a source of methyl groups for the methylation of CpG dinucleotides, which silences gene transcription and thus the transition from genotype to phenotype.[29] An example of such methylated genes with an important role in the pathogenesis of cardiovascular disease is the estrogen receptor-α, which is linked to risk of atherosclerosis. Finally, glycine is important in the interconversion of homocysteine to methionine, such that its deficiency (or that of vitamin B_{12}) leads to accumulation of homocysteine in the plasma and associated vascular damage. The offspring of low protein–fed rat dams show elevated plasma homocystine levels. In rats, the addition of glycine, or indeed folate, to the low-protein diet prevents the elevation of blood pressure in the offspring and the development of vascular dysfunction in these offspring.[51,52] In the liver, hypomethylation of glucocorticoid receptor (GR) and PPAR-α promotors was also prevented by addition of folic acid to the diet.[29]

The major provision of fetal glycine is not by direct transport from the mother. Placental glycine production from the conversion of serine by the serine hydroxymethyltransferase is now thought to be important in sheep, but not in humans, in whom serine hydroxymethyltransferase activity is low.[53] The serine itself enters the placenta from the maternal and fetal circulation via system A and ASC transporter systems.[54,55] Placental size relates not only to fetal growth but also to blood pressure in later life.[56] However, relatively few studies have been performed on placental transport function in relation to fetal growth and outcome.[26] It is of interest that placental system A activity increases with reductions in birth weight in the normal range[57] although an association exists between reduced system A activity and intrauterine growth retardation.[58] A deeper understanding of the complex mechanisms by which amino acids are transferred is crucial.[59]

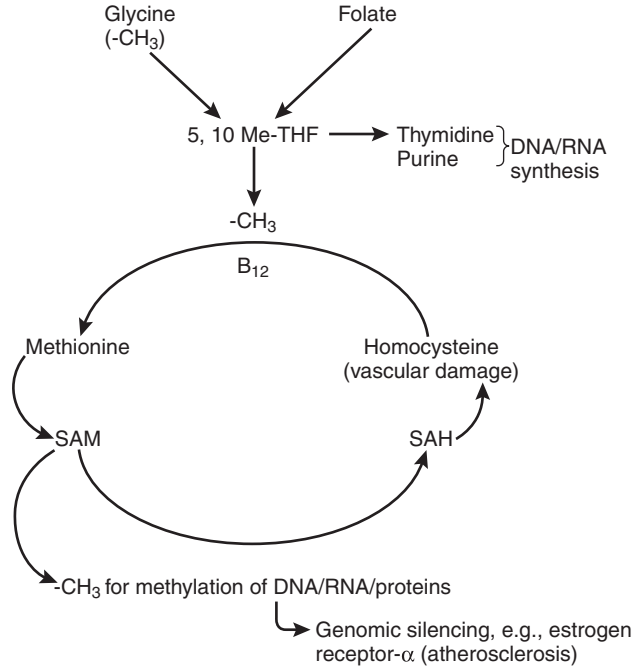

Figure 71-1 Diagram to illustrate the importance of glycine and folate in the processes that may underlie atherosclerosis. *B_{12},* Vitamin B_{12}; *-CH_3,* methyl group; *Me-THF,* methyl tetrahydrofolate; *SAH, S*-adenosyl-L-homocysteine; *SAM, S*-adenosyl-L-methionine.

FETAL ADAPTIVE RESPONSES

The incidence of singleton pregnancies in sheep allows the comparison of fetal growth patterns with human pregnancies, and their size and tolerance to surgery permits cardiovascular and growth measurements to be made during several weeks of gestation. However, studies of the fetal adaptations to perturbed nutrition are relatively few in number. The well-established "brain-sparing" cardiovascular phenomenon, in which a higher percentage of the combined ventricular output is directed to the brain at the expense of the developing fetus, has been demonstrated extensively in hypoxic fetuses. Brain-sparing is associated in the human fetus with late gestation asymmetric growth retardation, and the supposition has been that, if such fetuses are not hypoxic, the response is to reduced nutrition. The rapid phase of the vasoconstrictor component of the response to hypoxia is mediated by the carotid bodies; therefore it is of great interest that these chemoreceptors are also responsive to a reduction in plasma glucose in adults,[60] and recent data suggest that the differential fetal organ growth effects of maternal undernutrition is dependent on carotid sinus innervation.[61] Understanding of the fetal redistribution requires consideration of effects on individual organs, and one of particular interest is the developing fetal liver. Blood supply to the liver comes from a range of sources, primarily the oxygenated and highly nutritious blood from the umbilical vein. However, this blood entirely supplies the left lobe of the liver and, to a lesser extent, the right lobe, which also receives blood from the hepatic portal veins and the hepatic arteries (which is less well oxygenated and nutritious). A proportion of oxygenated umbilical blood is shunted through the

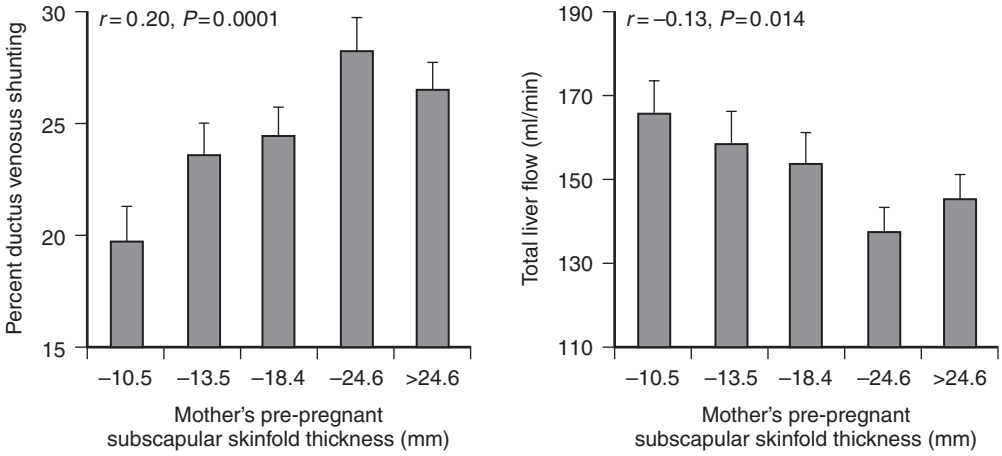

Figure 71-2 Data from 381 fetuses at 26 weeks gestation showing lower ductus venosus shunting and greater total liver blood flow in those mothers who had lower skinfold thicknesses before pregnancy. Maternal subscapular skinfold thickness is grouped into strict fifths of the distribution for presentation purposes; correlation analyses are based on continuously distributed variables. *(From Haugen G, Hanson M, Kiserud T, et al: Fetal liver-sparing cardiovascular adaptations linked to mother's slimness and diet. Circ Res 96,12, 2005.)*

ductus venosus towards the foramen ovale and through into the left atrium. The degree of shunting of this blood changes during gestation and is altered by challenges such as acute hypoxemia.[62] It is now known that the degree of shunting is also increased in late gestation fetuses of mothers with a high prepregnancy body mass index (BMI) or skinfold thickness[63] (Figure 71-2) and that low maternal weight gain is associated with preferential blood supply to the fetal left liver lobe and with higher birth weight and neonatal ponderal index.[64] This therefore fits with the notion that women with greater fat stores, or with altered endocrine status leading to increased body fat mass, produce fetuses with a more rapid trajectory of growth, at least in early gestation. If this growth imposes demands on the developing placenta that cannot be met, fetal cardiovascular redistributions must occur.

The extent to which concomitant changes in cardiovascular control and growth result from perturbations in the fetal nutrient supply line is unclear. Reduced maternal body condition at mating results in an elevated fetal blood pressure trajectory in late gestation fetuses[65] and the normal developmental increase in arterial pressure during late gestation in sheep is perturbed in small fetuses.[66] Restricted fetal nutrient supply by removal of placental caruncles before conception perturbs cardiovascular development and function in late gestation fetuses—with or without growth restriction.[67] Moreover, mild-moderate (15% to 30%) reduction in maternal nutrient intake for the first half of gestation lowered blood pressure in late gestation fetuses,[68] impaired vascular function in vitro[69] and enhanced the increase in peripheral vascular resistance in the hind limb in response to acute hypoxia,[36] with no change in fetal organ or body weight. Preliminary data (unpublished) in these fetuses indicate a redistribution of combined ventricular output in late gestation because baseline femoral blood flow tends to be lower and carotid blood flow tends to be elevated. Indeed recent data indicate that the prevailing glycemic environment (unknown etiology) of the fetus can influence its cardiovascular response to acute hypoxia[6] and that lower circulating blood glucose in late gestation is associated with greater vasoconstrictor activity in isolated vessels.[70] In addition, the fetus can make immediate cardiovascular adaptations to hypoglycemia, including a decrease in blood flow to the femoral bed, and this response is heightened by previous exposure to a restricted maternal diet around implantation.[71] Specific early-gestation moderate (30%) reduction of maternal protein intake markedly exacerbated the vascular dysfunction of isolated fetal resistance vessels[72] (Figure 71-3), indicating the importance of nutrient balance (see previous). Cleal and colleagues[73] recently observed that 50% maternal nutrient restriction for 31 days after conception increases fetal thymus and pancreas weight at midgestation. Undernutrition of a greater intensity leads to decreased fetal size, but the response depends on the rate at which growth is occurring: The growth of a rapidly growing fetus is slowed, whereas slow-growing fetuses fail to respond.[74] Such fetuses may have adapted to an earlier gestation insult, such as periconceptional undernutrition,[75] thereby protecting them from a subsequent late gestation challenge. These observations suggest that cardiovascular adaptations may be able to buffer changes in growth when faced with an altered nutrient supply, but it may be that when the upper limit in this buffering capacity has been reached, a change in growth will result. However, the same investigators also observed that undernutrition in early gestation did not alter size at birth but did cause a faster growth rate in the first 12 weeks after birth.[73] This concept fits with the epidemiologic observations that adult blood pressure is inversely related in a graded manner across the normal birth weight range[15] (see previous) but also that postnatal growth needs to be considered. Recent studies show that either periimplantation or late gestation maternal undernutrition decrease late gestation fetal myofiber density and that this is associated with decreased capillary density (Figure 71-4), and in the late restricted group with altered molecular markers of glucose uptake,[76] these changes are specific to the muscle bed. Overall these studies reinforce the idea that timing of undernutrition is important and highlight that to understand the link between growth and blood supply, mechanisms at the tissue level need to be considered along with hemorrheic control. Thus fetal adaptations, in the face of altered partitioning of nutrients between the maternal body, the placenta, and the fetus, may be beneficial in customizing fetal growth and development to the supply of oxygen and nutrients, but they may have long-term sequelae postnatally (see previous).

Prenatal and Postnatal Environmental Mismatch

Fetal growth and cardiovascular responses may be part of a survival strategy, or they may be of no immediate benefit, but rather be predictive adaptations in expectation of the postnatal environment. Current concepts suggest that, if these predictions are not met, and the pre- or postnatal nutritional environments are

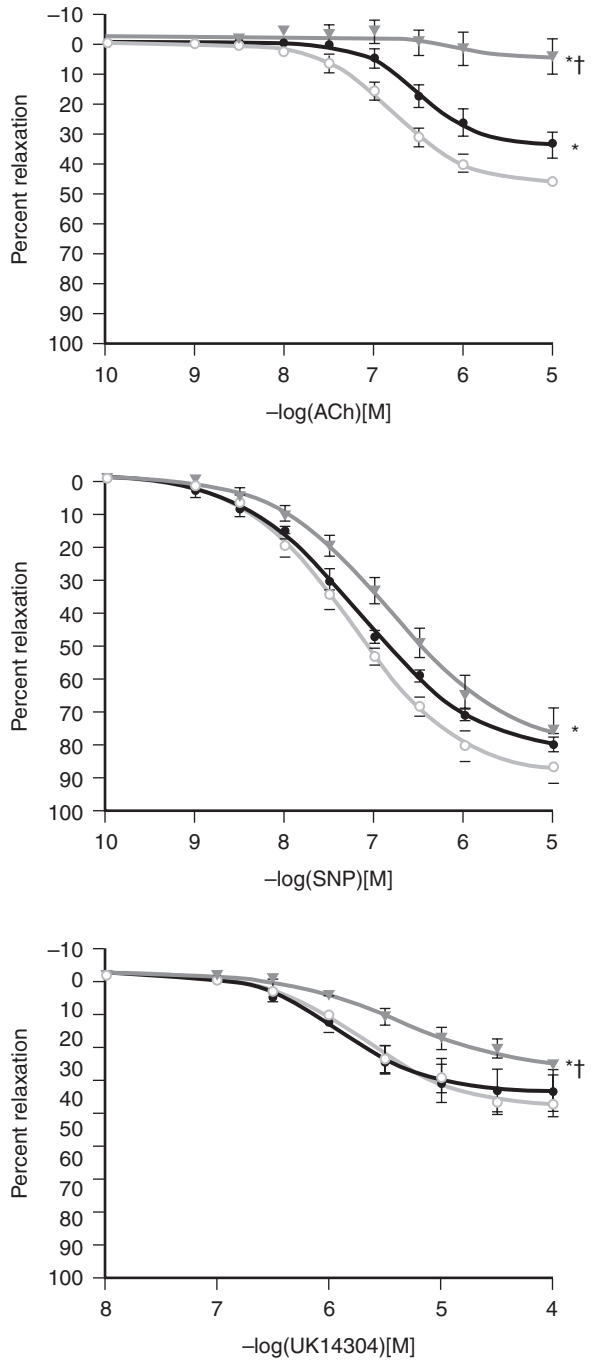

Figure 71-3 Vasorelaxation to acetylcholine (ACh), sodium nitroprusside (SNP) and UK14303 (α_2-adrenoceptor agonist) in femoral arteries of fetuses from control and nutrient restricted ewes. Data are expressed as a percentage of initial preconstriction. Values are mean ± SEM in control (○), 70% global (●), and 70% protein (▲) fetuses. *$p < .05$ (ANOVA), significantly different from control; † $p < .05$ (ANOVA), significantly different from global group. *(From Nisbina H, Green LR, McGarrigle HH, et al: Effect of nutritional restriction in early pregnancy on isolated femoral artery function in mid-gestation fetal sheep,* J Physiol *553:637, 2003.)*

mismatched, the risk of disease increases.[77] Indeed the window of opportunity for programming of cardiovascular function in early life does not stop at birth. The Helsinki study[78] showed that the effect of low ponderal index at birth on the risk of CHD in adulthood in men was amplified by increasing BMI during the first 12 years of life. Considerable interest exists about the effects of obesity in childhood (which in western societies may be 20% of children younger than 12 years of age and in the United Kingdom may affect 1 in 4 children younger than 16 years by 2050[79]) on risk for later disease. In addition, rat studies show that severe undernutrition during fetal life programs offspring, which are hyperphagic, obese, and insulin-resistant and demonstrate reduced physical activity.[80,81] This suggests a compounding of fetal programming effects by postnatal adaptations. In female sheep, early postnatal nutrient restriction (12 weeks of moderate intensity) improved later glucose handling through increased insulin sensitivity.[41] In men, this postnatal undernutrition altered cardiovascular function, but not if they were also exposed to a poor nutritional environment in early gestation and the effects of prenatal undernutrition of cardiovascular dysfunction were not seen when the early gestation nutrition was also poor.[38,39] In rats, dietary manipulation to minimize the mismatch between pre- and postweaning nutrition minimizes endothelial dysfunction, low heart rate, and the disruption of mechanisms regulating appetite and energy expenditure in offspring.[82,83] In sheep and rats, a greater pre- and postnatal dietary mismatch worsened the liver function and metabolic profile in offspring,[84] and in rats decreased lifespan.[85] In pigs, the coronary atherosclerotic effects of a high-fat diet were prevented by previous feeding of a similar diet to the pregnant mother.[86] Together, these studies support the concept that a greater mismatch between the pre- and postnatal nutrient environment increases the risk of later disease, including of the cardiovascular system, in an individual.

THE TRANSDUCTION OF ENVIRONMENTAL STIMULI

Cardiovascular adaptations of the mother to pregnancy provide another potential route whereby dietary or endocrine stressors may be transmitted to her fetus. The increase in blood volume and cardiac output during pregnancy[87] involves a redistribution of cardiac output in favor of the reproductive tract. In humans this is mediated primarily by a dramatic decrease in resistance in the spiral arteries supplying the endometrium, but there is an additional component of vasodilatation in the uterine bed provided by vascular endothelial growth factor/nitric oxide (NO) mechanisms.[88] Ahokas and colleagues[89] observed that with dietary restriction in the rat dam (50%), maternal liver blood flow was maintained at the expense of the pregnant uterus. In the low protein–diet rat model, Itoh and colleagues[90] found an impaired vasodilator response to vascular endothelial growth factor in late pregnancy uterine arteries in vitro. Innes and colleagues[91] recently reported a negative association between a women's birth weight and the risk of gestational diabetes mellitus. This effect persists after adjusting for gestational age and current BMI. Similarly, in hypertensive rat offspring of protein restricted dams, Brawley and colleagues[92] found a blunting of mesenteric vasodilator responses to acetylcholine. This effect clearly persists in the female offspring when they become pregnant, despite their adaptations to pregnancy, and even though they had not been exposed to any dietary challenge during postnatal life or pregnancy itself (unlike their mothers).[93]

Considerable work has been conducted on the mechanisms by which dietary imbalance in pregnancy may be transmitted to the fetus. Unraveling the relative contribution of the key mechanisms is likely to be complicated. Evidence is emerging to suggest that the fetal cardiovascular system may be able to respond to changes in nutrients other than oxygen and that this may be coordinated by the carotid chemoreceptors, which mediate rapid fetal cardiovascular adaptations to hypoxia and are responsive to reductions in circulating plasma glucose.[60,61,94] Thus common mechanisms of detection of changes in substrate (e.g., glucose) and oxygen may exist. Evidence from cultured rat hepatocytes indicates that regulation of glucagon receptor, insulin receptor, and L-type

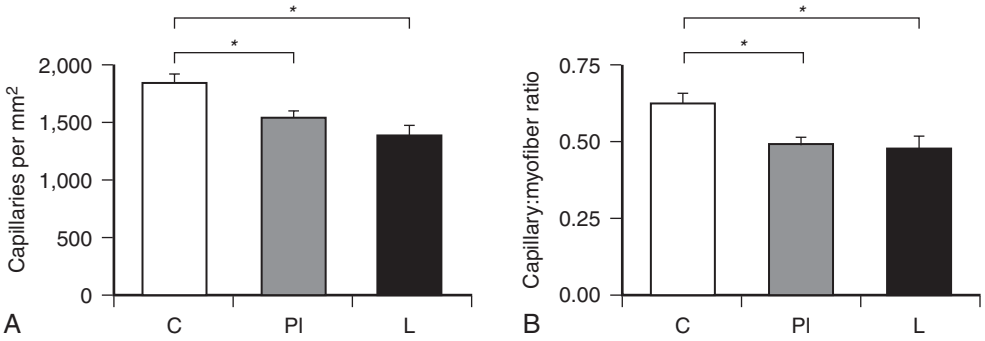

Figure 71-4 Capillary density and capillary:myofiber ratio in the triceps brachii muscle of late gestation fetuses. **A,** Capillary density and **B**, capillary:fiber ratio in control (*C*; $n = 6$), peri-implantation restricted (*PI*; $n = 9$), and late restricted (*L*; $n = 6$) groups. $^*p < .05$. *(From Costello PM, Rowlerson A, Astaman NA, et al: Peri-implantation and late gestation maternal undernutrition differentially affect fetal sheep skeletal muscle development,* J Physiol *586:2371, 2008.)*

pyruvate kinase gene expression by glucose and oxygen may be due to cross-talk between hypoxia inducible factor-1 (HIF-1) and glucose-responsive transcription factors at the glucose response element and hypoxia response element.[95] Otherwise, at the most basic level, a change in the quantity of a dietary component may have direct implications on the amount of substrate that is available for fetal metabolism, but maternal body composition (see previous) and maternal metabolic demands as well as placental metabolic demands have to be taken into account. An additional consideration is of the multiple genes and proteins that may respond simultaneously to altered nutrition—analogous to the 14-protein "stimulon" induced by glucose depletion in *Escherichia coli.*[96] As the available evidence indicates, the expression of a variety of genes, implicated in cardiovascular control and growth during fetal life, can be modulated by the direct action of nutrients; for example, IGF-II gene expression in cultured beta cells is regulated by glucose.[97] During fetal life, glucose appears to regulate *IGF-2* directly, but its effect on IGF-I is likely to be mediated by insulin.[98] Glucose activation of plasminogen activator inhibitor-1 gene expression in cultured rat vascular smooth muscle cells,[99] and of the osteopontin gene,[100] may be of relevance to vascular complications in patients with diabetes. High glucose stimulates angiotensinogen gene expression in rat kidney proximal tubular cells, mediated in part by the generation of reactive oxygen species.[101]

Currently much interest exists in fetal exposure to increased levels of glucocorticoid from the standpoint of the clinical use of steroids in pregnancy but also the potential "stress" experienced concomitant with altered nutrition. Glucocorticoids reduce fetal growth[102] and impact on the human platelet antigen hypothalam-pituitary-adrenal (HPA) axis of the developing fetus itself,[103] and administration in specific early gestation periods lead to postnatal hypertension, which persists into mature adulthood.[104] Glucocorticoids may mediate effects of altered maternal nutrition including via interaction with the expression of other genes,[105,106] NO signaling pathways,[107] and effects on DNA methylation.[108] Although some evidence is available that nutrient restriction in guinea-pigs elevates maternal plasma cortisol[109] and a high-fat diet in rats is associated with stimulation of the HPA axis,[110] but recent findings suggest that maternal cortisol is lower during undernutrition in early gestation,[73,111] and it has not been shown unequivocally in animals that altered maternal nutritional balance alters the level of plasma glucocorticoid in fetal life.[112,113] Even in the absence of such an elevation in maternal glucocorticoid the fetus may be exposed to greater levels of steroid as a result of a reduction in placental 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2).[114] In addition, at least in the hypertensive offspring of rat dams fed a low-protein diet, the tissue levels of GR are elevated and 11β-HSD2 activity is reduced, thereby exposing the tissues to greater levels of active steroid. Corresponding effects on 11β-HSD1 are not seen (reviewed in[115]). Finally, evidence for increased action of glucocorticoid tissues comes from the observation that glucocorticoid-responsive gene expression (e.g., Na^+,K^+-adenosine triphosphatase) is altered in programmed offspring.[115] The effect of gestational protein restriction on GR protein expression is greatest in the kidney This develops postnatally from 2 to 12 weeks, with similar effects seen in the liver and lung but not in the heart. In addition, despite no evidence of elevated late gestation fetal cortisol levels (at least in the sheep), fetal HPA axis responsiveness is altered after early gestation maternal nutrient restriction—although it is reduced, rather than being enhanced as predicted.[36] However, these observations are coupled to a reduction in GR messenger RNA in the pituitary in the "programmed" late gestation sheep fetuses,[116] and the implied reduction in feedback inhibition of the HPA axis is consistent with the hyperresponsiveness of the HPA axis seen in offspring from this sheep cohort at 3 months of age[36] and in adult men who were of a low birth weight studied in the Hertfordshire cohort.[117]

MECHANISMS

Several decades of work have contributed to current understanding of the mechanisms that underlie fetal cardiovascular control and growth under baseline conditions and during hypoxemia; such mechanisms include carotid chemoreflex mechanisms, hormonal factors (e.g., catecholamines, arginine vasopressin, adrenocorticotropic hormone, cortisol, angiotensin, the IGF system), and local mechanisms such as NO and endothelin-1.[3] The extent to which similar mechanisms mediate the fetal response to altered nutrition has not yet been fully elucidated. Likely candidates include components of the HPA axis, renin-angiotensin system and the IGF axis. Similar to the HPA axis (see previous), evidence exists that the fetal and postnatal renin-angiotensin system (RAS)[118-122] and IGF axis[123] are "programmable" by altered substrate supply during pregnancy. Indeed evidence is emerging that gestational dietary effects on angiotensin receptor expression in rats may be mediated via altered methylation in the promoter region.[124] The role of the kidney is uncertain because although studies in rats show that gestation-long protein restriction[125] or pharmacologic doses of dexamethasone[126] in early gestation sheep leads to postnatal hypertension and reduced nephron number, recent data find no evidence that periods of undernutrition in early or late gestation alter kidney structure or function in late gestation.[127,128] Fetal cardiovascular control (see earlier under "Fetal Adaptive Responses") and growth may be related in a graded manner in the face of altered nutrient supply. It is therefore conceivable that there are common mechanisms

integrating their control—a concept that is consistent with the dual roles for substances like AngII, IGF-I, and cortisol in cardiovascular control and growth.[3]

Ongoing postnatal studies in animals focus on the mechanisms by which programming alters peripheral vascular function. The observation that small resistance vessel responses to endothelium-dependent vasodilators, such as acetylcholine and bradykinin, are impaired in offspring of rat dams fed a low-protein diet during gestation[92] are supported by our finding that both basal and acetylcholine-stimulated NO release is reduced in the mesenteric arteries of such offspring.[92,129] Using global undernutrition during pregnancy, rather than the low-protein diet, Franco and colleagues[130] have shown that the adult offspring have reduced endothelial NO synthase activity and mRNA in the aorta. Feeding rat dams a diet high in soy isoflavones improves endothelial function and increases endothelial NO synthase and antioxidant gene expression in offspring.[131] Estrogen, acting via its α receptor, has a well-established vascular protective role mediated in part by its effects on NO production.[132] Endothelial responsiveness mediates flow-mediated vasodilatation in many vascular beds, and this can be studied in humans by techniques such as forearm plethysmography.[133] Such methods have demonstrated reduced flow-mediated vasodilatation with lower birth weight in adults[134] and an effect that is comparable to that of smoking. Similarly, endothelium-dependent vasodilator responses in the leg are reduced in obese persons with type 2 diabetes compared with control subjects.[135] Disorders of endothelial function predispose affected persons to atherosclerosis and hypertension. In adult sheep, vasoconstrictor tone after peri-implantation undernutrition was mediated in part by increased expression of myosin light-chain kinase expression, and the effect was minimized when the mismatch between the prenatal and postnatal nutrient environments was minimized.[39]

Mounting evidence suggests that epigenetic alterations may underlie many of the persistent effects of changes in the early nutrient environment on later cardiovascular phenotype. In sheep, depletion of B vitamins (B_{12} and folate) and methionine within normal ranges from the periconceptional diet of ewes led to widespread altered DNA methylation in the liver of adult offspring with associated elevated blood pressure.[136] In rat offspring evidence exists that hypomethylation of specific hepatic genes by a low-protein maternal diet can be prevented by folate supplementation.[29] It may be of great importance that grandchildren of the mothers exposed to a dietary impairment during pregnancy also show impaired vasodilator function.[93] This defect may depend more on endothelium-derived hyperpolarizing factor than on NO-mediated mechanisms and in this respect is similar to other models of hypertension in the rat.[137] This is potentially an extremely important observation because it demonstrates that programmed effects on vascular function can be passed in a transgenerational fashion, even in the absence of additional dietary or other stressors. Recently, similar transgenerational programming of risk for diabetes has been demonstrated for the male lineage.[138] The mechanisms underlying such transmission are not known, although it is of interest that the DNA methylation processes that mediate imprinting are known to be passed at least from mother to offspring,[139] and altered methylation of rat hepatic gene promotors (e.g., PPAR-α, GR) induced in the F1 generation by a maternal low-protein diet are transmitted to the F2 generation.[140] The implications of such findings for medicine are extensive, not least for the use of family linkage analysis in tracing the origins of diseases such as CHD.

CONCLUSION

The formation of the Developmental Origins of Health and Disease Hypothesis has made it necessary to take a new perspective on the mechanisms underlying fetal cardiovascular control. Moreover repeated demonstration of the association between size at birth and adult cardiovascular disease necessitates looking more closely at the link between cardiovascular control and growth during fetal life. A number of candidate mechanisms have been suggested from work in the field of fetal hypoxia, and in fact certain components of the renin-angiotensin system, HPA axis, and IGF system share physiologic endpoints in the regulation of cardiovascular control and growth. Work has begun on determining whether fetal growth and cardiovascular control are related in a graded fashion in the face of altered nutrition; this research is likely to be crucial to elucidation of fetal programming. The emergence of new concepts that it is the degree of mismatch between the pre- and postnatal nutrient environments that determines cardiovascular disease risk will be key to understanding the longer-term implications of such fetal adaptations and to the development of future intervention strategies to prevent disease in later life.

Physiology of Nitric Oxide in the Developing Lung

Since the recognition of nitric oxide (NO) as an important endogenous mediator of vasorelaxation in 1987,[1,2] its role in the regulation of pulmonary vasomotor tone has been intensively investigated. Because the successful transition from fetal placental dependence to survival at birth requires that pulmonary vascular resistance (PVR) rapidly declines and pulmonary blood flow increases,[3-6] the role of endogenous NO production in the fetal and newborn lung circulation has received considerable attention over the last 15 years. In particular, the physiology of NO-mediated vasoregulation in the fetal and neonatal lung has been of keen interest to developmental lung biologists because of the life-threatening clinical disorder of persistent pulmonary hypertension of the newborn (PPHN). Moreover, laboratory and clinical studies have also shown that, in addition to its effects on reducing pulmonary artery pressure, other beneficial effects of inhaled NO (iNO) may include improvements in ventilation-perfusion matching; decreasing lung inflammation and oxidant stress; and favorably modulating angiogenesis, growth, and extracellular matrix deposition in the immature lung. Thus considerable interest also exists in the potential role of iNO in premature newborns with respiratory failure. In this chapter we review the physiologic role of endogenous NO production in the fetal and transitional pulmonary circulation, the normal ontogeny of NO synthase (NOS) isoform expression in the fetal lung and alterations observed in animal models of PPHN and bronchopulmonary dysplasia (BPD), the effects of iNO on the lung of the term and preterm newborn, and the current clinical role of iNO.

ENDOGENOUS NITRIC OXIDE: FETAL AND TRANSITIONAL VASOREGULATION

Vasomotor tone in the fetus is modulated by both vasoconstrictor and vasodilator substances. The role of vasodilator substances such as NO has been of particular interest because of its role in

the marked pulmonary vasorelaxation that must occur at birth to assure a successful transition from fetal to neonatal life. NO was recognized as a potent vasodilator as early as 1979,[7] and in 1980 Furchgott and Zawadzki[7a] reported that acetylcholine-induced vasorelaxation was dependent on an intact endothelium through the elaboration of an endothelial-derived relaxing factor (EDRF) that diffused to the subjacent vascular smooth muscle.[1] In 1987 investigators from two separate laboratories reported that the biologic activity of EDRF was identical to that of NO or an NO-containing substance. Palmer and colleagues[1] induced the release of EDRF from porcine aortic endothelial cells in culture and compared the effects on superfused aortic strips with those of NO in solution. They found that the effects of EDRF were indistinguishable from those of NO. Ignarro and colleagues[2] used a bioassay cascade superfusion technique with intrapulmonary arteries and veins, identified EDRF pharmacologically and chemically as NO, and found that EDRF and NO produced similar vasorelaxation and were inhibited by common antagonists. Ignarro and colleagues[2] also recognized that NO was inactivated by combining with hemoproteins and speculated that hemoglobin could trap endogenously produced NO that diffused into the vascular lumen, thus preventing any "downstream" vasorelaxation by this paracrine mediator.

In mammalian cells, NO is produced from the terminal guanidino nitrogen of L-arginine on its conversion to L-citrulline by the enzyme NOS in a reaction that requires molecular oxygen.[8] NOS is a family of enzymes that includes three major isoforms known as neuronal NOS (nNOS), inducible NOS (iNOS), and endothelial NOS (eNOS).[9-15] The three isoforms, nNOS, iNOS, and eNOS, are also referred to as NOS-I, NOS-II, and NOS-III. The activity of nNOS and eNOS is calcium dependent, whereas the activity of iNOS is calcium independent.[10] nNOS and iNOS are primarily found in the soluble fraction, whereas eNOS is primarily in the membrane fraction, particularly in specialized signaling microdomains on the plasma membrane called caveolae.[16] All NOS isoforms are homodimers of subunits that range between 130 and 160 kDa.[17] nNOS and eNOS expression were first thought to be primarily constitutive in nature, whereas the expression of iNOS is initiated by cytokines.[10,18]

The recognition that the endogenous production of this EDRF-NO mediator could be competitively blocked by modified L-arginine analogues prompted early experiments into the effects of NO in the fetal and transitional pulmonary circulation. The earliest studies were performed in fetal lambs because the relatively large size of the ovine fetus allows for instrumentation with catheters to monitor vascular pressure and electromagnetic or ultrasound probes to monitor blood flow. Moreover, the ovine fetus is a suitable candidate for such experiments because operating on the fetus does not induce parturition, as commonly occurs in primate models. Abman and colleagues[19] performed the first experiments on the role of EDRF in the ovine model, demonstrating that endogenous EDRF-NO production modulates basal pulmonary vascular tone in the late-gestation fetus and that pharmacologic NO blockade inhibits endothelium-dependent pulmonary vasodilation. These investigators also showed that pharmacologic NO blockade attenuates the rise in pulmonary blood flow at delivery, thus implicating endogenous NO formation in postnatal adaptation after birth and linking this laboratory observation to the life-threatening clinical condition of PPHN (Figure 72-1). In addition, experiments using this ovine model showed that increased fetal oxygen tension augments endogenous NO release,[20,21] and the increase in pulmonary blood flow in response to rhythmic distention of the lung and high inspired oxygen concentrations are mediated in part by endogenous NO elaboration.[22]

Of interest, the major NOS isoform responsible for modulation of basal pulmonary vascular tone in the fetus and pulmonary vasodilation at birth may not be eNOS (NOS type III). Studies have shown that the iNOS isoform (NOS II) is expressed in airway epithelium and vascular smooth muscle in the late-gestation ovine fetus.[23] Moreover, in the late-gestation ovine fetus, selective inhibition of iNOS increases basal PVR, reduces shear stress–induced pulmonary vasodilation, and attenuates NO-mediated pulmonary vasodilation at birth.[24-26]

In contrast to the condition in the mature fetus, indirect evidence exists that *endothelium-dependent* pulmonary vasodilation in the premature pulmonary circulation is diminished until late in gestation. Acetylcholine and increased oxygen tension cause marked pulmonary vasodilation in the late-gestation ovine fetus, but dilator responses to these stimuli are decreased in the premature fetus.[27-29] Because acetylcholine and oxygen-induced fetal pulmonary vasodilation are partly mediated by endogenous NO formation, it appears that endogenous NO activity increases with advancing gestational age.[20-22] Similarly, no differences were found in relaxation of ovine fetal pulmonary artery rings compared with adult rings when both were exposed to an endothelium-independent vasodilator (sodium nitroprusside), but maturational changes in vasorelaxation were observed with endothelium-dependent vasodilators.[30]

NITRIC OXIDE SYNTHASES IN THE DEVELOPING LUNG

The cellular distribution of the three NOS isoforms has been evaluated in parallel, isoform-specific immunohistochemical analyses in developing ovine lung. In third-trimester fetal lung eNOS was found in vascular endothelium as expected, but it was also markedly abundant in bronchial and proximal bronchiolar epithelium. eNOS was not detected in terminal or respiratory bronchiolar epithelium or in alveolar epithelium. Similar to eNOS, iNOS protein was detected in bronchial and proximal bronchiolar epithelium but not in alveolar epithelium. However, iNOS was also expressed in terminal and respiratory bronchioles. nNOS protein was found in epithelium at all levels including the alveolar wall. In addition, positive immunostaining was found for iNOS and nNOS in airway and vascular smooth muscle. The cellular distribution of all three isoforms was similar in fetal, newborn, and adult ovine lung, and the observations made in the epithelium by immunohistochemistry were confirmed by isoform-specific reverse transcriptase–polymerase chain reaction assays and reduced nicotinamide adenine dinucleotide phosphate diaphorase histochemistry.[25] More recent studies in lungs from late-gestation fetal baboons have yielded similar findings, demonstrating that nNOS, eNOS, and iNOS are primarily expressed in the airway epithelium in the fetal primate.[31] Thus the three NOS isoforms are abundant and commonly expressed in proximal lung epithelium, and they are differentially expressed in distal lung epithelium. All three isoforms may be important sources of pulmonary NO throughout lung development.

Maturational changes in NOS isoform expression in the lung have also been delineated. The ontogeny of eNOS and nNOS expression was first determined in lungs from fetal and newborn rats. Both eNOS and nNOS proteins were detectable in 16-day fetal lung; they increased four-fold and three-fold, respectively, to maximal levels at 20 days gestation (term = 22 days); and they fell after birth (1 to 5 days). In parallel with the findings for eNOS protein, eNOS messenger RNA (mRNA) levels assessed with use of semiquantitative reverse transcriptase–polymerase chain reaction were increased from 16 to 20 days gestation and fell after birth. In contrast, nNOS mRNA abundance declined during late fetal life and rose after birth. Findings by reverse transcriptase–polymerase chain reaction were confirmed by Northern analyses. These observations indicate that eNOS and nNOS gene expression are developmentally regulated in rat lung, with maximal eNOS and nNOS protein expression near term. Furthermore, the regulation of pulmonary eNOS may primarily involve alterations in transcription or mRNA stability, whereas nNOS expression in

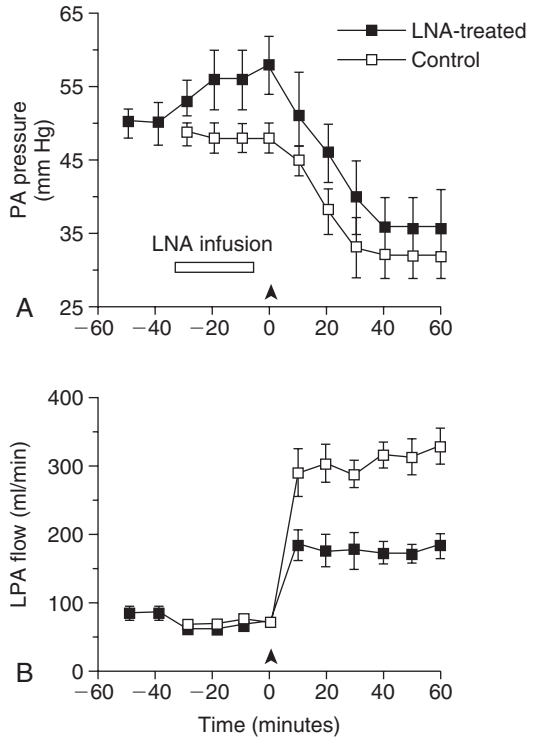

Figure 72-1 Inhibition of endogenous NO production attenuates the decline in PVR associated with birth-related events. *(From Abman SH, Chatfield BA, Hall SL, McMurtry IF: Role of endothelium-derived relaxing factor activity during transition of pulmonary circulation at birth,* Am J Physiol Heart Circ Physiol *259:H1921-H1927, 1990.)*

the maturing lung may also be mediated by additional posttranscriptional processes.[32] The developmental regulation of eNOS expression has also been discerned in ovine fetal lung. eNOS is present in the pulmonary vasculature of the premature ovine fetus as early as 43 days gestation (29% of term gestation[33]), with maximal eNOS mRNA and protein expression observed early in the third trimester.[34] Differences in the timing of eNOS upregulation in the sheep and rat may be related to the temporal features of lung development in the two species, with a greater proportion of maturation occurring after birth in the rat.[35]

To better understand the regulation of pulmonary NO production in the developing primate, maturational changes in NOS isoform expression and enzymatic activity have recently been determined in the proximal lung of third-trimester fetal baboons from 125 to 175 days gestation (term = 185 days) (Figure 72-2). A marked increase occurred in total NOS enzymatic activity from 125 to 140 days gestation because of elevations in nNOS and eNOS expression, whereas iNOS expression and activity were minimal. Total NOS activity was constant from 140 to 175 days gestation, and during the latter stage (160 to 175 days gestation) a dramatic fall in nNOS and eNOS was replaced by a rise in iNOS. Studies done within 1 hour of delivery at 125 or 140 days gestation revealed that the principal increase in NOS during the third trimester is associated with an elevation in exhaled NO levels, a decline in expiratory resistance, and greater pulmonary compliance.[18] These cumulative observations indicate that normal developmental increases occur in pulmonary NOS expression and NO production during the third trimester that may serve to optimize not only pulmonary vascular but also airway and parenchymal function in the immediate postnatal period.

Alterations in NO production and NOS expression have been evaluated in animal models of perinatal pulmonary vascular disease, with particular emphasis on eNOS action and expression. Chronic hypoxia is an important causal factor in the development of pulmonary hypertension in the perinatal period, and in newborn piglets chronic hypoxia attenuates acetylcholine-stimulated (eNOS dependent) pulmonary vasodilation, marked diminution occurs in both basal and acetylcholine-stimulated pulmonary NO production, and eNOS expression is attenuated.[36-38] In studies of the direct effects of varying oxygen exposure on isolated ovine fetal pulmonary artery endothelial cells, eNOS mRNA and protein expression were both attenuated by three-fold with hypoxia.[39] These findings suggest that decreased eNOS expression and resultant diminution in pulmonary NO production may contribute to the pathogenesis of hypoxic pulmonary hypertension in the newborn.

NOS expression has also been evaluated in a rat model of congenital diaphragmatic hernia (CDH). The development of CDH can be induced in approximately 50% to 60% of rat fetuses after maternal ingestion of the herbicide nitrofen early in gestation. Studies in this model have revealed that eNOS protein abundance is decreased by 42% in the lung ipsilateral to the hernia compared with lungs from control fetuses exposed to nitrofen but lacking CDH. Immunoblots for factor VIII–related antigen indicate that this is not related to alterations in endothelial cell density, and studies of nNOS protein reveal that this finding is unique to the endothelial isoform of NOS. eNOS mRNA abundance evaluated by reverse transcriptase–polymerase chain reaction assay is also decreased in CDH lung, falling to 22% of control levels.[40] These observations indicate that attenuated eNOS expression may contribute to PPHN in infants with CDH.

Potentially important observations have also been made in a lamb model of neonatal pulmonary hypertension created by ligation of the fetal ductus arteriosus 10 to 20 days before delivery. NO-dependent relaxation is attenuated in intrapulmonary arteries from these animals.[41] In parallel, eNOS protein expression is decreased by one half in the hypertensive lung, and nNOS expression is unaltered. Similarly, NOS enzymatic activity is decreased 45% to 75% in the hypertensive lung. Paralleling the declines in eNOS protein and NOS enzymatic activity, eNOS mRNA abundance is also decreased in the hypertensive lung.[42,43] Thus pulmonary eNOS gene expression is attenuated in the lamb model of neonatal pulmonary hypertension. As such, evidence exists of diminished NOS function in multiple models of PPHN in multiple species.

EXOGENOUS (INHALED) NITRIC OXIDE AS A SELECTIVE PULMONARY VASODILATOR

NO in its natural form exists as a gas, prompting its application to clinical medicine. The first clinical experiments with iNO gas were unrelated to its effects on pulmonary vasodilation. On the basis of the fact that iNO gas diffuses into the pulmonary circulation much faster than carbon monoxide, Borland and colleagues[44] tested the hypothesis that iNO could serve as a measure of diffusing capacity of the alveolar-capillary membrane in 1983. After the discovery that EDRF was actually NO, Higenbottam and colleagues[45] studied the effects of iNO on pulmonary vasodilation in adults with primary pulmonary hypertension in the cardiac catheterization laboratory. At a platform presentation during the American Thoracic Society meeting in 1988, they reported that, when compared with prostacyclin, iNO caused equivalent reductions in PVR, but without systemic vascular effects.[45]

These observations captured the interest of physiologists studying the newborn pulmonary circulation because, after birth and the initiation of air breathing, PVR rapidly declines and pulmonary blood flow markedly increases. These changes are essential for the normal transition to extrauterine life, and the potential of a selective pulmonary vasodilator was appealing, because available alternatives for the treatment of PPHN caused adverse systemic vascular effects.

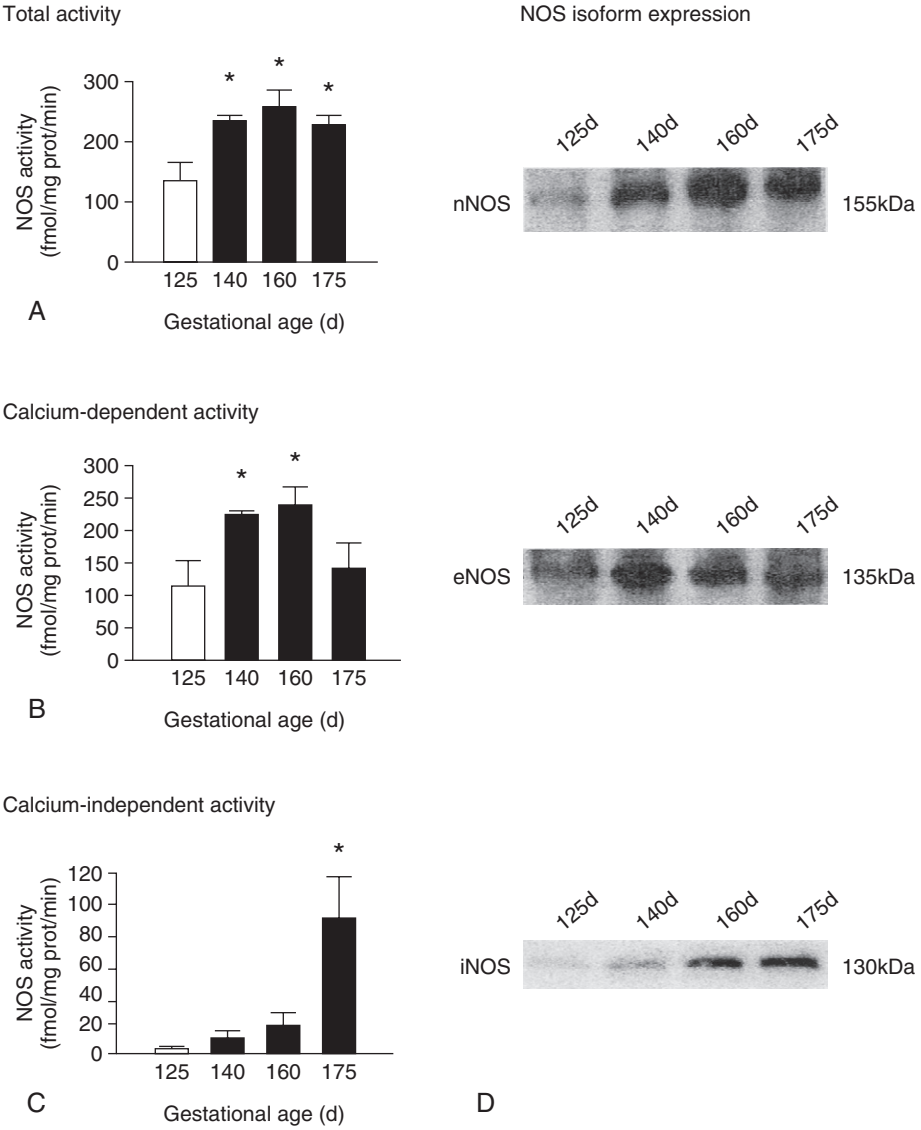

Figure 72-2 A-D, NOS enzymatic activity and NOS isoform expression in proximal baboon lung are developmentally regulated during the third trimester. *(From Shaul PW, Afshar S, Gibson LL, et al: Developmental changes in nitric oxide synthase isoform expression and nitric oxide production in fetal baboon lung,* Am J Physiol *283:L1192-L1199, 2002.)*

In 1991, prompted by the observations of Higenbottam and colleagues,[45] investigators commissioned an industrial gas manufacturer to combine NO with nitrogen to yield an NO concentration of 450 ppm, based on calculations designed to deliver 20 ppm NO within a continuous-flow, time-cycled, pressure-limited neonatal ventilator with a bias gas flow rate of 10 L/minute. The concentration of 450 ppm was chosen to balance environmental risk from sudden, complete tank evacuation against the obligate decrease in Fio_2 within the ventilator circuit during the administration of iNO. The first experiments of iNO in the late-gestation newborn lamb tested the effects at doses of 5, 10, and 20 ppm (based on the chronic ambient levels considered to be safe for adults by regulatory agencies in the United States[46]). Using vascular flow probes and radiolabeled microspheres to measure pulmonary and systemic blood flow, these investigators found that iNO caused potent, selective, and sustained pulmonary vasodilation in the late-gestation newborn lamb (Figure 72-3).[47] Moreover, cerebral blood flow and cerebral metabolic rate for oxygen were not affected by NO inhalation.[48] Frostell and colleagues[49] showed that iNO caused pulmonary vasodilation in adult animals during acute hypoxia and during pharmacologically induced pulmonary hypertension (U46619), and Roberts and colleagues[50] demonstrated that iNO reversed hypoxic pulmonary vasoconstriction in the juvenile lamb with respiratory acidosis. Corroborating studies in other animal models supported the observations that iNO is a selective pulmonary vasodilator at low doses (≤20 ppm),[51-54] and studies using a model of PPHN in which marked structural pulmonary vascular changes are induced by prolonged fetal ductus arteriosus compression demonstrated that, despite the loss of endothelium-dependent vasodilation, the response to iNO remained intact.[55,56]

The effects of iNO in the premature subject have also been of interest to translational physiologists. However, the premature fetus is characterized by both structural and functional pulmonary parenchymal and vascular immaturity. Thus separating the relative effects of pulmonary immaturity and its effects on lung inflation has been difficult because the pulmonary vascular, parenchymal, and airway responses of the premature lung to mechanical ventilation are uniquely different from those in the term subject. For example, surfactant deficiency compromises

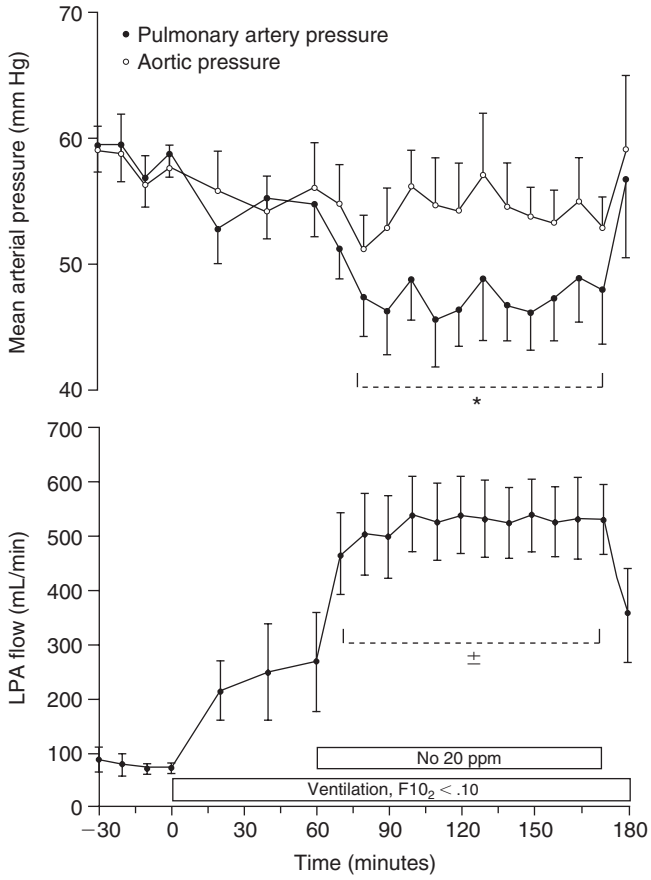

Figure 72-3 iNO causes potent, selective, and sustained pulmonary vasodilation in the term newborn lamb. *(From Kinsella JP, McQueston JA, Rosenberg AA, Abman SH: Hemodynamic effects of exogenous nitric oxide in ovine transitional pulmonary circulation,* Am J Physiol *1992;262:H875-H880.)*

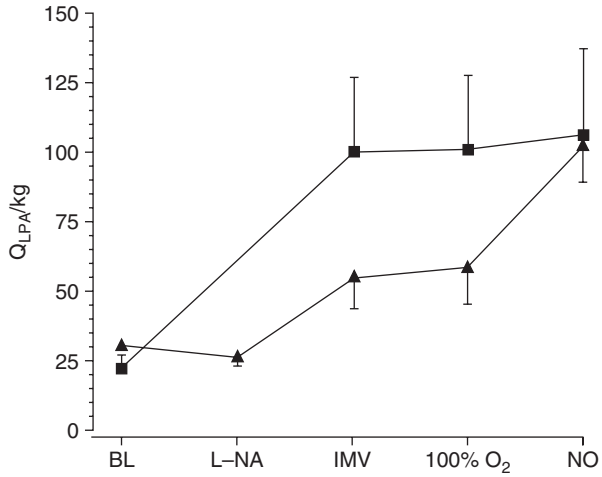

Figure 72-4 Inhibition of endogenous NO production in the premature lamb attenuates the increase in blood flow associated with birth-related events. Low-dose iNO increases pulmonary blood flow to normal levels. *(From Kinsella JP, Ivy DD, Abman SH: Ontogeny of NO activity and response to inhaled NO in the developing ovine pulmonary circulation,* Am J Physiol *267:H1955-H1961, 1994.)*

the normal increase in lung volume caused by tidal volume ventilation in extremely premature lambs. Although changes in PVR after delivery are mediated in part through the elaboration of vasoactive mediators by the pulmonary vascular endothelium, decreased lung volume exerts mechanical effects on the pulmonary circulation, which increases pulmonary vascular tone. The early observations of Dawes and colleagues[3] predicated the notion that the premature pulmonary vascular bed insufficiently dilated at birth and that this suboptimal vasodilation contributed to respiratory distress syndrome (RDS). Dawes and colleagues delivered four extremely premature lambs (76% to 83% of term gestation) and noted that the most immature animals had minimal reduction in PVR during tidal volume ventilation for 2 minutes after delivery, in contrast to the marked decrease in PVR noted in term animals. Indeed, pulmonary hypoperfusion was implicated in the evolution of "idiopathic" RDS.[57] However, after the seminal observations of Avery and Mead[58] and Fujiwara and colleagues,[59] the contribution of surfactant deficiency to respiratory failure in the premature newborn became the pivotal pathophysiologic focus.

Surfactant therapy has dramatically improved the outcome of infants born prematurely. However, surfactant treatment alone does not consistently cause sustained improvement in oxygenation in extremely premature lambs. Jobe and colleagues[60] found only transient improvement in oxygenation in response to exogenous surfactant in lambs delivered at 120 days gestation (82% of term), and repeated doses were less predictably effective. Walther and colleagues[61] showed that repeated doses of exogenous surfactant caused sustained improvement in oxygenation in lambs at 128 days gestation (87% of term), but serial surfactant replacement in more immature lambs at 118 days gestation (80% of term) did not modify the course of respiratory deterioration. These observations support the suggestion that other problems of prematurity (e.g., structural lung immaturity or altered vascular responses to dilator stimuli) contribute to respiratory failure in RDS. It is possible that persistent hypoxemia after surfactant replacement in the most immature subject is caused by pulmonary hypertension associated with decreased endogenous pulmonary vasodilator production.

After delivery, the fall in PVR in the premature lamb in response to birth-related events (rhythmic lung distention and increased inspired oxygen) is maximal with tidal volume mechanical ventilation and lung inflation alone, and little pulmonary hemodynamic response to high inspired oxygen occurs.[62] However, when endogenous NO production is blocked during delivery of the premature lamb, the normal increase in pulmonary blood flow associated with mechanical ventilation and lung inflation is markedly attenuated, and subsequent treatment with iNO increases pulmonary blood flow to the same level as in control animals (Figure 72-4).

The premature lamb has been extensively studied as a model of severe RDS.[63] Survival with exogenous surfactant treatment and mechanical ventilation at delivery varies depending on the gestational age of the lamb and the type of surfactant given.[60,64] In very immature lambs (115 days gestation), gas exchange worsens and PVR increases during mechanical ventilation beyond 60 to 90 minutes after birth, despite treatment with exogenous surfactant at delivery.

Several studies have examined the effects of iNO in the premature lamb with hyaline membrane disease. Skimming and colleagues[65] treated premature lambs (126 to 127 days gestation) with iNO at 5 and 20 ppm for brief periods and showed improvement in oxygenation and PVR. In another study, intermittent mandatory ventilation over a 2-hour period in the extremely premature ovine fetus (115 days gestation, 78% of term) resulted in progressive worsening of gas exchange and increased PVR. After 2 hours of ventilation, brief NO treatment lowered PVR and improved gas exchange.[66] Moreover, early and continuous treatment with iNO

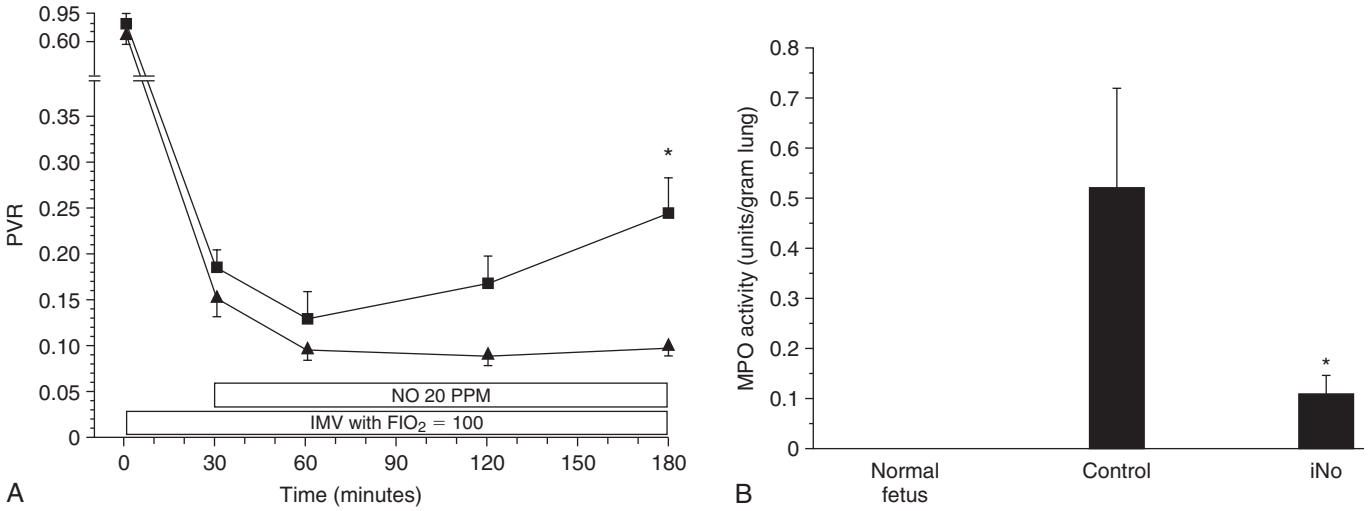

Figure 72-5 A, Low-dose iNO causes sustained pulmonary vasodilation in mechanically ventilated premature lambs with RDS. *(From Kinsella JP, Parker TA, Galan H, et al: Effects of inhaled nitric oxide on pulmonary edema and lung neutrophil accumulation in severe experimental hyaline membrane disease,* Pediatr Res *41:457-63, 1997.)* **B,** Low-dose iNO decreases lung neutrophil accumulation in the premature lamb with RDS.

(20 ppm) caused sustained improvement in gas exchange and pulmonary hemodynamics over 3 hours of mechanical ventilation in the extremely premature lamb. Lung recruitment strategies using high-frequency oscillatory ventilation (HFOV) have been shown to augment the response to low-dose iNO in premature lambs with RDS, emphasizing the critical role of adequate lung inflation during inhalational vasodilator therapy.[67]

Another reason iNO in the premature subject has been of interest is that, in addition to its effects on pulmonary hemodynamics and gas exchange during inhalation, endogenous NO has been shown to regulate vascular permeability and neutrophil adhesion in the microcirculation.[68] Although reports suggest that iNO may decrease capillary permeability in acute lung injury,[69,70] the immature lung is particularly susceptible to lung protein leak during mechanical ventilation.[71] This proteinaceous pulmonary edema causes atelectasis and ventilation-perfusion abnormalities, worsening gas exchange, and increasing PVR. Increasing pulmonary blood flow with iNO in the premature subject could also have potential adverse effects. For example, conditions associated with increased pulmonary blood flow in the premature infant (patent ductus arteriosus [PDA]) cause increased lung neutrophil accumulation.[72] The effects of iNO on pulmonary vascular permeability and lung leukosequestration in premature lambs with RDS have been reported.[73] In premature lambs delivered at 78% of term, low-dose iNO (5 ppm) increased pulmonary blood flow and improved gas exchange without increasing pulmonary edema, and decreased lung neutrophil accumulation (Figure 72-5). Sequestration of neutrophils in the lung is an early step in a complex inflammatory response mediated through the elaboration of oxy radicals, proteases, phospholipases, and lipid compounds.[74] Therapies that reduce neutrophil accumulation in the lung in hyaline membrane disease could potentially modify the early inflammatory process that amplifies acute lung injury and contributes to the development of chronic lung disease.[75]

In addition to the acute effects of iNO on pulmonary vasodilation, lung inflammation, and oxidant stress, evidence is increasing that impaired endogenous NO production contributes to the pathogenesis of BPD. For example, lung nNOS expression is decreased in the primate model of BPD (Figure 72-6), lung eNOS abundance is decreased in both the primate and ovine models of BPD (see Figure 72-6),[76,77] and mice genetically deficient for eNOS have abnormal distal lung architecture.[78,79] The potential

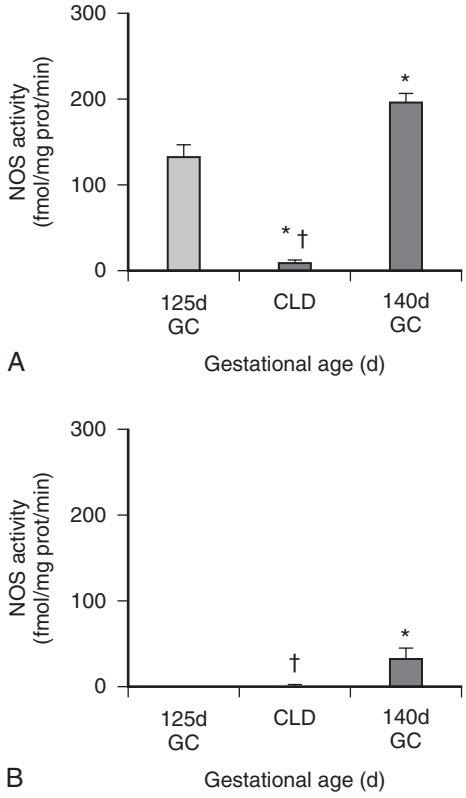

Figure 72-6 nNOS **(A)** and eNOS **(B)** are both decreased in the primate model of BPD. *(Modified from Afshar S, Gibson LL, Yuhanna IS, et al: Pulmonary NO synthase expression is attenuated in a fetal baboon model of chronic lung disease,* Am J Physiol Lung Cell Mol Physiol *284:L749-L758, 2003.)*

for iNO to modulate the evolution of lung injury in animal models of BPD has been the focus of recent studies, providing further experimental rationale for the role of iNO in premature subjects.[80] Lin and colleagues[81] found that hyperoxia exposure of neonatal rats inhibited lung vascular growth and impaired

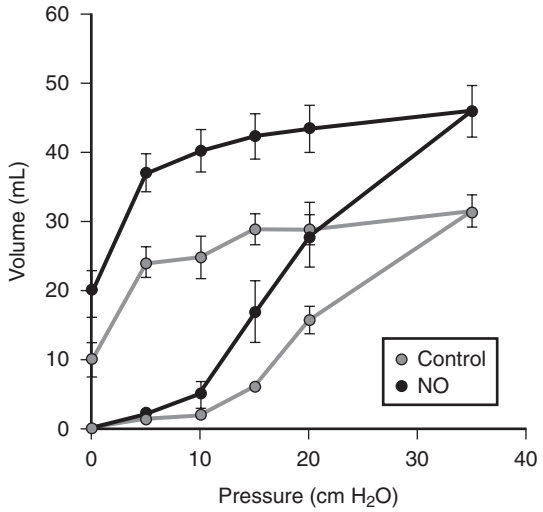

Figure 72-7 iNO improves pulmonary function in the primate model of BPD. Postmortem pressure-volume curves were performed after 14 days of control treatment or iNO administration. *(Modified from McCurnin DC, Pierce RA, Chang LY, et al: Inhaled NO improves early pulmonary function and modifies lung growth and elastin deposition in a baboon model of neonatal chronic lung disease,* Am J Physiol Lung Cell Mol Physiol *288:450-459, 2005.)*

alveolarization and that treatment with iNO after neonatal hyperoxia enhanced late lung growth and improved alveolarization in this model of BPD. McCurnin and colleagues[82] studied the effects of iNO in a baboon model of BPD over the first 14 days of life. They found that iNO improved pulmonary function (Figure 72-7) and favorably altered lung growth and elastin deposition (Figure 72-8) in mechanically ventilated premature baboons with evolving BPD. The tempering of elastin deposition with iNO was related to decreased elastin gene activation and fewer alveolar myofibroblasts (see Figure 72-8). In chronically ventilated premature lambs, Bland and colleagues[83] found that iNO administration preserved structure and function of airway smooth muscle and enhanced alveolar development. Thus compelling evidence suggests that endogenous NO plays a vital role in pulmonary vascular and alveolar development in the immature lung and that low-dose iNO may have beneficial effects on both the acute and chronic perturbations that are associated with the pathogenesis of BPD in the premature newborn.

CLINICAL EFFECTS OF INHALED NITRIC OXIDE IN THE TERM NEWBORN WITH PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

Early studies showed that iNO therapy caused marked improvement in oxygenation in term newborns with PPHN.[84-89] Multicenter randomized clinical studies subsequently confirmed that iNO therapy reduces the need for extracorporeal membrane oxygenation treatment in term neonates with hypoxemic respiratory failure.[90,91] Extensive supportive data have demonstrated its overall safety and efficacy, as evidenced by its recent approval by the U.S. Food and Drug Administration.

PPHN[92] is a syndrome associated with diverse neonatal cardiac and pulmonary disorders that are characterized by high PVR causing extrapulmonary right-to-left shunting of blood across the ductus arteriosus and/or foramen ovale.[93] Extrapulmonary shunting caused by high PVR in severe PPHN can cause critical hypoxemia that is poorly responsive to inspired oxygen or pharmacologic vasodilation. Vasodilator drugs administered intravenously, such as tolazoline and sodium nitroprusside, are often unsuccessful because of systemic hypotension and an inability to achieve or sustain pulmonary vasodilation.[94,95] Thus the ability of iNO therapy to selectively lower PVR and decrease extrapulmonary venoarterial admixture accounts for the acute improvement in oxygenation observed in newborns with PPHN.[96]

The first studies of iNO treatment in term newborns reported initial doses that ranged from 80 ppm[76] to 6 to 20 ppm (Figure 72-9).[77] The rationale for doses used in these clinical trials was based on concentrations that had previously been found to be effective in animal experiments by the same investigators.[47,50] Roberts and colleagues reported that brief (30 minutes) inhalation of NO at 80 ppm improved oxygenation in patients with PPHN, but this response was sustained in only one patient after NO was discontinued.[76] In the second report, rapid improvement in oxygenation in neonates with severe PPHN was also demonstrated, but this was achieved at lower doses (20 ppm) for 4 hours.[77] This study also reported that decreasing the iNO dose to 6 ppm for the duration of treatment provided sustained improvement in oxygenation. The relative effectiveness of low-dose iNO in improving oxygenation in patients with severe PPHN was corroborated in a study by Finer and colleagues.[97] Acute improvement in oxygenation during treatment was not different with doses of iNO ranging from 5 to 80 ppm.

Because of its selective pulmonary vasodilator effects, iNO therapy is an important adjunct to available treatments for term newborns with hypoxemic respiratory failure. However, hypoxemic respiratory failure in the term newborn represents a heterogeneous group of disorders, and disease-specific responses have clearly been described. For example, patients with extrapulmonary right-to-left shunting (PPHN) show acute improvement in oxygenation when PVR becomes subsystemic during iNO therapy, and patients with predominantly intrapulmonary shunting (e.g., RDS) have less dramatic responses.

Several pathophysiologic disturbances contribute to hypoxemia in the newborn infant, including cardiac dysfunction, airway and pulmonary parenchymal abnormalities, and pulmonary vascular disorders. In some newborns with hypoxemic respiratory failure, a single mechanism predominates (e.g., extrapulmonary right-to-left shunting in idiopathic PPHN), but more commonly several of these mechanisms contribute to hypoxemia. For example, in a newborn with meconium aspiration syndrome, meconium may obstruct some airways, decreasing V/Q ratios and increasing intrapulmonary shunting. Other lung segments may be overventilated relative to perfusion and cause increased physiologic dead space. Moreover, the same patient may have severe pulmonary hypertension with extrapulmonary right-to-left shunting at the ductus arteriosus and foramen ovale. Not only does the overlap of these mechanisms complicate the clinical management, but the tendency for time-dependent changes in the relative contribution of each mechanism to hypoxemia requires continued vigilance as the disease progresses. Therefore understanding the relative contribution of these different causes of hypoxemia becomes critically important as the inventory of therapeutic options expands.

Considering the important role of parenchymal lung disease in many cases of PPHN, pharmacologic pulmonary vasodilation alone would not be expected to cause sustained clinical improvement.[98] The effects of inhaled NO may be suboptimal when lung volume is decreased in association with pulmonary parenchymal disease.[99] Atelectasis and air space disease (pneumonia, pulmonary edema) will decrease effective delivery of iNO to its site of action in terminal lung units. In PPHN associated with heterogeneous (patchy) parenchymal lung disease, inhaled NO may be effective in optimizing ventilation-perfusion matching by preferentially causing vasodilation in lung units that are well ventilated. The effects of inhaled NO on ventilation-perfusion matching appear to be optimal at low doses (<20 ppm).[100]

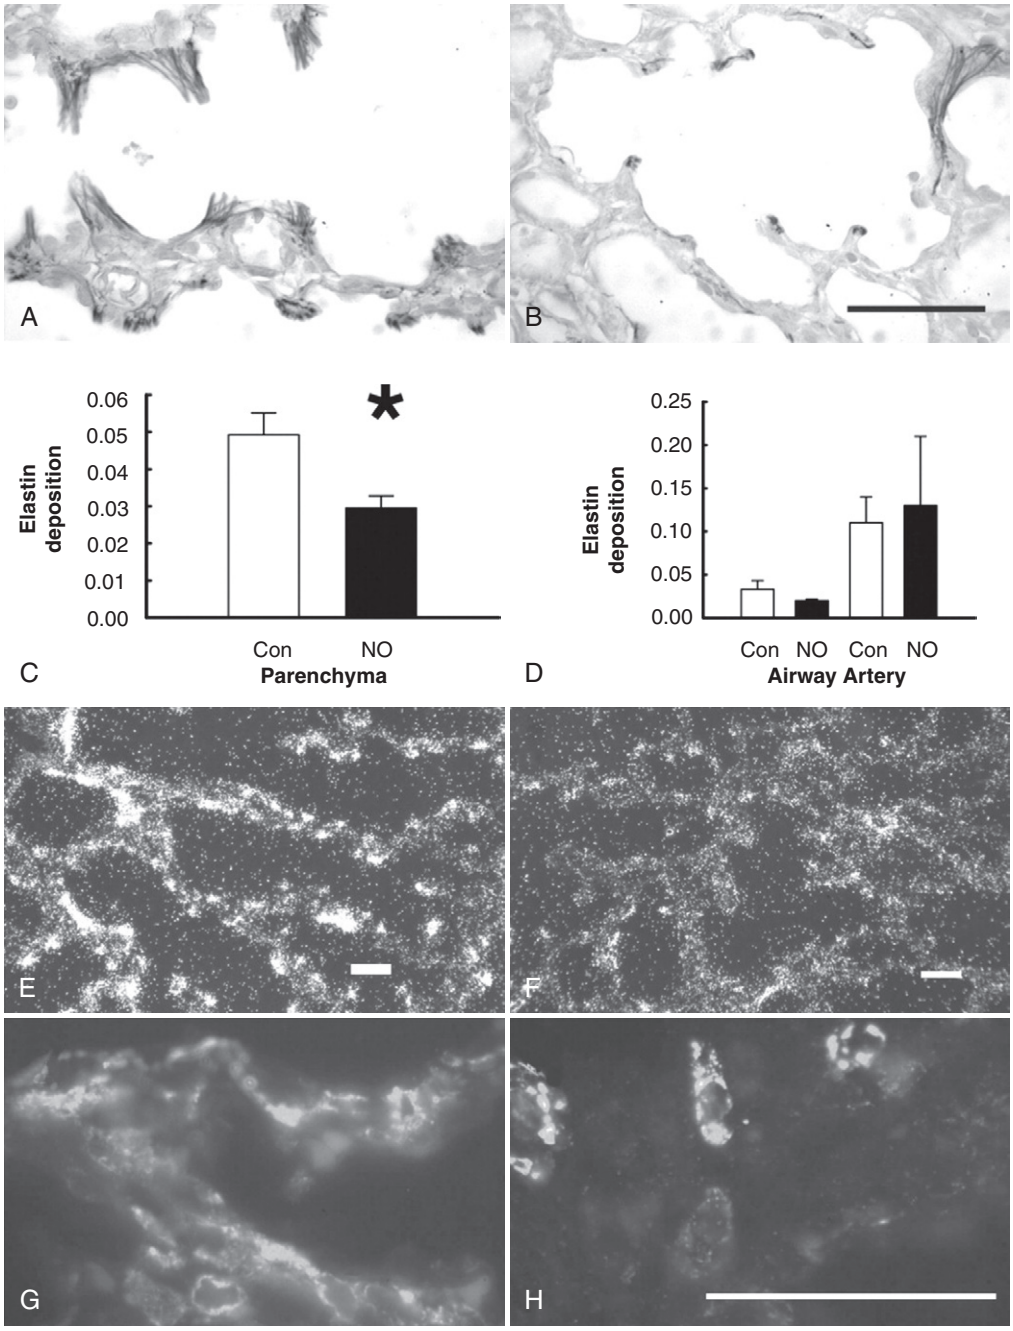

Figure 72-8 Elastin deposition in the primate model of BPD is tempered by iNO. Hart's staining of control **(A)** and iNO-treated lungs **(B),** and quantification of elastin deposition in the parenchyma **(C)** and airways and arteries **(D).** In situ hybridization for elastin mRNA in control **(E)** and iNO-treated lungs **(F),** and immunofluorescence for the alveolar myofibroblast marker α-smooth muscle actin in control **(G)** and iNO-treated lungs **(H).** *(From McCurnin DC, Pierce RA, Chang LY, et al: Inhaled NO improves early pulmonary function and modifies lung growth and elastin deposition in a baboon model of neonatal chronic lung disease,* Am J Physiol Lung Cell Mol Physiol *288:450-459, 2005.)*

However, in cases complicated by homogeneous (diffuse) parenchymal lung disease and underinflation, pulmonary hypertension may be exacerbated because of the adverse mechanical effects of underinflation on PVR. In this setting, effective treatment of the underlying lung disease is essential (and sometimes sufficient) to cause resolution of the accompanying pulmonary hypertension.

Along with iNO treatment, other therapeutic strategies have emerged for the management of the term infant with hypoxemic respiratory failure. Patients not responding to iNO can show marked improvement in oxygenation with adequate lung inflation alone.[78] High success rates in early studies were achieved by withholding iNO treatment until aggressive attempts were made to optimize ventilation and lung inflation with mechanical ventilation. These early studies demonstrated that the effects of iNO may be suboptimal when lung volume is decreased in association with pulmonary parenchymal disease, for several reasons. First, atelectasis and air space disease (pneumonia, pulmonary edema) may decrease the effective delivery of iNO to its site of action in terminal lung units. Second, in cases complicated by severe lung disease and underinflation, pulmonary hypertension

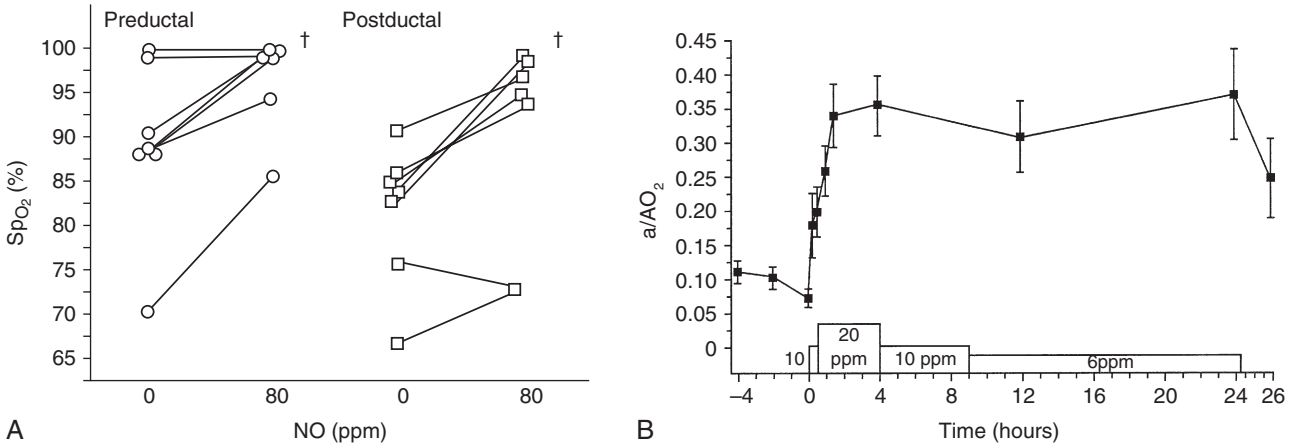

Figure 72-9 A, Brief treatment with 80 ppm iNO caused acute improvement in newborns with PPHN. *(From Roberts JD, Polaner DM, Lang P, Zapol WM. Inhaled nitric oxide in persistent pulmonary hypertension of the newborn,* Lancet *340:818-819, 1992.)* **B,** Treatment with low-dose iNO for 24 hours caused sustained improvement in oxygenation in newborns with PPHN. *(From Afshar S, Gibson LL, Yuhanna IS, et al. Pulmonary NO synthase expression is attenuated in a fetal baboon model of chronic lung disease,* Am J Physiol Lung Cell Mol Physiol *284:L749-758, 2003.)*

may be exacerbated because of the adverse mechanical effects of underinflation on PVR. Third, attention must be given to minimize overinflation to avoid inadvertent positive end-expiratory pressure and gas trapping that may elevate PVR from vascular compression. This commonly complicates the management of infants with asymmetric lung disease or airways obstruction as observed in meconium aspiration syndrome.

In newborns with severe lung disease, HFOV is frequently used to optimize lung inflation and minimize lung injury.[101] In clinical pilot studies using iNO, we found that the combination of HFOV and iNO caused the greatest improvement in oxygenation in some newborns who had severe PPHN complicated by diffuse parenchymal lung disease and underinflation (e.g., RDS, pneumonia).[102,103] A randomized, multicenter trial demonstrated that treatment with HFOV + iNO was often successful in patients who did not respond to HFOV or iNO alone in severe PPHN, and differences in responses were related to the specific disease associated with the complex disorders of PPHN (Figure 72-10).[78] For patients with PPHN complicated by severe lung disease, response rates for HFOV + iNO were better than HFOV alone or iNO with conventional ventilation. In contrast, for patients without significant parenchymal lung disease, both iNO and HFOV + iNO were more effective than HFOV alone. This response to combined treatment with HFOV + iNO likely reflects both improvement in intrapulmonary shunting in patients with severe lung disease and PPHN (using a strategy designed to recruit and sustain lung volume, rather than to hyperventilate) and augmented NO delivery to its site of action. Although iNO may be an effective treatment for PPHN, it should be considered only as part of an overall clinical strategy that cautiously manages parenchymal lung disease, cardiac performance, and systemic hemodynamics.

Pharmacologic augmentation of the iNO response may also prove to be effective in some patients with PPHN. Inhaled NO causes pulmonary vasodilation by stimulating soluble guanylate cyclase and increasing cyclic guanosine monophosphate (cGMP) content in vascular smooth muscle. Smooth muscle cGMP content is further regulated by cGMP-specific phosphodiesterase 5 (PDE5), which inactivates cGMP by hydrolysis.[104] Whether the inability to sustain cGMP contributes to the failure of some patients with PPHN to respond or to sustain improved oxygenation during iNO therapy is uncertain. Early clinical experience with dipyridamole, which has PDE5 inhibitory activity, has been variable. Although dipyridamole may enhance the

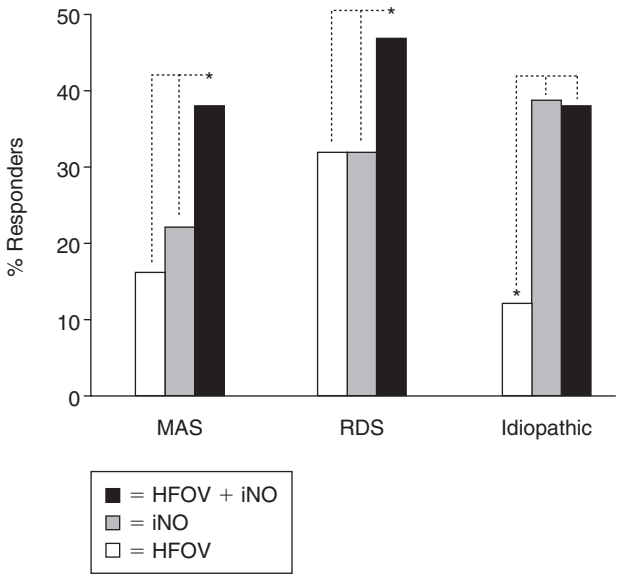

Figure 72-10 Lung recruitment with HFOV augments the response to iNO in patients with severe parenchymal lung disease. *(From Han RN, Babaei S, Robb M, et al. Defective lung vascular development and fatal respiratory distress in eNOS deficient mice: a model of alveolar capillary dysplasia?* Circ Res *94:1115-1123, 2004.)*

response to iNO in some patients,[105] its effects are variable and are not selective for the pulmonary circulation.[106] Further studies with more selective PDE5 antagonists (such as sildenafil) may lead to novel clinical strategies to enhance the treatment of pulmonary hypertension with iNO.[107] Moreover, other agents may enhance endogenous NO activity and potentially augment the effects of iNO, such as superoxide dismutase. Laboratory studies have shown that intratracheal administration of recombinant human CuZn superoxide dismutase causes pulmonary vasodilation and improves gas exchange during mechanical ventilation in animal models of pulmonary hypertension.[108,109] However, the independent and combined effects of superoxide dismutase and iNO have not been tested in a clinical trial in newborns with PPHN.

INHALED NITRIC OXIDE IN PREMATURE NEWBORNS

In the premature human neonate, severe respiratory failure is often the result of surfactant deficiency, and treatment with exogenous surfactant can cause dramatic improvements in oxygenation.[110] However, surfactant therapy results in suboptimal responses in up to 50% of human newborns with RDS.[111] Echocardiographic studies in human premature infants with RDS have shown that pulmonary hypertension may complicate the course of severe RDS.[57,112-115] Subsequent studies have also shown that the association of pulmonary hypertension with severe RDS leads to increased mortality despite surfactant therapy.[116] Walther and colleagues[116] performed echocardiographic studies in premature neonates with fatal RDS and found that severe pulmonary hypertension was an early and consistent finding in premature neonates who subsequently died. The frequency of severe pulmonary hypertension complicating RDS in premature neonates is unknown. However, the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network recently reported that respiratory causes of early death in premature neonates remain a significant problem despite the availability of surfactant therapy.[117] Among 2867 infants with birth weights <1500 g born between March 1993 and February 1994, a mortality rate of 19% (553) was reported. For 26% (146) of these premature neonates, the major cause of death was pulmonary related (RDS, chronic lung disease).

These observations suggest that factors other than surfactant deficiency may contribute to the cardiopulmonary failure associated with prematurity. Multiple mechanisms may be involved, including the production of pulmonary vasoconstrictor agents or diminished endogenous vasodilator formation causing increased PVR and extrapulmonary right-to-left shunting of blood across the ductus arteriosus and foramen ovale. Surfactant inactivation may also occur in severe RDS, caused by alveolar-capillary leak and pulmonary edema.[118,119] Surfactant inactivation results in atelectasis, disturbances in ventilation-perfusion matching, and intrapulmonary shunting.

Treatment of pulmonary hypertension and ventilation-perfusion mismatching in newborn infants has been limited by the lack of a selective pulmonary vasodilator. Nonselective pulmonary vasodilators have been used in RDS complicated by pulmonary hypertension, but their use has been marked by lack of responsiveness and inability to sustain vasodilation. Also, adverse systemic vascular effects may occur, and the risks of systemic hypotension are of particular concern in premature subjects, because of markedly reduced cerebral blood flow in the first days after delivery.[120,121] Moreover, vasodilators delivered to the lung by intravenous administration may worsen ventilation-perfusion matching by increasing blood flow to both well-ventilated and poorly ventilated areas of the lung.[100]

As described earlier, convincing evidence now exists that low-dose (≤20 ppm) iNO delivered directly to the pulmonary circulation by inhalation causes potent, selective, and sustained pulmonary vasodilation in premature animals. Because of the inhalational route of delivery, low-dose iNO also improves matching of ventilation with perfusion within the lung by vasodilating vessels associated with well-ventilated lung units and favorably modulates lung inflammation and vascular-alveolar maturation.

Preliminary studies in human premature neonates with severe hypoxemic respiratory failure supported the potential role of low-dose iNO as adjuvant therapy. Low-dose inhaled NO caused marked improvement in oxygenation in a premature neonate with group B streptococcal sepsis and severe pulmonary hypertension, allowing reduction in ventilator pressure and inspired oxygen concentration with complete clinical recovery.[122] Peliowski and colleagues[123] studied eight premature neonates with severe hypoxemia associated with prolonged oligohydramnios and suspected pulmonary hypoplasia who showed marked improvement in response to iNO therapy. Five patients survived in this trial, three with severe intracranial hemorrhage (ICH). Skimming and colleagues[124] also reported a dose-response study in premature infants, and concluded that 5 ppm was as effective as 20 ppm in improving oxygenation. In a small, unmasked, randomized trial of iNO (20 ppm) and dexamethasone treatment, no differences were found in survival, chronic lung disease, or ICH between iNO-treated infants and controls.[125] In another report, Van Meurs and colleagues[126] described a dose-response study of iNO in 11 premature newborns and noted that 5 ppm was as effective as 20 ppm. Seven (64%) of these infants had ICH, and five (45%) had ICH of grade 3 to 4. However, when the authors compared these results with the NICHD Neonatal Network database (for historical controls matched for severity of illness), the incidence of ICH in premature newborns not treated with iNO was identical (64%). One of the most concerning potential risks of iNO treatment for premature neonates is the prolongation in bleeding time described at NO doses of 30 to 300 ppm.[127] Endogenous NO inhibits platelet adhesion to the vascular endothelium, and this effect may be related to the formation of stable *S*-nitrosoproteins.[128,129] However, in a small study in premature infants given treatment with inhaled NO, no change in bleeding time occurred.[130] These observations illustrate the limitations of toxicity determinations without appropriately designed clinical trials.

The largest trials of iNO therapy in premature newborns reported to date include the single-center study of Schreiber and colleagues[131] and the multicenter trials of Van Meurs and colleagues,[132] Ballard and colleagues,[133] and Kinsella and colleagues.[134] All of these studies were randomized, controlled, and masked but have key differences in patient population, disease severity, dose and duration of therapy, and other factors.

Schreiber and colleagues[131] randomly assigned 207 infants to treatment with iNO or placebo. The main finding of the trial was a reduction in the incidence of BPD and death by 24% in the iNO group. These benefits appeared to accrue predominantly from the subset of newborns with relatively mild respiratory failure (oxygenation index [OI] <6.94). However, in addition to apparent pulmonary benefit caused by low-dose iNO, these authors also reported a 47% decrease in the incidence of severe ICH and periventricular leukomalacia (PVL). Moreover, in a subsequent report, the same group showed that the early decrease in ICH and PVL associated with iNO treatment manifested in improved neurodevelopmental outcome on follow-up examinations of this population.[135] In this follow-up study, 138 children (82% of survivors of the randomized controlled trial) were evaluated for neurodevelopmental outcome at 2 years of age. In the group given treatment with iNO in the newborn period, 24% had abnormal outcomes (defined as cerebral palsy, blindness, hearing loss, or one score of less than 70 on the Bayley Scale of Infant Development II), in contrast to 46% in the control group.

Van Meurs and colleagues[132] enrolled 420 newborns (401 to 1500 g birth weight) in a multicenter randomized controlled trial. Although the focus of this study was on premature newborns and the major outcome measure was BPD, the design of the trial was similar to that of the previous NINOS trial in which term newborns were enrolled and acute changes in oxygenation determined continued treatment with study gas. That is, an acute dose-response study was performed, and only patients who showed significant improvement in Pa_{O_2} continued to receive study gas. In striking contrast to other studies, the average duration of iNO treatment was only 76 hours. Overall, they found no difference in the incidence of death or BPD between the iNO and control groups. However, in post hoc analyses, infants with birth weight >1000 g showed a reduction in death or BPD after treatment with iNO (50% iNO vs. 69% control). But a worrisome outcome was suggested in a post hoc analysis of newborns weighing ≤1000 g. This analysis showed an increased risk

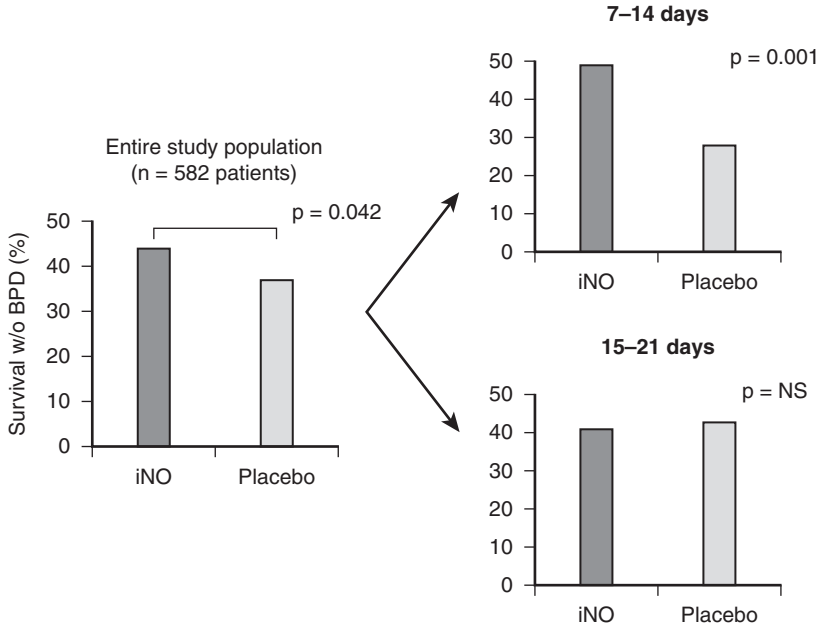

Figure 72-11 Effects of iNO on survival without BPD for infants enrolled between 7 and 21 days of age. As shown, iNO increased survival without BPD in infants who were treated before 14 days of age. *(From Ballard RA, Truog WE, Cnaan A, et al: Inhaled nitric oxide in preterm infants undergoing mechanical ventilation,* N Engl J Med *205:343-353, 2006.)*

of ICH or PVL (43% iNO vs. 33% control). However, as noted in an editorial by Martin and Walsh,[136] baseline ultrasound examinations were not performed, and it cannot be determined whether these very severely ill infants had ICH before iNO was initiated. Indeed, the severity of illness of infants in this trial of Van Meurs and colleagues[132] was also markedly different from the study of Schreiber and colleagues.[131] In the Van Meurs trial, the mean OI at enrollment for the iNO group was 23, compared with the median OI of 7.3 in the Schreiber study. This suggests that the degree of illness based on the severity of respiratory failure may be related to iNO safety and efficacy in this population; however, an increased risk of ICH or PVL was not observed in a previous trial of iNO in premature newborns with severe hypoxemic respiratory failure (OI = 30).[22] Other differences between these two trials may offer insights into the disparate outcomes, including the duration of iNO treatment (3 days vs. 7 days), birth weight (839 g vs. 992 g), and gestational age (26 weeks vs. 27.4 weeks). Thus Van Meurs and colleagues enrolled smaller, more immature infants with severe respiratory failure who were treated relatively briefly with iNO, making direct comparisons between these two trials problematic.

The results of the two largest randomized, controlled, and masked trials of iNO treatment in premature newborns have been reported. Ballard and colleagues[39] randomly assigned 582 premature newborns with birth weights of 500 to 1250 g who required ventilatory support between 7 and 21 days of age. Infants were given treatment with study gas for a minimum of 24 days and had an estimated OI of 7. They found that the incidence of survival without BPD was increased in the iNO treatment group (43.9%) compared with controls (36.8%) (p = .042). A major finding of this trial was that the benefit of BPD reduction derived almost entirely from the subset of patients enrolled between 7 and 14 days, suggesting that early treatment is important to prevent BPD (Figure 72-11). No differences were seen between the iNO and control groups in adverse events, including medical or surgical treatment of PDA, which is consistent with the lack of negative impact on ductal closure in the primate studies.[82] In addition, no differences were seen between the groups in ICH incidence; however, infants were enrolled after the first week of life. Thus this trial does not help inform the debate about iNO effects on brain injury in the premature newborn.

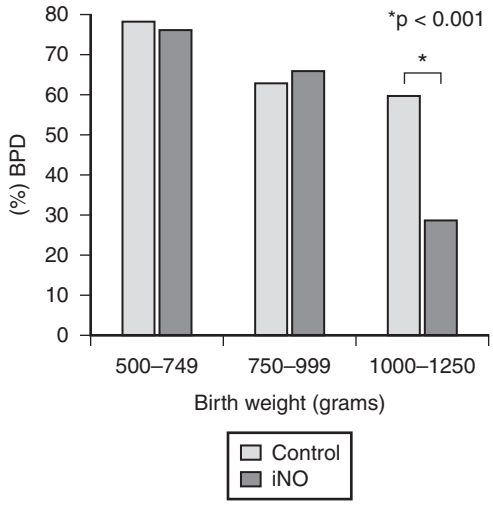

Figure 72-12 Effects of early treatment of preterm infants with low-dose iNO on BPD incidence by strata. Although no difference was seen on the incidence of BPD for the entire study group, this treatment strategy reduced BPD in infants >1000 g. *(From Kinsella JP, Cutter GR, Walsh WF, et al. Early inhaled nitric oxide therapy in premature newborns with respiratory failure,* N Engl J Med *205:354-364, 2006.)*

In the second trial, 793 premature newborns with birth weights of 500 to 1250 g and requiring mechanical ventilation in the first 48 hours of life were randomly assigned to treatment with 5 ppm iNO or placebo gas and given treatment for 21 days or until extubation.[40] Overall, no difference was found in the incidence of death or BPD between groups; however, iNO therapy reduced the incidence of BPD for infants with birth weight >1000 g by 50% (p = .001) (Figure 72-12). Low-dose iNO therapy reduced the incidence of PVL (p = .048), as well as the combined end points

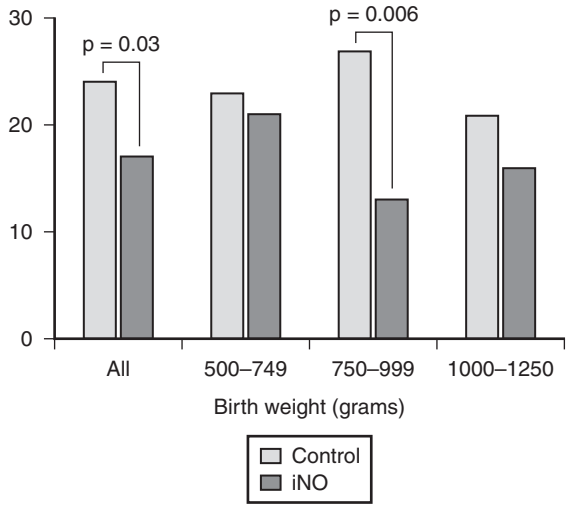

Figure 72-13 Effects of early treatment with low-dose iNO on brain injury (grade 3-4 ICH, PVL, ventriculomegaly) in preterm infants according to birth weight strata. iNO reduced ultrasound findings of brain injury for the overall group, with the largest effect in the 750- to 999-g strata. *(From Kinsella JP, Cutter GR, Walsh WF, et al. Early inhaled nitric oxide therapy in premature newborns with respiratory failure,* N Engl J Med *205:354-364, 2006.)*

of ICH, PVL, and ventriculomegaly for the entire study population (p = .032) (Figure 72-13). INO therapy did not increase the incidence of adverse events, including mortality, ICH, PVL, pulmonary hemorrhage, and PDA treatment in any subgroup. In this trial no relationship was found between OI and brain injury risk, in contrast to the findings of Van Meurs and colleagues.[132] Mechanisms through which iNO therapy might provide neuroprotection in the premature newborn are uncertain and warrant further study. Based on laboratory studies, several possibilities exist that include modulation of circulating cells (including neutrophils, monocytes, and platelets) that may occur during NO exposure as they transit the pulmonary circulation. Alternatively, iNO-induced down-regulation of lung-derived cytokines may also reduce distant organ injury.[137-139] Another possible mechanism may relate to distal delivery of NO or NO-related metabolites through the systemic circulation through red blood cell– or protein-mediated pathways.[75,140]

SUMMARY

The role of endogenous NO in pulmonary vasoregulation and modulation of pulmonary vascular homeostasis has been extensively investigated. Beginning with the observation that NO is the "endothelium-derived relaxing factor," translational physiology studies and clinical experimentation led to the approval of iNO as the first selective pulmonary vasodilator for the treatment of PPHN in term human newborns. Effective lung recruitment and vigilant management of cardiac performance appear vital to the effective use of iNO.

The available evidence from clinical trials suggests that low-dose iNO may be safe and effective in reducing the risk of death or BPD for a subset of premature newborns, in particular infants with birth weights >1000 g. A neuroprotective effect of iNO has been demonstrated in large randomized controlled trials, but the relationship of disease severity and ICH or PVL risk is uncertain. Treatment of premature newborns with respiratory failure between 7 and 14 days after birth appears to be safe and effective in reducing the incidence of BPD. Finally, early concerns about the potential adverse effects of iNO on surfactant function and PDA risk have been effectively eliminated with the cumulative results of both nonhuman primate studies and human clinical trials; however, routine use of iNO in premature newborns should await the results of follow-up studies from the largest clinical trials.

73 Mechanisms Regulating Closure of the Ductus Arteriosus

Ronald I. Clyman

The ductus arteriosus represents a persistence of the terminal portion of the sixth branchial arch. During fetal life, the ductus arteriosus serves to divert blood away from the fluid-filled lungs toward the descending aorta and placenta. After birth, constriction of the ductus arteriosus and obliteration of its lumen separates the pulmonary and systemic circulations. In term infants, obliteration of the ductus arteriosus takes place through a process of vasoconstriction and anatomic remodeling. In the preterm infant, the ductus arteriosus frequently fails to close. The clinical consequences of a patent ductus arteriosus (PDA) are related to the degree of left-to-right shunt through the PDA with its associated change in blood flow to the lungs, kidneys, and intestine.

INCIDENCE

Pulsed Doppler echocardiographic assessments of term infants indicate that functional closure of the ductus has occurred in almost 50% by 24 hours, in 90% by 48 hours, and in all by 72 hours. The rate of ductus closure is delayed in preterm infants, however; essentially all healthy preterm infants of 30 weeks gestation or greater will have closed their ductus by the fourth day after birth. Respiratory distress syndrome (RDS) delays ductus closure; however, in most infants who are 30 weeks gestation or greater, the actual impact of RDS on ductal shunting may be less than commonly assumed (only 11% are still open after 4 days). On the other hand, preterm infants of less than 30 weeks gestation with severe respiratory distress have a 65% incidence of persistent PDA.

The recent introduction of exogenous surfactant therapy has altered both the incidence and the presentation of the PDA. Although surfactant has no effect on the contractile behavior of the ductus, its effects on pulmonary vascular resistance lead to an earlier clinical presentation of the left-to-right shunt in preterm animals[1,2] and humans.[3,4] Infants who are small for gestational age,[5] receive magnesium before birth,[6] have late-onset septicemia,[7] or receive excessive fluid administration during the first days of life also are more likely to have development of a clinically symptomatic PDA.[8] On the other hand, nonwhite infants and those who receive antenatal glucocorticoids have a reduced risk.[9,10]

REGULATION OF DUCTUS ARTERIOSUS PATENCY

In the term infant, closure of the ductus arteriosus occurs in two phases: (1) "functional" closure of the lumen within the first hours after birth by smooth muscle constriction and (2) "anatomic" occlusion of the lumen over the next several days because of extensive neointimal thickening and loss of smooth muscle cells from the inner muscle media.

Balance Between Vasoconstriction and Vasorelaxation

Patency of the fetal ductus arteriosus is regulated by both dilating and contracting factors. The ductus normally has a high level of intrinsic tone during fetal life.[11] The factors that promote ductus constriction in the fetus have yet to be identified. The intrinsic ductus tone is due to components that are both dependent on and independent of extracellular calcium.[11] Permeabilized smooth muscle from the fetal ductus is significantly more sensitive to the contractile effects of calcium than is smooth muscle from the aorta and the pulmonary artery.[12] Endothelin-1 also appears to play a role in producing the basal tone of the ductus.[13]

The factors that oppose ductus arteriosus constriction in utero are better understood. The elevated vascular pressure within the ductus lumen (caused by the constricted pulmonary vascular bed) plays an important role in opposing ductus constriction.[14] The fetal ductus also produces several vasodilators that oppose the ability of the intrinsic ductus tone to constrict the vessel. Vasodilator prostaglandins appear to be the dominant vasodilators that oppose ductus constriction in the later part of gestation.[15] Inhibitors of prostaglandin synthesis constrict the fetal ductus both in vitro and in vivo. Prostaglandin E_2 (PGE_2) is the most potent prostaglandin produced by the ductus[16,17] and appears to be the most important prostanoid to regulate ductus patency. The response of the ductus to PGE_2 is unique among blood vessels in that it is extraordinarily sensitive to this vasodilating substance. PGE_2 produces ductus relaxation by interacting with several of the PGE receptors (EP2, EP3, and EP4).[18] In the ductus, all three of the EP receptors participate in vasodilation by activating adenylate cyclase.[18] The increased intracellular concentrations of cyclic adenosine monophosphate inhibit the sensitivity of the ductus's contractile proteins to calcium.[12] Inhibitors of phosphodiesterase (the enzyme that degrades cyclic adenosine monophosphate) prevent ductus constriction in utero.[19] In addition, one of the EP receptors (EP3) also relaxes the ductus smooth muscle by opening adenosine triphosphate potassium channels, which hyperpolarize the muscle and inhibit ductus tone.[18]

Both isoforms of the enzyme responsible for synthesizing prostaglandins (cyclooxygenase [COX]-1 and COX-2), are expressed in the fetal ductus.[20] Depending on the species, both nonselective (e.g., indomethacin) and selective cyclooxygenase inhibitors constrict the ductus. In the fetal mouse, COX-2 appears to be primarily responsible for the prostaglandins that dilate the ductus,[21] whereas, in the fetal sheep, both COX-1 and COX-2 play a role in ductus patency.[20]

In addition to the prostaglandins that are made within the ductus, the fetal ductus is also under the influence of circulating concentrations of PGE_2. Circulating concentrations of PGE_2 appear to be of placental origin.[22] Circulating concentrations of PGE_2 (approximately 1 nmol/L) in the late-gestation fetal lamb are close to those that produce maximal relaxation of the ductus.[23] PGE_2 concentrations are particularly high in the fetus because of the reduced pulmonary clearance of circulating prostaglandins resulting from the low fetal pulmonary blood flow.[24]

Nitric oxide (NO) is made by the fetal ductus arteriosus and appears to play an important role in maintaining ductus patency in rodent fetuses early in gestation.[15] Although NO is also made in the ductus of larger species, its importance in maintaining ductus patency under normal in utero conditions has not been conclusively demonstrated[25] (see later for the role of NO in fetuses exposed to indomethacin tocolysis and in premature newborns).

Carbon monoxide relaxes the ductus arteriosus, and both hemoxygenase-1 and -2 (the enzymes that make carbon monoxide) are found within the endothelial and smooth muscle cells of the ductus. Under physiologic conditions the amount of carbon monoxide made by the ductus does not seem to affect ductus tone; however, in circumstances where its synthesis is upregulated, for example, endotoxinemia, it may exert a relaxing influence on the ductus.[26] Little evidence exists to suggest that adenosine or β-adrenergic stimulation plays a significant role in ductus patency.[27]

Although pharmacologic inhibition of prostaglandin synthesis produces ductus constriction in utero, genetic interruption of either prostaglandin synthesis (i.e., homozygous combined COX-1 and COX-2–null mice[21]) or prostaglandin signaling (i.e., homozygous EP4 receptor–null mice[28]) does not produce ductus closure in utero. In contrast to what would be expected from the pharmacologic inhibition studies, both genetic interruptions produce newborn mice that fail to close their ductus after birth.[21,28] The mechanisms through which the absence of prostaglandin stimulation alters the normal balance of other vasoactive factors in the ductus have yet to be elucidated. The COX-null mice do have increased nitric oxide production.[29,30] However, inhibitors of nitric oxide production do not increase the rate of ductus closure in the COX-null mice.[31] Stimulation of the prostaglandin receptor EP4 increases hyaluronic acid content in the ductus and promotes intimal cushion formation and ductus closure (see later). Interruption of EP4 signaling decreases intimal cushion formation, which may contribute to delayed luminal occlusion after birth.[32] It is interesting to note that pharmacologic inhibition of prostaglandin synthesis in human pregnancy also is associated with an increased incidence of PDA after birth.[33] However, this appears to be due to the ability of indomethacin to produce ductus constriction in utero. Ductus constriction in utero produces ischemic hypoxia, increased nitric oxide production, and smooth muscle cell death within the ductus wall. These factors prevent the ductus from constricting after birth and make it resistant to the constrictive effects of postnatal indomethacin.[34,35]

After delivery several events promote ductus constriction in the term newborn: (1) an increase in arterial Po_2, (2) a decrease in blood pressure within the ductus lumen (caused by the postnatal decrease in pulmonary vascular resistance), (3) a decrease in circulating PGE_2 (caused by the loss of placental prostaglandin production and the increase in prostaglandin removal by the lung), and (4) a decrease in the number of PGE_2 receptors in the ductus wall.[18] Although the newborn ductus continues to be sensitive to the vasodilating effects of NO, it loses its ability to respond to PGE_2.[36,37] All of these factors promote ductus constriction after birth.

The postnatal increase in arterial Pao_2 plays an important role in ductus constriction. Oxygen's mechanism of action is still unknown. Although neural and hormonal factors possibly contribute to ductus closure under physiologic conditions, they do not mediate oxygen-induced vessel closure. Oxygen appears to constrict the ductus arteriosus by a mechanism that involves smooth muscle membrane depolarization and by a mechanism that is independent of membrane potential.[38] A cytochrome P450 hemoprotein that is located in the plasma membrane of the vascular smooth muscle cells appears to act as a receptor for the oxygen-induced events in the ductus.[39,40] In larger species, oxygen appears to constrict the ductus arteriosus primarily by a mechanism that involves smooth muscle depolarization with subsequent calcium entry through voltage dependent, L-type calcium channels[41] (Clyman, unpublished observations). Oxygen leads to K channel inhibition,[42,43] which depolarizes the ductus smooth muscle cells. Several O_2-sensitive K^+ channels have been found in the fetal ductus. These vary with species and gestational age and may account for the differing sensitivity of the ductus to oxygen throughout gestation.[44,45] In smaller species oxygen increases calcium entry through a mechanism that depends on membrane depolarization and one that is independent of membrane depolarization (possibly acting through store-operated calcium channels and/or through increased calcium sensitization by Rho kinase).[38,46-48]

Oxygen also increases the formation of the potent vasoconstrictor, endothelin-1.[49] However, the role of endothelin-1 in postnatal ductus closure has been questioned,[13,43,50,51] and the pathways through which oxygen alters membrane potential are still unclear.[42,52]

In contrast to the term ductus, the premature ductus is less likely to constrict after birth. This is due to several mechanisms. The intrinsic tone of the extremely immature ductus (<70% of gestation) is decreased compared with the ductus at term.[11] This may be due in part to the presence of smooth muscle myosin isoforms with a weaker contractile capacity in the immature ductus.[53,54] In addition, calcium entry through L-type calcium channels appears to be disrupted under hypoxic conditions in the immature ductus. The potassium channels that promote ductus relaxation also change during gestation (e.g., from K_{Ca} channels [which are not regulated by the postnatal increase in oxygen tension] to K_V channels [which can be inhibited by oxygen in sheep] [Clyman, unpublished observations]).[44,55] Premature infants have elevated circulating concentrations of PGE_2, which may play a significant role in maintaining ductus patency during the first days after birth. This is due to the decreased ability of the premature lung to clear circulating PGE_2.[24] In addition, during episodes of bacteremia and necrotizing enterocolitis, circulating concentrations of PGE_2 reach the pharmacologic range and are often associated with reopening of the ductus arteriosus.[7] The most important mechanism that prevents the preterm ductus from constricting after birth is its increased sensitivity to the vasodilating effects of PGE_2 and NO.[56] The increased sensitivity is not due to an increased number of PGE_2 receptors but rather to enhanced coupling between the receptors and the downstream signaling pathways leading to increased intracellular cyclic adenosine monophosphate.[57] As a result, inhibitors of prostaglandin production (e.g., indomethacin, ibuprofen, and mefenamic acid) are usually effective agents in promoting ductus closure in the premature infant. It follows that drugs interfering with NO synthesis or function also could become useful adjuncts, especially in situations where indomethacin has proved to be ineffective.[58]

The endogenous factors that alter the ability of the preterm ductus to constrict with advancing gestation are unknown. Prenatal administration of vitamin A has been shown to increase both the intracellular calcium response and the contractile response of the preterm ductus to oxygen.[59] During normal fetal development, an increase in circulating cortisol occurs near the end of gestation. Elevated cortisol concentrations in the fetus have been found to decrease the sensitivity of the ductus to the vasodilating effects of PGE_2[60]; consistent with these findings, prenatal administration of glucocorticoids causes a significant reduction in the incidence of PDA in premature humans and animals.[10,60-64] The postnatal administration of glucocorticoids also has been shown to reduce the incidence of PDA.[65] However, postnatal glucocorticoid treatment also seems to increase the incidence of several of the other neonatal morbidities.[66]

Anatomic Closure—Histologic Changes

In the term newborn progressive intimal thickening and fragmentation of the internal elastic lamina occur after delivery. As the intima increases in size, it ultimately forms mounds that occlude the already constricted lumen. The increase in intimal thickening is due (1) to migration of smooth muscle cells from the muscle media into the intima and (2) to proliferation of luminal endothelial cells. The process of intimal cushion formation starts with the accumulation of hyaluronic acid (HA) below the luminal

endothelial cells. This is accompanied by the loss of laminin and collagen IV from the basement membrane of the endothelial cells and their subsequent separation from the internal elastic lamina. The hygroscopic properties of HA cause an influx of water and widening of the subendothelial space; this creates an environment well suited for cell migration. Accompanying the increase in HA is an increase in fibronectin and chondroitin sulfate in the neointimal space.[67] The endothelial and smooth muscle cells of the ductus arteriosus differ from those of the adjacent vessels in their rate of HA accumulation and their ability to form neointimal cushions. The increase in HA appears to be due to increased production of transforming growth factor β in the ductus.[68] Prostaglandins, acting through the EP4 receptor, also appear to play a critical role in HA production in the ductus.[32]

HA makes ductus smooth muscle cells migrate faster than aortic smooth muscle cells. The potentiating effect of HA on ductus smooth muscle cells is mediated through an HA-binding protein (RHAMM). Ductus smooth muscle cells synthesize more RHAMM than aortic smooth muscle cells and concentrate it at the leading edges of the cells. Antibodies against RHAMM will reduce the migration of ductus smooth muscle cells to the level found in aortic smooth muscle cells.[69]

Ductus smooth muscle cells also secrete more fibronectin and chondroitin sulfate than those of the aorta or pulmonary artery.[70] This does not appear to be due to transforming growth factor β. Fibronectin plays an important role in facilitating ductus smooth muscle cell migration. When fibronectin production in the ductus is inhibited, intimal cushion formation is blocked.[71] On the other hand, fibronectin has no effect on the migration of aortic smooth muscle cells. The increased production of chondroitin sulfate appears to have no direct effect on either ductus or aortic smooth muscle cell migration.[72]

Ductus arteriosus smooth muscle cells use a family of cell surface receptors, called integrins, to interact with, adhere to, and migrate through the extracellular matrix that surrounds them. When smooth muscle cells of the ductus are in a quiescent, contractile state, they express the same integrins on their cell surface as smooth muscle cells of the aorta. However, when ductus smooth muscle cells of the inner muscle media begin to migrate into the subendothelial space, two new integrin complexes appear on their cell surface: the αvβ3 and the α5β1 receptors. The αvβ3 integrin is a promiscuous receptor that interacts with most extracellular matrix glycoproteins and is essential for migration of ductus smooth muscle cells in vitro. The α5β1 integrin binds exclusively to fibronectin and mediates the potentiating effects of fibronectin on ductus smooth muscle cell migration. During the process of migration, ductus smooth muscle cells secrete laminin, which also has an important promigratory role.

Intimal cushion formation in the ductus is also associated with striking alterations in elastin fiber assembly. In contrast to the aorta, where formation of well-developed elastic laminae are seen between layers of muscle cells, smooth muscle cells of the ductus muscle media are surrounded by thin and fragmented elastin fibers. Smooth muscle cells in the neointima are surrounded by even fewer elastin fibers.[73] The disruption of normal elastin fiber assembly in the ductus does not appear to be due to increased elastase activity or decreased tropoelastin production. Rather, it appears to be due to a developmental mechanism that reduces insolubilization of elastin and prevents formation of intact elastic laminae. Vascular smooth muscle cells synthesize a 67-kDa elastin-binding protein (EBP) that is central to the assembly of soluble tropoelastin molecules into a mature matrix of insoluble elastic fibers.[74] The 67-kDa EBP binds the hydrophobic tropoelastin molecule intracellularly, escorts it through the smooth muscle cell's secretory pathways, and attaches it to the cell's surface. When galactosugars come in contact with the lectin-binding site of the 67-kDa EBP, the bound tropoelastin is released from the cell membrane. Coordinated presentation of galactosugars regulates the orientation and proper alignment of tropoelastin for cross-linking during normal elastin fiber assembly. On the other hand, excess galactosugars, from other matrix elements, may compete with this process and lead to abnormal assembly (see later).[75]

Ductus smooth muscle cells have less 67-kDa EBP on their cell surface when compared with aortic smooth muscle cells.[76] As a result, ductus smooth muscle cells deposit little insoluble elastin when compared with aortic smooth muscle cells. In addition, the increased amounts of chondroitin sulfate in the ductus may dissociate tropoelastin from the cell surface (through its galactosugar side chains); this would further interfere with elastin fiber assembly.[76]

The exact relationship between impaired elastin assembly and smooth muscle migration into the neointima is still open for speculation. Ductus smooth muscle cells are able to migrate through elastin membranes that restrain aortic smooth muscle cell migration. Treatment of aortic smooth muscle cells with chondroitin sulfate causes the release of the 67-kDa EBP from the aortic cell's surface and enables them to migrate through elastin membranes at the same rate as ductus smooth muscle cells.[77] In addition, tropoelastin fragments may act as a chemoattractant for smooth muscle cells.[78] Thus mechanisms appear to exist that link elastin fragmentation with formation of ductus intimal cushions. Conversely, in some genetic forms of PDA, the elastic laminae of the ductus appear abnormally well developed and similar to those in the aorta; when this occurs, intimal cushions fail to develop.[73]

Relationship Between Vasoconstriction and Anatomic Closure

In term animals, loss of responsiveness to PGE_2 shortly after birth prevents the ductus arteriosus from reopening once it has constricted.[36,37] This is due, in part, to the decreased synthesis of PGE_2 receptors in the ductus. Both the loss of vasodilator regulation and the anatomic events that lead to permanent closure appear to be controlled by the degree of ductus smooth muscle constriction. Experimental models that alter the ability of the ductus to constrict at term also prevent the normal histologic changes that occur after birth.* Constriction produces ischemic hypoxia of the vessel wall.[81] In the term newborn ductus, the ischemic hypoxia that accompanies constriction occurs even before luminal flow has been eliminated and depends on the presence of intramural vasa vasorum.[82] With advancing gestation, the thickness of the ductus wall increases in size to a dimension that requires the presence of intramural vasa vasorum to provide nutrients to its outer half. These collapsible, intramural vasa vasorum provide the ductus with a unique mechanism for controlling the maximal diffusion distance for oxygen and nutrients across its wall. In the term newborn, ductus constriction obliterates vasa vasorum flow to the outer muscle media, which turns the entire thickness of the muscle media into a virtual avascular zone. The profound ischemic hypoxia that follows the compression of the vasa vasorum inhibits local production of PGE_2 and NO, induces local production of growth factors (e.g., transforming growth factor β and vascular endothelial growth factor), and produces smooth muscle apoptosis in the ductus wall. Vascular endothelial growth factor plays a critical role in the migration of the ductus smooth muscle cells into the neointima and in the proliferation of intramural vasa vasorum.[83] After postnatal ductus constriction, several genes known to be essential for vascular remodeling (HIF1α, VCAM-1, E-selectin, IL-8, MCSF-1, CD154, IFNγ, IL-6, and TNFα) are increased in the ductus wall. In addition, VLA4-positive monocytes and macrophages (CD68 and CD14 positive) adhere to the ductus wall. The inflammatory response that follows postnatal ductus constriction may be as necessary for ductus remodeling because the extent of neointimal remodeling

*References 14, 21, 28, 71, 79, 80.

is significantly correlated with the degree of mononuclear cell adhesion.[84]

In preterm infants, the ductus frequently remains open for many days after birth. Even when it does constrict, the premature ductus frequently fails to develop profound hypoxia and anatomic remodeling. The preterm infant seems to require a greater degree of ductal constriction than the term infant to develop a comparable degree of hypoxia. In contrast with the term ductus, the thin-walled preterm ductus does not depend on intramural vasa vasorum to provide oxygen and nutrients to its wall. The absence of intramural vasa vasorum leaves the preterm ductus without a mechanism to rapidly increase the diffusion distance across its wall during postnatal constriction. As long as any degree of luminal patency exists, the thin-walled preterm ductus fails to become profoundly hypoxic and fails to undergo anatomic remodeling after birth. As a result, the preterm ductus requires complete cessation of luminal flow before it can develop the same degree of hypoxia as found at term. Once the preterm ductus develops the same degree of hypoxic ischemia as the term ductus, most of the anatomic changes seen at term will occur.[11,58] However, if the premature ductus does not develop the profound degree of ischemic hypoxia that is necessary to induce anatomic remodeling, it will not develop smooth muscle cell death and will remain essentially fetal in appearance. Without anatomic remodeling, the preterm ductus is still susceptible to vessel reopening.

In contrast to the term newborn ductus, where all of the PGE_2 EP receptors are down-regulated after birth, the preterm newborn ductus increases its synthesis of the dominant PGE_2 receptor, EP4, and continues to respond to PGE_2 after birth. In addition to its persistent responsiveness to PGE_2, the premature ductus synthesizes increased amounts of other vasodilators (e.g., NO, tumor necrosis factor α, and interleukin 6) after birth in response to the postnatal ductus wall hypoxia.[83,84] As a result, a change occurs in the relative balance of the vasodilators that maintain ductus patency after birth. Ductus patency becomes less dependent on prostaglandin generation and more dependent on other vasodilators during the first weeks after birth. In addition, adenosine triphosphate concentrations are significantly altered in the preterm ductus, even when the ductus remains patent after birth. The decreased adenosine triphosphate concentrations prevent the immature neonatal ductus from contracting as vigorously as the fetal ductus.[85] These postnatal changes could explain why the effectiveness of indomethacin wanes with increasing postnatal age.[86,87] In premature animals and humans, the combined use of a nitric oxide synthase-inhibitor and indomethacin produces a much greater degree of ductus constriction than indomethacin alone.[58,88] It follows that drugs that interfere with NO synthesis could become useful, especially in situations where indomethacin has been found to be ineffective.[58]

HEMODYNAMIC AND PULMONARY ALTERATIONS

The pathophysiologic features of a PDA depend both on the magnitude of the left-to-right shunt and on the cardiac and pulmonary responses to the shunt. Important differences exist between immature and mature infants in the heart's ability to handle a volume load. Immature infants have less cardiac sympathetic innervation. Before term, the myocardium has more water and less contractile mass. Therefore in the immature fetus the ventricles are less distensible than at term and also generate less force per gram of myocardium (even though they have the same ability to generate force per sarcomere).[89] The relative lack of left ventricular distensibility in immature infants is more a function of the ventricle's tissue constituents than of poor muscle function. As a result, left ventricular distention resulting from a large left-to-right PDA shunt may produce a higher left ventricular end-diastolic pressure at smaller ventricular volumes. The increase in left ventricular pressure increases pulmonary venous pressure and causes pulmonary congestion.

Studies in preterm lamb and human newborns[90,91] have shown that, despite these limitations, preterm newborns are able to increase left ventricular output and maintain their "effective" systemic blood flow, even with left-to-right PDA shunts equal to 50% of left ventricular output. With shunts greater than 50% of left ventricular output, "effective" systemic blood flow falls, despite a continued increase in left ventricular output. The increase in left ventricular output associated with a PDA is accomplished not by an increase in heart rate, but by an increase in stroke volume.[90,91] Stroke volume increases primarily as a result of the simultaneous decrease in afterload resistance on the heart and the increase in left ventricular preload. Despite the ability of the left ventricle to increase its output in the face of a left-to-right ductus shunt, blood flow distribution is significantly rearranged. This redistribution of systemic blood flow occurs even with small shunts.[90] Blood flow to the skin, bone, and skeletal muscle is most likely to be affected by the left-to-right ductus shunt. The next most likely organs to be affected are the gastrointestinal tract and kidneys. These organs receive decreased blood flow because of a combination of decreased perfusion pressure (resulting from a drop in diastolic pressure) and localized vasoconstriction. These organs may experience significant hypoperfusion before any signs of left ventricular compromise exist.[91,92] This decrease in organ perfusion may contribute to some of the morbidities that have been associated with ductus patency: decreased feeding tolerance, necrotizing enterocolitis, and decreased glomerular filtration rate.[86,93,94] Reversal of aortic flow during diastole has been found to be a good predictor of necrotizing enterocolitis.[95]

The decreased ability of the preterm infant to maintain active pulmonary vasoconstriction may be responsible in part for the earlier presentation of a "large" left-to-right PDA shunt.[96,97] In addition, therapeutic maneuvers (e.g., surfactant replacement) that lead to a more rapid drop in pulmonary vascular resistance can exacerbate the amount of left-to-right shunt in preterm infants with RDS and lead to pulmonary hemorrhage.[4,98] Randomized, controlled trials have shown that early ductus closure decreases the incidence of significant pulmonary hemorrhage.[86,99,100]

The factors responsible for preventing plasma fluid and protein from moving into the lung interstitium and from the interstitium into the air spaces have been described elsewhere in this text. With a wide-open PDA, the pulmonary vasculature is exposed to systemic blood pressure and increased pulmonary blood flow. Because the premature infant with RDS frequently has low plasma oncotic pressure and increased capillary permeability, increases in microvascular perfusion pressure that result from a PDA may increase interstitial and alveolar lung fluid. Leakage of plasma proteins into the alveolar space inhibits surfactant function and increases surface tension in the immature air sacs,[101] which are already compromised by surfactant deficiency. The increased Fio_2 and mean airway pressures required to overcome these early changes in compliance may be important factors in the association of PDA with chronic lung disease.[86,102,103] However, these changes in pulmonary mechanics appear to occur only after several days of exposure to a PDA. Although it is true that preterm animals with a PDA have increased fluid and protein clearance into the lung interstitium, resulting from an increase in pulmonary microvascular filtration pressure, a simultaneous increase in lung lymph flow appears to eliminate the excess fluid and protein from the lung. This compensatory increase in lung lymph acts as an "edema safety factor," inhibiting fluid accumulation in the lungs. As a result, no net increase occurs in water or protein accumulation in the lung and no change occurs in pulmonary mechanics.[1,86,104-106] This delicate balance between the PDA-induced fluid filtration and lymphatic reabsorption is consistent with the observation, made in human infants, that closure of the ductus arteriosus, within the first 24 hours after birth, has

no effect on the course of the newborn's hyaline membrane disease. However, if lung lymphatic drainage is impaired, as it is in the presence of pulmonary interstitial emphysema or fibrosis, the likelihood of edema increases dramatically. After several days of lung disease and mechanical ventilation, the residual functioning lymphatics are more easily overwhelmed by the same size ductus shunt that could be accommodated on the first day after delivery. As a result, it is not uncommon for pulmonary edema and alterations in pulmonary mechanics to develop in infants with a persistent PDA at 7 to 10 days after birth. In these infants, improvement in lung compliance occurs after closure of the PDA.[107-109]

The factors responsible for these alterations in pulmonary mechanics have recently been examined in a premature baboon model (McCurnin, Yoder, Seidner, and colleagues, unpublished results). These animals were delivered at 67% term gestation (equivalent to 26 weeks human gestation) and were given surfactant and mechanically ventilated for 2 weeks. One group was treated with a cyclooxygenase inhibitor to close the ductus whereas the other group had a persistent PDA for 2 weeks. No differences were found in surfactant secretion, epithelial protein permeability, or increase in surfactant inhibitory proteins when the preterm baboons were exposed to an open PDA for 2 weeks after birth. Although numerous changes occurred in the genes that regulate inflammation and tissue remodeling in the preterm lung after birth, the presence of an open ductus did not appear to alter the expression pattern of these pro-inflammatory genes or of the genes involved in lung remodeling. The animals with an open ductus had both an increased amount and an altered distribution of water in their lungs. In contrast with the term lung, which mobilizes fluid rapidly after birth, the preterm lung mobilizes lung fluid much more slowly. A persistent PDA led to a small but significant increase in lung water at 2 weeks after delivery. Closure of the PDA with a cyclooxygenase inhibitor, such as indomethacin or ibuprofen, produced increased expression of epithelial sodium channels and increased removal of fluid from the alveolar compartment. In addition, pharmacologic closure of the PDA was associated with improved lung development. In contrast to preterm animals with an open ductus, where an arrest in alveolar development (the hallmark of the new "bronchopulmonary dysplasia") was noticeable by 2 weeks after birth, pharmacologic closure of the PDA led to improved alveolarization. The same improvements in pulmonary mechanics and alveolar surface area were not observed after surgical ligation of the PDA.[110] Ductus ligation, although eliminating the detrimental effects of a PDA, appears to introduce its own set of problems in the preterm newborn.[111]

Not all of the changes associated with a PDA are necessarily detrimental to the immature infant with RDS. Persistence of the left-to-right shunt maintains an elevated Pa_{O_2} in the presence of atelectasis. Decreases in systemic arterial O_2 content have been observed after PDA closure, despite the absence of any alterations in pulmonary mechanics. This phenomenon is due to recirculation of oxygenated arterial blood through lungs that are not fully expanded.[90,112]

74 Regulation of Umbilical Blood Flow

S. Lee Adamson, Leslie Myatt, and Bridgette M. P. Byrne

OVERVIEW

Oxygen, carbon dioxide, nutrients, metabolic wastes, and hormones are transported by blood flowing between the placenta and the fetal body in the umbilical cord. Normal fetal growth and development depend on ever-increasing umbilical blood flow to meet the growing demand for exchange with the maternal circulation. Growth of the placenta with the corresponding creation of new vascular channels provides an important mechanism for the long-term regulation of umbilical blood flow.[1,2] However, the focus of this chapter is the vasoactive regulation of umbilical blood flow, which is accomplished by numerous mediators that influence vascular resistance in umbilicoplacental circulation. Umbilical blood flow regulation plays a role in maintaining fetal growth and central arterial pressure, in perfusion-perfusion matching within the placenta, and in the closure of the umbilical vessels at birth.

The umbilicoplacental circulation is critically important for the normal growth and development of the fetus. This interesting vascular bed has many unique features. For instance, the umbilical artery and vein are extremely long and muscular, and the resistance of the placental microcirculation is low. This means that a significant proportion of the total vascular resistance in this circulation resides in the umbilical vessels themselves. Under normal in utero conditions, the umbilicoplacental circulation appears to be nearly maximally dilated, yet the umbilical vessels are highly vasoactive and, unlike most large vessels, are capable of constricting so vigorously that the lumen is obliterated (e.g., at birth). The umbilical artery is sensitive to many circulating vasoconstrictors but has the unusual feature of being refractory to active vasorelaxation by the cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) pathways.[3,4] Perhaps the absence of active relaxation contributes to the vasospasm of the umbilical vasculature after birth. How the umbilical vessels are maintained in a nearly fully relaxed state throughout pregnancy is an interesting unanswered question.

This chapter begins with a brief description of the anatomy of the umbilicoplacental circulation and the sites of blood flow regulation in this bed. The important functions of blood flow regulation and the factors involved are then reviewed, after a brief outline of the major experimental methods that have been used to obtain this information. Finally abnormalities in umbilical blood flow regulation in intrauterine growth restriction (IUGR), a common and serious cause of mortality and morbidity in human pregnancy, are described.

ANATOMY OF THE HUMAN UMBILICOPLACENTAL CIRCULATION

The umbilical arteries in the human arise from the internal iliac arteries (Figure 74-1), then curve upward along either side of the bladder. At the umbilicus, they enter the umbilical cord, where

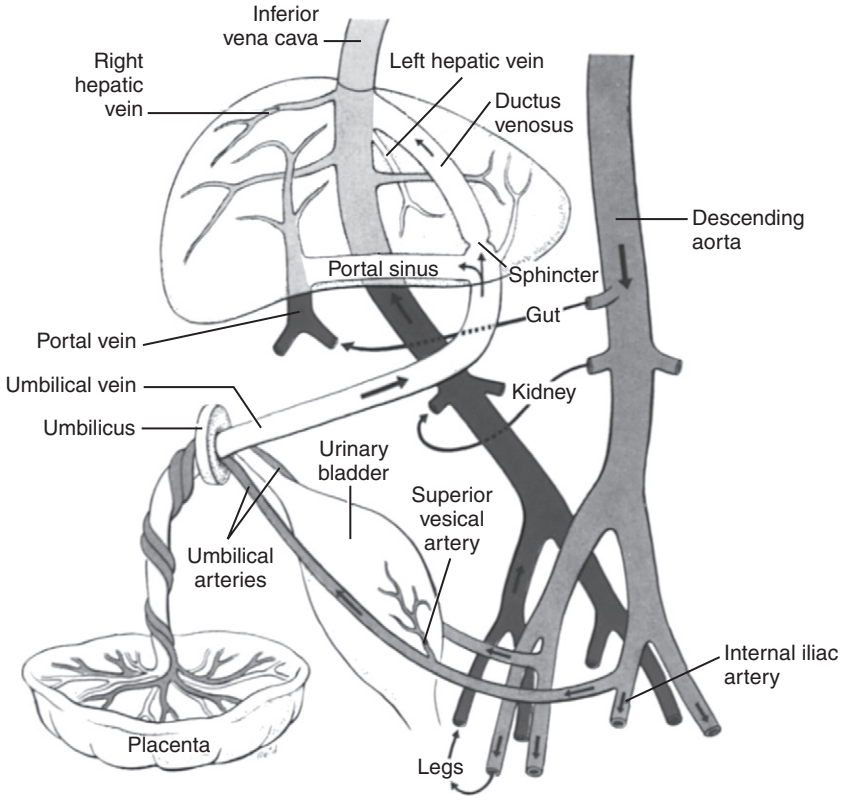

Figure 74-1 A simplified scheme of the human umbilicoplacental circulation. The umbilical arteries arise from the internal iliac arteries, then curve upward to the umbilicus on either side of the bladder. After emerging from the umbilicus, the arteries form a spiral around the umbilical vein before branching into the chorionic arteries on the surface of the placenta. Villous arteries penetrate the surface of the placenta then branch further, ultimately reaching the gas exchange surfaces in the terminal placental villi. Villous veins return blood from the placenta to the chorionic veins, visible on the surface of the placenta; blood then enters the umbilical vein in the umbilical cord. Within the abdomen, the umbilical vein enters the liver, where flow passes to the inferior vena cava either through the ductus venosus or the hepatic circulation. Not drawn to scale. *(Modified from Moore KL, Persaud TVN:* The Developing Human, *ed 5, Philadelphia, WB Saunders, 1993, p 344.)*

the arteries form a loose spiral around a single umbilical vein. The umbilical vessels are embedded in Wharton jelly within the umbilical cord, which is approximately 60 cm long at term.[5,6] The umbilical arterial wall is atypical because it has a high wall thickness relative to its lumen diameter, the vascular smooth muscle cells form several layers that differ in cellular orientation from circular near the outside to longitudinal near the lumen, and no internal elastic lamina separates the smooth muscle from the endothelial cells lining the lumen of the vessel.[7,8] The thick arterial muscle wall is sparsely supplied by vasa vasorum.[8,9] The umbilical arteries are joined by Hyrtl anastomosis near the surface of most placentas (approximately 96%) so that arterial pressure is equalized near the placental surface.[5,6]

The umbilical arteries branch at the fetal surface of the discoid human placenta to form many radially oriented chorionic arteries located on the surface of the chorionic plate. Distal branches of the chorionic arteries penetrate the fetal surface of the human placenta to supply 60 to 70 villous arteries, which in turn supply 10 to 40 cotyledons.[10] Cotyledonary units are separated by decidual septa arising from maternal tissue. Within the villous trees, the arteries continue branching to ultimately form arterioles within the intermediate villi. Exchange with maternal blood in the intervillous space of the cotyledons occurs primarily across the fetal capillaries of the terminal villi.

Veins within the villi merge progressively to return blood from the placenta to the chorionic veins on the fetoplacental surface. Blood then enters a single umbilical vein. The wall of the umbilical vein is highly muscular with circularly oriented smooth muscle cells arranged in concentric sheets loosely connected by ground substance.[7,8] Venous blood is then returned to the fetal inferior vena cava through the parallel arrangement of the ductus venosus and the hepatic vessels. The component of umbilical blood flow bypassing the hepatic circulation through the ductus venosus decreases from approximately 30% to 40% at midgestation to between 15% and 20% at term.[11,12]

HEMODYNAMICS OF UMBILICAL BLOOD FLOW

Umbilical arterial blood flow consists of a mean blood flow component (i.e., the mean flow over the cardiac cycle) with a superimposed pulsatile component (i.e., the phasic flow within a cardiac cycle). In terms of the net transport of substances to and from the placenta, it is the mean blood flow component that is of primary importance. The sites and mechanisms regulating these two components of arterial blood flow differ; for this reason they are considered in separate sections of this chapter.

Mean Blood Flow

Mean umbilical blood flow (Q_{Um}) depends on the pressure gradient that drives flow from the iliac artery in humans (BP_A) to the inferior vena cava (BP_{IVC}), and on the total vascular resistance of the serially arranged segments of the umbilicoplacental pathway (R_{tot}). Total vascular resistance represents the sum of the resistances in the umbilical artery and its branches (R_{UmA}), in the placental microcirculation (R_{Pl}), in the umbilical vein and

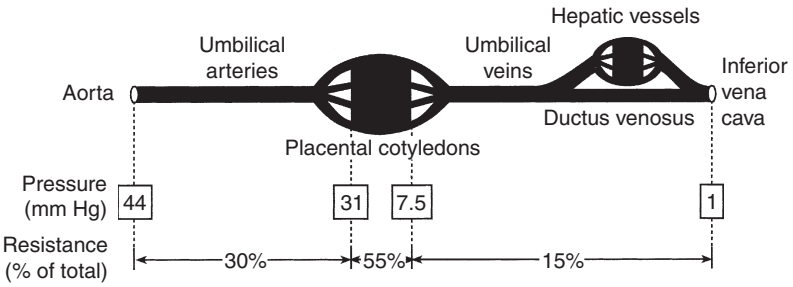

Figure 74-2 Distribution of blood pressures and vascular resistances within the sheep umbilicoplacental circulation near term (128 days gestation). Flow through this circulation is approximately 200 mL/min/kg. *(Data from Adamson SL, Whiteley KJ, Langille BL: Pulsatile pressure-flow relations and pulse-wave propagation in the umbilical circulation of fetal sheep,* Circ Res *70:761, 1992.)*

its branches (R_{UmV}), and in the parallel arrangement of the ductus venosus (R_{DV}) and hepatic circulation (R_H). Each of these segments is a potential site for regulation of mean blood flow through this bed.

$$Q_{Um} = (BP_A - BP_{IVC}) / R_{tot}$$

$$R_{tot} = R_{UmA} + R_{P1} + R_{UmV} + (1/R_{DV} + 1/R_H)^{-1}$$

In most systemic vascular beds, large arteries and veins contribute little to the total vascular resistance of the circulation and therefore are not important regulators of organ blood flow. However, the umbilicoplacental circulation is unusual in that the umbilical artery and vein are extremely long and muscular, and the resistance of the placental microcirculation is very low. In sheep, although the largest fraction of the total vascular resistance resides in the placental microcirculation (approximately 55%), almost half the total resistance resides in the umbilical vessels and their major branches, and in the ductus venosus–hepatic circulation[13,14] (Figure 74-2). Human umbilical vessels are perhaps four times longer than in sheep, so it is possible that the human umbilical vessels make an even larger contribution to total umbilicoplacental vascular resistance. The greater prevalence of Hyrtl anastamoses in humans (approximately 96%) than sheep (approximately 50%) may be caused by the greater need for pressure equalization at the placenta as a result of the much greater length of the umbilical artery in humans.

Pulsatile Blood Flow

The pulsatile component of umbilical arterial blood flow is driven by the pulsatile component of pressure at the entrance to the umbilical artery. The pulse amplitude of umbilical arterial flow depends on the pulse amplitude of arterial pressure and on the so-called vascular input impedance that is primarily dependent on the attributes of the umbilical artery, its radius, wall thickness, and wall stiffness.[15] Umbilical input impedance is also influenced by the properties of the chorionic and stem arteries, but it is entirely independent of the properties of the vessels past the point where all pulsations generated by the heart have been attenuated (i.e., past the arterioles). The pulsatile component of flow is not important for transport because there is no net motion when it is averaged over the cardiac cycle; even so, this pulsatility may be important in promoting endothelial nitric oxide production and maintaining low placental vascular resistance, as suggested by bypass experiments in fetal sheep.[16] It is also of interest clinically because the pulse amplitude of the flow velocity waveform in the umbilical artery is the numerator in the so-called pulsatility index, as well as being an important factor in other indices of pulsatility. Indices of pulsatility are elevated in the umbilical artery of fetuses with IUGR that are at highest risk for poor outcome.[17] The pulse amplitude of umbilical arterial flow tends to decrease with distance along the umbilical cord due to viscous losses in the blood and vessel wall. This attenuation results in a progressive decrease in indices of pulsatility when blood velocity waveforms are obtained at more distant sites along the cord.[18]

Atrial contraction of the heart generates pulse waves that are transmitted away from the heart into the venous system causing brief negative deflections in the predominantly forward-moving blood in the veins in association with the cardiac cycle. This effect can cause pulsatililty in the blood velocity waveform of the umbilical vein and ductus venosus. Although such pulsatility is normal in early human pregnancy, when propagation distances are short, pulsatility in the umbilical vein and ductus venosus typically is not observed in late pregnancy unless the fetus has cardiovascular pathology resulting in augmentation of the strength of atrial contraction or of the efficiency of pulse wave propagation in the venous system.[12] Wave propagation into the umbilical vein and ductus venosus is increased by dilation of the ductus venosus alone or in combination with constriction of the umbilical vein, such as may occur during fetal hypoxia or hemorrhage.[12]

METHODS USED TO STUDY UMBILICAL BLOOD FLOW REGULATION

Ultrasound Imaging

Pulsed Doppler ultrasound imaging provides a sensitive and noninvasive means of detecting the velocity of red blood cells in the umbilical artery or vein in humans[19] and other species including sheep,[19] guinea pigs,[20] and mice[21] (Figure 74-3). The shift in the frequency of the echo relative to the transmitted Doppler sound wave is directly proportional to the velocity of the red blood cells that generate the echo. For accurate velocity determination, angle correction is required if the angle between the transmitted wave and the direction of red blood cell motion exceeds approximately 20 degrees. Measurement of this angle can be problematic in the umbilical artery because of its spiral path but can be reasonably accurate in the much straighter intraabdominal umbilical vein. Blood velocity can be used to calculate blood flow by multiplying by vessel cross-sectional area determined from blood vessel diameter measurements. Flow per kilogram of fetal body weight can be calculated using an estimate of fetal body weight determined from ultrasound measurements of fetal abdominal and head circumferences.[22-24]

Perfused Placenta in Vitro

Early studies investigated the vasoactivity of the human umbilicoplacental circulation by perfusing the entire placenta through the umbilical cord after delivery at a fixed flow rate and then recording the change in perfusion pressure induced by vasoactive agents delivered into the umbilical artery.[25] Obtaining a completely undamaged (i.e., leak-free) placenta was difficult, however,

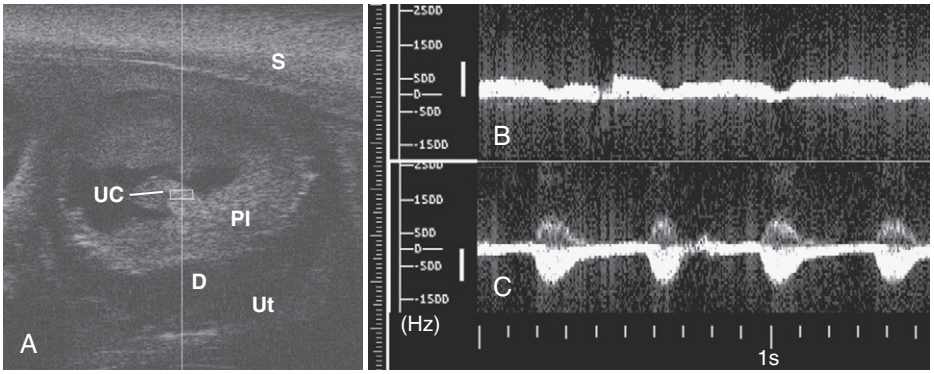

Figure 74-3 High-frequency ultrasound technology permits Doppler blood velocity measurements in the umbilical cord throughout embryonic and fetal development in the mouse. This, combined with the potential for exploring gene function in genetically modified mice, makes it an attractive new model for future research. **A,** The placenta *(Pl)* and umbilical cord *(UC)* of a mouse embryo at day 10.5 of gestation. The anesthetized pregnant mouse was imaged transcutaneously using 40 MHz ultrasound. The locations of the maternal skin *(S),* decidua *(D),* and uterus *(Ut)* are indicated. The *box* shows the location of the Doppler sample volume on the umbilical cord. By moving the sample volume slightly, the Doppler blood velocity waveform was obtained separately in the umbilical vein **(B)** and umbilical artery **(C)** of the embryo. The smallest division on the *scale bar* in **A** is 100 μm. The *vertical white bar* along the *y* axis in **B** and **C** shows a Doppler shift frequency of 0 to 1000 Hz. *(Unpublished data from the work of Zhou YQ, Adamson SL, 2002.)*

so most current work perfuses a single peripheral placental cotyledon through cannulas inserted into a chorionic artery and vein on the fetal placental surface and through two or more cannulas inserted into the corresponding intervillous space through the maternal placental surface. This method, originally developed to study placental transfer,[26] has been used to investigate vasoactivity. The cotyledon is perfused at a fixed flow rate so that an increase in perfusion pressure in the fetal chorionic artery indicates an increase in fetoplacental vascular resistance. The preparation is viable for 12 hours or more of perfusion.[27]

Umbilicoplacental Vessels in Vitro

The vasoactivity of segments, rings, or strips of larger vessels in the human umbilicoplacental circulation has been extensively studied in vitro. In early studies, endothelial cell damage may have occurred before the importance of the endothelium in regulation of smooth muscle tone was recognized. The vasoactivity of vessel strips or rings is studied by recording muscle tension with a strain gauge, whereas the vasoactivity of a vessel segment is detected by perfusing the segment at a constant rate and recording changes in perfusion pressure.[28] The vasoactivity of umbilical and chorionic vessels, as well as villous stem arteries, and of their second- and third-order branches has been studied using these methods.[29] The production of vasoactive substances by placental vessels can be studied by determining the effect of placental vessel effluent on a strip of isolated smooth muscle used as a detector tissue. The degree of contraction or relaxation of the detector muscle provides a bioassay for vasoactive substances.[30] Differences in vasoactivity between different segments of the umbilicoplacental circulation have been observed[31,32] (see Table 74-1).

Implanted Instrumentation

Fetal sheep are most commonly used for studies requiring implanted instrumentation, although similar studies are possible in other species such as goats and baboons. For studies on the umbilicoplacental circulation, chronic instrumentation is preferred to avoid the elevated umbilicoplacental vascular resistances observed in acutely instrumented fetal sheep under halothane anesthesia (approximately a 2.5-fold increase).[13,33] Mean blood pressure is measured using fluid-filled catheters implanted in arteries or veins that are coupled to strain-gauge pressure transducers outside the animal. Most studies measure only the total pressure gradient across the umbilicoplacental circulation (aorta to inferior vena cava) so that only total vascular resistance is determined. However, several studies have measured pressure gradients across individual segments of the umbilicoplacental circulation, enabling determination of segmental vascular resistance.[13,33-35] These studies have revealed large differences in vasoactivity among the umbilical arteries, veins, microcirculation, ductus venosus, and hepatic circulation in fetal sheep. Mean blood flow is measured using electromagnetic transducers or ultrasound transit-time transducers implanted around the common umbilical artery or vein[36,37] or by using labeled microspheres,[38] Fick's principle (e.g., with antipyrine),[39,40] or dye dilution methods.[41] It is now recognized that antipyrine is not an ideal tracer for flow studies because it inhibits prostaglandin synthesis and has measurable physiologic effects in fetal sheep.[42]

IMPORTANCE OF UMBILICAL BLOOD FLOW REGULATION

The umbilicoplacental circulation is nearly maximally dilated[35] and the fetal biventricular cardiac output is near maximal under basal conditions in the near-term fetal sheep.[43] Thus umbilical blood flow can be increased little by further dilating this vascular bed to reduce the resistance to flow or by increasing the driving pressure for flow by increasing cardiac output (hence mean arterial pressure). Nevertheless, umbilical blood flow can be increased by increasing vascular resistance in the fetal body to increase mean arterial pressure and thereby direct a larger proportion of the biventricular cardiac output to the placenta. In practice, however, umbilical blood flow is remarkably constant. During episodes of breathing activity in fetal sheep, fetal oxygen consumption increases and Pa_{O_2} decreases significantly, yet umbilical blood flow and mean arterial pressure remain essentially constant.[44] Umbilical blood flow also changes little when the fetal sheep changes sleep state.[45] Even when the sheep fetus is made hypoxemic, umbilical blood flow remains nearly constant in fetuses near term.[46] This has led to the impression that the umbilicoplacental circulation is passive. Nevertheless, short-term regulation of vascular resistance does occur in this vascular bed, and it plays important physiologic roles in optimizing placental exchange by matching regional maternal and fetal

blood flows, in maintaining mean arterial blood pressure during hemorrhage, and in causing complete closure of this vascular bed at birth. In addition, abnormalities in vasoactive control of the umbilicoplacental circulation may contribute to the etiology of IUGR. Each of these roles is described in detail later in the chapter.

Support of Fetal Growth

Umbilical blood flow gradually increases as the fetus grows and placental exchange requirements increase. In humans, umbilical blood flow increases in direct proportion to the increase in fetal body weight so that flow expressed relative to fetal weight remains approximately constant at 110 to 125 mL/min^{-1}/kg^{-1} during the last third of pregnancy.[23,47-49] Human fetal biventricular cardiac output is approximately 450 mL/min^{-1}/kg^{-1}, and it remains approximately constant over this gestational age range.[24,50] Thus umbilical blood flow represents approximately 30% of fetal biventricular cardiac output.[24]

In IUGR, fetuses fail to achieve their full growth potential for a variety of reasons, including infection, drug abuse, maternal malnutrition, and placental insufficiency caused by increased umbilicoplacental resistance or unknown etiology. The fetus appears to respond to inadequate placental transfer of nutrients or oxygen by restricting growth to conserve limited resources for more essential functions, thereby maintaining viability. Umbilical blood flow and umbilical blood flow per kilogram estimated fetal body weight are lower than normal in growth-restricted fetuses.[49,51] Early work suggested that umbilical blood flow in the sheep fetus normally exceeds that required so that there is a margin of safety in umbilical flow. This was based on evidence that acute reductions in umbilical blood flow caused an increase in oxygen extraction and no change in fetal oxygen consumption until flow was reduced by more than 40% to 50%.[52,53] However, a 30% to 40% reduction in umbilical blood flow that was maintained for 10 to 14 days reduced fetal growth and oxygen consumption, suggesting little margin of safety in umbilical blood flow with respect to fetal growth.[54,55]

Perfusion-Perfusion Matching to Optimize Maternal-Fetal Exchange

To maximize exchange, highly perfused regions on the maternal side of the placenta should be matched with well-perfused regions on the fetal side. This matching, analogous to ventilation-perfusion matching in the lung, makes teleologic sense, and this mechanism is supported by evidence from experiments in the perfused human placental cotyledon and in fetal sheep. Human cotyledons in vitro are usually perfused through the maternal intervillous space with media that have been equilibrated with 95% O_2 and 5% CO_2, which results in a perfusate Po_2 that exceeds 500 mm Hg. A large reduction in maternal perfusate Po_2 (to approximately 25 mm Hg) results in a rapid vasoconstrictive response in the fetal placental vasculature; an effect that is rapidly reversed by increasing maternal perfusate Po_2.[56] Hypoxic vasoconstriction of the fetal placental microcirculation has been postulated to mediate perfusion-perfusion matching in the human placenta,[56] and it appears to be mediated by an hypoxia-induced decrease in nitric oxide production.[57]

In sheep, regional maternal and fetal blood flows measured using radioactive microspheres within cotyledons are correlated under baseline conditions.[58] When maternal blood flow to a placental region is reduced (e.g., by ligating maternal vessels or by embolizing with microspheres) fetal blood flow to the corresponding region decreases within 24 hours.[59] The mechanisms that increase umbilicoplacental vascular resistance in response to a decrease in maternal placental blood flow in sheep are not fully understood. However, they may be mediated by hypoxic vasoconstriction, as occurs in ventilation-perfusion matching in the lung. In the fetal sheep near term, fetal hypoxia induced by maternal inhalation of a low-oxygen mixture causes only a small increase in umbilicoplacental vascular resistance (e.g., 20%).[14,60] Some evidence suggests that hypoxic vasoconstriction in the placenta may beis reversed by enhanced β-adrenergic activity caused by fetal hypoxia.[61] The small increase in umbilicoplacental resistance during fetal hypoxia is caused specifically by a more than 100% increase in resistance of the umbilical vein and hepatic circulation, which is mediated by the α-adrenergic system.[14,60,62] In preterm fetal sheep (at approximately 95 days gestation), fetal hypoxia causes a larger (e.g., 50%) increase in umbilicoplacental resistance.[63] The site and the mechanism of vasoconstriction in these preterm fetuses are not known. It is possible that locally mediated hypoxic vasoconstriction within the placenta is not so effectively reversed by systemic hypoxic responses in preterm fetuses.

Maintenance of Fetal Arterial Blood Pressure

The umbilicoplacental circulation appears to play a role in maintaining central arterial blood pressure during hemorrhage in fetal sheep. During mild hemorrhage (approximately 15% loss of fetal blood volume), vascular resistance of the umbilicoplacental circulation increases to a similar extent as the fetal body (20%) so that the proportion of biventricular cardiac output directed toward the placenta remains unchanged.[64] With life-threatening, severe hemorrhage (approximately 40% loss of fetal blood volume), however, vascular resistance in the umbilicoplacental circulation increases 260%, thereby helping to maintain central arterial pressure.[65] Resistance increases significantly in all segments: the umbilical arteries and placenta (+250%), the umbilical veins (+390%), and the hepatic circulation (+540%), and nonsignificantly in the ductus venosus (+190%).[65] Umbilicoplacental vasoconstriction may be mediated by increased circulating concentrations of catecholamines, angiotensin II (AT II), and vasopressin, individually or in combination.[65-68]

Factors affecting the exchange of water between the maternal and fetal circulations at the placental interface could influence fetal blood volume and hence play a role in maintaining fetal arterial blood pressure. The net transfer of water across the placenta is presumably controlled by the balance of osmotic and hydrostatic pressures across placental capillary walls, as in other microcirculatory beds. It has been proposed that a decrease in placental capillary blood pressure may promote the movement of water from the maternal to the fetal circulation, thereby increasing fetal blood volume and thus fetal arterial blood pressure.[69] In experiments in sheep, however, when pressure in the umbilicoplacental circulation was decreased 33% by partially occluding the fetal distal aorta for 2 weeks, hematocrit did not decrease, suggesting that no increase occurred in either plasma volume or central arterial blood pressure.[54] Thus it remains unknown whether alterations in water transport caused by physiologic alterations in placental capillary pressure play an important role in maintaining fetal arterial blood pressure.

Closure of Umbilicoplacental Circulation at Birth

In humans, umbilical blood flow rapidly decreases after delivery of the fetus to less than 20% of the normal fetal value[23] by 40 to 60 seconds after delivery.[70,71] This is accompanied by significant decreases in umbilical artery and vein diameters within 120 seconds.[72] The factors responsible for the rapid constriction of the umbilical vessels and the rapid increase in umbilicoplacental vascular resistance at birth are poorly understood.

It is possible that the sudden exposure of the umbilical cord after birth to a cool, more highly oxygenated room air environment plays a role. Cooling human umbilical vein segments from

37° C to 20° C caused vasoconstriction mediated by increased prostaglandin and thromboxane synthesis.[73] Cooling in this temperature range also caused constriction of human umbilical artery rings, but the contraction was transient, lasting less than 5 to 10 minutes,[74] which suggests this mechanism may not be important in the sustained closure of umbilical vessels at birth. Similarly, an increase in oxygen tension elicits a transient vasoconstriction of the umbilical artery, which is mediated by increased thromboxane synthesis.[74-76] An increase in oxygenation also enhances the contractile effects of bradykinin and serotonin[28,75,76] but not endothelin-1[31] on the human umbilical artery. Nevertheless, umbilical artery and vein diameters decrease markedly within 2 minutes after delivery despite no significant increase in arterial or venous pO_2.[72] Thus factors other than an increase in oxygenation (contraction precedes it) and cooling (contraction is transient) are likely involved in the rapid constriction of the umbilical vasculature at birth.

Local mediators produced by cells in the vicinity of the umbilical vessels may be the primary source of vasoactive agents that effect closure of these vessels after birth.[74] Serotonin in particular may have sufficient potency and efficacy and a sufficiently long duration of action (longer than 2.5 hours) to effect cord closure.[74] Alternatively vasoconstriction may be stimulated by mechanical stretch of the cord.[77] Umbilical vessels may be prone to vasospasm due to the absence of active vasodilation by cAMP or cGMP pathways.[3,4]

FACTORS THAT REGULATE UMBILICAL BLOOD FLOW

Mean blood flow through the umbilicoplacental circulation depends on the total pressure gradient driving flow and the sum of the resistances in each segment of this vascular bed (see Figure 74-2). Vasoactive factors, as well as changes in heart rate, can indirectly affect umbilical blood flow by altering the central blood pressures that drive flow through this circulation. However, umbilical flow can be affected more directly by alterations in vascular resistance within the umbilicoplacental vascular bed.

Vasoactive Mediators

The effects of numerous vasoactive mediators on different segments of the human umbilicoplacental vasculature, as reported by numerous groups of investigators, are summarized in Table 74-1; relevant studies are referenced in the table. Of note, vasodilator activity typically is evaluated in vessels that have been preconstricted with substances such as AT II, the prostaglandin $PGF_{2\alpha}$, or thromboxane. The mediators are listed in alphabetical order in the table because it is difficult to divide vasoactive substances into extrinsic (humoral) or intrinsic (local, paracrine-autocrine) categories; substances that act locally postnatally (e.g., PGE_2, endothelin) circulate in relatively high concentrations in the fetus[115,153] and may therefore have humoral effects. Similarly, other classic hormones (e.g., corticotropin-releasing hormone) are produced in the placenta[108,109] and may therefore have local effects. It is also difficult to divide them into dilators and constrictors because some mediators may cause vasoconstriction in one segment but vasodilation in another (e.g., histamine), and others usually considered to be vasodilators cause vasoconstriction in this bed (e.g., acetylcholine, bradykinin).

Observation of a vasoactive effect for a specific exogenous mediator, as identified in Table 74-1, does not necessarily mean that the mediator has an important physiologic role in controlling placental perfusion. Further evidence for such a role thus would include detection of the mediator in cord blood and the presence of local sites of synthesis within the umbilicoplacental circulation, as well as the presence of receptors. This information also has been included in Table 74-1. A role for endogenous production of a mediator also can be shown by blocking its synthesis or receptors and observing that this elicits a change in vascular resistance. Studies that have taken this approach are summarized and referenced in Table 74-2.

The effects of vasoactive mediators on the human umbilicoplacental vasculature usually are studied using isolated tissues in vitro that were collected after delivery at term. However, it is important to keep in mind that responses may differ from those observed in vivo (umbilical arteries, for example, may not fully relax in vitro[156]), and that responses may also change during gestation. For example, relative to umbilical arteries collected after preterm delivery (less than 35 weeks), arteries collected after delivery at term (38 weeks and beyond) constrict much less vigorously in response to AT II but more vigorously to vasopressin, norepinephrine, and PGE_2.[74]

Innervation

Except in the immediate vicinity of the umbilicus, adrenergic or cholinergic nerve fibers are not detectable in the human placenta or in human or sheep umbilical cord vessels.[5,8] By contrast, the intrafetal portion of the human umbilical artery is innervated,[5] as is the ductus venosus in sheep.[157] This innervation apparently exerts little influence over ductus venosus blood flow under basal conditions[157] or during increased α-adrenergic activity induced by hypoxia in fetal sheep[62,158] so the function of this innervation is unknown. Similarly, a significant neural role in control of the intrafetal portion of the umbilical artery has not been demonstrated to date. The absence of innervation of extrafetal umbilical cord vessels and the placenta indicates that these vessels are not under neural control.

Wall Shear Stress

Changes in the flow rate or viscosity of fluid moving through a vessel alters the wall shear stress (i.e., viscous drag) imposed on the endothelial cells lining the vessel lumen. Shear stress is an important stimulus for the tonic secretion of vasodilators, such as nitric oxide, from endothelial cells.[159,160] In the perfused human cotyledon, alterations in endothelial shear stress effected by alterations in flow appear to alter endothelial nitric oxide release.[161] Furthermore, in small placental arteries, flow-induced vasodilation is observed, and this effect is blocked by nitric oxide synthase inhibitors.[162] Flow-induced vasodilation may not occur in umbilical arteries, however, because the smooth muscle cells of these vessels exhibit little or no relaxation response to nitric oxide.[3,128] Alternatively, other mediators could regulate this response.[160]

UMBILICAL BLOOD FLOW IN INTRAUTERINE GROWTH RESTRICTION

Umbilical blood flow and umbilical blood flow per kilogram of estimated fetal body weight are lower than normal in human fetuses with IUGR,[49,51] indicating that either the vascular resistance of the umbilicoplacental circulation is high or the driving pressure for flow is low. In addition, many fetuses with IUGR have umbilical arterial blood velocity waveforms that are highly pulsatile.[49,163] Diastolic blood velocity in these fetuses may be reduced, absent, or even reversed (i.e., blood returns toward the heart) compared with the normally high diastolic velocities recorded in the umbilical artery in the latter part of normal pregnancy.[164]

Fetuses with IUGR, especially those with highly pulsatile umbilical arterial velocity waveforms, are often hypoxemic,[165,166] but hypoxemia itself does not increase blood flow pulsatility in the umbilical artery when induced experimentally in fetal sheep.[167,168] High pulsatility can be induced, however, by increasing the vascular resistance of the placental microcirculation.[169-171] In IUGR, elevated placental vascular resistance may be caused by structural abnormalities of the fetoplacental vasculature[172-176] or by

[a]Acetylcholine does not stimulate release of nitric oxide from umbilical artery or umbilical vein segments.[30]

[b]Angiotension II (AT II) response is likely mediated by AT_1 receptors in the placenta because the AT_2 subtype is not detectable.[88] Vasoconstrictive response is greatest in villous stem arterioles, moderate in chorionic arteries, and nearly absent in umbilical artery near term.[32,74,91] Preterm umbilical arteries (<35 weeks) do not vasoconstrict in response to AT II.[74]

[c]BNP (brain natriuretic peptide) is a more potent vasodilator of perfused cotyledons than ANP (atrial natriuretic peptide).[93]

[d]CGRP (calcitonin gene–related peptide) mediated vasodilation in the perfused cotyledon appears to be independent of nitric oxide synthesis and mediated by both CGRP-1 and CGRP-2 receptors.[107]

[e]CRH (corticotropin-releasing hormone) acts by way off the nitric oxide/cyclic guanosine monophosphate pathway[110] to vasodilate the placenta cotyledon at physiologic concentrations.[112]

[f]Subthreshold doses of endothelin-1 increase the sensitivity of the umbilical artery to other vasoconstrictors.[125] Bolus doses cause prolonged vasoconstrictive responses (45 to 60 minutes) in the perfused cotyledon.[122]

[g]Histamine's vasodilator effects may be mediated, at least in part, by endothelial cell–derived relaxing factor (presumably nitric oxide).[30]

[h]Neuropeptide Y constricts umbilical arteries collected at term but not when collected preterm.[74,121]

[i]PGI_2 release by the perfused cotyledon is increased during angiotensin II–mediated vasoconstriction[146], thereby attenuating the vasoconstrictive response to angiotensin II.[142]

[j]PTHrP (parathyroid hormone–related peptide) is ~100 times more potent than PTH (parathyroid hormone) as a vasodilator of the perfused placental cotyledon.

[k]Or the thromboxane analogue U46619.

Cb, Chorionic vein; *ChA,* chorionic artery; *D,* decidua; *PGE,* prostaglandin E; *PGF,* prostaglandin F; *Pl,* placenta; *SA,* stem artery; *UmA,* umbilical artery; *UmV,* umbilical vein; *VIP,* vasoactive intestinal peptide; +, construction; −, relaxation; +/0, little or no constriction; 0/−, little or no relaxation.

abnormalities in placental vasoconstrictor tone.[177,178] Of interest, perfused cotyledons of such fetuses do not require significantly higher pressures to achieve the same perfusion rate, indicating that their vascular resistances are near normal in vitro.[110,179] Therefore, if elevated pulsatility of umbilical arterial velocity waveforms in these fetuses is caused by elevated resistance in vivo, then elevated vascular resistance appears to be mediated by vasoactive factors or at a site not represented in the perfused cotyledon in vitro.[15,179] The possibility that resistance is elevated within the umbilical cord, hepatic circulation, or ductus venosus in at least in some cases of IUGR warrants further consideration.[180]

Pulsatility of umbilical arterial velocity waveforms can be improved by bed rest,[181,182] maternal hydration,[182] or oxygen administration,[183] further suggesting that, at least in some cases, altered vasoactive tone rather than anatomic abnormalities of the umbilicoplacental circulation is involved. Some evidence does support abnormalities in vasoactive mediators in pregnancies with IUGR. For instance, vasoconstriction of the placental vasculature may be augmented by AT II, endothelin-1, or by the proinflammatory cytokine, tumor necrosis factor-α, all of which are elevated in the umbilical cord blood of fetuses with IUGR.[177,184,185] Alternatively, elevated circulating AT II levels may be offset by reduced protein level, binding capacity, and affinity of the angiotensin receptor AT_1 in placentas affected by IUGR.[88,186] Vasoconstriction may also be enhanced by decreased expression of heme oxygenase-2 and thus the reduced production of the

TABLE 74-2

Effects of Inhibitors of Vasoactive Mediators on the Human Umbilicoplacental Circulation

Vasoactive Substance	Inhibitor	Response
Cyclooxygenase	Indomethacin	No effect on basal tone of umbilical vein, perfused placental cotyledon, or stem villous arterioles[29,100,142,154]
Nitric oxide synthase	L-NAME	Increases basal tone and sensitivity to vasoconstrictors in perfused placental cotyledons[79,155]
Angiotensin II	Saralasin	Inhibits angiotensin II constriction of perfused placental cotyledons[89,90]
Heme oxygenase	Zinc protoporphyrin	Increases basal tone in perfused placental cotyledons[105]

L-NAME, Nitro-L-arginine methyl ester.

vasodilator carbon monoxide by the endothelium in placentas with IUGR.[101] Thromboxane and vasoconstrictor prostaglandins do not appear to be involved as production of these mediators is not enhanced in perfused placental cotyledons from fetuses with IUGR.[187] Vasocontrictive influences may be offset, at least in part, by a four-fold increase in cord blood concentrations of the vasodilator corticotropin-releasing hormone,[188-190] the activity of which is mediated by nitric oxide[110] and by increased expression of endothelial nitric oxide synthase in placental villous vessels.[191]

SUMMARY AND CONCLUSION

Many potentially important mechanisms regulate umbilicoplacental vascular resistance in vivo. Evidence from relevant studies supports an important physiologic role for the local production of corticotropin-releasing hormone and nitric oxide in promoting the normally low vascular resistance of the umbilicoplacental circulation. Many factors also are capable of vasoconstricting the umbilicoplacental circulation; endothelin-1 and thromboxane are among the most potent. Local alterations in resistance in the placental microcirculation may play a physiologic role in matching flow with the corresponding flow on the maternal side of the placenta. In addition, vasoconstrictors may play a critical physiologic role in the closure of the umbilicoplacental circulation after birth. In fetuses with IUGR, abnormalities in levels or in responsiveness to vasoactive factors may increase umbilicoplacental vascular resistance, thereby reducing umbilical blood flow and resulting in impaired fetal growth.

Fetal and Placental Circulation During Labor

PHYSIOLOGIC BACKGROUND

A sufficient maternal blood supply to the placenta is of utmost importance to the fetus during pregnancy and labor. It has long been recognized that uterine contractions diminish uteroplacental blood flow. Contractions of myometrium compress the vessels traversing the uterine wall and increase intrauterine pressure, thus influencing the intervillous space pressure as well. The intrauterine pressure during labor usually ranges from 25 to 100 mm Hg. In contrast, the mean pressure in small arteries is 70 to 95 mm Hg and only 15 mm Hg at the capillary venous end. Compression and even collapse of the myometrial vessels during labor is thus probable. Even a slight reduction in the diameter of an artery results in reduction of flow, because resistance of flow is inversely proportional to the fourth power of the vessel radius according to the Poiseuille law. Obviously, during a contraction, the uterine veins are affected first, and the restricted venous outflow results in a reduction of the pressure gradient over the placenta. With use of radioangiographic technique in pregnant women, it has been shown that the maternal blood flow to the placenta decreases markedly during contraction.[1] Similarly, in the rhesus monkey, diminished arteriolar jets have also been demonstrated.[2] Flow to the intervillous space, however, appears to remain constant.

The intermittent decrement in the blood flow during myometrial contractions has been found to be inversely related to the increase in intrauterine pressure.[3-6] During uterine relaxation after a contraction, an increase in the blood flow—a reactive hyperemia—has been observed,[4,6] which compensates for the decreased oxygen delivery during the preceding contraction.

With the progress of labor, the peak intrauterine pressure during each contraction increases, and the time-averaged blood flow in the uterine artery diminishes[7] (Figure 75-1). Woodbury and co-workers[8] described a "maternal effective placental arterial pressure," defined as the arterial pressure minus the pressure within the uterus (which opposes the inflow of maternal blood). To ensure the perfusion of the placenta, the maternal central blood circulation responds to contractions by increasing both blood pressure and cardiac output.[9,10]

The circulation of a healthy fetus in uncomplicated labor usually remains unaffected. The umbilical circulation is relatively

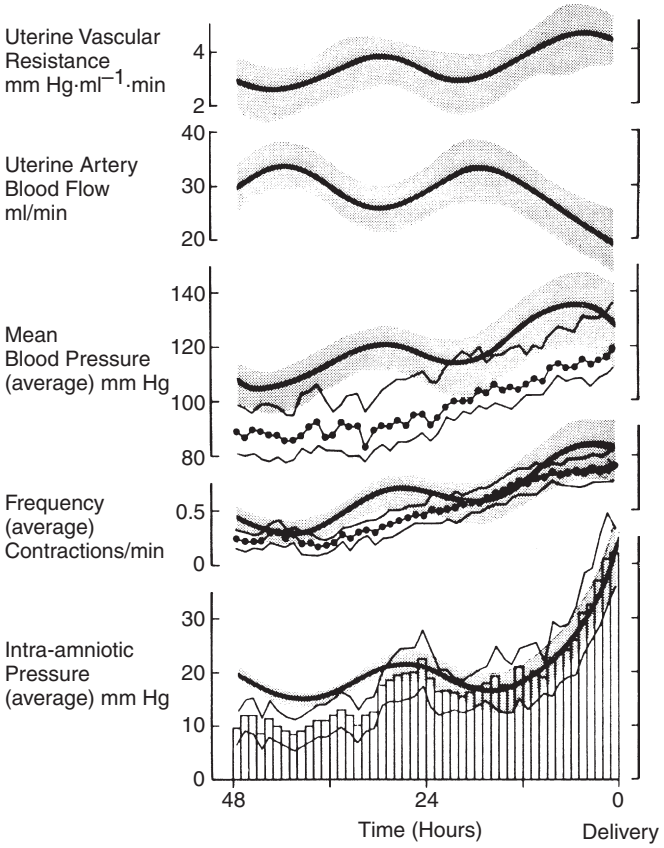

Figure 75-1 Composite drawing showing the incorporation of the circadian changes of uterine dynamics into the process of labor and delivery. The open bars of intraamniotic pressure and the solid points depicting frequency of contractions and mean blood pressure represent data obtained from five patients monitored continuously during the last 48 hours of pregnancy. Each bar and point represent the mean of hourly average values. The thin solid lines delineate the 95% confidence intervals. The heavy solid lines of intraamniotic pressure, frequency of contraction, mean blood pressure, uterine artery blood flow, and uterine vascular resistance were calculated from continuous recordings made in 15 monkeys during the 48 hours terminating in spontaneous labor and delivery. The shaded areas represent the 95% confidence intervals determined for individual mean values. Uterine vascular resistance was calculated by the formula: aortic blood pressure minus intraamniotic pressure divided by uterine artery blood flow. *(From Harbert GM Jr: Circadian changes in uteroplacental blood flow. In Rosenfeld CR, editor:* The uterine circulation. Reproductive and perinatal medicine, *vol X, Ithaca, NY, Perinatology Press, 1989, p 157.)*

unreactive and does not seem to respond to the changes in intrauterine pressure or to the short-term changes in the maternal placental blood flow during contractions. During normal labor, uterine contractions are not of sufficient magnitude to negatively affect gas exchange over the placenta. Therefore they do not endanger the fetus. In labor with a pathologic course, in which uteroplacental blood flow is diminished, fetal hypoxemia can develop. In that situation, the fetus reacts with changes in heart rate, blood pressure, and blood flow.[11] Uterine contractions can also cause a direct compression of the umbilical cord with restriction of the umbilical blood flow, leading to changes in the fetal circulation.

METHODS OF RECORDING HUMAN FETAL AND UTEROPLACENTAL BLOOD FLOW

Previously, most of our knowledge of uteroplacental and fetal circulation was based on animal experiments, in which invasive methods have been used. Approximately 20 years ago, a noninvasive method making use of Doppler ultrasound was introduced in the field of perinatal medicine and has made it possible to obtain data on blood flow in human pregnancies.[12,13]

Flow Probe Techniques

Measurement of the uterine, uteroplacental, or fetal blood flow using a flow probe technique (measuring the flow in a single vessel by evaluating changes caused by the blood flow in either the electromagnetic field or the ultrasound passage time) requires an application of the probe on an exposed vessel. Only in exceptional circumstances has the electromagnetic method been used on a human uterine artery during laparotomy for hysterectomy in pregnancy.[14]

Radioangiography

The radioangiographic technique, with injection of contrast medium followed by serial x-ray exposures, has made it possible to establish the time of appearance and disappearance of contrast dye in various parts of the uteroplacental circulation.[1] However, absolute flow cannot be determined, and, because of the high radiation hazard to the fetus, this method is not acceptable for use in humans.

Placenta Scintigraphy

Radioactive isotopes (^{24}Na, ^{133}Xe) can be injected into either the myometrium or the intervillous space, and the time rate of washout can then be determined by external measurement. This gives a semiquantitative measure of the maternal placental blood flow. To circumvent the disadvantage of the method's invasiveness, placenta scintigraphy has been developed that uses an intravenous injection of a radionuclide tracer (^{99m}Tc, ^{133}Xe, or ^{113m}In) and external measurement of accumulation or disappearance of radioactivity over the placenta.[15] Clinical application of this method is limited because it cannot be used for continuous measurement of the changes in placental blood flow over time, and only the anterior placenta can be examined. The most serious drawback of the method is exposure of the fetus to ionizing radiation.

Thermistor Method

The relative uterine blood flow can be evaluated by placing a preheated thermistor pearl into cervical tissue and then recording heat dispersal.[16] This method has the disadvantages of being invasive and of measuring flow in the cervix and lower segment of uterus and not directly in the placenta.

Doppler Ultrasound Method

Physical Principle

The Doppler ultrasound technique makes it possible to estimate blood velocity and blood flow in maternal and fetal vessels in a noninvasive way during late pregnancy and labor. The first report on the detection of flow signals from the umbilical artery was published in 1977 by FitzGerald and Drumm.[13] In recent years, the Doppler velocimetry has become a method of choice for evaluation of the uteroplacental and fetal circulation.

According to the Doppler principle, wave energy is reflected by a moving reflector with a wavelength (frequency) that is

different from the emitted wavelength. The change in frequency (Doppler shift) is proportional to the velocity of the reflector. In the situation of blood flow measurement, ultrasound with a frequency of 1 to 10 MHz is transmitted to the tissue and reflected by the moving red cells within the vessel. The frequency of the received ultrasound is higher than the emitted frequency when the blood is moving toward the transducer, and it is lower when the blood is moving away from the transducer. The Doppler shift (f_d) is defined by the formula:

$$f_d = 2 \cdot f_0 \cdot V \cdot \cos\theta / c$$

where f_0 is the ultrasound frequency, V is the blood velocity, θ is the angle between the ultrasound beam and the bloodstream direction, and c is the velocity of ultrasound in tissue. The Doppler shift frequencies are within the range of audible sound. They can be analyzed, for example, by the fast Fourier transform and displayed as a Doppler shift spectrum (Figure 75-2). From the spectrum, the mean and the maximum velocity can be estimated and further processed.

Doppler ultrasound can be used in four modes: continuous-wave Doppler ultrasound (CW), pulsed-wave Doppler ultrasound (PW), color flow imaging, or power Doppler imaging. In the first mode, CW Doppler ultrasound is continuously transmitted by one piezoelectric crystal, and the reflected ultrasound is received by another crystal. Signals of blood flow are obtained from all vessels traversed by the ultrasound beam. The CW Doppler instruments are technically simpler than are the instruments of the other Doppler modes and thus are usually cheaper. However, the application of CW Doppler ultrasound is limited because of the lack of range resolution.

In the PW mode, one single piezoelectric crystal is used for transmission and reception of the ultrasound bursts. By changing the time delay between the transmission and reception of signals, it is possible to determine the range within the tissue from which the Doppler-shifted signals are received. In other words, it is possible to choose a specific vessel for recording of blood velocity signals. The PW ultrasound is usually combined with imaging ultrasound (linear array or sector real-time scanner) to locate and identify the vessel of interest.

The color flow imaging enables a color coding of the received Doppler signals, usually red for the blood flow toward the transducer and blue for the flow in the opposite direction. The color signals are then superimposed on the two-dimensional real-time image. Color flow imaging facilitates detection of flow even in very small vessels, for example, fetal cerebral vessels or maternal spiral arteries. It is often combined with PW Doppler ultrasound for quantification of flow velocity.

The amplitude of the received Doppler shift signals can be used to characterize the signal power that is proportional to the number of blood cells moving within the investigated area, thus reflecting the perfusion of examined organs. The power Doppler signals can also be color coded and displayed in the two-dimensional image. The power Doppler mode allows detection of blood flow with low velocity; however, the information is nondirectional. In obstetric applications, this mode has been used for evaluation of perfusion of fetal organs, for example, lungs[17] or placenta.[18] The power Doppler signals can also be collected from a tissue volume and presented in three dimensions. However, the three-dimensional display of flow has not yet been used for quantitative analyses.

Volume Flow Estimation

The information on the time-averaged mean velocity *(V)* obtained from a specific vessel and corrected for the cosine θ can be used for calculation of the volume flow *(Q)* in milliliters per minute according to the formula:

$$Q = V \cdot d^2 \cdot \pi / \cos\theta \cdot 4$$

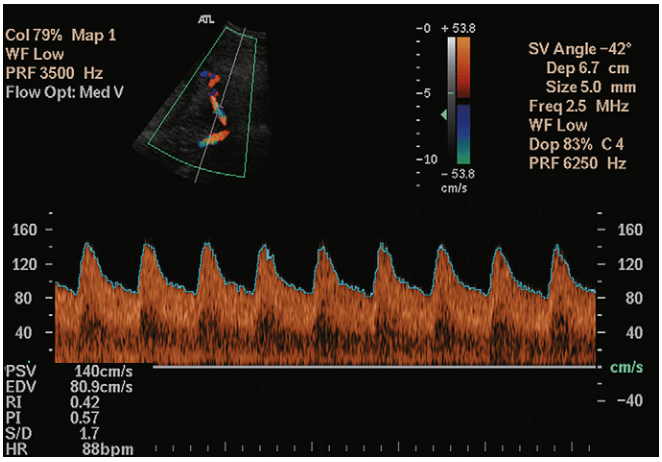

Figure 75-2 Doppler shift spectrum recorded from the uterine artery in a term pregnancy. The high proportion of diastolic flow velocity indicates a very low resistance to flow in the uteroplacental circulation.

This assumes that the diameter of the vessel *(d)* is known for the calculation of the cross-sectional area of the vessel. Originally, the method has been applied for estimations of volume flow in large fetal vessels, that is, abdominal aorta and umbilical vein.[12]

The measurement of vessel diameter using the two-dimensional ultrasound image is relatively inaccurate. The estimation of the volume blood flow also requires knowledge of the insonation angle and uniform insonation of the vessel for reliable estimation of the mean velocity. Because of all these possible sources of error, this method has not found wide application.[19] Nevertheless, it can be expected that further technical development will enable a more reliable estimation of flow. A certain revival of this method has occurred, and measurements of flow also in vessels of small caliber, for example, maternal uterine arteries and umbilical arteries, have been reported.[20,21] Nevertheless, the reported variability in the resulting values was of similar magnitude as in original reports 30 years ago and is, obviously, a combination of the physiologic variability and method errors.

Velocity Waveform Analysis

The maximum blood velocity (i.e., the envelope of the Doppler spectrum) recorded from an artery can be analyzed for its waveform and characterized by various indices (Figure 75-3). These indices are angle independent. The diameter of the vessel need not be known for waveform analysis, and the maximum velocity is easier to record than is the mean velocity. Thus a number of errors involved in the estimation of blood flow are eliminated. However, this method does not directly reflect flow, and the interpretation of results is not always obvious.

The diastolic part of the flow velocity waveform is mainly influenced by the peripheral vascular resistance; an increase in the resistance lowers the diastolic velocity and, consequently, increases the values of the waveform indices described in Figure 75-3. However, the waveform and its indices are also influenced by cardiac performance, blood pressure, vessel wall properties, and the viscosity of blood.

A simple semiquantitative evaluation of the waveform recorded from the umbilical artery or fetal descending aorta with regard to the presence or lack of the end-diastolic flow (blood flow classes) has proved useful in the identification of fetuses with growth restriction and fetuses at risk for intrauterine asphyxia[22] (Figure 75-4). In the cerebral vessels of hypoxic fetuses, an increase in

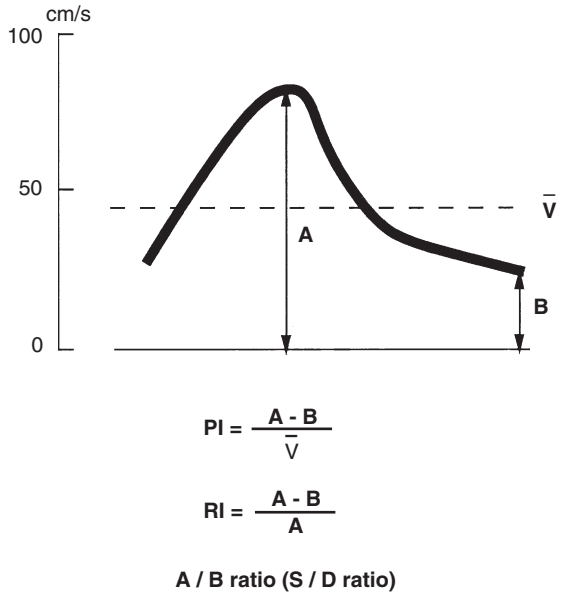

Figure 75-3 Schematic drawing demonstrating waveform analysis of the fetal arterial maximum blood velocity. *A (S),* Peak maximum velocity; *B (D),* minimum diastolic velocity; $\bar{V}$, mean velocity over the cardiac cycle; *PI,* pulsatility index according to Gosling and King[107]; *RI,* resistance index according to Pourcelot[108]; A/B ratio according to Stuart and colleagues.[109]

diastolic velocity can be observed as an expression of decreased resistance in the cerebral vascular bed and redistribution of blood flow (brain-sparing phenomenon).

The resistance to flow in the uterine artery is reflected in the pulsatility index (PI) of the uterine artery waveform. With increasing resistance, for example, in cases with intrauterine growth restriction and/or preeclampsia, the PI increases and a notch in the early diastole can occur. A bilateral notch in the uterine artery persisting after 26 weeks gestation has been shown to be associated with increased risk for development of preeclampsia and intrauterine growth restriction. For clinical use, a scoring system (uterine artery score) has been designed to characterize the resistance in both uterine arteries.[23]

SAFETY ASPECTS OF USING DOPPLER ULTRASOUND IN PREGNANCIES

Ultrasound with high intensity levels has known biologic effects, for example, thermal effects and cavitation. Therefore it is necessary that the users be constantly alert to the possibility of adverse effects of diagnostic ultrasound.[24] Hitherto, no harmful effects of ultrasound on human tissues have been found at the intensities used for diagnostic purposes, and epidemiologic follow-up studies have failed to elicit any evidence of adverse effects of exposure to diagnostic ultrasound in utero. Nevertheless, it is important that users of the Doppler ultrasound be aware of the output ultrasound energy of the equipment they are using for examining pregnancies. Some of the Doppler devices can produce considerable output energy exceeding the upper limit for

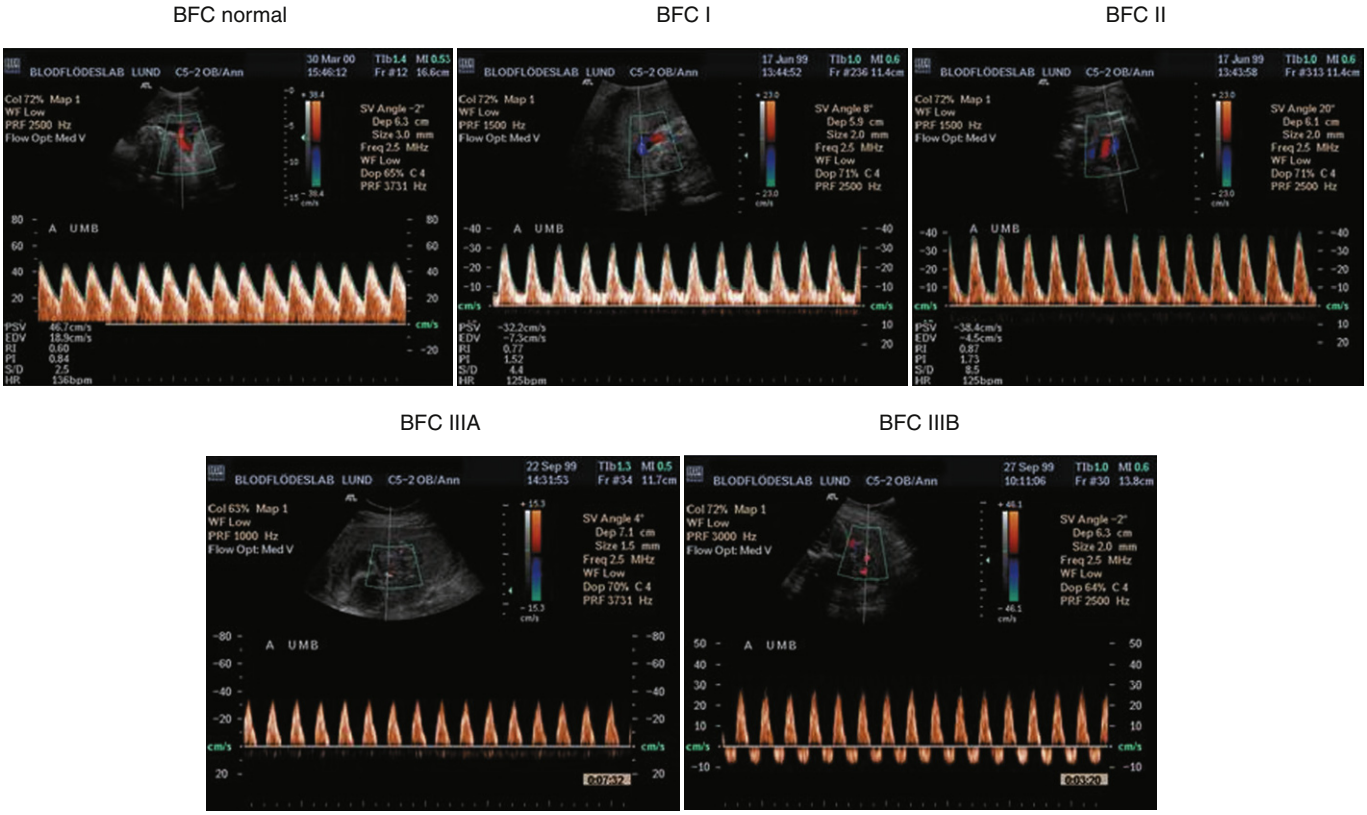

Figure 75-4 Blood flow classes (BFC) of the umbilical artery flow velocity waveforms. *BFC normal,* Positive diastolic flow, PI within normal limits; *BFC I,* positive diastolic flow, PI > mean + 2 SD and ≤ mean + 3 SD of the reference curve[110]; *BFC II,* positive diastolic flow, PI > mean + 3 SD of the reference curve; *BFC IIIA,* absent end-diastolic flow velocity; *BFC IIIB,* reverse end-diastolic velocity.

energy output to be used in pregnancy (720 mW/cm^2); it is the responsibility of the ultrasound operator to control the output on the basis of the output displays in the form of the mechanical index and thermal index.[25] The operator should always follow the ALARA principle, that is, to use ultrasound energy "as low as reasonably achievable."

HUMAN UTEROPLACENTAL BLOOD FLOW DURING LABOR

PW Doppler ultrasound has been used for recording of flow velocity signals from the uteroplacental vessels in labor.[26,27] CW Doppler ultrasound was also used for this purpose.[28,29] All Doppler studies on uteroplacental vessels in labor have shown that, during uterine contractions, both the systolic and diastolic blood velocities diminish, suggesting a decrease in blood flow. At the acme of contraction, the diastolic velocities disappear completely. An inverse linear relationship has been found between the intensity of the contraction, measured as the intrauterine amniotic pressure, and the degree of the end-diastolic flow. When intraamniotic pressure exceeds 60 mm Hg, an elimination of end-diastolic flow velocity occurs in all cases[30] (Figure 75-5).

A similar pattern of blood velocity changes as in spontaneous labor contractions was described for contractions induced by oxytocin challenge test (OCT).[31] At the time of the top of induced contractions the diastolic flow velocities in the uterine artery diminished, were undetectable, or even were reversed. The reversal was significantly more often seen during induced contractions as compared with spontaneous contractions in a control group.[31]

During the third stage of labor, PW Doppler studies of uterine arteries have shown that after a latent phase, during the contraction and detachment phase, a significant increase occurred in the resistance to flow reflected by an increase in PI.[32] After placental separation, a slight uterine relaxation occurred resulting in decreased resistance to flow in the uterine arteries. By using color flow imaging, the changes of blood flow between myometrium and placenta can be followed.[33] In cases with normal placental separation, blood flow between myometrium and placenta ceases immediately after delivery of the infant during the latent phase. In patients in whom manual removal of placenta was necessary, the blood flow continued into the placenta beyond the latent phase. Thus color Doppler examination might be used to diagnose placenta accreta.

HUMAN FETAL BLOOD FLOW DURING LABOR

Umbilical Artery Blood Flow

According to several reports, the waveform indices (PI and A/B ratio) of flow velocities recorded from the umbilical artery of healthy fetuses in uncomplicated labor do not change during contractions or with the progression of labor.[28,30,32-36] This suggests that normal uterine activity in labor does not increase the vascular resistance on the fetal side of the placenta, which helps the fetus to withstand the stress of labor. Fleischer and associates[37] found that the umbilical artery waveform did not change over a wide range of uterine pressures in labor. Conversely, Malcus and co-workers[38] examined 575 fetuses in early labor and found a significant increase in the PI during contraction, as compared with the recording taken before the onset of contraction. Nevertheless, the absolute difference in the PI was small and probably without importance for an undisturbed fetus. In fetuses with already compromised umbilical blood flow, however, such a slight increase in placental resistance might be of pathophysiologic and clinical importance. This is in agreement with the observation that fetuses that exhibit a lack of end-diastolic velocity during pregnancy often have signs of distress in labor and frequently require operative delivery.[22,39,40] In a study that recorded umbilical artery waveform changes continuously through different stages of labor, a significant increase in S/D ratio was observed during contractions in the second stage of labor.[41] The increase in S/D ratio correlated well with a decrease in umbilical artery pH. No significant changes in the umbilical artery velocity waveform were observed during the first stage of labor.

During Braxton Hicks contractions the PI in the umbilical artery did not change, and the authors concluded that Braxton Hicks contractions have no effect on fetal hemodynamics and on fetal oxygenation in the healthy near-term fetus.[42]

In pregnant women with decelerations in the fetal heart rate (FHR) during contractions in labor, a concomitant increase in the PI,[34] or S/D ratio,[43] has been found. Sakai and colleagues[44] have found that the increase in the umbilical artery resistance

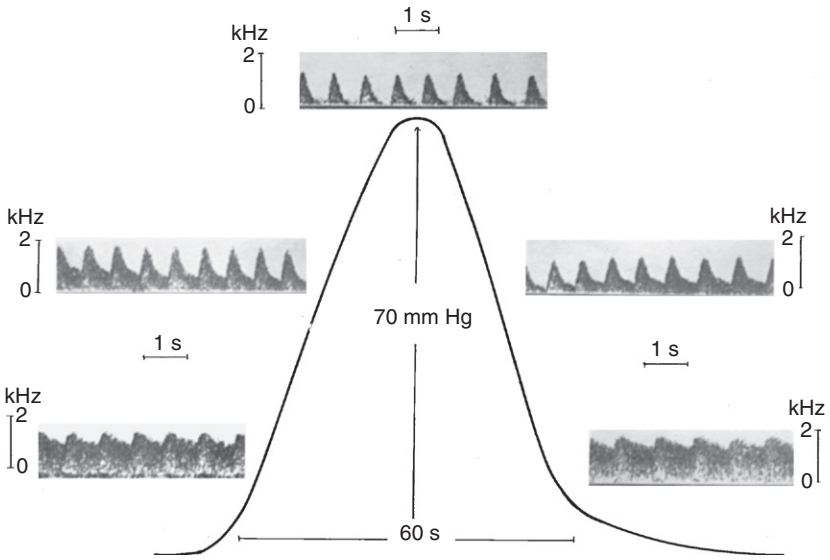

Figure 75-5 Changes of the Doppler velocity waveforms recorded from the uterine artery before, during, and after uterine contraction. *(From Fendel H, Fettweis P, Billet P, et al: Dopplеruntersuchungen des arteriellen utero-feto-plazentaren Blutflusses vor und während der Geburt,* Z Geburtshilfe Perinatol *191:121, 1987.)*

index (RI) was particularly pronounced at downward and bottom stages of variable decelerations. During early decelerations or during contractions not associated with FHR decelerations, no changes were found in the resistance to flow. Tadmor and colleagues,[45] using computerized analysis of umbilical artery velocity waveforms, recorded an increase in S/D ratio and PI in approximately 50% of FHR variable decelerations. They have shown that in one group of pregnancies the increase in the resistance to flow preceded the decrease in FHR. In other cases, the deceleration was not preceded by a measurable increase in umbilical artery resistance. The authors considered this to reflect impaired fetal oxygenation.

Operative delivery is significantly more frequent in patients with abnormal PI values. Brar and associates[46] compared the S/D ratio (see Figure 75-3) in a group of patients with late decelerations with the S/D ratio in matched controls: the mean S/D ratio in the former group was significantly higher than that in the latter group. Among women with late decelerations, a progressive increase also was seen in the incidence of adverse pregnancy outcome with increasing abnormality in the waveform. Patients with late decelerations and a normal umbilical S/D ratio had an incidence of adverse pregnancy outcome similar to that of controls. Murakami and co-workers[47] showed that the blood flow in the intraabdominal part of the umbilical vein decreased in association with late and variable FHR decelerations. The reduction of blood flow was more pronounced with variable than late decelerations, and the blood flow change preceded the deceleration.

Feinkind and colleagues[48] performed a similar analysis of the relationships among FHR tracings and umbilical artery velocity waveform during the first stage of labor and outcome of pregnancy in 273 unselected patients. Both the umbilical A/B ratio and the FHR had similar low positive predictive values (30% and 23%, respectively). If the two methods were combined, the predictive value increased to 56%. In the study by Somerset and colleagues[49] the positive predictive values for prediction of cesarean section for fetal distress were 31% for umbilical artery S/D ratio and 15% for admission FHR recording. The positive predictive value of the umbilical artery PI in early labor was also examined by Malcus and co-workers[38] and was found to be 19% for fetal distress and 15% for intrauterine growth restriction. Similar results have been subsequently reported by others.[50,51]

The rupture of membranes or amniotomy does not seem to have any influence on the umbilical velocity waveform.[36-38,52]

Li and colleagues[53] examined umbilical artery flow velocities during OCT performed in a group of high-risk pregnancies. In cases of positive OCT according to Freeman,[54] the umbilical artery PI increased significantly both during and between contractions induced by oxytocin.[54]

Umbilical artery Doppler velocimetry has been shown to be a clinically useful test when applied for antenatal monitoring of fetal health in high-risk pregnancies.[55] However, the clinical studies on umbilical artery velocimetry in labor reviewed by Farrell and colleagues[56] do not seem to provide similarly convincing results. Therefore this method has not found widespread clinical application in laboring patients.

Fetal Aortic Blood Flow

The fetal aortic volume blood flow, estimated on two occasions during the first stage of uncomplicated labor, has been shown to increase with progression of labor.[57] These measurements were performed between contractions, and the finding of increased fetal flow might be a phenomenon similar to reactive hyperemia in the uteroplacental circulation described in animals.[9] In the study by Lindblad and associates,[57] no change was found in the aortic PI with advancing labor, and no difference was seen between patients with and patients without ruptured membranes. Fendel and colleagues[30] measured the mean fetal aortic velocity in labor and found a drop in the velocity during contractions. The aortic PI and RI remained unchanged.

Fetal Cerebral Blood Flow

The flow velocity in cerebral arteries of fetuses during uncomplicated labor has been examined by using the transcervical access without imaging with either CW[58] or PW[59] Doppler ultrasound. Dougall and co-workers[58] did not find any change in the mean velocity or the RI of the anterior cerebral artery with advancing labor. During contractions, a fall occurred in the diastolic velocities, suggesting that an increase might exist in the cerebral vascular resistance caused by head compression during contractions (assuming that the fetal cardiac output and blood pressure remain unchanged). The mean RI was 0.69 between and 0.81 during contractions ($p < .001$). However, this finding was not confirmed by Maesel and colleagues[59] in the fetal middle cerebral artery.

More recently, several research groups have examined the fetal cerebral circulation in labor, using a combined two-dimensional real-time and PW Doppler ultrasound method. The waveforms of velocities recorded from the fetal internal carotid artery and middle cerebral artery were similar to those recorded before birth.[60,61] Furthermore, no significant difference was found in PI values of velocities recorded between and during uterine contractions.[61] In the late first and second stages of labor, lower values of PI were found in the middle cerebral artery, suggesting a decrease in impedance to flow in fetal cerebral circulation with progress of labor.[35,62] It has been shown that fetal cerebral oxygenation decreases in the second stage of labor,[63] which might lead to vasodilation of the cerebral vascular bed. This has been confirmed by Sütterlin and colleagues,[64] who have measured fetal oxygen saturation simultaneously with Doppler waveforms of the fetal middle cerebral artery. They have shown that, in fetuses with abnormal heart rate patterns and oxygen saturation <30%, the PI and RI of the middle cerebral artery were significantly lower than in control fetuses. More recently, these findings were confirmed.[65]

During uterine contractions in late labor, transient increases in the PI were observed in the fetal internal carotid artery[66] and middle cerebral artery[67] as an expression of higher intrauterine pressure, compared with that in early labor.

During the OCT of fetuses suspected of intrauterine growth restriction, the PI of fetal middle cerebral and anterior cerebral arteries decreased significantly if the PI was primarily within normal limits.[68] No difference was seen between the two vessels in the PI response. No PI decrease occurred in cases where the PI was below the normal lower limit, that is, if signs of so-called brain sparing were already seen before the OCT.

Fetal Venous Blood Flow

Fetal ductus venosus blood flow velocity waveforms during the first stage of labor have been described by Krapp and colleagues.[69] In a group of normal term fetuses, they found that between contractions the mean values of PI for veins and peak velocity index for veins were 0.48 (SD 0.19) and 0.44 (0.18), respectively. During contractions, the mean values increased to 1.66 (0.85) and 1.46 (0.65), respectively. The authors proposed Doppler examinations of ductus venosus in labor to be possibly useful in fetuses at risk. Szunyogh and colleagues,[70] who measured ductus venosus PI between contractions, reported that in term pregnancies with premature rupture of membranes the PI was significantly increased.

The pattern of umbilical venous flow velocities during labor was evaluated by Ghosh and co-workers.[71] They found the occurrence of pulsatile flow to be predictive of fetal hypoxia and operative delivery for fetal distress.

PHARMACOLOGIC EFFECTS ON UTEROPLACENTAL AND FETAL BLOOD FLOW IN LABOR

The possible effects on the fetal and uteroplacental circulation of drugs used in clinical obstetrics for treatment of preterm labor (tocolysis) or for obstetric analgesia in labor have been examined in a number of studies with use of various techniques. Ritodrine given to patients with preterm labor results in a significant decrease in the uterine and umbilical S/D ratio.[72] A concomitant increase in both the maternal heart rate and the FHR occurs, suggesting that the response of the S/D ratio might be secondary to the changes in the heart rate. In a study comparing the effects of nifedipine and ritodrine in preterm labor, no significant effect on umbilical artery Doppler velocimetry was reported for either of the two treatments.[73] On the contrary, Gokay and colleagues[74] reported a decrease in the umbilical artery PI during ritodrine infusion. In addition, they found a selective increase of left cardiac output indicating redistribution of fetal blood flow. Furthermore, an increase occurred in PI of the fetal middle cerebral artery. They commented that these changes might be of importance in preterm fetuses. In the study by Brar and co-workers,[72] magnesium sulfate tocolysis was not associated with any significant changes in the S/D ratio, the maternal heart rate, or the FHR. Keeley and colleagues[75] observed a decrease in the uterine artery PI and an increase in the fetal middle cerebral artery PI during the administration of magnesium sulfate. They interpreted these findings as a physiologic normalization process related to the stressed preterm fetus during labor.

Treatment of preterm labor with indomethacin has been shown to cause a constriction of the fetal ductus arteriosus in approximately 50%.[76] In these cases, Doppler recordings showed very high ductal blood flow velocities. After discontinuation of the indomethacin, normal function of the ductus arteriosus usually returned. No increase in the ductal flow velocity was observed when a selective cyclooxygenase-2 inhibitor (celecoxib) was used in a comparative study by Stika and colleagues.[77]

Tocolysis with an oral dose of 30 mg nifedipine, followed by an additional oral dose of 20 mg after 4 hours, did not influence either fetal or uteroplacental circulation.[78] This is in agreement with other reports on sublingual administration of nifedipine[79] and with the observation from a study using oral nifedipine in women with pregnancy-induced hypertension.[80] Two days after nifedipine maintenance tocolysis (80-120 mg nifedipine daily), a decrease in the uterine artery PI and fetal middle cerebral artery PI was found.[81]

Nitric oxide donors administered for treatment of preterm labor sublingually or transdermally did not influence the RI or PI in the umbilical artery and fetal middle cerebral artery, respectively, but they decrease the resistance in the uteroplacental circulation.[82,83]

After epidural analgesia, a rapid uptake of local anesthetics in the maternal circulation and a rapid transport to the fetus occur. Epidural analgesia for labor uncomplicated by hypotension is, however, not associated with any alterations in placental blood flow as measured by placental scintigraphy.[84,85] Fetal aortic blood flow in women receiving epidural analgesia during labor increases with advancing labor in a fashion similar to that in women without any obstetric analgesia. Furthermore, no signs of negative effects on the fetal circulation are seen.[57] Several Doppler studies have examined umbilical and uterine artery S/D ratios or RI in term parturients before and after establishing epidural block, and in none have any changes been found.[86-89] A similar observation was reported by Mires and colleagues[90] for women with normal pregnancy and uncomplicated labor. However, in women with pregnancy-induced hypertension, epidural analgesia led to a fall in maternal blood pressure and concomitant decrease in umbilical artery S/D ratio.[90] Oláh[91] studied the effects of an epidural top-up in labor and did not find any change in the umbilical artery PI. However, a transient increase in the uterine artery PI was observed, with a maximum at 15 minutes after the top-up. This change in uteroplacental circulation was preceded by an increase in the maternal femoral artery flow, probably causing a loss of circulating volume in the uterine circulation.

Pethidine crosses the placenta rapidly, and maximum concentrations are found in fetal scalp blood and umbilical arterial blood between 1 and 5 hours after an intramuscular injection in the mother.[92] After the intramuscular injection of 75 to 100 mg pethidine, the fetal aortic blood flow has been shown to decrease.[57]

Considerable maternal plasma and fetal scalp concentrations of local anesthetics have been found 20 to 30 minutes after paracervical block.[93] Reduced placental flow has been proposed as the cause of the fetal bradycardia that is sometimes observed after paracervical block.[94] However, no change in the intervillous blood flow[18] or in the uterine artery PI[95] has been observed after paracervical block. As long as no fetal bradycardia occurred, the umbilical artery PI remained unchanged.[95] In the study by Manninen and colleagues[96] paracervical block initiated a significant increase in uterine artery PI, suggesting a vasoconstrictive effect.

FETAL HEART RATE IN LABOR

Rhythmic contractions of the fetal heart are initiated by electric stimuli generated in the pacemaker, the sinus node. The rate of cardiac contractions is subject to autonomic central nervous influences, humoral factors, and the metabolic condition of the myocardium. The main determinants of FHR are the sympathetic and parasympathetic nervous systems, which are in continuous counteraction. This interplay causes changes in beat-to-beat intervals, expressed as heart rate variability. The variability also reflects the function of the fetal central nervous system and shows cyclic changes related to fetal behavioral states. The variability changes due to fetal behavior continue even during labor.[97]
