Foreword 1

The most common gynecological surgeries performed in the world are hysterectomies which date back to ancient time and were mainly associated with noncancerous conditions. The Italian anatomist Berengario da Carpi of Bologna carried out the first authenticated vaginal hysterectomy in 1507. In Manchester, England, Charles Clay performed the first recorded abdominal hysterectomy in 1843, and in 1853, by accident Walter Burnham performed the first successful abdominal hysterectomy in Lowell, Manchester. The early hysterectomies, either vaginal or abdominal, were performed without anesthesia, and with a fatality rate ranging from 70 to 90 %. In the absence of an alternative management of cervical cancer, the radical hysterectomy was introduced. The first radical hysterectomy was performed by John Clark at Johns Hopkins in 1985, and in 1898, Ernst Wertheim of Vienna performed the first extended radical hysterectomy. The more radical extension of vaginal hysterectomy was developed by Karl Schuchardt of Gottingen, and in 1901, Friedrich Schauta described radical vaginal hysterectomy in detail. With the advent of antiseptics, anesthesia, antibiotics, blood transfusion, new technologies, and advances in surgical techniques, by the 1940s, total abdominal hysterectomy had become the norm, and hysterectomy had become a safer surgical procedure for women worldwide. The fatality rate dropped significantly.

As science and technology advanced, Kurt Semm, in Kiel, Germany, in 1984, was the first to describe a technique for laparoscopic assistance in vaginal hysterectomy, thereby laying the foundation for all endoscopic procedures. Laparoscopic hysterectomy is increasingly performed in many countries in the world; however, conservative and less invasive operative managements, such as hysteroscopic surgery and the application of ulipristal acetate, may reduce the traditional indications for hysterectomy. The limitations of conventional laparoscopy and advances in robotic surgery have led to the increased use of robotic techniques in hysterectomy. Diaz-Arrastia reported the first series of successful robotic laparoscopic hysterectomies in 2002, and surgeries using robotic techniques for hysterectomy are now rapidly expanding.

The indication and performance of hysterectomies in general have changed with the change in techniques and procedures and have been adapted to the request of women to retain their uterus; therefore, the need for a comprehensive textbook on hysterectomy to improve the knowledge, skills, and competencies of surgeons has become very evident.

Ibrahim Alkatout and Liselotte Mettler have compiled the very first comprehensive medical textbook of its kind, *Hysterectomy*: *A Comprehensive Surgical Approach*, dealing with all surgical techniques of hysterectomy (vaginal, abdominal, laparoscopic, and robotic-assisted) and their extended operations, such as lymphadenectomy and omentectomy, with excellent illustrations. This textbook contains 132 chapters contributed by over 100 renowned international authors. This book is an important addition to the literature on hysterectomy techniques, accessible to gynecologists worldwide, and thereby contributing towards the global improvement of healthcare for women.

I believe this textbook will be very valuable and find extensive use in developed and developing countries. I am honored and privileged to write this foreword.

WHO Representative to Namibia

Foreword 2

Hysterectomy ranks among the most frequently performed procedures in gynecology. Since modern surgical techniques have allowed the reduction of intra- and postoperative complications to a considerable degree, it has become a well-established option in the treatment of a wide variety of conditions, including cancers of the reproductive system, certain types of endometriosis and adenomyosis, uterus myomatosus, chronic pelvic pain, or uncontrollable bleeding.

The range of procedures used is broad, not only in regard to surgical techniques – laparoscopic, robotic-assisted, vaginal, abdominal – but also in regard to the extent of the surgery, depending on which organs are included, in addition to the uterus itself, e.g., the cervix, the vagina or parts of it, the parametrium, the lymph nodes, the fallopian tubes, the ovaries, or the omentum.

With its comprehensive overview of all surgical techniques and its illustrated step-by-step descriptions, this book will provide not only a valuable decision aid for surgeons in their choice of method but also a training guide for surgeons at every level of education and experience. It can be considered an additional advantage that this book also covers anatomical and diagnostic aspects of hysterectomy, including questions of when hysterectomy is indicated.

This book is the successor to Liselotte Mettler's *Manual of New Hysterectomy Techniques* (2007), an indispensable handbook on vaginal and laparoscopic hysterectomy. This new volume, edited by a team, Ibrahim Alkatout and Liselotte Mettler, benefits in a similar way from the high standards of the Kiel School of Gynaecological Surgery, of which Liselotte Mettler is one of the distinguished protagonists. Along with Kurt Semm, she initiated the "minimally invasive revolution" of laparoscopic hysterectomy, thus establishing the foundation of today's procedures in the field.

This book's widened scope, now including all available techniques, diagnostic guidance, and in-depth background information, puts itself forward as a standard reference in the field of gynecological medicine.

Foreword 3

It is with great pleasure that I write a forward for this book edited by Ibrahim Alkatout and Liselotte Mettler. Liselotte Mettler has lived on the cutting edge of advanced laparoscopic surgery from its beginning, and by beginning, I mean 1985 when we presented together at AAGL, known previously as a tubal ligation society. The next year, we were both teaching the advanced course at the AAGL. She has continuously worked as a leader to advance the surgical care of women and still does. She is active as a teacher worldwide, especially concerning hysterectomy, and was a founder of the Kiel School of Gynaecological Endoscopy, one of the first training centers in this specialty.

I have known and worked with Liselotte Mettler for over 30 years. Her work with Kurt Semm progressed along parallel paths with mine until we met in 1985–1986. Kurt and Lilo called me Mr. Electrosurgery at that time as Kurt used sutures for oophorectomy, while I pioneered the use of bipolar desiccation for large vessel hemostasis. It was then that Kurt told me, "If I learned to suture, I would be king." So I learned how to suture!

Somewhat lost in these discussions is that I started as a vaginal surgeon. Vaginal surgery was my passion! Abdominal mutilation was our common enemy. After 10 years of doing vaginal hysterectomy surgery with the occasional use of the laparoscope for salpingo-oophorectomy, I began to do the whole operation using laparoscopic visualization with desiccation of both the uterine arteries and the ovarian arteries in 1988. Laparoscopic supracervical hysterectomy came soon thereafter by Kurt and Lilo.

Now, Lilo and her associates from the Kiel School of Gynaecological Endoscopy have put everything about hysterectomy together with this textbook describing different techniques in a relatively comprehensive manner. I must admit that my favorites are both the vaginal and the laparoscopic approaches. So, I look forward to reading those sections to determine if the difference between a colpotomy and a culdotomy has been finally resolved.

I believe that this is a much-needed textbook, and I am sure that most gynecologists will benefit from reading it.

Harry Reich, MD, FACOG, FRCOG
Pioneer in the Development of Laparoscopic Hysterectomy, Shavertown, PA, USA

Honorary Member of AAGL, Pennsylvania, USA

Foreword 4

Hysterectomy is the most common major surgical procedure in modern gynecology. In the USA alone, approximately 600,000 hysterectomies are performed each year. All gynecologists will, at some stage of their training, learn how to perform the hysterectomy procedure independently. What is so special about a hysterectomy, compared to most other surgical procedures, is that there is such a variation of methods and surgical routes for this surgery. More than 90 % of all hysterectomy procedures are performed for benign indications. Thus, there are special needs concerning safety, efficiency, and cost-effectiveness in relation to this nonvital, quality of life-enhancing surgery.

A hysterectomy procedure can take anytime from 15 min to several hours. However, a hysterectomy that spans several hours may be as rewarding for the patient and the surgeon as a quick hysterectomy. I personally have probably performed the longest hysterectomy procedure. In a series of nine abdominal total hysterectomies that took place in 2013, the surgical duration was between 10.5 and 13 h. What is also so special is that these nine abdominal hysterectomies were performed to increase the quality of life of another woman and not the operated woman herself.

My co-surgeon, Pernilla Dahm-Kähler, and I performed the surgery through a midline incision and apart from the uterus also long extensive vascular pedicles, including the uterine and internal iliac arteries and veins, were harvested. The hysterectomy specimen was flushed and cooled ex vivo, before transplantation into the pelvis of the recipient (in most cases the daughter). Up until today, five healthy babies have been born from these transplanted uteri, and three out of these five recent mothers also grew themselves inside the same uterus as their babies.

Dr. Dahm-Kähler and I would never have been able to conduct these successful hysterectomies and uterus transplantations without a structured training in several different hysterectomy procedures during our early years of surgical training and more importantly, without the parallel acquisition of a great understanding of the anatomy of the pelvis. All these important aspects are covered in this comprehensive book. Another important point is that a prolonged duration of surgery does not necessarily equate with inadequate surgical skills. During my early training, I would closely record the time and would not be satisfied by a long duration of a seemingly easy hysterectomy. Today, I try to teach the residents in training that they should strive for minimal bleeding and follow the natural anatomic layers to minimize the tissue damage and thereby shorten the recovery time of the patient.

The editors, Ibrahim Alkatout and Liselotte Mettler, have been able to recruit a large number of absolute top clinicians/scientists in the field of gynecology and surgical hysterectomy to contribute chapters to this book. The impressive list of authors guarantees the readers not only up-to-date information on each aspect of hysterectomy but also that the opinions and surgical tips have passed the critical eyes of world-renowned doctors in academic medicine. Notably, this book covers not only the surgical techniques of all various hysterectomy procedures but also the important aspects of indications and presurgical diagnostics.

I am convinced that *Hysterectomy: A Comprehensive Surgical Approach* will become one of the classic books in the field of gynecology.

Preface

This comprehensive surgical approach to hysterectomy rests on the pillars erected by the great masters in our specialty. The first hysterectomy was performed as a vaginal hysterectomy and dates back to ancient times. The procedure was performed in the time of Soranus of Ephesus, 120 years after the birth of Christ. There were many reports of its use in the Middle Ages, nearly always for the extirpation of an inverted uterus, and the patients rarely survived. Hysterectomy became safer with the introduction of anesthesia, antibiotics and antisepsis, blood transfusions, and intravenous therapy. During the 1930s, Richardson introduced the total abdominal hysterectomy to avoid serosanguinous discharge from the cervical remnant and the risk of cervical carcinoma developing in the stump.

Apart from this innovation, and the transverse abdominal incision introduced by Johannes Pfannenstiel of Kiel in the 1900s, there was little advance in hysterectomy techniques until the advent of endoscopic surgery and the performance of the first laparoscopic hysterectomy by Kurt Semm in Kiel in 1984 and Harry Reich in Kingston, Pennsylvania, in 1988. With his never-ending dedication to the teaching of laparoscopy, Kurt Semm stimulated his coworkers in Kiel and courageous followers around the world to move forward with laparoscopic total and radical hysterectomy.

Thoralf Schollmeyer was a pupil of Semm and head of the Kiel School of Gynaecological Endoscopy from 2007 until his early death at the age of 52 in 2014. He continues to inspire us and was the driving force behind the decision of the Kiel School to go ahead with the second edition of the *Manual of New Hysterectomy Techniques* (2007).

In this age of global communication, it is a great privilege to publish a specialist surgical book on hysterectomy which features the leading surgeons, researchers, and teachers as contributing authors. With the assistance of over 200 multidisciplinary authors, we have been able to compile a book that hopefully meets the requirements of a broad base of readers.

This book brings into balance theoretical background, clinical experience, and scientific findings in a readily comprehensible form with numerous illustrations and tables. For the beginner, this book could become a reliable companion, providing background information and assistance for all procedures associated with hysterectomy. This includes abdominal, vaginal, conventional laparoscopic, and robotic-assisted surgical procedures. But also the experienced surgeon will be able to broaden his spectrum and learn experimental and innovative surgical approaches as this is the first textbook on hysterectomy including traditional, up-to-date, and innovative surgical methods.

Additionally, the book contains a large proportion of interdisciplinary aspects, and we believe it will make a substantial contribution to meeting the growing requirements of interdisciplinary medical treatment. It offers related disciplines (especially general surgery and urology) the opportunity to describe the areas of common overlap and how these can be treated. This multidisciplinary approach is of advantage not only for gynecologists but also for general surgeons and urologists.

The wide range of the contents developed in the course of the conception of the book. Extended hysterectomy procedures cannot be separated from procedures on the internal genital organs or those involving the anatomical and functionally relevant surrounding area.

Finally, we would like to thank Joni Fraser for her continuous support and valuable assistance in preparing the book for production. Special thanks also go to Lizzy Raj, Julia Megginson, and Melissa Morton at Springer International Publishing for allowing us the freedom to design a book according to our ideas and supporting us in the realization of what turned out to be a mammoth project. Tribute is also due to the illustrators for their creative visual implementation of complex issues.

The editors are conscious of the privilege of having access to the most advanced treatment concepts of our time. In an unstable world, our foremost intention is to share the greatest good, the ability to cure one's fellow human beings.

Kiel, Germany, 2017 Ibrahim Alkatout and Liselotte Mettler

Contents

Part I Historical Background

1 The History of Hysterectomy 3
Christopher J. G. Sutton

2 History of Radical Hysterectomy 29
Karl Tamussino

Part II Topographical Anatomy

3 Topographical Anatomy for Hysterectomy Procedures 37
Thilo Wedel

Part III Imaging and Diagnostics

4 Clinical Diagnostics Before Hysterectomy 63
Stefan Rimbach

5 Ultrasound Imaging 69
Werner Dürr

6 Radio-Imaging for Benign Uterine Disease 95
Céline D. Alt-Radke

7 Radio-Imaging for Malignant Uterine Disease 109
Céline D. Alt-Radke

8 Interventional Diagnostics Before Hysterectomy 125
Sergio Haimovich

Part IV Extended Aspects Regarding Indications and Contraindications

9 Evidence Based Review of Hysterectomy and Sexuality 133
Farah Lone

10 Guidelines and Recommendations of Scientific Societies and Associations for Hysterectomy 139
Klaus Neis and Felix Neis

11 Choosing the Correct Hysterectomy Technique 143
Linda-Dalal J. Shiber and Resad Pasic

12 Indications for Salpingectomy 149
Roberta Venturella

13 Indications for Oophorectomy and Adnexectomy 155
William H. Parker

14 Uterine Sarcomas and Atypical Smooth-Muscle Tumors: Clinic, Diagnostics and Appropriate Surgical Therapy 161
Günter Köhler and Marek T. Zygmunt

15 Uterine Morcellation 219
Courtney J. Steller and Charles E. Miller

Part V Surgical Education and Training

16 Learning by Doing: How to Teach Hysterectomy 235
Carolin Spüntrup, Marc Banerjee, and Elmar Spüntrup

17 Communicative and Ethical Aspects of the Doctor-Patient Relationship in Extreme Situations 249
Ibrahim Alkatout

Part VI Macroscopic and Microscopic Pathological Aspects

18 Processing and Histopathological Workup of Hysterectomy Specimens 259
Lars-Christian Horn and Anne K. Höhn

Part VII Specific Hematological and Anesthesiological Aspects

19 Perioperative Management of Antithrombotic Therapy in the Periprocedural Period of Patients Undergoing Hysterectomy 299
Verena Limperger, Florian Langer, Rolf Mesters, Ralf Ulrich Trappe, and Ulrike Nowak-Göttl

20 Anaesthesia in Gynaecology 307
Michael Sonntagbauer

Part VIII Laparoscopic Hysterectomy and Extended Procedures for Benign and Malignant Indications

21 Indications and Contraindications for Laparoscopic Hysterectomy 323
Helder Ferreira and António Braga

22 Preparation (Medical History, Surgical Set-Up, Antibiotics, Anticoagulants) 331
Magdalena Zalewski and Mohamed Elessawy

23 Instrumentation Systems, Apparatus and Materials in Hysterectomy 337
Liselotte Mettler, Ibrahim Alkatout, and Artin Ternamian

24 Uterine Manipulators for Total Laparoscopic Hysterectomy 359
Prashant Mangeshikar and Abhishek P. Mangeshikar

25 Diagnostic Laparoscopy and Final Site Recognition 369
Julia Serno

26 General Aspects and Their Handling: Adhesions 373
Andreas Hackethal, Jörg Engel, Hans-Rudolf Tinneberg, and Sebastian F.M. Häusler

27 Comorbidities 381
Ralf Rothmund

28 General Surgery Conditions and Techniques for Gyne-Endoscopic Surgeons 385
John E. Morrison

29 Fibroids in Laparoscopic Hysterectomy 401
Xiaofeng Zhao, Lu Huang, and Sheng Xu

30 Symptomatic Fibroids as Main Indication for Laparoscopic Hysterectomy and Their Handling 413

Part I

Historical Background

The History of Hysterectomy

1

Christopher J.G. Sutton

Introduction: The Ancient Greek Understanding of Female Pelvic Anatomy

There was a certain mystique about female anatomy in ancient times so the Greeks believed that the uterus (hysteros) was the seat of the soul. The Pythagoreans believed that the uterus was bifid which almost implies a knowledge of embryology but probably arose from the fact that they were permitted to dissect animals but human dissection was forbidden. They hypothesised that the left uterine horn represented the west, or darkness, from which females were derived whereas the right side represented the east, or light, in which males developed. They believed that the uterus wandered around the abdominal cavity and that when the organ was displaced the poor woman developed signs of hysteria [1]. Such male orientated thinking persisted until the late nineteenth Century allowing gynaecologists to remove normal ovaries, popularised by the American Surgeon Robert Battey – for a range of dubious indications ranging from hysteria, menstrual madness, insanity and even nymphomania and masturbation [2]. Such a practice performed at a time when operative mortality was around 75 % represented the zenith of morality in the specialties of gynaecological surgery and psychiatry and was probably the greatest scandal in medical history [3].

The First Vaginal Hysterectomies

Although the history of vaginal hysterectomy is shrouded in the mists of antiquity there are reports of it having been performed 50 years before the birth of Christ by Themison of Athens [4, 5]. Most of our knowledge of surgery in Greek and Roman times is derived from *Gynaecology,* the oldest published work on obstetrics and gynaecology written by Soranus [6]. Soranus (Fig. 1.1) was born in Ephesus in Asia Minor, and being situated between India and Greece absorbed the early medical ideas of these two great cultures [7]. Ephesus, which has a well preserved stone amphitheatre, was originally a Greek city but is now situated in Turkey on the Aegean Sea north of Izmir.

Soranus received his medical training in Alexandria in Egypt and later worked in Rome during the reigns of Emperor Trajan (AD 98–117) and Emperor Hadrian (AD 117–138).

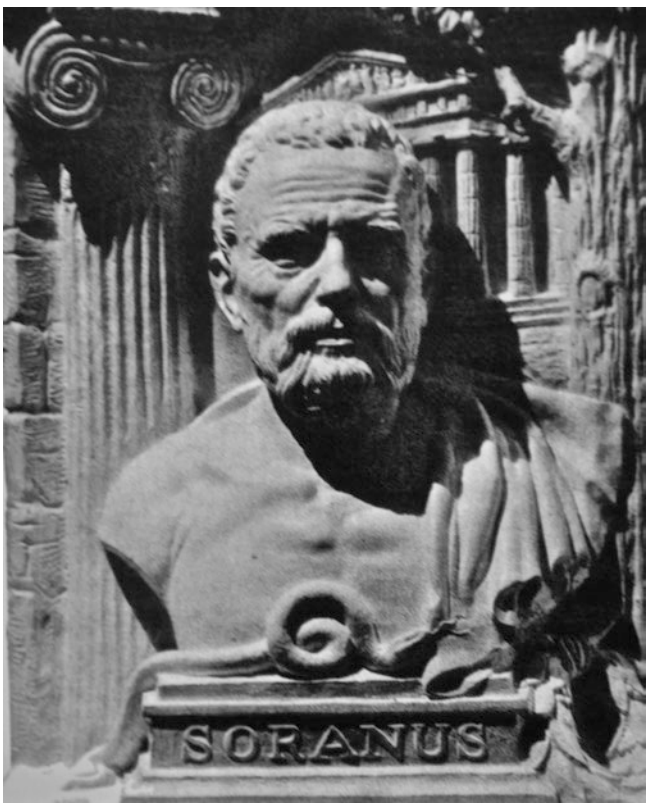

Fig. 1.1 Soranus of Ephesus (AD 98–138) who wrote the first textbook of Gynaecology and described a vaginal hysterectomy he performed (Photo: Dr. Chris Sutton taken at the Amphitheatre in Ephesus,Turkey)

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_1

In his book *Gynaecology* there is a well documented case of a vaginal hysterectomy which explained in detail an operation performed by the author which involved the removal of an inverted uterus that had become gangrenous and had turned black in colour [8]. The ureters, and often the bladder, were part of these early surgical excisions and the patients invariably died [1, 9].

Nevertheless in the writing of the eleventh century Arabian physician, Alsaharavius he clearly states that if the uterus had prolapsed externally and could not be reinserted, then he advised his pupils that it should be surgically excised and it is unlikely that he would have advocated this practice if death was the inevitable result of such intervention.

There is another report from a Latin translation of a Hebrew text in 1287 that Abumeron Avenzoar (?1092–1162), generally regarded as the greatest Moslem physician of the Western Caliphate was the first to attempt total extirpation of the uterus [10].

The Middle Ages

In fact there are several reports of patients surviving vaginal hysterectomy in the Middle Ages, and these are referred to in medical writings in the sixteenth and seventeenth centuries. The first authenticated case was reported by Giacomo Berengario da Carpi who lived in Bologna, the site of one of the oldest medical schools in Europe. In 1507 he was reputed to have performed a partial vaginal hysterectomy and added that his father had also performed one in the same year [11].

Schenck of Grabenberg reported 26 cases during the early part of the seventeenth century and the operation was also performed by Andreas da Crusce in Italy in 1560 and by Valkaner of Nuremberg in Germany in 1675, when the patients appear to have survived [12]. Modern medical historians are somewhat sceptical about some of these early reports and, as usual, have largely ignored the contribution of the midwives of Europe who, from time to time, amputated prolapsed or inverted puerperal uteri. They have also overlooked an early example of self-help: Faith Howard, a 46 year old peasant woman who performed the operation on herself. This case was well documented and reported in 1670 by Percival Willoughby, an early male midwife and lifelong friend of William Harvey, who famously discovered the circulation of blood. Apparently, while she was carrying a heavy bucket of coal one day, Faith's uterus prolapsed completely and, frustrated by this frequent occurrence, she grabbed the offending organ, pulled as hard as possible and "cut the whole lot off with a short knife". In his report, Willoughby states that "there was a mighty bleeding which eventually stopped" and Faith lived on for many years after this "with water passing from her insensible day and night", obviously from a vesico-vaginal fistula [13, 14].

The famous French *accoucheur,* Jean- Louis Baudeloque , the inventor of the pelvimeter, introduced the technique of artificially prolapsing the uterus and then, in favourable cases cutting it off together with the adnexal organs and he performed 23 of these procedures over 10 years from 1800. He was a fervent supporter of Caesarean Section, as opposed to symphysiotomy, and his external pelvimeter was used to measure the diameter of the external conjugate to predict those women who were likely to have an obstructed labour. He attended the first confinement of Napoleon's wife, Empress Marie-Louise, and his reputation in Paris was such that he was called '*le grand Baudeloque'* [15].

It seems that the first vaginal hysterectomy on a non-puerperal uterus was an unfortunate accident. Dr. G.B.Paletta of Milan carried out the operation on 13 April 1812 assisted by an eminent Milanese surgeon Dr. D.B. Monteggia. He intended to amputate what he thought was a cervical cancer, but to his great surprise found that he had removed the entire uterus vaginally. Unfortunately the patient died 3 days later from peritonitis [7].

The First Elective Vaginal Hysterectomies

Most of these procedures were performed on puerperal uteri and were undertaken on an emergency basis, but the first planned elective hysterectomy was by Friedrich Osiander (1759–1822) of Gottingen in Lower Saxony in Germany just over two hundred years ago in 1801 who employed the vaginal approach. He did not report the case until he had operated on his ninth patient [16].

It is interesting to reflect that almost all women subjected to caesarean section at this time died from shock, haemorrhage or sepsis. In the early 1800's Ossiander wrote: "Before undertaking this procedure, one should allow the patient to draw up her will and grant her time to prepare herself for death" [15]. A rather extreme example of informed consent long before the modern epidemic of litigation might make this seem reasonable in certain circumstances.

The first deliberate planned vaginal hysterectomy for endometrial carcinoma was by Conrad Langenbeck (Fig. 1.2) who, interestingly, also came from Gottingen and was possibly the most distinguished surgeon of his time and the Surgeon-General of the Hanoverian army. He performed this operation in 1813 but did not report it until 4 years later [17].

Langenbeck, the inventor of the retractor that is familiar to all surgeons, was himself a surgeon of such supreme swiftness that he once amputated the shoulder of a wounded infantry officer whilst a colleague who had come to watch the procedure had turned around to take a pinch of snuff thereby totally missing the operation he had travelled far to observe [18, 19].

Having little precedent to follow, Langenbeck had to devise his own plan for the removal of the entire uterus. He

Fig. 1.2 Conrad Langenbeck from Gottingen, Lower Saxony, Germany: Surgeon General to the Hanoverian Army, who performed the first elective vaginal hysterectomy for endometrial cancer in 1813 (Reproduced with permission of Jaypee Brothers Medical Publishers, India)

performed a retroperitoneal dissection taking great care not to enter the peritoneal cavity. Towards the end of the procedure he encountered uncontrollable bleeding from the uterine artery and called upon his assistant, a Surgeon Commander afflicted with gout, to come and help but the gentleman was enormously overweight and could not rise from his chair. Langenbeck had no alternative but to compress the bleeding artery with his left thumb and forefinger and with his right hand he placed a ligature- carrying needle through the tissues behind the bleeding point and tied the ligature by grasping one end between his teeth and secured the pedicle with a one handed slip knot tied with his right hand. Following the procedure he could detect no opening into the peritoneal cavity and the patient made a surprising and uneventful recovery but after this extraordinary display of technical virtuosity, none of his colleagues believed that the operation had taken place since there was no visible scar. As is so often the case the operative specimen had been lost on the way to the pathology laboratory, the Surgeon Commander with gout died the following week and the patient herself was demented so was unable to provide reliable testimony. For the next 26 years Langenbeck was subjected to ridicule and the jibes of his colleagues and accused of being a liar and a charlatan and was only finally able to substantiate his claim when the patient died of senility and an autopsy showed that she had indeed had her uterus removed in its entirety [9].

The First Laparotomy: Christmas Day 1809

In order to put these events into historical perspective the vaginal hysterectomy for endometrial cancer performed by Conrad Langenbeck described above took place in 1813 at the time when Napoleon's *Grande Armée* was retreating from Moscow after the failure of his Russian Campaign. It was only 4 years before, on Christmas day 1809, that the human abdomen was deliberately opened for the first time in order to remove a diseased organ, in this case a massive ovarian cyst.

Until the beginning of the nineteenth Century there was no possible way of removing a large tumour because it was considered that surgical opening of the peritoneal cavity resulted in certain death. A little over 200 years ago an event took place which has had a momentous impact on our survival as individuals and as a species and yet it has been remembered by relatively few. That day saw the birth of operative abdominal surgery which has saved countless lives, yet it did not take place in one of the great University Teaching Hospitals but in the front parlour of the house of an American country doctor in the small frontier town of Danville in Kentucky [20, 21].

On the morning of Christmas Day 1809 the brave surgeon Ephraim McDowell (Fig. 1.3) performed the world's first elective laparotomy to remove a massive tumour from the equally brave patient, Jane Todd Crawford (Fig. 1.4) who had to withstand the horrific pain of a large abdominal incision without the benefit of an anaesthetic. The doctor was brave because the abdominal cavity had never been deliberately opened with a surgical knife before and it was widely accepted that such an intervention would inevitably result in death.

Legend has it that the townsfolk of Danville had gathered in the square outside his house on the morning of the operation and were erecting a gallows so that if Jane Todd Crawford died at the hands of the "dreadful doctor" he would be hanged in public [22].

The Father of Abdominal Surgery: Ephraim McDowell

McDowell's family were of mixed Irish and Scottish extraction and he was born in Rockbridge County, Virginia in 1771, the ninth of twelve children. When he was 13 years old the

family moved to Danville, a frontier town that was the first capital of the State of Kentucky, where his father was appointed Judge of the small community of some "150 homes and some tolerably good buildings" [23]. The young Ephraim decided on a career in medicine early in his life and served as an apprentice to a family physician, Dr. Alexander Humphreys in Staunton, Virginia. When he was 22 he spent 2 years studying anatomy in Edinburgh under Alexander Munro and surgery under the tutelage of John Bell. For financial reasons he had to return home to Danville without earning a medical degree but even without the letters after his name the prestige of being educated at one of the most famous Medical Schools in the world ensured that he rapidly built up an extensive surgical practice and he came to be regarded as "the best doctor west of Philadelphia" [24] He was renowned for his swift amputations, hernia repairs and lithotomies and would typically operate in the homes of patients with family members gathered round to hold the unfortunate sufferer down. One of his patients was James Polk who, as a 14 year old boy had several bladder stones removed, and later became the eleventh president of the United States [25].

McDowell's fame spread locally among the frontier people because this was an area that was expanding rapidly after Dr. Thomas Walker had opened up the Wilderness Trail through the Cumberland Gap from Virginia into Kentucky accompanied by frontiersmen and Indian fighters such as Daniel Boone and Davy Crockett [21].

The Patient: Jane Todd-Crawford

Jane Todd-Crawford lived with her family of five children in a small log cabin in Motley's Glenn near Greensburg, Kentucky, some 60 miles from Danville and at the age of 44 she was thought to be carrying another child and was causing concern with the local doctors and midwives because she was 2 months beyond her due date and " she was afflicted with excrutiating pains similar to those of labour, which were incessant" [26]. The two attending physicians were in despair and had tried various potions and enemas used to induce labour and in desperation had even employed two midwives to jump up and down on her extremely distended abdomen. All this was to no avail and the poor woman had such a swollen abdomen that she could barely breathe and in desperation they decided to summon the "surgeon from Danville to assist with the delivery".

Although the journey from Danville to Greensburg can nowadays be easily accomplished in an hour or so using modern highways, in 1809 it required a lengthy and difficult journey on horseback, crossing many mountain ridges and fording deep rivers and when McDowell set out on this arduous journey the snow had already fallen deeply and there were added hazards from bands of skirmishing Indians, to say nothing of predatory wolf packs and bears. When he

Fig. 1.5 Massive ovarian cyst. When removed it weighed half of the weight of the patient (Photo: Chris Sutton. St. Luke's Hospital, Guildford)

arrived he quickly appraised the situation and saw that the swollen abdomen did, indeed, have the appearance of a pregnancy, possibly a multiple one, with a size that was indeed making it difficult for the patient to breathe.

Without recourse to sophisticated imaging techniques it is often difficult clinically to distinguish a massive fibroid from a large ovarian tumour (Fig. 1.5) or, indeed, from a term pregnancy [27]. Possibly because of his education in Edinburgh under the tutelage of the anatomist Alexander Monroe (Secundus), he performed a more thorough examination than had been performed by the local physicians and this included a vaginal examination where he found that the mass was inclined to one side and was mobile and his examining fingers felt a normal sized uterus and cervix which were pushed to the other side, all of which indicated that the mass was an "enlarged ovarium".

Clearly, he was very depressed by his findings and in an account written many years later to a medical student, Robert Thompson, he wrote "I told the lady that I could do her no good and candidly stated to her, her deplorable situation; informed her that John Bell, Hunter, Hay and A Wood, four of the first and most eminent surgeons in England and Scotland, had uniformly declared in their lectures that such was the danger of peritoneal inflammation that opening the abdomen to extract the tumour led to inevitable death."

She was clearly devastated by this pronouncement but told him that it was impossible to continue to live in her present situation since she was almost unable to breathe and felt that she would die anyway. He therefore continued "but, notwithstanding this, if she thought herself prepared to die, I would take the lump from her if she would come to Danville." He ended this account by stating simply "she appeared willing to undergo an experiment" [28]. This must surely be the first documented case in the world of informed consent.

The Operation on McDowell's Kitchen Table

Dr. McDowell returned to Danville expecting to hear no more from her because the journey with the increasing snowfall that winter was long and difficult and dangerous by horseback, but she was a tough frontier woman and a few days later appeared on his doorstep. Unfortunately the arduous journey had caused considerable bruising over the lower abdomen, where she had rested the enormous tumour on the pommel of her saddle. He therefore determined to wait for a few days before deciding to perform the operation and, being a deeply religious man, he timed the procedure to occur on the morning of Christmas Day when many of the townsfolk were in church so that they could bring the efforts of their combined prayers onto his endeavour. He was joined by his nephew, Dr. James McDowell, who had graduated a few months previously from the first Medical School in America, in Philadelphia, to join the practice as a partner and he did his best to dissuade his uncle from "the experiment". The kitchen table was dragged into the front room and Jane Todd Crawford was placed on her back on the table and tilted slightly to the right side (Fig. 1.6) and then "he removed all her dressing which might in any way impede the operation". He then offered up a prayer saying " Direct me, O God, in performing this operation, for I am but an instrument in thy hands, and am but thy servant, and if it is thy will, oh! spare this poor afflicted woman."

Many years later when he wrote about the procedure he described it as follows: "I made an incision about 3 inches from the rectus abdominus muscle on the left side, continuing the same 9" in length, parallel with the fibres of the above-named muscle, extending into the cavity of the abdomen. The tumour then appeared full in view but was so large that we could not take it away entire. We put a strong ligature around the fallopian tube near the uterus and then cut open

Fig. 1.6 The first laparotomy in the world on Christmas Day 1806 performed on the kitchen table in Ephraim McDowell's House in Danville, Kentucky. Painting by Dean Cornwell *" the Dawn of Abdominal Surgery"* (Reproduced courtesy of McDowell House and Museum, Danville, Kentucky)

the tumour, which was the ovarium and fimbrious part of the fallopian tube, very much enlarged. We took out 15 lbs of a dirty gelatinous-looking substance, after which we cut through the fallopian tube and extracted the sac, which weighed 7 lb and one-half. As soon as the external opening was made the intestines rushed out upon the table and so completely was the abdomen filled by the tumour that they could not be replaced during the operation which was terminated in about 25 minutes. We then turned her upon her left side so as to permit the blood to escape, after which we closed the external opening with the interrupted suture, leaving out at the lower end of the excision the ligature which surrounded the fallopian tube."

During the whole of this ghastly painful procedure Jane Todd-Crawford remained motionless and merely recited the Psalms in order to calm herself during her ordeal.

She stayed in McDowell's house and the bed in which she lay can still be seen because the entire house and gardens have been turned into a museum to commemorate this amazing feat of pioneering surgery. Several years ago the American College of Obstetricians and Gynaecologists donated the wooden door knocker from the front door of McDowell House to the Royal College of Obstetricians and Gynaecologists in London and it is still used to this day as a gavel on ceremonial occasions.

Ephraim McDowell visited Mrs. Crawford on a daily basis and on the 5th day he found her making her own bed and reprimanded her severely. She continued to make an excellent recovery and 25 days later she returned home in good health by the same route that she had come, which is now a long distance footpath named "The Jane Todd Crawford Trail".

The two of them never met again during their lives. Ephraim McDowell died at the age of 59 years of "an acute attack of inflammation of the stomach" which was probably appendicitis and long before the time when a laparotomy could be performed to remove the infected organ. Jane Todd Crawford outlived him and died at the age of 78 years and a picture of her in her old age (Fig. 1.7) shows her displaying a locket with the picture of Abraham Lincoln, who was born in a log cabin at Sinking Spring Farm very close to where she grew up in Greensburg County and to whom she was related as a cousin when he married one of her sisters who thus became America's First Lady as Mary Todd Lincoln.

The often repeated story that the townsfolk had gathered in the square outside his house and had erected a gallows to hang him in the event of Jane Todd Crawford dying during the operation is almost certainly anecdotal and untrue for several reasons. Firstly he was considered the most famous, knowledgeable, and skilful surgeon in that frontier area which probably had few doctors and he would have been treated with the greatest respect and unlikely to have been publicly hanged. Furthermore his father was the County Judge and his elder brother was the Sheriff of Danville who was sadly killed a few weeks later when he was involved, along with Davy Crockett and Daniel Boone, in a skirmish with a local Indian tribe at Blue Lick in Kentucky [21].

The Ovariotomists: Pioneers of Ovarian Surgery

Unlike his modern counterparts, Ephraim McDowell did not immediately rush off to get this operation published and waited until he had performed two more successful operations on ovarian tumours in 1813 and 1816 before reporting it in a journal with a limited readership, "The Eclectic Repertory and Analytical Review of Philadelphia" [29]. Two years later he published two further cases in the same journal, one of whom survived, but the other died of peritonitis on the third post-operative day. During his lifetime he performed three further ovarian operations between 1822 and 1826. One involved merely drainage but the patient lived for a long time afterwards, the second underwent complete excision, but the third had to be abandoned because of extensive adhesions.

There were a further three that are mentioned in letters and on reading his descriptions it does seem that, although he styled himself as an ovarian surgeon, at least two of his cases were large pedunculated myomas [30, 31]. News of great surgical advances took a long time to percolate across the Atlantic and, even in America, McDowell's achievement was greeted with a certain amount of scepticism and even outright disbelief [32]. It was 14 years later that the first ovariotomy was carried out in Europe by John Lizars, a fellow student from Edinburgh, but the patient died and he then made three more successful attempts [33]. It appears that the Edinburgh Surgeon, J.Y.Simpson, the inventor of the anaesthetic agent chloroform was the first to introduce the word 'ovariotomy', a strange choice for the name of this operation in an age when most surgeons were reared in the classics and therefore etymologically correct [32]. The initial years of abdominal surgery were associated with an enormous mortality rate, mainly due to uncontrolled haemorrhage or peritonitis and sepsis but the few women that survived spawned a new generation of pioneering surgeons who finally realised that opening the human abdomen with a surgical incision did not result in certain death.

The World's First Abdominal Hysterectomy November 17th 1843

The greatest of the ovariotomists in Europe was Charles Clay of Manchester, in the North of England [34]. He studied at the Manchester Royal Infirmary and, like Ephraim McDowell received part of his medical education in Edinburgh. Like McDowell he also started in surgical practice in a small rural community, Ashton-under-Lyne under the shadow of the Pennine Hills in Cheshire. After 16 years he moved to the industrial city of Manchester where he established his surgical reputation. He was a member of the Reform Club and was a friend of my great grandfather, William Sutton, who was a successful businessman in this thriving Victorian metropolis. Charles Clay is shown in Fig. 1.8 at the peak of his surgical career, profoundly confident and appearing dapper with his top hat.

The first four of his ovariotomies survived but with the fifth he was not so lucky and this turned out to be the first abdominal hysterectomy recorded and it was a complete disaster. The operation was performed on 17 November 1843 in the first floor room above his Consulting Rooms in Piccadilly, the large square in the centre of Manchester. As was usual in those days he was accompanied by several

friends and medical students as spectators and since it was before the time of Pasteur or Lister no one wore masks or surgical gloves and the patient was given brandy and milk to alleviate the pain of the operation since this was a long time before anaesthesia was introduced by WRT Morton at the Massachusetts General Hospital in Boston in 1846 [35]. He was certain that he was dealing with a massive ovarian cyst so he made a long 60 cm surgical incision from the xiphisternum to the pubis. Unfortunately once the peritoneum was entered the patient coughed and the massive tumour was extruded (Fig. 1.9) and he realised to his horror that it was a huge fibroid and since the patient was now struggling and had to be forcibly restrained by the medical students and it was impossible to replace the hugely enlarged uterus back in the abdominal cavity he had no option but to proceed and performed a subtotal hysterectomy. By an extraordinary coincidence a few days later on the 21st of November, A M Heath who was also an ovarian surgeon in Manchester, found himself in a similar situation operating on a huge fibroid instead of an ovarian cyst. Unfortunately both patients died of a massive haemorrhage a few hours later [19].

The next year, Clay was more successful with a similar case but on this occasion he placed a ligature of Indian hemp around the supra-vaginal cervix to prevent haemorrhage from the uterine arteries. The patient lived for 15 days when she fell out of bed in a coma and never regained consciousness. Although this was tragic for the patient it was also sad for Clay since she had survived the critical post-operative period and not succumbed to sepsis which was the usual cause of death following a laparotomy.

From reading contemporary accounts of this woman's post-operative course it is difficult to determine the exact mode of death. She could have had a pulmonary embolus or she could have fallen out of bed in uraemic coma due to occlusion of both ureters by the ligature but popular Mancunian folklore suggests that she was dropped on the floor by a couple of incompetent porters whilst the nurses changed her bed linen. If this is true then her death was

entirely unrelated to the operation and Charles Clay could have claimed to have performed the first successful hysterectomy in the world [22, 36].

In fact it was not for a further 20 years that he attempted another hysterectomy and this time the patient survived. Interestingly he mentioned this almost as an aside during his important presentation to the Obstetrical Society of London in 1863 when he presented his experience of 395 ovariotomies with only 25 deaths [37].

The First Successful Abdominal Hysterectomy in the World

The first successful removal of a fibroid uterus was by Walter Burnham in Lowell, Massachusetts in 1853 [18, 38, 39]. The patient, a 42 year old woman, was referred to him by another physician who had observed a slowly growing abdominal mass over the previous 6 years that was without any other symptoms but had recently become persistently painful. Burnham diagnosed an ovarian cyst but told her there was no treatment available other than surgical removal and even '… this course of action could not be adopted without placing her life in imminent danger'. He advised her to seek a second opinion and ' also to consult her friends as to the propriety of running so great a risk' [15].

Nevertheless she elected to have the operation which took place on 25 June 1853 with two surgical assistants and in the presence of a large number of medical gentlemen as was often the case with these early surgical interventions. This operation took place in the early days of anaesthesia and the chloroform caused the patient to vomit so when he made a long midline incision from the sternum to the pubis, a large pedunculated fibroid attached to an enlarged fibroid uterus was extruded through the incision when in fact Burnham was anticipating a massive ovarian cyst. It proved impossible to replace the large fibroid and he had little choice but to proceed with a subtotal hysterectomy tying off both ovarian and uterine arteries. The patient recovered, apparently with the aid of brandy and opium, and the fact that the original diagnosis was incorrect should not detract from his achievement.

Early records of the first abdominal hysterectomies read like a disaster saga until Burnham produced the first survivor, but even in that instance the diagnosis was wrong (Table 1.1).

However, later the same year Gilman Kimball (Fig. 1.10) who, also resided in Lowell, carried out the first deliberate hysterectomy to remove a fibroid, and the patient survived the operation [40]. In this particular case the surgeon correctly diagnosed a large fibroid of about the size of a 6 month pregnancy but it was not the size that was the problem but the severe menorrhagia that was causing the loss of a large quantity of blood each month which had become life-threatening.

Table 1.1 A summary of the abdominal hysterectomies performed in the early years (1843–1863)

Date	Operator	Diagnosis	Outcome
1843	Clay	Ovarian tumour	Massive haemorrhage a few hours after the operation and died
1843	Heath	Ovarian tumour	Massive haemorrhage a few hours after the operation and died
1844	Clay	Ovarian tumour	Dropped on the floor on day 15 and died
1846	Bellinger	Fibroids	Haemorrhaged on day 5 and died
1853	Burnham	Ovarian tumour	Survived but diagnosis wrong
1853	Kimball	Fibroids	Survived and diagnosis correct
1863	Clay	Fibroids	Survived. First successful operation in Europe
1863	Koeberle	Fibroids	Survived

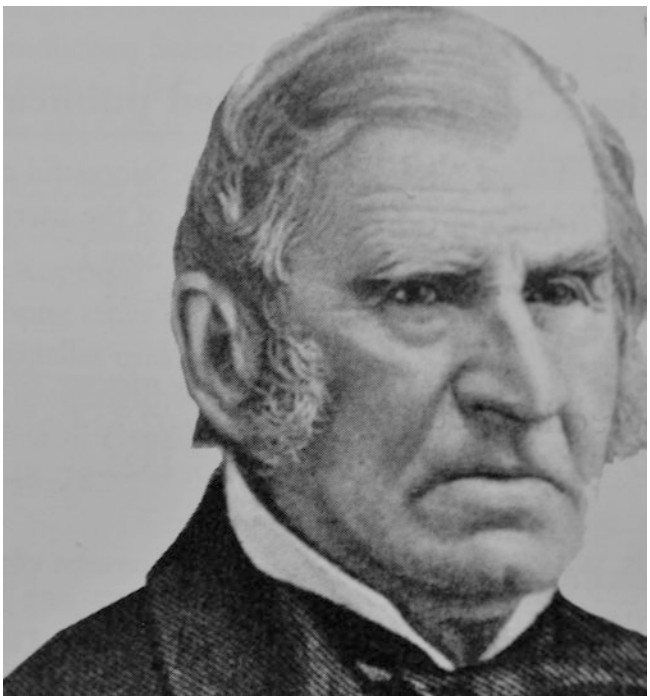

Fig. 1.10 Gilman Kimball (1804–1892) from Lowell, Massachusetts who performed the first successful hysterectomy in the world with the correct pre-operative diagnosis on 1 September 1853 (Reproduced with permission from RCOG Press, London)

During the consultation with her other physicians Kimball felt that ' Rather than give up the case as utterly hopeless, I would propose, as a last resort, the removal of the uterus itself …. Extraordinary and hazardous as this suggestion seemed, the feeling was unanimously and unhesitatingly expressed by everyone present at the consultation, that this

procedure offered the only possible chance of saving the patient from impending death. This conclusion was no sooner made known to the patient, than it was readily consented to – both she and her husband claiming that a chance of life by an operation however small that chance might be, was better than the certainty of a speedy death" [40].

They wasted no time and the same afternoon the patient was anaesthetized with chloroform and a relatively small incision was made through the linea alba directly over the most prominent part of the tumour. Kimball's plan was to perform a myomectomy and having reduced the size of the uterus to then proceed to sub-total hysterectomy. This is essentially what he achieved and the patient made a full and complete recovery, although the protruding ligatures were still causing inconvenience 8 months later.

It is interesting that these two surgeons came from a small town in rural Massachusetts and considering that hysterectomy is the second most common operation performed on women, second only to Caesarean Section, that enquiries I made at the tourist office last year as to where these operations actually took place lead nowhere and it seems that the burghers of that small town of Lowell are quite unaware of the fame that should be the just due of these two pioneering surgeons.

Walter Burnham was the son of a doctor and studied medicine under the tutelage of his father and graduated from the University of Vermont in 1829. He moved to Lowell in 1846 and carried out general and gynaecological surgery and was one of the early advocates of ovariotomy having performed 300 procedures in 30 years with a survival rate of 75 % which were excellent results for those times. His hysterectomy results were not so good and after the first survivor he performed a further 15 hysterectomies during the following 13 years but only two survived – the rest succumbing to sepsis, peritonitis, haemorrhage and exhaustion.

Walter Burnham was a member of the Massachusetts House of Representatives and was instrumental in securing the passage of the Anatomy Act in 1855,which authorised the medical profession to obtain bodies of dead paupers for dissection and anatomical research. During the American Civil War (1862–1870) he was surgeon to the Sixth Massachusetts Regiment of Volunteers. He died at his home in Lowell on 16 January 1883 at the age of 75 [41].

Gilman Kimball also served as a Brigade Surgeon in the American Civil War and was Medical Director to General Butler. Following his first successful operation at the Lowell Hospital he became Professor of Surgery at the Berkshire Medical Institute and the Vermont Medical College and was awarded an honorary MD at Yale College in Connecticut in 1856. In 1877 he was elected to Fellowship of the American Gynaecological Society and became President of that Society in1883. He died in his 88th year in 1892 [41].

The First Successful Abdominal Hysterectomy in Europe

Eugene Koeberle from Strasbourg was one of the greatest surgeons in Europe in the latter half of the nineteenth Century and the French usually claim that he performed the first successful hysterectomy in Europe. The operation was for fibroids and the diagnosis was correct and in order to obtain haemostasis he used a device of his own invention called a serre-noeud which was a wire loop tightened by a screw device (Fig. 1.11) that held the cervix like a clamp and allowed it to be exteriorised through the wound (Fig. 1.12). Eventually the avascular cervical stump necrosed and fell back into the pelvis [22]. This operation took place on 2 April 1863 and was certainly the first in Continental Europe but in his lecture to the Obstetrical Society of London Charles Clay had briefly mentioned a successful case of "the entire removal of the uterus and its appendages" which he had performed in Manchester a couple of months earlier on 3 January 1863 [37]. It would appear there-

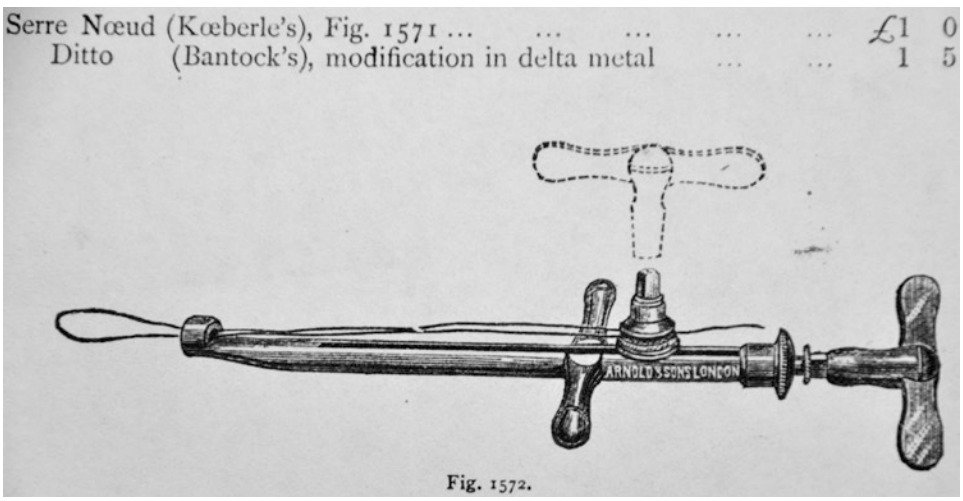

Fig. 1.11 The serre-noeud from a commercial catalogue of Arnold and Sons, Instrument Makers, London priced at £1 (1.38 Euros) (Photo by Chris Sutton. Company no longer in existence)

fore that the first successful hysterectomy in Europe was performed by an English surgeon albeit by only 3 months.

Anaesthesia was employed regularly and Lister had promulgated the theory of antisepsis and had devised a carbolic spray to prevent infection and peritonitis [42], although there is no actual reference in Clay's writings that he used these methods. In this particular case, which was deliberately undertaken to remove a uterine fibroid, he determined to cut through the cervix and not to open the vagina. The case is well authenticated by three doctors from Preston, Sheffield and Manchester, and immediately after the operation, Professor J Y Simpson, (Fig. 1.13) the inventor of chloroform,

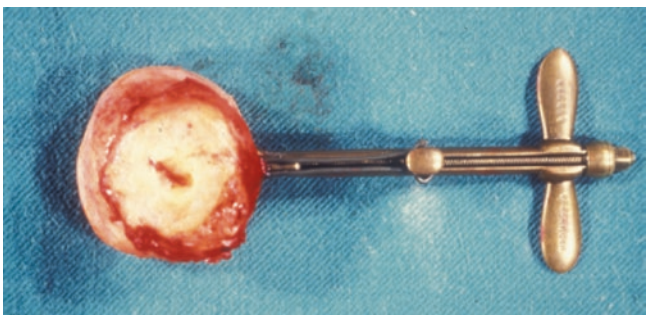

Fig. 1.12 The serre-noeud introduced by Koeberle of Strasbourg, who performed the first successful hysterectomy in continental Europe on 2nd April 1863 (Photo: Chris Sutton taken at St. Luke's Hospital, Guildford)

Fig. 1.13 James Young Simpson, Professor of Midwifery at the University of Edinburgh and inventor of chloroform and Simpson's Forceps (Photo: Chris Sutton from a contemporary portrait)

arrived unexpectedly from Edinburgh. He was greatly interested in the case and took the specimen back to Edinburgh from whence, some time later, he returned a description and a sketch, ending his letter with 'your case may turn out as a precedent for operative interference in some exceptional cases of large fibroids of the uterus and I congratulate you most sincerely on the happy recovery of your patient' [22].

James Young Simpson was the Professor of Midwifery in Edinburgh where he had enrolled in the University at the tender age of 14 initially to study the arts. He had difficulties with administering ether to patients in prolonged labour and sought an alternative solution by inventing chloroform [43] which could more easily be given as a small droplet inhaled on a handkerchief. He famously experimented on himself and his guests after a dinner party in his house, among them Matthew Duncan (of placenta fame) and George Keith, the brother of Thomas Keith (*vide infra*) and all the guests slid off their chairs and were found next morning soundly asleep on the floor.

He used it on many patients having prolonged painful labours and on children undergoing surgery but had to face criticism from religious objectors who quoted the Bible citing Genesis 3:16 '…. *in sorrow and suffering thou shal*t *bring forth children….'* With his wide knowledge of literature and the scriptures Simpson was able to quote back to them Genesis 2:21: ' *And the lord God caused a deep sleep to fall upon Adam, and as he slept he took one of his ribs and closed up the flesh instead thereof '* [44].

The criticism continued until Dr. John Snow successfully administered chloroform to Queen Victoria during the birth of Princess Charlotte and after this widely publicised regal event, ' *Chloroform à la Reine ',* the technique became widely accepted and for that and other contributions to Midwifery such as the design of Simpson's Forceps he was eventually made a Knight of the Realm [41].

Gynaecological Surgery in the Late Nineteenth Century

The initial mortality in these operations was extremely high since many of the early abdominal surgeons employed the long ligature hanging out of the lower part of the incision in order to allow the drainage of '*laudable pus'* from the peritoneal cavity, in much the same way as when they were amputating limbs in battlefield surgery. Charles Clay used the long ligature procedure throughout his career but Lawson Tait, (Fig. 1.14) of Birmingham, the first surgeon to successfully operate on an ectopic pregnancy, believed that if the ligature was short and the wound completely closed, the mortality rate would probably fall to 6 or 8 %. Such results were achieved by Isaac Baker Brown who cauterized the ligated ovarian pedicle before closure of the abdominal wound on 40 patients with

only four deaths. He was a Consultant Gynaecological Surgeon at London's greatest teaching hospital, St. Mary's Hospital in Paddington (Fig. 1.15) and sadly went the way of so many in the medical profession in the past. He somehow went off at a tangent and in 1865 published a paper on 'The cureability of some forms of insanity, epilepsy and hysteria by clitoridectomy' [45]. Unfortunately, he also advertised the success of this procedure and as a result he fell from grace and was expelled from the Obstetrical Society of London and died in obscurity [46]. Because of this, his technique of ovariotomy failed to be adopted and it fell to Thomas Keith, an apprentice of James Young Simpson, to rediscover this manoeuvre.

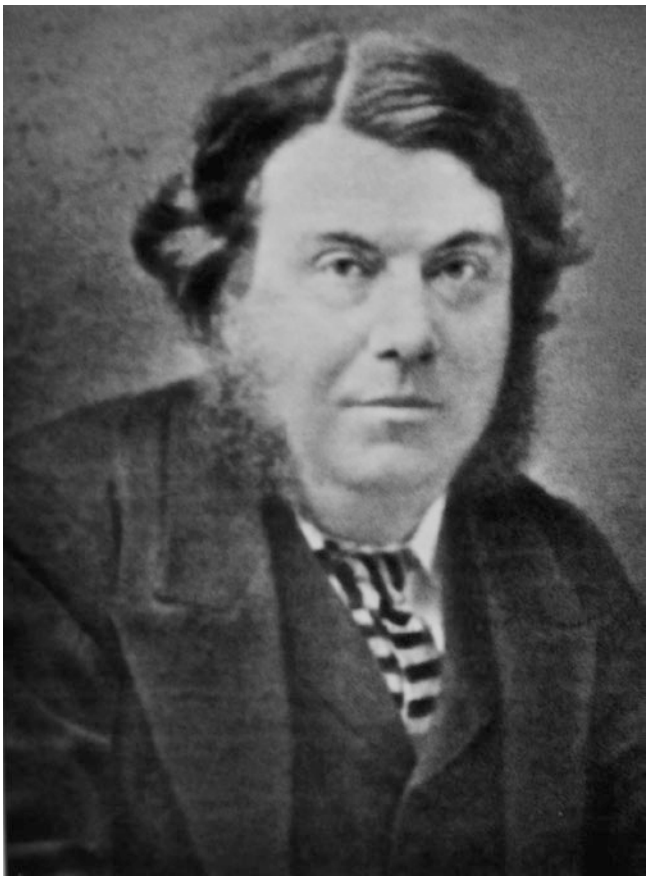

Fig. 1.14 Lawson Tait from Birmingham , an industrial city in the Midlands of England was one of the greatest surgeons of his generation and had a low mortality due to rigorous attention to cleanliness and aseptic principles (Figure reproduced courtesy of Jaypee Brothers Medical Publishers, India)

Dr. Keith Ends the Dark Period of Appallingly High Mortality

Thomas Keith was probably the greatest analytical surgeon in our speciality during the late nineteenth-century. He was a wild looking man, born in the Manse of St. Cyrus, near Montrose in the Scottish Borders and was a lifelong sufferer from cysteine stones for which he required many operations which probably accounts for his rather startling appearance (Fig. 1.16). Thomas Keith performed his first ovariotomy in September 1862, but his initial mortality was high. This was around the time that Lister was advocating antiseptic surgery, although Keith found that the carbolic spray did not help to reduce his operative mortality. He therefore turned his attention to the method of wound closure, abandoning the long ligature and exteriorized clamp that Koeberle and, later, Spencer Wells (Fig. 1.17) had popularized and instead cauterized the pedicle and dropped it into the peritoneal cavity, which he then drained.

He was also a vigorous opponent of the technique of blood-letting, and out of 156 cases reported only six deaths (3.8 % mortality). His hysterectomy results were no less impressive and by the time he left Edinburgh for London he had recorded 33 cases with only three deaths [22].

Appalling results were achieved by Spencer Wells, a society dilettante who considered himself the greatest

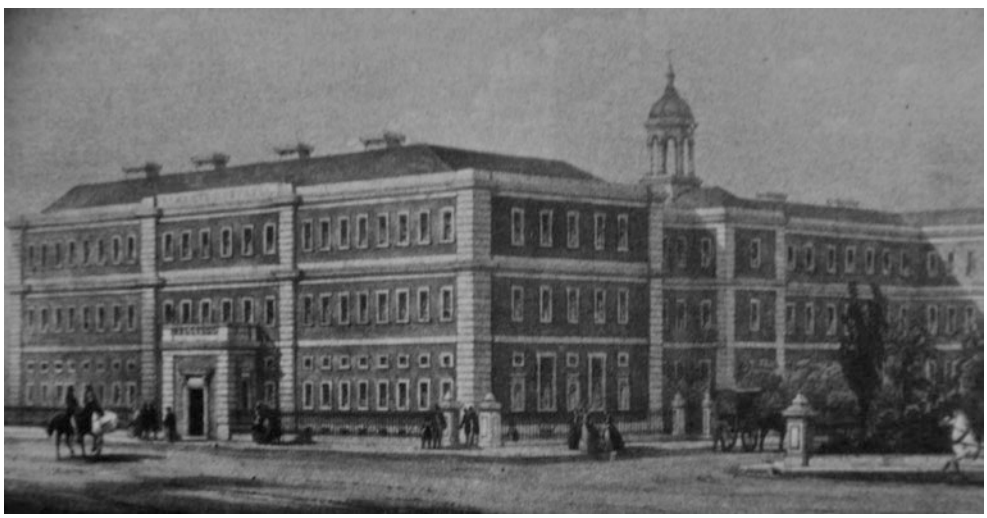

Fig. 1.15 The original St. Mary's Hospital, London in the nineteenth century. Where Isaac Baker Brown and Thomas Spencer Wells worked as Consultant Gynaecological Surgeons and the room on the corner of the second floor was the laboratory of Alexander Fleming where he discovered penicillin (Courtesy of the Archivist of St. Mary's Hospital, London)

gynaecological surgeon in Europe at that time and drove from hospital to hospital in London in his 'brougham and four silver grey horses' and produced results that were appalling and out of 40 hysterectomies performed for fibroids, there were 29 deaths–a mortality rate of 73 % [47].

His poor results were vigorously criticized in public by Charles Clay and he was joined in his disapproval by Lawson Tait, a rather aggressive Surgeon from Birmingham in the Midlands. Tait loathed Spencer Wells, and found that despite using the carbolic spray he still had a 38 % mortality with his first 50 ovariotomies. He then realized that it was not the spray that had given Keith his excellent results (indeed there is no evidence that Keith ever used it) but the intra-peritoneal method of dealing with the pedicle. He immediately adopted this technique, abandoned the carbolic spray and of his next 73 patients only two died – a remarkable achievement at that time. Lawson Tait also learned the value of cleanliness from both Lister and Keith that was unusual in those days, as no surgeons wore gloves and very few washed their hands before operating. He also preferred to operate in the home of the patient because hospitals at that time, and sadly now, are riddled with infection and before closing rinsed the abdominal and pelvic cavity with sterile water.

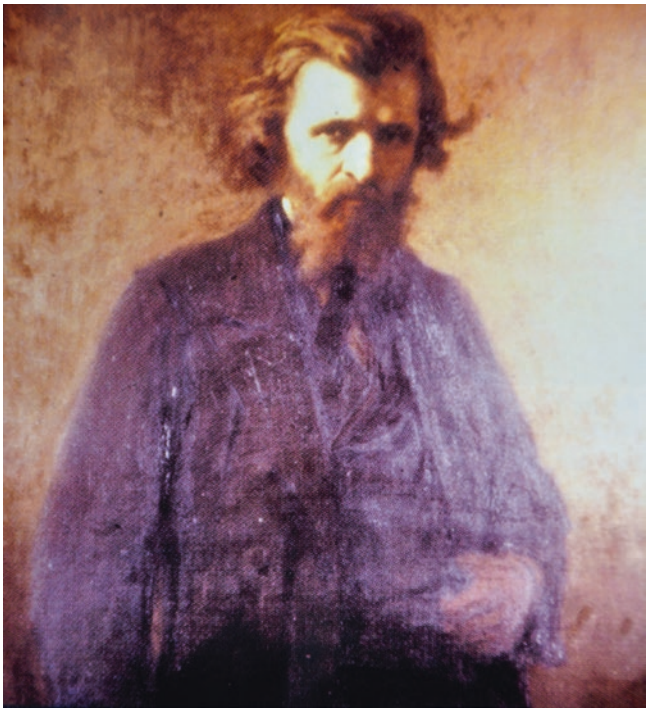

Fig. 1.16 Thomas Keith from Melrose, Scotland, who drastically reduced the mortality and morbidity of hysterectomy by his treatment of the cervical stump (Figure reproduced courtesy of Jaypee Brothers Medical Publishers, India)

Lawson Tait was a formidable character in the history of gynaecological surgery and was without doubt one of the most audacious and talented surgeons of his generation. He was aggressive and opinionated and successful and, as is often the case with large men of short stature, he was arrogant but often right. As can be seen from Fig. 1.14 his physical appearance was remarkably similar to that of Sir James Young Simpson (Fig. 1.13) with whom he lived after entering Edinburgh University at the tender age of 15 and also assisted him with his operations when still a teenager. Since Lawson Tait was born in Edinburgh in 1845 at the time of antidisestablishmentarianism when many clergymen were on strike against the idea of disestablishment of the church so no birth certificates were issued at this time thus fuelling speculation that Lawson Tait was the illegitimate son of JY Simpson [22].

Tait was prominent in the movement to start the Birmingham and Midland Hospital for Women and established many 'firsts' in gynaecological surgery including the first successful treatment of ectopic pregnancy in 1881, the first oophorectomy for sepsis, first bilateral oophorectomy for intractable menorrhagia as well as the removal of hepatic hydatid cysts and an appendicectomy in 1880.

Not only was he a gifted surgeon but he wrote more than 200 scientific papers and several books and also produced leading articles in the *Birmingham Morning News* and was

elected to the Birmingham Town Council but was unsuccessful in his bid to be elected as a Member of Parliament. He founded and became the first President of the Medical Defence Union to counter the growing number of litigation cases against doctors. He was appointed Professor of Gynaecology at Queen's College in Birmingham and founded the British Gynaecological Society and was the first President in 1886.

He lived well and ate, drank and smoked excessively and was enormously successful and very wealthy owning two mansions and two luxury yachts and his own nursing home for his private patients. In the end this proved to be his undoing since he personally employed several nurses who were sexually attractive and it is alleged that three of them became pregnant by him and one of them cited him in a paternity case and at the same time he lost a libel case. Such behavior was not tolerated in times of strict Victorian prudery and his fall from grace was swift and coincided with declining health due to chronic pyelonephritis. He became anuric and died in Llandudno in North Wales after smoking his last cigar '… a very good Laranga - and the last I shall ever smoke'. Lawson Tait was cremated and his ashes laid in Warriston Cemetery, Edinburgh close to the grave of James Young Simpson [41].

The early hysterectomies were sociable affairs and it was considered good form to bring along friends, both medical and non-medical, to witness these momentous surgical events. Figure 1.18 shows the legendary French surgeon Jules Pean operating. There are a large number of onlookers, many wearing beards and Pean himself wears neither a mask nor surgical gloves. Since this operation occurs in a Paris Hospital the painter has been given a certain amount of artistic liberty in allowing the lovely French patient to display her *très jolie poitrines* whilst the anaesthetist, in keeping with modern practice, appears to be busy with the crossword puzzle.

Table 1.2 A summary of the hysterectomies performed for fibroids (1880–1884)

Operator	Date	Cases	Deaths	Mortality (%)
Lawson Tait	1882	30	10	33
Spencer Wells	1882	40	29	73
Koeberle	1882	19	10	52
Schroder	1884	100	32	32
Pean	1881	51	18	35
Keith	1883	25	2	8

Lawson Tait summed up the end of this rather dark era in gynaecological surgery as "the ovarian tumour was the battlefield whereupon the first abdominal engagements were fought. Whereas ovariotomy undoubtedly opened the gateway to abdominal surgery, Spencer Wells by his outmoded technique and resultant mortality of 73% for abdominal hysterectomies undoubtedly held back progress, because no one would submit women to such fearful risk unless life were already threatened. Dr Thomas Keith ended this dark period by showing us how to operate on the abdomen without fear and with little risk" [27]. (Table 1.2).

Refinements of Technique at the End of the Nineteenth Century

The latter years of the nineteenth century witnessed further development and technique for abdominal hysterectomy which was refined and standardised by Freund who performed the first successful abdominal hysterectomy for cervical cancer and was the first German surgeon to use Lister's Carbolic Spray [48]. Czerny following Langenbeck's original description, did the same for vaginal hysterectomy [49].

The first planned hysterectomy performed on a gravid uterus took place in 1876 and was performed by Porro from Milan in Italy [50].

In spite of advances in anaesthesia and antisepsis in the latter part of the nineteenth century the incidence of fatal haemorrhage and peritonitis remained high. Eduardo Porro (1842–1902) was an analytical surgeon who reviewed his own cases of contracted pelvis, mainly from rickets, and after experimental operations on pregnant rabbits and cadavers offered an alternative solution by removing the uterus after delivering the baby by caesarean section. He sutured

the cervical stump to the abdominal incision thus diverting the potentially septic contents of the cervix and vagina away from the peritoneal cavity. He performed this operation at his clinic for the first time on 21 May 1876 when he was presented with a rachitic primigravida in obstructed labour with a true conjugate of 4 cm and the woman survived and left hospital with her baby 6 weeks later [51].

For a time after his publication this approach found favour but later Ferdinand Kehrer and Max Sänger found that careful suture allowed the uterus to be reconstituted and allow for its conservation [52]. With the introduction of specially modified instrumentation, anaesthesia and antisepsis, the mortality rate for vaginal hysterectomy dropped precipitously and by 1886 was approximately 15 %; by 1890 it had reached 10 % and by 1910 it was as low as 2.5 %.

Unfortunately, abdominal hysterectomy lagged far behind and even as late as 1872 the mortality was so high that the procedure was formally condemned by the Academy of Medicine in Paris. In spite of this it was still performed though more often for fairly tenuous indications such as the relief of menstrual hysteria and 8 years after this pronouncement from Paris, TG Thomas reported on 365 consecutive cases with a mortality of 70 % [53].

In spite of these disastrous results, progress in abdominal hysterectomy was being made. Mikulicz abandoned the *serre-noeud* after using it for 13 years and instead placed triple ligatures on the broad ligaments and tied them off separately [53].

In 1878, Freund introduced techniques for packing off the intestines, ligating the major blood vessels and covering the cervical stump with peritoneum, which, in the same year, had been practised independently by both Schroeder and Spencer Wells.

In 1889 Lewis Stimpson had advocated the systematic ligation of the main ovarian and uterine vessels separately rather than tying off the entire broad ligament in one large ensnaring suture, and 3 years later Bare, of Philadelphia, the father of the modern subtotal hysterectomy, tied the uterine vessels 'outside of, but close to, the cervix'. He was also the first to advise gynaecological surgeons to 'take care' to avoid the ureter [54] then described an immaculate technique for subtotal hysterectomy little different from that employed today. Thus in the space of one decade, exterior fixation of the cervix by the *serre-noeud*, the Spencer Wells clamp or long ligature had been replaced by the intraperitoneal treatment of the cervical stump, which itself was modified and became extraperitoneal again, by covering the stump with pelvic peritoneum. These new techniques are reflected in the dramatic fall in mortality shown in the figures from the London teaching hospitals in 1896 and 1906 showing an impressive drop in mortality from 22 to 3.5 % [54] (Table 1.3).

Radical Hysterectomy for Cervical Cancer

Radical hysterectomy for cervical cancer was first performed by Dr. John G Clark of the Johns Hopkins Medical School in Baltimore in the United States of America who published details of two cases in which all of the parametra were removed [55]. The operation was refined by the addition of lymphadenectomy in certain cases and popularised by Ernst Wertheim (Fig. 1.19) the famous Austrian gynaecological cancer surgeon from Vienna, after whom the operation is now somewhat unfairly named [56]. Clark at the time was a 28 year old second year resident in gynaecology and had made a careful pathological study of cervical cancer and found that in most specimens that he examined the broad ligaments were cut too close to the uterus and too small a portion of the vagina had been removed [57].

Ernst Wertheim (1864–1920) was born in Graz in Austria and worked as assistant to Friedrich Schauta at the German University in Prague and later they moved to Professorial Chairs at the First and Second University Departments of Obstetrics and Gynaecology in Vienna, initially on an amicable basis but later disagreed due to the inability of Schauta's Radical Vaginal Hysterectomy to adequately remove the lymph nodes even though the vaginal approach was undoubtedly safer [58]. Even with the enlarged perineal relaxing incision introduced by Karl Schuchardt (1856–1901) who, like Ossiander and Langenbeck came from Gottingen, there was sufficient view to remove the parametrium but it was still not possible to remove all the involved lymph nodes [59]. Karl Schuchardt became a Professor at Stettin State Hospital but sadly died at the young age of 45 from sepsis following a surgical needle stick injury in the same way as Semmelweiss a few years later.

Ernst Wertheim performed his first radical abdominal hysterectomy and pelvic lymphadenectomy on Madame Rudd on 16th November 1898. He had carefully studied the

Fig. 1.19 Ernst Wertheim, Professor of the First Gynaecology Clinic of the University of Vienna, who ultimately performed 1300 radical hysterectomies with complete follow up (Photo courtesy of RCOG Press, London)

pathology and usual mode of lymphatic spread of cervical cancer and the procedure was based on an operation designed in 1878 by William Alexander Freund of Breslau who had carried out 66 radical operations with appalling results that included 55 deaths which occurred during the operation. These were mainly due to haemorrhage since this was before the introduction of blood transfusion since Landsteiner, from Vienna, only discovered the first four blood groups in 1900 [7].

The mortality rate in Wertheim's first 100 patients was high at 30 % [60] but as time went on his technique improved and when he had performed 500 radical hysterectomies the mortality rate had dropped to 19 % [61]. In those days there were no trained anaesthetists and patients died of shock due to the length of the procedures as well as blood loss and some were so feeble they were unable to bear the strain of the operation. In addition there were ureteric injuries, vesico-vaginal fistulas, pyelonephritis and recurrences. In those pre-antibiotic days there was still a high mortality from peritonitis and sepsis from the abdominal wound. It has to be said however that the infection rate could have been lowered had Wertheim adhered to some of the aseptic principles used by Keith and Lawson Tait because although surgical rubber gloves were available since 1900 Wertheim refused to wear them since he claimed they interfered with his sense of touch.

During his visit to London to deliver a lecture at the Royal College of Obstetricians and Gynaecologists a Consultant Gynaecologist from one of the poorer communities in the East End of London asked him to operate on a suitable patient with cervical cancer. Wertheim agreed and they set off for the hospital in their horse-drawn carriages and Wertheim examined the patient and later demonstrated his technique of radical hysterectomy. At one stage he needed an extra assistant and one of the junior doctors who was performing a post-mortem in the mortuary was summoned to come up to the operating theatre to help. As was the custom in England at the time the young doctor started to wash his hands prior to putting on a gown and surgical gloves but Wertheim admonished him and told him that was not necessary since he was needed immediately to assist in the surgery. The patient survived the operation but died 5 days later from peritoneal sepsis.

Ernst Wertheim was an expert skier and skater and once crossed the Alps in a hot-air balloon. He was prone to bouts of depression and was a difficult man to deal with and had an abrupt and defensive demeanour. He died at the age of 56, a victim of the pandemic of Spanish Influenza, and was buried in the Vienna City Cemetery next to the grave of Friedrich Schauta [41].

The Development of Hysterectomy in the Twentieth Century

As late as the mid-1940s the universal approach to hysterectomy was the subtotal procedure which involved retaining the cervix with the reduced chance of pelvic infection and ureteric injury but mainly, in the pre-antibiotic era, to reduce the chance of ascending infection and peritonitis, which was almost invariably fatal. Once the problem of ascending infection and peritonitis had been eradicated by the development of antibiotics, hysterectomy almost invariably included removal of the cervix.

The first total hysterectomy was performed by E.H. Richardson of the USA in 1929 [62]. His main concern in moving away from the traditional subtotal procedure, was to prevent the occurrence of cervical stump carcinoma, yet even in the days before cervical screening with Papanicolaou smears was available, the actual incidence of neoplastic change in retained cervical stumps was only 0.4 % in 6600 cases in the USA [63] and only 0.1 % in Finland [64]. As Thomas Lyons from Atlanta, Georgia, USA , a keen advocate

of laparoscopic subtotal hysterectomy has pointed out, this is similar to the rate of vaginal cancer following total abdominal hysterectomy and yet no one has seriously recommended the removal of the vagina at hysterectomy as prophylaxis against this [65].

During the past 100 years the introduction of antibiotics, intravenous therapy, anticoagulation, safe anaesthesia and blood transfusion has reduced the mortality for both vaginal and abdominal hysterectomy to around 0.1 %. There has also been a concomitant reduction in morbidity, reflected by a shorter hospital stay and the use of the transverse incision introduced by Johannes Pfannenstiel from Breslau in 1900 which gives a stronger and better cosmetic result [66]. Nevertheless, it took many years for this incision with its higher tensile strength making it less prone to wound dehiscence and incisional hernia, to gain universal acceptance.

Hermann Johann Pfannenstiel (1862–1909) received his medical degree from the University of Berlin and later moved to the Breslau Frauernklinic then to the University of Giessen and in 1907 became Chairman of the University Department of Obstetrics and Gynaecology at Kiel University where he remained until his premature death. Sadly Pfannenstiel died at the age of 47 following a needle-stick injury to the middle finger of his left hand sustained during the removal of a tubo-ovarian abscess [41].

Other famous surgeons including Karl Schuchardt, who was also from Breslau, had died at a relatively early age from similar injuries and it is salutatory to note that these injuries are not uncommon during various surgeries, and many doctors would have suffered a similar fate were it not for the revolutionary, but accidental, discovery of penicillin by Alexander Fleming at my own teaching hospital, St Marys Hospital in London.

Increased surgical skill and prowess from an apprenticeship type of training has ensured that the operation now is extremely safe with an incidence of ureteric injury of 0.2–0.5 % and a mortality of 0.12 % [67, 68].

The advent of prophylactic anticoagulants and antibiotics has further increased the safety of this procedure. Dicker et al. showed the superiority of vaginal hysterectomy (morbidity, 24.5 %) compared with abdominal hysterectomy (morbidity, 42.8 %). Although these statistics appear favourable to the vaginal approach they are, in fact, an eloquent testimony to the efficacy of prophylactic antibiotics, since those who had a vaginal hysterectomy had the benefit of these drugs, whereas those who had an abdominal hysterectomy did not [69].

Inevitably the increased safety of the operation with a mortality rate of approximately 12 per 10,000 led to an explosive increase in the number of hysterectomies performed so that it is now the second most common operation undertaken in the USA with over 650,000 being performed annually at a cost of approximately three billion dollars. With this increased safety the indications for the procedure had become wider, to the extent that up to 50 % of American women at the end of the past decade underwent hysterectomy [70]. Not only had the procedure become open to a certain amount of abuse, but technological advances, apart from endometrial ablation and embolization of fibroids, had largely by-passed hysterectomy and up until the mid part of twenty-ninth century, gynaecological surgery was in the doldrums.

The Modern Era: The Introduction of Laparoscopic Surgery

During the middle part of the twentieth century apart from a more conservative approach to the treatment of ovarian cysts and fibroids and the surgical refinements in instrumentation and technique introduced by tubal microsurgeons, few technical advances were made in gynaecological surgery.

A revolution in surgical technique could not occur until a different way of accessing the peritoneal cavity was invented and essentially this involved a method whereby the contents of the abdominal cavity could be visualised.

In 1901 Dr. Georg Kelling (Fig. 1.21) who was a Professor in Dresden in an address he gave to the German Biological

Fig. 1.20 Hans Christian Jacobaeus of Stockholm.The first person to perform laparoscopy on humans (Photo from the Archives of the Minimal Access Therapy Training Unit, Guildford, UK)

Fig. 1.22 Dr. Raoul Palmer from Paris. Generally considered the " Father of Operative Laparoscopy" (Photo by kind permission of the late Mme Elizabeth Palmer)

and Medical Society in Hamburg described the visual examination of the stomach and oesophagus in the human and additionally the use of a cystoscope to visualise the viscera of a dog using air filtered through cotton wool to produce a pneumoperitoneum [71].

In that same year of 1901 von Ott from Saint Petersburg in Russia published a different technique of viewing the pelvis of a pregnant woman by way of culdoscopy through an incision in the posterior vaginal fornix and using as his light source reflected light from a head mirror. He called this technique Ventroscopy [72].

However the credit for the first true laparoscopy on a human goes to Hans Christian Jacobaeus (Fig. 1.20) from Stockholm who coined the term 'laparoscopy' and in 1910 described his technique for the inspection of the human peritoneal, thoracic and pericardial cavities [73]. Only 1 month later Kelling reported a series 45 laparoscopies and described the appearance of the liver, tumours and tuberculosis.

Laparoscopy became popular mainly with general physicians or internists for the diagnosis and treatment of tuberculosis and liver disease and to them must go the credit for the development of laparoscopy over the next 40 years [74].

This changed radically with the introduction of laparoscopic surgery by pioneers in Europe such as Raoul Palmer (Fig. 1.22) in Paris [75] and Hans Frangenheim in Konstanz [76] in the 1940s but such advances were hampered by the lack of communication across the Atlantic during the Second World War and the Americans, although using laparoscopy in the 1930's, had mysteriously reverted to culdoscopy for visualization of the pelvis. It required the publication of the first text book on this new technique in the English language in 1967 by Patrick Steptoe (Fig. 1.23) one of the pioneers of In-Vitro Fertilisation, working in a small district hospital in Oldham, near Manchester in Lancashire, to allow the widespread dissemination of this new technique to the English speaking world after he had learned the technique from Frangenheim and Palmer in Continental Europe [77].

Initially laparoscopy was used for diagnosis and relatively simple therapeutic procedures such as female sterilisation and puncture or fenestration of benign ovarian cysts but gradually became more sophisticated owing much to the

Fig. 1.23 Patrick Steptoe from Oldham, near Manchester, England, One of the pioneers of In-Vitro Fertilisation who wrote the first book in English on Laparoscopy (Photo supplied by the late Patrick Steptoe)

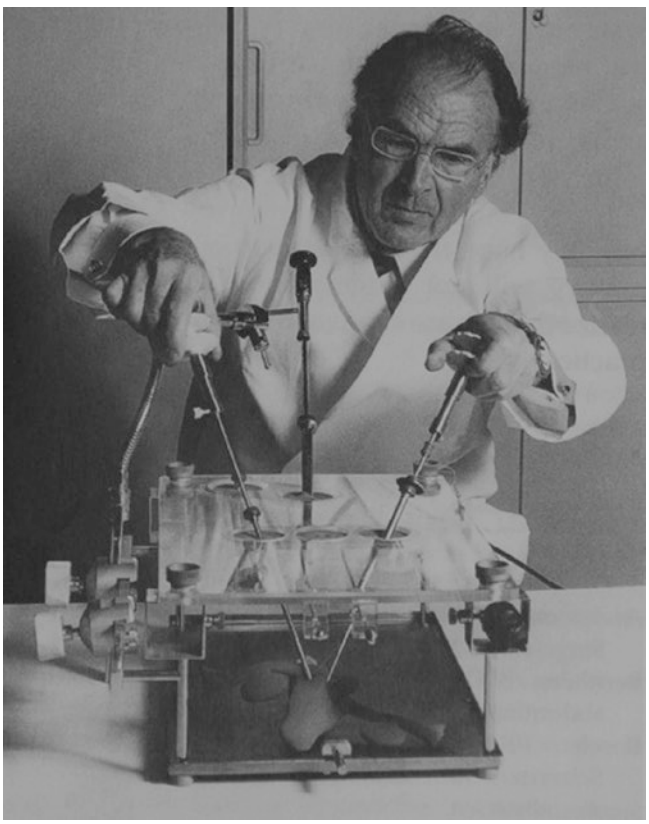

Fig. 1.24 Professor Kurt Semm from Kiel one of the great advocates and teachers of laparoscopic surgery and an inventor of much of the original equipment (Photo taken by Chris Sutton on a visit to the Minimal Access Therapy Training Unit in Guildford, UK)

Fig. 1.25 Professor Maurice Bruhat from the University of the Auvergne in Clermont Ferrand in France who performed the first laparoscopic removal of an ectopic pregnancy with Dr. Hubert Manhes (Photo given to Chris Sutton by the late Maurice Bruhat)

pioneering work of Professor Kurt Semm (Fig. 1.24) of Kiel University in Northern Germany who could claim to have performed the first Laparoscopic Hysterectomy using the CISH (Classic Intrafascial Supracervical Hysterectomy technique using the SEMM (Serrated Edged Macro Morcellator) [78, 79] although this would not be strictly classified as a total laparoscopic hysterectomy[80].

Professor Maurice Bruhat (Fig. 1.25) and Hubert Manhes and their gifted team from the University of Clermont Ferrand in the Auvergne in the Massif Central in France were a major influence on the development of laparoscopic surgery and were the first to treat ectopic pregnancy laparoscopically[81].

By the 1980s, minimally invasive surgery had become a reality but for a long time gynaecologists struggled with primitive equipment relying on advances in laser technology and electrosurgical devices to achieve cutting and coagulation. This was before the time of disposable instruments and self-sharpening scissors and it was necessary to return laparoscopic scissors to the factory and wait several weeks whilst they were sharpened.

The advent of laparoscopic cholecystectomy and its rapid uptake by our general surgical colleagues enabled industry to see the full potential of this new type of surgery and there were rapid developments in the quality of instrumentation and

sophistication in optics with the introduction of the rod lens system and external cold light source by Professor Harold Hopkins [82] of Reading University in the UK and later with the development of silicone chip cameras and high resolution television monitors to enable surgeons to operate comfortably and to usefully employ assistants to help with the operation.

In a remarkably short time these techniques were adopted universally to the extent that at least 80 % of gynaecological operations can now be performed using endoscopic techniques with several small incisions for the access of surgical instruments resulting in less pain, shorter hospital stays and rapid recovery compared with conventional laparotomy [83]. Nevertheless these techniques required special visual skills and hand-eye coordination which can not be achieved by all surgeons and the universal uptake of minimal access surgery, which was so confidently predicted in the 1990s, has not become a reality and conventional techniques are still employed by the majority of practicing gynaecological surgeons in the UK and USA although the adoption of this surgical revolution has been more successful in France and Germany.

Dr. Reich Performs the First Total Laparoscopic Hysterectomy

With the increasing skill of laparoscopic surgeons and the sophistication of the equipment laparoscopic operations became increasingly complex and it was only a matter of time before the first total laparoscopic hysterectomy was performed and this was in the Autumn of 1988 at the William Nesbit Memorial Hospital in Kingston, Pennsylvania by Dr.Harry Reich (Fig. 1.26). He published a description of this technique the following year [84].

The original operation proposed by Reich was an impressive display of technical virtuosity since the whole procedure was performed laparoscopically, including dissecting out part of the ureter and individually ligating and tying off the uterine artery and veins with extracorporeal sutures. He also performed the colpotomy incision laparoscopically in order to remove the uterus and repaired it with laparoscopic sutures. As a routine at the end of all advanced laparoscopic procedures he performs a cystoscopy, after injection of Methylene blue dye, to check that there had been no damage to the ureters.

Fig. 1.26 Dr. Harry Reich who performed the world's first Total Abdominal Hysterectomy at the William Nesbit Memorial Hospital, Kingston, Philadelphia in October, 1988 (Photo by Chris Sutton)

After the success of his first total laparoscopic hysterectomies he toured the United States demonstrating this new operation and then travelled the world, demonstrating it in the different countries that practiced laparoscopic surgery at that level. He performed the first demonstration in the UK in my own Department at the Royal Surrey Hospital in Guildford and I had the honour of being able to act as first assistant. The patient did extremely well and went home the following day with little pain and required only mild analgesics such a paracetamol and ibuprofen and was able to return to work 2 weeks after the operation. Nevertheless the procedure took five and a half hours occupying an entire morning operating session in which we would normally be expected to perform five or six laparoscopic operations of various types and difficulties.

At around this time I was performing about 35 laparoscopic operations per week whereas various American surgeons I had spoken to performed only 2–3 so clearly this procedure was more suited to a private based medical system than the socialised healthcare system operating in most European countries [85].

Laparoscopic hysterectomy was designed to replace abdominal hysterectomy and if a vaginal hysterectomy could be performed then that was clearly the minimal access procedure of choice. Nevertheless the original total laparoscopic hysterectomy (TLH) was too complicated and time consuming and required a very high level of laparoscopic skills so was soon replaced by many surgeons with the laparoscopic assisted vaginal hysterectomy (LAVH) whereby the upper pedicles were ligated, electrocoagulated or stapled while the remaining part of the operation was performed as a routine vaginal hysterectomy. It soon became evident that none of the laparoscopic part of the operation did anything to make the vaginal approach easier and because there is no descent until the utero-sacral and cardinal ligaments are transected. Most surgeons found that, with the limited access involved, the procedure became a very difficult vaginal hysterectomy. Cynics pointed out that this was in fact a complicated way of performing a vaginal hysterectomy, but it certainly had the advantage of honing vaginal surgical skills and allowed dissection of bowel adhesions laparoscopically, as well as the treatment of any existing endometriosis, particularly deep infiltrating endometriosis in the recto-vaginal septum, and the easier removal of ovaries where this was indicated.

It also had the advantage that the internal incision could be inspected at the completion of the procedure and any residual bleeding vessels could be sealed by bipolar diathermy ensuring at the end of the procedure the field was absolutely dry. Theoretically this had the advantage of preventing secondary haemorrhages occurring a few days later and preventing subsequent haematoma formation but in reality this was not always achieved.

Advances in instrumentation such as the ultrasonic scalpel, more effective techniques to coagulate large vessels using plasma kinetic energy and ingenious uterine manipulators and vaginal tubes to delineate the vaginal fornices have led some surgeons to persevere with the total laparoscopic approach and in recent years the time taken to perform these procedures has been considerably decreased but it remains a difficult procedure and one that can only really be performed by highly trained laparoscopic surgeons with a high level of skill.

These various criticisms led some laparoscopic surgeons to search for a simpler approach that could be universally employed by laparoscopic surgeons who had slightly lower skill levels or who were required by hospital administrators to perform the operation in a much shorter time and also discharge patients earlier, preferably on a day case basis. The simplest way to do this was to devise a simpler procedure that avoided any possibility of a secondary haemorrhage from the vaginal vault after the patient had left hospital and this meant performing a laparoscopic version of the outmoded subtotal hysterectomy.

Development of Laparoscopic Subtotal Hysterectomy and Introduction of New Laparoscopic Instrumentation for Hysterectomy

In 1993 Semm developed the intra-fascial laparoscopic supra-cervical hysterectomy with a technique of coring out the whole of the transformation zone and the central core of the uterus using a macro-morcellator with a serrated edge reamer turned manually in a clockwise direction to achieve cutting. The idea of this was to remove the entire transformation zone to avoid the subsequent development of cancer and also to decrease the chance of post-operative bleeding and monthly sero-sanguinous discharge [86, 87].

In 1991, we published our initial experience of supracervical laparoscopic hysterectomy and removal of the transformation zone using a modification of Semm's technique using the artificial sapphire tip of an ND-YAG laser (Laserscope, Cwmbran, UK) and endocoagulating the vaginal aspect of the cervical stump at the end of the procedure. Our technique also differed from the one described by Semm because he used sutures to secure the vascular pedicles whereas we used the Endo GIA 30 stapler (Autosuture Ltd., Ascot, UK) which was quick and effective and in those patients where it was not technically possible to secure the uterine vessels with the device, we used bipolar diathermy [88]. The mean operating time in our small series of eleven procedures was 111 min, with a mean blood loss of 185 ml. The mean duration of hospital stay was 3 days and the mean time to full recovery was 20 days and there were no complications. The reason for the long operating time was due to the fact that the SEMM (Serrated Edged Macro-Morcellator) was a manual device requiring long and arduous rotation and several of my Residents developed an occupational disease unique to laparoscopic surgical assistants – morcellator's thumb. This condition, which fortunately was only temporary, was due to injury to the peroneal nerve to the thumb causing numbness and hyperaesthesia in the skin distribution of that nerve.

Lyons [89] described a slightly different technique of laparoscopic supracervical hysterectomy also using the artificial sapphire tip of the ND-YAG laser but he did not merely coagulate the ascending branches of the uterine arteries, but actually included the main branch of the uterine artery and divided the utero-sacral ligaments making an inverted cone through the cervix, also removing the transformation zone but effectively leaving only the rim of the cervix. This was a slightly more radical procedure but almost certainly resulted in less long-term problems involving bleeding or serosanguinous discharge from the cervical stump [90, 91]. The team from UCH-Louvain in Brussels published a large series of 500 cases which also used the Nd:YAG laser to cut across the cervical stump but removed the transformation zone by a large loop electrosurgical excision in much the same way as that used for the removal of the transformation zone when treating cervical intra-epithelial neoplasia [92].

Further refinements have been made in recent years with the introduction of the Lap-Loop™ (Medsys, Gembloux, Belgium) invented by Jacques Dequesne in Lausanne [93]. whereby an electric wire loop is threaded around the cervix once the ascending branches of the uterine artery have been coagulated and cut and the bladder pushed down slightly. After making sure that there is no bowel close to the wire posteriorly, a 100–120 W cutting current is applied and the "noose" formed by the wire is slowly tightened as the heated wire slices through the tissue coagulating many small vessels and providing a very effective method of rapidly severing the cervix from the uterine fundus. In a study comparing the loop device with conventional methods (laparoscopic monopolar scissors or ultrasonic scalpel) the mean time for detaching the cervix from the fundus with the loop electrode was 6.6 min compared with 14.4 min in the control group [94].

Further advances have been made with more effective laparoscopic ligation instruments to effectively seal even large arteries and veins (Ligasure, Covidien Commercial Ltd., Gosport, UK; Enseal· Ethicon Endo-Surgery, Edinburgh, UK; Plasma Kinetic energy system, Olympus, KeyMed Ltd.,

Southend, UK; Gyrus International, Berkshire,UK) thus reducing the risk of secondary haemorrhage from major vessels and with the decreased operating time makes laparoscopic sub-total hysterectomy eminently suitable for day case surgery.

Some of these recently introduced electrosurgical devices that operate in a liquid field use the word plasma when describing their *modus operandi* but in reality use radiofrequency electrosurgery via specially designed bipolar electrode systems to seal vessels. Examples of this is the so-called PlasmaKinetic technology used in the Olympus (Gyrus ACMI) Plasma-Knife and the ArthroCareCoblation device, which only generates non-thermal plasma within the tiny bubbles formed in the fluid on the surface of their electrodes but in reality relies on basic electrosurgery for its tissue effect. Another new device, the Peak PlasmaBlade may generate a non-thermal plasma at the interface of the handpiece blade with the tissue or fluid medium in which it is used but, notwithstanding this, it is the rapid pulses of high-voltage energy that create the surgical effect [95]. All of these devices allow rapid sealing of large vessels and allow a new generation of gynaecological surgeons to dispense with the need for traditional sutures. It remains to be seen whether these new vessel sealing devices will have a wider application and increase the uptake of vaginal hysterectomy or if they are only used by laparoscopic surgeons because traditional abdominal and vaginal surgeons seem to have more faith in traditional sutures to seal vessels. Virtually all of these vessel sealing devices are single use only and add considerably to the cost of the procedure although they contribute to a shorter operating time.

The remaining problem is the removal of the detached fundus which can be via a colpotomy incision but this adds to the complexity and difficulty of the operation. High speed electromechanical morcellators such as the Gynecare X-Tract Ethicon Inc., Somerville, New Jersey) are not only very expensive but require considerable care and skill to operate and have been associated with serious accidents many of which have been fatal and will be described later.

Nevertheless in spite of these caveats laparoscopic subtotal hysterectomy (LSH) underwent a massive upsurge in popularity particularly in California where the rate increased from 6.9 to 20.8 % between 1997 and 2003 [96] and also in Scandinavia, particularly in relatively conservative countries such as Denmark when in a similar time frame it increased by 375 % so that 22 % of all hysterectomies were subtotal [97].

It is generally assumed that retaining the cervix enables a quicker procedure than TAH, and several laparoscopic series have confirmed this. If the cervix is retained, the surgeon needs only to secure the ascending branches of the uterine artery and vein, thus averting the need for dissection in the highly vascular tissue in the paravaginal area close to the ureter. It is claimed that STH is associated with fewer perioperative complications, in particular, hemorrhage because the main uterine artery is not ligated and the vaginal angles are left untouched.

In the 1980s a plethora of extravagant claims about other advantages of retaining the cervix had arisen, mainly from Finland, backed up by some poorly designed comparative clinical trials [98]. Among the claims of the advantages of STH over TAH are the reduced intra-operative complications, particularly ureteric injury, and no possibility of vault dehiscence but it was also claimed that there are fewer difficulties with post-operative bladder function, less subsequent pelvic floor complications and, particularly, less dyspareunia. It was also suggested that there was a considerable increase in sexual satisfaction, increased libido and better quality of orgasm and even an increased number of multiple orgasms. It was this latter suggestion that was seized on by the popular press and encouraged many women to come forward to seek this particular variety of hysterectomy if given the choice.

Although these claims seem compelling on superficial reading, we live in an age of evidence-based medicine largely due to the example shown by Dr. Archie Cochrane of Wales, and until recently these advantages have not been supported by adequate randomized controlled trials (RCTs) that have fulfilled the conditions required by the Cochrane Collaboration. However one study by St. George's Hospital in London [99] assessed urinary, bowel, and sexual function in great detail before surgery and at 6 and 12 month intervals afterwards with a series of carefully validated questionnaires. In addition, urinary function was determined with the use of twin-channel subtracted cystometrography and uroflowmetry, and definitions of urinary incontinence conformed to those of the International Continence Society.

There was no significant difference in any of the urinary symptoms between women who underwent TAH or STH. Urodynamic studies demonstrated a reduction in stress incontinence after surgery in both groups. Insofar as bowel symptoms were concerned the rates of constipation, hard stools, urgency, straining, use of laxatives, and incontinence of flatus were similar in the two groups after surgery.

Sexual function , which in the studies by Kilkku and colleagues [100] was greatly improved after STH, was remarkably similar in both groups in this study, which reasonably included only women who were sexually active at all three points in time: preoperatively and 6 and 12 months postoperatively. The frequency of intercourse, desire for intercourse, and initiation of intercourse did not differ significantly between the two groups; however, there was a significant increase in the frequency of intercourse in both groups (p 5.01). The type of surgery had a similar outcome insofar as frequency of orgasm, frequency of multiple orgasms, extent of vaginal lubrication, and rating of the sexual relationship with a partner. Deep dyspareunia was

reduced significantly in both groups at 6 and 12 months, whereas superficial dyspareunia decreased at 6 months but increased in both groups at 12 months, the reasons for which were not clear.

From the results of this carefully planned double-blind, randomized, prospective, controlled trial with adequate patient numbers and duration of follow-up, there was little to chose between the two types of abdominal hysterectomy other than the shorter operating time and decreased perioperative complications associated with subtotal abdominal hysterectomy. This brilliant study, published in arguably the most prestigious medical journal in the world, The New England Journal of Medicine, sadly did not include laparoscopic subtotal hysterectomy (LSH). We are therefore left to wonder whether its inclusion would have resulted in different conclusions, although it is clear from this study that abdominal hysterectomy, whether performed as a total or subtotal procedure, with the large painful scar associated with it and the prolonged recovery period, resulted in considerable patient satisfaction at 12 months of follow-up. It is a great shame that this otherwise excellent study which was conducted by urogynaecologists did not include an arm with laparoscopic subtotal hysterectomy because St. George's Hospital has some highly skilled laparoscopic surgeons who, I am sure, would have been happy to have taken part in this trial.

This was a great shame because the last time I did a thorough search of the literature I was only able to find one prospective randomized study comparing surgical complications and clinical outcomes after supracervical vs total laparoscopic hysterectomy in 141 patients followed up for 2 years, and that article was published only in Italian [101]. There were no statistically significant differences in the rates of complications, degree of symptom improvement, or activity limitation, although patients assigned to STH tended to have more hospital readmissions. Patients weighing more than 100 kg at study entry were more than twice as likely to be readmitted to the hospital during the 2 years of follow-up.

The Introduction of Robotic Laparoscopic Surgery

The most recent development in endoscopic hysterectomy is the development of hysterectomy techniques using robotic arms with wristed instruments rather than "straight sticks" with limited movements and a high fulcrum. This both exaggerates movement and requires the movement outside the body to be in the opposite direction as that inside the abdominal cavity, which is a primary reason for the learning curve in laparoscopic surgery. The wristed instruments powered by the robotic arms enable both a full range of movement and this movement can be slowed for fine manipulation. The only commercially available robotic systems the da Vinci S and the da Vinci SI (Intuitive Surgical, Inc., Sunnyvale, California) are equipped with a double optic, which gives the operator who works from a distant console, but not any of the observers, 3-dimensional vision, enabling much improved visualisation of the pelvis, which compensates for the loss of haptic feedback using the robotic arms. This is probably the main advantage of robotic surgery since it enables the operator to work with virtually no fatigue enabling several cases to be performed in one operating session. The wristed instruments, however, mean that the more recently available "safe" power sources such as the ultrasonic devices and bladed instruments are not available, and the only power sources are monopolar or bipolar diathermy, the latter now available with impedance feedback control. There have been several important publications that relate to the use of robotic techniques but they are primarily in surgery to treat malignant disease although recently increasingly they include benign disease particularly advanced stage endometriosis [102] and the thorny issue of cost effectiveness [103]. In this study from Lund in Sweden a randomized controlled trial (Canadian Task Force classification 1) of 122 women with a uterine size of less than 6 weeks who were scheduled to undergo minimally invasive hysterectomy for benign disease, who were not considered candidates for vaginal surgery, were assessed for hospital costs and short term clinical outcomes to compare laparoscopic hysterectomy with robot-assisted hysterectomy. All women underwent surgery as randomized and vaginal hysterectomy was possible in 41 % at a mean hospital cost of $4579 compared to $7509 for traditional laparoscopic hysterectomy and, surprisingly given that the robot is a pre-existing investment, the use of the robot only added $993 per case. If the calculation included the share of the purchase of the robot and maintenance this increased to $1607 extra per case but the robotic group had less blood loss and postoperative complications. The Robotic arms facilitate suturing in difficult situations such as the prostatic capsule in radical prostatectomy, and has been adopted in institutions that perform many of these procedures, predominantly by urologic oncologists. Case series have demonstrated that in appropriately skilled hands, radical hysterectomy performed using robotic techniques was comparable with laparotomy, and required significantly shorter time than laparoscopy, with equal lymph node harvest and significantly reduced blood loss and length of stay (2 days) [104].

Robotic hysterectomy to treat benign disease has now also become popular after the initial reports by Reynolds and Advincula of 16 consecutive patients with no conversions to laparotomy, a short hospital stay, and a complication rate comparable with routine laparoscopic (straight stick) surgery [103]. Their experience now includes patients with obliterated pelvic cul-de-sacs, six of whom have undergone hysterectomy with resection of the underlying disease safely and

with no conversions to laparotomy, which demonstrates that with the appropriate experience and training, robotic surgery is a useful tool for dealing with this associated disease [104].

An early limitation of robotic surgery was the need to dock the robot between the patient's legs, which meant that access to the vagina for uterine manipulation was difficult; however, this has been overcome by repositioning the robotic arms and docking the robot to the side of the patient where the surgeon would stand. The ports are relatively big, 8 mm for the robotic arm ports and 12 cm for the optical and accessory ports, and they need to be placed high in the abdomen, resulting in more obvious scarring.

Although robotic surgery is an exciting advance with great possibilities, it comes at considerable financial cost. The robot and optic cost $2 million, and limited-life reusable instruments cost $2000 each plus associated support costs. Despite the costs, there are now hundreds of units in place in the United States, and in the hands of enthusiasts, the techniques are gaining popularity in Europe and the United Kingdom.

The Choice of the Best Route for Hysterectomy

The last 80 years has witnessed a revolution in surgery from operations performed through a large painful abdominal incision with long hospital stays to minimal access procedures which are essentially the same operations but owing to the small incisions allow surgery often to be undertaken on a day care basis with much less pain and discomfort, rapid recovery and early return to work or domestic activity.

In this chapter I have described the amazingly brave interventions of pioneering surgeons when an abdominal incision was almost tantamount to a sentence of death and slowly seeing an improvement throughout the ages with the gradual reduction of associated morbidity and mortality until we final arrive in the modern era, when laparoscopic hysterectomy is performed to improve quality of life rather than to remove a threat to life as in former times. The sophistication of new instrumentation and optics together with the long training of the surgeon has ensured that the complication rate is low and technological progress is still continuing so that surgery can now be performed with the assistance of robots.

There has also been a steady progression from early reports from pioneers of each type of surgery and then a collected series by individual experts or teams from centres of excellence which have invariably given a favourable outcome for the procedure they are describing and finally a more evidence based approach with well constructed prospective comparative studies which, I feel sure, will be dealt with in detail in other chapters in this book. Some of these studies such as the excellent eVALuate Study have shown that when some of these procedures are put into general use the complication rate is inevitably higher than when a series is reported from an individual expert or centre of excellence [105]. Although this can result in unfair criticism from some quarters it is nevertheless essential that we face the obvious truth that the complication rate is likely to increase when the procedure is universally adopted but this is important when confronting the patient with the likelihood of complications associated with each type of procedure.

Much of this can be addressed by adequate training and experience but it must be realized that laparoscopic surgery requires special skills and excellent hand – eye coordination and this appears not to be available to all surgeons and it is essential that all surgical practitioners are aware of their own limitations. The ultimate choice of the type of hysterectomy to be chosen depends on a frank discussion between the patient and the doctor keeping the above factors in mind.

It is difficult to predict the future for however much increasing popularity seems to support a particular operation such was the case with laparoscopic subtotal hysterectomy in the past decade there was a severe setback when morcellation, which is a convenient way to rapidly remove the uterus after is has been severed from the cervix, has been associated with reports of dissemination of malignant material and, suddenly, the leader of the pack suffers a reversal of fortune until adequate ways are found to prevent this problem [106].

The ingenuity of doctors and scientists never ceases to amaze me and I remember some times ago being fascinated when seeing a video of an appendicectomy performed endoscopically by the passage of a multi channeled endoscope via the nose and entering the peritoneal cavity through a small incision in the stomach and finally removing the appendix without any abdominal incision and retrieving the specimen through the nose after repairing the small hole in the stomach. Thus a new chapter was born in this ongoing saga under the general title of Natural Orifice Endoscopic Surgery but gynaecologists should always remember that the vagina provides the natural orifice of our specialty and allows us to access the pelvis without painful abdominal incisions and in spite of all the advances that I have described it would appear that vaginal hysterectomy throughout the ages has remained the best, quickest and safest way of performing minimal access hysterectomy.

History of Radical Hysterectomy

2

Karl Tamussino

At the end of the nineteenth century, cervical cancer was a scourge for which there was no early detection and no cure. In an era where the average life expectancy was about 50 years, cervical cancer was the most common cause of cancer death in women, as it still is today in parts of the world. "It is enough to make a physician's heart sink within him to make the diagnosis of cancer uteri," wrote Charles Meigs in [12], "for such a diagnostic is ipso facto a prognostic of death."

This dire state of affairs led to heroic efforts to remove uteri to cure cancer. The first abdominal removal of a cancerous uterus was apparently performed in 1878 by W. A. Freund in Breslau (Wroclaw, then Germany, now Poland). Three mass ligatures were placed on each side of the uterus. The ligatures contained the ovarian ligaments, the round ligaments, and the paracervical tissue. The last ligature was placed by "leading a suture from in front of the base of the ligamentum latum through the anterior lateral part of the vaginal fornix behind the base of the ligamentum latum into the pouch of Douglas" [7]. The patient went home 19 days after surgery. Sixty-six Freund operations performed by 1880 entailed 49 perioperative deaths (72 %) [3].

Surgeons worked to improve the Freund operation. In 1881 Linkenheld, an assistant of Freund's, noted that all the patients who survived the Freund operation developed a recurrence within two and a half years at the latest. He ascribed this to the fact that "in all these cases, the neoplasia exceeded the limits of the uterus and spread to the adjacent parametria, and that the operation had not removed all diseased tissue." Like surgeons who removed the tissue in the axilla of patients undergoing surgery for cancer of the breast, Linkenheld suggested "removing the parametria, of course avoiding injury to the ureters, under all circumstances." This entailed omitting the mass ligatures, since "they present a barrier to outward dissection. Instead, after circumcision of the portio, the uterus must be removed like a tumor, and the various vessels ligated individually. The parametria should then be removed bluntly, as is done in the removal of the axillary tissue" [10].

Consistent with the philosophy of extended mastectomy envisioned and advocated by William Halsted for women with breast cancer, surgeons continued to push the limits of parametrial excision. Brunet [1], in studies of Mackenrodt's surgical specimens, found that 60 % of those that were considered negative at palpation contained disease. Also, 42 % of the specimens showed spread to the upper third of the vagina. Increasing resection of the parametrial tissue soon led to the issue of the ureter [4, 20, 21]. The work of these surgeons built the foundation for what is today known and thought of as radical hysterectomy.

In the late 1890s, Ernst Wertheim (1864–1920) in Vienna began to standardize the operation that later came to bear his name. Wertheim was born and studied medicine in Graz, then moved to Vienna and Prague to train with Friedrich Schauta. He performed his first radical operation in 1898 and reported on the first 29 patients in 1900 [30]. His rationale was that simple removal of the uterus was providing poor results for patients with uterine cancer and that "to obtain better results – as for the surgical approach to cancers in other organs – in addition to the primary focus one should remove as much as possible of the surrounding tissue". This was the Halstedian vision applied to uterine cancer.

Wertheim's famous monograph describing 500 radical abdominal operations appeared in 1911 [31] and was soon translated into English [32]. The monograph is a monumental effort. It assiduously tabulates his first 500 patients, including their postoperative courses and outcomes. It provides detailed descriptions of the clinical findings. Descriptions such as "cauliflower like", "infiltration to the pelvic wall", "cervix replaced by neoplasia", "portio replaced by necrotic mass" are the rule. Obviously none of these were screening-detected lesions and many we today would not

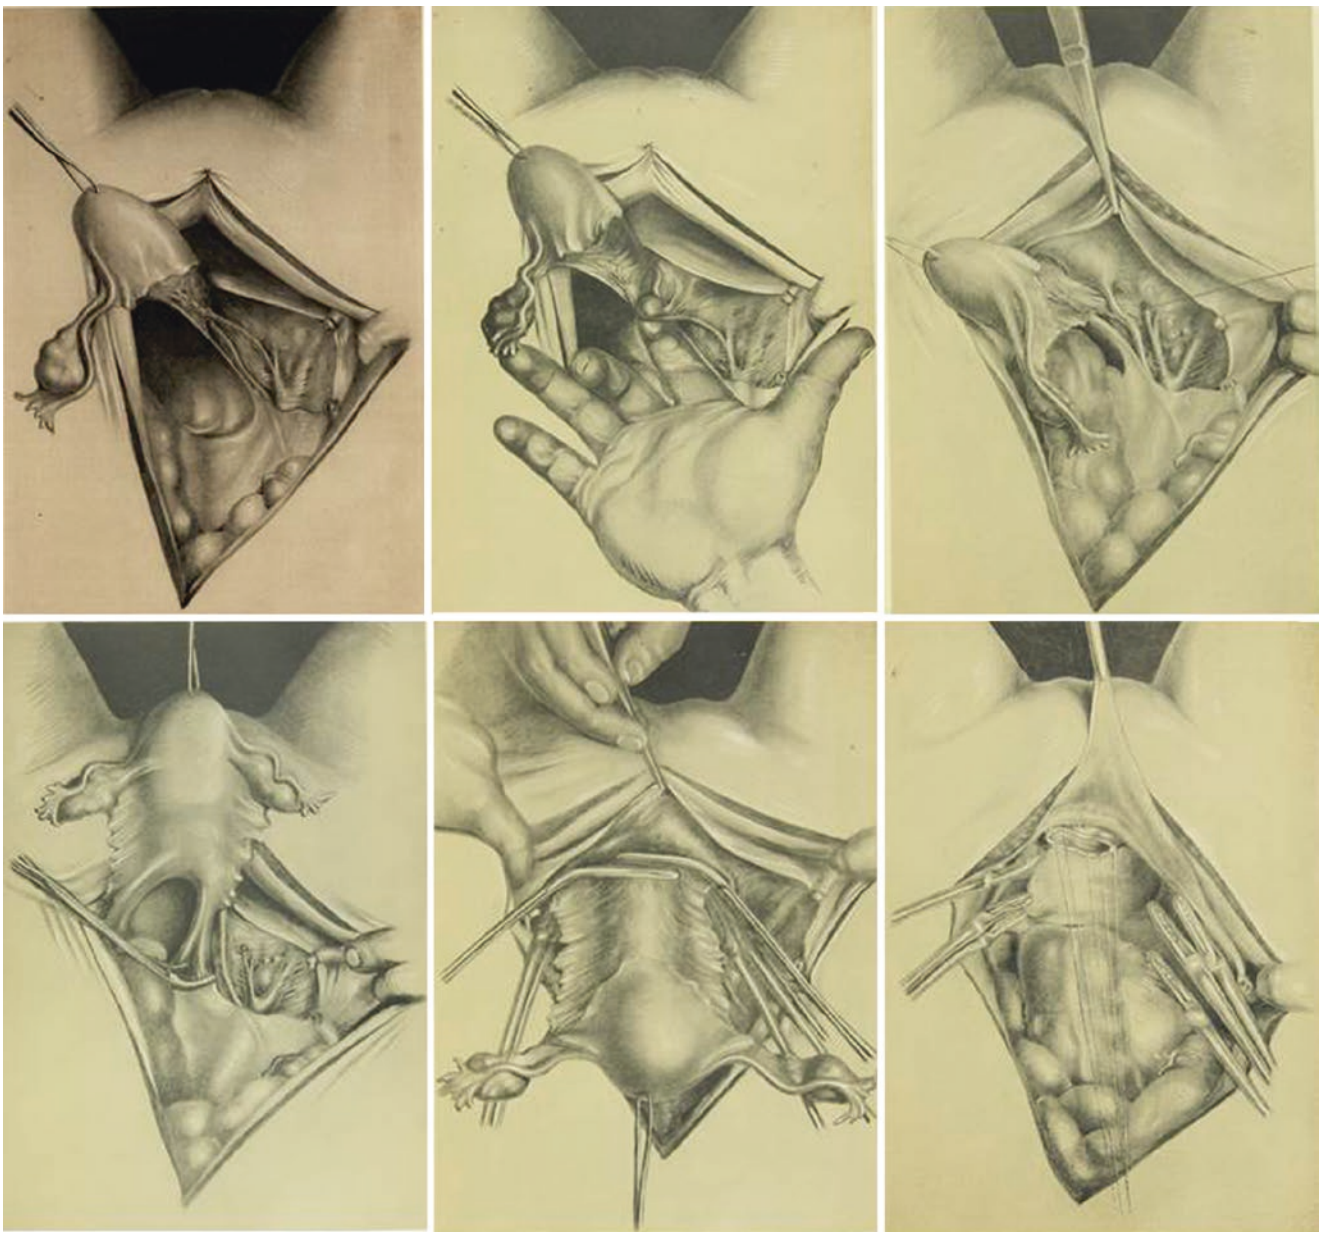

Fig. 2.1 Plates from Wertheim's original description of his extended hysterectomy (Wertheim [31])

consider for surgical treatment at all. The monograph lists the operating times (consistently under 2 h), the postoperative course (including 38 % mortality amongst the first 50 patients), and follow-up with information on time and site of recurrence.

Key steps of Wertheim's technique were digital separation of the leaves of the broad ligament, isolation of the ureter down to its entrance into the parametrium, a maneuver of poking the index finger through the parametrium along the ureter to isolate and ligate the uterine vessels, dissection of the bladder, dissection of the rectum, division of the parametria "from" the pelvic wall with specially designed clamps. Finally, the vagina was clamped and divided below the clamps to excise the specimen without contaminating the surgical field with malignant cells (Fig. 2.1).

Notably, Wertheim performed the hysterectomy first and then did a "search for and extirpation of enlarged lymph glands". Spaces were not systematically developed, and lymph nodes not removed systematically. Thus, a key feature of Wertheim's technique was that he did the hysterectomy first and then turned his attention to the lymph nodes, and then removed only enlarged nodes. Of course, issues regarding the indications for lymphadenectomy and which nodes to remove are still avidly debated for many cancers more than 100 years later.

Latzko and Schiffmann [9] in Vienna, like Peiser [17] before them but in contrast to Wertheim, began the operation

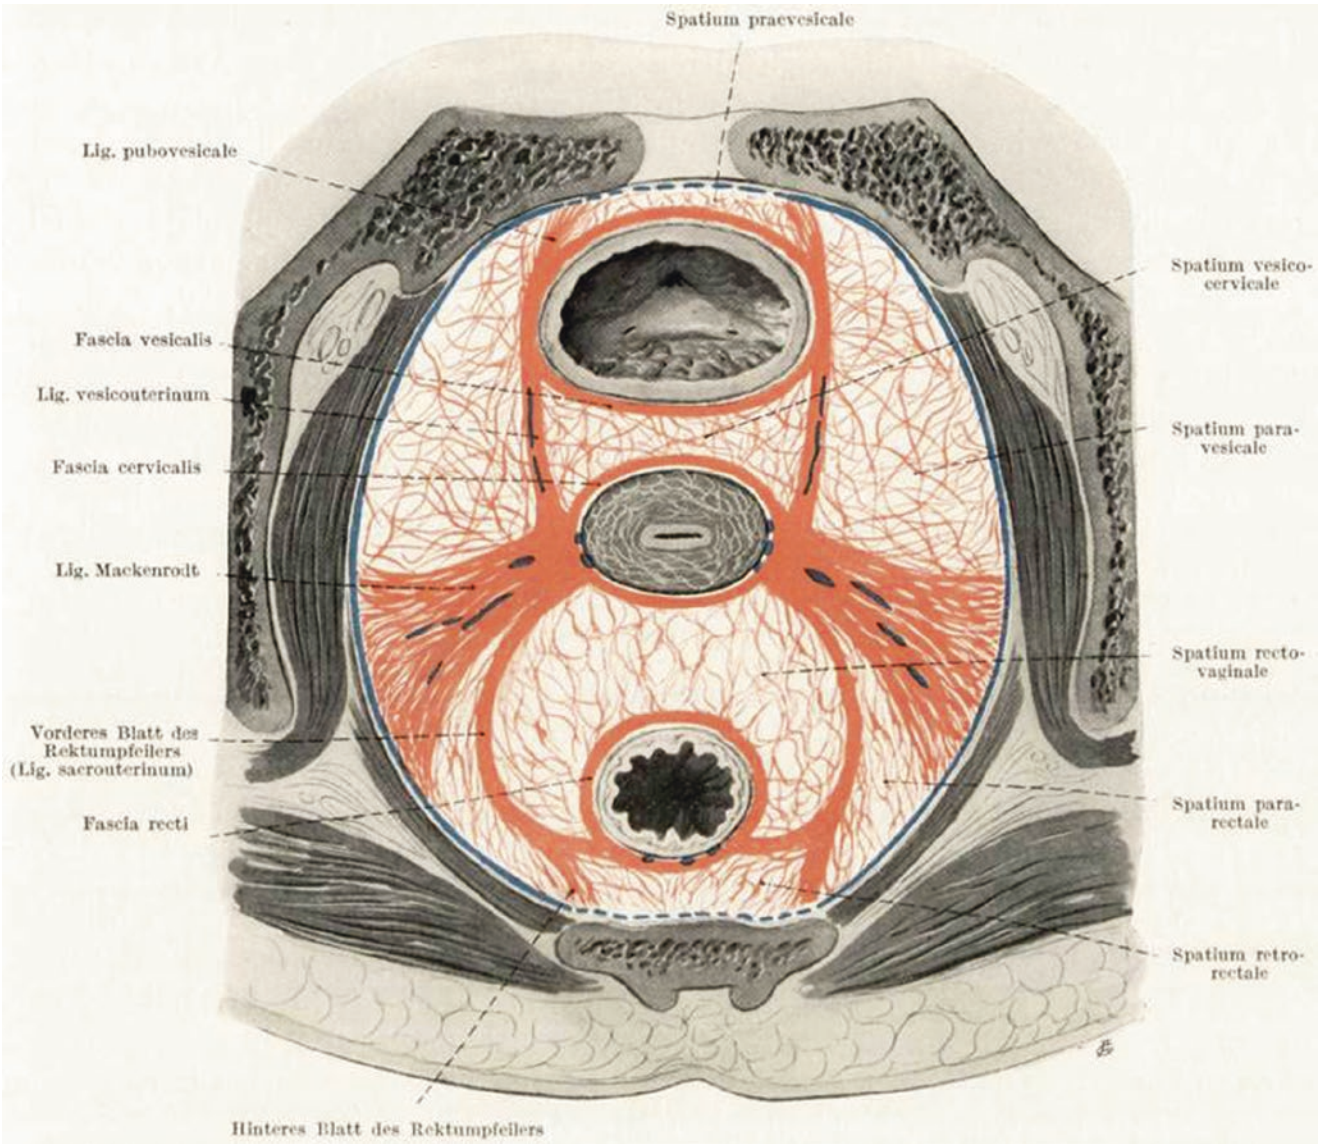

Fig. 2.2 Original schema of the potential spaces in the pelvis (Reprinted from Peham and Amreich [16], with permission from Elsevier)

with systematic lymphadenectomy. Thus, "the object of the operation was isolated according to the anatomic conditions." This was done by opening the paravesical and pararectal spaces (although these were not named) and freeing the ureter from its attendant tissue. The sacrouterine ligament was completely demonstrated and divided close to the sacrum. Isolating the specimen in this way made it possible to resect the parametrial tissue directly at the pelvic wall. By systematically removing lymph nodes before removing the uterus, and thereby "setting up" the operation, Latzko and Schiffmann [9] describe the radical hysterectomy much as we think of it today, but did not name the potential spaces they developed to set up the operation.

The schema with the names of the potential spaces in the pelvis that is the basis of today's surgical anatomy of the pelvis was first described by Peham and Amreich of Vienna in a classic textbook published in [15] (Fig. 2.2).

Lymphadenectomy was associated with radical hysterectomy from early on. The impulse came from anatomic studies by Wagner [29] and Cruveilhier [5] that had found involved nodes in more than 50 % of women who died of cervical cancer. Veit [28] and Mackenrodt [11] repeatedly found tumor deposits in the lymphatics of the parametrial tissue, even before the cervix was "completely infiltrated by tumor to its outer layers." Macroscopically normal parametrial tissue was therefore capable of containing tumor.

General surgeons were already working on removing all accessible regional lymph nodes (not just palpable nodes) in patients undergoing surgery for cancer. Schuchardt [25] stipulated this requirement for cancers of the uterus. In 1898,

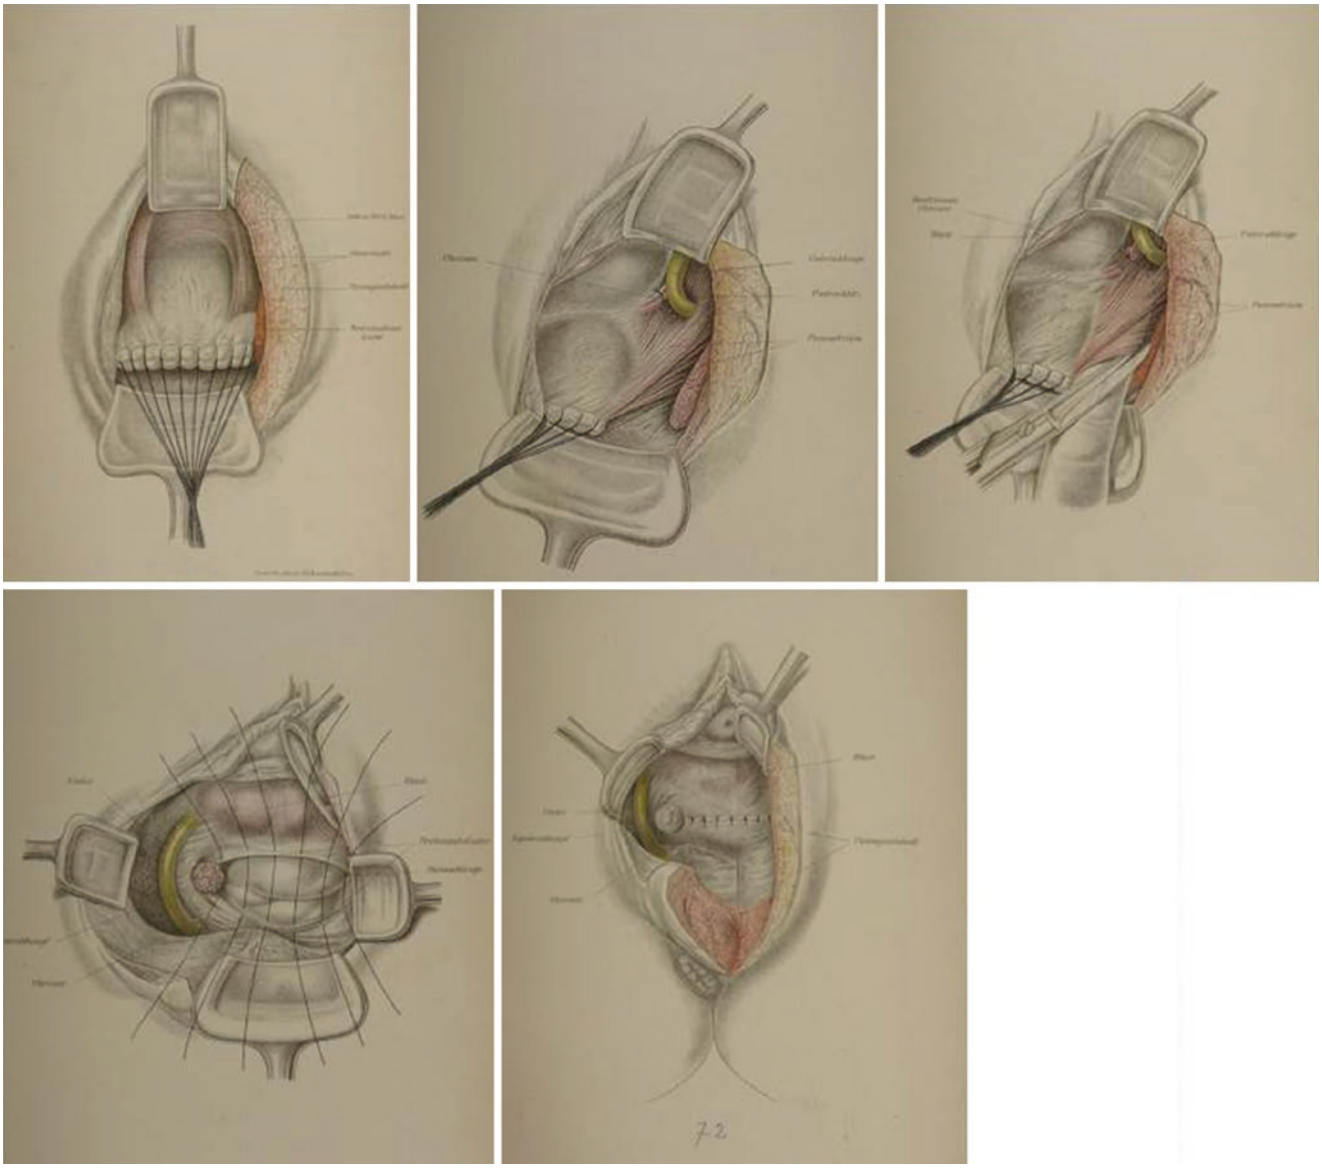

Fig. 2.3 Plates from Schauta's original description of extended vaginal hysterectomy (Schauta [22, 24])

Peiser published anatomical and clinical studies of the lymphatic system of the uterus. He saw a need for systematic lymphadenectomy by also removing the lymphatic channels between the cervix and the pelvic wall. This amounted to total excision of the parametrial tissue. Peiser's publication prompted Wertheim to make "a search for lymph nodes" part of his operation. Schauta [22–24], a proponent of radical vaginal hysterectomy, came out against the "needless search for glands," and stated that, at autopsy, nonenlarged and impalpable nodes could contain cancer. Thus, he unintentionally provided the rationale for systematic removal of the nodes. Latzko and Schiffmann [9] stated that searching for enlarged nodes was fundamentally different from their systematically rempoving node bearing tissue. This still holds true. In contrast to Wertheim, Latzko and Schiffmann performed lymphadenectomy at the beginning of the operation, thereby setting up the subsequent radical hysterectomy.

While Wertheim and others were pursuing an abdominal approach, Friedrich Schauta, Wertheim's erstwhile teacher, was working on the radical vaginal procedure first described by Schuchardt [25]. Schauta, also of Vienna, did for radical vaginal hysterectomy what Wertheim did for radical abdominal hysterectomy. In 1908 he published an assiduous and beautifully illustrated monograph with a list of 258 consecutive operations (Fig. 2.3). Like Wertheim, Schauta provides clinical descriptions, perioperative results and complications, and follow-up (25 % considered cured at 5 years).

Interestingly, Schauta and Wertheim were first teacher (Schauta) and student (Wertheim), later bitter rivals. Their dispute concerned the approach to radical hysterectomy

(vaginal vs. abdominal) and the issue of lymphadenectomy. Wertheim considered the removal of involved glands therapeutic, Schauta was not convinced. Of course, these arguments continue to the present day, and not just for cervical cancer. Both Schauta and Wertheim devote passages in their monographs to disparaging the other's approach. The tone is not friendly. It is ironic that the two rivals received honorary graves in the Vienna Zentralfriedhof, almost next to each other.

The exacting and self-critical work done by Schauta and Wertheim – with clinical descriptions, perioperative morbidity and mortality, and long-term outcome – also remind us that evidence-based surgery is not new.

Late in his life, in the late 1910s, Wertheim was despondent at the thought that his life's work on the treatment of cervical cancer was being made obsolete by the advent of radium treatment for this disease. Wertheim's last publication, which appeared in 1919, the year before he died, was a monograph on a vaginal, uterine-sparing operation for uterovaginal prolapse.

In the United States, Taussing [26] and Meigs [13] were influential in making lymphadenectomy a part of radical surgery for cervical cancer. An influential book edited by Joe V. Meigs of Boston, *Surgical Treatment of Cancer of the Cervix* [14], pulled together authors and the arguments for surgical treatment of cervical cancer and led to a renaissance of surgical treatment for this disease.

Improvements in surgical technique, anesthesiology, blood replacement, perioperative care and technology made possible longer and more complex operations. Pelvic exenterations were a further push to extend the reach of surgical treatment of cervical cancer. These were pioneered by Alexander Brunschwig (1901–1969) of New York [2]. These are complex operations with considerable complication rates and sequelae but continue to have a place in the surgical treatment of recurrent cervical cancer.

Differences in surgical approaches, anatomical concepts and terminologies have led to some confusion and attempts to classify what is understood under the term "radical" or "extended" hysterectomy. The classification put forth by Piver et al. in [18], which distinguished five classes of extended hysterectomy, has probably gained the most traction. Class I (which they called the the TeLinde modification) amounts to a standard total hysterectomy and was used for in situ and microinvasive carcinomas. Class II is a "moderately extended radical hysterectomy", with removal of the medial half of the cardinal ligament. A Class III procedure is the classic Latzko-Meigs concept with pelvic lymphadenectomy and excision of the cardinal ligaments at the pelvic wall, of the uterosacral ligaments at the sacrum, and of the upper half of the vagina. Class IV radical hysterectomy entails excision of three-fourths of the vagina and class V hysterectomy includes resection of involved areas of the ureter and bladder (but is short of exenteration). In Querleu and Morrow [19] developed a more detailed (and thus more complex) classification.

With the advent of cytologic screening after the Second World War, based on the work of George Papanicolaou, the spectrum of cervical cancers seen in developed shifted toward early, screening-detected lesions. Simultaneously, advances in radiation and chemoradiation therapy were made for the treatment of bulky or locally advanced disease. Accordingly, instead of continuously extending radicality, surgeons began to explore whether certain patients with smaller lesions could undergo less aggressive surgery and thus be spared morbidity. This was the basis for nerve-sparing radical hysterectomies [27], radical trachelectomies (with preservation of the uterus and thus of fertility) [6], and sentinel lymph node biopsy. Also, Japanese surgeons developed an anatomical approach to nerve-sparing radical hysterectomy that dates back to Okabayashi in the 1930s [8]. Evidence that small cervical cancers infrequently involve the parametrial tissue is the basis for an ongoing multinational randomized trial of simple vs. radical hysterectomy for early cervical cancer.

The story of radical history contains much of the history of gynecologic surgery and gynecologic oncology and reflects the enormous progress that has been made in combating what was once the leading cause of cancer death in women. The operation is fundamental to our understanding of the surgical anatomy of the pelvis. Wertheim need not have worried, the operation continues to evolve to serve the needs of women with cervical cancer.

Topographical Anatomy

Topographical Anatomy for Hysterectomy Procedures

3

Thilo Wedel

Compartments of the Female Pelvic Cavity

The female pelvic cavity is divided into an anterior, middle and posterior compartment (Fig. 3.1). In contrast to the male pelvic cavity which is confined to two compartments and contains parenchymatous organs (e.g. prostate and seminal glands), all three female compartments consist of hollow visceral organs resting upon the pelvic floor:

- Anterior compartment: urinary bladder and urethra
- Middle compartment: uterus with uterine adnexa and vagina
- Posterior compartment: rectum and anal canal

The peritoneum covers the organs contained in these pelvic compartments from above. While the urinary bladder and rectum are only partially lined by peritoneal serosa, almost the entire uterus and the complete adnexa including the ovaries and uterine tubes are wrapped by peritoneum and, thus, readily accessible by transperitoneal approach. The peritoneum reflects from the uterine body anteriorly on to the fundus of the urinary bladder forming the vesicouterine pouch delimited laterally by the vesicouterine folds and posteriorly on to the rectal wall forming the rectouterine pouch delimited laterally by the rectouterine folds. Except for the posterior vaginal fornix directly facing the rectouterine pouch, the vagina is located extraperitoneally. Both peritoneal pouches are often filled with small intestinal loops, sigmoid colon or greater omentum, thus requiring proper exposure by moving the content upwards.

The pelvic compartments are separated by septa mainly composed of connective tissue and intermingled smooth muscle tissue. Between the anterior vaginal wall and both the urinary bladder and urethra extends the vesico−/urethrovaginal septum, between the posterior vaginal wall and the anterior rectal wall extends the rectovaginal septum. The connective tissue septa are devoid of major blood vessels and serve as separating gliding layers between the three pelvic compartments reflecting the different ontogenetic origins of the urinary, genital and digestive tract. Thus, if surgical dissection follows these self-opening planes between the pelvic compartments, the uterovaginal complex can be readily delineated from the urinary bladder and urethra anteriorly and the anorectum posteriorly without relevant bleeding risk [1–3].

Female Pelvic Floor

The female pelvic floor (Fig. 3.2) is of larger dimension than in males displaying a wider urogenital opening, although its muscle strength is generally lower and its nerve supply less developed. These peculiar features allow vaginal delivery, but also predispose to an higher susceptibility for structural and functional insufficiency and pelvic organ prolapse.

The pelvic floor is composed of a pelvic diaphragm consisting of the levator ani muscle and a urogenital diaphragm comprising the transverse perineal muscles. The levator ani muscle corresponds to a flattened and funnel-shaped muscle closing most of the lower pelvic aperture. However, along the ventral midline openings are left for the urethra and vagina (urogenital hiatus) and the anal canal (anal hiatus).

The largest portion of the levator ani muscle are the ileococcygeal muscles extending from the pelvic side walls to a midline raphe. The rather thin muscle layer originates at the tendinous arc of the levator ani muscle formed by condensed

Note In regards to the nomenclature of anatomical structures, eponymes although commonly used in medical literature (e.g. Lee/Frankenhäuser ganglion, Poupart ligament, Mackenrodt ligament, Cooper ligament, Denonvillier fascia, Waldeyer fascia, Sampson artery, Richard fimbria, Latzko and Okabayashi spaces, etc.) are avoided to prevent confusions frequently resulting from misinterpretation of the historical descriptions.

connective tissue of the obturator fascia ("white line"). The hammock-shaped pubococcygeal muscle originates from the pubic bone and extends towards the coccygeal bone, whereas the sling-shaped puborectal muscle bends arround the anal canal to produce the anorectal angle.

Innervation of the pelvic floor muscles is mainly provided by infralevatory branches of the pudendal nerve. In addition, also direct nerve branches the from sacral spinal nerves S3–S4 contribute and extend from the sacral concavity to reach the levator ani muscle from above. Thus, when exposing the pelvic floor muscle during extended deep lymphadenectomy, care must be taken to preserve these direct supralevatory nerve branches [1–3].

Uterus

The uterus (Fig. 3.3) is a pear-shaped hollow muscular organ of 7–9 cm length with its long axis nearly at right angle to that of the vagina (anteversion of uterine cervix plus anteflexion of uterine corpus) depending on the filling state of the urinary bladder. The anteroposteriorly flattened uterine corpus narrows caudally and continues into the cylindrical uterine cervix. The convex upper part of the uterine corpus is defined as the uterine fundus. On either side, a uterine cornu is formed to receive the uterine tube. Anterior to the uterine cornu inserts the uterine round ligament, posteroinferior to it attaches the ovarian ligament. The uterine cervix is 2–3 cm long, far less mobile than the uterine corpus due to its fixating ligaments and divided into a supravaginal and vaginal portion. Posteriorly the uterine cervix is covered by peritoneum, laterally it is in close relationship to the uterine arteries and the ureters flanking the uterine cervix at a distance of ca. 1–2 cm. The uterine cervical canal connects the uterine cavity with the vaginal lumen [3].

Uterine Adnexa

The uterine adnexa comprise the ovaries, ovarian tubes and ligaments adjacent to the uterus on both sides (Figs. 3.1 and 3.3). The ovaries lie in the ovarian fossae posterolateral to the uterus and medial to the external iliac vessels. They are attached to the uterus by the ovarian ligaments extending from the uterine pole of the ovary to the uterine cornu. The peritoneal fold raised by the ovarian ligament corresponds to the mesovarium containing the ovarian branch of the uterine artery (Figs. 3.5 and 3.8).

The tubal pole of the ovary is connected to the fimbriated end of the uterine tube. Between the tubal pole and the dorsolateral pelvic wall extends the infundibulopelvic ligament corresponding to a peritoneal fold raised by the ovar-

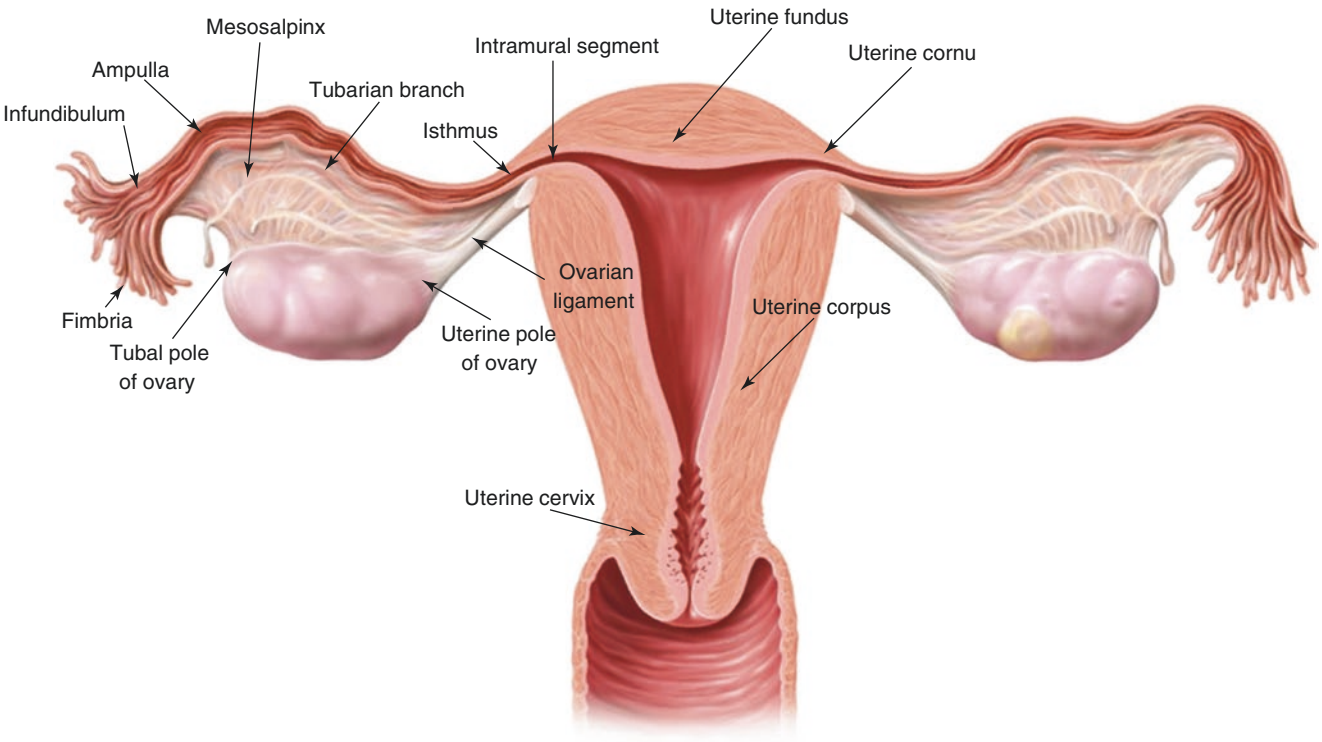

Fig. 3.3 Internal female genital organs. Frontal section, dorsal view. Broad ligament, parametrium and paracolpium removed (Reproduced from Schünke et al. [24])

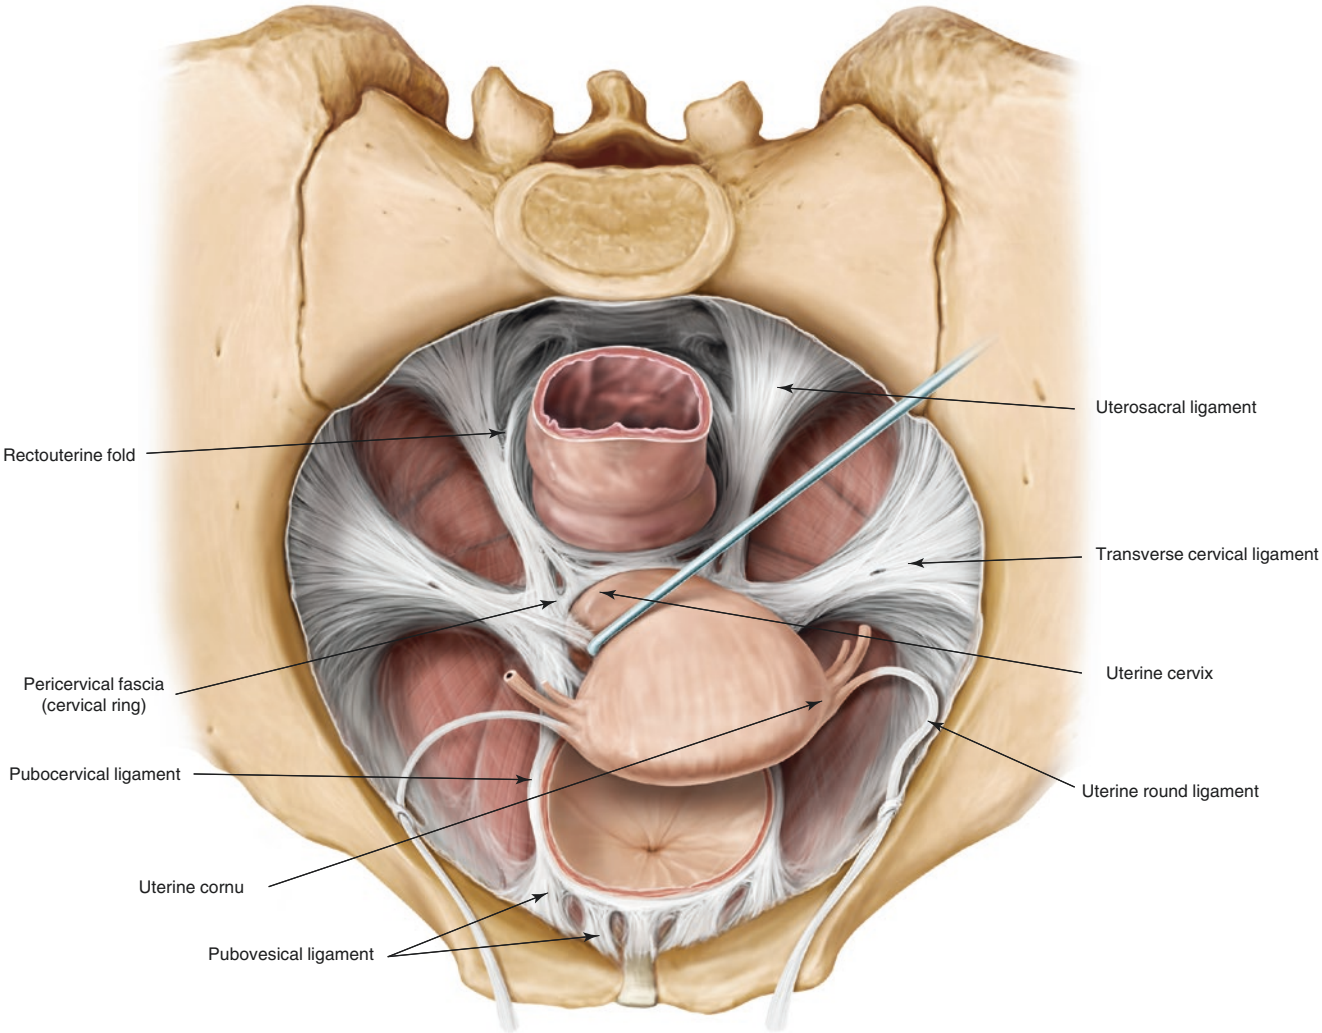

Fig. 3.4 Uterine ligaments. Cranial view. Rectum and urinary bladder are cut transversely, the uterus is shifted to the left side (Reproduced from Schünke et al. [24])

ian blood vessels. The synonym "suspensory ligament of the ovary" is inadequate, as the ovary is not substantially suspended by this peritoneal duplicature. When mobilizing the uterine adnexa, attention should be paid to the fact that the infundibulopelvic ligament together with the ovarian blood vessels cross the external iliac blood vessels ca. 1–2 cm anterolateral to the ureter. Moreover, due to its considerable intraperitoneal mobility the ovary may come into close proximity to both the external and internal iliac vessels and the ureter at the pelvic brim (Figs. 3.1, 3.5, 3.6, 3.9, and 3.7).

The uterine tube is ca. 9–11 cm long and connects the tubal pole of the ovary with the uterus. The infundibulum of the uterine tube is funnel-shaped and displays several fimbriae of which the ovarian fimbria is attached to the tubal pole of the ovary. The widened ampulla shows a luminal diameter of up to 10 mm and narrows at the isthmus to 0.1–0.5 mm. The uterine or intramural portion of the uterine tube is ca. 10 mm long and opens into the uterine cavity via the uterine os located at the uterine cornu. The peritoneal fold raised by the uterine tube corresponds to the mesosalpinx and contains the tubal branch of the uterine artery (Figs. 3.3, 3.5, and 3.8) [3].

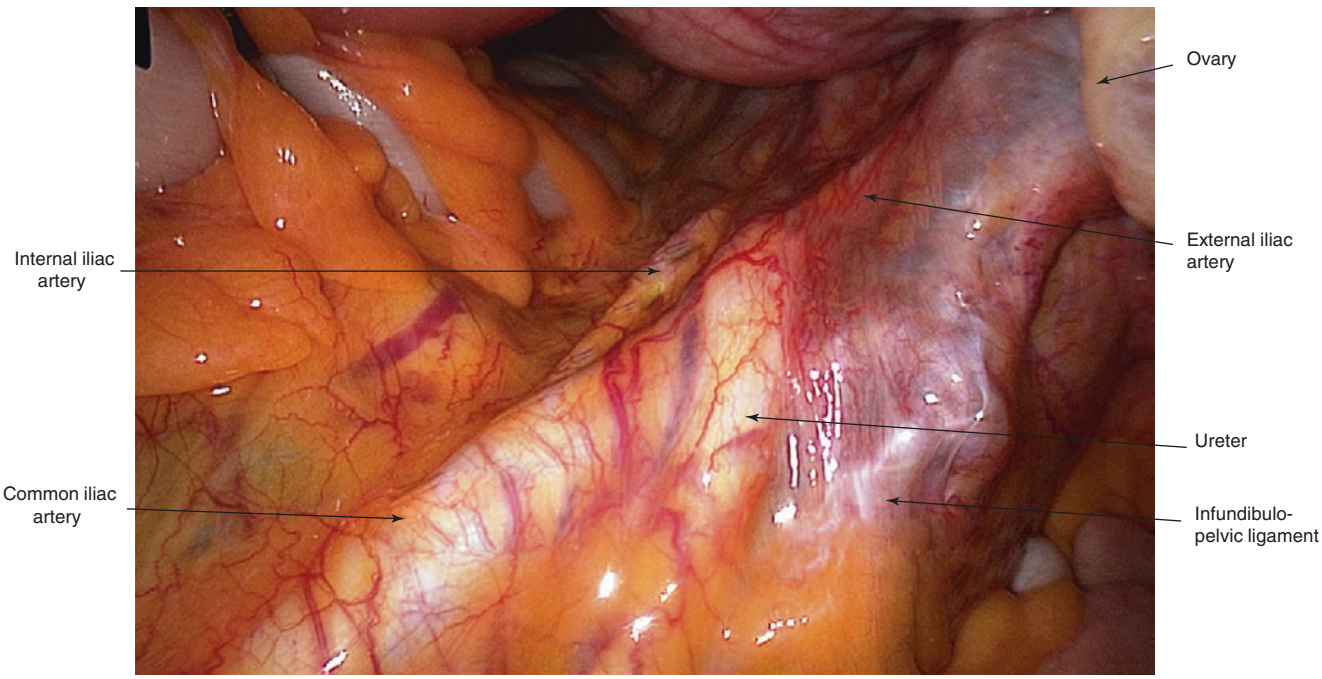

Fig. 3.6 Iliac vessels at the entrance into the right-sided female pelvis. Laparoscopic cranial view. The ureter crosses the pelvic brim running over the external iliac artery and medially to the infundibulopelvic ligament and the ovary

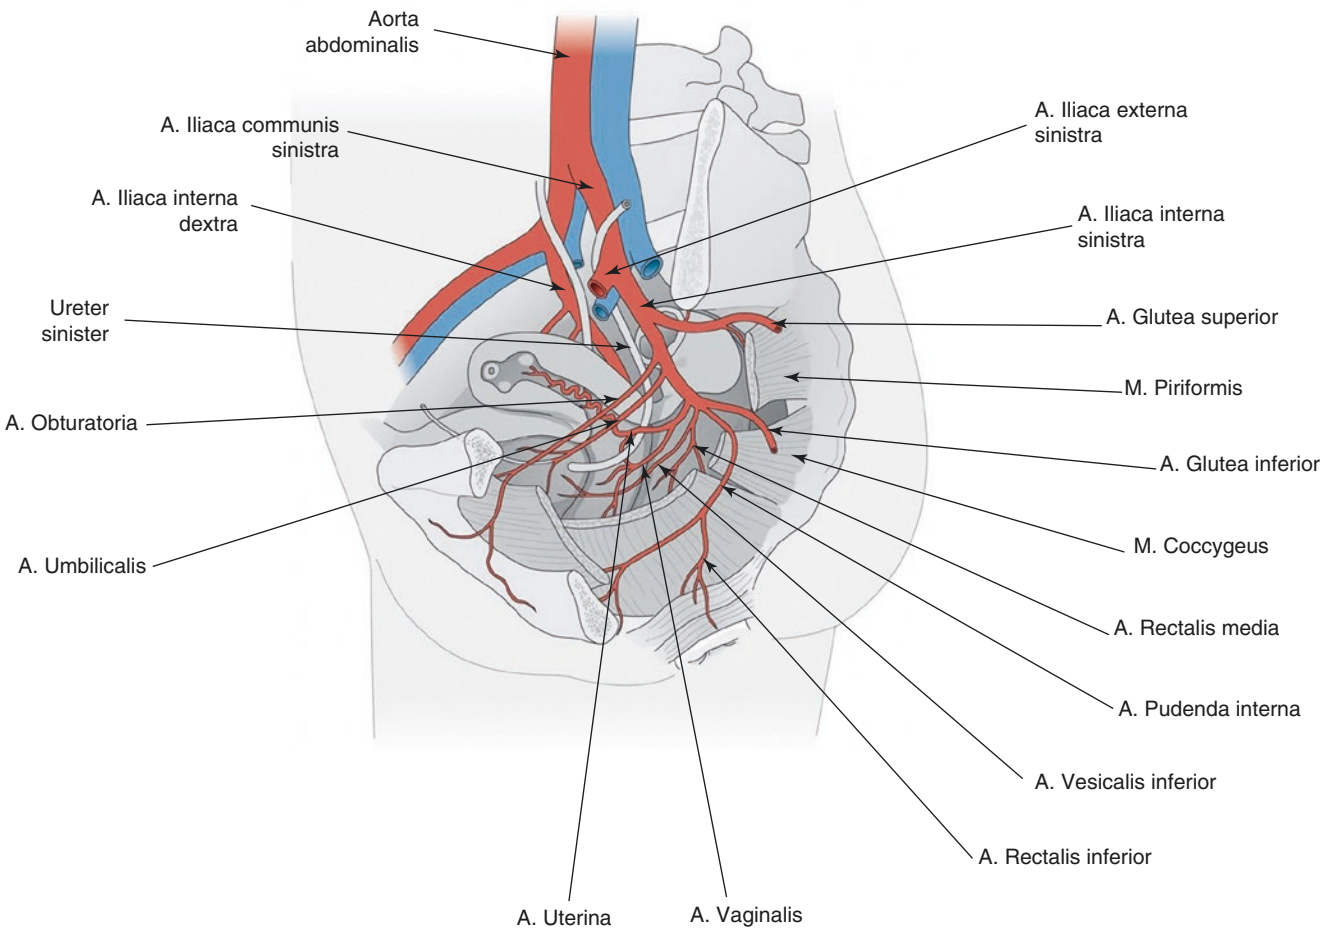

Fig. 3.7 Branches of the internal iliac artery in a female pelvis. Parasagittal section, view form left side. The left broad ligament is sectioned (Reproduced from Schünke et al. [24])

Uterine Ligaments, Parametrium and Mesometrium

Fixation of the uterovaginal complex is achieved on the one hand by the support of the pelvic floor (Fig. 3.2), on the other hand by uterine ligaments providing connections either to other pelvic organs or to the pelvic wall (Fig. 3.4). There is still an ongoing discussion about the exact tissue composition, topographic anatomy, functional relevance and terminology of these ligamentous, parauterine structures [1, 2, 4–7].

Broad Ligaments

The broad ligaments are named according to the fact that they provide a wide-stretched and ample connection between the middle pelvic compartment and the pelvic side walls. The peritoneal covering is lifted up by the broad ligaments and descends anteriorly to cover the paravesical space (anterior leaf) and posteriorly to cover the pararectal space (posterior leaf) on both sides. When viewed from above, the broad ligaments display three peritoneal folds on each side converging from different origins of the inner abdominal and pelvic walls towards the uterine cornu (Fig. 3.5):

- Funicular meso (anterior fold)
- Mesosalpinx (middle fold)
- Mesovarium (posterior fold)

The funicular meso corresponds to the peritoneal fold raised by the uterine round ligament extending from the uterine fundus below and lateral to the uterine cornu to the deep inguinal ring. The fibromuscular bands pass along the paravesical fossa and are accompanied by a branch from the uter-

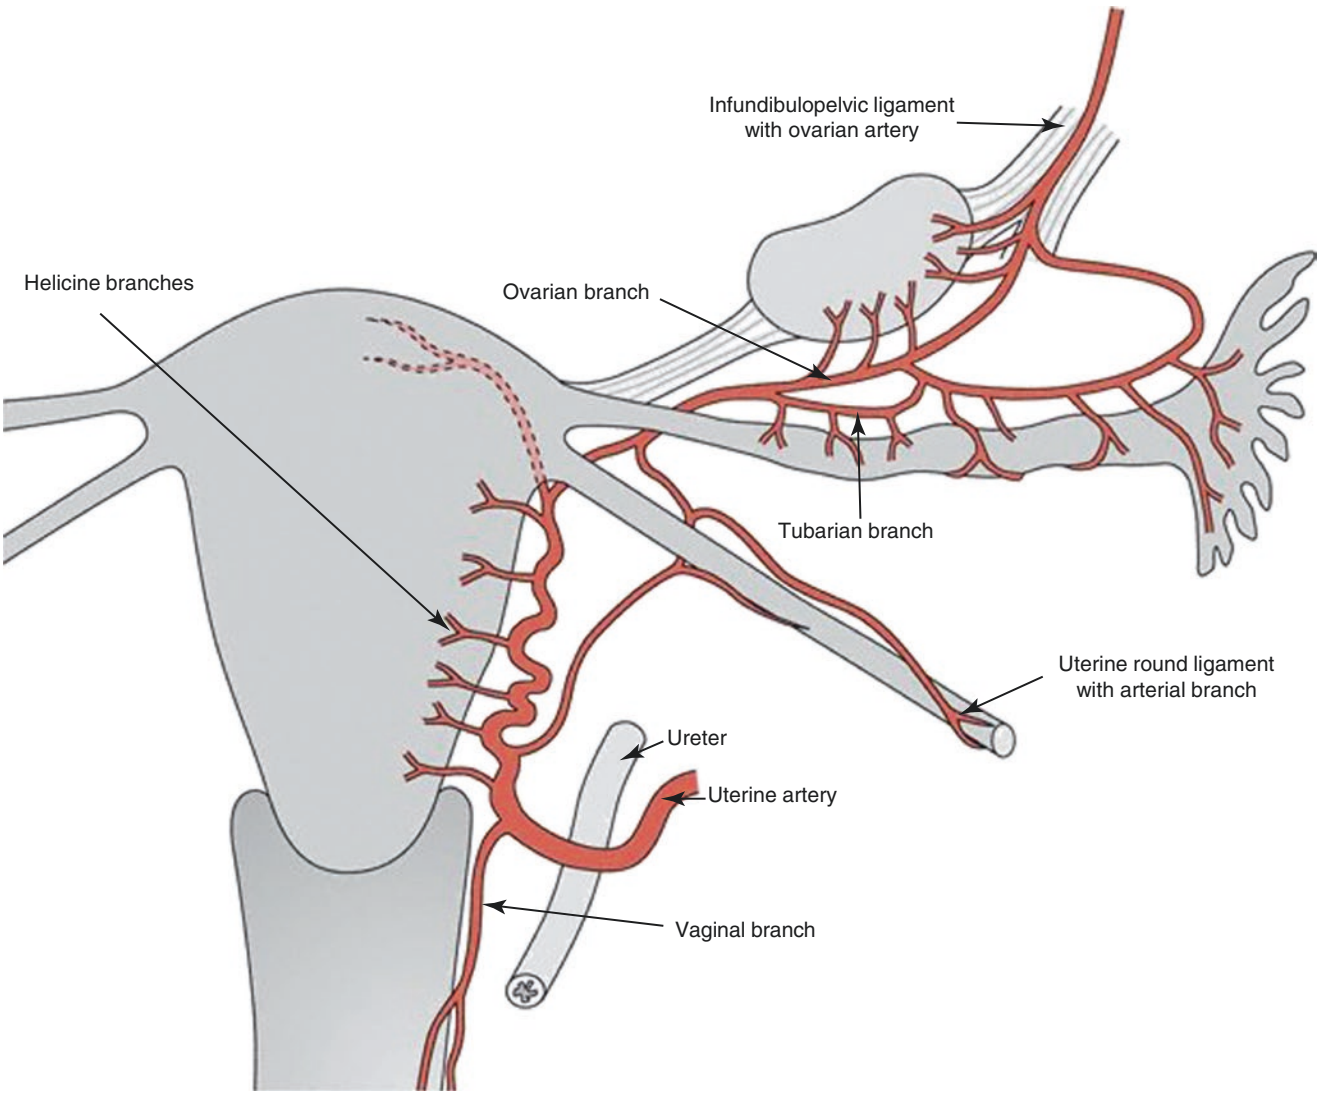

Fig. 3.8 Arterial supply of internal female organs. Ventral view. Branches of the left ovarian and uterine artery (Reproduced from Schünke et al. [24])

ine artery and lymphatic vessels draining to superficial inguinal lymph nodes. The mesovarium and mesosalpinx have been described previously (see section "Uterine Adnexa").

Parametrium and Transverse Cervical Ligaments

Beneath the peritoneal covering the broad ligaments consist of condensed connective tissue connecting the pelvic side walls with the uterus (parametrium) and the vagina (paracolpium) – comparable to those densifications of connective tissue extending lateral to the urinary bladder (paracystium) and rectum (paraproctium). The fibrous tissue contained within the parametrium/paracolpium corresponds to the transverse cervical ligaments (cardinal ligaments) which predominantly attach to the uterine cervix and vaginal fornix. Although composed of connective tissue providing a certain degree of mechanical suspension, the transverse cervical ligaments primarily resemble a mesentery-like structure serving as main routes of vascular, lymphatic and nervous supply of the uterus. The transverse cervical ligaments and parametrial tissue compartment are ca. 10 cm long and traversed by the ureter at its intermediate segment (Figs. 3.3, 3.4, 3.5, 3.10, 3.11, and 3.12) [4–6].

Uterosacral Ligaments

The uterosacral ligaments (Figs. 3.3, 3.4, and 3.5) attach to the uterine cervix and upper vagina and are often confluent with the uterine insertion site of the transverse cervical ligaments.

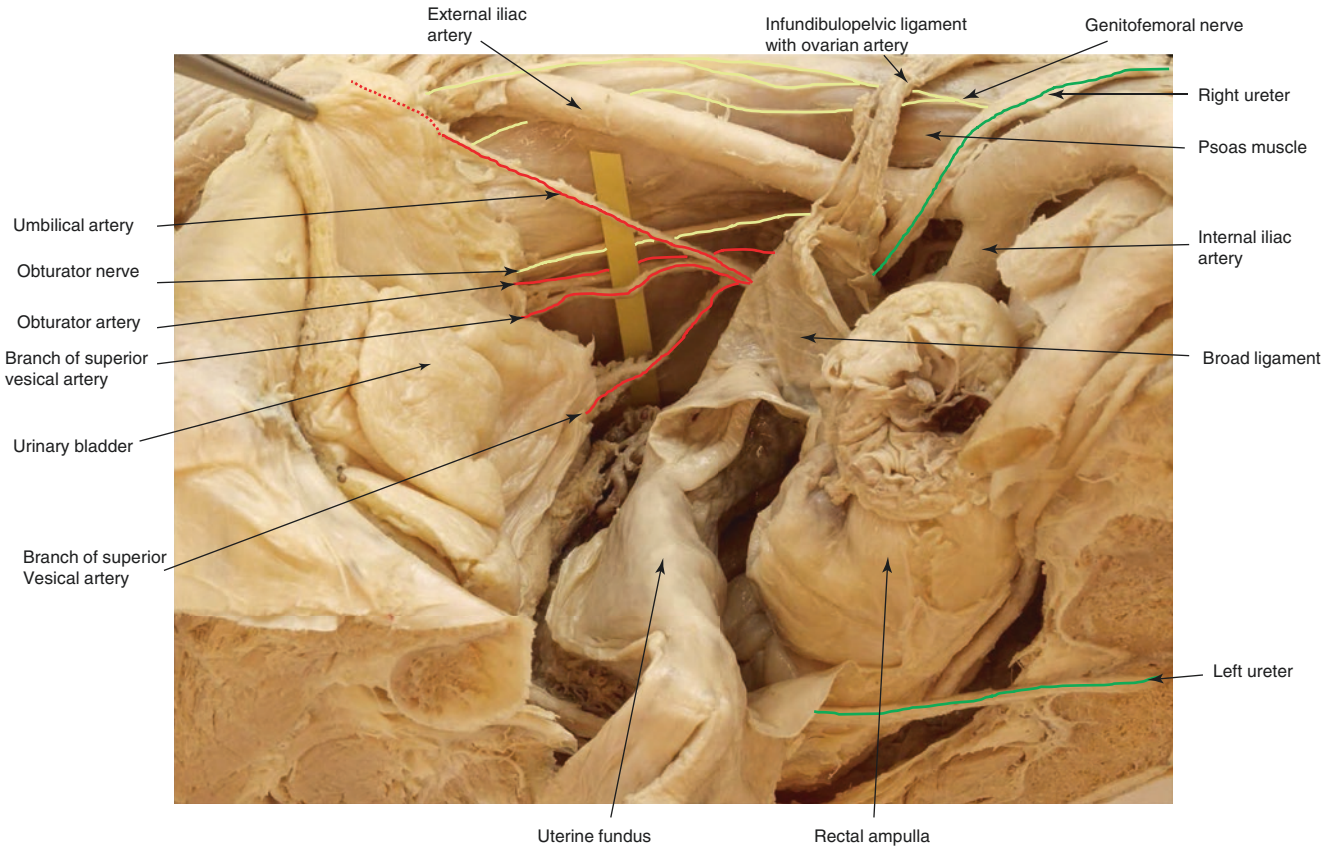

Fig. 3.9 Female right-sided hemipelvis. Parasagittal section, view from left side. The peritoneum is partially removed and incised, the anterior leaf of the right broad ligament is reflected dorsally, the urachus and the bladder roof are pulled upwards by a forceps, the obturator artery and nerve are marked by a yellow plastic strip. Arteries are highlighted by *red lines*, nerves by *yellow lines*, the ureter by *green line*. Formaldehyde-fixed specimen (same specimen also displayed in Fig. 3.10)

The fibrous bands extend dorsally along the rectal sidewalls to reach the sacrum. On their way to the sacrum they create the rectouterine folds and fan out before inserting at the sacral vertebrae S2–S4. The uterosacral ligaments serve as suspension of the uterine cervix and the vaginal tube ensuring the craniodorsal orientation of its long axis. In close proximity extend autonomic nerve fibers of the inferior hypogastric plexus passing immediately lateral to the uterosacral ligaments [4, 7–9].

Pubocervical Ligaments

The pubocervical ligaments (Fig. 3.4) connect the back side of the pubic bone with the uterine cervix. On their way to the uterus the pubocervical ligaments diverge around the urethra and bladder neck. In fact, all uterine ligaments – transverse cervical ligaments from both sides, uterosacral ligaments from behind, and pubocervical ligaments from front – insert at the uterine cervix. The insertion site is reinforced by a connective tissue condensation radially running around the uterine cervix termed cervical ring or pericervical fascia.

Mesometrium

The term mesometrium refers to the embryologically defined tissue compartment of the middle pelvic compartment that contains the neurovascular supply and major lymphatic drainage routes of the uterus – comparable to the mesorectum wrappend around the rectum in the posterior pelvic compartment. The mesometrium actually corresponds to the parametrial tissue, however further emphasizing its mesentery-like function provided by the lymphofatty tissue and accompanying uterine blood vessels and its clear delineation by fascial envelopes preventing early tumor transgression [6, 10].

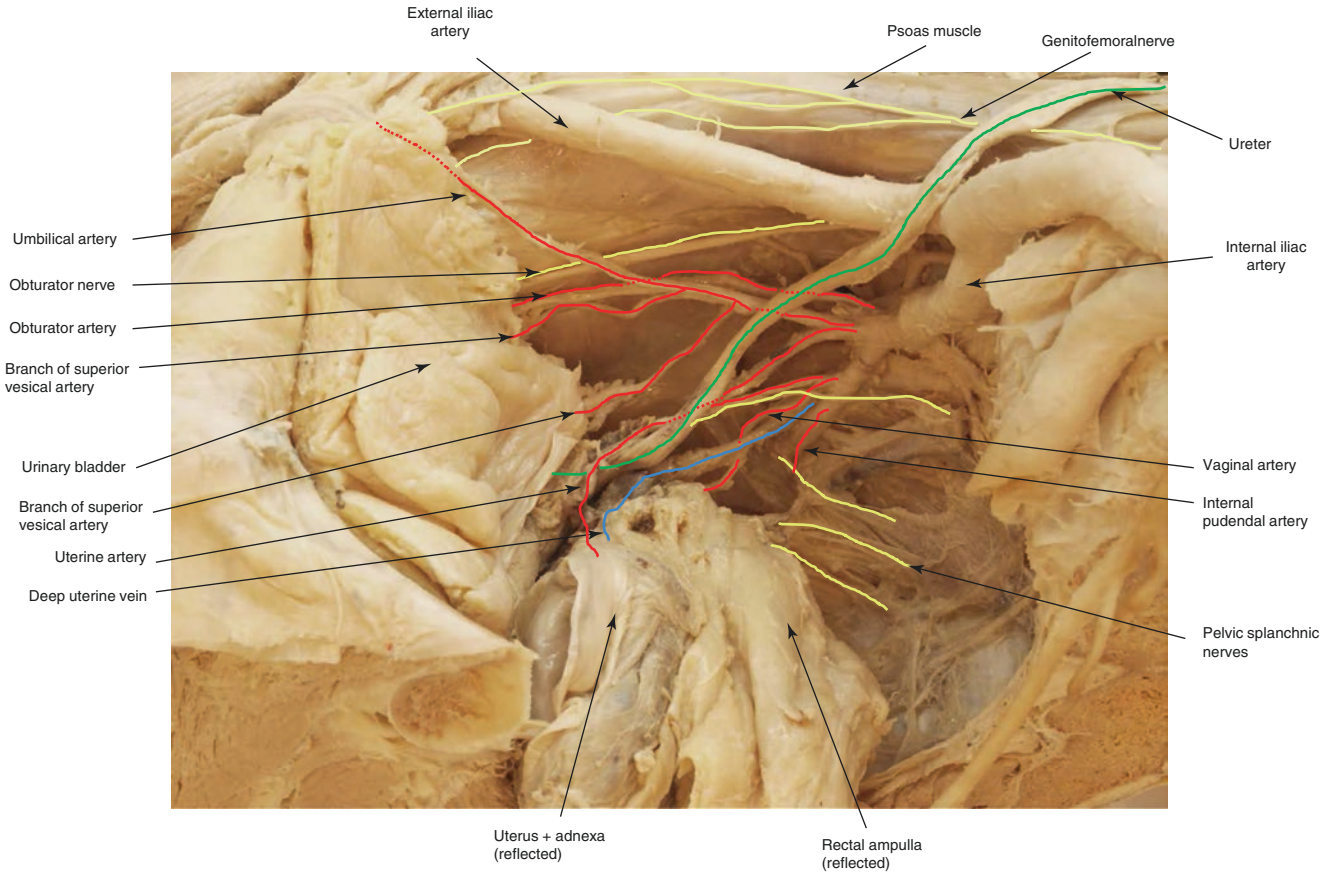

Fig. 3.10 Female right-sided hemipelvis. Parasagittal section, view from left side. The peritoneum is partially removed and incised, uterus and rectum are shifted to the left side to expose the blood vessels, nerves and ureter at the right pelvic sidewall. Arteries are highlighted by *red lines*, veins by *blue lines*, nerves by *yellow lines*, the ureter by *green line*. Formaldehyde-fixed specimen (same specimen also displayed in Fig. 3.9)

The clinical significance of the mesometrium has received special attention after the introduction of total mesometrial resection (TMME) for uterine cancer – in turn comparable to total mesorectal excision (TME) [11] carried for rectal cancer or complete mesocolic excision (CME) [12] recently introduced for colon cancer. All these surgical approaches are commonly based on the concept that tumor spread is initially confined to permissive ontogenetic compartments and its corresponding lymh node basins, so that complete removal of these embryologically defined packages will result in both optimal tumor control and low morbidity, if the resection margins are properly respected [10, 13, 14].

The uterine tubes, uterus and upper vagina are derivates of the paramesonephric ducts (Müllerian ducts). The distal fusion of the Müllerian ducts induces the development of the uterovaginal canal and the formation of the broad ligaments and the mesometrial tissue. According to Höckel the mesometrium can be subdivided into a vascular mesometrium containing the uterine vessels and surrounding lymphofatty tissue with mesometrial lymph nodes and a ligamentous mesometrium corresponding to the uterosacral ligaments and rectovaginal septum [10].

Blood Vessel Supply of Female Pelvic Viscera

The female pelvic viscera are mainly supplied by the internal iliac arteries (Figs. 3.5, 3.6, and 3.7) [3] The common iliac arteries originate at the aortic bifurcation in front of the left side of the fourth lumbar vertebra. They pass along the medial borders of the psoas major muscle without giving off branches and diverge into external and internal iliac arteries. Whereas the external iliac arteries follow the psoas major muscle until traversing the lacuna vasorum through the femoral ring to reach the lower limb, the internal iliac arteries descend into the pelvic cavity in posterocaudal direction over ca. 4 cm and then divide into an anterior and posterior trunk. To expose the inter-

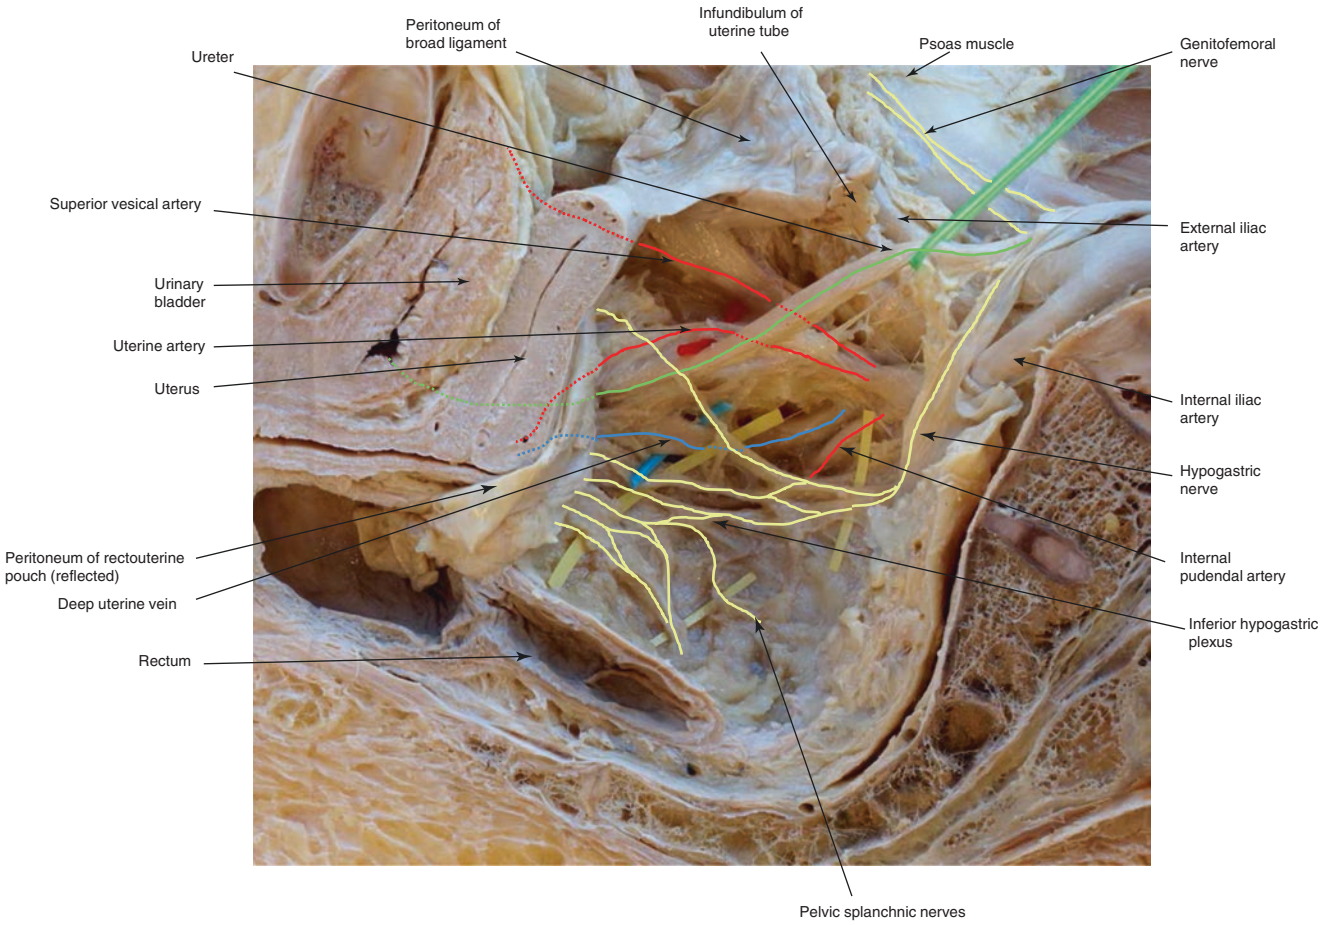

Fig. 3.11 Female right-sided hemipelvis. Midsagittal section, view from left side. The peritoneum is partially removed and shifted to the left side to expose the blood vessels, nerves and ureter at the right pelvic sidewall. The ureter is marked by a green vessel loop, the pelvic autonomic nerve plexus by yellow plastic strips, the uterine artery by a red plastic strip, the uterine vein by a blue plastic strip. In addition, arteries are highlighted by *red lines*, veins by *blue lines*, nerves by *yellow lines*, the ureter by *green line*. Formaldehyde-fixed specimen

nal iliac artery the adjacent and sometimes overlying infundibulopelvic ligament and ovary have to be shifted upwards. The common, external and internal iliac veins are located medially or dorsomedially to their arterial counterparts.

The anterior trunk or division of the internal iliac artery comprises the following branches:

Superior Vesical Artery

The superior vesical artery (Figs. 3.5, 3.7, 3.8, 3.9, 3.10, 3.11, and 3.12) is the first visceral branch and corresponds to the proximal, patent segment of the fetal umbilical artery. The artery follows the pelvic sidewall medially to the obturator vessels and nerve and craniolaterally to the urinary bladder. Before reaching the urinary bladder the superior vesical artery splits into various branches mostly for the vesical fundus and corpus but also for the distal ureter. The obliterated segment corresponds to the medial umbilical ligament ascending from the vesical fundus along the anterior abdominal wall to the umbilicus thereby forming the medial umbilical fold underneath the parietal peritoneum (Figs. 3.20 and 3.21). Gentle traction applied to the medial umbilical ligament allows easy identification of the superior vesical artery and usually thereby also of the uterine artery, as both arteries originate either from a common trunk or close to each other.

Uterine Artery

The uterine arteries supply (Figs. 3.5, 3.7, 3.8, 3.10, 3.11, 3.12, and 3.13) the entire uterus including the uterine tubes and uterine round ligaments and also the upper third of the vagina. The uterine artery originates from the internal iliac artery either as a separate branch or as a common trunk together with the superior vesical artery. Although the supe-

rior vesical and uterine arteries supply different pelvic compartments, vesicovaginal anastomoses are often observed, in particular regarding the corresponding veins.

The uterine artery runs through the parametrial tissue covered by the broad ligament towards the uterine cervix. The ureter crosses underneath the uterine artery ca. 1–2 cm lateral to the uterine cervix and lateral vaginal fornix and receives a supplying branch. Whereas in most of the cases one single uterine artery is present on each side, multiple uterine veins of different sizes can be observed which drain the uterine venous plexus. The uterine veins often do not directly follow the course of the uterine artery, but often pass underneath the ureter. The most caudally located vein is also termed deep uterine vein.

The main branch of the uterine artery ascends lateral to the uterus in meander-like course towards the uterine cornu where it gives off an ovarian branch running within the mesovar and a tubal branch running within the mesosalpinx. These branches establish anastomoses with the ovarian artery. An additional branch originates at the uterine cornu to follow and supply the uterine round ligament.

From the tortuous segment of the uterine artery multiple helicine branches enter in the uterine wall, divide into arcuate arteries and supply the myometrial and endometrial layers by giving off radial and spiral branches. The right and left uterine arteries establish extensive intramural anastomotic connections across the midline, so that the uterine blood supply is not seriously compromised after unilateral ligation. At the level of the uterine cervix branches descend to the vagina and anastomose with branches of the vaginal artery to form two longitudinal vessels. These vaginal azygos arteries run along the anterior and posterior vaginal wall.

Vaginal Artery

In addition to vaginal branches of the uterine artery one or more arteries originating from the internal iliac artery directly run to the vagina. These vaginal arteries (Figs. 3.5, 3.7, and 3.10) correspond to the inferior vesical artery in males and supply the vagina, vaginal vestibule as well as the vesical trigone and urethra.

Middle Rectal Artery

The last visceral branch of the internal iliac artery is the middle rectal artery (Figs. 3.5 and 3.7) running above the levator ani muscle within the lateral rectal pedicles together with autonomic nerve fibers of the rectal plexus to reach the rectal wall. However, in contrast to both the superior vesical and uterine arteries the middle rectal arteries are much smaller in size and inconstantly present, as the rectal blood supply is mainly provided by the more promiment superior rectal artery running within the mesorectum (Figs. 3.17 and 3.18).

Obturator Artery

The obturator artery (Figs. 3.5, 3.7, 3.9, 3.10, and 3.13) is one of the first branches of the internal iliac artery. However, it does not primarily supply the pelvic viscera, but leaves the pelvic cavity via the obturator canal to approach the adductor muscles of the medial thigh. In the pelvis the artery passes medially to the internal obturator muscle and caudally to the obturator nerve which converges with the obturator vascular pedicle at the entrance foramen of the obturator canal. At its proximal segment the obturator artery is located in close proximity both to the ureter and the ovary and it gives off iliac branches supplying the iliopsoas muscle. From the distal segment vesical branches may ramify and pass medially to the urinary bladder.

Frequently, an anastomotic connection between the obturator and inferior epigastric artery is provided by a pubic branch running across the pubic bone over the pectineal ligament (Figs. 3.13, 3.14, and 3.20). A prominent pubic branch is also termed corona mortis (“crown of death”), because in earlier times an inadvertent injury of this vessel during inguinal or femoral hernia repair has led to serious bleedings. In up to one third of cases the obturator artery does not originate from the internal iliac artery but from the inferior epigastric artery or even the external iliac artery sending an enlarged pubic branch directly towards the obturator canal. In any case, special attention should be payed to these vascular variations, when operating in the obturator fossa and paravesical space, e.g. for extended pelvic lymphadenectomy.

Internal Pudendal Artery

The internal pudendal artery (Figs. 3.7, 3.10, and 3.11) is one of the terminal branches of the anterior division of the internal iliac artery and supplies the perineal region, anal canal, external genital organs, and pelvic floor muscles. The artery descends laterally in front of the piriformis muscle and sacral nerve plexus roots, leaves the pelvis through the infrapiriform hiatus of the greater sciatic foramen and bends around the ischial spine to enter into the ischioanal fossa via the lesser sciatic foramen. The artery is accompanied medially by the internal pudendal vein and pudendal nerve. Branches of the internal pudendal artery include muscular branches for the pelvic and gluteal region, inferior rectal artery, perineal arteries, posterior labial branches, branches to the vestibular bulb and vaginal introitus, deep and dorsal artery of the clitoris.

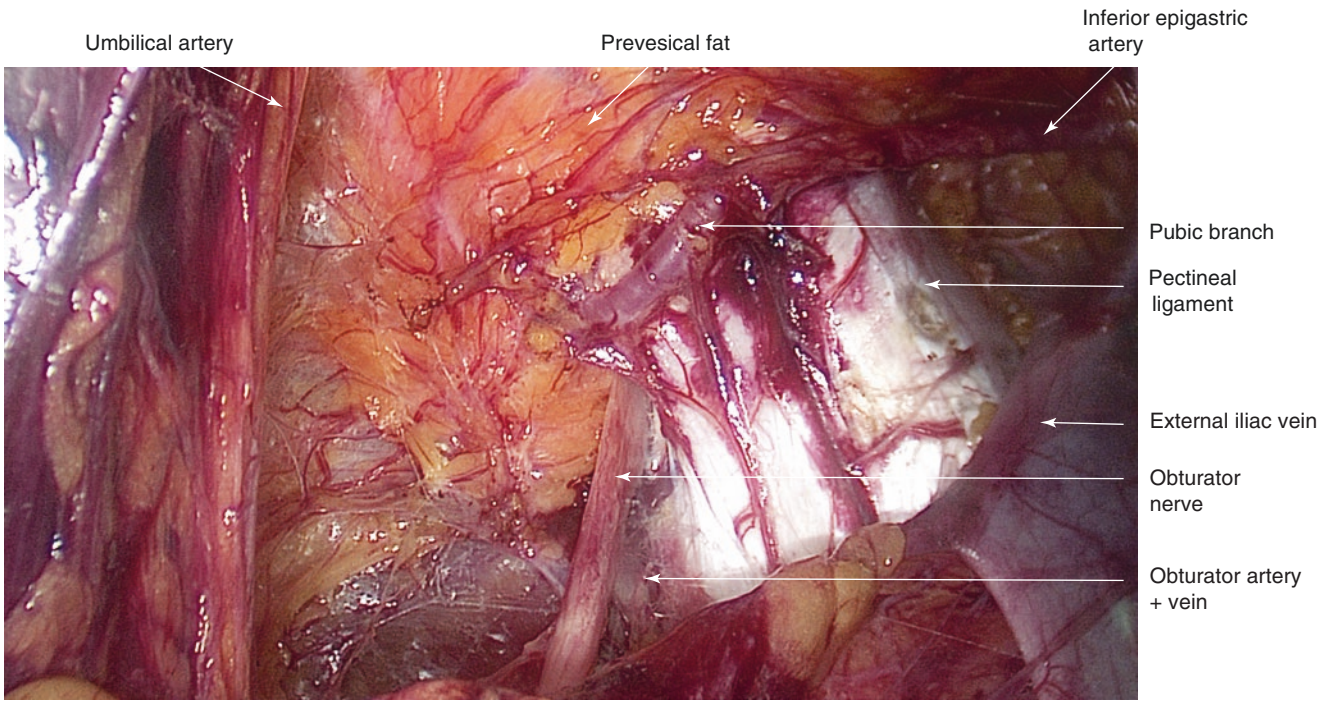

Fig. 3.14 Exposure of right-sided prevesical space and obturator fossa. Laparoscopic cranial view. A prominent pubic branch is visible crossing the pectineal ligament and the superior pubic ramus

Inferior Gluteal Artery

The inferior gluteal artery (Fig. 3.7) is the other terminal branch of the anterior division of the internal iliac artery, however often originating from a common stem together with the internal pudendal artery. It also decends anterior to the piriformis muscle and sacral nerve plexus, but then passes posteriorly between the ventral rami of the sacral spinal nerves and traverse the infrapiriform hiatus of the greater sciatic foramen to reach the gluteal and posterior femoral region.

The posterior trunk or division of the internal iliac artery comprises the following branches:

Iliolumbar Artery

The iliolumbar artery is the only ascending branch of the internal iliac artery passing posterior to the external iliac vessels and obturator nerve in front of the sacroiliac joint to reach the psoas muscle. The iliac and lumbar branches supply the muscles of the corresponding regions and establish anastomoses with the gluteal and deep circumflex iliac arteries.

Lateral Sacral Arteries

Usually a superior and inferior branch originate from the internal iliac artery, descend and approach the anterior sacral foramina to supply the sacral canal and dorsal sacral region. The lateral sacral arteries anastomose from both sides with the median sacral artery.

Superior Gluteal Artery

The superior gluteal artery (Fig. 3.7) corresponds to the terminal branch of the posterior division of the internal iliac artery. Immediately after its origin the large vessel traverses between the first ventral rami of the sacral spinal nerves to leave the pelvis via the suprapiriform hiatus of the greater sciatic foramen. Deep and superficial branches of the superior gluteal artery supply the gluteal and sacral region and anastomose with the inferior gluteal, deep circumflex iliac and circumflex femoral arteries.

Pelvic Veins

As a general rule, larger veins such as the common, external and internal iliac veins follow the course of their arterial counterparts. In most cases, the veins run medially or dorsomedially to the arteries. The same observation holds true for most of the parietal branches (e.g. obturator, pudendal, gluteal veins) of the internal iliac artery, whereas the visceral branches display different features: the urinary bladder, uterus and vagina are drained by venous plexus which are interconnected with each other and release the blood into multiple vesical, vaginal and uterine veins. These veins do

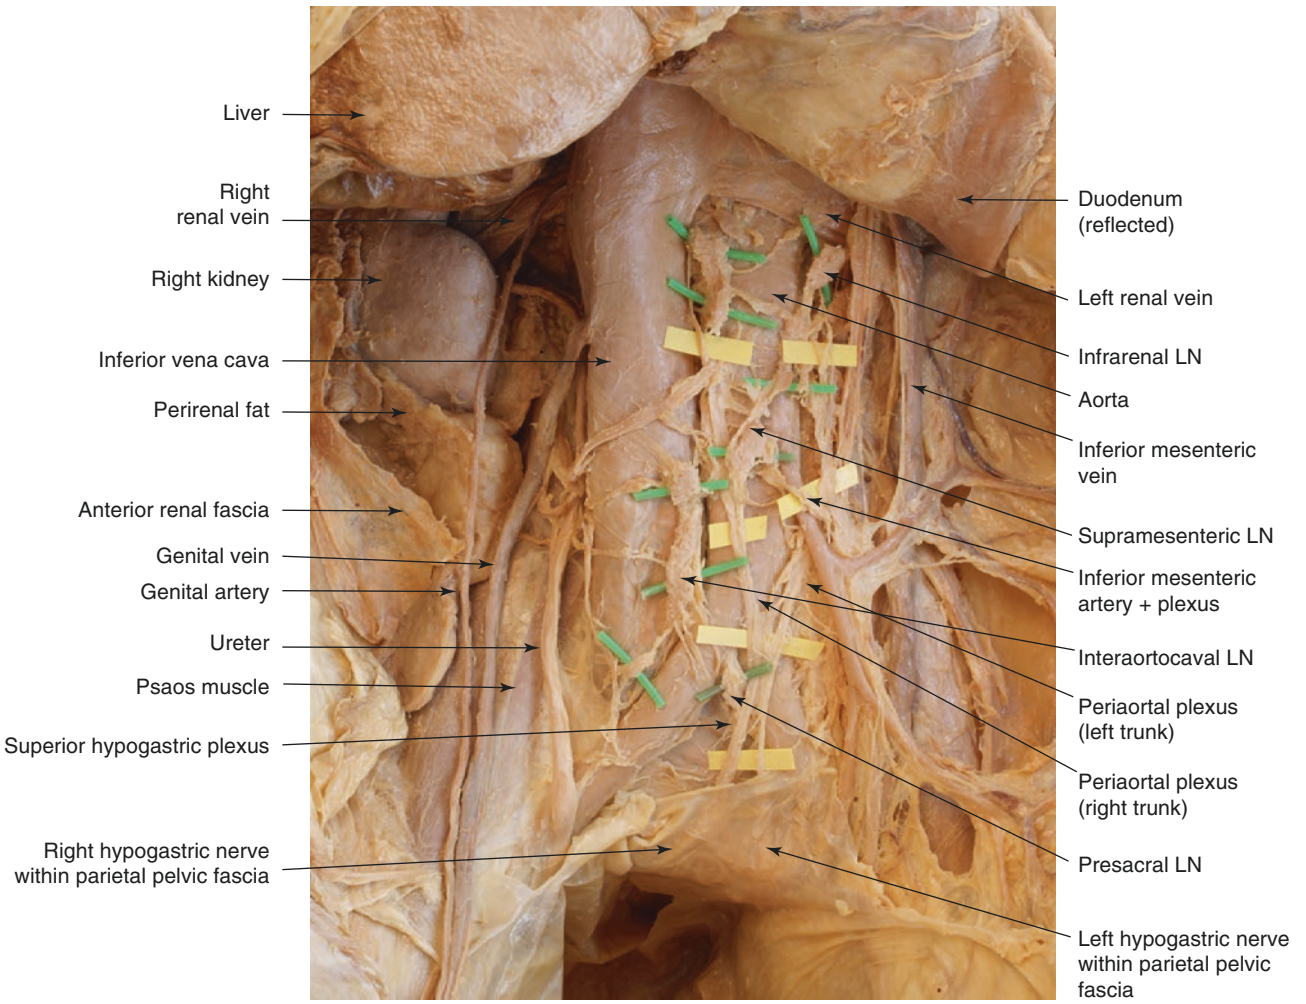

Fig. 3.15 Prevertebral and retroperitoneal region. Ventral view. The parietal peritoneum is removed down to the entrance into the pelvic cavity on both sides, the anterior renal fascia is removed on the left side. Lymph nodes (LN) are marked by green plastic tubes, nerves by yellow plastic strips. Formaldehyde-fixed specimen

not strictly accompany and parallel the arteries until they have entered into the internal iliac vein.

It has to be emphasized that during laparoscopic or roboter assisted surgery, pelvic veins often collapse due to the intraperitoneal pressure exerted by gas insufflation onto the thin venous walls. Thus, special care must be taken to clearly identify and respect the pelvic veins, because injury may occur inadvertently and lead to troublesome bleeding sometimes only evident after diminishing the intraperitoneal pressure.

Lymph Nodes and Lymphatic Drainage of the Uterus and Uterine Adnexa

In general, lymphatic drainage follows the blood supply of the corresponding organs and is realized by a network of rather thin-walled lymphatic vessels and lymph nodes grouped along the nutrient vascular branches and enveloped by fatty and loosely arranged connective tissue. As the arterial supply of the uterus and uterine adnexa originates from two sources (uterine and ovarian arteries), the main lymphatic drainage involves both pelvic and paraaortic routes and is therefore complex and multidirectional due to the peculiar ontogenetic anatomy of the female genital tract [3]. However, direct lymphatic drainage pathways into the anterior pelvic compartment via the vesicouterine ligaments or into the posterior compartment via the uterosacral ligaments could not be demonstrated [15, 16].

Lymphadenectomy is considered to be an integral component of the surgical treatment for uterine carcinoma. Due to the topographic complexity of lymphatic drainage and close proximity between lymph nodes and both blood vessels and nerves, pelvic and paraaortic lymph node dissection are challenging and often time consuming procedures. Therefore, profound anatomical knowledge of the different lymph node

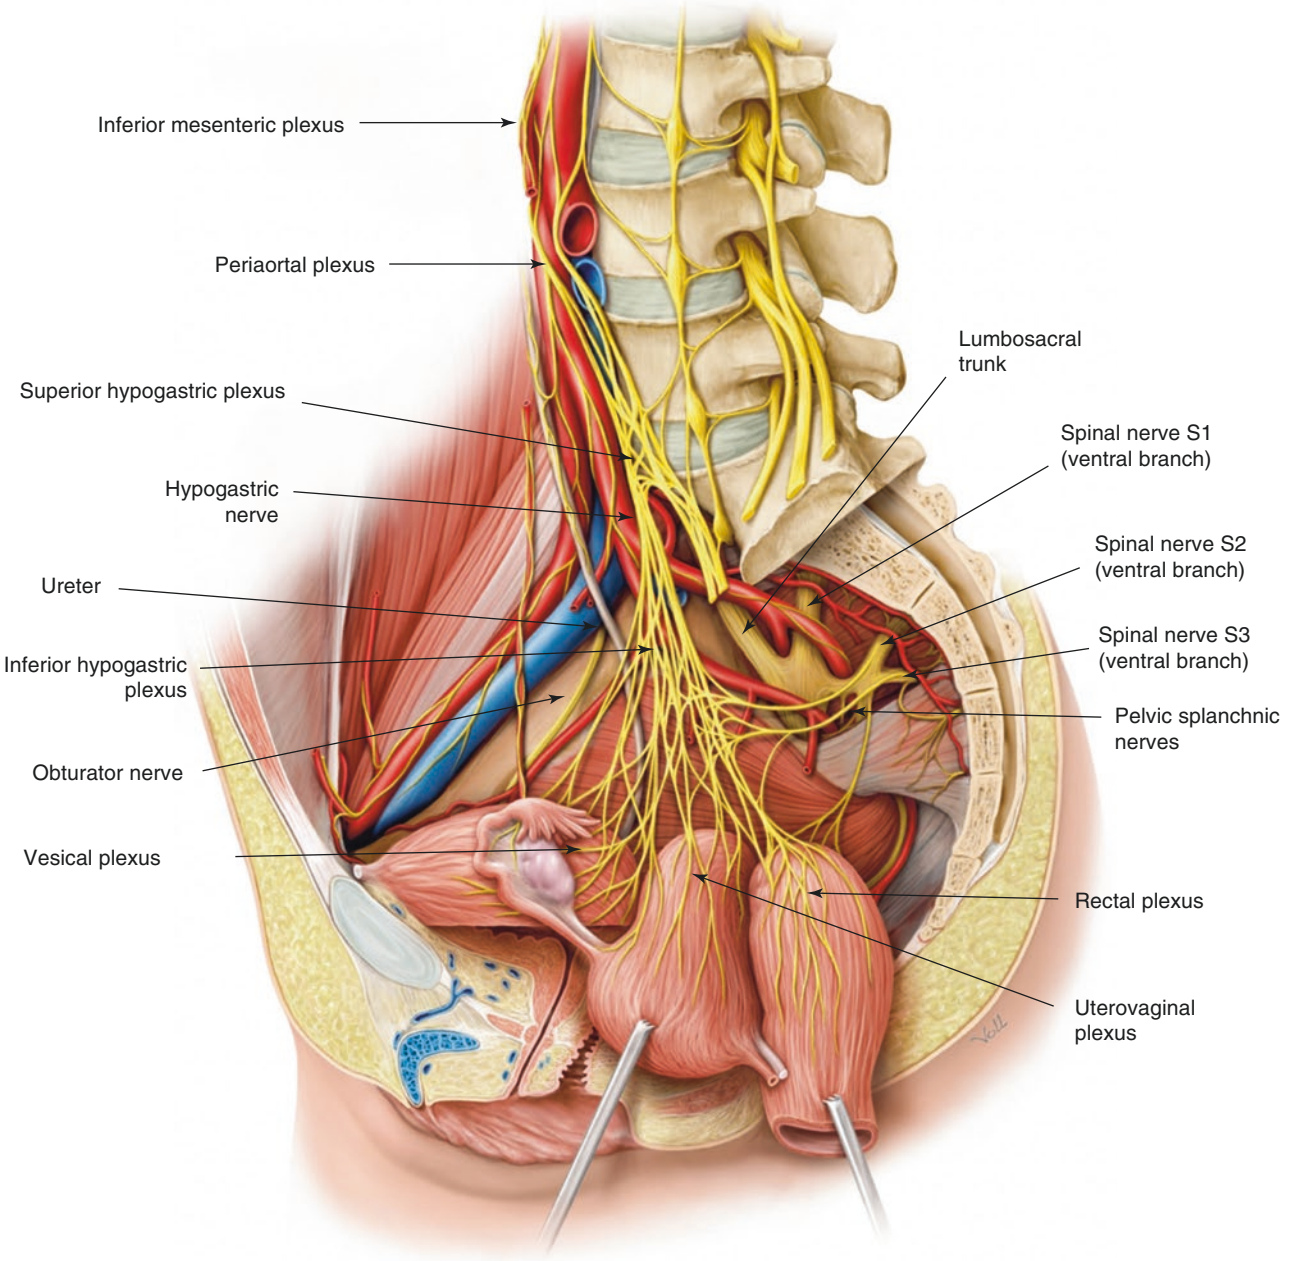

Fig. 3.16 Nerve supply of female pelvic viscera. Midsagittal section, view from left side. Uterus and rectum are shifted to the left side to expose the pelvic autonomic nerve plexus, (Reproduced from Schünke et al. [24])

regions is required to be familiar with the anatomical landmarks which help to identify and preserve structures at risk when removing the areolar fibrofatty tissue pads harbouring the relevant lymph nodes.

The pelvic lymphatic system is composed of parietal lymph nodes and trunks following the major pelvic blood vessels and of organ-related lymph nodes intercalated into the different mesenteries supplying the pelvic viscera. The following pelvic lymph node compartments or basins can be described: [13, 17, 18].

External Iliac Lymph Nodes

The external iliac lymph basin (Figs. 3.9, 3.10, 3.12, and 3.13) extends from the common iliac bifurcation down to the femoral ring along the psoas muscle. The medial border of the compartment is defined by the paravesical and obturator fossa. Lymph nodes may be further subdivided into a lateral group located between the external iliac vessels and the psoas muscle, an intermediate group between the artery and vein, and a medial group between the vein and the pelvic

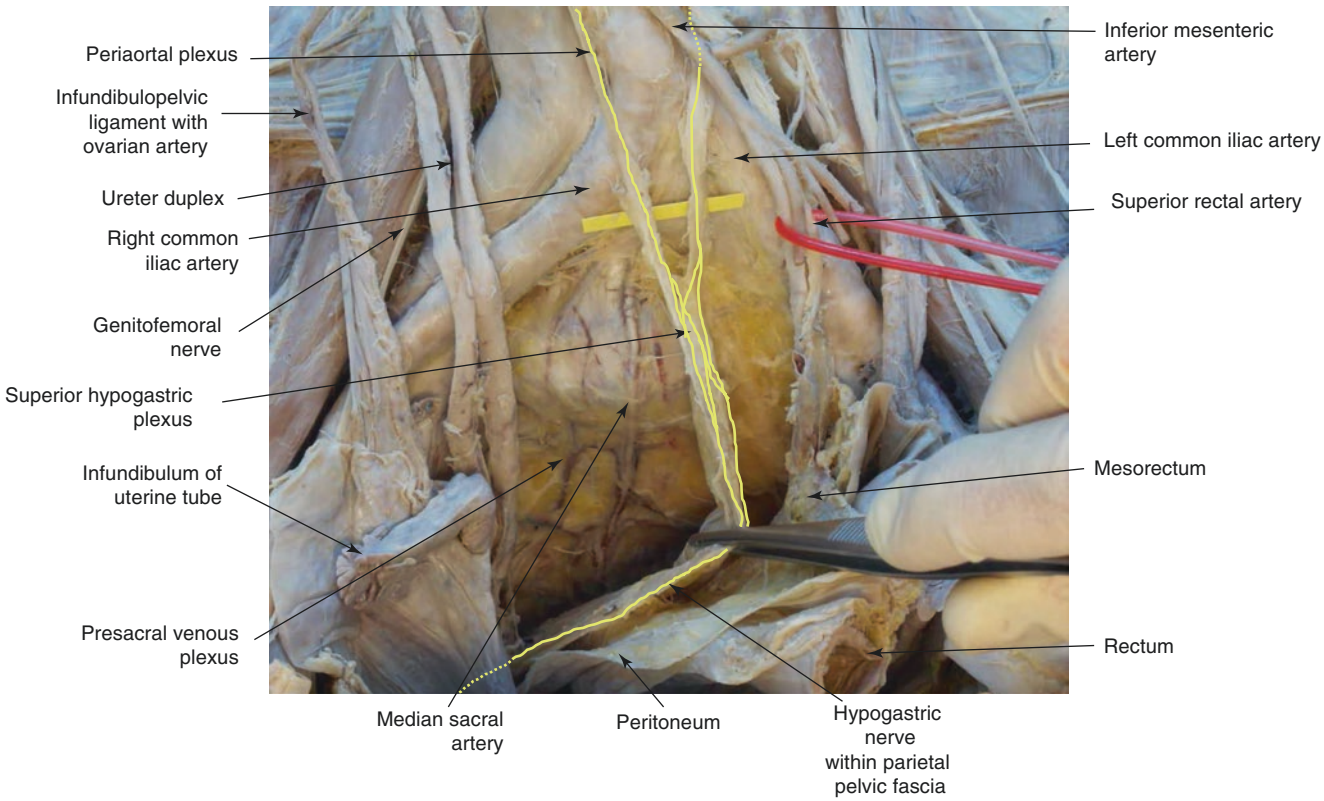

Fig. 3.17 Presacral region of a female pelvis. Ventral view. The peritoneum is removed, the rectum and mesorectum are shifted ventrally towards the left side, the pelvic parietal fascia is grasp by a forceps and also pushed ventrally to left side. The superior rectal artery is marked by a red vessel loop, the autonomic nerves are highlighted by *yellow lines* and plastric strip. Formaldehyde-fixed specimen

sidewall. Structures at risk during lymph node dissection are the external iliac vessels, in particular the vein when lifted up for harvesting medial lymph nodes, and the genitofemoral nerve when harvesting lymph nodes lateral to external iliac vessels. In some instances, minor branches originating from external iliac vessels to supply the psoas muscle may be torn and bleed during lymph node removal in this compartment.

Internal Iliac Lymph Nodes

Internal iliac lymph nodes (Figs. 3.10, 3.11, 3.12, and 3.13) follow the anterior and posterior trunk of the internal iliac artery and its corresponding branches, thus collecting lymphatic fluid from parietal/somatic structures, e.g. gluteal, perineal, sacral regions, as well as visceral organs, e.g. bladder, uterus, rectum. The compartment originates at the common iliac bifurcation and extends dorsally onto the piriformis muscle, caudally down to the levator ani muscle and ventrally to the origin of the visceral arterial branches for the urinary bladder and uterus. Most important for lymph node dissection is the direct vicinity of both the ureter and the delicate branches of the inferior hypogastric plexus approaching the internal iliac branches and lymph nodes from the medial side.

Common Iliac Lymph Nodes

The common iliac lymph nodes (Figs. 3.9, 3.10, 3.12, and 3.13) drain the external and internal iliac lymph nodes and follow the common iliac vessels towards the aortic bifurcation. Like the external iliac lymph nodes, they can be further subdivided into a lateral group facing the iliolumbar fossa, an intermediate group intercalated between the common iliac vessels adjacent to the lumbosacral trunk, and a medial group located along the pelvic brim underneath the common iliac vein. Structures at risk during lymph node dissection are the genitofemoral nerve on the lateral side, the lumbosacral trunk and obturator nerve at the dorsocaudal aspect and the ureter crossing the common iliac bifurcation.

Presacral Lymph Nodes

In front of the promontorium and underneath the aortic bifurcation the bilateral common iliac lymph routes drain into presacral lymph nodes (Figs. 3.12, 3.15, 3.16, 3.17, and 3.18), also termed promontory, midsacral or subaortic lymph nodes. The presacral compartment extends from the aortic bifurcation down to the end of the second sacral vertebra.

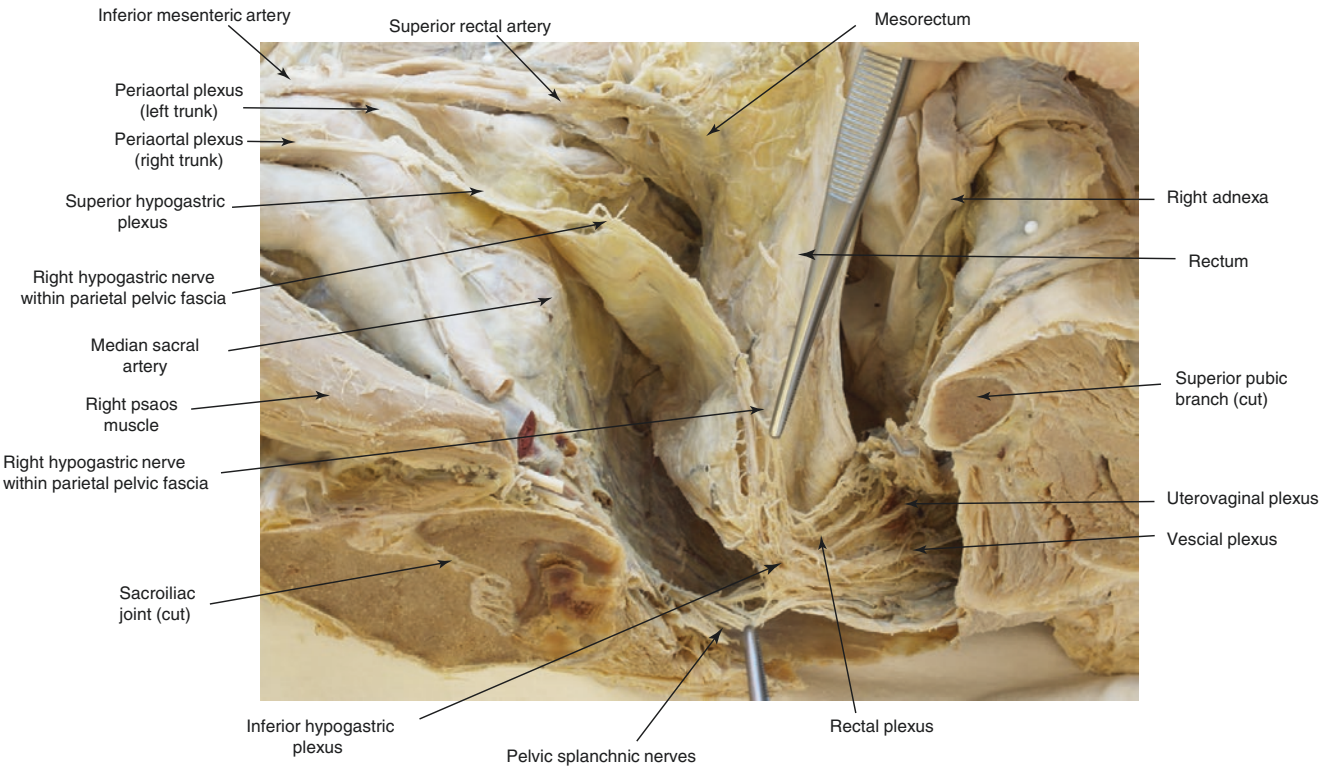

Fig. 3.18 Female left-sided hemipelvis. Parasagittal section, view from right side. The peritoneum is removed, the rectum and uterine adnexa are shifted ventrally, the forceps grasps the right hypogastric nerve embedded within the parietal pelvic fascia. Formaldehyde-fixed specimen with previous hysterectomy

Structures at risk during lymph node dissection are the median sacral artery and the presacral venous plexus as well as the thin-walled common iliac veins, in particular the left one due its exposed course running above the promontorium. Moreover, the promontorium region is crossed slightly left by the superior hypogastric plexus giving off the hypogastric nerves on both sides.

Obturator Lymph Nodes

The obturator lymph nodes (Figs. 3.9, 3.10, 3.12, 3.13, and 3.14) are distributed within the areolar fibrofatty tissue pad extending along the pelvic sidewall formed by the internal obturator muscle, the tendinous arcs of levator ani muscle and parietal pelvic fascia, and the levator ani muscle itself. The upper border is defined by the pelvic brim and the external iliac vessels, the dorsal border by the common iliac bifurcation, and the medial border by the visceral branches of the internal iliac artery. The obturator fossa is traversed by the neurovascular obturator pedicle composed of the obturator nerve recognizable by its pearl-white colour and the obturator artery and vein which join the nerve coming from below. The neurovascular obturator pedicle enters into the obturator canal beneath the superior pubic branch and frequently displays a pubic branch anastomosing with the inferior epigastric artery.

Lymph nodes in this compartment may be further subdivided into supraobturator (superficial) and infraobturator (deep) lymph nodes according to its position related to the obturator pedicle. Complete lymphadenectomy of the obturator fossa requires also subtle clearance of infraobturator nodes located below the obturator pedicle and along the upper surface of levator ani muscle. However, care must be taken not to injure the obturator pedicle itself as well as the neurovascular pedicles of the urinary bladder, in particular the vesical venous plexus.

Obturator and internal iliac lymph nodes may also be subsumed as paravisceral lymph nodes, as they are located adjacent to pelvic visceral organs which they drain – that is the urinary bladder and the uterus.

Parametrial/Mesometrial Lymph Nodes

Those lymph nodes located in close topographical vicinity to the uterus underneath the broad ligament (parametrium) and intercalated into the uterine mesentery (mesometrium)

correspond to the parametrial/mesometrial lymph nodes (Figs. 3.10, 3.11, and 3.12). They are embedded in areolar fibrofatty tissue and follow the branches of the uterine artery (vascular mesometrium). On the one hand, the aim of oncologic surgery is to completely remove these organ-related lymph nodes. On the other hand, the vesical neurovascular pedicles supplying the urinary bladder and the ureters crossing the parametrial compartment have to be preserved during lymphadenectomy of the parametrial/mesometrial tissue.

The paraaortic lymphatic system composed of the lumboaortic lymphatic chains extends beyond the pelvic lymph nodes and may be affected by lymphatic spread of tumors involving the uterine body and/or fundus and uterine adnexa. In these cases, lymphadenectomy should include removal of the lymph routes following the infundibulopelvic ligament and the ovarian vessels up to the paraaortic lymph basins. The following paraaortic lymh node compartments can be described:

Inframesenteric Lymph Nodes

Inframesenteric lymph nodes (Figs. 3.12 and 3.15) extend from the origin of the inferior mesenteric artery along the aorta and inferior vena cava down to the aortic and caval bifurcation. The lateral borders of this compartment are defined by the ureters running in front of the psoas muscles and undercrossing the ovarian vessels. On the left side, the ureter also undercrosses the root of the sigmoid mesocolon and the inferior mesenteric pedicle which has to be lifted up to achieve full exposure and protection of the ureter. The paraaortic lymph nodes are grouped into a readily discernible ventral chains including interaortocaval lymph nodes and less obvious dorsolateral chains. Thus, complete inframesenteric lymph node removal requires full exposure of both pericaval and periaortal tissue compartments.

However, dissection should be carried out carefully avoiding a too rigorous "cleaning" of the large prevertebral vessels to preserve or at least minimize the damage of the perivascular autonomic nervous network. Nerve fibers emerge from paravertebral sympathetic ganglia and form an aortic plexus composed of a left and right periaortal trunk with multiple interconnecting fibers crossing in front of the aortal wall. While the inferior mesenteric plexus follows the corresponding artery into the inferior mesenteric pedicle for the left and rectosigmoid colon, the superior hypogastric plexus descends in front of the aorta to divide in front of the promontorium into the left and right hypogastric nerves. Preservation of these autonomic nerve plexus is best achieved, when both the inferior mesenteric pedicle and superior hypogastric plexus are gently lifted up to gain access to the paraaortic lymph nodes. Care should also be taken to preserve the segmental lumbar arteries and veins and the small blood vessels approaching the ureter from the medial side.

Supramesenteric/Infrarenal Lymph Nodes

Supramesenteric lymph nodes (Fig. 3.15) include those lymph nodes of the paraaortic compartment located superior to the inferior mesenteric root and inferior to the left renal vein. Like in the inframesenteric compartment, supramesenteric lymph nodes are grouped around and in between the large vessels. Additionally, lymph nodes from the renal hilus drain into this compartment and autonomic nerve fibers derived from the aortic nerve plexus diverge to both sides to form the renal nerve plexus following the corresponding vessels (Fig. 3.12).

Autonomic Nerves of the Female Pelvis

As pointed out in the introduction, the challenge of oncologic surgery is twofold: aiming at the highest radicalness to ensure curative therapy and lowest loss of function to maintain quality of life after surgery. The latter one depends essentially on the preservation of those autonomic sympathetic and parasympathetic nerves mediating urogenital and anorectal functions [8, 9, 19–21].

Sympathetic nerves support the filling phase of the urinary bladder under resting conditions by relaxing the detrusor vesicae muscle and closing the internal urethral sphincter and bladder neck, thereby contributing to urinary continence. For controlled micturition, parasympathetic nerves suppress the sympathetic input and initiate contraction of the detrusor vesicae muscle and opening of the urethra and bladder neck. Thus, injury of the vesical nerve plexus may lead to both urinary incontinence and urinary bladder dysfunction.

Similar actions of autonomic nerves are also exerted for the control of anorectal function: While sympathetic nerves contribute to fecal continence by mediating internal anal sphincter contraction and rectal filling, parasympathetic nerves initiate defecation by relaxing the internal anal sphincter and enhancing rectal motility.

Moreover, both sympathetic and parasympathetic nerves are involved in regulating sexual functions. Sympathetic nerves mediate contraction of the musculature of the clitoris, vagina and uterus. Parasympathetic nerves are responsible for the lubrification of external genital organs and the filling of cavernous bodies thereby inducing swelling of the clitoris. Sexual dysfunctions due to surgically induced pelvic autonomic nerve injury are generally more evident in male patients, e.g. leading to erectile dysfunction and impaired ejaculation. However, the impact of autonomic nerve damage in female patients, such as inability to experience orgasm and insufficient lubrification, should not be underestimated.

The extent of autonomic nerve injury that will result in definite postoperative impairment of urinary and fecal continence as well as sexual functions remains unclear. The autonomic innervation of pelvic organs is characterized by its

functional redundancy, anatomically reflected by a bilateral organization of intrapelvic nerve plexus abundantly ramifying and connecting both sides with each other. Thus, partial or unilateral damage may be compensated by the remaining intact contralateral nervous input.

Sympathetic Nerves

The preganglionic sympathetic nerve fibers emerge from lower lumbar and upper sacral spinal cord segments and pass along the descending aorta on both sides as periaortal trunks. The periaortal nervous network fuses ventrolaterally to form the inferior mesenteric and superior hypogastric plexus. In front of the promontorium and slightly left to the midline the superior hypogastric plexus divides into the left and right hypogastric nerves. The hypogastric nerves often consist of various nerve bundles and are embedded within the parietal pelvic fascia extending in front of the sacral concavity. Gentle traction of the hypogastric nerve will lift up this fascial sheath in a tent-like fashion thereby illustrating its course along the pelvic side wall down to the inferior hypogastric plexus (Figs. 3.11, 3.15, 3.16, 3.17, and 3.18) [22].

Parasympathetic Nerves

Parasympathetic nerves derive from the sacral part of the parasympathetic nervous system residing in the sacral spinal cord. Together with ventral branches of the sacral spinal nerves S2–S4, these pelvic splanchnic nerves leave the ventral sacral foramina and pierce the parietal pelvic fascia on both sides to join the hypogastric nerves. The pelvic splanchnic nerves coming from dorsocaudally and the hypogastric nerves coming from dorsocranially converge to form the inferior hypogastric plexus (Figs. 3.10, 3.11, 3.16, and 3.18).

Inferior Hypogastric Plexus

The inferior hypogastric plexus is a mixed autonomic nerve plexus composed of both sympathetic and parasympathetic nerves. As this abundant nerve network provides the autonomic nerve supply to all pelvic viscera, the inferior hypogastric plexus is also termed pelvic plexus. In fact, several subgroups of delicate nerve fiber bundles diverge from the main plexus towards the different pelvic compartments to supply the corresponding organs: rectal plexus, uterovaginal plexus, vesical plexus.

Like the hypogastric and pelvic splanchnic nerves, the inferior hypogastric plexus is embedded within the parietal pelvic fascia covering the pelvic sidewalls. The nervous meshwork extends medially to the internal iliac artery and follows its branches to the pelvic organs. Posteriorly, the rectal plexus diverges at the level of the rectal ligaments/pedicles and enters into the rectal wall accompanied by the middle rectal artery. Anteriorly, the inferior hypogastric plexus widens in a fan-like manner and releases a lateral and medial trunk. The lateral trunk corresponds to the vesical plexus running to the bladder lateral and underneath the ureter. The nerve bundles follow the branches of the vesical artery and further ramify to innervate the distal ureter, urinary fundus and neck, and internal urethral sphincter. The medial trunk corresponds to the uterovaginal plexus passing to the uterine cervix and vagina medial and underneath the ureter. The nerve bundles follow the uterine artery after its intersection with the ureter and innervate the uterus and urinary bladder from both sides (Figs. 3.11, 3.16, and 3.18).

Ureter

Special attention should be paid to the topographic anatomy of the ureter [3, 23] due to its high vulnerability to intraoperative injury for the following reasons:

- considerably long course (25–30 cm) along the interface between the retro- und intraperitoneal space exhibiting segments susceptible to damage at virtually all levels.
- hampered identification caused by obesity, previous surgery or radiation, inflammatory or neoplastic events, scarce peristaltic movements.
- morphological appearance and size similar to vascular structures.
- relatively common congenital anomalies (e.g. ureter duplex, ureter fissus, crossed ureter, retrocaval ureter).

Abdominal Segment

The abdominal segment (Figs. 3.12, 3.15, and 3.16) extends from the renal pelvis to the pelvic brim in front of the psoas muscle. The course of the ureter may vary from a paravertebral position close to either the vena cava or aorta to a lateral position along the outer border of the psoas muscle. The ureter is crossed anteriorly by the ovarian vessels and posteriorly by the genitofemoral nerves. On the left side, the ureter additionally undercrosses the root of the sigmoid mesocolon and the inferior mesenteric pedicle. Inspite of the close proximity between the ureter and the digestive tract, both are clearly separated by the anterior renal fascia delimiting the intraperitoneal from the retroperitoneal organs to which the ureter belongs.

While the ovarian vessels extend further laterally to form the infundibulopelvic ligaments, the ureters run medially creating ureteric peritoneal folds. Thus, at the pelvic brim the

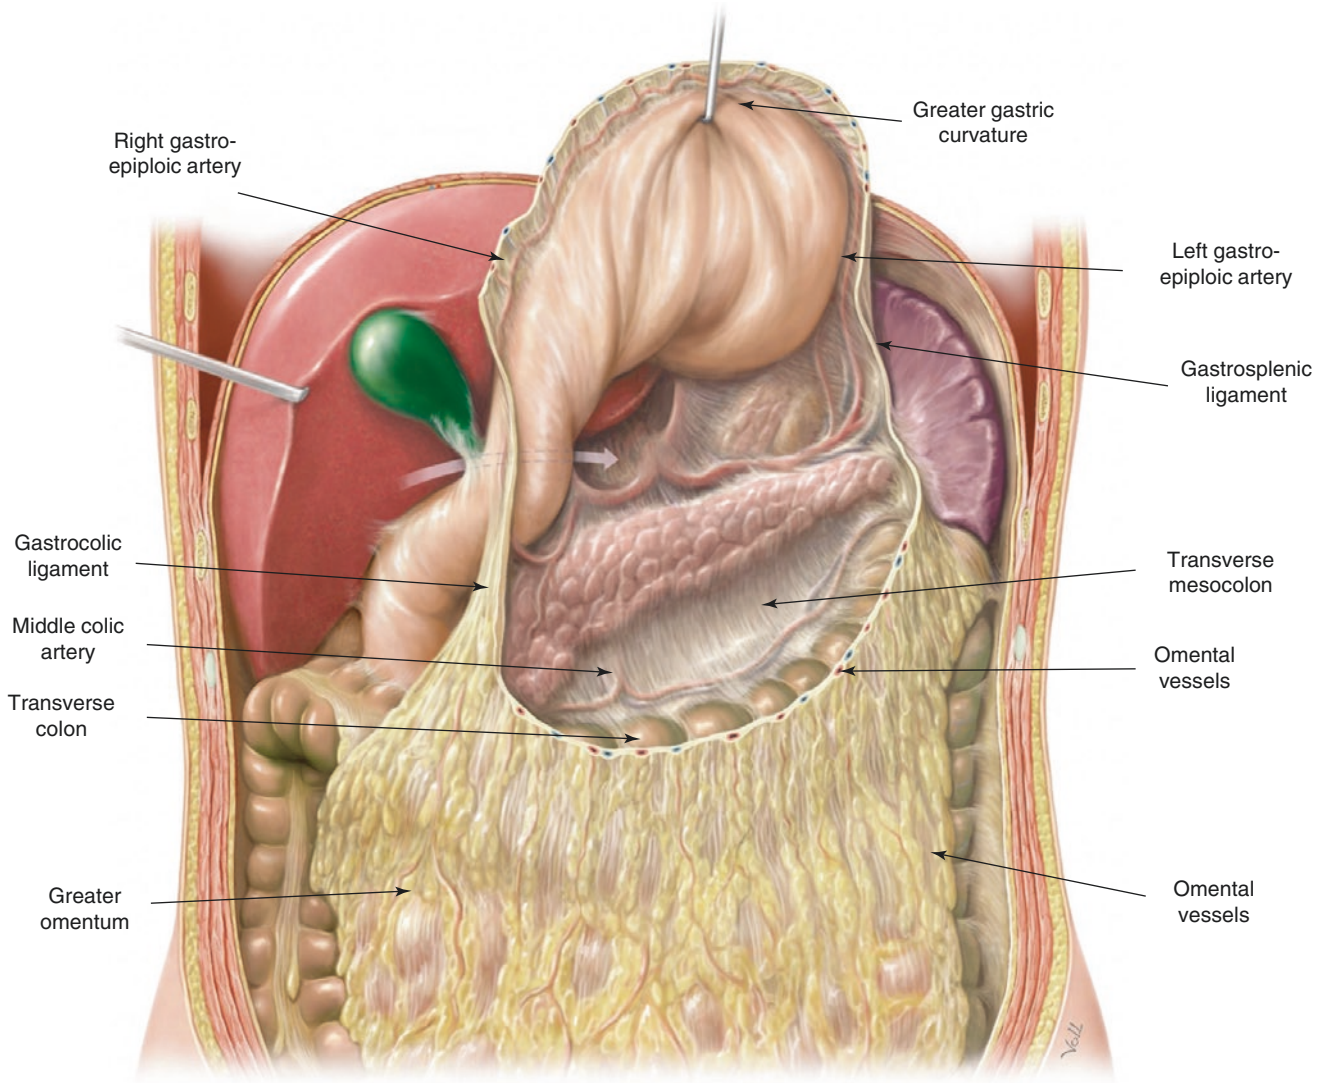

Fig. 3.19 Greater omentum. Ventral view. The gastrocolic ligament is partially cut, the stomach is flipped upwards to expose the lesser sac (Reproduced from Schünke et al. [24])

ureteric fold is closely related to and located medially to both the infundibulopelvic ligament and the ovary, so that care should be taken to protect the ureter underneath its peritoneal fold when mobilizing the uterine adnexa (Figs. 3.6, 3.9, 3.11, 3.12, and 3.17).

Pelvic Segment

In most cases the ureter enters the pelvic cavity anterior to the common iliac artery on the left side and anterior to the external iliac artery on the right side. The ureter further descends underneath the peritoneum and is related laterally to the branches of the internal iliac artery (obturator, superior vesical and uterine artery) and the obturator nerve and medially to the uterosacral ligament and its corresponding rectouterine fold as well as to the inferior hypogastric plexus.

Before the ureter reaches the urinary bladder via the vesicouterine ligament, the parametrium has to be traversed at the level of the uterine cervix (paracervix). The distance of the ureter from the uterine cervix and lateral vaginal fornix is ca. 1–2 cm. While the uterine artery bends medially to reach the uterine cervix, the ureter undercrosses the vessel in anterior oblique direction. As this area is a common site of ureter injury, the distance between the ureter and both the uterine cervix and artery can be enlarged by shifting the uterus to the contralateral side, e.g. by means of a uterus manipulator (Figs. 3.5, 3.8, 3.10, 3.11, 3.12, 3.13, and 3.17).

Blood Vessel and Nerve Supply

Due to its considerable length the ureter is supplied by various sources of blood vessels including branches from the aorta, renal, ovarian and internal iliac arteries. Of note is the observation that the nutrient arteries approach the abdominal segment from the medial side and the pelvic segment from the lateral side. Consequently, when mobilizing or dissecting the ureter, special care has to be taken to preserve the blood vessels at the medial side of the ureter above the pelvic brim and at its lateral side below the pelvic brim. Moreover, excessive denudation of the ureter over a long distance should be avoided to preserve the adventitial layer together with the mesoureter which contain an elaborated vascular plexus. Due to this intramural anastomotic system interruption of one blood supply can be compensated by the remaining vascular sources given that the periureteric tissue is left intact.

The autonomic innervation of the ureter mediates its peristaltic movements and pain perception. The nerve fibers derive from the aortic, superior and inferior hypogastric plexus. The distal ureter is innervated by nerve fibers originating from the lateral trunk of the inferior hypogastric plexus and running within the superior portion vesical plexus. To prevent bladder and sexual dysfunctions due to injury of the vesical plexus, manipulation of the distal ureter at the region of the vesicoureteric junction and vesical trigone should be avoided.

Greater Omentum

Both infragastric and infracolic omentectomy require knowledge of the topographic anatomy of the greater omentum (Fig. 3.19). Embryologically, the greater omentum is part of the dorsal mesogastrium which descends from the greater gastric curvature to cover the small intestinal loops and ascends back to reach the transverse colon and become adherent with the transverse mesocolon. The portion extending between the greater gastric curvature and the transverse colon is also termed the gastrocolic ligament. The gastrosplenic ligament corresponds to the continuation of the greater omentum at its left border connecting the stomach with the spleen. Although the greater omentum is fused to the transverse colon, both structures can be separated from each other by gently detaching the adherent peritoneal surfaces. Once the greater omentum has been released from the transverse colon or the gastrocolic ligament has been split, the omental bursa is opened.

At a distance of approximately 1–2 cm and parallel to the greater gastric curvature, the right and left gastroepiploic arteries run within the gastrocolic ligament and give off nutrient branches to the gastric wall. Descending branches of the gastroepiploic arc traverse the greater omentum to supply both the infragastric and infracolic parts.

The space between the peritoneal layers is usually filled with adipose tissue which may be massive in obese patients. On the other hand, the greater omentum may be thin, translucent or even congenitally absent. Beside fat storage the greater omentum functions as immuncompetent organ by means of its high content of macrophages and the ability to cover and thereby limit intraperitoneal inflammations [3].

Anterior Abdominal Wall

The topographic anatomy of the anterior abdominal wall (Figs. 3.20 and 3.21) [3] is particularly relevant, when multiple trocar incisions are applied in minimal invasive techniques bearing the risk of vascular, nerve or organ injuries. The abdominal wall is composed of the following layers:

- Skin
- Subcutaneous tissue
- Musculofascial layer
- Transversalis fascia
- Preperitoneal space
- Parietal peritoneum

Below the umbilicus the peritoneal layer displays five folds:

- 1 median umbilical fold (obliterated urachus)
- 2 medial umbilical folds (obliterated umbilical arteries)
- 2 lateral umbilical folds (inferior epigastric vessels)

The median umbilical fold is continuous with the urinary bladder fundus and sometimes stretches the urinary bladder cavity cranially which may lead to inadvertent injury of the urinary bladder wall during suprapubic trocar placement. The medial umbilical folds separate the supravesical from the medial inguinal fossae. Although the umbilical arteries are mostly obliterated, in some cases these vessels are still patent and may cause bleeding when the medial umbilical folds are perforated inadvertently by trocars.

While both the median and medial umbilical folds converge upwards to reach the umbilicus, the lateral umbilical folds pass laterally to the umbilicus behind the rectus abdominis muscle. The lateral umbilical folds extend between the medial and lateral inguinal fossae – the latter ones corresponding to the deep inguinal rings into which the uterine round ligaments enter. The inferior epigastric vessels originate medially to the deep inguinal ring and ascend under-

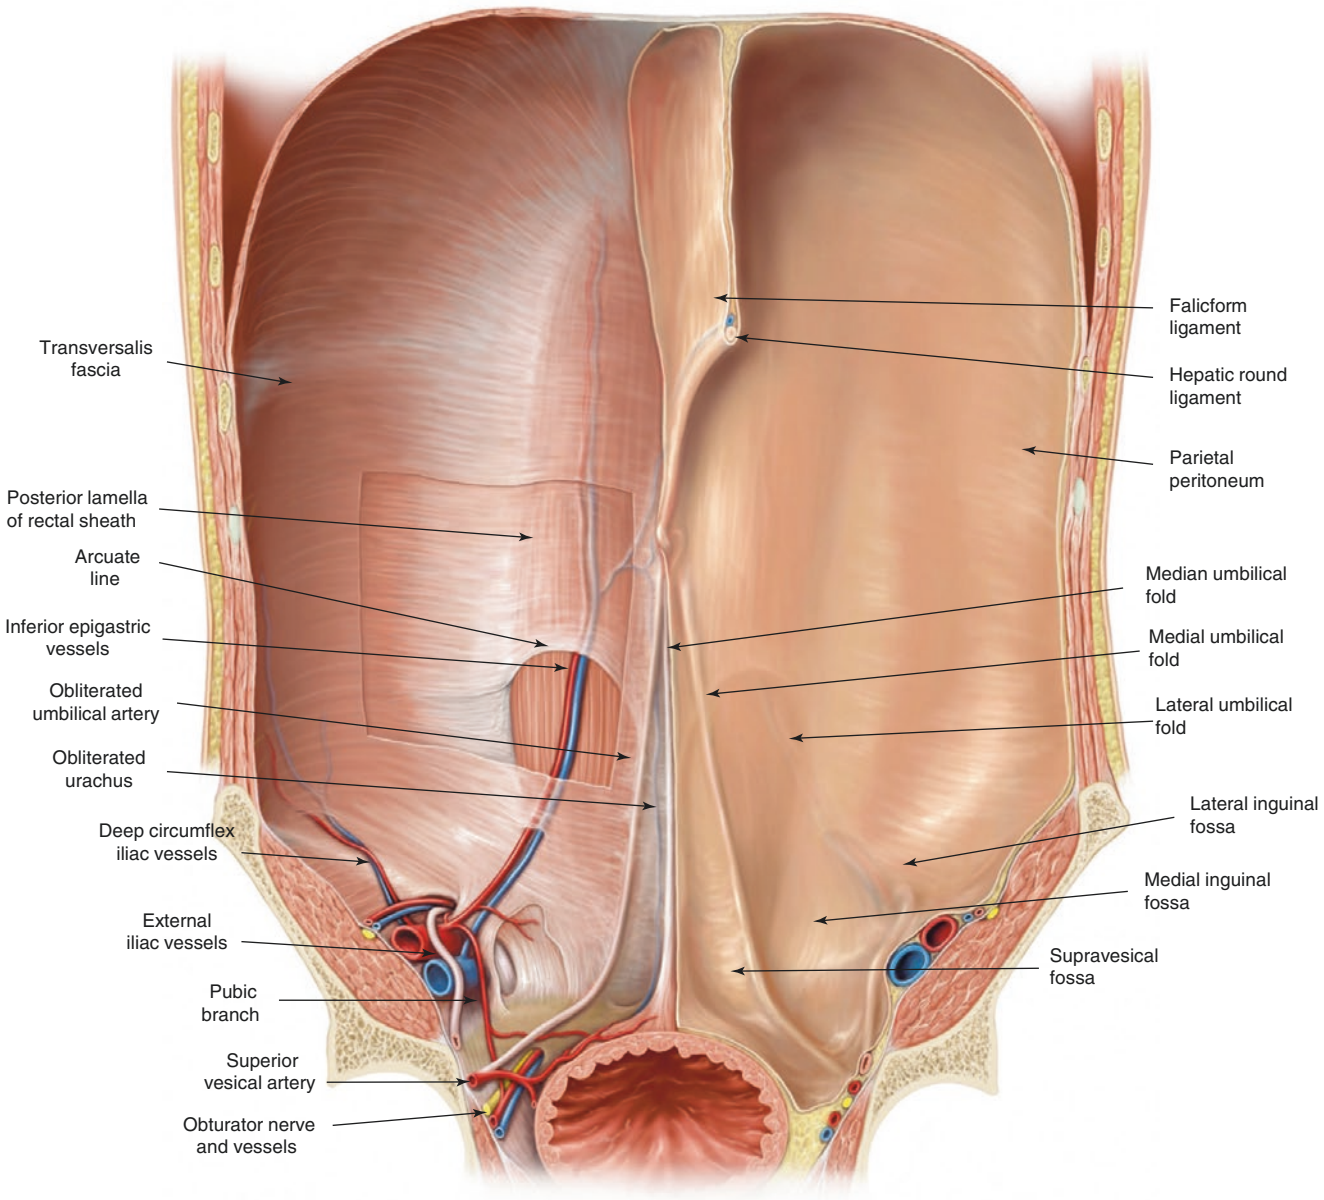

Fig. 3.20 Backside of the anterior abdominal wall. Frontal section, dorsal view. On the left side the peritoneum and part of the transversalis fascia are removed

neath the peritoneum and transversalis fascia to reach and enter into the rectus abdominis muscle. Frequently, the inferior epigastric vessels give off a pubic branch which passes along the femoral fossa and over the pectineal ligament to anastomose with the obturator vessels.

Whereas the transversalis fascia is ubiquitously present and most developed in the lower abdominen, the posterior lamella of the rectus sheath is only present in the upper addomen and fades out at the level of the arcuate line below the umbilicus. The preperitoneal space extends between the transversalis fascia and the parietal peritoneum and is filled by fat. In obese patients an increased content of adipose tissue may considerably thicken the preperitoneal space – which has to be considered during trocar placement to avoid unwanted insufflation of this tissue compartment.

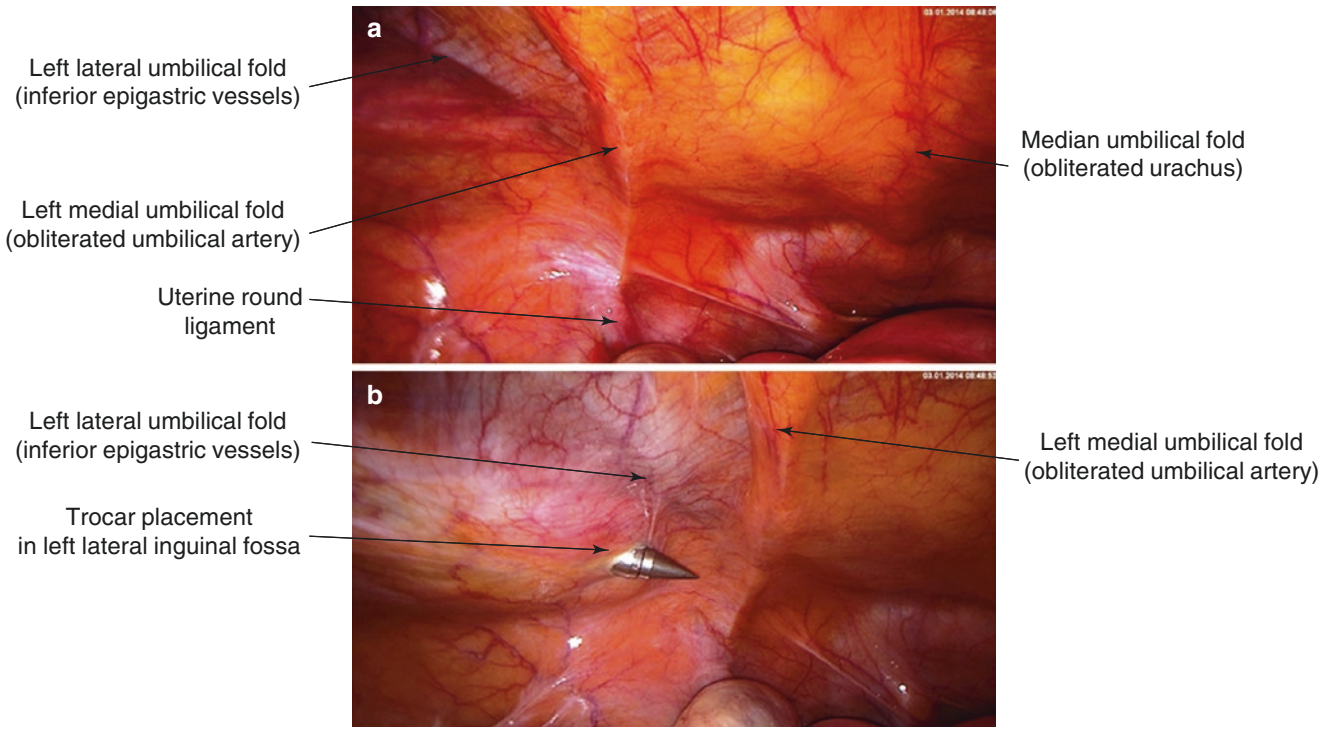

Fig. 3.21 Backside of the left anterior abdominal wall. Laparoscopic view. The three umbilical folds are discernible (**a**), the entry site of the trocar (**b**) is lateral to the lateral umbilical fold

Part III

Imaging and Diagnostics

Clinical Diagnostics Before Hysterectomy

4

Stefan Rimbach

Introduction

Diagnostic measures before hysterectomy aim to ensure patients general perioperative safety with regard to risk management as well as to prepare accuracy, safety and success of the planned surgical procedure.

In order to be efficient, tools and extent of diagnostics should allow to

- prove the indication for hysterectomy
- assess general pre-operative risk (including co-morbidity and anaesthesiological factors)
- reveal individual (risk-) factors referring to
  - surgical procedure planning
  - individualized surgical strategy (e.g. interdisciplinary procedure)
  - ressource management (e.g. operating room time)
  - individualized perioperative management
- reveal/exclude unsuspected additional findings (e.g. adnexal masses)
- reveal/exclude unsuspected malignancy
- exclude contraindications
- save as a basis for patient information to achieve informed consent

Diagnostic Tools Overview

Basic (mandatory):

- anamnesis/patient history
- physical examination
- gynecological examination: inspection, palpation
- cervical cytology

Additional (optional):

- colposcopy
- vaginal ultrasonography (endometrium, intracavitary pathology, myometrium, myometrial pathology, adnexa, pouch of douglas
- renal sonography
- MRI
- (MR) urography

Laboratory investigations:

- according to institutional standard
- and to individual risk profile
- pregnancy test in premenopausal women

Patient History

Patient history comprises personal as well as family history. Familial disorders may influence surgical and perioperative planning. E.g. hereditary diseases of the blood coagulation system may be of utmost importance for perioperative thrombosis prevention, choice of anaesthesia and pain therapy as far as catheter methods are concerned, and for coagulation management during surgery; rare conditions such as HLRCC-syndrom (hereditary leiomyomatosis and renal cell carcinoma) predispose to malignancy such as sarcoma in case of presumed benign myoma. Personal patient history informs the surgeon about individual risks such as co-morbidity, previous surgery (e.g. leading to adhesions), medication influencing procedural planning (e.g. anti-coagulation), but also feasibility aspects for the planned hysterectomy (e.g. history of vaginal births vs cesarean sections influencing the route of hysterectomy in terms of vaginal vs abdominal approach). Menstrual history may not only lead to the hysterectomy indication itself in case of bleeding disorders, but also add information on the risk of malignancy in case of irregular bleeding. A typical history of dysmenorrhea may lead to the suspicion

of endometriosis. Inquiring about bladder and intestinal function may reveal (pre-)existing incontinence problems and play a role for procedure planning as well as for the evaluation of potential post-surgical conditions or presumed complications. The same applies for anamnestic pain or neurological symptoms. Psycho-social aspects should not lack in a complete patient history.

Physical and Gynecological Examination

Gynecological examination including inspection and bimanual palpation allow to evaluate size, position and mobility of the uterus, as well as the adnexa, parametria and pouch of douglas.

Inspection of the vaginal fornix may e.g. reveal vaginal endometriosis (Fig. 4.1), malformations like a vaginal septum (Fig. 4.2) or raise suspicion of vaginal infection, usually rendering hysterectomy contraindicated until successfully treated.

In some instances, such as suspected endometriosis, rectovaginal palpation may additionally give informations on the rectovaginal septum . Palpation may be focally painful, reveal induration or resistance, caused at level of the sacro-uterine ligaments (Fig. 4.3) or the rectovaginal space (Fig. 4.4).

Size and mobility of the uterus as determined by palpation may decide about the surgical approach to hysterectomy or indicate further imaging such as MRI. In case of prolapse, inspection and palpation may allow differentiation between levels and compartments affected and different forms of cele formation. Depending on the clinical impression further functional testing such as urodynamics and ultrasound may be indicated.

Physical examination does also comprise inspection and palpation/percussion of the abdomen, the inguinal regions, back with renal beds and case depending the breast/thoracic area, extremities and head/neck area.

Fig. 4.1 Inspection of the vaginal fornix: blue spots as a sign of vaginal endometriosis

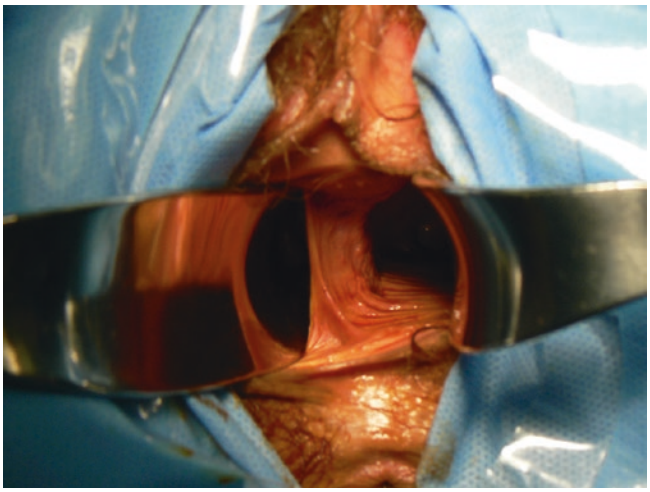

Fig. 4.2 Inspection of the vagina (foto taken during surgery): vaginal septum

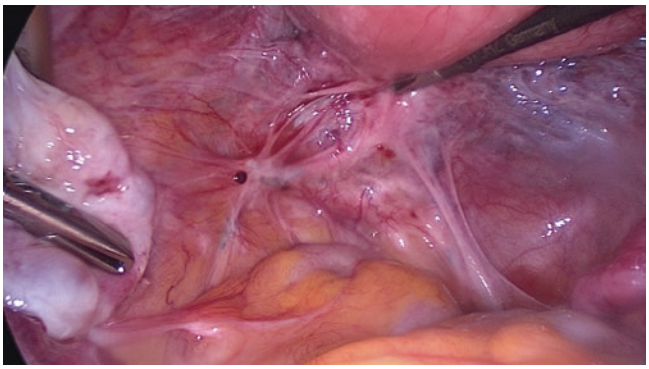

Fig. 4.3 Laparoscopic aspect of the palpatory painful and indurated sacro-uterine ligament on the left side affected by deep infiltrating endometriosis

Cervical Cytology and Colposcopy

Cervical cytology is important to exclude cervical pathology before hysterectomy, and colposcopy may add detailed information relevant to surgical strategies, e.g. when discussing total versus supracervical procedure. HPV-testing may also add helpful information.

Imaging Techniques: Ultrasonography and MRI

Vaginal sonography as an adjunct to clinical examination allows to double check clinical information on size and position of the uterus, but especially gives further insight to the structure of the endometrium and myometrium [1, 2]. Thus, intracavitary pathology such as polyps, submucous fibroids or irregular formations suspect for malignancy can be detected and hysterectomy indication adapted, or further

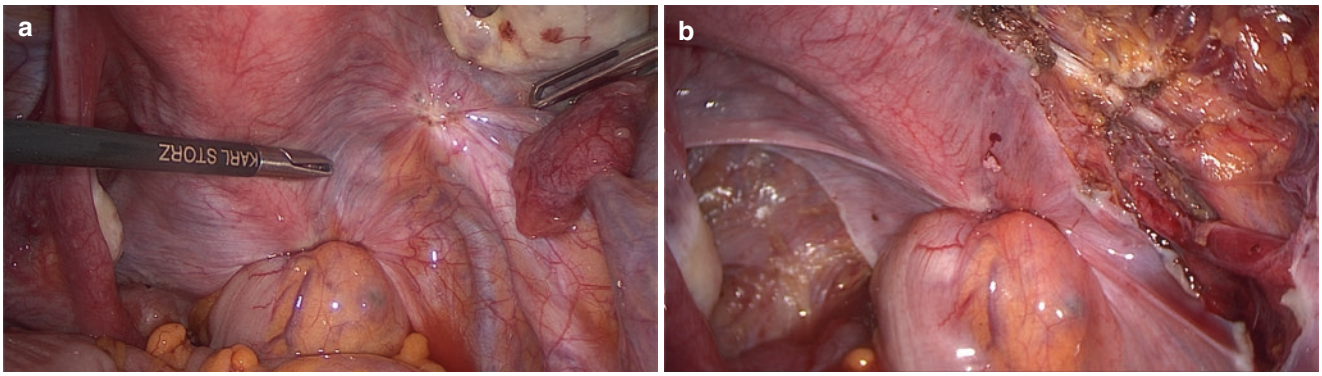

Fig. 4.4 Laparoscopic aspects (**a** = overview, **b** = close-up during preparation) of the palpatory painful and indurated recto-vaginal septum affected by a nodule of deep infiltrating endometriosis

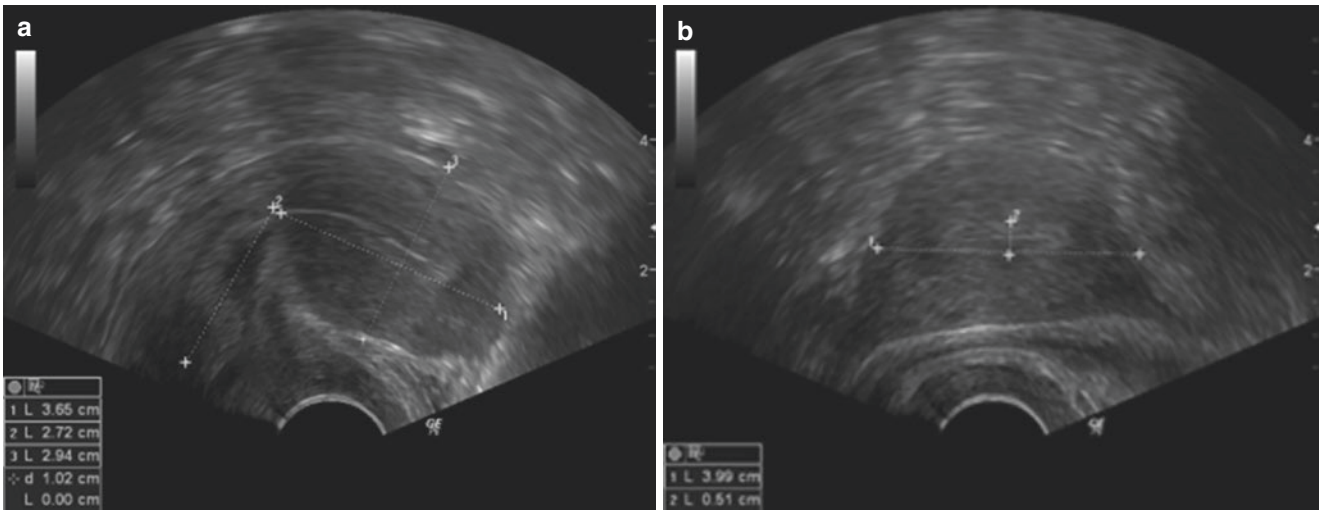

Fig. 4.5 (**a**, **b**) Preoperative vaginal sonography of a regular uterus

investigations such as hysteroscopy or endometrial biopsy scheduled prior to hysterectomy [3].

Figure 4.5 shows the vaginal-sonographic appearance of a uterus before hysterectomy (in this case for dysfunctional uterine bleeding). Detectable pathologies are absent. Size and position of the organ, endometrium and myometrium can be described.

Figures 4.6, 4.7, and 4.8 show examples of endometrial, myometrial and intracavitary pathology as can be detected and described by vaginal sonography.

With regard to additional findings such as endometriosis, ovarian tumors, ascites, sonographic investigation of the adnexa, pouch of douglas, and kidneys may be helpful. Examples are given in Figs. 4.9, 4.10, and 4.11, showing cystic adnexal tumors of tube and ovary.

MRI may play a role in diagnosing and staging endometrial tumors, e.g. in case of an endometrial carcinoma as shown in Fig. 4.12.

Large fibroids may be better visualized by MRI than sonography, if relevant to the projected surgery (Fig. 4.13). MRI may also add valuable informations to vaginal sonography and Doppler results when findings are suspicious for sarcoma [4–7], a question which is most relevant before hysterectomy when morcellation is discussed.

Ureteral compression with subsequent renal dilation may be detected by urography, which is advisable especially if obstruction is presumed or ureters shall be visualized by intraoperative preparation (Figs. 4.14 and 4.15). Postoperative control may be advisable when there was a risk of ureteral impairment during hysterectomy.

Laboratory Investigations

Laboratory investigations are done above all to exclude individual risks with regard to anaesthesia. Usually there exist institutional standards or individual risk profile requires serum specimens [8]. In order to exclude pregnancy, a serum or urinary test is performed in premenopausal women.

Conclusion

As a basis for clinical indication, counselling and decision making, patient history and physical examination are required when hysterectomy is considered. Cervical cytology seems mandatory in order to exclude or diagnose cervical dysplasia. Imaging serves as an adjunct to clinical examination. Vaginal sonography will be helpful and applied in most cases before hysterectomy. In selected circumstances, MRI may add valuable information. The necessity of laboratory investigations beyond a pregnancy test in fertile patients varies depending on the indication and co-morbidity of the individual patient. The results of clinical examinations before hysterectomy serve to verify the indication and exclude contraindications, minimize risks, and allow individualized procedure planning as well as adequate patient information in order to achieve informed consent.

Ultrasound Imaging

5

Werner Dürr

Abbreviations

EMJ — Endometrial-myometrial junction [1]. Anatomically, an inner layer of myometrium surrounding the endometrium differentiated sonographically and by MRI from the other myometrium by lower echogenity (Figs. 5.2 and 5.3). This layer is also part of the endometrial-subendometrial unit "archimetra" [2], which evolutionary is an old part of the uterus. According to the theory of Leyendecker, the EMJ is of importance for uterine peristalsis by performing contractions and is believed to play a role in fertility and the development of adenomyosis and endometriosis [3].

Glass body — 3D glass-body rendering. Grey values in a transparent mode and color presentation together give a glass-like image of vascularization (Fig. 5.5). Color Doppler alone without grey values shows the vascularization without any surrounding tissue (Fig. 5.6).

Inversion mode — Image presentation of surfaces in a technically inverted way. Findings of low or no echogenity present echogenic (Fig. 5.7) whereas echogenic structures present low echogenic.

OmniView — Image presentation on the basis of a stored volume and a chosen plane of section.Used to render structures in planes not ordinarily visible in real time e.g. the uterus can be shown in a frontal scan in its whole length without its usual flexure, so to say "stretched" (Fig. 5.1).

TAS — Transabdominal sonography

TUI — Tomographic ultrasound imaging. Imaging of a sonographic finding in diverse, simultaneously presented parallel planes of section on the basis of a stored volume (Fig. 5.4)

TVS — Transvaginal sonography

US — Ultrasound

VCI — Volume contrast imaging. Image presentation in a certain selectable slice thickness for better contrast and suppression of artifacts on the basis of a special technique with assemblage of diverse, parallel scans of close vicinity and their following superposition with the effect of better discrimination between structures of different echogenity (Fig. 5.1).

Introduction

Independent of the indication for hysterectomy, each operating surgeon will be highly interested in the detailed information on the uterus given by preoperative imaging methods, such as sonographic imaging.

To know what to expect enables the surgeon to define an adequate surgical management and prevents unexpected intraoperative findings. This is one of the most important reasons for preoperative sonographic imaging.

Especially transvaginal sonography (TVS), more so than transabdominal sonography (TAS), gives us the opportunity to closely approach the regions of interest within the minor pelvis. Because of the short distances within the minor pelvis, probes of high frequency with corresponding high resolution can be used to discover even very small uterine alterations.

Developments such as color Doppler and volume scan give additional diagnostic extensions and refinements.

As sonography is an imaging method, this chapter will be primarily image-based appropriate to the saying, "A good image tells more than a thousand words".

Normal Findings

It is important to know the normal sonographic appearance of the uterus (Figs. 5.8 and 5.9) to be able to identify uterine alterations as findings deviating from the norm. In addition to the classic B-mode sonography, other techniques, such as OmniView and VCI, are demonstrated in this section (see Fig. 5.1). Normal findings of the so-called EMJ are also demonstrated by images (Figs. 5.2 and 5.3).

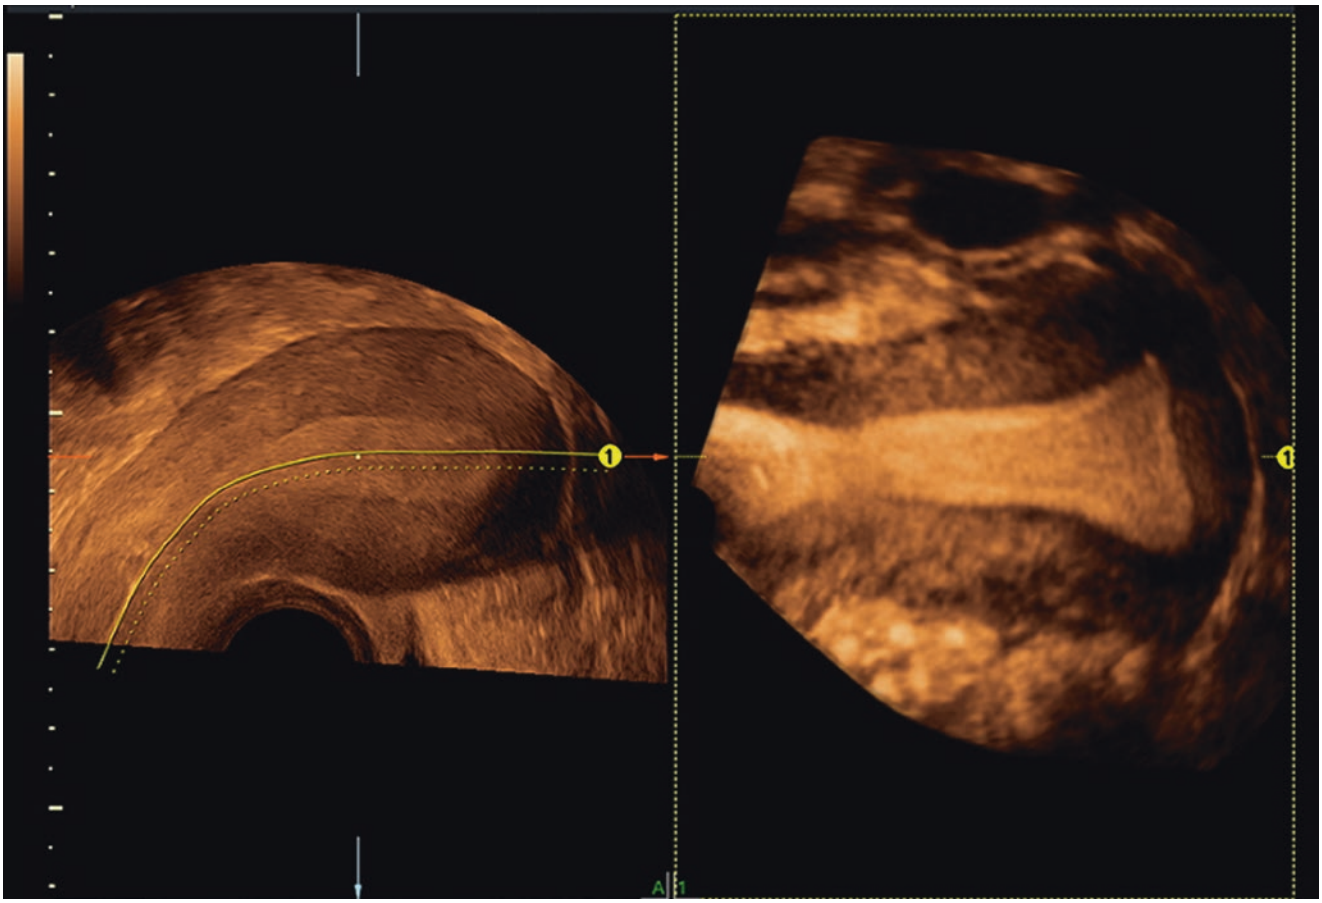

Fig. 5.1 To demonstrate OmniView and VCI technique, a frontal scan to present the uterus in its total length, so to speak "stretched" (*right image*). VCI technique is used to give a more plastic impression of the endometrium (*right image*) (Image from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

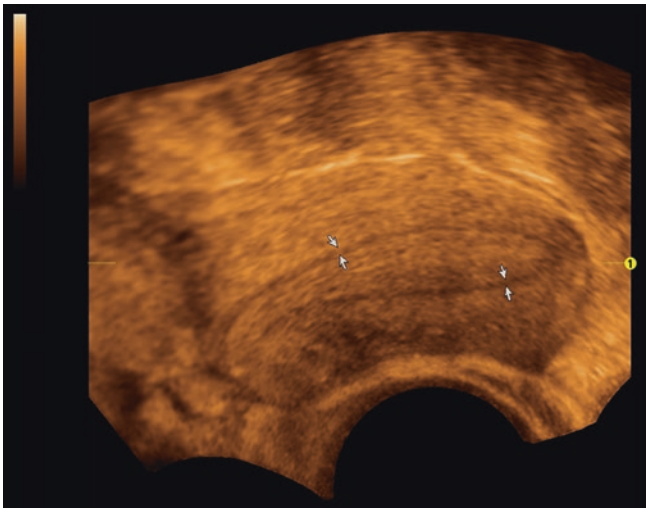

Fig. 5.2 This longitudinal scan in 3D technique shows an anteverted, anteflected, normal sized uterus with a remarkably clear and sharp demarcation, in comparison to endometrium and myometrium hypoechoic line (*arrows*) which represents the inner layer of myometrium, surrounding the endometrium. This endometrial-myometrial junction (EMJ) is of importance for uterine peristalsis by performing contractions and is believed to play a role in fertility and the development of adenomyosis and endometriosis [2–4]. It is unusual to see the EMJ as clear and demarcated as in this image (Image from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

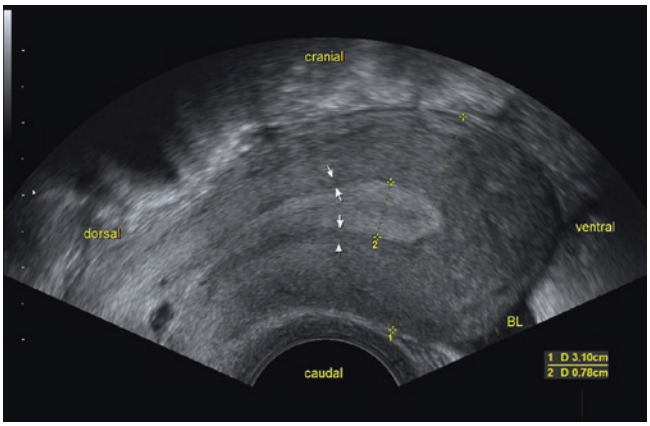

Fig. 5.3 This longitudinal scan shows an anteverted, anteflected, normal sized uterus with a fundal uterine wall thicker than expected, in comparison to the anterior and the posterior uterine wall. As an additional finding, a normal EMJ (*arrows*) (Image from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

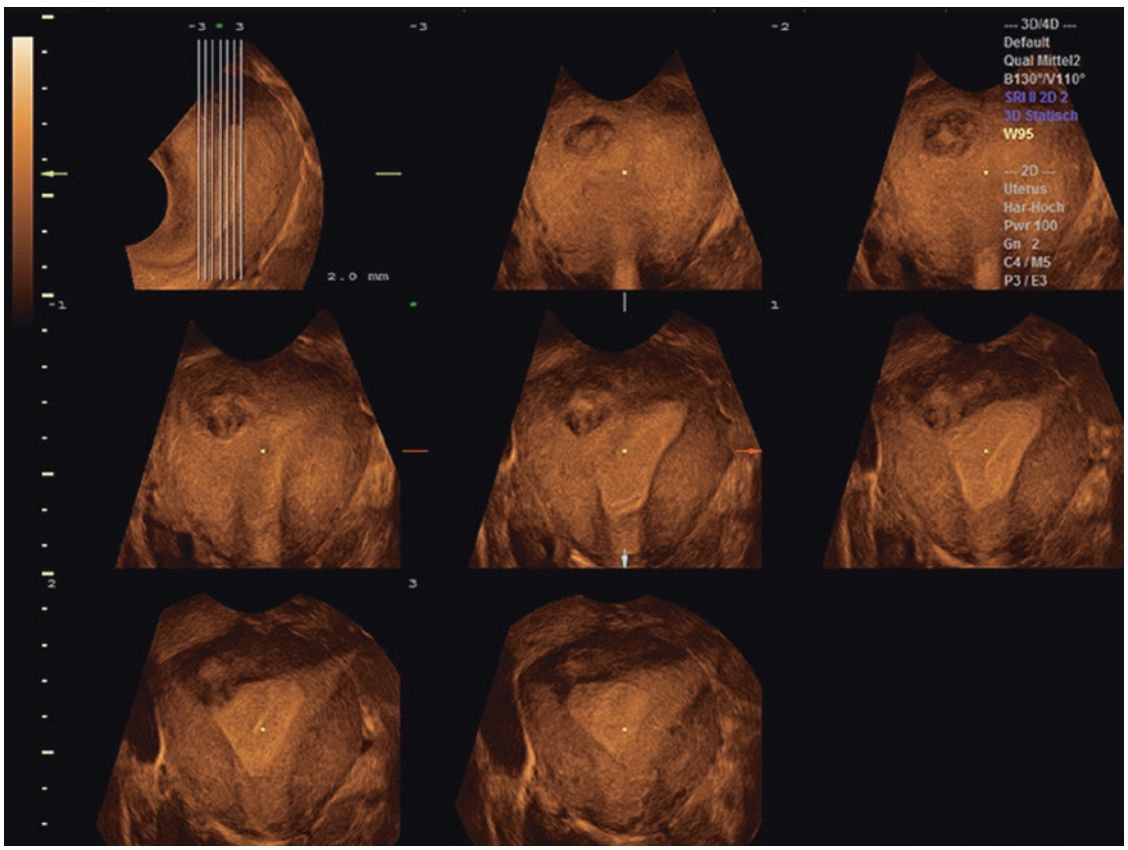

Fig. 5.4 A myoma, for example, as shown by Figs. 5.19, 5.20, and 5.21, can also be presented by a tomographic technique, such as TUI, as shown in this image (Image from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

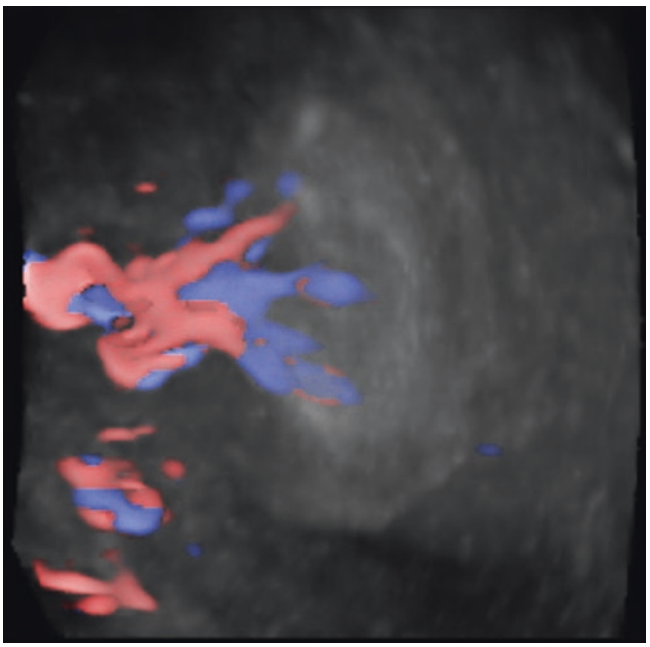

Fig. 5.5 3D color Doppler glass body modus shows impressively pedicle vessels and their branching as well as the diminuating echogenity of endometrial polyp, endometrium and myometrium

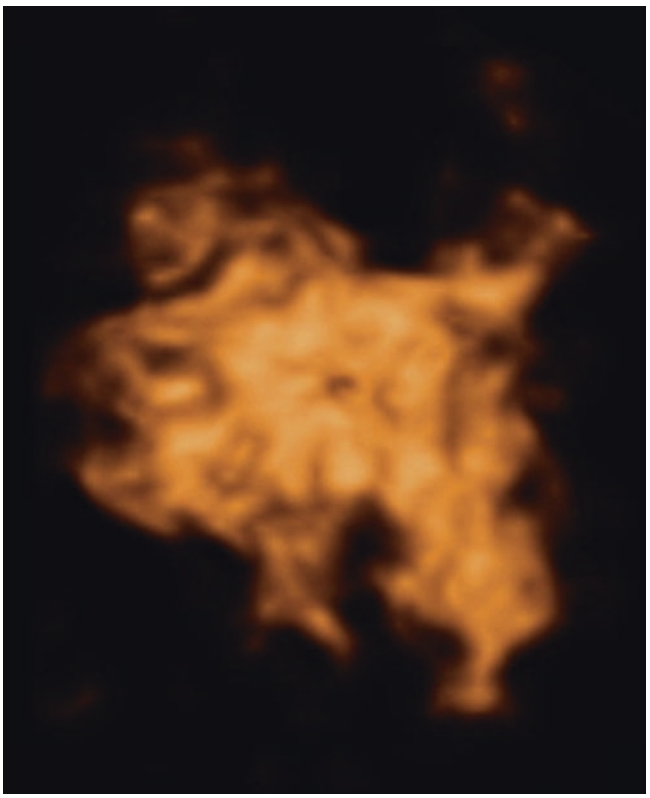

Fig. 5.7 3D presentation of a deep infiltrating endometriosis, inversion modus. The very irregular surface and the pedicle-like extensions give an impression of the highly aggressive potential of this kind of endometriosis and its suspected tendency to progress (Image from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

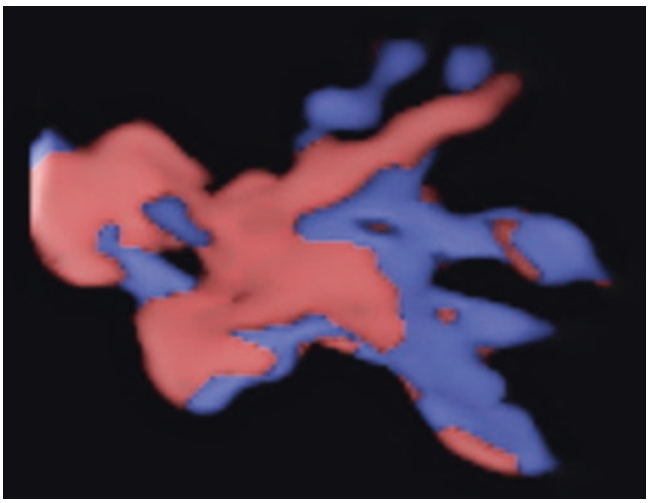

Fig. 5.6 Pure color Doppler without any surrounding tissue shows precisely the branching pedicle vessels (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

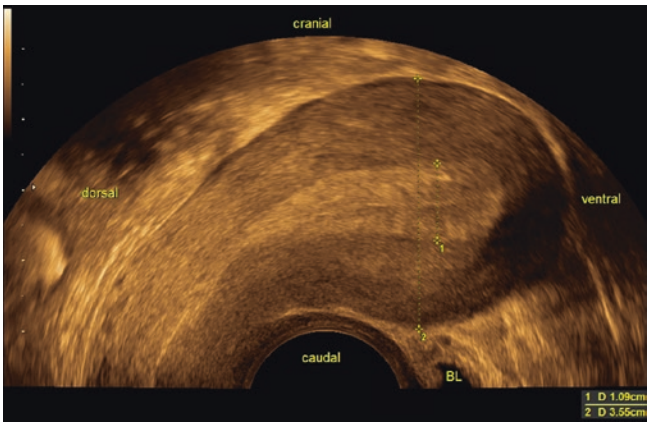

Fig. 5.8 Longitudinal scan of anteverted, anteflected, normal sized uterus with nearly homogeneous echodense endometrium typical for the progestogenic second phase of the cycle

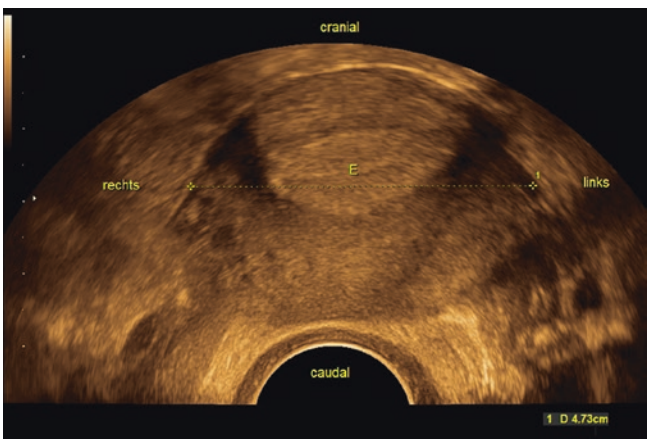

Fig. 5.9 The same uterus, transverse scan through the corpus uteri at its widest lateral extension. See above additionally Fig. 5.1 which demonstrates OmniView and VCI techniques (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

Congenital Uterine Anomalies

Some of these anomalies can easily be missed by US if only a longitudinal scan, showing a normal uterus, is performed. Once the investigator has documented a normal uterus he does not always think of a second one, such as a uterus duplex or bicornis or a septate uterus. By performing a transverse scan, it is hard to miss such uterine malformations. Within a few seconds the transverse scan reveals these anomalies, here for example an arcuate uterus (Figs. 5.10, 5.11, and 5.12), see also Fig. 5.3, and a septate uterus (Figs. 5.13 and 5.14). Additionally, an overview of uterine malformations is given by schematic drawings (Fig. 5.15).

Fig. 5.10 Additionally to Fig. 5.3 a longitudinal scan of the same uterus presenting the cervical part, showing the cervical channel with a small amount of (anechoic) mucus and, at the level of the internal os, a small retention cyst. The distance from internal to external os, here measured at 2.4 cm, corresponds to the cervical length. Close to, but distinct from the external uterine orifice, the dorsal vaginal wall can be seen, here indicated by the two measuring points which demonstrate the wall- thickness of 3.3 mm

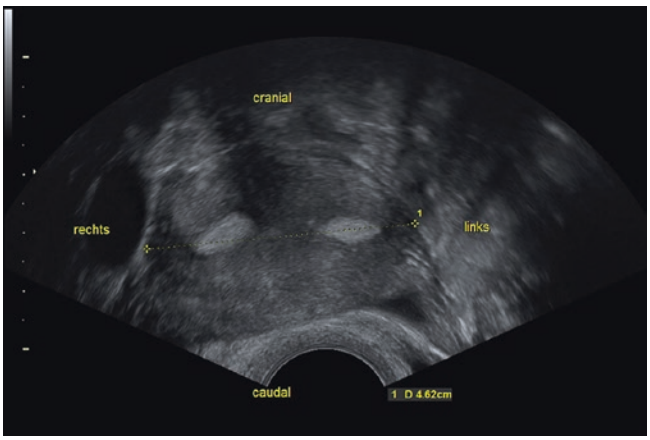

Fig. 5.11 Also additionally to Fig. 5.3 a transverse scan at the fundal region of the corpus uteri clearly showing two endometrial parts separated from each other

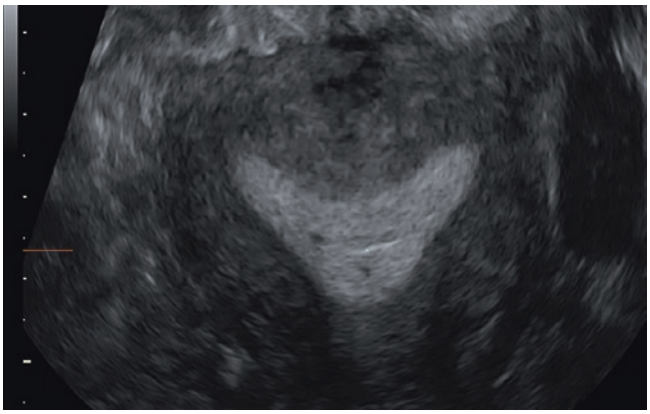

Fig. 5.12 Representation of the endometrium in the fundal region by 3D sonography indicates an arcuate uterus which explains the thicker than expected fundal uterine wall, see above Fig. 5.3 (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

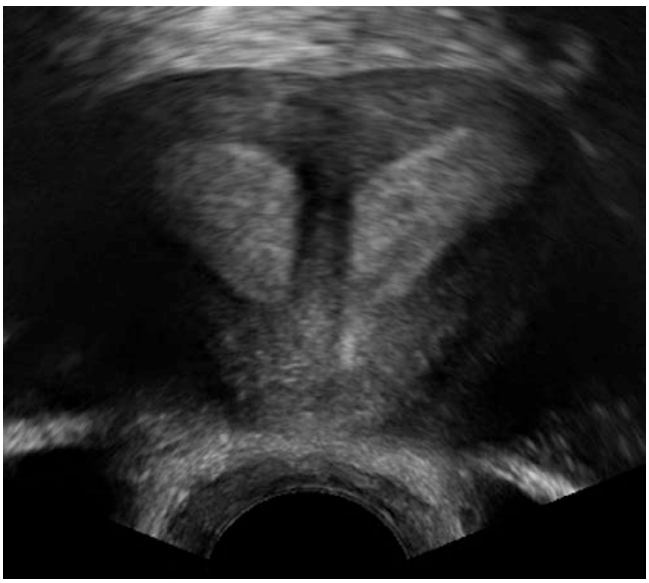

Fig. 5.13 Corpus uteri, transverse scan, showing two parts of endometrium separated from each other. Suspicion of a septate uterus becomes firmer by performing continuous transverse scans from the fundal to the cervical uterine region and reverse

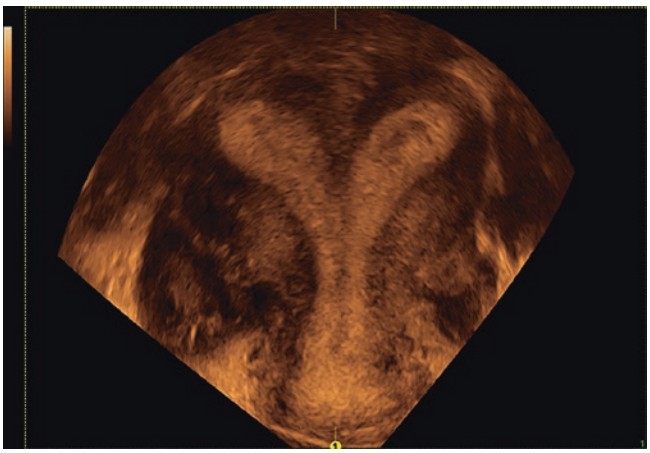

Fig. 5.14 Presentation of the whole uterus in its length by a frontal scan, using the 3D OmniView technique, impressively demonstrates the septate uterus (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

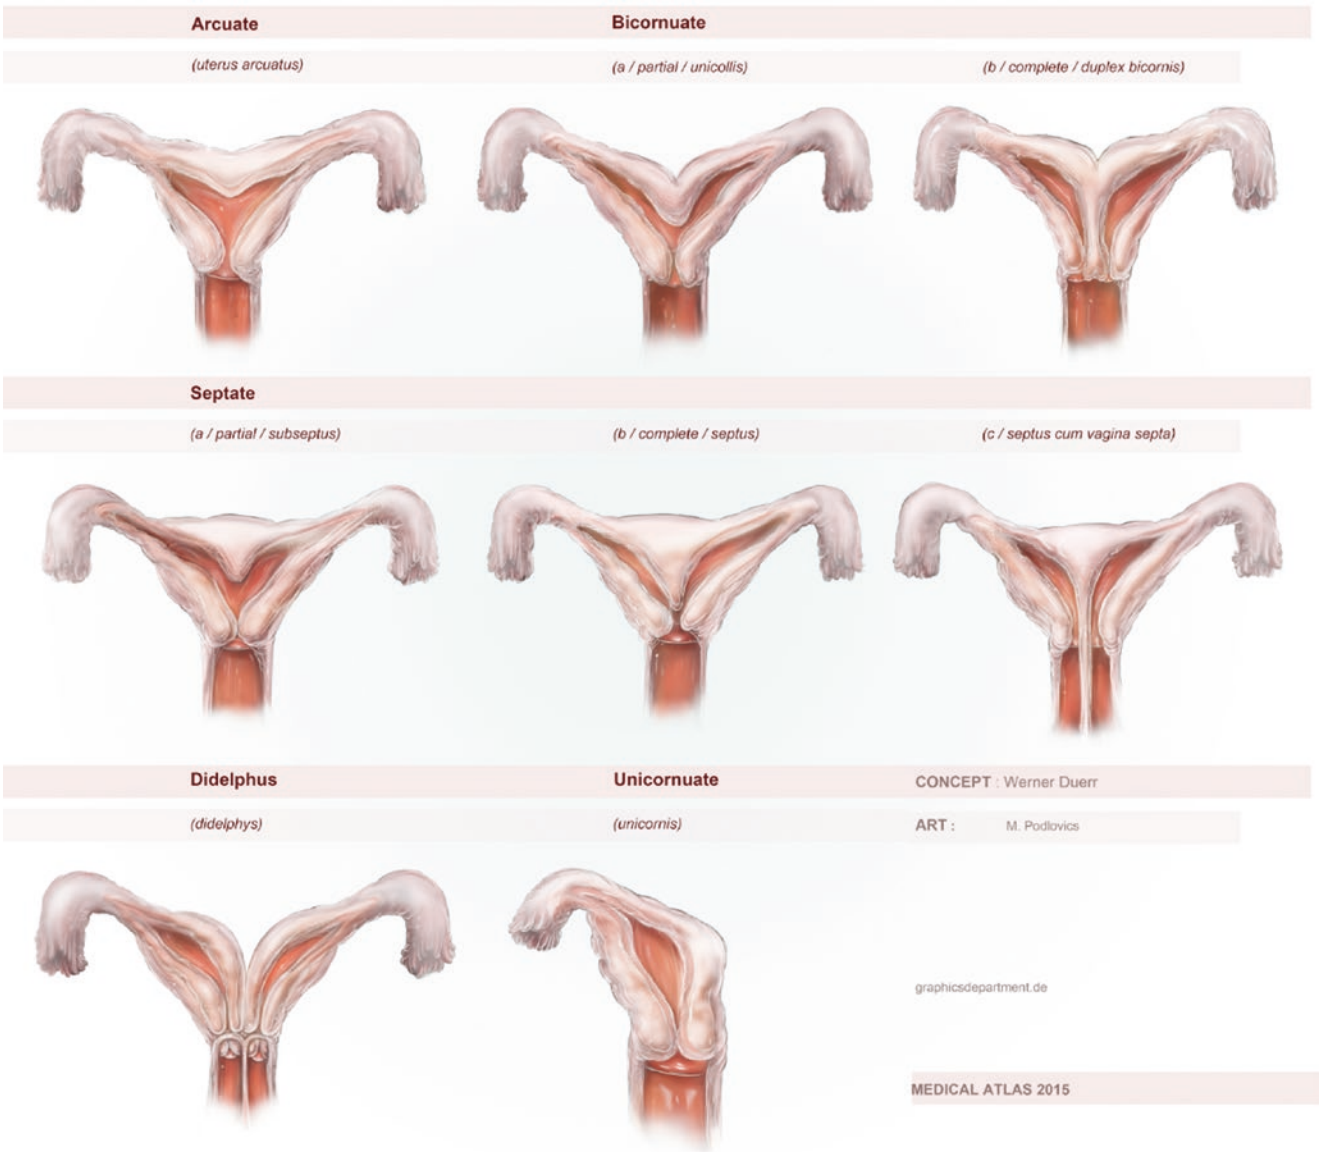

Fig. 5.15 An overview of uterine malformations by schematic drawings

Uterine Myomata

Uterine myomata are the most common benign uterine alterations.

Their location can be intramural, subserosal, submucosal, subserosal-intramural, submucosal-intramural (Fig. 5.16) and subserosal-intramural-submucosal (Figs. 5.17 and 5.18), however, all begin to develop within the uterine wall. Similar to congenital uterine malformations, small myomata, located laterally from the uterine midline, can be missed by TVS in a longitudinal scan whereas a transverse scan reveals the myoma within a few seconds. To prevent overlooking uterine myometrial or intracavitary alterations not located in the midline, it is necessary, or at least helpful, to perform not only a longitudinal but also a transverse scan. This is illustrated by images and additional information gained by 3D (Figs. 5.19, 5.20, 5.21, and 5.22) and TUI techniques, see Fig. 5.4.

To differentiate between myomata and other myometrial or intracavitary alterations, e.g. adenomyosis or endometrial polyps, the use of color Doppler is helpful because myomata usually present typical surrounding blood vessels feeding the myoma (Fig. 5.23). This is in contrast to the more diffuse vascularization of adenomyosis (Figs. 5.24 and 5.25) and the very characteristic vascular pedicle of mostly pedunculated endometrial polyps (Fig. 5.26).

Some examples of myomata and their vascularization are given by the images Figs. 5.16, 5.17, 5.18, 5.23, 5.27, and 5.28.

In some cases the differentiation between subserosal myoma and adnexal tumor can be very difficult by US (Fig. 5.29); however, this is very important with regard to the further diagnostic and therapeutic proceeding. If, using color Doppler, a vascular connection between the suspected adnexal tumor and the uterus is found, the diagnosis would be subserosal myoma (Fig. 5.30). If no vascular connection exists or can be found by color Doppler, further diagnostic and therapeutic steps have to be performed.

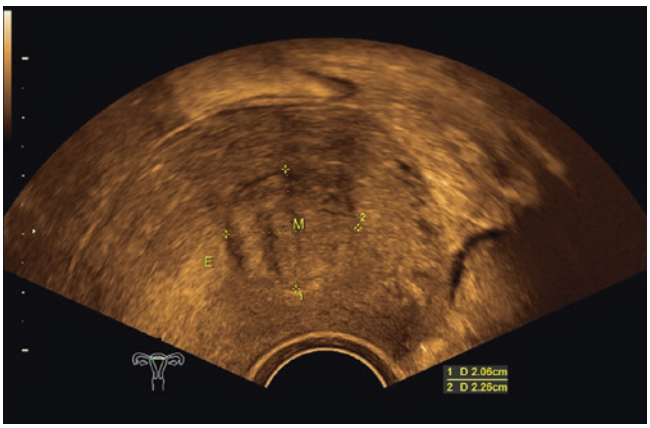

Fig. 5.16 Corpus uteri with a partial submucosal myoma left of the more echodense endometrium, transverse scan

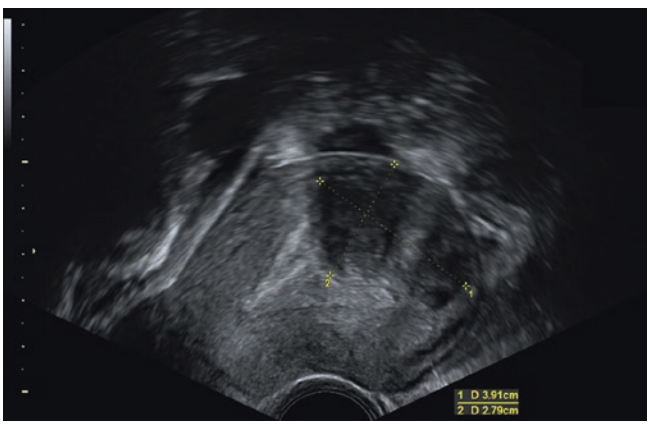

Fig. 5.17 Corpus uteri with a subserosal-intramural-submucosal myoma impressing the endometrium. This image shows the typical differences of echogenity between myometrium which is of middle echodensity, endometrium with its mostly higher echodensity and myoma which is usually hypoechoic in comparison to both

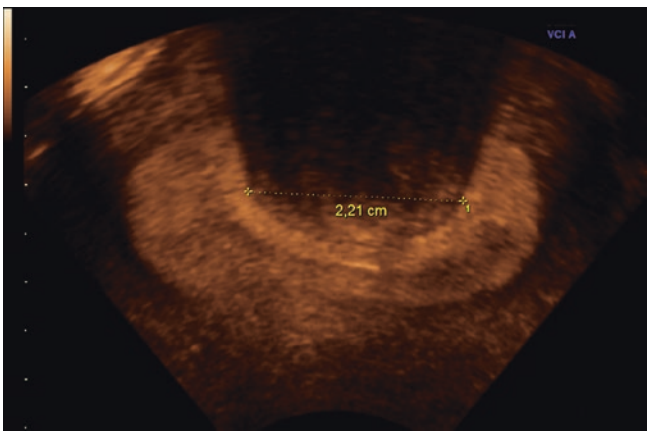

Fig. 5.18 Corpus uteri, transverse scan using 3D and VCI technique to show more impressively the relationship between endometrium and the submucosal part of the myoma

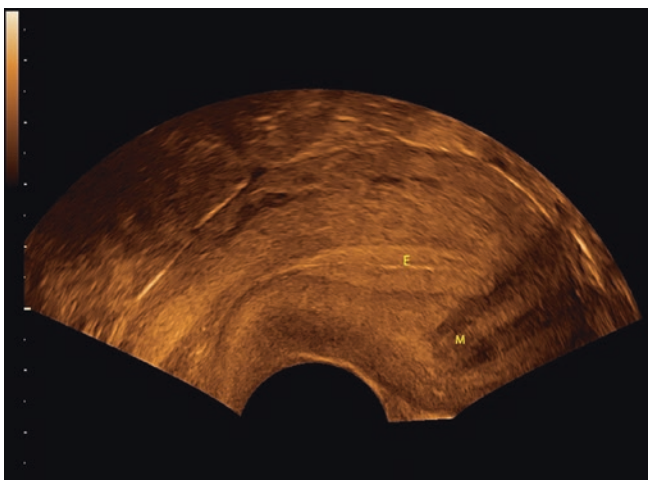

Fig. 5.19 Normal-sized, anteverted, anteflected uterus in a slightly oblique longitudinal scan, including the right paramedian anterior uterine wall, showing a small intramural myoma in the anterior uterine wall, right of the midline

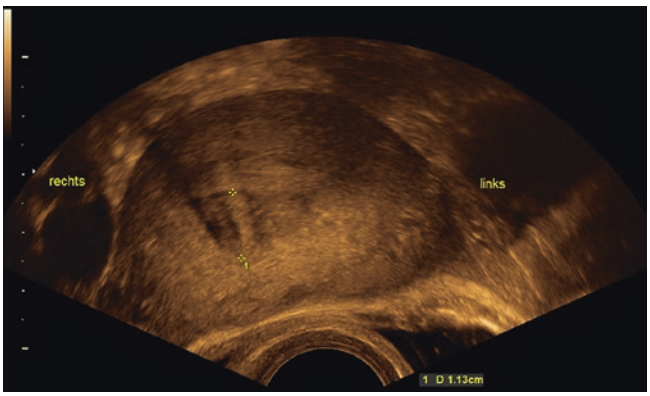

Fig. 5.20 The transverse scan reveals not only the intramural but also the submucosal location of the myoma on the right side

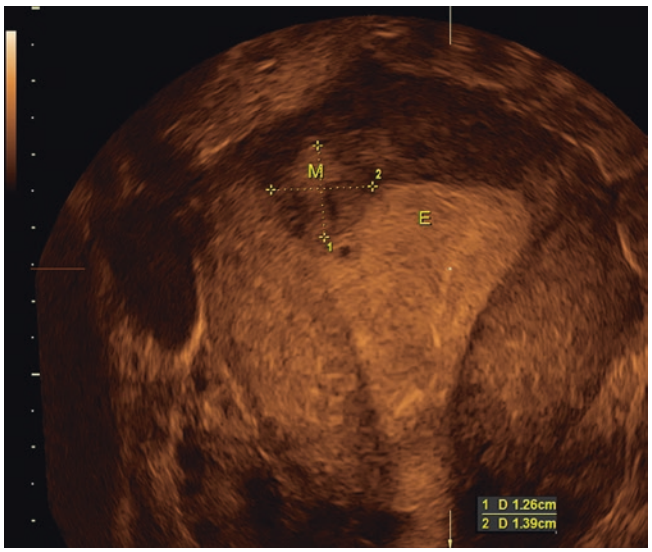

Fig. 5.21 The additional 3D image confirms the intramural and submucosal location of the myoma, at the right tubal angle with possible negative effects on the patency of the interstitial tubal part. Such detailed information is important, especially in cases of fertility disorder. See above also Fig. 5.4, showing the myoma presented by a tomographic technique, such as TUI

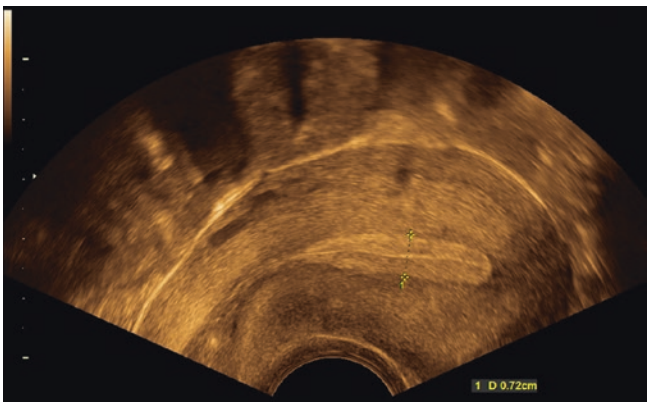

Fig. 5.22 Here, to demonstrate how easily this myoma could have been missed by TVS, a longitudinal scan exactly in the midline where the myoma cannot be seen. This emphasizes the necessity of a transverse scan in addition to the obligatory longitudinal scan when investigating the uterus by US (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

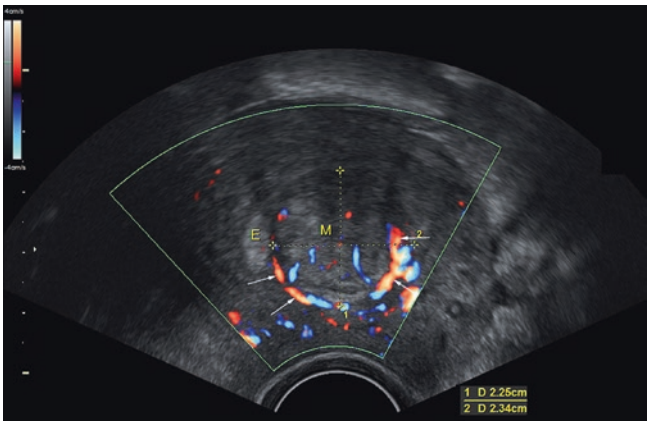

Fig. 5.23 Colour Doppler impressively shows the typical feeding vessels surrounding the myoma and some vessels entering the myoma. See above Fig. 5.16, which presents this myoma without colour Doppler (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

Endometrial Polyps

Endometrial polyps are to be found in the uterine cavity, seldom sessile, mostly pedunculated, possibly reaching into the cervical channel and presenting there. The echogenity of these polyps is usually higher than in the endometrium (Fig. 5.31). The differentiation from submucosal myoma is easy by color Doppler when the typical vessel in the vascular pedicle can be seen. This feeding vessel begins in the myometrium, crosses the EMJ and ends within the polyp, see Fig. 5.26. The branching of this feeding vessel within the polyp is shown by Fig. 5.32, see also Figs. 5.5 and 5.6.

Endometrial Hyperplasia

Endometrial hyperplasia is predominantly found in the adolescent and climacteric transitional phase when, because of anovulatoric cycles with corresponding progestagenic deficiency, usually as a result of follicular persistence, the endometrial proliferation, induced by ovarian estrogen, is not opposed sufficiently by progesterone and, therefore, no endometrial transformation with following regular menstrual discharge is

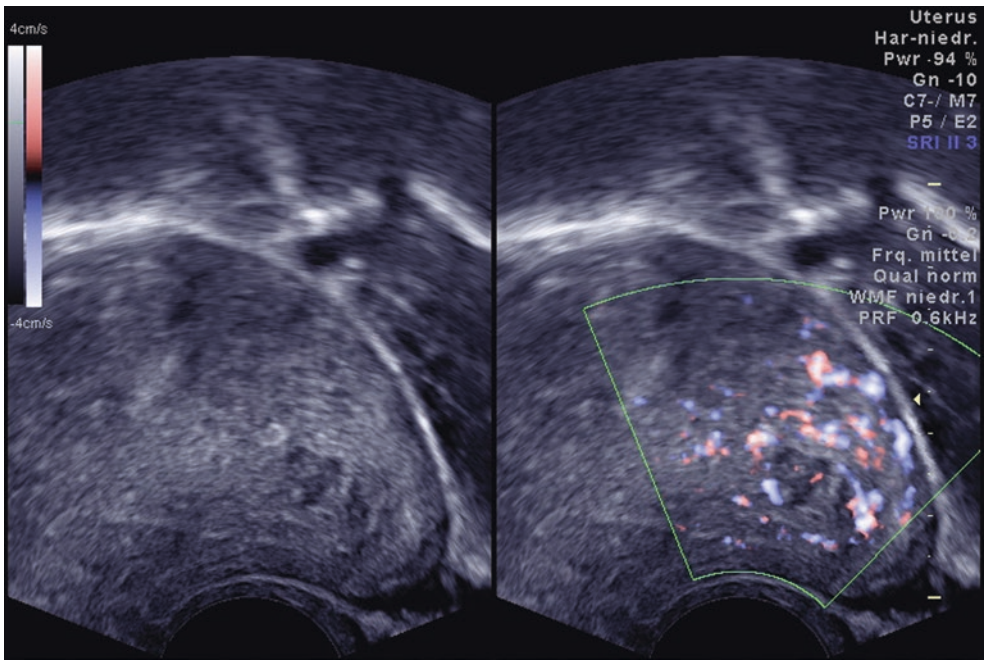

Fig. 5.24 Color Doppler shows a markedly higher and more irregular vascularization of the area affected by adenomyosis in comparison to the regular vascularization by preexisting vessels (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

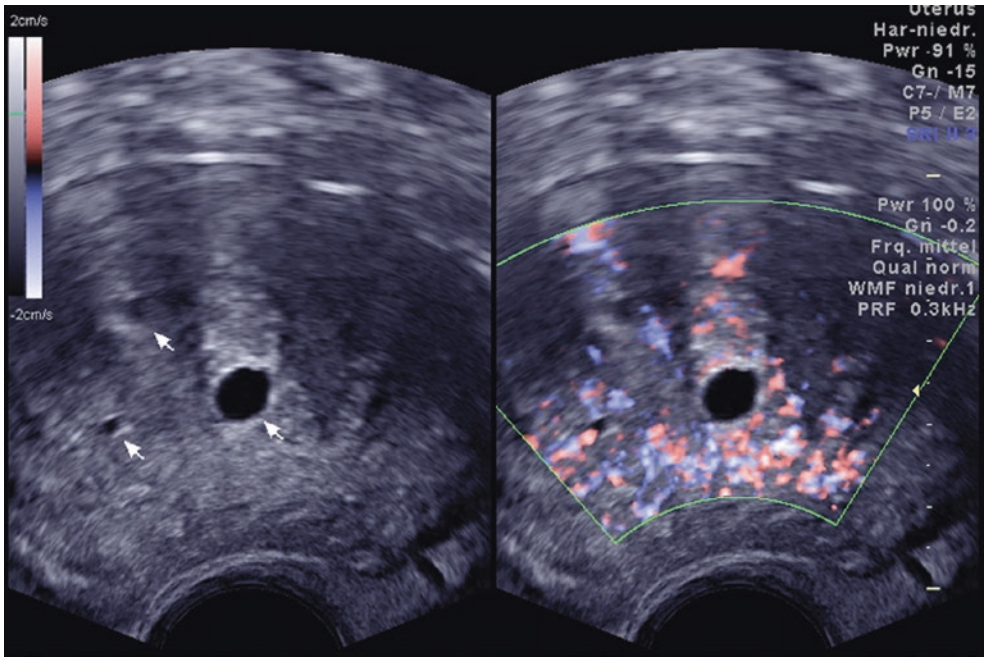

Fig. 5.25 In another area of the same uterus as shown by Fig. 5.72, cystic structures, surrounded by an echogenic endometrium-like margin, are to be found. Color Doppler shows a very marked and diffuse neovascularization in the cystic area as a sign of adenomyosis with a tendency to progress. It seems to be that streaky shadows indicate older processes and cystic findings more recent afflictions of adenomyosis (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

possible. Instead of this continuous bleedings occur as a result of highly proliferated endometrium which is no longer fed in its upper layers whereas proliferation continues.

High resolution TVS can show the typical microcysts within an endometrial hyperplasia, well known from the histological term "cystic glandular hyperplasia" (Fig. 5.33).

Endometrial hyperplasia can be treated with progestin to induce an endometrial transformation and withdrawal bleeding. This is an alternative to possible sequential curettages (Figs. 5.33, 5.34, and 5.35).

Endometrial Carcinoma

Endometrial carcinoma, the most common malignant gynecological tumor, can be detected and described in its extension by sonography, especially TVS, with the help of color Doppler. The sonographic finding is mostly an inhomogeneous intracavitary echo which shows an irregular vascularization, such as neovascularization typical for malignant tumors. The EMJ is penetrated by tumor vessels in areas where myometrial invasion has taken place (Figs. 5.36, 5.37, 5.38, 5.39, and 5.40).

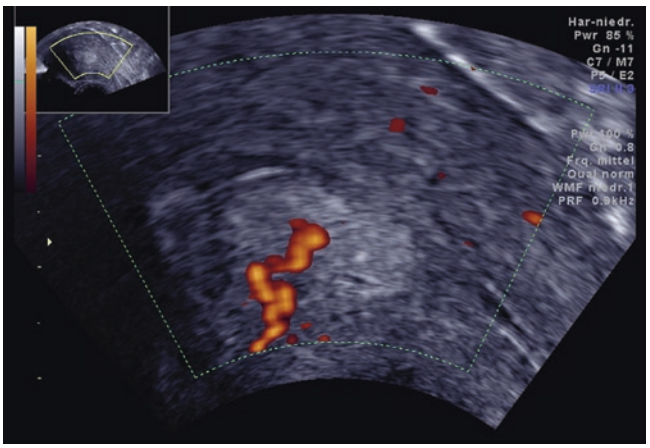

Fig. 5.26 Color Doppler demonstrates a well-defined feeding vessel crossing the EMJ, ending in an intracavitary echodense clearly demarcated mass. This pedicle vessel indicates an endometrial polyp and makes sure that indeed the finding is doubtless nothing else, no submucous myoma, no endometrial hyperplasia, for example

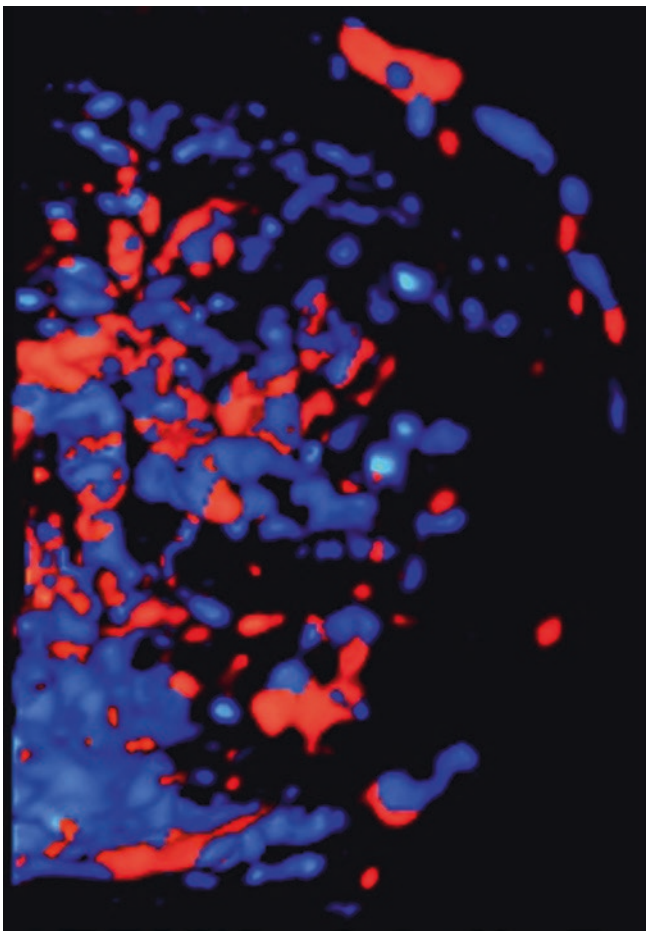

Fig. 5.28 3D color flow shows a very intense vascularization and perfusion of the myoma (see Figs. 5.17 and 5.18) as a possible sign of its tendency to grow. In this case the tendency was confirmed by comparison of the actual findings with the preceding findings (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

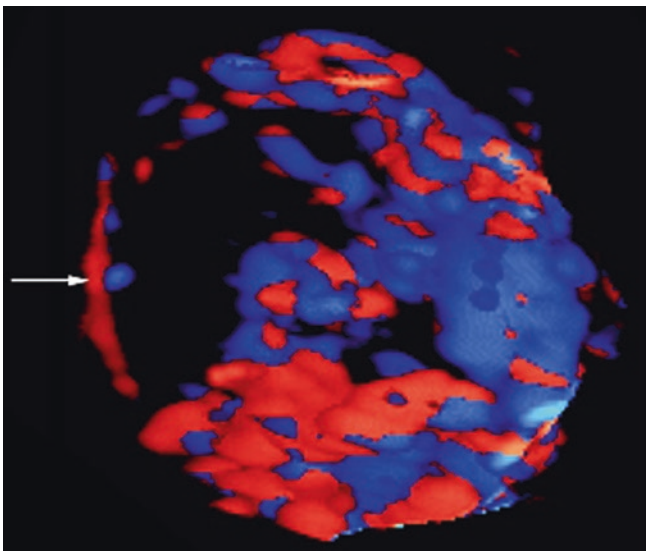

Fig. 5.27 3D color flow demonstrates, like an angiogram, the relatively intense vascularization of this myoma (see Figs. 5.16 and 5.23) as a possible expression of its tendency to grow (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

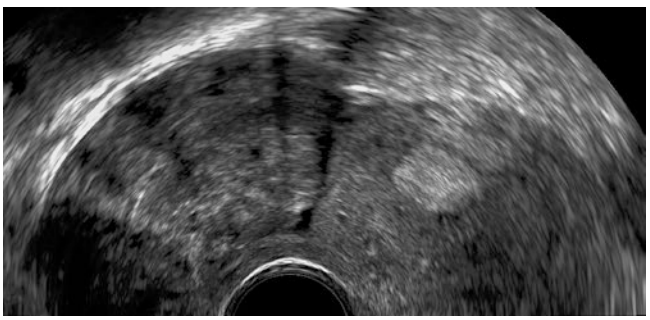

Fig. 5.29 A tumor-like mass in the right adnexal region, as large as the corpus uteri, seems to displace the corpus uteri (identifiable by the echogenic endometrium) from the midline to the left side. Echogenity and clear demarcation of this mass as well as its close vicinity to the corpus uteri give suspicion of a subserosal myoma

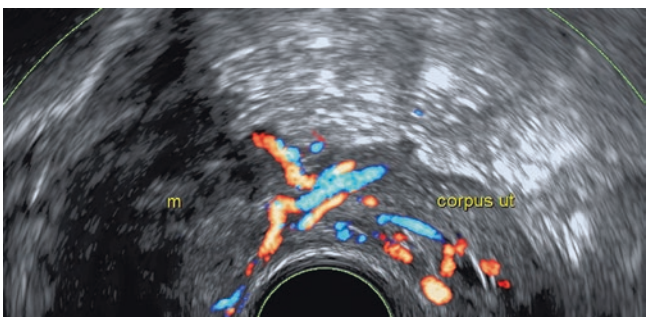

Fig. 5.30 Intensive search by color Doppler succeeded in showing not only a vascular connection between corpus uteri and tumor-like mass but also the typical feeding vessels surrounding the myoma, originating from the corpus uteri. Thus, the diagnosis subserosal myoma could be confirmed and a tumor, originating from the right adnexal region, was excluded (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

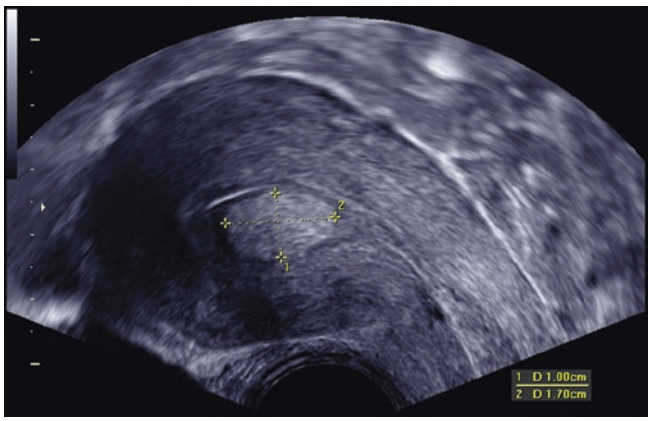

Fig. 5.31 Uterus in a longitudinal scan showing an intracavitary, echodense, clearly demarcated mass, at first sight resembling an endometrial polyp. Additional Color Doppler – see Fig. 5.26 – demonstrates a well-defined feeding vessel crossing the EMJ. This pedicle vessel indicates an endometrial polyp

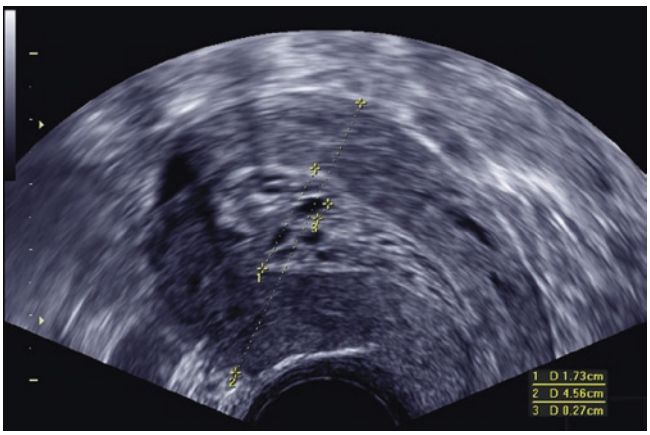

Fig. 5.33 Uterine longitudinal scan shows a microcystic intracavitary echo, thickness a.-p. 17.3 mm. In connection with an existing follicular persistence in a 47-year-old woman with continuous bleeding, this finding should be an endometrial hyperplasia

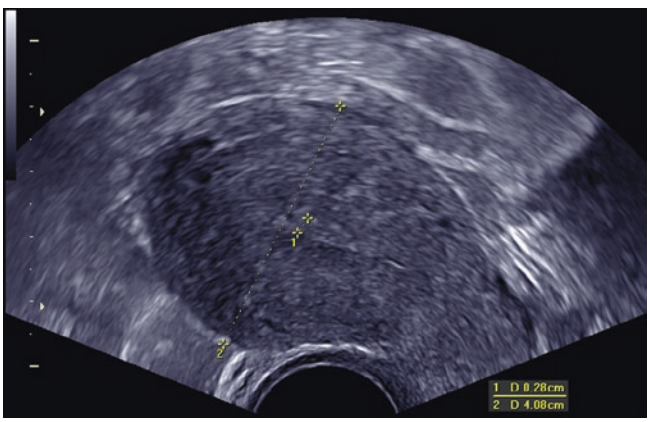

Fig. 5.35 Thus, as endometrial hyperplasia was expected on the basis of sonographic diagnostics in connection with anamnestic data, administration of an exogenous progesterone agent should therapeutically be at least as helpful as a curettage. The image demonstrates the uterine cavity as nearly empty after gestagen-induced transformation and following withdrawal bleeding (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

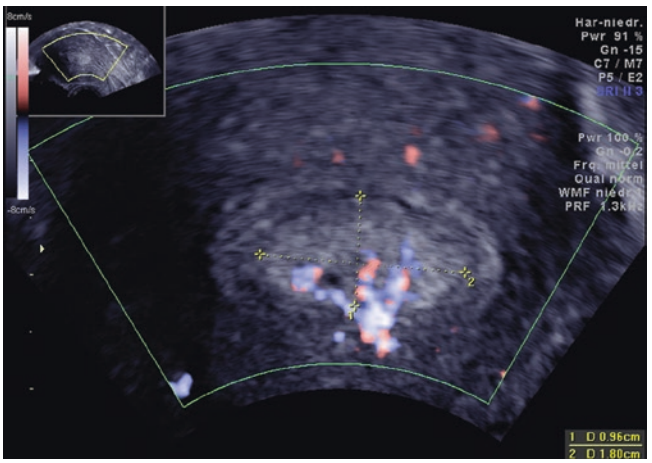

Fig. 5.32 The transverse scan shows a branching of the pedicle vessel within the endometrial polyp. See above additionally Figs. 5.5 and 5.6 which demonstrate sonographic-technical possibilities and are less part of the daily routine proceedings (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

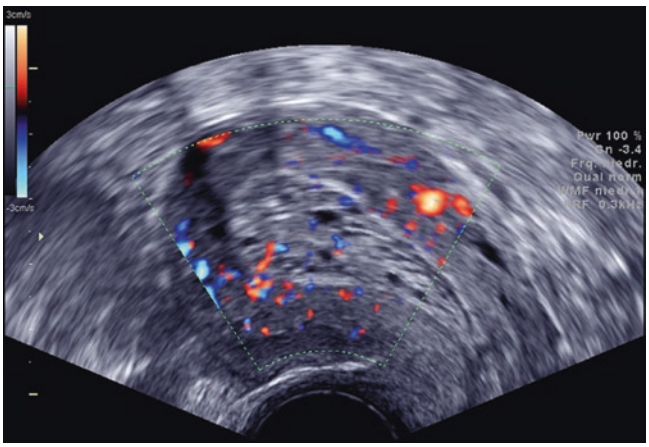

Fig. 5.34 To exclude an endometrial polyp, which looks very similar when of cystic-fibrous texture, color Doppler is used. Only a spiral artery-like vessel, no pedicular vessel typical for an endometrial polyp, can be found

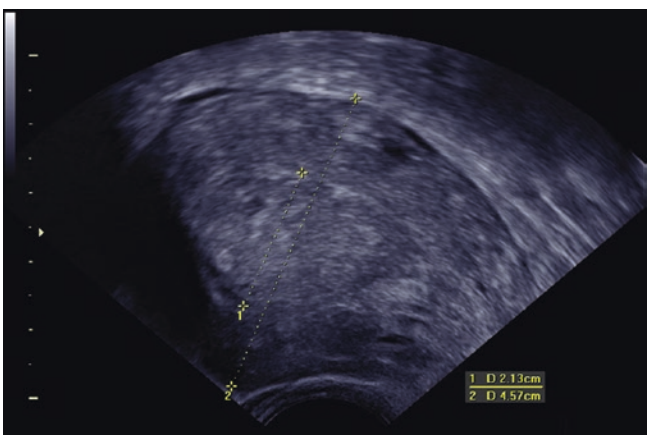

Fig. 5.36 Uterus of a 55-year-old woman with postmenopausal bleeding. The longitudinal scan shows a markedly thickened inhomogeneous endometrium of 21.3 mm which seems distinctly demarcated from the myometrium

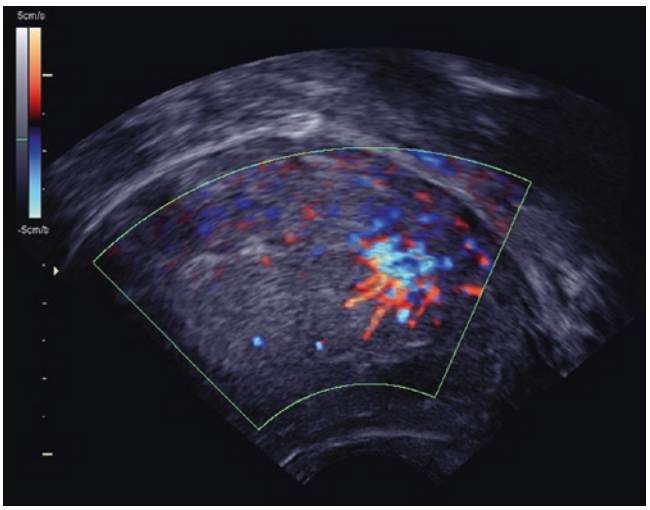

Fig. 5.37 Transverse scan in the fundal region of the corpus uteri. The color Doppler reveals on the left side a chaotic neovascularization typical for malignant growth, with vessels penetrating the EMJ in this zone of myometrial invasion

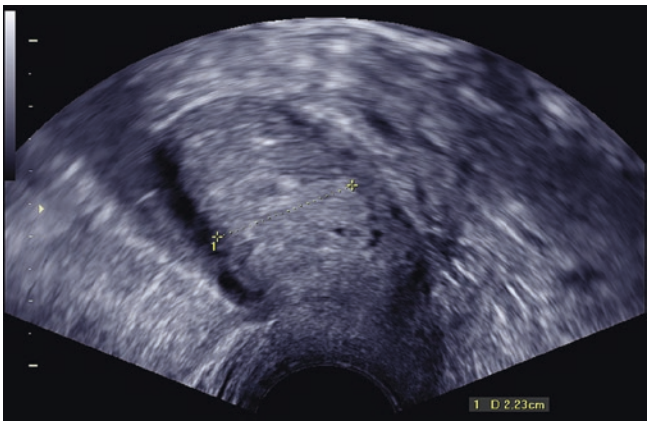

Fig. 5.39 Corpus uteri with endometrial cancer, longitudinal scan. The extension and respective myometrial invasion of the tumor can easily be estimated and measured when, as in this case, there is a clear demarcation by markedly different echogenities between tumor (higher echogenity) and the non-invaded myometrium (lower echogenity)

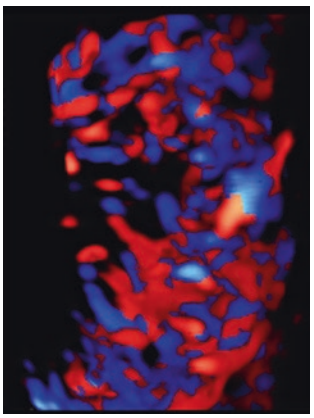

Fig. 5.38 3D color presentation of this zone confirms the tumor-suspicious neovascularization. Postoperative histological diagnosis: endometrial carcinoma pT1a (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

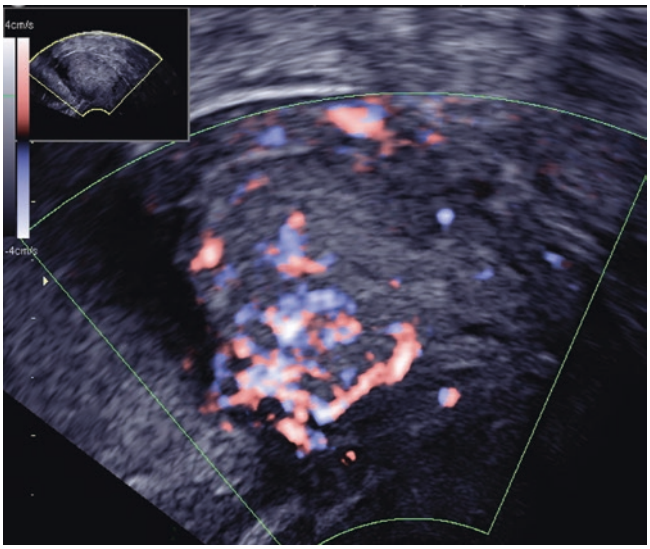

Fig. 5.40 Color Doppler shows the irregular vessels of a typical tumor neovascularization which involves the endometrium and the myometrium (Images by courtesy of Dr. Isabel Wallrafen)

Uterine Sarcoma

Uterine sarcoma, a very rare tumor, is often mistaken for a fast growing myoma. Color Doppler can be helpful to confirm the suspicion of malignancy when an extraordinarily high vascularization of tumor-like pattern is detected. Every fast-growing uterine tumor, even in the case of well-known myomata, warrants further evaluation for uterine sarcoma. Myomata do not exclude sarcoma; however, not all sarcomas grow markedly fast and not all sarcomas present the typical tumor neovascularization.

Other sonographic signs of malignancy could be central anechoic or low echogenic areas, caused by tumor-necrosis or hemorrhage; however, these findings are sonographically indistinguishable from very similar looking areas of central liquefaction in myomas without any additional malignancy.

In summary, we have no really reliable sonographic signs to diagnose or exclude uterine sarcomas preoperatively. Nevertheless, sonography with the help of color Doppler is and will most likely remain an important diagnostic tool in the preoperative differentiation of benign from malignant uterine mass.

If sonographically there is any suspicion of malignancy, morcellation should not be performed and no other uterine incision except for total hysterectomy to prevent, as far as possible, tumor tissue or cell dissemination.

In future, a risk score for uterine sarcomas, based not only on imaging parameters, but including all other known

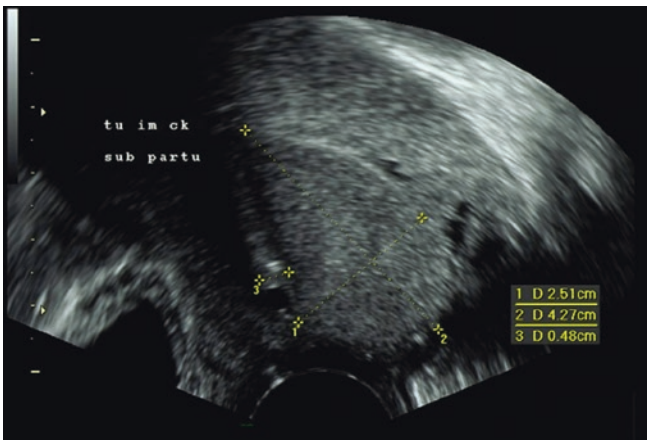

Fig. 5.41 Longitudinal scan of the uterine cervix showing a tumor in the cervical channel, seeming to be "sub partu"

Fig. 5.42 Color Doppler shows a remarkably high but totally irregular perfusion of this polyp-like tumor. Postoperative histological diagnosis: "leiomyosarcoma of low malignancy" (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

relevant risk factors, could be helpful in decreasing the number of coincidentally, intraoperatively or postoperatively, histologically found sarcomas, by increasing the number of preoperatively suspected and thus adequately operated tumors.

Examples of uterine sarcomas and their vascularization are given by the images Figs. 5.41, 5.42, 5.43, and 5.44.

Cervical Carcinoma

The diagnosis of cervical carcinoma is not the domain of sonography although more progredient tumors can be estimated sonographically (Figs. 5.45, 5.46, and 5.47). It has been successfully proven that early diagnosis of cervical cancer is still the domain of cytology and histology after biopsy.

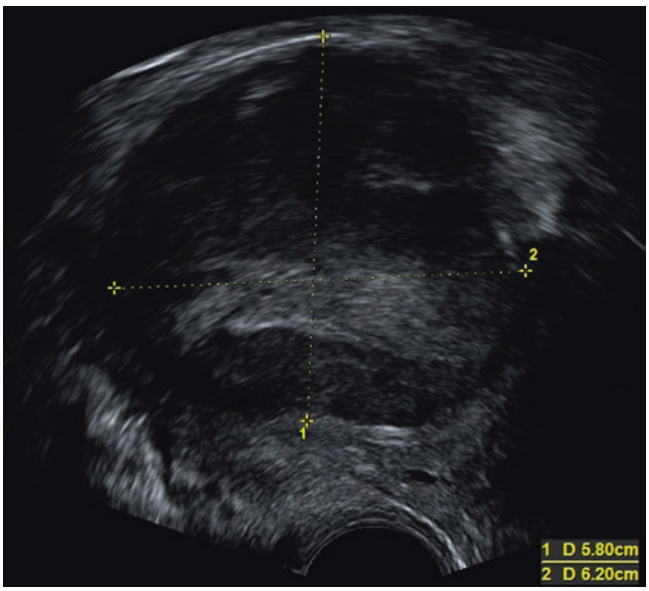

Fig. 5.43 Cross section of a previously known myoma which seems to have grown markedly since the last control some months ago

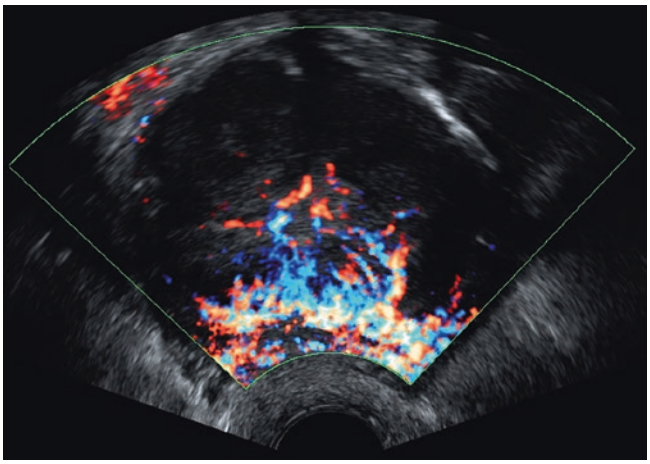

Fig. 5.44 Color Doppler reveals an extremely high vascularization with the pattern of typically chaotic tumor neovascularization. The postoperative histological diagnosis was uterine sarcoma.(Images by courtesy of Dr. Isabel Wallrafen)

Tamoxifen-Induced Intrauterine Alterations

Sonographically, uterine alterations under Tamoxifen treatment usually look like cystic intracavitary proliferations, but in reality are subendometrial extended cysts with atrophy of the endometrium. The uterine cavity is often totally smooth except when additional intracavitary proliferations, such as endometrial polyps, are present. The subendometrial cysts can differ in size from very small, similar to the microcysts in cystic glandular hyperplasia or cystic fibrous endometrial polyps, to relatively large, as shown in the image (Fig. 5.48).

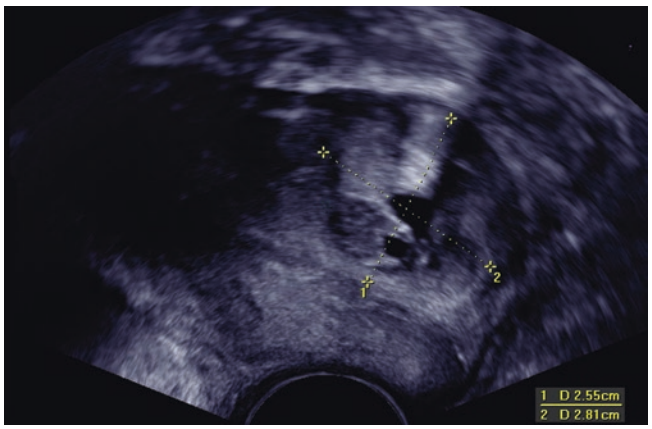

Fig. 5.45 In this image, left is anterior and right is posterior. The longitudinal scan of a cervix shows a clear, demarcated area in the posterior wall with different echogenities from echodense to anechoic. The described finding is also palpable as a strong knot similar to a cervical myoma. Diverse, previously known myomata are palpable as subserosal myomata originating from the uterine corpus

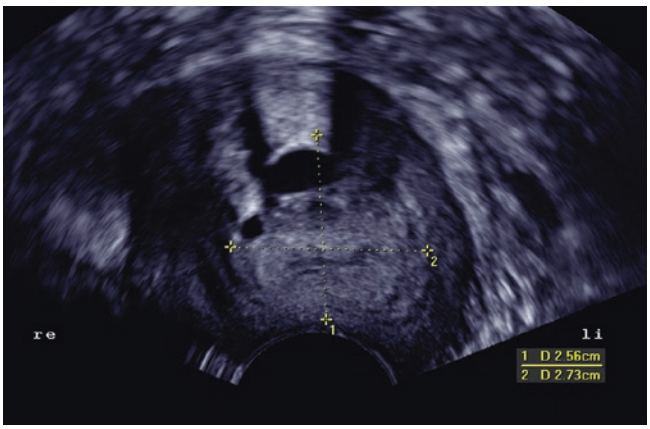

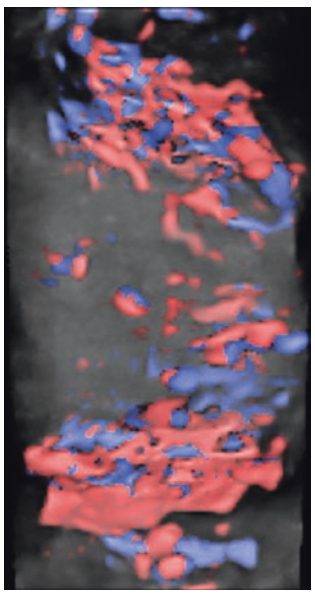

Fig. 5.46 Transverse scan demonstrates that the alteration also includes, but to a lower degree, the anterior cervical wall without direct connection to the cervical channel. The intact-looking circular layer of cervical endometrium around the cervical channel may correspond to an inconspicuous pap smear taken some months previously. Therefore, the differential diagnosis could tend more to a cervical myoma with zones of liquefaction rather than cervical carcinoma

Fig. 5.47 3D color Doppler in glass body modus reveals a very remarkable vascularization over the whole cervix with the pattern of typical tumor neovascularization, corresponding to a cervical carcinoma, as was histologically confirmed

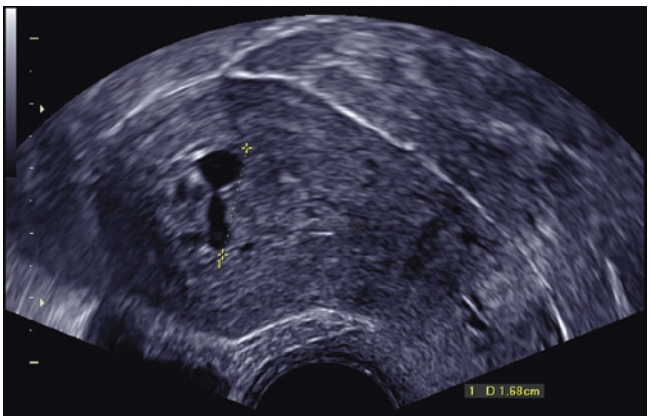

Fig. 5.48 Uterus in a longitudinal scan with intracavitary-looking cystic proliferations which in reality are typical subendometrial cysts under Tamoxifen treatment, whereas the endometrium is atrophic (Image by courtesy of Dr. Annette Philippi)

Intrauterine Fluid Collection (Serometra)

Intrauterine fluid collection presents sonographically as anechoic. Sonographically confirmed intrauterine fluid collection is often seen by chance in postmenopausal women with cervical stenosis (Fig. 5.49). In these cases no further treatment is necessary, provided there are no other intracavitary findings.

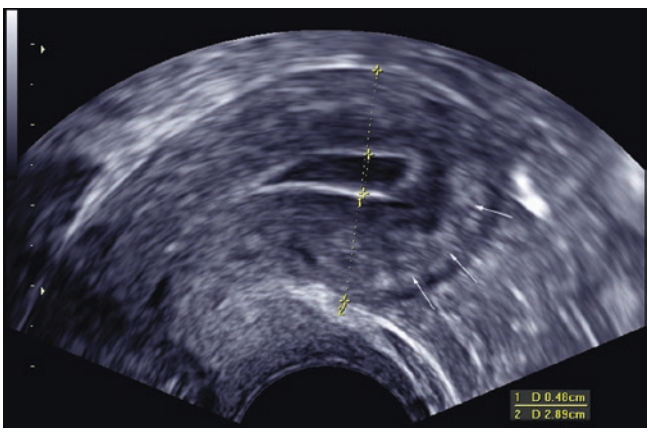

Fig. 5.49 Intrauterine fluid collection (Serometra) in a 75-year-old woman. Noticeable is not only the small amount of intracavitary serous liquidity but also the hyperechoic zones in the outer myometrial region (*arrows*) as a sign of atheromatous alterations in the arcade arteries (Image from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

Hematometra

Hematometra refers to a uterus with an intracavitary accumulation of blood. The causes for this condition vary and must be clarified. The intracavitary echo is homogenous because of the corpuscular contents of blood and, as to be expected, intracavitary vascularization will not be found (Figs. 5.50 and 5.51).

Pyometra presents sonographically very similar to hematometra.

Adherent Placental Remnants

Remnants of pregnancy can remain intrauterine after delivery and after abortion. Sonographic controls can be helpful to detect and remove them, if necessary. Remaining placental tissue has the potential for malignant degeneration and must be removed (Fig. 5.52).

The leading sign of a vital and therefore potentially dangerous placental remnant is vascularization within the sonographic finding. Vessels can be seen crossing the EMJ, usually reaching deep into the myometrium (Figs. 5.52 and 5.53). This is not found in blood clots. Another sign of a remaining "vital" placental remnant is possible hormonal activity. Both signs, vascularization and hormonal activity, can easily be assessed, the one by color Doppler, the other by serodiagnosis of HCG.

If, to prevent possible uterine damage, expectant management with regard to a possible spontaneous resolving of the suspected placental remnant is chosen, sonographic and serodiagnostic short time controls are strongly indicated. If there is no rapid decrease in vascularization and especially in HCG-values, operative removal has to be performed sooner rather than later.

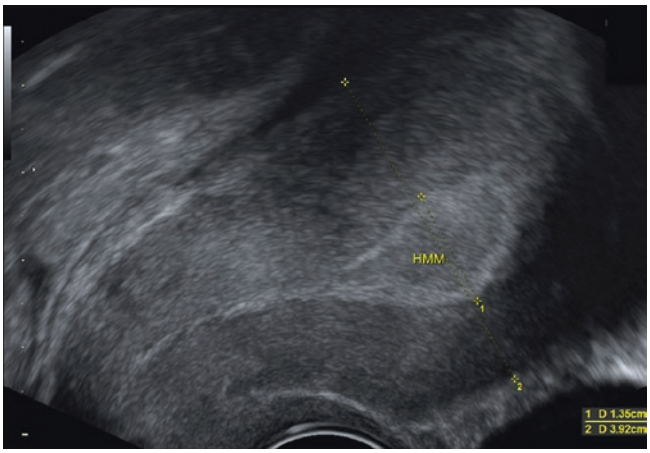

Fig. 5.50 Hematometra after spontaneous abortion. Homogenous intracavitary echo as a sign of liquid, not yet clotted blood

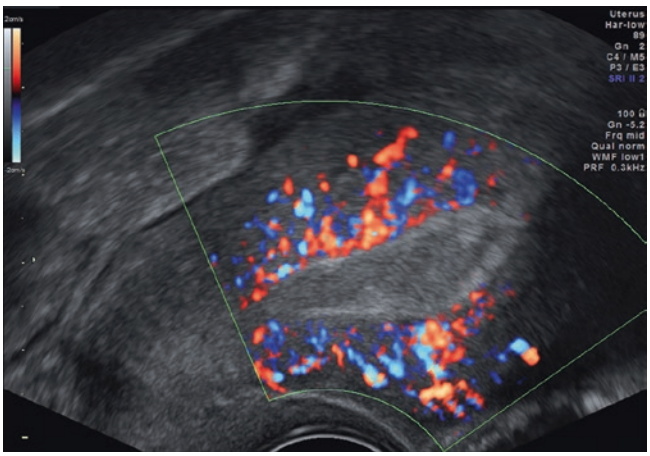

Fig. 5.51 Color Doppler shows, as expected, no intracavitary vascularization. The increased myometrial and subendometrial vascularization ends exactly at the wall of the uterine cavity (Images from of Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

Intrauterine Adhesions

Intrauterine adhesions can develop after intrauterine surgery, e.g. curettage, and can be a cause of infertility. They disrupt the EMJ and present sonographically as endometrial defects (Figs. 5.54, 5.55, 5.56, 5.57, 5.58, and 5.59).

Subendometrial Fibrosis

Subendometrial fibrosis can occur after intrauterine surgery, such as a curettage, and seems to be without significant effect on endometrial function. Sonographically subendometrial fibrosis presents as echogenic foci in the basal endometrium [1] (Fig. 5.60).

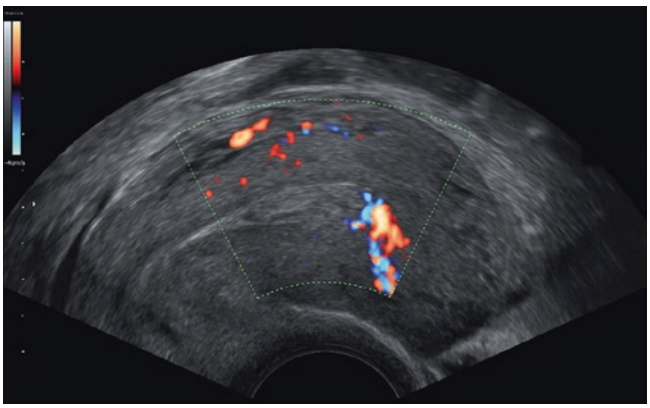

Fig. 5.52 Uterus was scanned because of continuous bleeding 3 months after spontaneous abortion. An intracavitary, spindle-like mass with a very marked vascularization in the fundal part crosses the EMJ and reaches deep into the myometrium

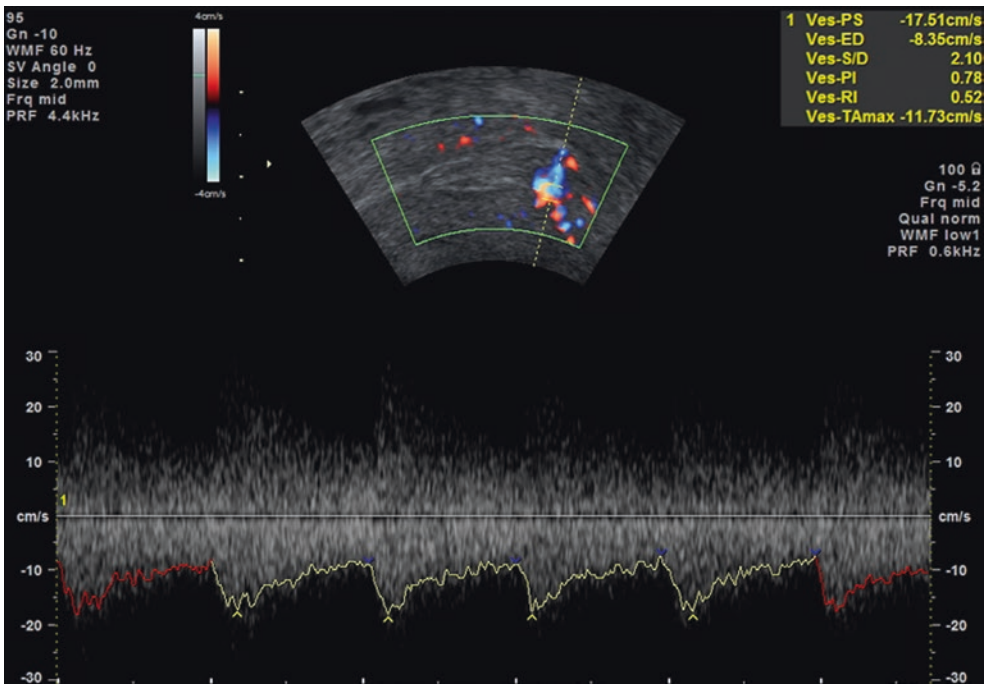

Fig. 5.53 Spectral Doppler shows the typical low impedance of neovascularization. This, in connection with the color flow image and the anamnestic information, leads to the suspicion of hormonal active "vital" placental remnants. Corresponding to this suspicion, beta-HCG was 720 mIE/ml and the histologically confirmed diagnosis after curettage: "regressive altered abortion material with partial mole-like degeneration of the villi. In the presented material no signs of malignant growth." (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

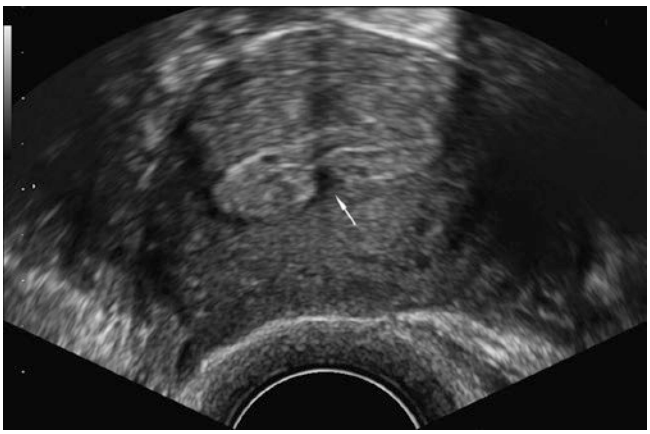

Fig. 5.54 The image shows an endometrial defect (*arrow*) with focal interruption of the EMJ, typical for intrauterine adhesion

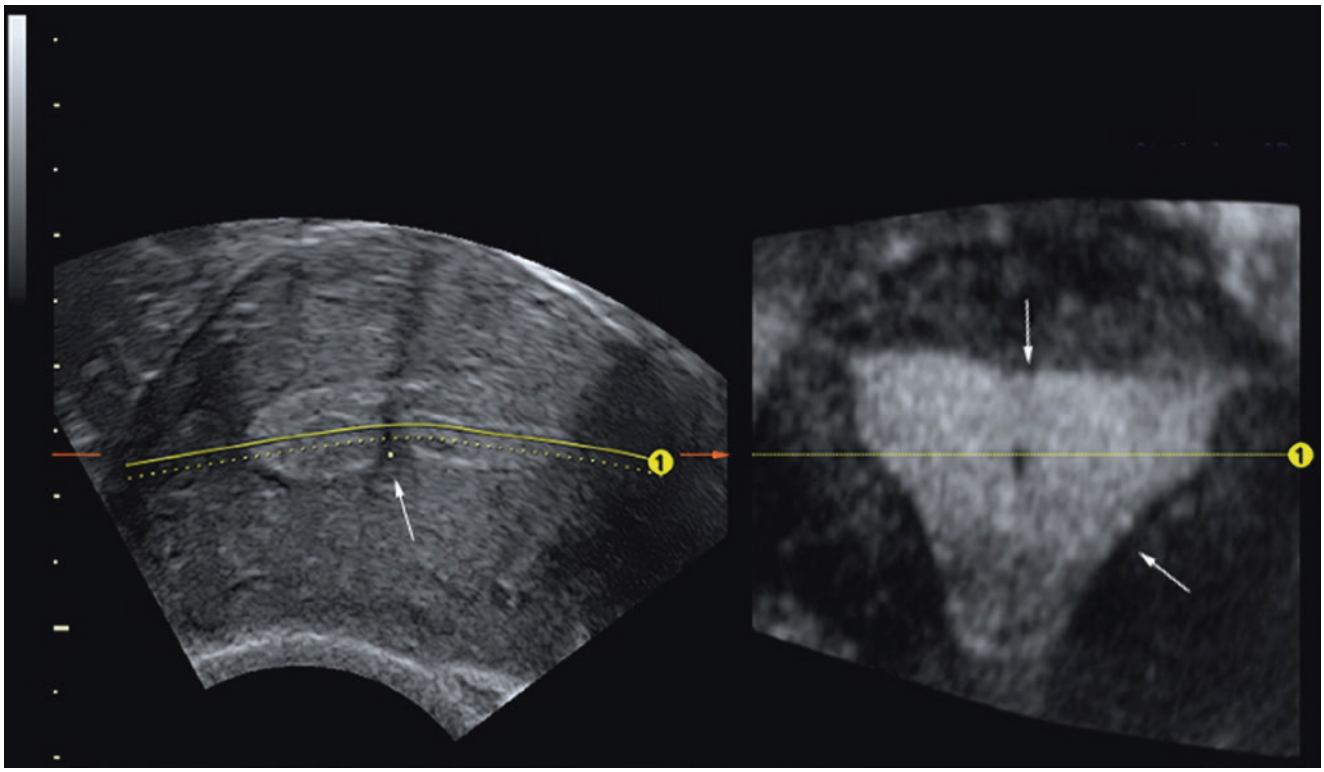

Fig. 5.55 Frontal scan by 3D OmniView technique for better localization and presentation of the very thinly marked adhesion

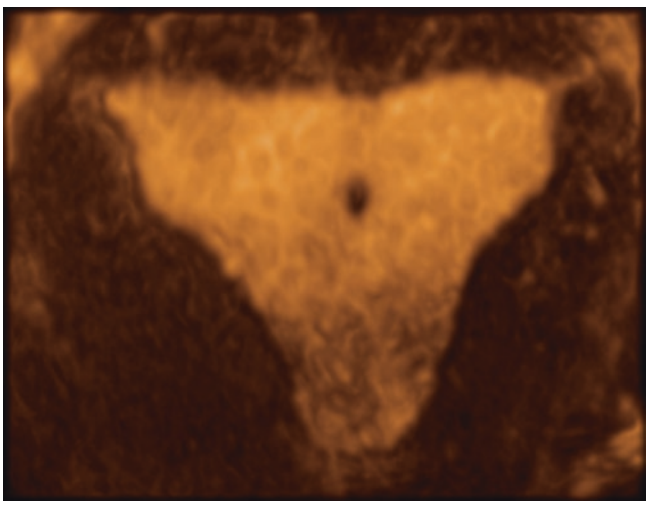

Fig. 5.56 The same frontal scan augmented and colored for better optical perception. Supplementary case history: state after curettage because of abortion (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

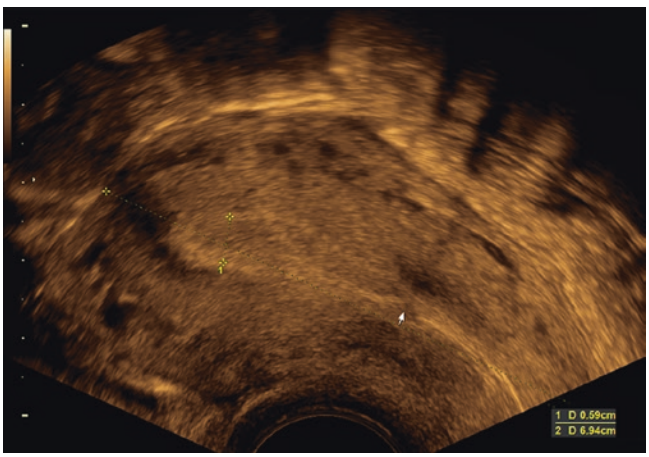

Fig. 5.57 A second example of an endometrial defect with focal interruption of the EMJ, located in the lower part of the uterine cavity (*arrow*), suspicious for intrauterine adhesion

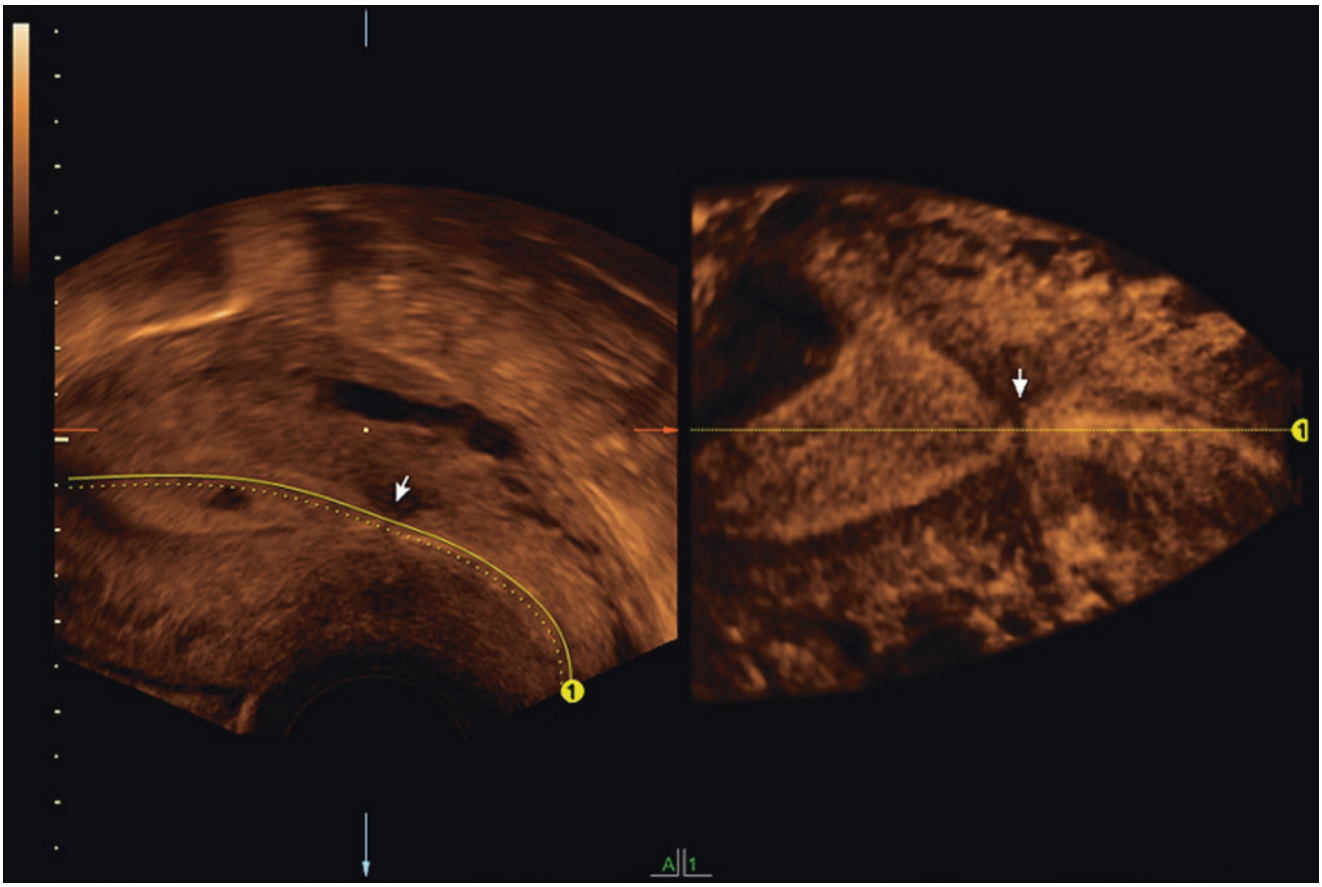

Fig. 5.58 Frontal scan by 3D OmniView technique shows the suspected adhesion (*arrow*) better than a 2D scan

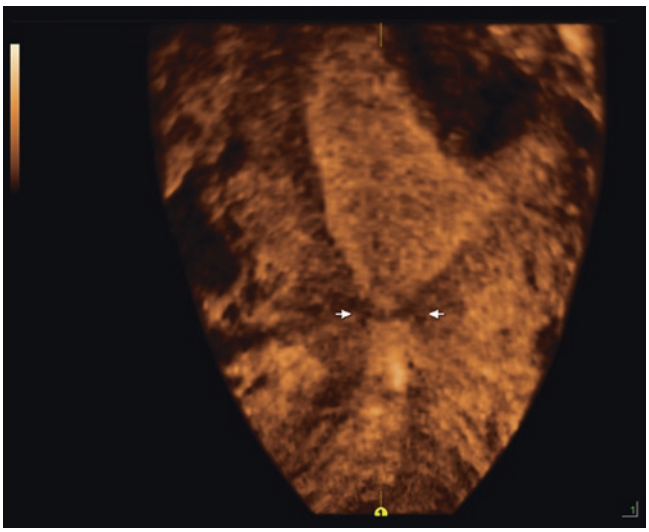

Fig. 5.59 The same frontal scan augmented and turned in the usual position for frontal scans impressively shows the endometrial interruption at the expected level (*arrows*). Supplementary case history: At this level (*arrows*) a strong, impenetrable obstacle was found when a sounding test was made before insertion of an intrauterine contraceptive device. These findings are to be seen in connection with a state after curettage due to retained pregnancy remnants (Images by courtesy of Dr. Isabel Wallrafen)

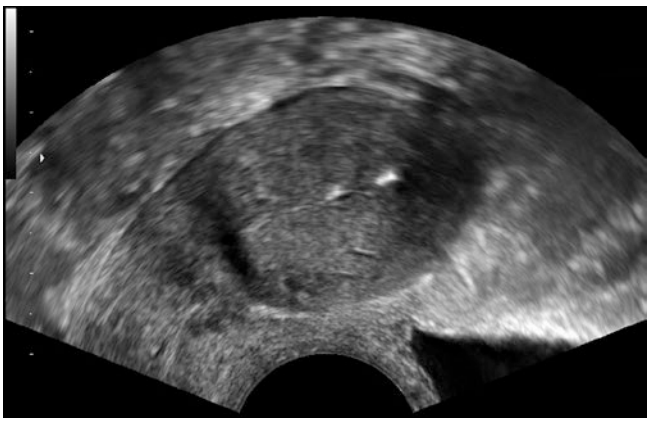

Fig. 5.60 Uterus with two echogenic foci as signs of subendometrial fibrosis (Image from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

Cesarean Section Scar

Cesarean scars are usually found in the lower uterine segment of the anterior uterine wall and present sonographically as a structure of low echo density reaching from the uterine serosa to the endometrium, interrupting the endometrial-myometrial continuity (Fig. 5.61).

Scar defects (dehiscences, niches) of smaller and larger size (Figs. 5.62, 5.63, and 5.64) are common sonographic findings after cesarean section. Different authors have published different findings on the prevalence of scar defects, but agree that the defects occur not seldom but more or less frequently. For example, O. Vikhareva Osser et al. found scar defects "in 61 % (66/108), 81 % (35/43) and 100 % (11/11) of the women who had undergone one, two and at least three cesarean sections" [4].

The larger the defect the greater is the loss of myometrial thickness at the level of the scar defect, with possible negative effects on the stability of the anterior uterine wall during pregnancy. But, quite astonishingly, even in more advanced pregnancies, where sonographically the remaining myometrium at the defect is found to be very thin (Fig. 5.64), its stability is usually better than expected. Nevertheless, uterine rupture is possible and sequential sonographic surveillance is obligatory.

Another consequence of scar defects, depending on their extension and shape, can be the retaining of menstrual blood and therefore irregular bleedings.

But the most severe aspect of cesarean scar defects are cesarean scar pregnancies (CSP) with the high risk of developing placental attachment disorders, such as placenta accreta, increta, and especially percreta.

These developments could be due to the loss of normal endometrium at the level of the scar with its interrupted EMJ. "The loss of functional endometrium results in inadequate decidualization at the scar site; the absence of decidua is considered to be the main factor explaining the propensity of trophoblast to penetrate deep into myometrium, beyond the EMJ, when future pregnancies are implanted into a deficient cesarean scar" [5].

As cases of CSP are described with placental implantation "on" the scar as well as cases with placental implantation "in" the niche of a defect scar [6], it seems that not only scar defects but also scars without (sonographically visible) defects are a risk for CSP.

Because of the high risk of CSP developing the above-mentioned severe placental disorders with all their severe consequences of blood loss, loss of uterus and fertility, all pregnant patients with previous cesarean section should have an early first trimester TVS, preferably between 6 and 8 weeks (p.m.), to localize the gestational sac and placental insertion. If a CSP is found, the patient should be counseled in detail "to enable

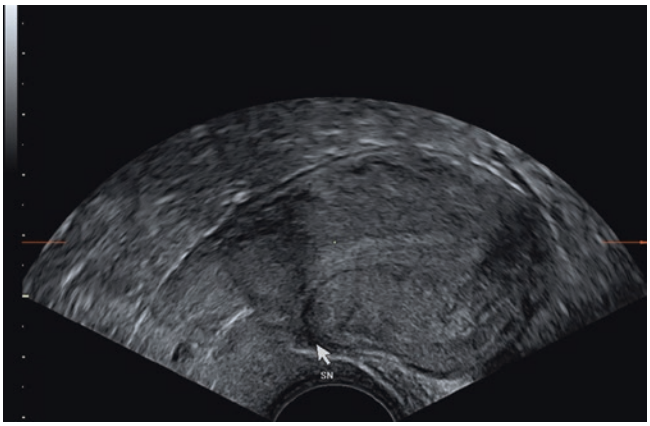

Fig. 5.61 Typical cesarean scar in the anterior wall of the lower uterine segment (Image from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

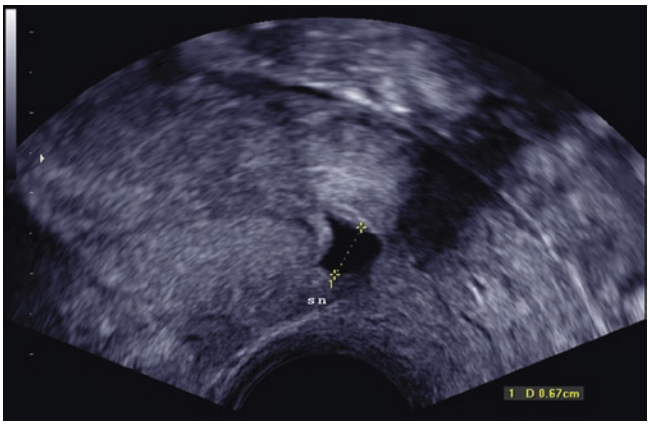

Fig. 5.62 Longitudinal scan of the lower part of the uterus (in this image, left is anterior and right is posterior). Cesarean scar defect filled with anechoic fluid, no pregnancy (Image from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

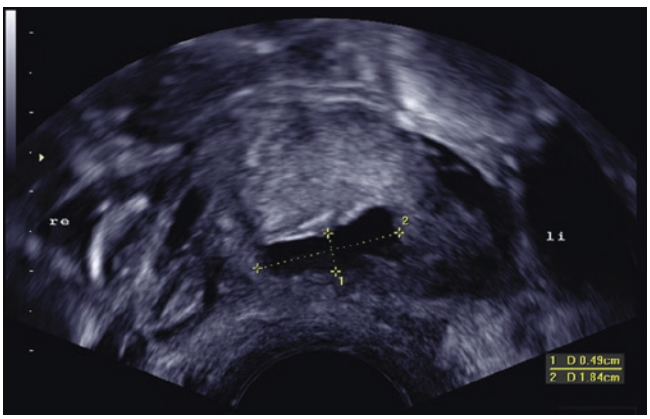

Fig. 5.63 The same case: transversal scan at the level of the scar defect (Image from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

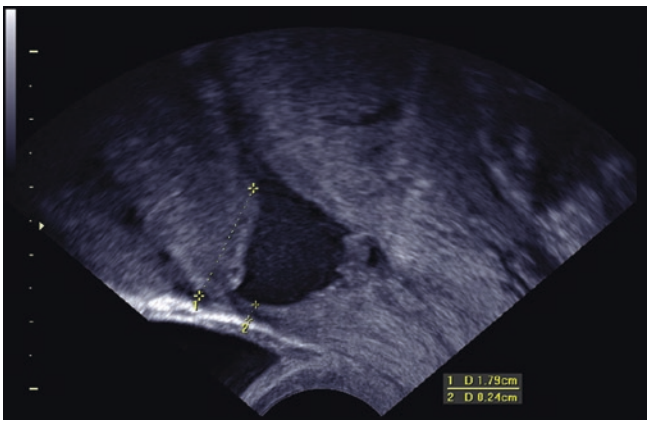

Fig. 5.64 A different case. Longitudinal scan of the lower part of the uterus (in this image, left is anterior and right is posterior). Cesarean scar defect during pregnancy at 26 weeks. The defect is much extended and sharply delineated by amniotic fluid. The remaining myometrial thickness at the scar level is very thin, only 2.4 mm compared to the normal thickness of 17.9 mm at this level (measurements within the image). The course of this pregnancy with sequential sonographic controls was finally terminated by cesarean re-re-section at 36 weeks. The intraoperatively found anterior uterine wall at the level of the cesarean scar was paper-thin but not ruptured. The newborn baby was in good condition (Image from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

her to make an informed choice between first trimester termination and continuation of the pregnancy, with its risk of premature delivery and loss of uterus and fertility " [6]. In this connection, it is well worth reading the article of Timor-Tritsch et al. with its very instructive images of cesarean scar pregnancies and their development in the course of pregnancy [6].

Intrauterine Ectopic Pregnancy

Ectopic pregnancies can be implanted not only extrauterine but also ectopic within the uterus, which is a life-threatening condition and a challenge for therapeutic treatment (Figs. 5.65 and 5.66).

Intrauterine Contraceptive Devices

The position of these devices within the uterus can easily be documented by 2D-sonography and more accurately by 3D sonography (Figs. 5.67,5.68, 5.69, and 5.70).

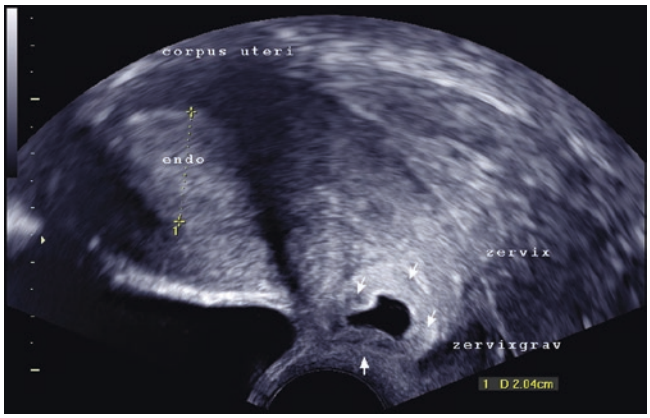

Fig. 5.65 In this longitudinal scan the anterior uterine wall is on the left side of the image. Within the anterior cervical wall a round, in comparison to the surrounding myometrium, more echodense area with a central liquid zone can be seen

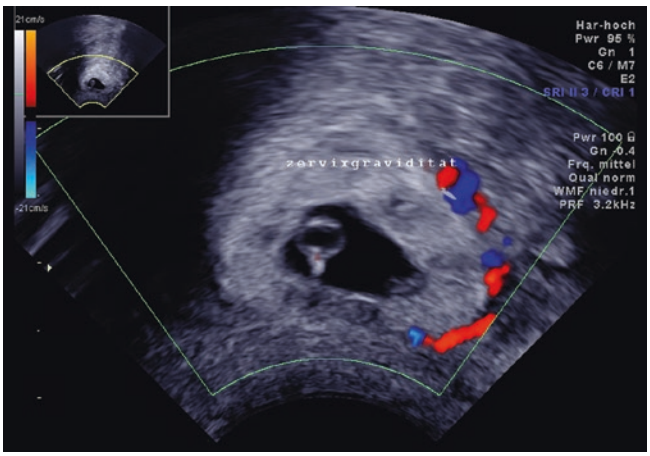

Fig. 5.66 Color Doppler and augmentation show the finding of a vital early pregnancy with the typical neovascularization around the trophoblast (Images by courtesy of Drs. Sibylle Haase and Isabel Wallrafen)

Fig. 5.67 As far as can be estimated by 2D sonography, the image shows a correctly positioned intracavitary IUD. The marked echo indicates a copper-armed IUD

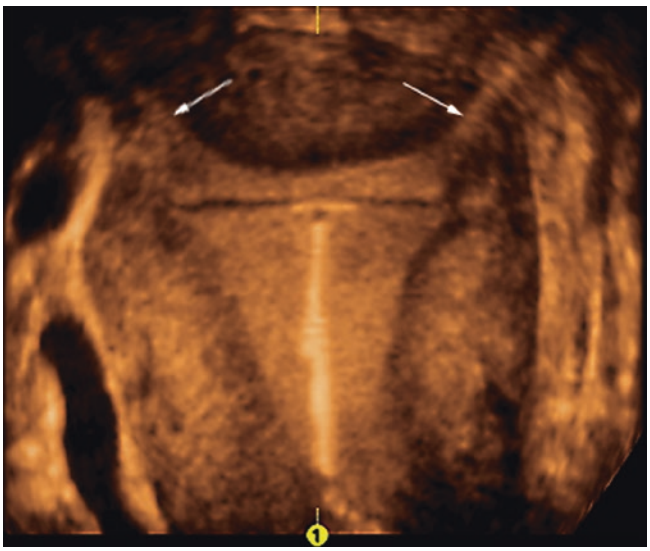

Fig. 5.68 The frontal scan by the 3D OmniView technique demonstrates the correctly extended side arms of this "Copper-T" IUD (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

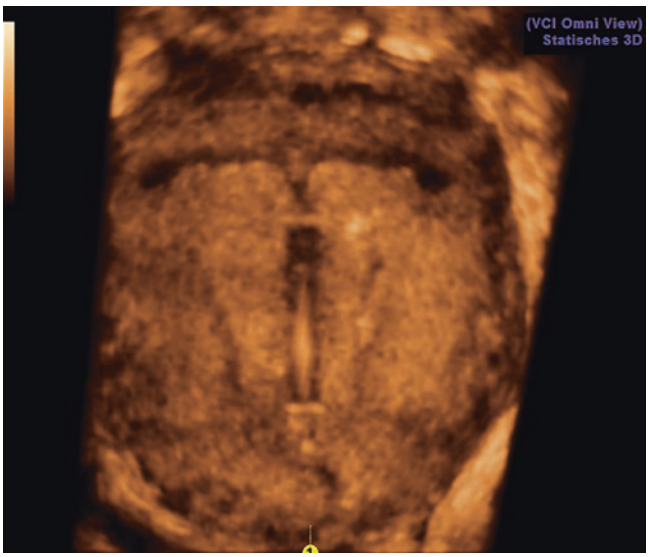

Fig. 5.70 The frontal scan by the 3D OmniView technique demonstrates the correctly extended side arms of the levonorgestrel-bearing IUD Mirena (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

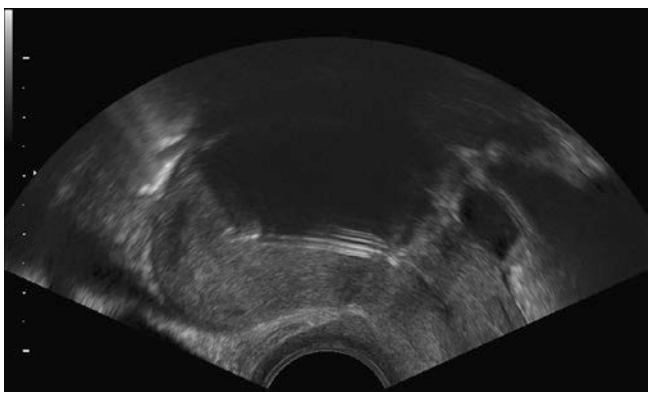

Fig. 5.69 As far as can be estimated by 2D sonography, the image shows a correctly positioned intracavitary IUD. The very marked shadowing behind the IUD indicates a gestagen-delivering IUD

Adenomyosis Uteri Interna or Endometriosis Interna

Adenomyosis is a uterine disease, caused by protrusion of vital endometrium from the basal layer into the myometrium, forming focal or widespread alterations within the myometrium on the other side of the EMJ. This disease is characterized by endometrial glands and stroma, surrounded by hypertrophic myometrium. Each focus can be seen as a "mini-uterus" within the uterus.

According to the theory of Leyendecker, autotraumatization of the uterus, caused by hyperperistalsis and dysperistalsis of the EMJ (archimetra) with consecutive increase of intrauterine pressure, leads to the dislocation of basal endometrium [3]. If basal endometrium fragments settle within the myometrium, the term adenomyosis uteri interna or endometriosis uteri interna is used. If the fragments enter the cavum uteri and from there by retrograde menstruation the peritoneal cavity and settle there, the term endometriosis externa is used.

A common trait of adenomyosis (interna) and endometriosis (externa) is an "infiltrative expansion of the archimetra" into the surrounding uterine wall. Consequently, a disease of the archimetra, that is a disease of the uterus, is the primary phenomenon and "endometriosis of the peritoneal cavity is not an obligatory secondary phenomenon" (Leyendecker).

So much for the shortened theory of Leyendecker.

The spreading of adenomyosis can be focal or multifocal diffuse, with a more infiltrative expansion which, contrary to myomata, shows no clear demarcation from the surrounding tissue. In contrast to myomata the vascularization (angiogenesis) is increased more within the affected area and less around this area. Calcifications are not found within adenomyosis.

A very easy and immediately recognizable sonographic sign of adenomyosis, even with older or low grade ultrasound equipment, is a marked asymmetry between the non or less affected and the more affected uterine wall (Fig. 5.71), provided that the asymmetry is not caused by myomata.

Streaky shadowing within the affected areas, caused by marked differences in sonographic impedances, indicates the older, advanced processes (Fig. 5.72) whereas cystic, clear demarcated adenomyotic islands indicate the more recent processes, see above Fig. 5.25.

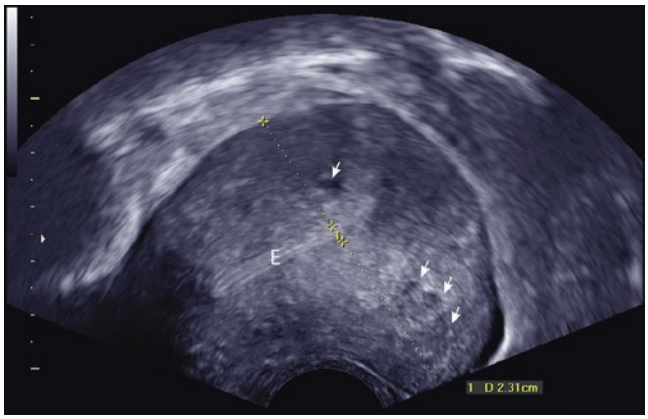

Fig. 5.71 This longitudinal scan demonstrates the common finding of a uterine asymmetry in a case of adenomyosis. "*E*" in the image indicates the mid uterus. One uterine wall contains more adenomyotic foci (*arrows*) than the other, with only one focus (*arrow*), and therefore is markedly thicker. This sign of asymmetric uterine walls can easily be assessed even by low grade US equipment. See above also Fig. 5.24 Color Doppler shows a markedly higher and more irregular vascularization of the affected area in comparison to the regular vascularization by preexisting vessels (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

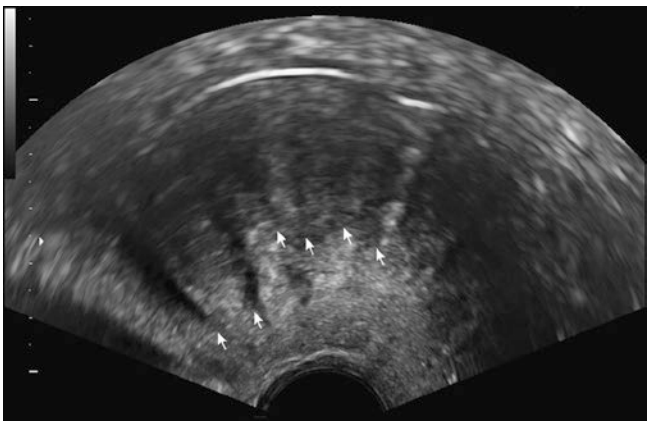

Fig. 5.72 In this longitudinal scan streaky shadowing indicates a widespread adenomyosis. See above also Fig. 5.25: In another area of the same uterus cystic structures, surrounded by an echogenic endometrium-like margin, are to be found. Color Doppler shows a very marked and diffuse neovascularization in the cystic area as a sign of adenomyosis with a tendency to progress. It seems to be that streaky shadows indicate older processes and cystic findings more recent afflictions of adenomyosis (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

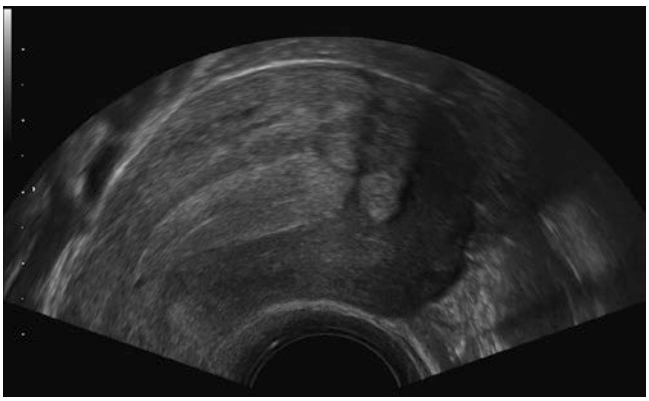

In some cases it can be difficult to differentiate between signs of adenomyosis and myomata when they do not present the signs in a typical manner and especially when both adenomyosis and myomata are present.

The symptoms and consequences of adenomyosis vary, depending on the progression of the disease, from very heavy dysmenorrhea, algopareunia, continuous pain, sterility, to a more or less symptomless course of the disease with normal or only slightly reduced fertility.

Therapeutically medical treatment can be attempted in the form of drugs often given in cases of endometriosis (externa), but it is not really effective. More promising seems to be the intrauterine application of levonorgestrel by means of the intrauterine device Mirena (Schering).

Hysterectomy is the surgical choice for reliably removing all foci. However, if fertility should be conserved as far as possible, organ-preserving methods with excision or electric coagulation of the foci could be considered, depending on the extent of the disease.

Adenomyosis is a very common disease and is detected increasingly more by high resolution TVS in the hands of well-trained investigators whereas in earlier times diagnosis was usually made by chance, histologically.

Flg. 5.73 The longitudinal scan shows two adenomyotic foci close to the endometrium

The examples of adenomyosis presented here (Figs. 5.71, 5.72, 5.73, 5.74, 5.75, 5.76, and 5.77), and see above Figs. 5.24 and 5.25, demonstrate the high value of TVS and color Doppler in the diagnosis and assessment of this disease. In addition to this today's primary tools, MRI can be necessary for special demands, such as "mapping" before surgical treatment.

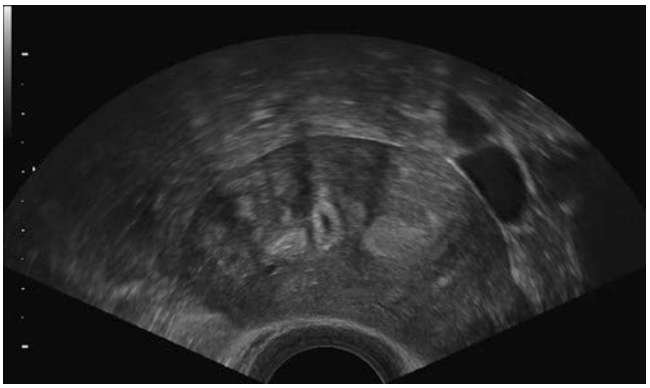

Fig. 5.74 The transverse scan in the fundal region shows some larger and many smaller adenomyotic foci which are more distant from the endometrial part where protrusion into the myometrium has begun

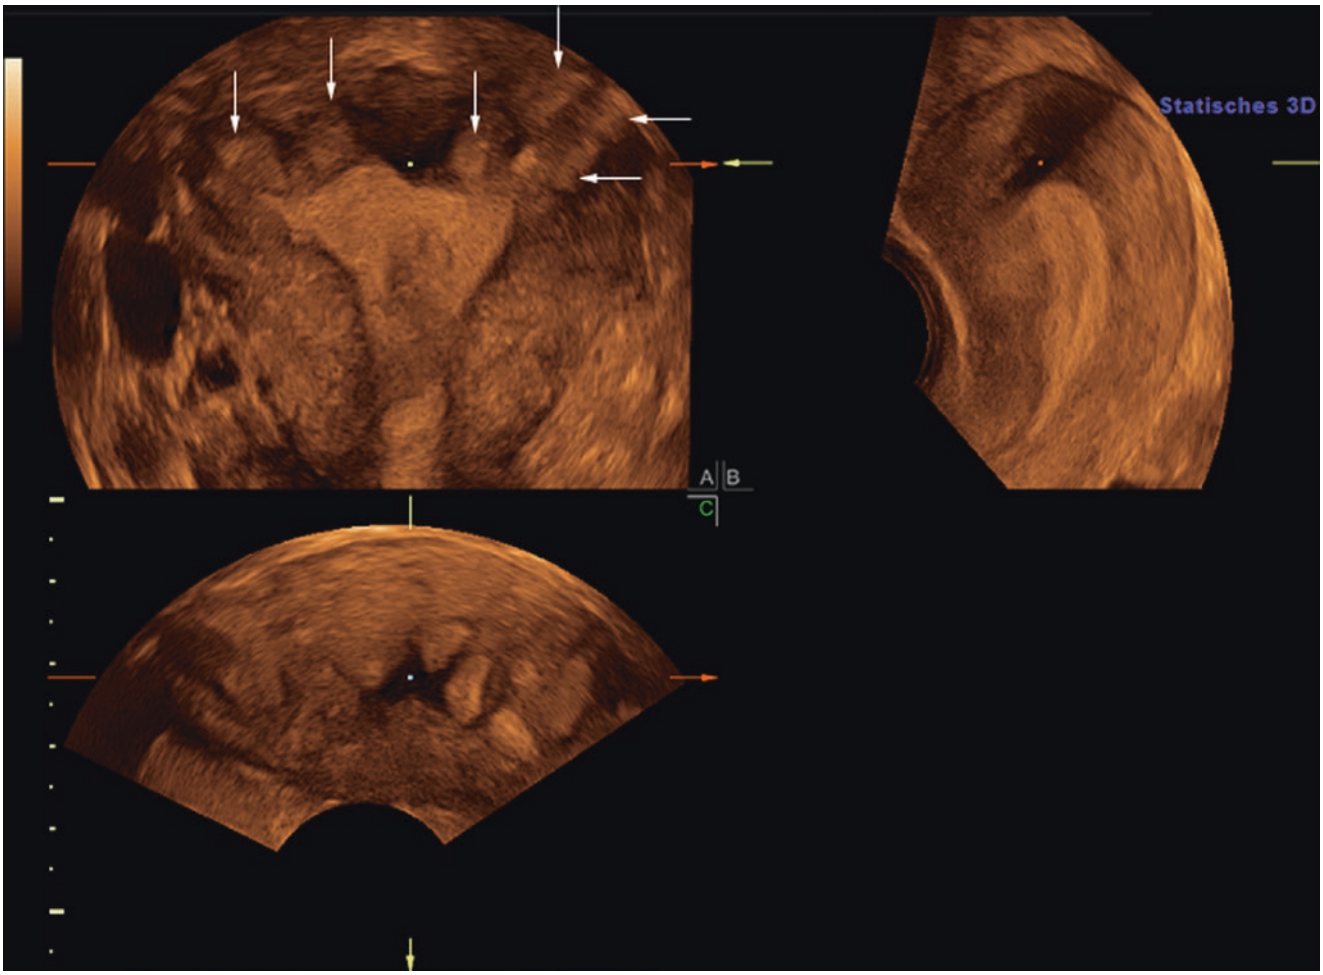

Fig. 5.75 The 3D frontal scan shows multiple adenomyotic foci (*arrows*) which obviously started from the fundal endometrium, as is often found in cases of adenomyosis

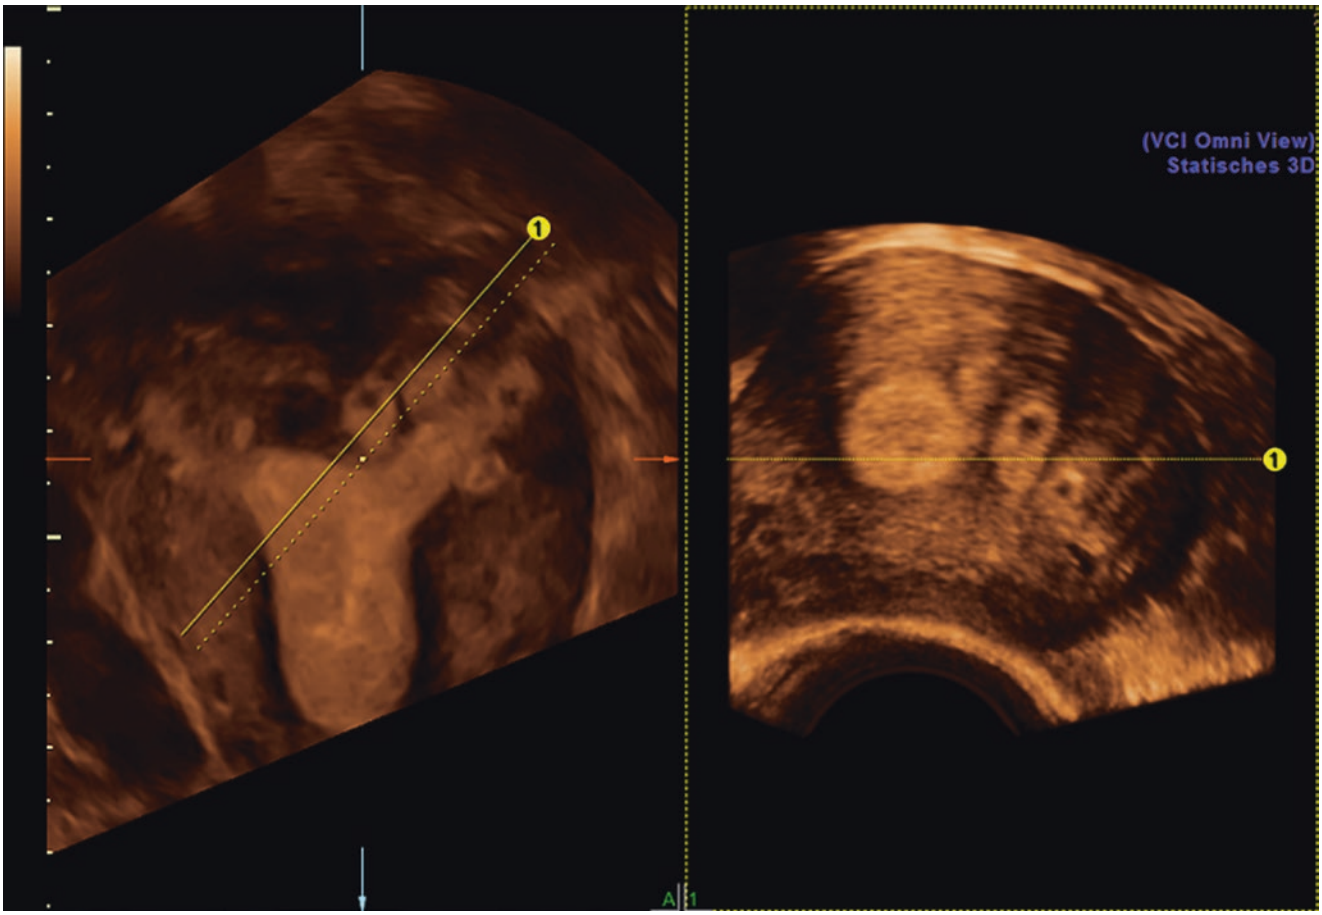

Fig. 5.76 The frontal scan on the left side of the image shows the EMJ as a low echogenous seam surrounding the middle and lower part of the endometrium. In the fundal region the EMJ is no longer visible because of multiple adenomyotic activities with their partially destroying effect on the EMJ. On the right part of the image endometrium and adenomyotic islands are presented more vividly by using OmniView and VCI techniques. The chosen plane of section is indicated by the line 1

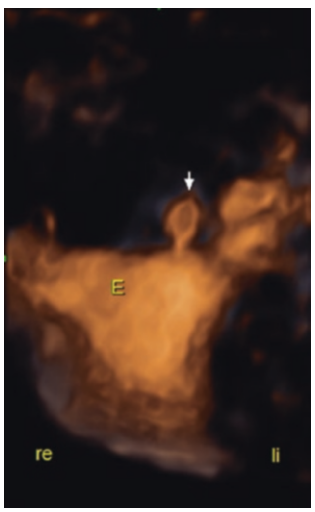

Fig. 5.77 This frontal scan in the fundal region demonstrates an adenomyotic focus in the early phase of development, still connected to the endometrium (Images from Dürr, Transvaginale Sonographie in der Gynäkologie, De Gruyter, 2nd Edition, 2015)

Deep Infiltrating Endometriosis or Adenomyosis Externa

Deep infiltrating endometriosis, described by Donnez et al. [7] as a form of "adenomyosis" invading deep into the rectovaginal space, affects the bowel wall in the rectosigmoid area, the uterus with its ligaments and the paraprocticum. Sonographically, the nodular alteration can be shown as a low echogenic, relatively clear demarcated structure between the cervical part of the uterus and the anterior rectal wall that is invaded in its muscular part (Fig. 5.78), see also Figs. 5.79, 5.80, 5.81, 5.82, and 5.83. To improve the surgical management, the extension of deep infiltrating endometriosis should be assessed by TVS before surgical treatment.

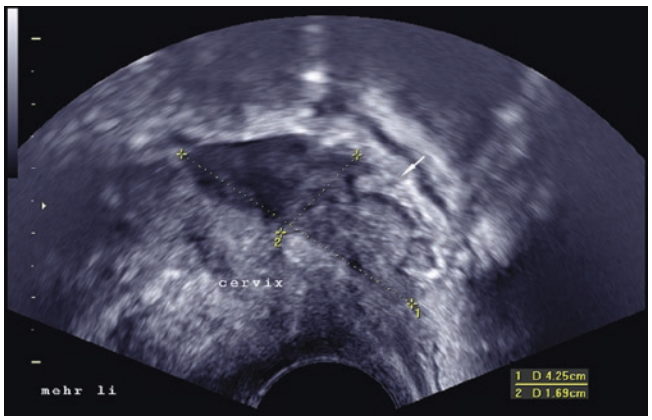

Fig. 5.78 Longitudinal cervical scan, left paramedian. In this and the following images, left is anterior and right is posterior. A retrocervical, rectovaginal deep endometriosis is shown sonographically as a relatively clear, demarcated structure of low echogenity, extended between the posterior cervical wall and the vicinal bowel (rectum) which is infiltrated in its frontal muscular wall. The non-affected mucosal part of the bowel is indicated by high echogenity (*arrow*). Measurements within the image

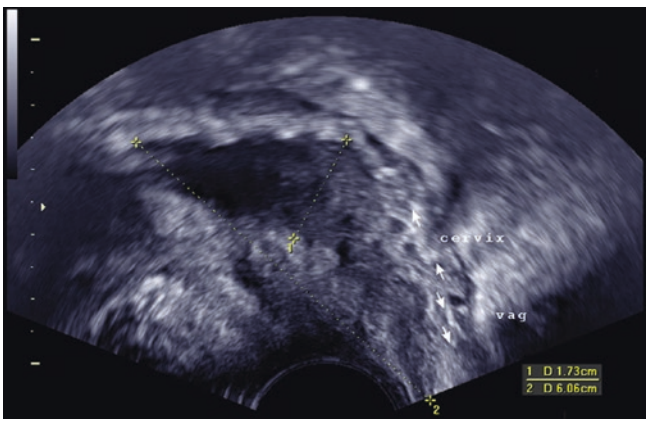

Fig. 5.79 The wide spread of the endometriosis towards the vagina is indicated by two *arrows* and towards the *cervix* by one *arrow*. Measurements within the image

Céline D. Alt-Radke

Introduction

Magnetic Resonance Imaging (MRI)

Native high-resolution T2-weighted images (T2WI) are essential for morphological differentiation of pelvic organ tissue (Fig. 6.1). Contrast-enhanced T1-weighted images (T1WI) give important additional information in almost every problem and should be therefore routinely performed [1–6]. However, kidney functions (kreatinine) should be checked before the intravenous application of contrast media. As intravenous MR contrast agent is gadolinium (Gd)-based, thyroid function is therefore not required to be checked. In recent years, diffusion weighted imaging (DWI) gains more and more attention. This imaging technique was designed to depict alterations in thermally induced random (Brownian) motion of water molecules within tissues and the degree of this motion is known as diffusion [7]. DWI can be performed quickly, without the necessity of contrast i.v. The technique yields qualitative and quantitative information about tissue cellularity and cellular membrane integrity. High cellularity and cell membrane integrity restrict water mobility and therefore diffusion, as seen e.g. in tumors. During MR-performance, diffusion sensitivity can easily be varied by changing the *b* value used during image acquisition [7]. Quantitative analysis of diffusion may be performed by obtaining and mapping apparent diffusion coefficient (ADC) values [7].

For the evaluation of inflammation or fistulas, T2WI with fat saturation are helpful, especially with patients where no contrast media application is possible. For the differentiation between hemorrhage or lipid contents, a native T1-weighted sequence without and with fat saturation is helpful. For lymph node detection, a native T1-weighted sequence or proton-weighted (PD) sequence is helpful (Table 6.1) [8].

Computed Tomography (CT)

With a multidetector CT (MDCT) the examination of a region of interest can be performed in axial plane in a short examination time with submillimeter resolution. The row data can be postprocessed in any plane with approximately the same resolution. It should be noticed that intravenous contrast application is essential for soft tissue contrast because even CT in venous phase has less tissue contrast compared to native MRI (Figs. 6.2, 6.3, and 6.4) [9]. Before performing contrast enhanced CT (CECT), kidney function (kreatinine) and thyroid function (TSH, fT3, fT4) should be checked to be with normal values.

Leiomyoma

Leiomyomas have a pseudo-capsule, are almost clearly defined and can be located submucosal (growth intraluminal), intramural or subserous (growth to the outside), yet can also be pedunculated. More localisations are cervical, vaginal or intraligamental [10]. Usually, the diagnosis is based on the clinical-vaginal examination and ultrasound. In case of myomas large in size or number, a high-resolution MRI of the pelvis may be helpful for the planning of an individual therapy (hysterectomy, myomectomy, open versus laparoscopic surgery, uterine artery embolisation, MR guided focused ultrasound) or the distinction between benign or malignant appearance (Fig. 6.5). Depending on their content,

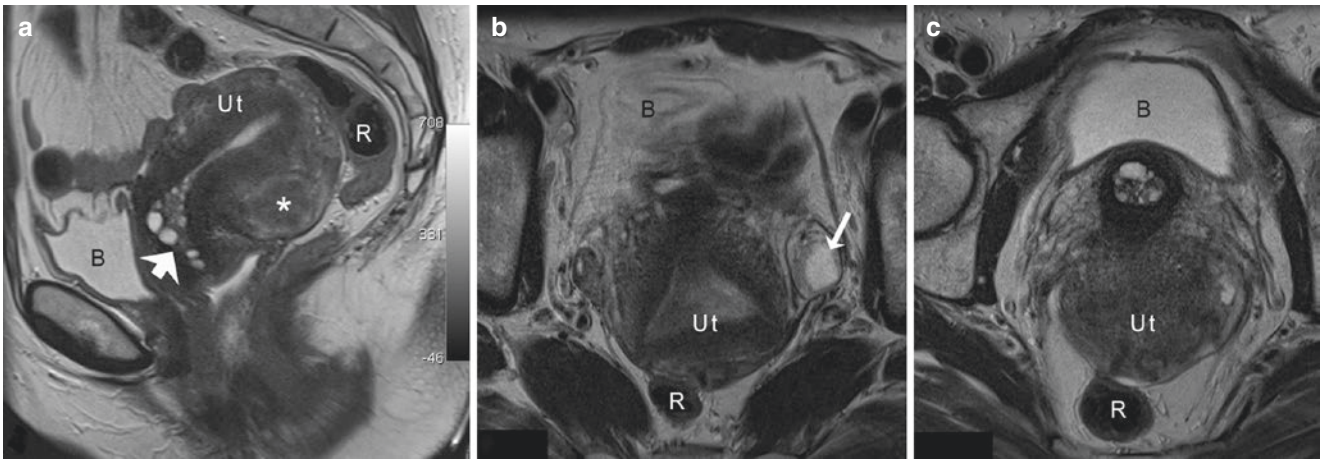

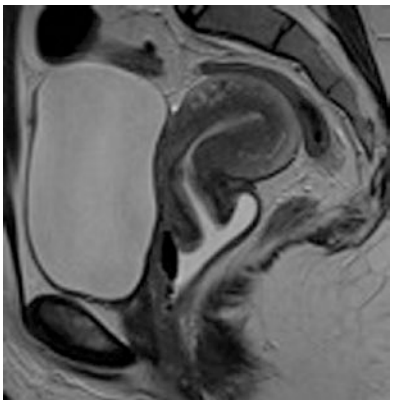

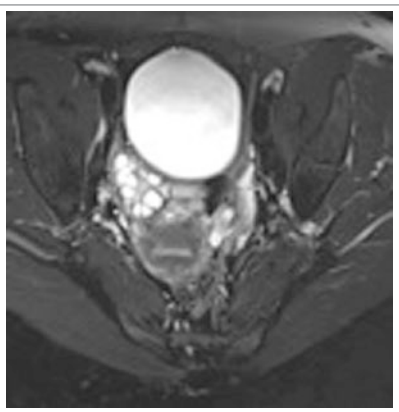

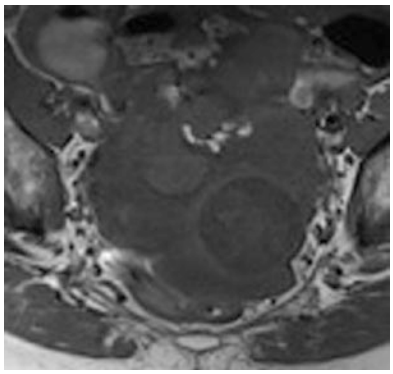

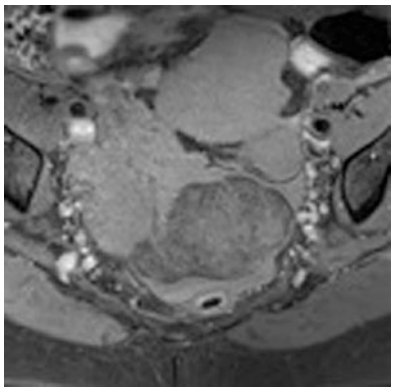

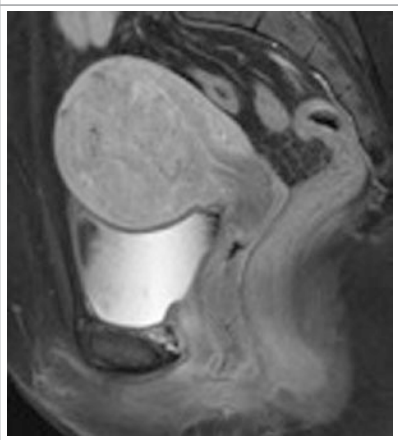

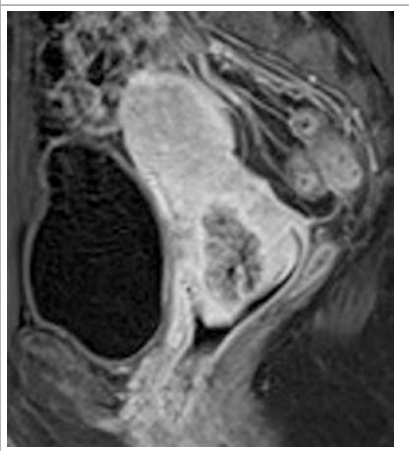

Fig. 6.1 Information given by native T2-weighted MRI of the female pelvis: (**a**) on sagittal plane, the uterus presents retroflected with a normal three-layer appearance and an intramural leiomyoma of the posterior wall (*asterisk*). The cervix contains nabothian cysts (*arrowhead*). (**b**) On T2-weighted transverse oblique plane to the cervix, additional information can be given for the left ovary containing a corpus luteum cyst (*arrow*). (**c**) On T2-weighted transverse plane oblique to the cervix, the hypointense stromal ring of the cervix presents intact, the cervical cavity presents with nabothian cysts. *Ut* uterus, *B* bladder, *R* rectum

Table 6.1 Common MR-sequences used for female pelvic imaging

	Sequence	Specification	Example	
1	High resolution T2WI	Morphology of pelvic organs		[Table 6.2 image 1]
2	T2WI with fat saturation	Oedema, inflammation, fistula		[Table 6.2 image 2]

(continued)

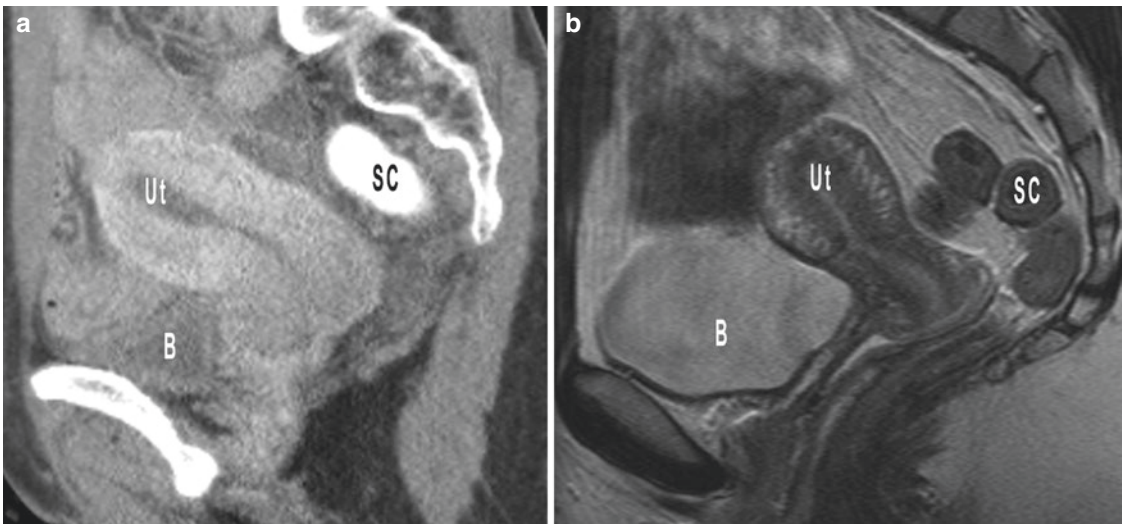
Table 6.1 (continued)

	Sequence	Specification	Example	
3	T1WI native/with fat saturation	Lymph nodes/ differentiation between lipids or hemorrhage		
4	DWI (diffusion weighted imaging)	Diffusion restriction in inflammation, differentiation between benign to malignant lesions		[Table 6.2 image 3.1 and 3.2 are above] [Table 6.2 image 4 here] [Table 6.2 image 5.1 and 5.2 are below]
5	DCE (dynamic contrast enhanced)	Evaluation of tissues in arterial and venous phase, vascularisation, hyperemia		

T2WI T2-weighted imaging, *T1WI* T1- weighted imaging

myomas are shown with different signal behaviour in MRI [10]. A non-degeneratively changed (fibrous) leiomyoma is rich in fibrous tissue, round to ovally shaped, clearly defined and circumscribed, and is hypointense in T1WI and highly hypointense in T2WI in comparison to the myometrium. After application of contrast media i.v., signal behaviour tends to be non-homogenous. Often, a pseudo-capsule can be detected [3, 11]. Due to inlaid calcifications or hyaline, fat or liquid contents, degenerated leiomyomas show heterogenous signal behaviour as early in as in native sequences (Figs. 6.6, 6.7, and 6.8) [11]. If myomas are classified as secondary findings in CT-examinations, they commonly show early enhancement in the arterial phase and are more likely to be hypodense in the late phase. Depending on their size, myomas are homogenous (small myomas) or heterogenous (large myomas) (Fig. 6.4). Ring-shaped calcifications, which can be more easily discerned in CT than in MRI, are often part of myomas. Hyperdense foci in CT may point to hemorrhage, whereas hypodense areas may be a sign of necrosis or infection (Figs. 6.8 and 6.9).

Possible differential diagnoses for leiomyomas are polyps (if submucous myoma) (Fig. 6.10), adenomyosis (if intramu-



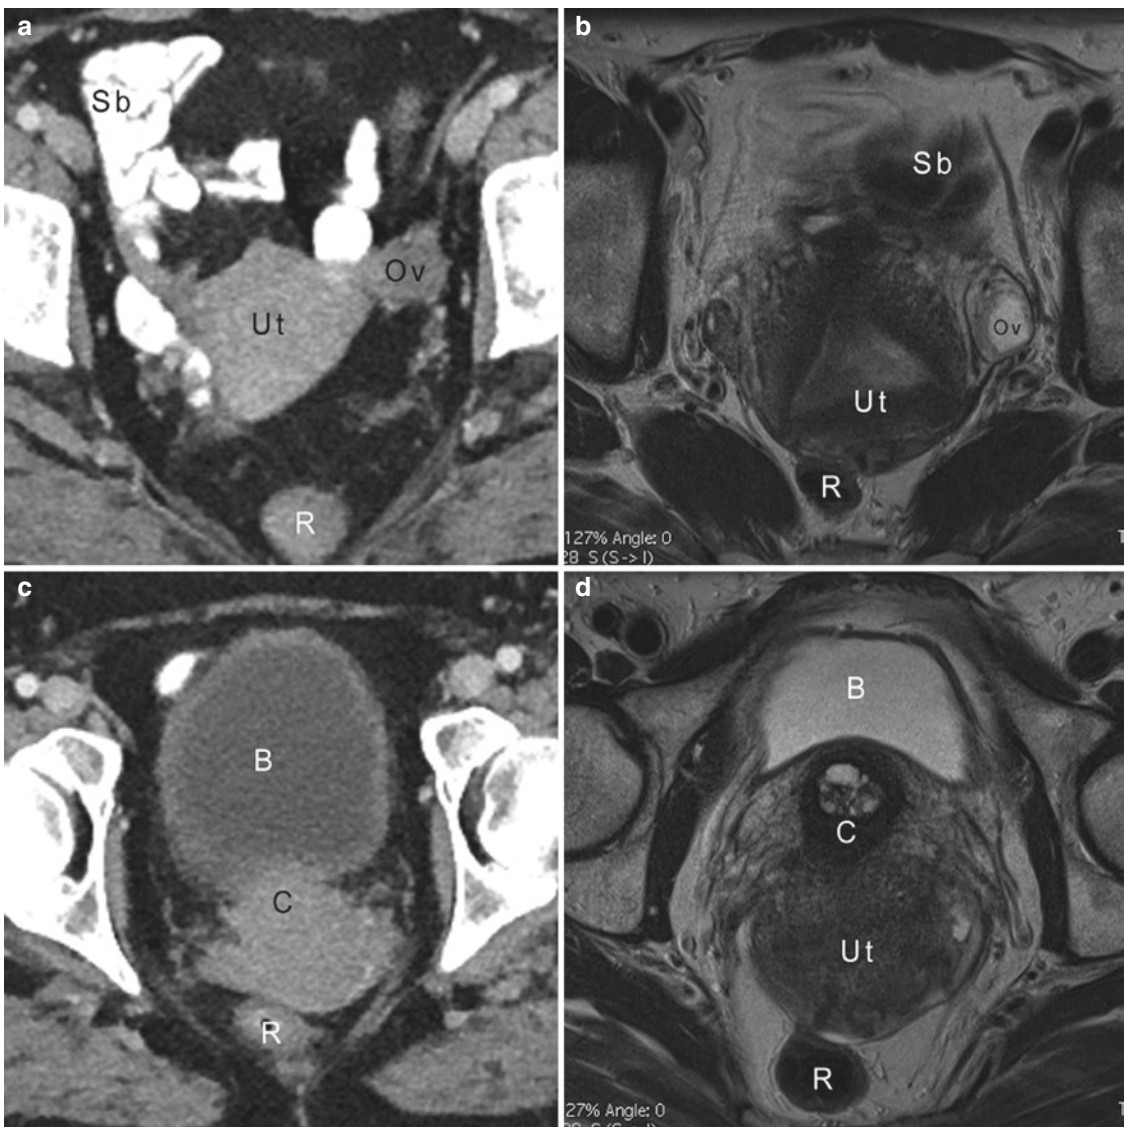


Fig. 6.2 Two patients presenting with sagittal images of the entire pelvis. (**a**) contrast enhanced CT gives an overview of the pelvic organs but lacks of good morphological differentiation. (**b**) High resolution T2 weighted image on MRI presents with a high soft tissue contrast and allows differentiation of different tissues, e.g. the differentiation between endometrium, junctional zone, myometrium and perimetrium. *B* bladder, *Ut* uterus, *SC* sigmoid colon

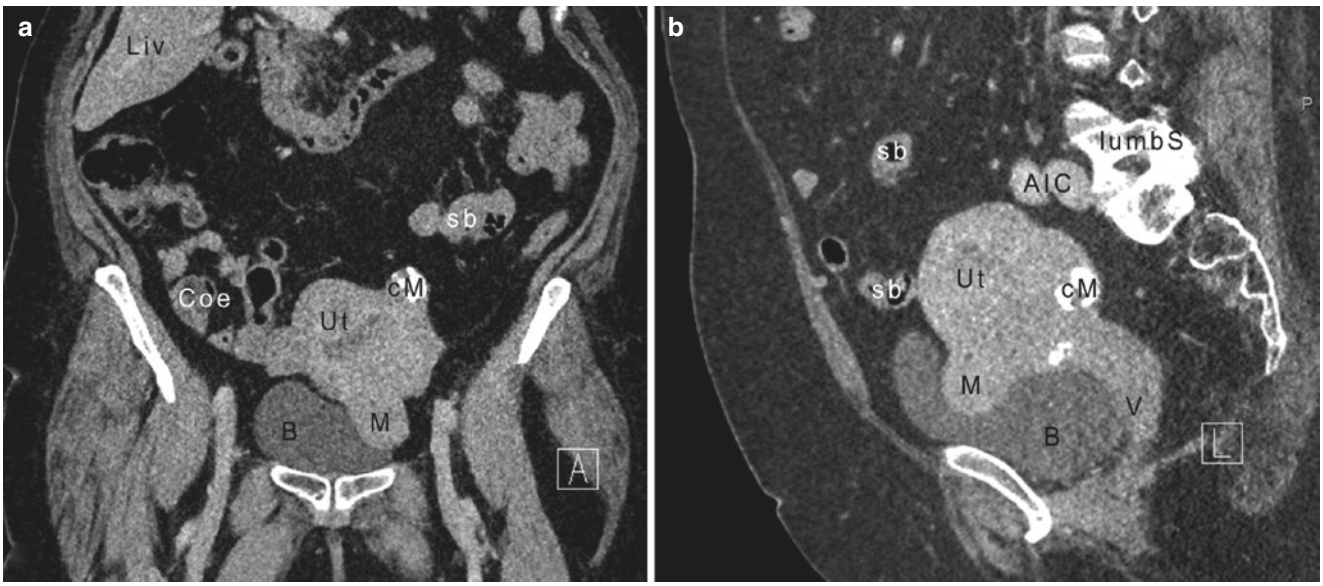

Fig. 6.4 Contrast enhanced CT performed for another indication. As a secondary finding, the woman presents with uterus myomatosus, partially calcified. Image on coronal (**a**) and sagittal (**b**) plane for anatomical landmarks. *Ut* uterus, *M* myoma, *cM* calcified myoma, *V* vagina; *B* bladder, *R* rectum, *Liv* liver, *sb* small bowel, *Coe* coecum, *AIC* common iliac arteries, *lumbS* lumbar spine

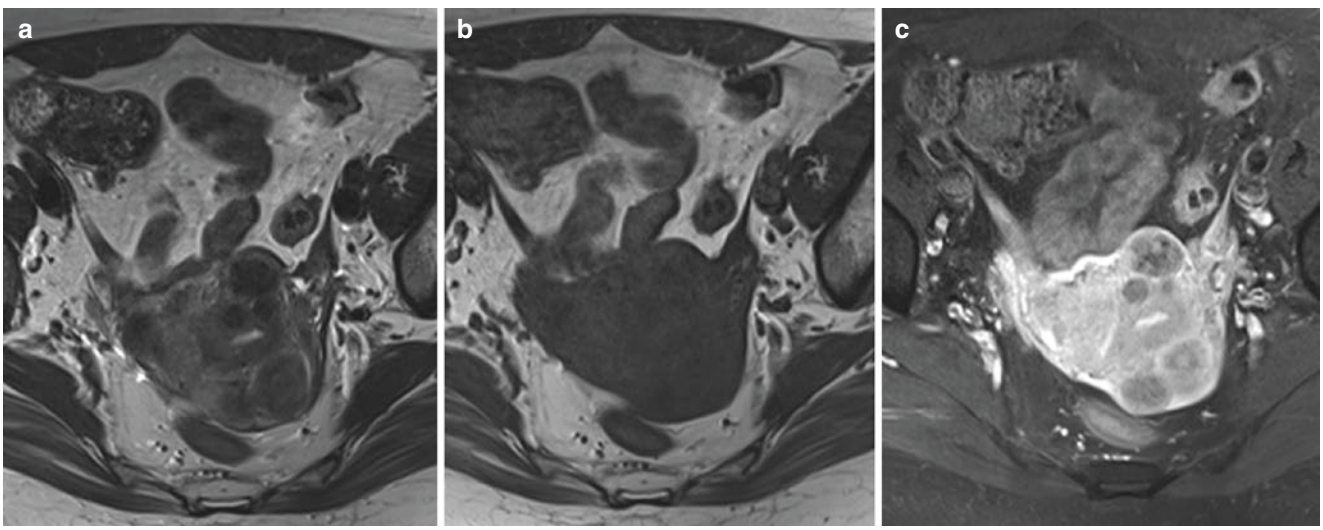

Fig. 6.5 Patient presenting with symptomatic uterus myomatosus. Without cross sectional imaging, the clear differentiation between degenerated/non degenerated leiomyoma, the number and localisation and the differentiation to small bowel loops, respectively, may be challenging with ultrasound alone. These images at transversal plane show the uterus myomatosus with at least 6 leiomyomas at this slice on (**a**) T2WI (**b**) native T1WI and (**c**) after contrast i.v

Fig. 6.3 Comparison of contrast enhanced CT (*left*) to native MRI of the female pelvis (*right*). The excellent soft tissue contrast of MRI without radiation gives more detailed information of the female pelvis as CT is able to. Therefore, whenever possible, MRI with an adopted gyne protocol should be performed instead of CT. *Ut* Uterus, *Ov* ovary; *C* cervix, *B* bladder, *Sb* small bowel, *R* rectum

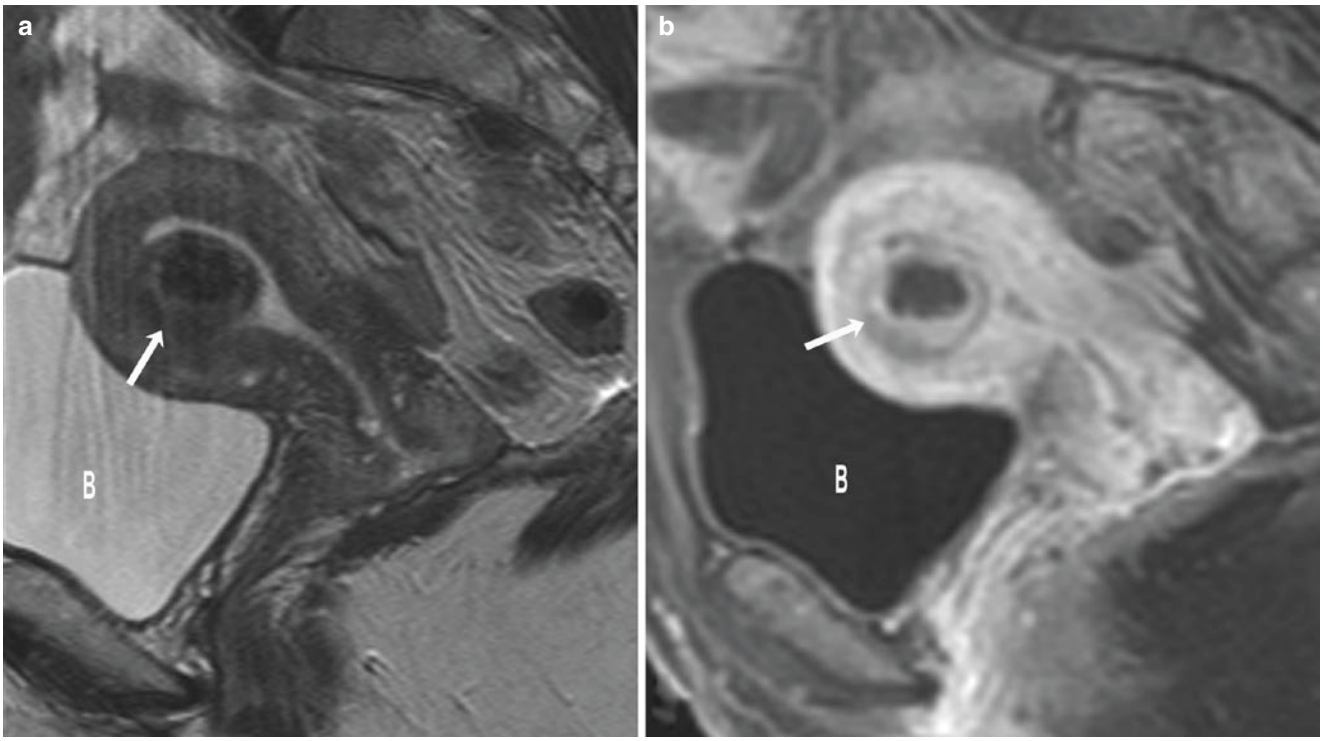

Fig. 6.6 Presentation of a submucous leiomyoma of the anterior wall of the uterine corpus with a wide based connection to the endometrium (*arrow*). (**a**) It presents with a hypointense center with an isointense ring shape on T2WI. (**b**) After application of contrast i.v., the center of the leiomyoma remains hypointense, possibly due to calcifications. *B* bladder

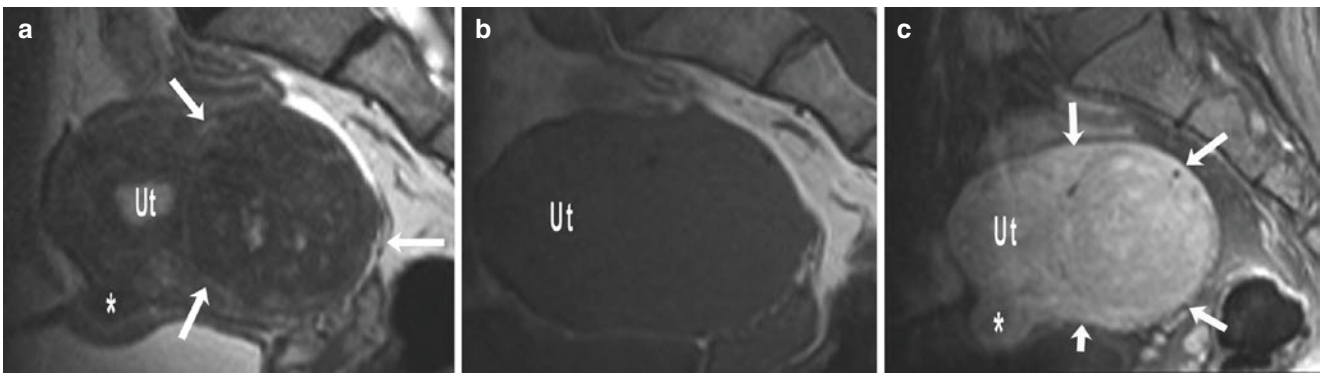

Fig. 6.7 Huge subserous non-degenerated leiomyoma of the uterus (*arrows*). (**a**) The leiomyoma is hypointense with some minor hyperintense spots at T2WI. (**b**) It presents with the same signal intensity as the myometrium at native T1WI. (**c**) It enhances homogenously after contrast i.v., comparable to the myometrium. Additionally, the claw sign is present (the serosa surrounds of the fibroid). There is a small second subserous leiomyoma at the anterior wall (*asterisk*). *Ut* uterus

Fig. 6.10 Presentation of an endometrial polyp on contrast enhanced CT scan (**a**) and MRI (**b**). (**a**) On CT scan, a homogenously enhancing lesion, located at uterine cavity is present (*arrow*). A clear identification cannot be made between submucous myoma, hemorrhage or polyp, histopathologically proven as endometrial polyp. (**b**) T2-weighted MRI presents with a well circumscribed hypointense lesion at the hyperintense uterine cavity with a small peduncle to the endometrium (*arrow*). Clear identification of a polyp can be made, histopathologically proven. Secondary finding is a follicle cyst right sided with partial hemorrhage

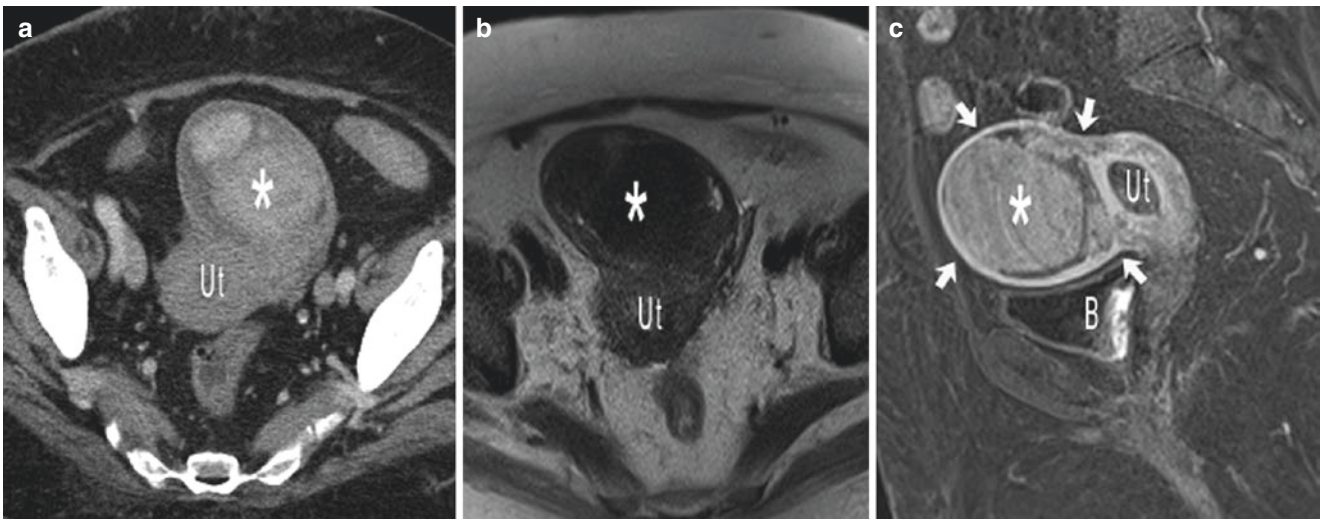

Fig. 6.8 (**a**) CT scan of the pelvis presents with a mass like lesion of the uterus with heterogenous densities (*asterisk*). (**b**) MRI in the same patient shows this mass as hypointense on T2WI associated with the uterus and well defined margins (*asterisk*). (**c**) application of contrast i.v. shows the typical claw-sign for subserous leiomyoma (*arrows*). This result was histopathologically proven. *B* bladder, *Ut* uterus

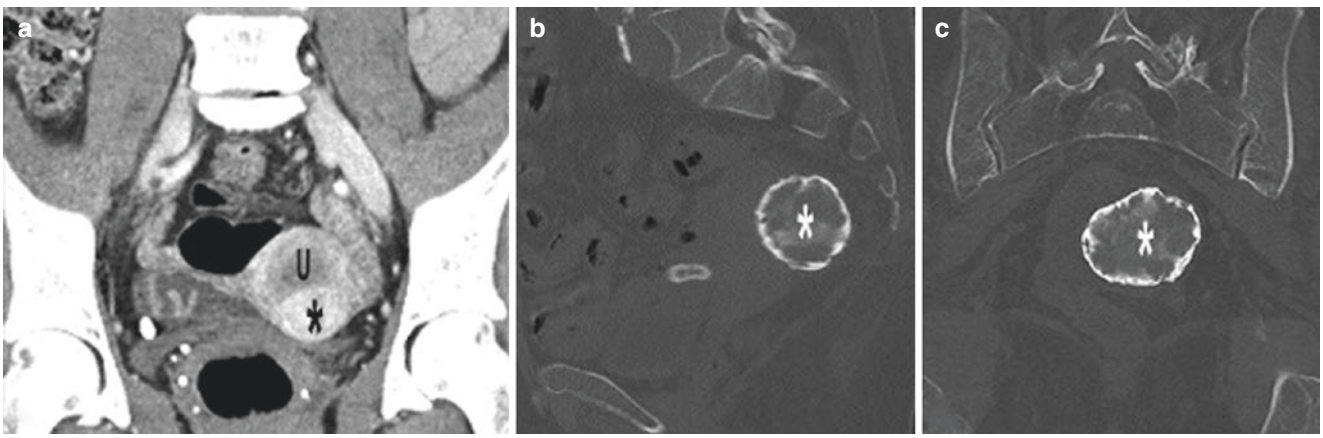

Fig. 6.9 (**a**) Presentation of a subserous non degenerated leiomyoma of the uterus at CT at venous phase (*asterisk*). The lesion is slightly more hyperdense than the myometrium. The uterine cavity presents as hypointense (*U*). Tissue contrast is reduced compared to MRI. (**b**) and (**c**) Degenerated myoma with ring-shape calcifications in another patient as a secondary finding on CT in sagittal and coronal plane (*asterisk*). Using the bone window, calcifications are best seen. This leiomyoma is located directly presacral and may be a cause for unspecific lower lumbar pain

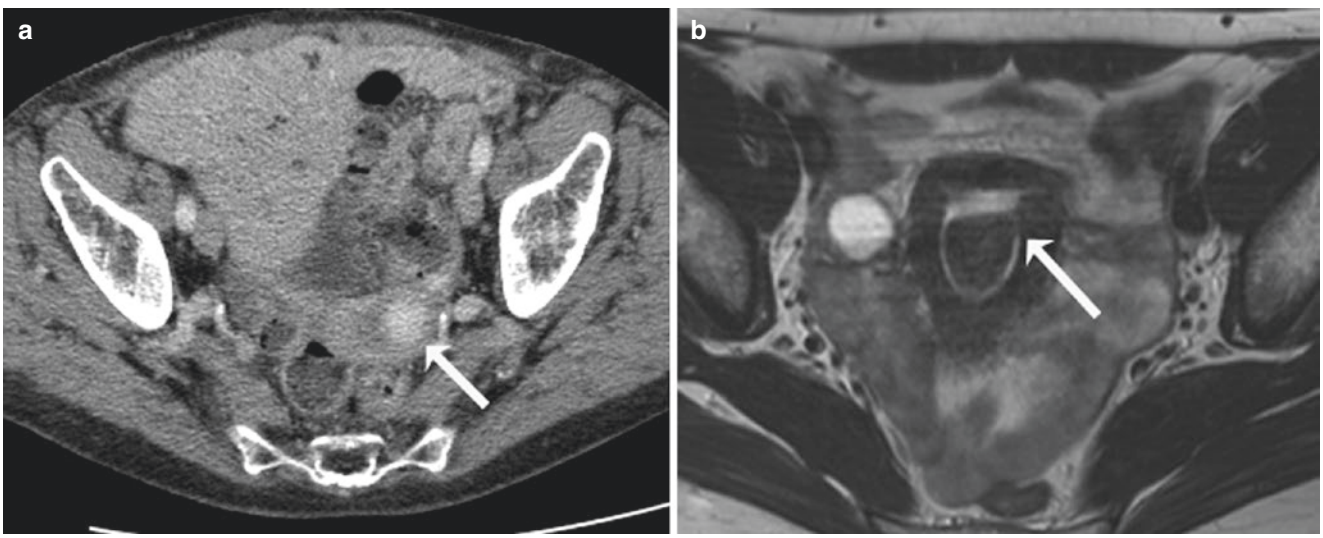

Table 6.2 Cross sectional imaging modalities for female pelvic pathologies

	Native MRI	CE MRI	Native CT	CECT	PET/CT	Specification of disease
1	+	+	–	(+)	–	Localisation, number, morphology, possible suspicious areals (early focal enhancement)
2	+	+	–	–	–	Differentiation and detection of adnexal, uterine or subperitoneal manifestations
3	+	–	–	–	–	Evaluation of entire pelvis with dynamic sequences during valsalva maneuver
4	+	+	–	(+)	–	Visualisation of fistulas and their origin/entry/re-entry better detection with rectal and/or vaginal filling with ultrasound gel MRI modality of choice for fistulas, CECT only if use of MRI is limited due to contraindications
5	+	+	–	+	+	CE MRI of the pelvis including the level of the renal veins for local staging and lymph node detection CECT of the abdomen and thorax for pretreatment staging in advanced stages CECT of the pelvis only if MRI is impossible to perform (e.g. pacemaker, implants) CE MRI for local recurrence PET/CT for diffuse or occult metastases
6	+	+	–	+	+	CE MRI of the pelvis including the level of the renal veins for local staging and lymph node detection CECT of the chest and abdomen for pretreatment staging in advanced stages CECT of the pelvis only if MRI is impossible to perform (e.g. pacemaker, implants) CE MRI for local recurrence PET/CT for diffuse or occult metastases

CE contrast enhanced, *MRI* Magnetic Resonance Imaging, *CECT* Contrast Enhanced Computed Tomography, *PET* Positron Emission Tomography

ral ill-defined myoma), uterine sarcoma (especially in fast growing intramural myoma), leiomyosarcoma of the cervix or vagina, ovarian fibroma or ovarian cancer (if subserous or pedunculated myoma). If local tumor differentiation is required, MRI of the pelvis is the imaging modality of choice (Table 6.2).

Endometriosis

MRI is recommended in cases with suspicion for subperitoneal endometrioses or in cases with unclear dysmenorrhoea and suspicion for adenomyosis [12–14].

Subperitoneal Implants of Endometriosis

Suberitoneal implants from endometriosis may be detected with MRI from at least 7 mm in diameter. Endometrial implants are hypointense in native T1WI and T2WI images. Sometimes T1WI hyperintense spots may be present in between the implant [12, 15]. If endometriosis is implanted in the abdominal wall, detection is made with a T1WI sequence with fat saturation. Angulation of the MR-sequences to the uterine corpus is essential for correct visualisation of the sacrouterine ligament, the torus uterinus and the fornix vaginae. Slice thickness should not exceed 3–4 mm for detection of small implants [16]. There is no indication for CT performance in endometriosis [17].

Adenomyoma/Adenomyosis Uteri

The adenomyoma and the adenomyosis uteri are two special forms of subperitoneal endometriosis and are located in the myometrium or the junctional zone of the uterus. Areas of endometriosis found within a myoma are defined as adenomyoma. The adenomyoma is almost ovally shaped and slightly blurred around its border with the surrounding myometrium when compared to an intramural leiomyoma. The signal intensity is comparable between both forms of myomas (Figs. 6.11 and 6.12) [11].

One distinguishing feature may be the fact that in adenomyoma, the junctional zone is commonly an integral part of the lesion, whereas in leiomyoma, even a small myometrial layer is notable close to the junctional zone.

An adenomyosis uteri is characterised by haphazardly scattered endometrial tissue within the uterus wall (Fig. 6.9). Using ultrasound, the adenomyosis uteri often represents heterogenous and includes microcysts. The accuracy using ultrasound was reported by Bazot et al. with 88 % and a sensitivity of 65 %, a specificity of 97.5 %, a PPV of 93 % and a NPV of 89 % when combining transvaginal and transabdominal ultrasound in patients without

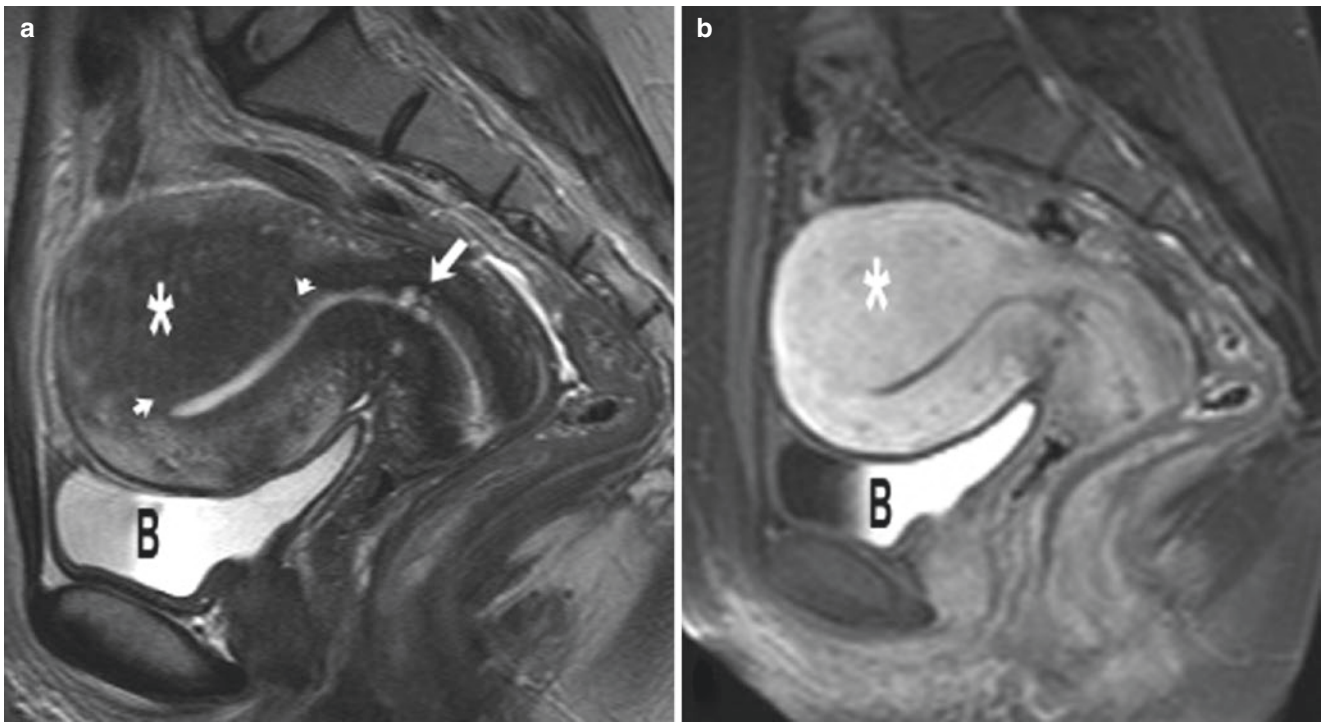

Fig. 6.11 Presentation of an adenomyoma in the posterior uterine wall with slightly blurry margins to surrounding myometrium (*asterisk*). Additionally, the adjacent junctional zone is not well defined (*arrowheads*). In the anterior wall there are several hyperintense spots, which are typical for diffuse adenomyosis. Small nabothian cysts as secondary findings (*arrow*). *B* bladder

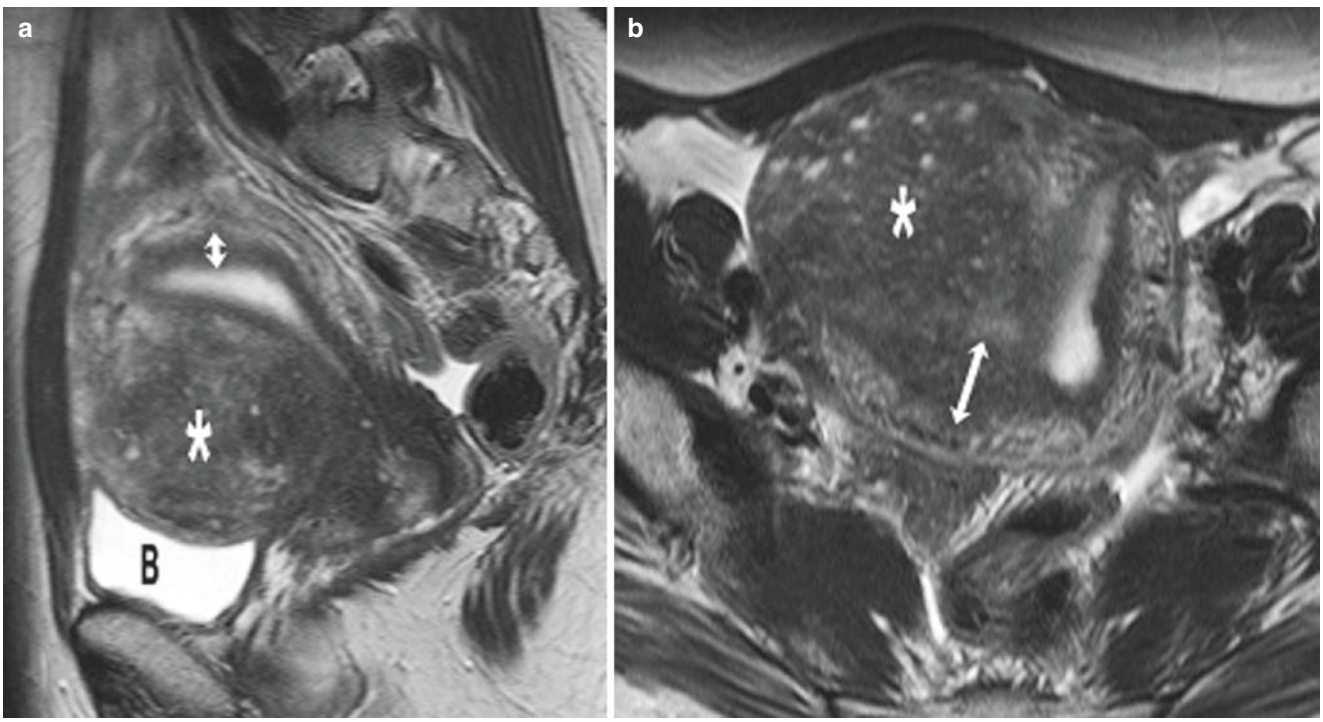

Fig. 6.12 (**a**) Presentation of an adenomyoma in the anterior uterine wall on T2WI on sagittal plane with slightly blurry margins to surrounding myometrium and several hyperintense spots. (**b**) The junctional zone is thin despite of a focal thickening at the posterior wall (*distance arrows*). This finding is typical for focal adenomyosis. *B* bladder

Fig. 6.13 Presentation of diffuse adenomyosis with heterogenous signal intensity of the myometrium and a thickened junctional zone with hyperintense spots on T2WI. Retroflected uterus. *B* bladder, *R* rectum

associated uterine disorders [18]. However, in patients with accompanied uterine disorders, e.g. leiomyomas, or with an enlarged uterus, ultrasound is limited in correct diagnosis of adenomyosis [18]. In those cases, MRI is able to visualize the uterine corpus on its whole extent and free of superimposition [19].

Using MRI, an adenomyosis characteristically shows a thickened junctional zone of more than 12 mm (the norm being max. 5 mm), hyperintense spots on T1WI and microcysts (Fig. 6.13). The accuracy using MRI was reported to be 87.5 % with a sensitivity of 77.5 %, a specificity of 92.5 %, a PPV of 84 % and a NPV of 89 % [18]. Typically, a discrepancy between the anterior and posterior wall of the uterine corpus can also be detected [20]. Differential diagnoses for adenomyoma are leiomyoma or uterine sarcoma. A study by Moghadam et al. evaluated the predictive value of an preoperative MRI in differentiating between leiomyoma and adenomyosis compared with pathologic findings in 153 women, suggesting that pelvic MRI is highly specific in the diagnosis of adenomyosis with 91 % and highly sensitive for leiomyomas with 94 % [19].

Fistulas

Vaginal fistulas may commonly occur after surgery (e.g. hysterectomy), radiation therapy or with the background of (chronic) inflammatory disease. Surgical reconstruction of such fistulas may be challenging, wherefore the detection and exact location of the fistula is crucial for therapy planning. With thin sliced T2-weighted or PD-images with fat saturation angulated to the vaginal cavity, the fistula presents hyperintense and is commonly well delineable to the surrounding tissue (Table 6.1). Patient's preparation with vaginal and rectal filling with ultrasound gel helps to better identify the origin of the fistula (Figs. 6.14 and 6.15). CT is mostly unable to detect small fistulas, why indication is usually not authorized.

Symptomatic Pelvic Floor Dysfunction

The prevalence of pelvic organ prolapse in developing countries is reported to be around 19.7 % [21]. Vaginal childbirth was demonstrated to be a predictor for levator ani trauma and an increased prevalence of pelvic floor dysfunction (PFD) even in younger, parous women [22–26]. Affected women may suffer from an abnormal frequency and urgency of emptying of the bladder, organ protrusion, pelvic pain or from dyspareunia, as well as from urinary or fecal incontinence [27–30]. To evaluate the pelvic floor structures and its integrity, MRI with high resolution T2 weighted images are performed at rest. This is best done in three planes [31–34]. The dynamic MR scans are performed during straining or defecation in the sagittal plane to evaluate pelvic organ prolapse (POP) and concordant PFD. The radiological report should give standardized measurements of pelvic organ prolapse, as well as a quantitative description of the pelvic organ position at rest and during straining or evacuation (Figs. 6.16, 6.17, 6.18, and 6.19) [35]. This precise description gives an impression of an individual woman's pelvic support in addition to an accurate, observer-independend, site-specific observation of the stability or progression of prolapse over time. Similar judgments are made regarding the outcome of surgical repair of prolapse, without interpreting the data using a grading system [36]. It was shown that the visualization of pelvic organ mobility, the detection of all involved structures and the extent of POP, detached from a grading system based on maximal prolapse values, might have more impact for intraindividual evaluation [37].

Dynamic MRI has benefits especially in regard to women suffering from re-prolapse after surgical repair and in the

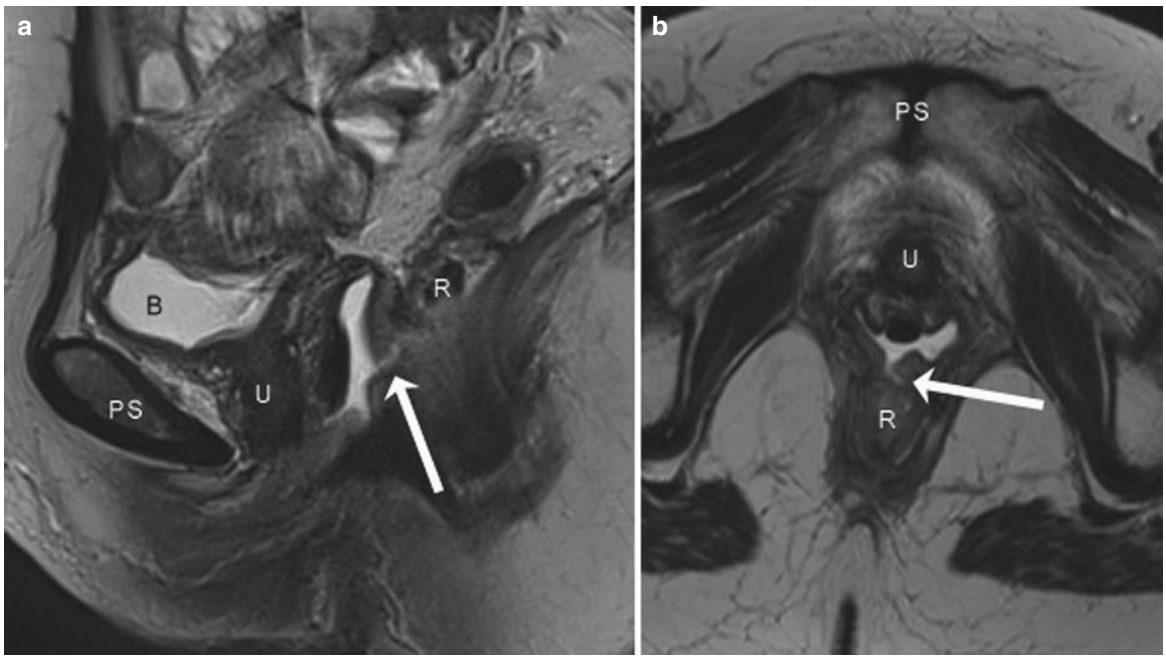

Fig. 6.14 Recto-vaginal fistula on high-resolution T2-weighted images. (**a**) on sagittal plane, the vaginal vault is filled and distended with ultrasonic gel. The fistula to the rectum with its angled form is also filled with gel, why detection is easy (*arrow*). (**b**) On transverse plane, the fistula starts at the posterior vaginal wall at 6 o'clock (*arrow*). At this level, the rectal wall is still intact. The entry to the rectum is located above (see (**a**)). *PS* pubic symphysis, *B* bladder, *U* urethra, *R* rectum

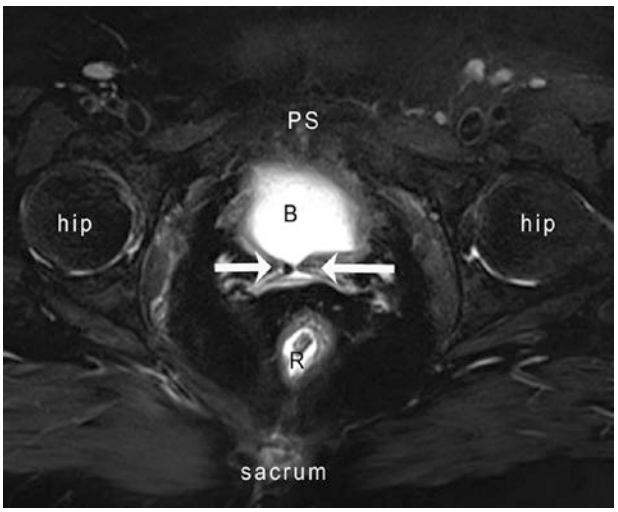

Fig. 6.15 Patient with vesico-vaginal fistula. T2-weighted images on transverse plane with fat saturation easily detect the fistula due to the high contrast of urine in the bladder and the vaginal filling with ultrasonic gel (*arrows*). The rectum was also filled with ultrasonic gel. *PS* pubic symphysis, *B* bladder, *R* rectum

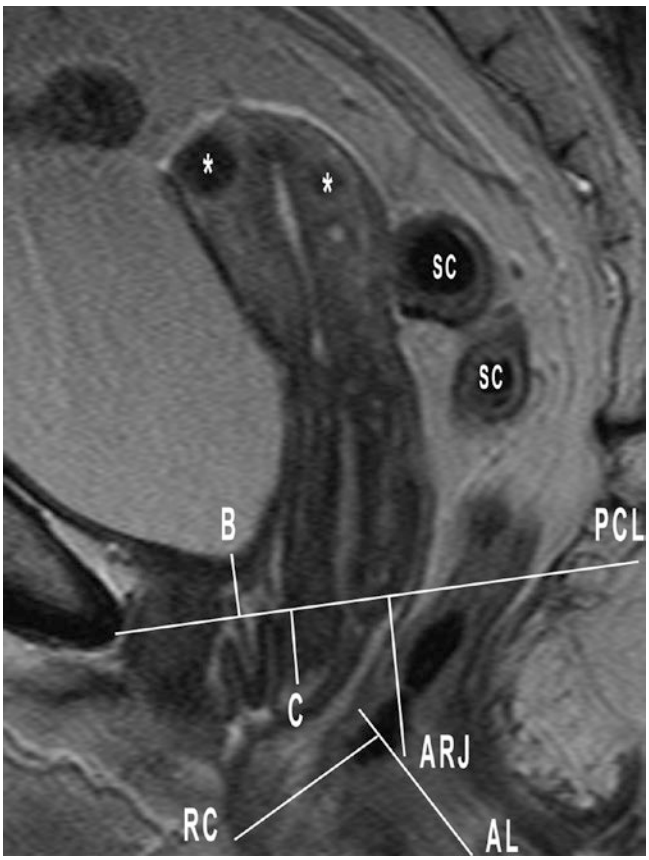

Fig. 6.16 T2WI on sagittal plane at rest in a 62 year old female. Even at rest, a partial uterine prolapse (*C*), a small rectal descent (*ARJ*) and a small rectocele (*RC*) can be noted. The bladder base (*B*) is above the reference line (*PCL*). Two small intramural leiomyomas are seen at T2WI on sagittal plane (*asterisk*). *AL* anal line (reference line for rectoceles), *SC* sigmoid colon, *ARJ* anorectal junction

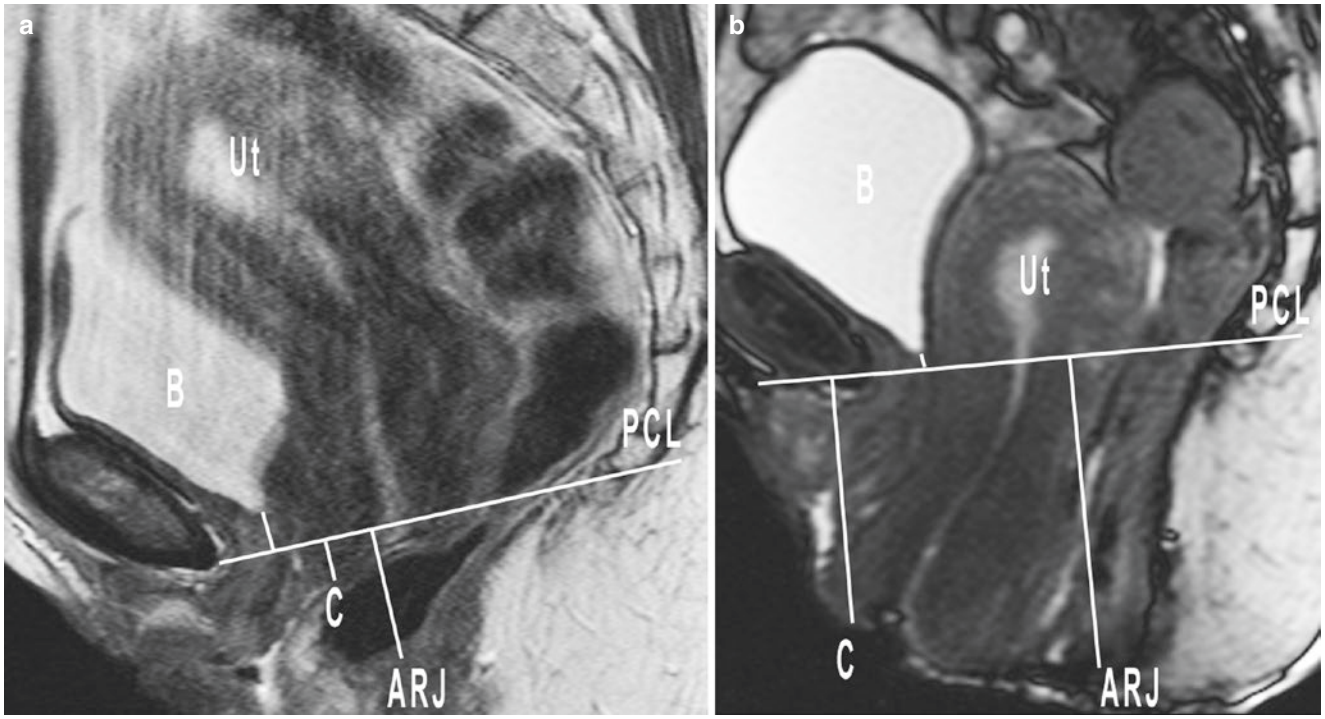

Fig. 6.17 (**a**) T2WI on sagittal plane at rest presenting with small descent of the cervix and a small rectal descent (*ARJ*). (**b**) During maximum strain presentation of a partial uterine prolapse and a severe rectal descent. The bladder is moved ventrally to the pubic symphysis. No bladder descent due to lack of hiatal space. *PCL* pubococcygeal line, *B* bladder, *Ut* uterus, *C* cervix, *ARJ* anorectal junction

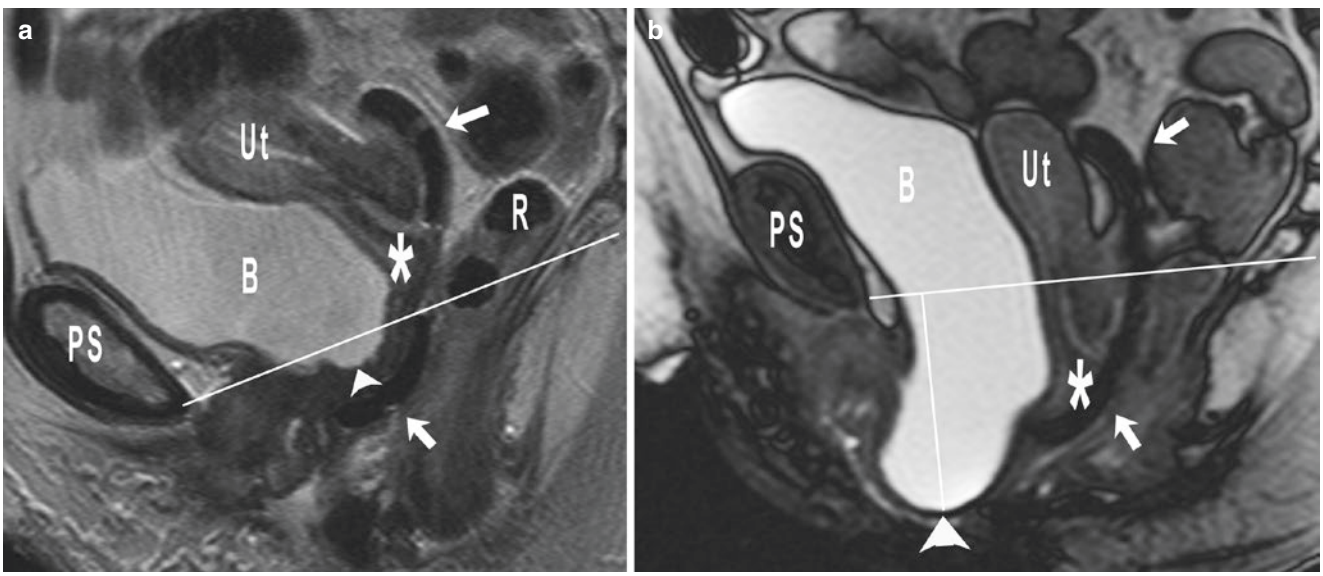

Fig. 6.18 (**a**) T2 W sagittal image at rest showing a moderately filled bladder with the bladder base slightly below the reference line (PCL). The uterus and cervix are also located above the reference line, supported by a pessary (*arrows*). (**b**) During maximum strain, the bladder base, as well as the cervix descent below the reference line, irrespective of the pessary presenting with a distraction cystocele (lateral defect of the endopelvic fascia) (*arrowhead*) and a partial uterine prolapse (*asterisk*). Additionally, hypermobility of the urethra is present (*thin arrows*). *B* bladder, *Ut* uterus, *PS* pubic symphysis

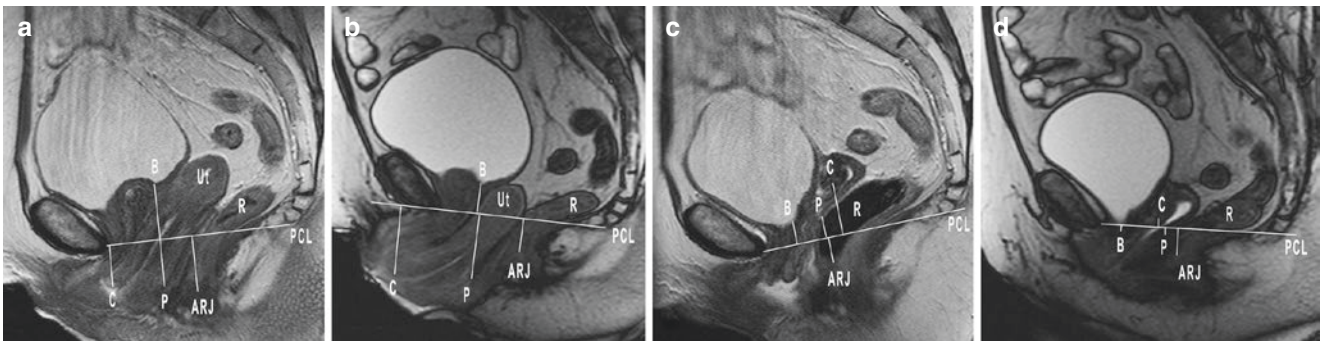

Fig. 6.19 Dynamic MRI of the pelvic floor (**a**) at rest and (**b**) during maximum strain before treatment presenting with partial uterine prolapse (*C*), peritoneocele (*P*) and rectal descent (*R*). Dynamic MRI of the pelvic floor 12 weeks after total mesh repair surgery combined with supracervical hysterectomy (**c**) at rest and (**d**) during maximum strain presenting reconstructed pelvic floor without pelvic organ descent. *B* bladder base, *C* cervix, *P* pouch of Douglas, *ARJ* anorectal angle, *PCL* pubococcygeus line

increasing sensitivity of findings in symptomatic women after surgery without findings during clinical examination [38]. MRI is able to detect the mechanisms responsible for topographic changes, which cannot be fully reached by the POP-Q system only, but are frequently needed to determine the steps necessary for successful surgical repair [39–42]. Therefore, MRI needs more attention before planned surgical repair to identify all involved compartments in POP and to detect incidental pathologic conditions in order. This is done to minimize the risk of incomplete surgical repair or recurrence [26, 27, 43, 44]. CT has no indication in evaluating POP [45].

Radio-Imaging for Malignant Uterine Disease

7

Céline D. Alt-Radke

Introduction

Magnetic Resonance Imaging (MRI)

Native high-resolution T2-weighted images (T2WI) are essential for morphological differentiation of pelvic organ tissue. Contrast-enhanced T1-weighted images (CE T1WI) give important additional information in almost every problem and should be therefore routinely performed [1, 3, 6–9]. However, kidney functions (kreatinine) should be checked before the intravenous application of contrast media. In recent years, diffusion weighted imaging gains more and more attention. This imaging technique was designed to depict alterations in thermally induced random (Brownian) motion of water molecules within tissues and the degree of this motion is known as diffusion [5]. Diffusion-weighted MR imaging (DWI) can be performed quickly, without the necessity of contrast i.v. The technique yields qualitative and quantitative information about cellularity and cellular membrane integrity. High cellularity and cell membrane integrity restrict water mobility and therefore diffusion, as seen e.g. in tumors. During MR-performance, diffusion sensitivity can easily be varied by changing the *b* value used during image acquisition [5]. For gynecologic malignancies, b-values up to 800–1000 are recommended for local tumor staging and the evaluation of lymph node affection [10–12]. Quantitative analysis of diffusion may be performed by obtaining and mapping apparent diffusion coefficient (ADC) values [5]. This technique can be performed in patients with contraindication for contrast i.v., which is of great benefit for further evaluation in case of tumorous. For lymph node detection, a native T1WI sequence or proton-weighted (PD) sequence is helpful [13].

Computed Tomography (CT)

With a multidetector CT (MDCT) the examination of a region of interest can be performed in axial plane in a short examination time with submillimeter resolution. The row data can be postprocessed in any plane with approximately the same resolution. It should be noticed that intravenous contrast application is essential for soft tissue contrast because even CT in venous phase has less tissue contrast compared to native MRI (see Fig. 6.1) [14]. Before performing contrast enhanced CT (CECT), kidney function (kreatinine) and thyroid function (TSH, fT3, fT4) should be checked to be with normal values.

Endometrial Cancer

Regardless of hormone status, the normal endometrium is always hyperintense in native T2w images, the junctional zone is hypointense and the outer myometrium is of moderate signal intensity [15]. Endometrial cancer is moderately hyperintense in T2WI. However, small tumors can be isointense in regard to the endometrium and may be therefore difficult to detect. CE T1WI sequence with fat saturation is therefore recommended, as the tumor then represents hypointense compared to the myometrium (best delineation approx. 2 min after contrast media injection i.v.) (Figs. 7.1, 7.2, and 7.3) [1].

Diffusion weighted images may also be helpful for tumor detection, as this shows a stronger signal decrease in ADC map than the surrounding normal myometrium [12]. The lack of the fat layer between organs (best seen in the native T1WI), as well as a thickened bladder or rectal wall, are an indicator for a beginning infiltration of the bladder or the rectal mucosa [1]. Staging is done using UICC-criteria (Union Internationale Contre le Cancer), the most recent version dating to 2010 [2, 16].

A CT-examination is not used for local staging. However, it is used for radiation planning or for complete staging for

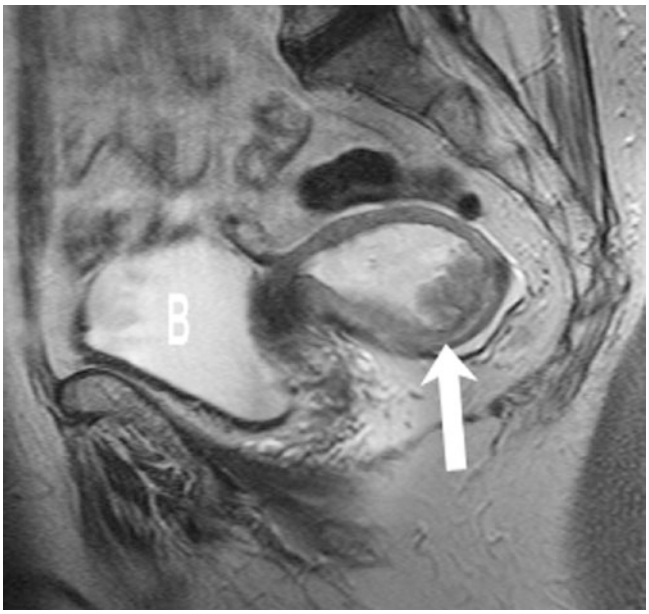

Fig. 7.1 Histopathologically proven early stage endometrial cancer in a retroflected uterus with mucos retention in the uterine cavity. There is no infiltration of the myometrium, as there is a clear demarcation on T2WI of the hypointense junctional zone between the intraluminal endometrial mass and the myometrium (*arrow*). T-Stage T1a. *B* bladder

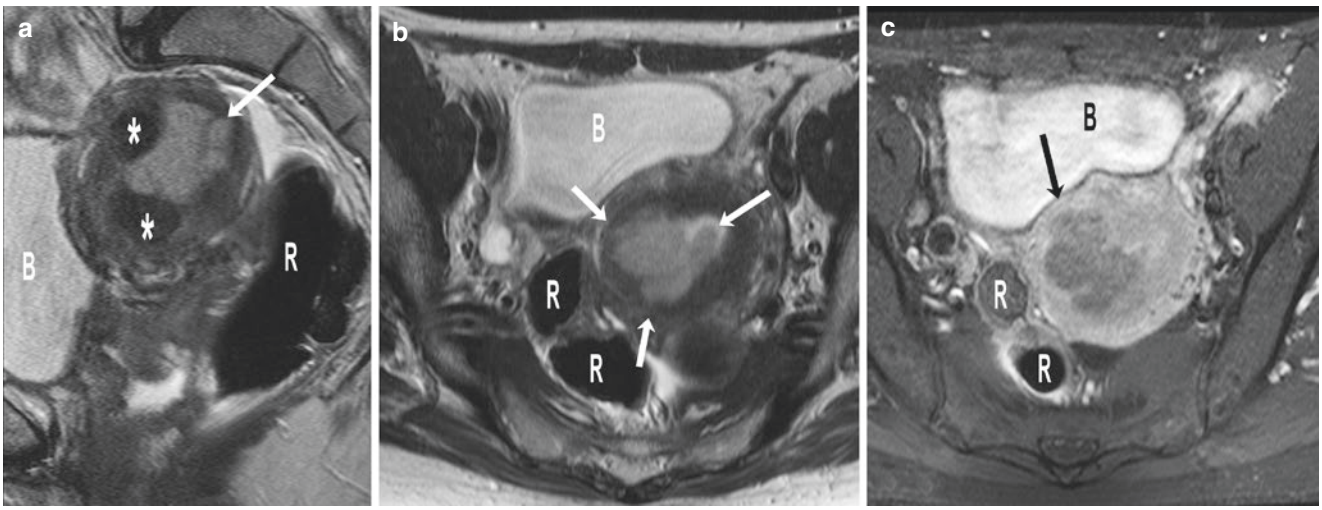

Fig. 7.2 Uterus myomatosus (*asterisk*) with the presence of an hyperintense endometrial mass (*arrow*), biopsy proven endometrial cancer. (**a**) The endometrial cancer is hyperintense on T2WI. (**b**) It presents hypointense after application of contrast i.v. Myometrial invasion is partly more than 50 %, defined on T2WI images on transversal oblique plane and was verified after contrast i.v. with hypointense demarcation of the tumor compared to surrounding myometrium on transversal oblique plane (*arrows*). T-stage T1b. This result was histopathologically proven. *B* bladder, *R* rectum

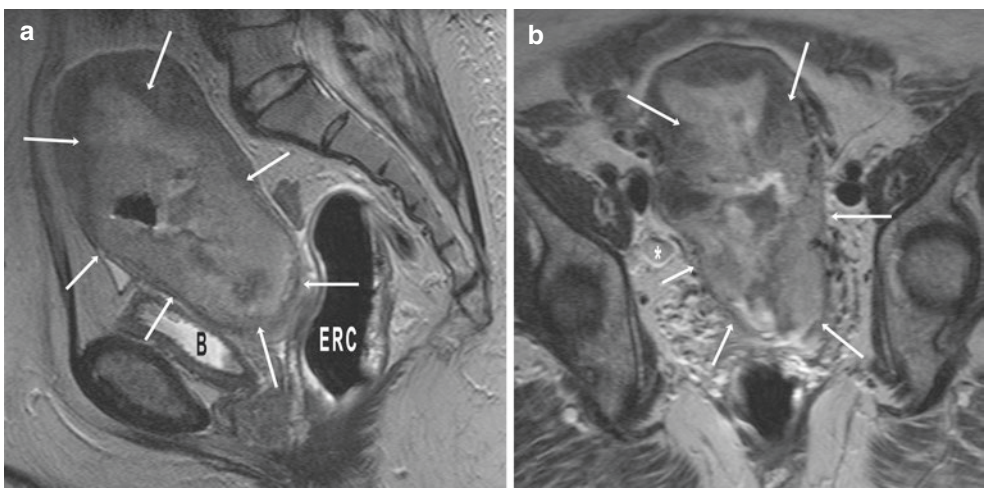

Fig. 7.3 (**a**) Locally advanced endometrial cancer (*arrows*) with infiltration of the cervix. The serosa is intact. No vaginal infiltration. T-stage T2. (**b**) One lymph node at the right pelvic sidewall is suspicious for metastatic affection (*asterisk*). N-stage N1. This result was histopathologically proven

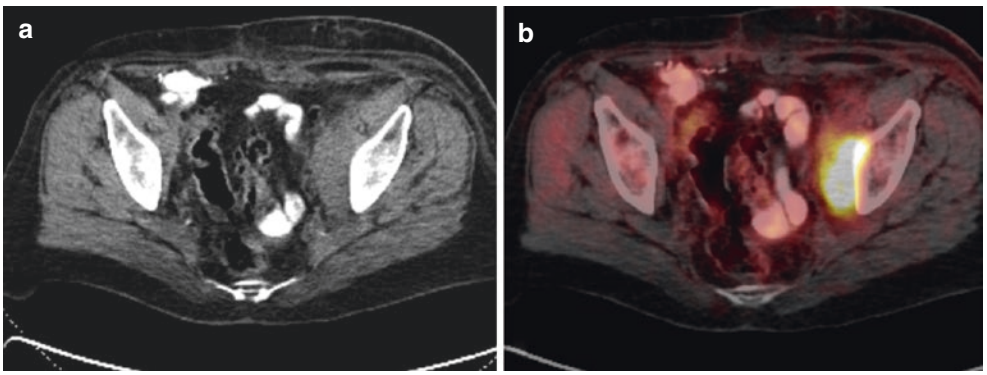

Fig. 7.4 PET/CT scan of a patient with suspected recurrence of endometrial cancer. (**a**) CT scan gives the anatomical overview. (**b**) PET presents with the pathological tracer uptake (*yellow*). Metastasis was found at the left pelvic side wall. Without any other manifestation of occult or visible metastases, the patient underwent radiation therapy

distant metastases (especially pulmonary, hepar, retroperitoneal lymph nodes). If CECT is performed for another indication, an endometrial cancer represents as a hypodense mass in the endometrial cavity. The evaluation of the depth of myometrial infiltration with CECT is made more difficult due to the low contrast of soft tissue as sensitivity is only around 58–61 %. If the cervix is heterogenous and thickened, suspicion of infiltration must be filed. If a tumor expands beyond the serosa a blurred reticular streaking can be expected. A bladder or rectum infiltration is to be presumed when the fat layer is missing. When solid tissue expansions in the lumen can be proven, an infiltration is the case [17]. The PET/CT has a standing in the diagnosis of distal metastases and in the diagnosis of recurrent disease (Fig. 7.4) [1].

Cervical Cancer

The decision for primary surgery or primary combined chemoradiation or brachytherapy, respectively, is based in particular on tumor size and the discovery of an infiltration of the parametrium [6]. With the expansion of cervical cancer along the parametrium to the pelvic wall or to the lower third of the vagina, the probability of positive paraaortal or inguinal lymph nodes grows. Metastases in the liver, the lungs or bones could exist in the advanced tumor stages. For this reason, a complete cross-sectional imaging based staging including MRI of the pelvis and CT of the body and chest is recommended before treatment. Ultrasound is often not sufficient for a complete evaluation of a local finding. However, this technique is used to exclude hydronephrosis or liver metastases.

In MRI, the mucosa of the normal cervix represents hyperintensive in the native T2WI, whereas the cervical stroma is hypointense [15]. Cervical cancer represents hyperintensive in the native T2WI in relation to the hypointense stroma tissue (Fig. 7.5). If the cervical stromal ring appears intact on T2WI on transverse oblique plane, parametrial invasion is present in 0–6 % of cases [20]. In a large meta-analysis by Rigon et al., the authors found an overall sensitivity of 66 % and a specificity of 84 % for detection of parametrial invasion in 1341 patients using 1.5 T MRI [21]. In rare cases, the tumor is isointense to the surrounding tissue in the T2WI or too small in diameter, as this may be residual tumor tissue after curettage. In these cases, DWI or CE T1WI with fat saturation is relevant for tumor detection (Fig. 7.6) [6]. There is a signal decrease on ADC map and a hypointense signal in early phase after application of contrast i.v. in T1WI with fat saturation compared to surrounding tissue. Best delineation will be reached 15–30 s after contrast injection. In late phase, however, the tumor represents hyperintense compared to uterine myometrium. Dynamic contrast enhanced sequences are therefore recommended (Figs. 7.7, 7.8, 7.9, 7.10, 7.11, and 7.12) [18, 19].

The staging for cervical cancer is done according to UICC-criteria (Union Internationale Contre le Cancer), the most recent version dating to 2010 [2, 16].

While the intravenous application of contrast i.v. can be forgone during primary detection as the tumor is easily detectable in the native T2WI in most cases, such an application is compulsive for therapy control after brachytherapy, after combined chemoradiation or after surgery to differentiate between a residual tumor or scar-like changes [6].

The CT is not necessary for primary diagnosis but is used for planning radiation or detecting distal mestastases (lungs, liver, bones) or peripheral lymph node metastases [3]. In case of a contrast media-enhanced CT, cervical cancer usually represents as a thickening of non-centric cervical tissue with a diameter of more than 3.5 cm (Fig. 7.13) [17]. Parametrial involvement is probable if cervical borders are blurry, thickened and spiculated (Fig. 7.14) [19]. An infiltration of the bladder or rectal wall represents in an irregular

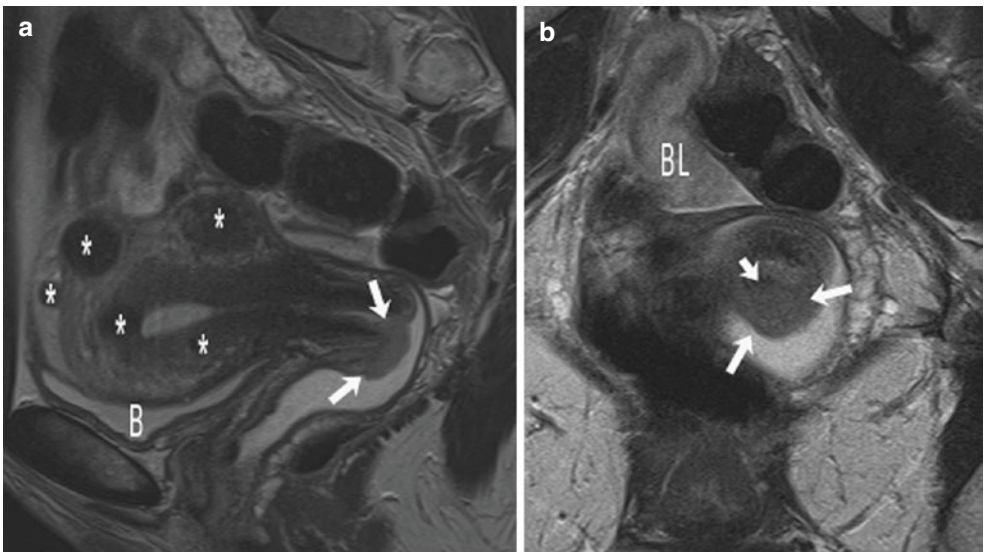

Fig. 7.5 (**a**) T2WI on midsagittal plane. Vaginal filling with ultrasound gel distends the vaginal cavity and gives a better demarcation of the cervical structures and the vaginal fornices. Due to this preparation, the dome-shaped mass of the anterior cervical lip is well visible and tumor extent can be easily detect (*arrows*). As a secondary finding, uterine corpus presents with 5 leiomyomas (submucosal – transmural – subserosal) (*asterisk*). (**b**) Transversal oblique plane of the cervix shows the circumscribed tumor extent (*arrows*). Cervical cancer at T-stage T1b1, histopathologically proven. *B* bladder, *BL* bowel loops

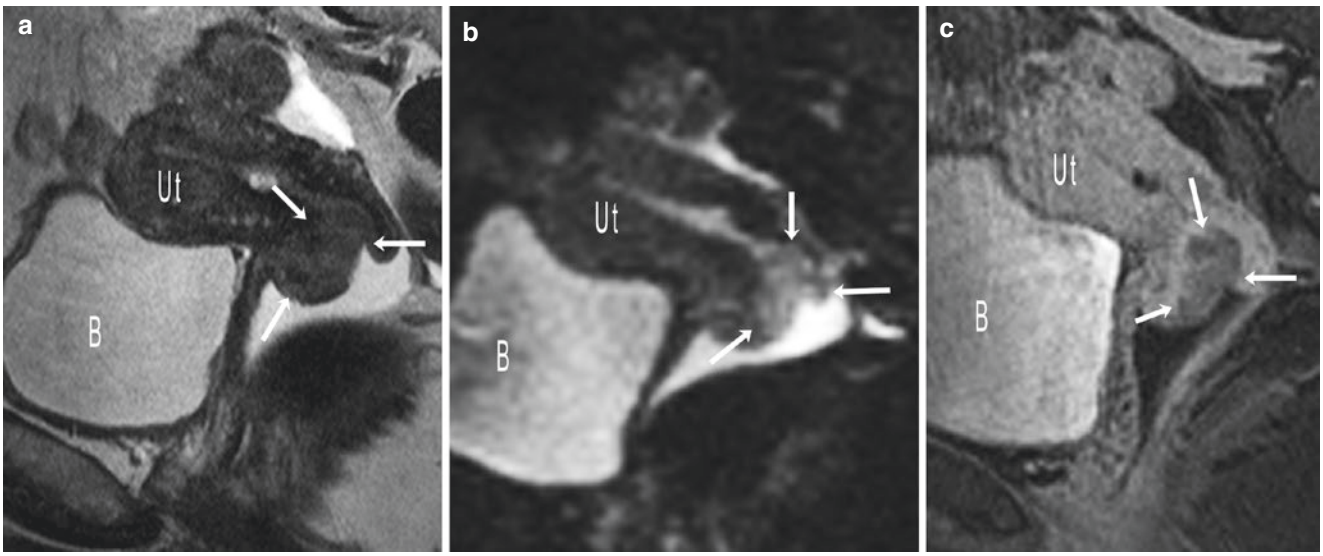

Fig. 7.6 Biopsy proven cervical cancer. MRI performed for pretherapeutic staging. (**a**) T2 WI presents a mass like lesion of the cervix originating from the anterior cervical lip (*arrows*). In this case, the tumor is not well delineated on T2WI and functional imaging techniques like diffusion weighted imaging or dynamic contrast enhanced images are helpful. (**b**) Diffusion weighted imaging with a *b*-value of 800 shows high signal intense tumor, well delineatable from surrounding tissue (*arrows*). (**c**) after application of contrast i.v. the tumor delineates as hypointense compared to surrounding tissue (*arrows*). *B* bladder, *Ut* uterus

thickening of the wall or a solid tumor that extends into the cavity and is probably present, if the fat layer is missing (Fig. 7.15) [17].

The PET/CT has a standing with locally advanced cervical cancer, especially for the detection of morphological, at first glance seemingly harmless lymph node metastases [22].

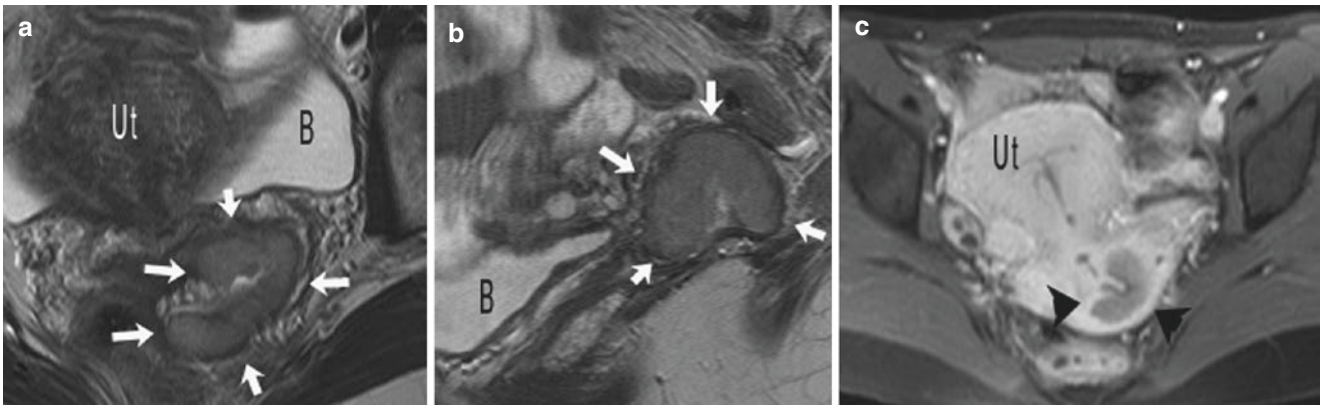

Fig. 7.7 Horseshoe-like mass of the cervix with well defined margins and a maximum diameter of >4 cm presented on (**a**) transversal oblique and (**b**) sagittal plane. (**c**) After application of contrast i.v. the tumor demasks hypointense to the surrounding cervical stroma (*black arrow head*). The cervical stroma ring is not interrupted, no infiltration of adjacent structures. T-stage T1b2, histopathologically proven. *B* bladder, *Ut* uterus

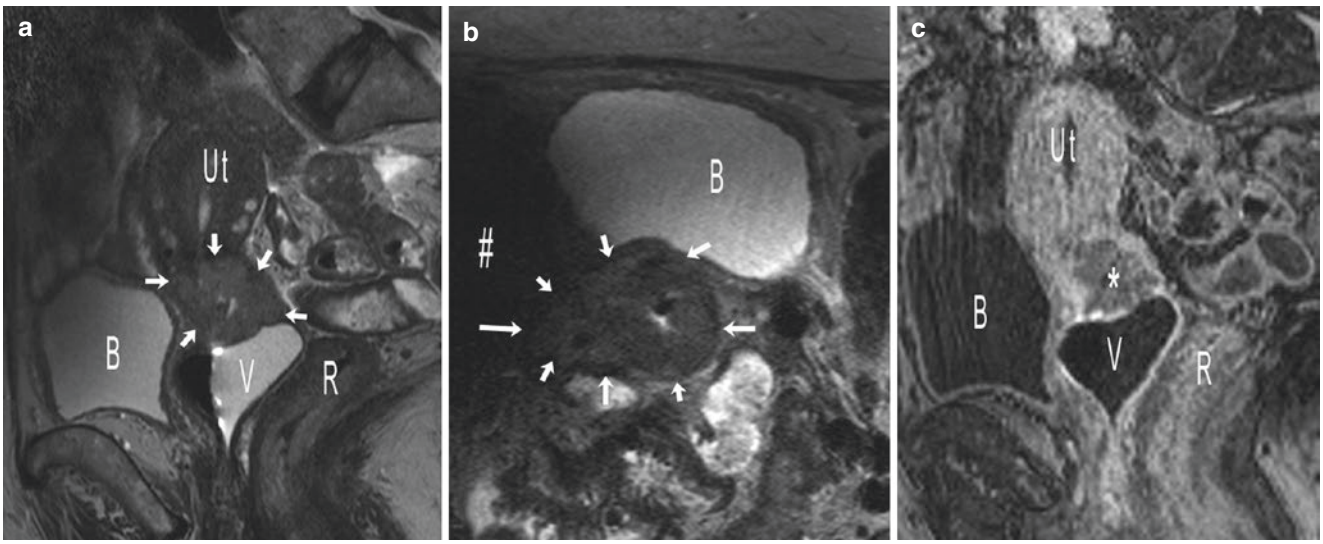

Fig. 7.8 Histopathologically proven cervical cancer. (**a**) T2WI on sagittal plane with vaginal filling with ultrasound gel. This preparation better delineates the cervical cancer with moderate hyperintense signal intensity (*arrows*). The vaginal fornix becomes infiltrated. (**b**) The cervical carcinoma invades the right parametrium, whereas the cervical stroma is still well delineated to the left parametrium on transversal oblique sequences (*arrows*). (**c**) Hypointense demarcation of the carcinoma after application of contrast i.v. (*asterisk*). *B* bladder, *V* vagina, *Ut* uterus, *R* rectum, *#* artefact due to endoprothesis of the right hip

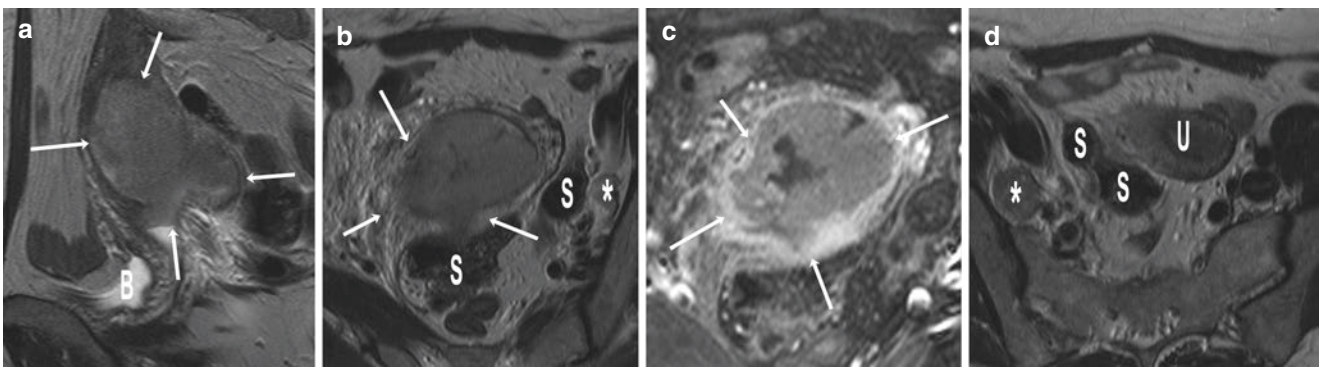

Fig. 7.9 Biopsy proven cervical cancer with invasion into the uterine corpus and the proximal vagina (*arrows*) on T2WI on sagittal plane. (**b**) Invasion into the right parametrium on T2WI on transversal oblique plane. (**c**) After application of contrast i.v. the carcinoma presents hypointense to surrounding tissue with central necrotic parts. T-Stage T2b. (**d**) Additionally, a large lymph node metastasis iliacal right sided is present (*asterisk*). N-stage N1. This result was histopathologically proven. *S* sigmoid colon, *U* uterus

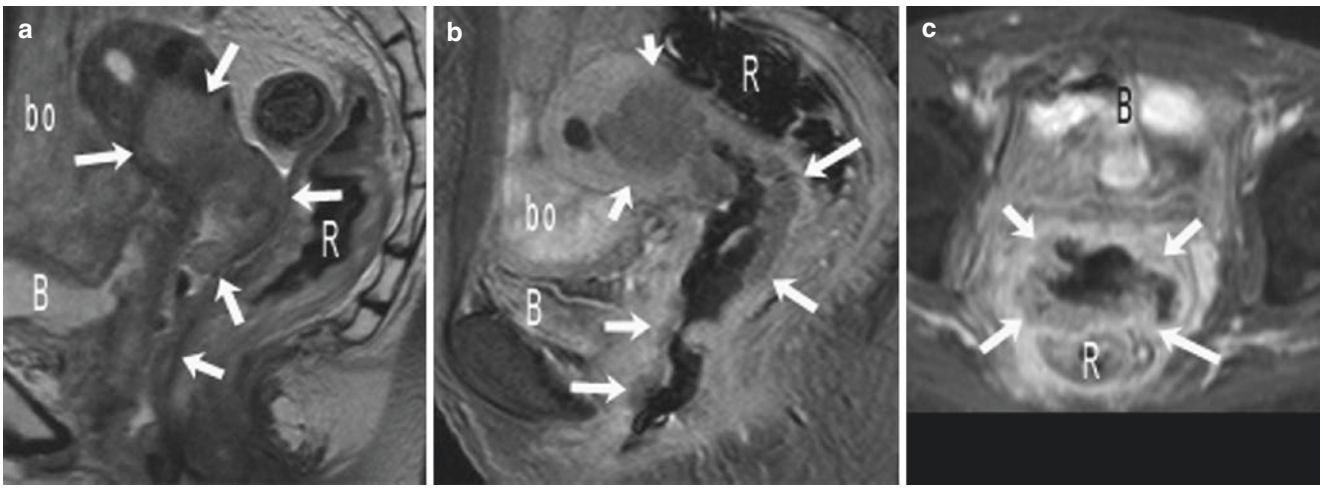

Fig. 7.10 Biopsy proven cervical cancer. (**a**) MRI with T2WI on sagittal plane shows infiltration of the uterine corpus and the vaginal wall until the lower third (*arrows*). (**b**) After contrast i.v. the tumor presents as hypointense (*arrows*). (**c**) CE T1WI on transversal oblique plane shows an intact layer to anterior rectal wall. T-stage T3a. This patient underwent primary chemoreadiation therapy. *B* bladder, *R* rectum, *bo* bowel

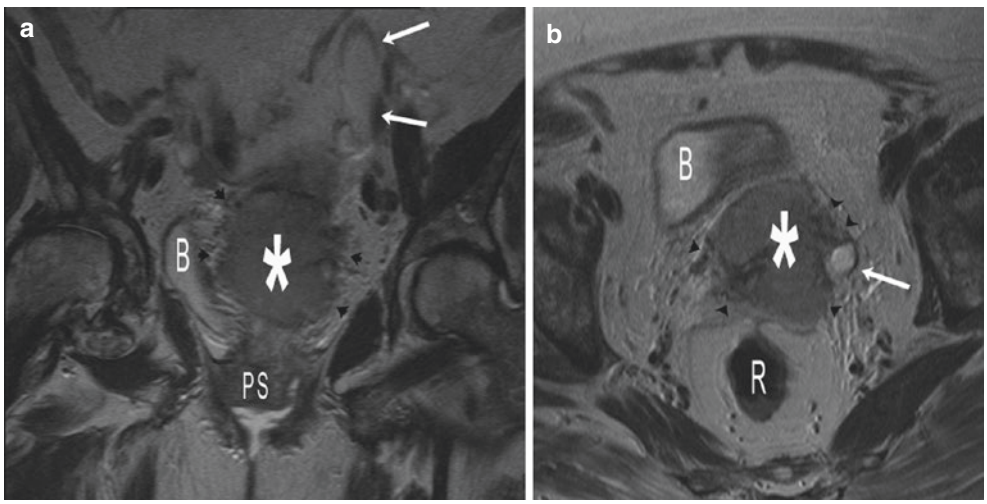

Fig. 7.11 Biopsy proven cervical cancer (*asterisk*). (**a**) The T2WI on coronal oblique plane shows a dilated left ureter (*arrows*). (**b**) On T2WI on transversal oblique plane invasion of the parametrium bilaterally with impression of the left distal ureter is present (*arrow*). T-stage T3b. This patient underwent splint implantation into the ureter bilaterally and underwent primary chemoradiation therapy. *B* bladder, *R* rectum, *PS* pubic symphysis

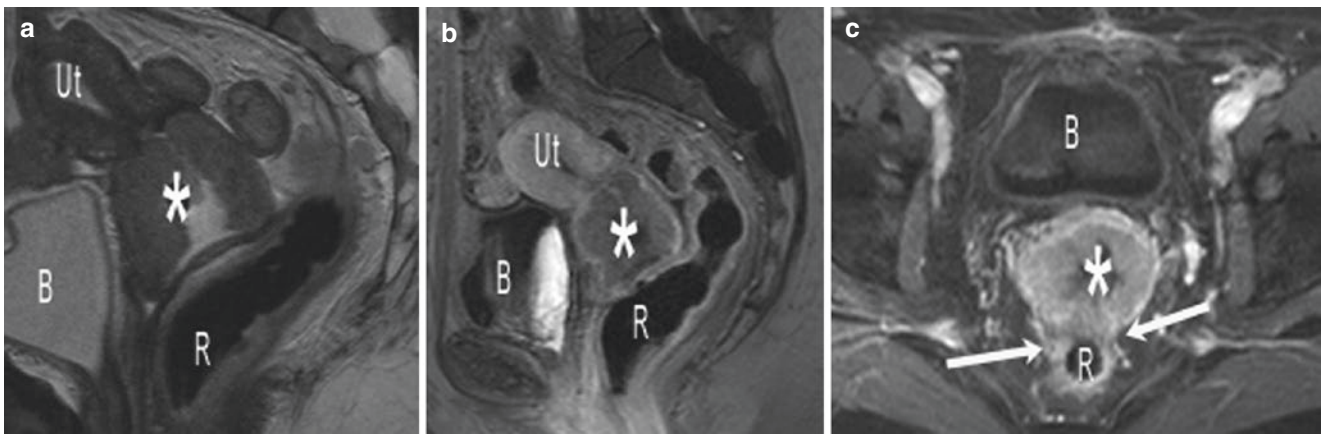

Fig. 7.12 (**a**) Cervical cancer (*asterisk*) on sagittal plane with infiltration of the isthmus uteri. (**b**) Better tumor demarcation after contrast i.v. suggesting local tumor disease. (**c**) On transversal oblique plane, however, the tumor (*asterisk*) invades the anterior rectal wall (*arrows*). T-stage T4. This result was proven by rectoscopy. The patient underwent primary chemoradiation therapy. *B* bladder, *Ut* uterus, *R* rectum

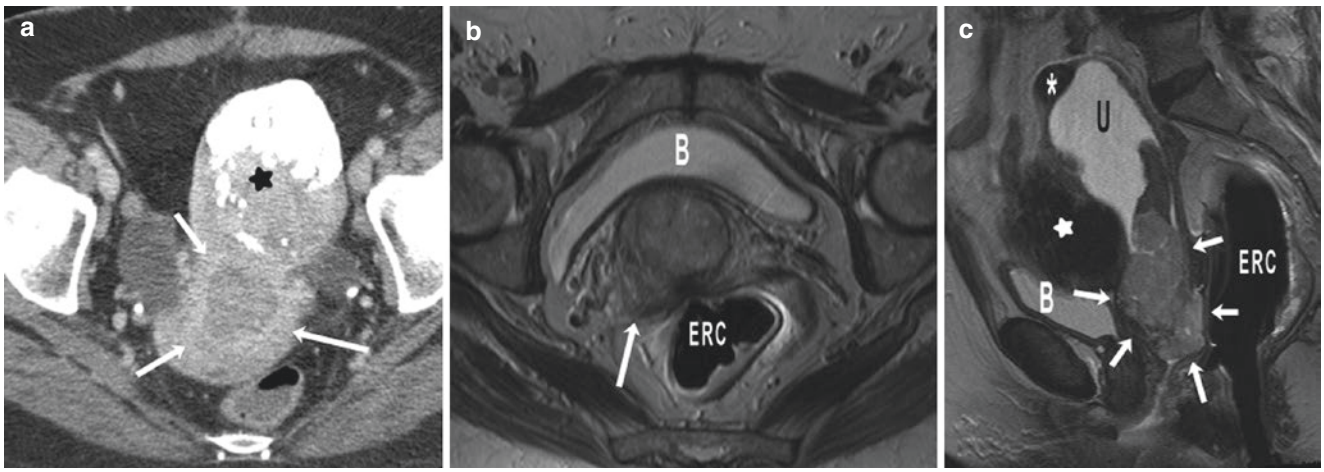

Fig. 7.13 (**a**) Axial CT scan at venous phase shows an enlarged cervix with centrally hypointense area (*arrows*). A subserous leiomyoma with calcifications is located ventrally (*star*). (**b**) MRI of the same patient shows cervical mass with infiltration of the right parametrium on transversal oblique plane (*arrow*). *B* bladder, *ERC* endorectal coil. (**c**) On sagittal plane, invasion of the uterine corpus and the upper third of the vagina is visible (*arrows*). The fat layer between the bladder and the rectum wall is present. Cervical carcinoma at T-stage T2b, histopathologically proven. The calcified leiomyoma presents as hypointense on T2WI (*star*). There is a small subserous leiomyoma at the fundus (*asterisk*). *B* bladder, *ERC* endorectal coil, *U* uterus

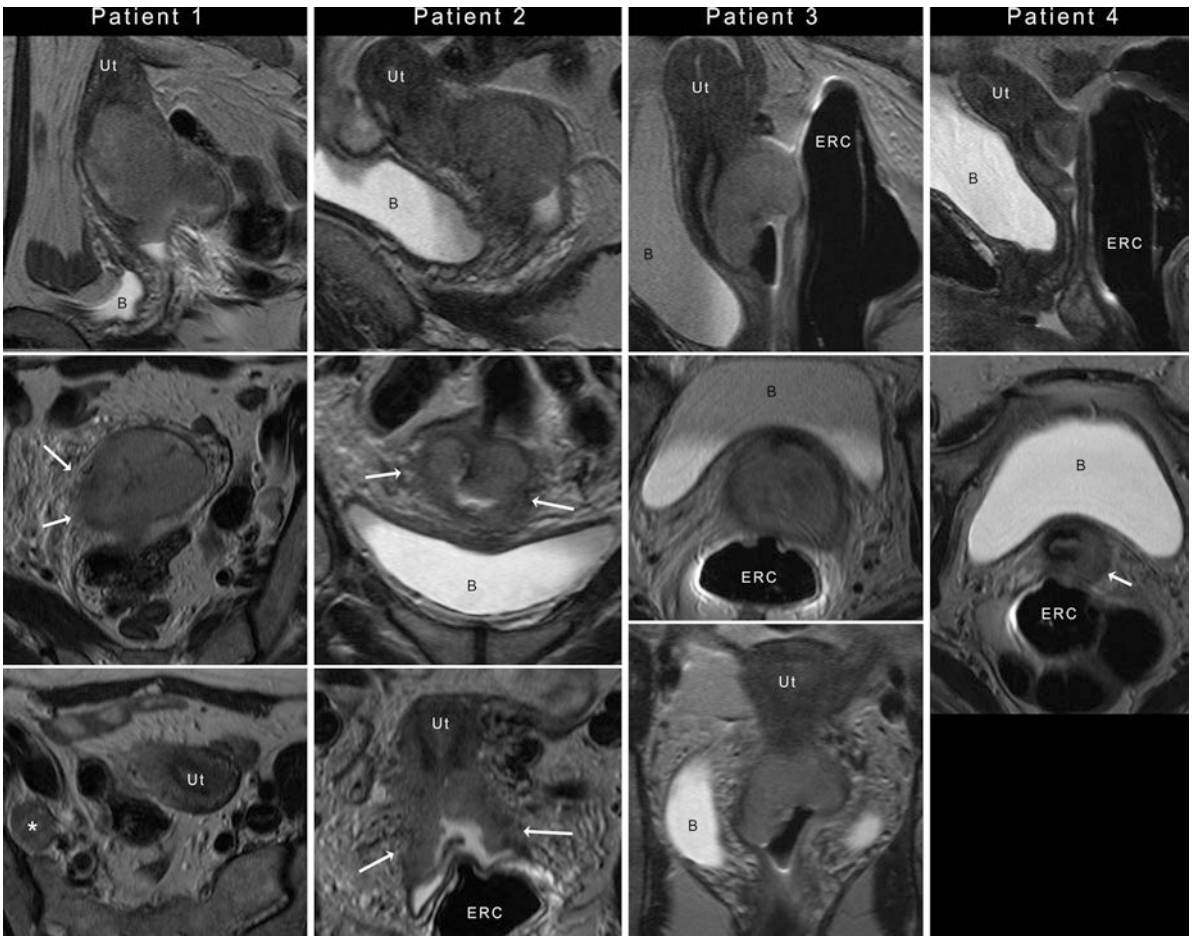

Fig. 7.14 Four patients with histopathologically proven cervical cancer stage T2b. Patient 1: Cervical cancer with infiltration into the uterine corpus, the proximal anterior vaginal fornix and the right parametrium (*arrows*). Patient 2: Cervical cancer with invasion of the vaginal fornix and bilateral parametrial invasion (*arrows*). Patient 3: Cervical cancer originating from the posterior cervical lip. The stromal ring is only intact ventrally, whereas the margins to the parametrium are blurry bilaterall. Patient 4: Cervical cancer with invasion into the left parametrium (*arrow*). The hypointense cervical stromal ring is well delineated at the right side. *B* Bladder; *Ut* uterus; *ERC* endorectal coil

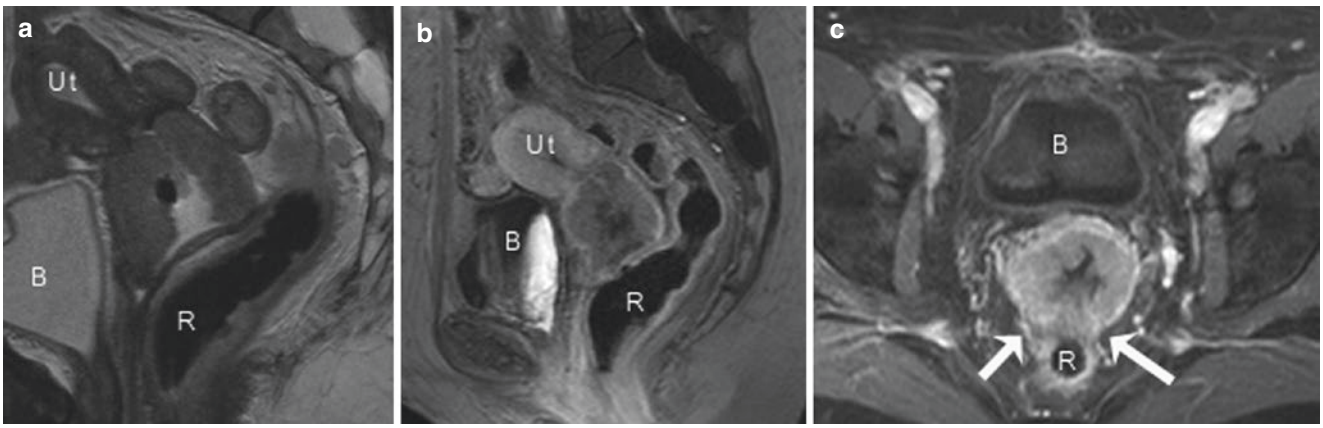

Fig. 7.15 (**a**, **b**) Patient presenting with a pseudo-well described cervical cancer on sagittal plane. (**c**) On transverse oblique plane to the cervical cavity, the wide based invasion of the upper part of the anterior rectal wall is visible (*arrows*). *B* bladder, *R* rectum, *Ut* uterus

Uterine Sarcoma

Uterine sarcoma can be classified into three histological subtypes: leiomyosarcoma (commonly myometrial origin), endometrial stromal sarcoma, *and* adenosarcoma (commonly endometrial origin) [16]. The transvaginal ultrasound is used as the primary standard image modality. In addition to this, MRI offers relevant additional informationen about tumor expansion. The CECT provides an overview of the infiltrated surrounding structures, distant metastases, ascites or peritoneal implants (Figs. 7.16 and 7.17) [23]. The PET/CT offers promising possibilities for staging, grading and therapy control for sarcomas [24]. All in all, differentiating between leiomyoma and leiomyosarcoma is challenging by using MRI. Apart from a fast growth, a large heterogenous tumor, hypervascular foci or central necrotic components can be indicators [25, 26]. Endometrial stromal sarcoma commonly represents an infiltrative mass with cystic parts. The endometrium as well as the myometrium is involved (Figs. 7.18 and 7.19).

Leiomyosarcoma, however, is mostly shown through heterogenous signal intensity with a fuzzy boundary. Commonly, at least 50 % are hyperintense on T2WI, with additional hyperintensities on T1WI (Fig. 7.20). On CECT, the uterus commonly presents as a heterogeneous mass with ill defined boundaries and irregular central zones, commonly due to necrosis (Fig. 7.21).

The adenosarcoma is often defined as a large, multiseptated, cystic mass with heterogenous solid components in the uterine cavity. The solid components are mostly hypointense in the native T2WI, which represent with strong contrast enhancement in CE T1WI [27]. Adenosarcoma may also presents as a large polypoid mass occupying the endometrial cavity, possibly protruding into the vaginal cavity (Fig. 7.22) [28]. Staging is done according to UICC-criteria (Union Internationale Contre le Cancer), the most recent version dating to 2010 [16].

Fig. 7.16 Histopathological proven uterine sarcoma, which can be depict with CECT as a inhomogenous mass with impression of the bladder and the uterine corpus right sided (*white arrows*). The right ureter is dilated (*black arrowhead*) due to tumor impression. The right kidney presents with concecutive hydronephrosis °IV (*asterisk*) with already narrow width of the parenchyma

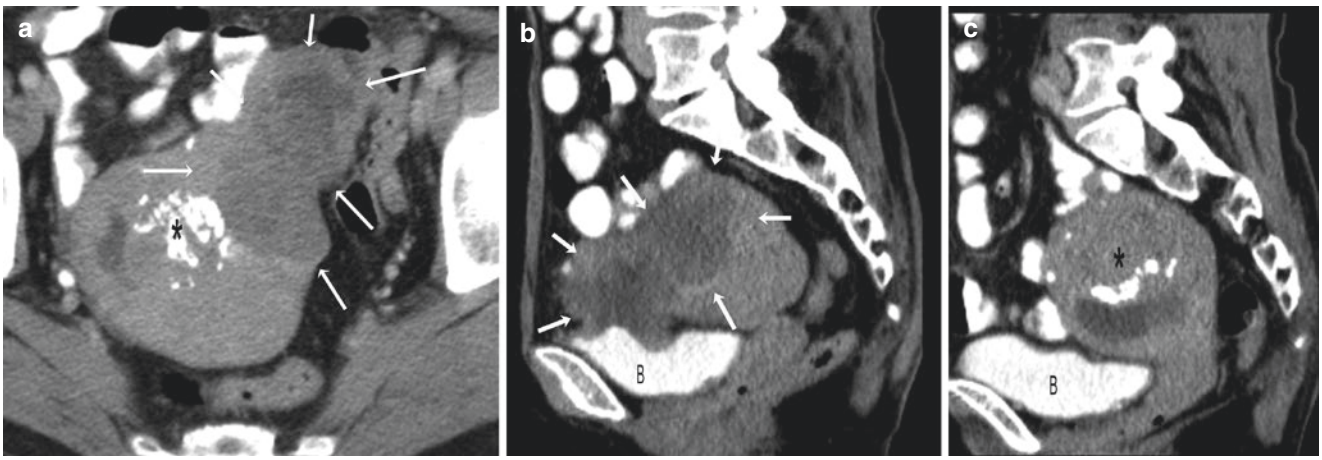

Fig. 7.17 Contrast enhanced CT with positive contrast of the small bowel loops. (**a**) On axial plane uterine calcifications (*black asterisk*) and a hypodense mass ventrally (*arrows*) is present. (**b**, **c**) On sagittal plane in two different slices presenting the hypodense mass (*arrows*) and the calcifications (*black asterisk*). Histologically proven as uterine sarcoma ventrally and a degenerated leiomyoma with calcifications. *B* bladder

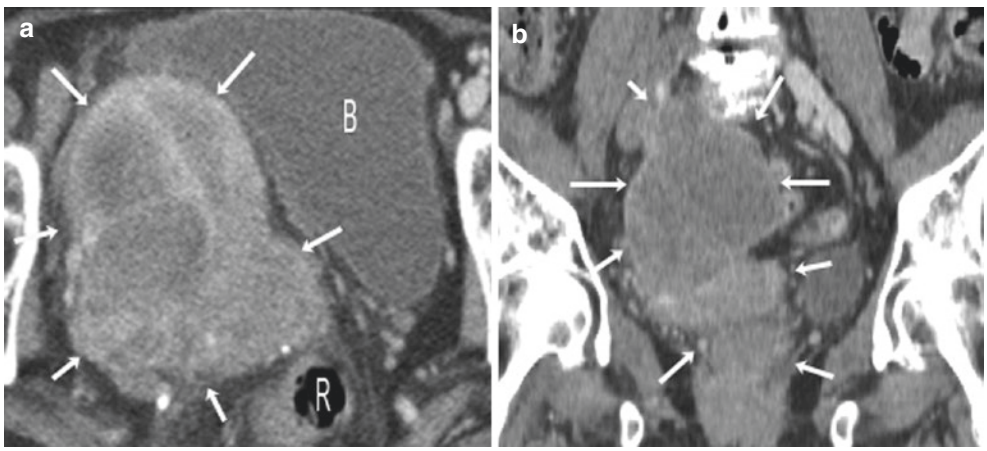

Fig. 7.18 On contrast enhanced CT in venous phase (**a** axial, **b** coronal), the uterus presented as oedematous, with ill defined margins and with a heterogenous density (*arrows*). Histopathological proven as endometrial stromal sarcoma. *B* bladder, *R* rectum

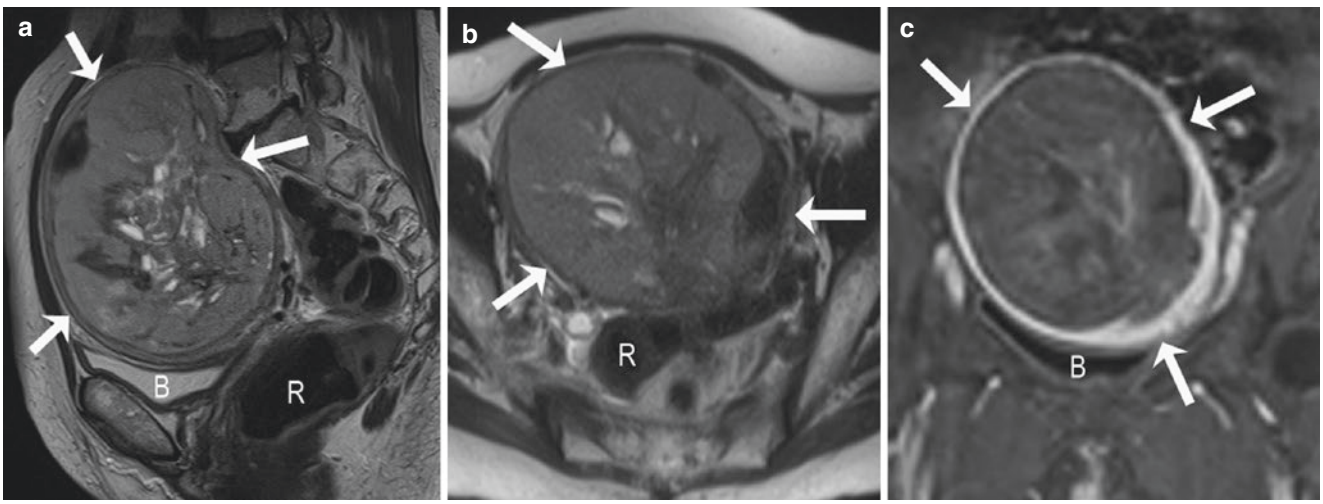

Fig. 7.19 Patient with medical history of uterus myomatosus underwent MRI before planned hysterectomy. (**a**) T2WI image on sagittal plane presents a huge and heterogenous, but well circumscribed, mass in the uterine cavity (*arrows*). (**b**) Even on transverse plane, the mass seems to be well circumscribed with a pseudo-capsule (*arrows*). (**c**) Contrast-enhanced MRI on transverse plane shows the enhanced myometrium (*arrows*) and the heterogenous hypointense mass in the uterine cavity. Histopathological result was endometrial stromal sarcoma. *B* bladder; *R* rectum

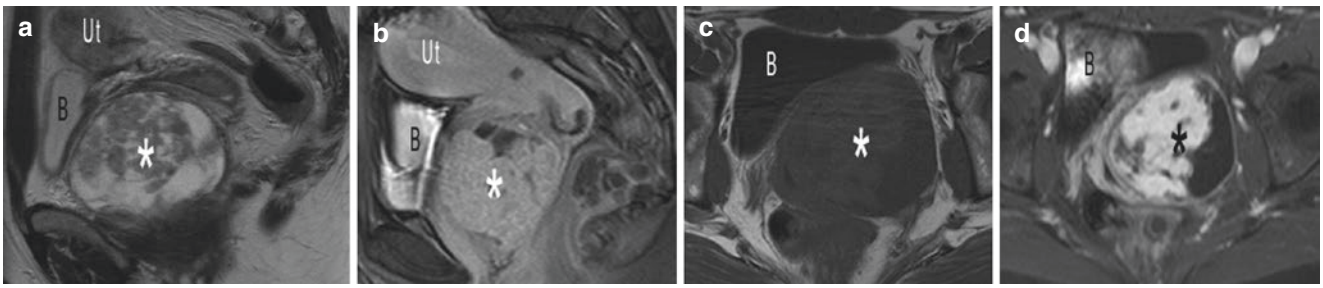

Fig. 7.20 (**a**) Huge inhomogenous mass in entire pelvis with septa and different signal intensities at T2WI (*asterisk*). (**b**) CE T1WI on sagittal plane shows homogenous enhancement of the solid parts of the mass (*asterisk*). The vagina is distended. (**c**) The mass presents as hypointense on native T1WI (*asterisk*). (**d**) On dynamic contrast enhanced images, the mass presents with hypervascular areas on arterial phase (*asterisk*). Histopathologically proven as leiomyosarcoma of the uterus. *B* bladder, *Ut* uterus

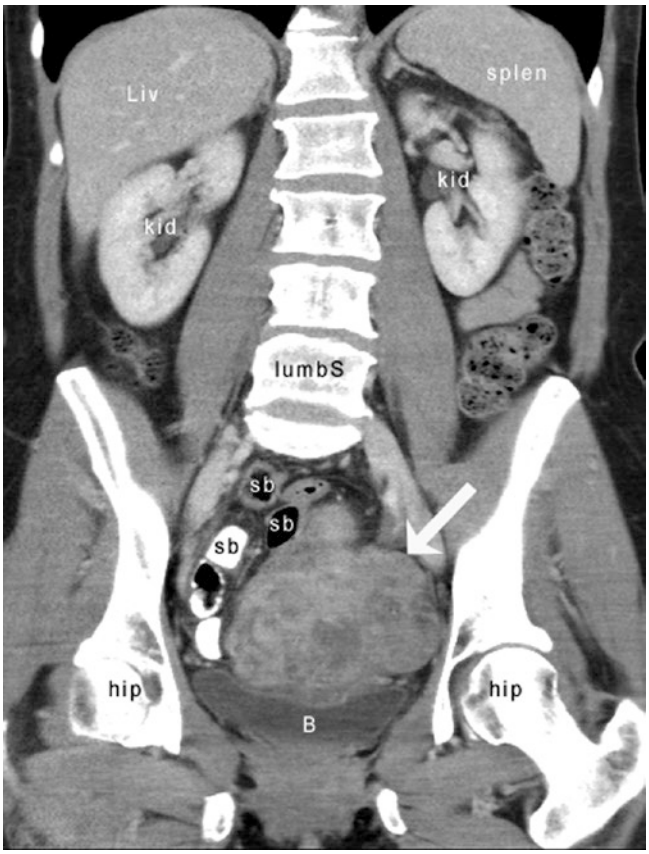

Fig. 7.21 Contrast enhanced CT scan in coronal plane. The entire pelvis presents with a huge heterogeneous mass (*arrow*) impressing the bladder. Hypointense central areas suggest central necrosis. The tumor was histopathologically confirmed as leiomyosarcoma of the uterus. *B* bladder, *sb* small bowel, *Liv* liver, *kid* kidney, *lumbS* lumbar spine

Uterine Lymphoma

Non-Hodgkin-lymphoma of the uterus and the cervix are very rare (<1 %) and may affect women between the ages of 20–80 [29].

Local tumor detection can be undertaken by using ultrasound. However, in some case the entire extent of the lymphoma cannot be depicted, so cross sectional image modality may be useful. If there is already a clinically based suspicion of a tumor extent beyond the small pelvis, a CECT of the abdomen for therapy planning and for follow-up examinations should be initiated (Fig. 7.23) [30]. For the visualisation of local findings, contrast enhanced MRI of the pelvis ought to be the image modality of choice. Using MRI, uterine lymphomas are mostly visible as homogenous, hyperintense masses in native T2WI, without a clear differentiation to the surrounding tissue and with a strong enhancement after contrast application [31].

Recurrent Tumor Disease

Recurrence of endometrial cancer after primary surgery mostly occur within the first 2 years. Metastases can be found as solid mass within the vagina and the parametrium or as lymph node metastases (Fig. 7.24). Recurrence of endometrial cancer after primary radiation therapy can often be found within the uterus or the ovaries [32]. For local recurrence, MRI is the cross sectional imaging modality of choice, however, if there is suspicion for distant metastases, CECT gives a better overview and is commonly performed for the chest and the body in one examination (Fig. 7.25).

Recurrence of a cervical cancer is seen in approx. 10–42 % of primary surgically treated patients. They often show as a solid mass at the vaginal vault, but can also manifest themselves within the vagina, the parametrium, the pelvic wall or the bones (Figs. 7.26, 7.27, and 7.28) [17, 32]. If there is a clinicial suspicion of tumor recurrence in the entire pelvis, contrast enhanced MRI for detection and diagnosis of its extent is relevant. The differentiation to scar tissue is especially important. Scar tissue as well as residual tumor tissue shows as moderately hyperintense in native T2WI. For differentiation, the CE T1WI is used: scar tissue is hypointense due to missing enhancement, inflamed/ tumorous tissue mostly absorbs contrast media and represents hyperintense (Fig. 7.29) [19]. It is to be mentioned however, that differentiation may be challenging in between the first 6 month due to contrast enhancement of fibrous scar tissue [19].

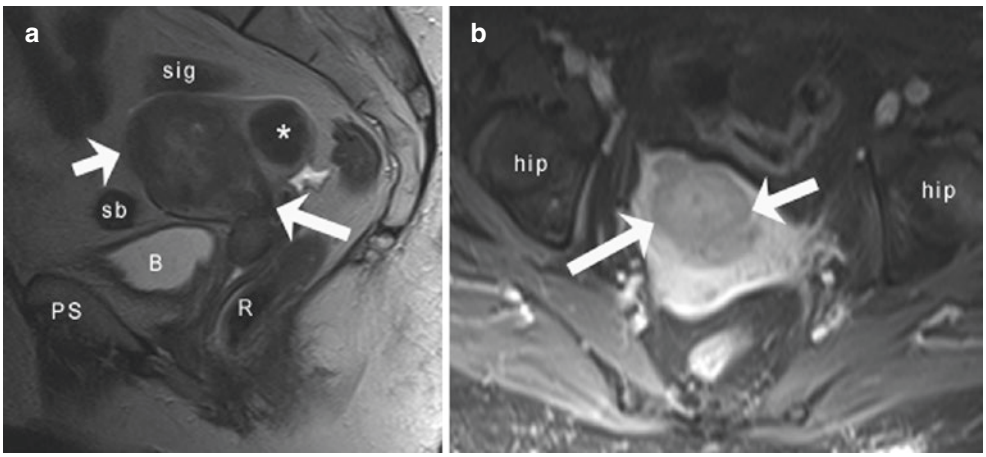

Fig. 7.22 MRI of a women with histopathologically proven adenosarcoma of the uterus. (**a**) On T2WI image on sagittal plane the uterine cavity is filled with a solid mass (*arrows*), the serosa is slightly interrupted at the fundus. Secondary finding is a subserous leiomyoma (*asterisk*). (**b**) On CE T1WI images with fat saturation on transverse oblique plane, the mass presents with a relatively homogeneous contrast enhancement (*arrows*), although the surrounding myometrium presents with a stronger enhancement. *PS* pubic symphysis, *B* bladder, *R* rectum, *sb* small bowel, *sig* sigmoid colon

Fig. 7.23 (**a**) On contrast enhanced CT (venous phase) on coronal plane, a large pelvic mass with homogenous density is present (*black arrows*). The distal ureter is bilaterally impressed, why the ureter is bilaterally splinted (*white arrows*). The renal pelvis is slightly dilatated due to the reflux through the splints in supine position during the examination. (**b**) The mass invades the bladder wall and the rectal wall (*white arrow heads*). Histologically proven as diffuse large-cell B-cell lymphoma. *B* bladder, *R* rectum

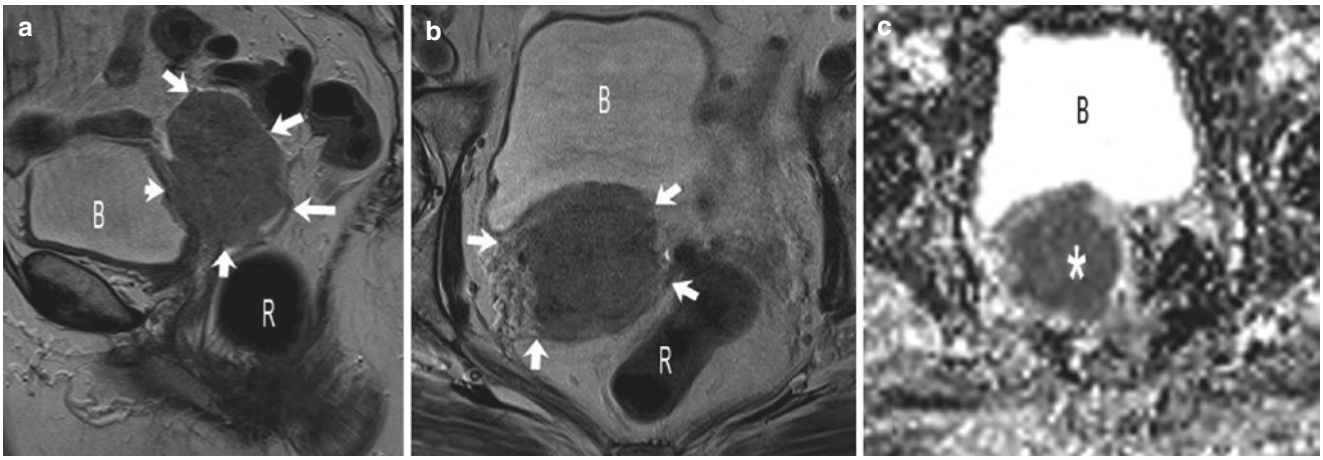

Fig. 7.24 Histologically proven recurrence of endometrial cancer. (**a**) T2WI on sagittal plane presenting with a huge mass at the vaginal vault (*arrows*). (**b**) T2WI on transversal oblique plane presents without infiltration of adjacent structures (*arrows*). (**c**) Diffusion weighted imaging shows restriction in tumor tissue (*asterisk*), delineating well the tumor margins. Tumor is close to the bladder wall, but no transmural invasion. *B* bladder, *R* rectum

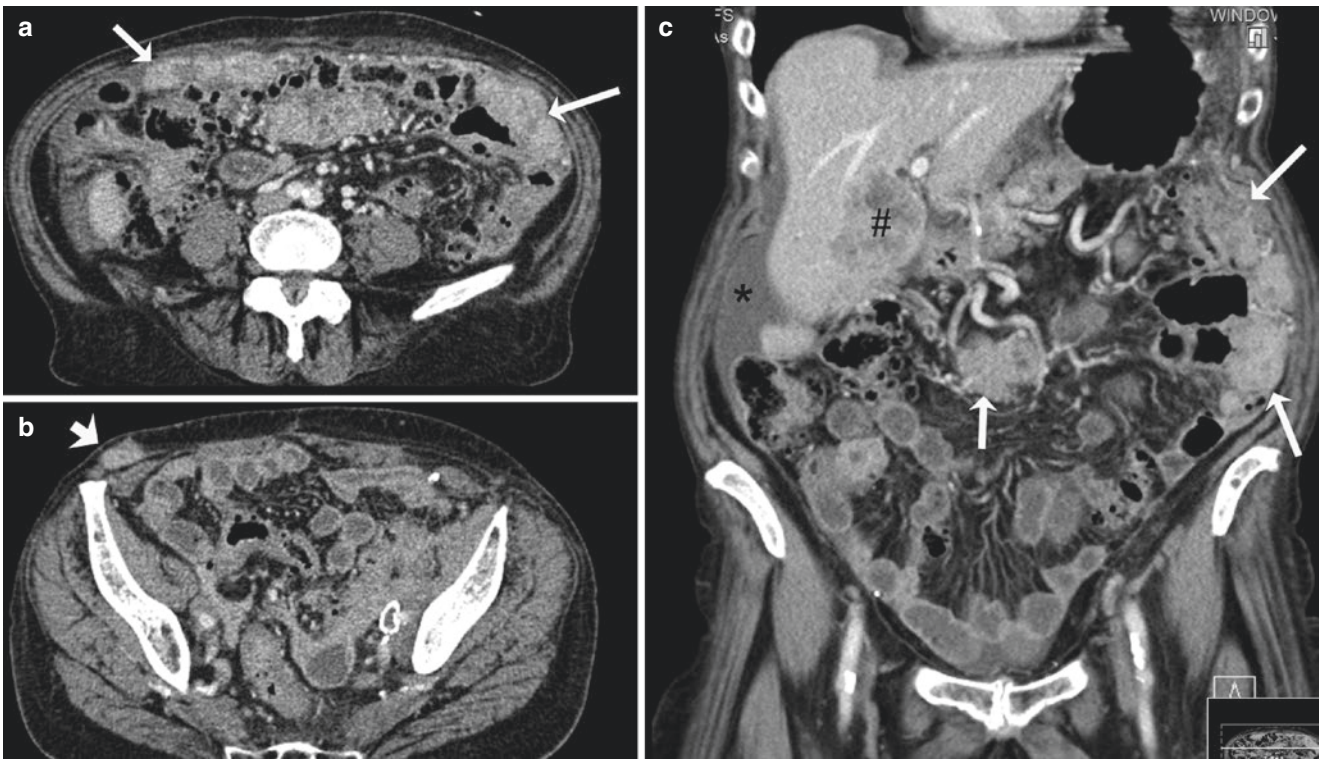

Fig. 7.25 Patient with recurrence of endometrial cancer. (**a**, **b**) Contrast enhanced CT scan on axial plane in different planes detects multiple peritoneal implants (*arrows*) and a cutaneous metastasis (*arrowhead*). (**c**) The coronal reconstruction of the same patient additionally shows a huge liver metastasis (#) and ascites (*)

Fig. 7.26 Histologically proven recurrence of cervical cancer after hysterectomy, located between the vaginal vault and the bladder wall (*arrow*). The tumor presents slightly hyperintense on T2WI. *B* bladder, *V* vagina, *R* rectum, *PS* pubic symphysis, *sbl* small bowel loops

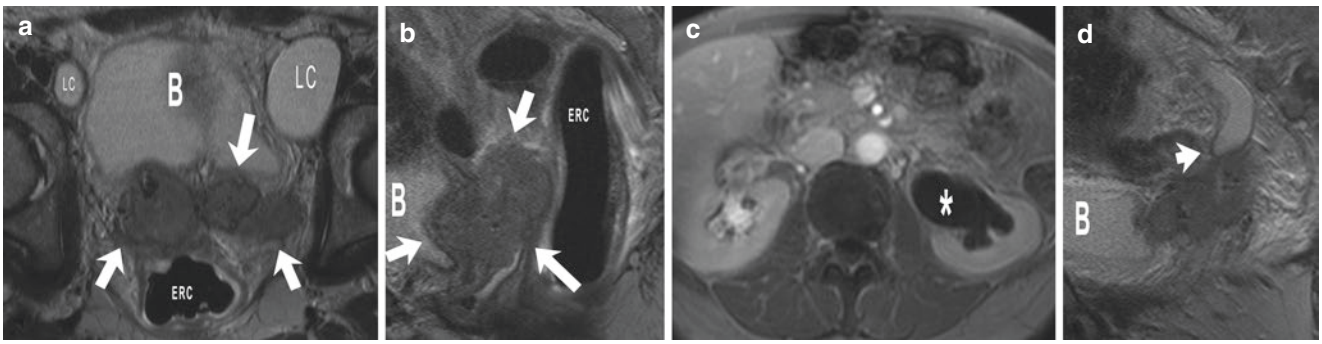

Fig. 7.27 Case of a patient after hysterectomy 4 month ago due to cervical cancer T2b N1 (same patient as in Fig. 7.21). (**a**) In entire pelvis, one solid lesion at the vaginal vault and two solid lesions close by are present, hyperintense on T2WI (*arrows*). The bilaterally inguinal oval cystic-like lesions correspond to lymphoceles (LC). (**b**) The vaginal vault mass is well delineated between the bladder wall and the rectal wall (*arrows*). (**c**) Hydronephrosis of the left kidney (*asterisk*). (**d**) The left distal ureter is compressed by the mass (*arrowhead*). *B* bladder, *ERC* endorectal coil

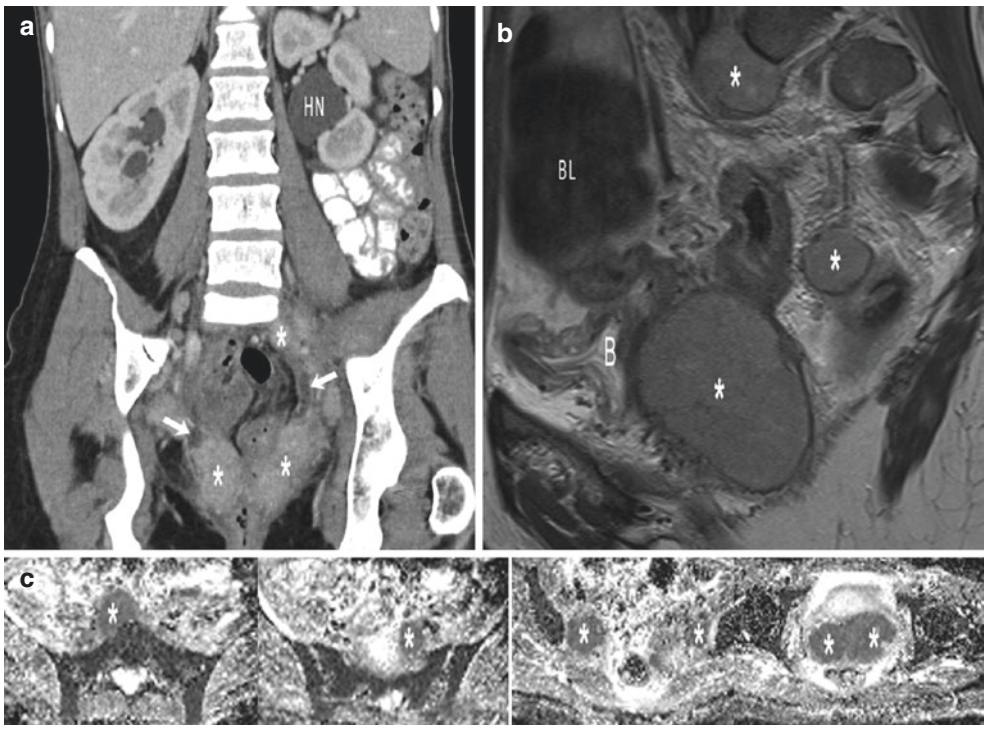

Fig. 7.28 Histologically proven recurrence of cervical cancer. (**a**) On contrast enhanced CT scan in coronal plane, hyperdense masses are present in entire pelvis as well as at the level of the aortal bifurcation (*asterisk*). The ureter is dilatated bilaterally (*arrows*) with concecutive hydronephrosis (HN). (**b**) On T2WI on sagittal plane, the masses are slightly hyperintense and well defined (*asterisk*). (**c**) Diffusion weighted imaging on axial plane on severeal slices present with multiple diffusion restriction tissues, defining tumor recurrence (*asterisk*). *B* bladder

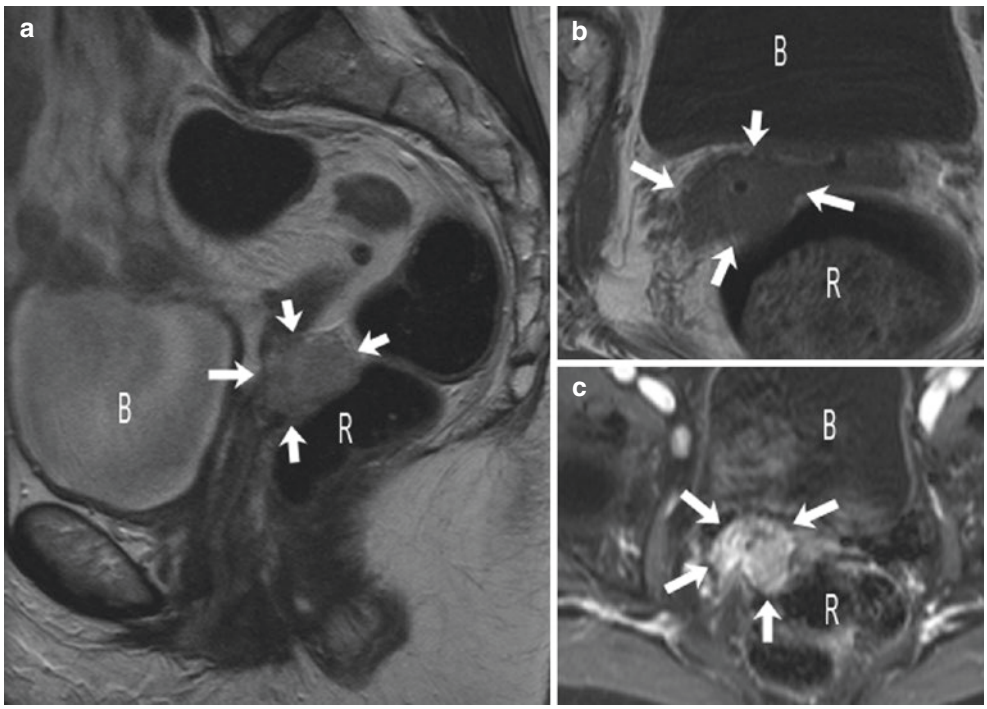

Fig. 7.29 (**a**) On T2WI on sagital plane a hyperintense mass at the vaginal vault is present (*arrows*), histopathologically proven as recurrence from cervical cancer. (**b**) On native T1WI on transversal plane, the mass is hypointense with slightly blurry margins (*arrows*). (**c**) After contrast i.v. the mass shows increased contrast enhancement (*arrows*). No infiltration into surrounding structures. *B* bladder, *R* rectum

Interventional Diagnostics Before Hysterectomy

8

Sergio Haimovich

Office Hysteroscopy

It was in 1980 when Hamou, considered the father of modern hysteroscopy, designed the first microcolpohysteroscope, offering a new combination of hysteroscopy and microscopy. His device allowed for multiple magnifications (X1, X20, X60, and X150) for cellular exploration and it presented new diagnostic opportunities (Fig. 8.1).

Introduction of bipolar system 'Gynecare Versa Point' by Ethicon Inc. in 1997 was the turning point of modern office hysteroscopy. This technology enabled to increase spectrum of intrauterine surgical procedures by means of thin miniaturized instruments without both anesthesia and dilatation of cervix at outpatient clinics. It was de beginning of the "see and treat" concept that is applied in the hysteroscopy units now a day.

The office setting hysteroscopy is becoming prevalent based among others in the convenient and efficiency of the procedure for both the physician and patient. An additional benefit of office-based hysteroscopy has been suggested by Lindheim et al. [1], who more than a decade ago, noted the cost saving per case of at least 50 % when compared with the hospital equivalent. The approach with vaginoscopy or "no touch" technique, without using speculum, tenaculum or even anesthesia is another well tolerated advantage of office hysteroscopy and patients reported just little discomfort [2].

Hysteroscopy is currently considered the best technique for investigating the uterine cavity [3, 4]. Several comparative studies between hysteroscopy and histology have demonstrated that hysteroscopy has a very high diagnostic accuracy for most intrauterine abnormalities [4] and for endometrial cancer [5, 6].

In 2002 Clark and coworkers in a systematic review concluded that diagnostic accuracy of hysteroscopy is high for endometrial cancer but only moderate for endometrial disease (cancer or hyperplasia) [7].

Fig. 8.1 Hamou microcolpohysteroscope

Indication for Office Hysteroscopy

When is a diagnostic hysteroscopy indicated? There are different clinical conditions as abnormal uterine bleeding (AUB). AUB is the most common indication in women over 45 years old.

Based on suspicious images especially by transvaginal ultrasound (TVUS) but also by CT or MRI, the endometrial pathology can be divided to focal (polyps and myoma) or diffuse (hyperplasia with or without cytological atypia and adenocarcinoma) (Table 8.1).

Any image of suspected endometrial cavity occupation by focal or diffused pathology is an indication for performing a diagnostic hysteroscopy.

When diffuse endometrial pathology is suspected (thickened endometrium image) the first choice is to obtain tissue sample by using a Pipelle. It has a low false positive rate but the false negative rate can be over 20 %, for this reason a diagnostic hysteroscopy is indicated after a negative result [8].

The similarity in morphological appearance of endometrial atypia hyperplasia (EAH) and well-differentiated

Table 8.1 Hysteroscopy indications

Clinical features	Images of suspected uterine occupation
Post-menopausal bleeding	Focal (polyp/myoma)
Abnormal Uterine Bleeding	Non Focal – Endometrial Thickness >5 mm (Hyperplasia/ Adenocarcinoma)

endometrial carcinoma represents a major challenge to histopathologists. When a diagnosis of atypical hyperplasia is made, there is a risk of concomitant invasive carcinoma in the uterus. This discrepancy between endometrial specimens and hysterectomy specimens on histopathological examination has been found in several reports, with 7–50 % of women with endometrial hyperplasia with cytological atypia reported to have concomitant carcinoma in subsequent hysterectomy specimens [9–14].

On biopsy specimens, the distinction between well-differentiated carcinomas and atypical hyperplasias, on the basis of distortion of glands architecture and cytologic atypia, is neither simple nor reproducible even by experienced pathologists [15]. On Figs. 8.2 and 8.3, it is possible to see the great difficulty to differentiate between Hyperplasia and Adenocarcinoma.

We define the pathology that will end in a hysterectomy as High Risk Endometrial Pathology, this group includes:

1. Adenocarcinoma on a polyp (AP)
2. Endometrial adenocarcinoma (EA)
3. Endometrial atypical hyperplasia (EAH).

Except in EA were the hysteroscopy has a great grade of accuracy with histopathology, both in AP and EHA many times hysteroscopic images are no so easy to interpret.

The hysteroscopic appearance of an endometrial carcinoma is quite typical, and this visual diagnosis is generally based on the presence of a gross distortion of endometrial cavity, because of focal or extensive nodular, polypoid, papillary or mixed patterns of neoplastic growth. Focal necrosis, friable consistency, and atypical vessels are other features almost invariably associated with endometrial cancer and easily detected by hysteroscopic inspection (Fig. 8.4).

High-risk polyps are presented in postmenopausal women as an image of more than 10 mm and symptomatic (bleeding or spotting). It is important to perform a complete hysteroscopic dissection of the polyp and no to leave any tissue including the pedicle, sometimes adenocarcinoma can be find in the polyp's base.

Narrow Band Imaging (NBI) and Hysteroscopy

An element that helps in the diagnosis of endometrial high-risk pathology when applied during hysteroscopy is the narrow-band imaging (NBI). This technology is a real-time, on-demand endoscopic imaging technique designed to enhance visualization of the vascular network and surface texture of the mucosa in an effort to improve tissue characterization, differentiation, and diagnosis [16] (Fig. 8.5).

Enhancement of particular mucosal features with NBI is achieved by observation of light transmission at selected wavelengths (or colors) because the interaction of particular tissue structures with light is wavelength dependent.

Selective light transmittance is accomplished by optical filtering of white light (WL) in NBI. The use of a band of light of 415 nm, blue light, correspond to the peak light absorption of hemoglobin, and this enables NBI to make the organization of blood vessels on the surface of the analyzed structures clearer and sharper with respect to observation with WL. Narrow-band blue light displays superficial capillary networks, offering an extremely high-contrast image of the tissue surface.

NBI has a very good correlation with histology especially in the difficult cases like atypical hyperplasia. Lasmar et al. have reported that the sensitivities of hysteroscopy for endometrial hyperplasia (EMH) and endometrial carcinoma are 56.3 and 80.0 %, respectively [17].

In the last years many authors have published their results in the use of NBI during hysteroscopy showing an improvement in the diagnostic sensitivity for atypical endometrial hyperplasia or endometrial carcinoma, compared with conventional hysteroscopy [18–20]. With NBI helps a variety of atypical blood vessels were observed in the mucosa of endometrial malignant lesions, including vessels with expanded, tortuous, and zigzagged shapes; variable diameter; inflectional, interrupted, papillary shapes; and sea anemone shapes. The visualization of this patterns helps in the orientation of high-risk endometrial pathology [18].

Figure 8.6 shows the enhancement of the capillary vascularization with NBI compared with WL in a case of EHA shows the difference between WL and NBI on a polyp's pedicle.

Hysteroscopy and Endometrial Cancer

As seen in this chapter endometrial sampling for histopathology examination is essential to diagnose endometrial cancer. Hysteroscopy provides an accurate evaluation of the endometrial cavity and allows directed sampling of suspected lesion.

However, there have been concerns that endometrial cells could be flushed into the fallopian tubes and the peritoneal cavity. It is a controversial subject with no enough evidence in order to achieve a clear conclusion.

In one study, Vilos at al found that hysteroscopy did not adversely affect the 5-year survival and the long-term prognosis in 14 women with endometrial cancer [21].

Polyzos et al. in a Meta-Analysis [22] estimated the risk for disease upstaging associated with the hysteroscopic procedure before surgery in women with endometrial cancer. The outcomes considered were the incidence of malignant cells in peritoneal washings before hysterectomy, incidence of tumour upstaging due solely to the presence of a positive peritoneal cytological feature in patients with apparent clinical early-stage disease limited to the uterus; overall survival, disease-free survival, and disease recurrence.

The results showed that hysteroscopy in patients with endometrial cancer resulted in statistically significant higher endometrial cancer cell seeding within the peritoneal cavity [OR: 1.78; (95 % CI, 1.13–2.79)]. Sensitivity analysis including only trials in which hysteroscopy with isotonic sodium chloride was used showed a further increased risk [OR, 2.89; (95 % CI, 1.48–5.64)], as well as sensitivity analysis including only trials in which inflated distension medium pressure reached or exerted 100 mmHg [OR 3.23; (95 % CI, 0.94–11.09)].

Also a statistically significant higher tumour upstaging was found when hysteroscopy was performed in patients with disease limited to the uterus compared with no hysteroscopy [OR, 2.61; (95 % CI, 1.47–4.63)]. Data regarding overall survival and disease recurrence supported the notion that no significant difference for the prognostic outcomes tested was observed.

The possible risk of the spreading into the abdominal cavity of neoplasic cells should not limit the use of hysteroscopy in favor of blind techniques (LEVEL OF EVIDENCE II, STRENGH OF THE RECOMMENDATION A).

In order to minimize the small risk of cancer dissemination, hysteroscopy should be performed with an intrauterine pressure of less than 80 mmHg, and the duration of the procedure should be as short as possible.

Prognosis Value of Diagnostic Hysteroscopy

The staging of endometrial cancer by hysteroscopy has not demonstrated its utility. In 1988, Cronjé et al. found no differences between dilatation curettage and hysteroscopy in pre surgical staging of endometrial adenocarcinoma [23].

Cervical involvement may vary between free tumor cells in the endocervical canal and endometrial infiltration of the endocervix. Cervical involvement is important to determinate staging, prognosis, and adjuvant treatment [24].

The prevalence of cervical involvement in endometrial cancer is between 10 and 20 % [25].

Panoramic hysteroscopy is the best procedure for excluding cervical involvement from endometrial cancer [26]. Moreover, as hysteroscopy enables us to estimate the extent of the cancerous spread within the uterine cavity, it could indirectly be predictive of tumoral size.

The cervical spreads is shown by irregularly eroded endocervical lining, well-marked coarse undulation of cervical mucosa, and endocervical exophytic growth of tissue displaying vascular atypia consistent with tumor growth were the hallmarks defining the spread of endometrial neoplasia to the endocervical canal.

In a group of 87 women with endometrial cancer, Villegas et al. found with a predictive positive value of hysteroscopy in the detection of cervical cancer was of 80 %, concluding that Hysteroscopy is a useful method for assessing cervical invasion in endometrial carcinoma, as it allows direct visual inspection of the uterine cavity and guided biopsies [27].

Hysteroscopy is the best and probably the only diagnostic tool for a preoperative estimation of the extent of endometrial lining involvement from endometrial carcinoma [28, 29].

Although unproven, a direct relationship between the extention of endometrial spread detected hysteroscopically and tumor volume appears rational. Morrow and Curtin's suggested in their work [30] that 50 % endocavity tumor spreading assessed by hysteroscopic view can be assumed as a reliable cutoff for selecting patients at high risk of metastatic disease.

Part IV

Extended Aspects Regarding Indications and Contraindications

Evidence Based Review of Hysterectomy and Sexuality

9

Farah Lone

Sexuality and Prevalence of Female Sexual Dysfunction

Sexuality, its expression and intimacy remains important throughout the lifespan of a woman, and hence needs to be well understood in health as well as in illness. Sexuality contributes to some of the most complex aspects of human behaviour. Sexual dysfunction is more prevalent in women than men (43 vs 31 %).

Prevalence studies of female sexual dysfunction (FSD) are confounded by a lack of consistent methodology. Classification and determination of FSD are complicated by variability in levels of normal sexual function and the importance of sexual function to individuals and cultural beliefs. Community studies indicate that the prevalence of female sexual dysfunction ranges from 25 to 63 %. An important population-based study, a sub study of the National Health and Social Life Survey, was conducted in 1992 [1]. It provides a probability sample among 1749 women and 1410 men living in the USA, aged 18–59 years, and is based on face-to-face interviews conducted by trained interviewers. The population was matched for age, education level and marital status. Following are the ranges of dysfunctions across the age groups:

- Lack of interest in sex: 27–32 %
- Unable to achieve orgasm: 22–28 %
- Pain during sex: 8–21 %
- Sex not pleasurable: 17–27 %

Comparable prevalence rates were calculated by Hayes et al. from 11 published prevalence studies that included assessment of all FSDs [2]. Similar results have been reported by another population-based telephone survey of women aged 30–70 years to ascertain prevalence of FSD [3] using the validated Profile of Female Sexual Function and Personal Distress Scale instruments [3].

Women's sexuality can be associated with personal, physical, social and cultural factors. Therefore sexual problems may be associated with significant distress including a low self-esteem, a reduction in life satisfaction and a decline in the quality of the relationship with her partner [4, 5].

It is estimated that more than 600,000 hysterectomies (an average of more than one per minute) are performed in the United States per annum [6]. Amongst other concerns with hysterectomy, is the possible effect of the surgery on woman's sexual response. In the United Kingdom 33–46 % of women report decreased sexual response after hysterectomy with oophorectomy. Although sexual problems are highly prevalent, a very small proportion of women consult a physician.

Indications for Hysterectomy

These include benign conditions such as menometrorrhagia, uterine fibroids (leiomyoma), adenomyosis, endometriosis, pelvic pain and for actual and possible malignancies.

Types of Hysterectomy

- Total (i.e., removal of uterus and cervix)
- Subtotal (supracervical i.e., removal of uterus), with or without unilateral or bilateral oophorectomy.

Surgical Routes for Hysterectomy

- Abdominal
- Vaginal
- Endoscopic (including robotic).

Reasons for Decreased Sexual Response

Various reasons have been described for reduction in sexual response following a hysterectomy, including hormonal changes, psychological factors, and anatomical factors.

Hormonal Changes

Common hormones produced by the ovaries include estrogen, progesterone and testosterone. Women who have had bilateral oophorectomy lose most of their ability to produce the hormones estrogen and progesterone, and lose about half of their ability to produce testosterone, and subsequently enter what is known as "surgical menopause" (as opposed to normal menopause, which occurs naturally in women as part of the aging process). In natural menopause the ovaries generally continue to produce low levels of hormones, especially androgens, even after menopause. These symptoms are commonly addressed through hormone therapy, utilizing various forms of estrogen, testosterone, progesterone or a combination.

There is paucity of consistent evidence to draw a conclusion as to the effect on sexuality of oophorectomy with or without hormone replacement therapy (HRT). Almost half the papers do not specify whether HRT was administered, other papers report that some of the women in their study received oophorectomy, and some received HRT, but contingent relationships are not specified between hysterectomy with or without oophorectomy and its impact on sexuality. However, the available data shows no significant difference in changes in women's perception of their sexual functioning has been reported before and after hysterectomy based on whether the women had their ovaries conserved or removed, with or without receiving hormone replacement therapy [7].

Psychological Factors

A wide range of psychological characteristics influence sexual function after hysterectomy.

Psychological factors with a negative impact on sexuality after hysterectomy [8–11]*:*

- Preoperative psychiatric morbidity
- Depression
- Unsatisfactory preoperative sexual relations with poor outcome

Psychological factors with a positive impact on sexuality after hysterectomy [9, 11, 12]*:*

- Frequency of coitus
- Frequency of desire
- Orgasmic response
- A healthy relationship with a partner
- Good general health of both partners
- Being stress free

Therefore those women who retained an overall desire for sexual activity, and were presumably affected by negative symptoms might be expected to experience an improvement in their sexual function after hysterectomy.

Anatomical Factors

Anatomical factors include:

(a) The lack of the uterine contractions which in some women are an important aspect of orgasm.

(b) Scar tissue preventing expansion of vagina, which may make intercourse difficult.

(c) Scarring or nerve damage causing discomfort and interference with feeling sexual pleasure.

(d) Reduced quantity of tissue resulting in diminished vasocongestion may reduce sexual arousal and the probability of multiple orgasms, and also the disruption of vaginal blood flow, local nerve supply and anatomical relationships, which could have a negative effect on overall pelvic floor function [13–16].

In addition to these factors, the pathology for which the hysterectomy is performed may differentially affect sexual response. It has been reported that women who had a hysterectomy due to endometriosis reported more difficulty and less satisfaction with orgasm than women who had a hysterectomy for other reasons. There is considerable evidence that simple abdominal hysterectomy does not have an adverse affect on pelvic organ function (bladder, bowel and sexual) [17].

Evidence-Based Review of Effects of Hysterectomy on Sexuality

Hysterectomy is the most frequently performed gynecological operation. Therefore, the myths regarding hysterectomy need to be dispelled and women requiring hysterectomy should be counseled using the best available evidence.

Simple Hysterectomy {Total Abdominal (TAH), Subtotal Abdominal (STAH) and Vaginal Hysterectomy (VH)}

Farrell and Kieser performed a systematic review of sexuality after hysterectomy and found that research in this area was largely retrospective without the use of validated outcome measures [18]. Most studies showed either no change or enhancement of sexuality following

hysterectomy. Theoretically hysterectomy should increase sexual pleasure by removing the fear of pregnancy, relieving dyspareunia and uterine disease particularly cancer. Roussis et al. [19] performed a retrospective study to assess the patient's own appraisal of their sexual responsiveness after hysterectomy (61 TAH, 22 STAH, 42 VH) and found that sexuality did not diminish after any type of hysterectomy. Alexander et al. [20] performed a prospective randomised trial comparing hysterectomy with endometrial ablation using validated measures of psychological and sexual function both pre and postoperatively. They found no difference in post operative sexuality after 12 months. Differences in libido and sexual sensitivity following various types of hysterectomies have been evaluated by Wierrani et al. [21] and found no difference at 12 months follow-up. Galyer et al. compared sexual function in women who had undergone TAH with those who had VH and found no difference in sexual desire postoperatively [22]. Roovers et al. in a prospective study over 6 months, found a reduction in sexual problems VH, TAH or STAH [23]. A large prospective study (the Maryland Women's Health study) which enrolled 1299 women who were interviewed with validated questionnaire preoperatively and at 6, 12, 18 and 24 months after hysterectomy for benign condition and found significant increase in frequency of sexual activity, a decrease in dyspareunia and a reduction in low libido [16]. Overall this study found substantial improvements in sexual function after hysterectomy.

It has been hypothesised that the disturbance of innervation of cervix and upper vagina after total hysterectomy interferes with lubrication and orgasm. Other factors that might contribute to sexual problems include a reduction in cervical mucus and vaginal shortening [24]. However Weber et al. do not agree with these views [25]. Kilkku et al. highlighted the influence of anatomical changes by comparing coital frequency, dyspareunia, libido and frequency of orgasm before and at 6 weeks, 6 months and 1 year in 105 women with TAH and 107 with STAH [26, 27]. Both groups showed an equal but slight reduction in coital frequency and dyspareunia with statistically significant deterioration after STAH. The frequency of orgasm was significantly reduced in TAH group but not in STAH group. However two randomised studies by Thakar et al. [28] and Zobbe et al. [29] found no difference in frequency of intercourse or orgasm between TAH and STAH. However there was a significant increase in frequency of intercourse [30] and decrease in dyspareunia [30, 31] after hysterectomy.

Current evidence suggests that dyspareunia reduces after hysterectomy. Sexual function does not usually deteriorate after a simple hysterectomy although a few women may develop sexual problems. There does not appear to be a difference in sexual function in women who have STAH and TAH.

Radical Hysterectomy (RH)

Women after surgery for genital cancer have to deal with not only the fear and anxiety generated by the diagnosis, treatment and prognosis, but also with the constant fear of recurrence. These women are often unaware of the consequences of the operation on sexual function. Although there is extensive evidence in the literature that shows adverse sexual functioning after treatment for cervical cancer [32–34], most studies report on heterogeneous groups of patients undergoing surgery, radiotherapy or both [35]. Primary or adjuvant radiotherapy has been reported to result in more severe sexual difficulties than hysterectomy alone [33, 36]. Patients treated with radical hysterectomy alone seem to regain their full sexual capacity and satisfaction more frequently [37]. Bergman et al. compared 256 women who had been treated for early cervical cancer and 350 controls [36]. They found that treatment of cervical cancer caused changes in vaginal anatomy and had negative effect on sexual function. These changes included decreased lubrication and reduction in perceived vaginal length and elasticity during intercourse. However the difference in the two groups with respect to frequency of intercourse, orgasmic frequency and pleasure were small. Grumann et al. prospectively compared 18 patients with stage 1B cervical cancer undergoing RH with 20 women undergoing hysterectomy for a benign cause-over 8 months using standardised questionnaires [37]. The cancer patients showed slightly better sexual function preoperatively than the other group but this deteriorated with time. Sexual function among patients with benign disease showed steady improvement indicating that RH for stage 1B cervical cancer is not associated with major disruption in sexual function. However this study had a small sample size so must be interpreted with caution. A large prospective study comparing 173 patients who had RH with age-matched controls indicated that RH had a persistent and negative impact on patients' sexual function, whereas majority of vaginal problems disappear over time [38]. Maas et al. objectively assessed sexual arousal in women who had RH (n = 12), TAH (n = 12) and 17 age-matched controls by measuring vaginal blood flow during sexual arousal using erotic films [39]. The authors suggested that although RH appears to be associated with a disturbed blood flow after sexual response, larger studies are needed for confirmation.

Overall, however, while RH affects some aspects of female sexuality, the majority appears to be transient and may be influenced by other overriding issues related to the diagnosis of cancer.

Laparoscopic Hysterectomy

A prospective case control study found no alteration of sexual function in premenopausal women undergoing either conventional or single port laparoscopically assisted

Table 9.1 Effects of hysterectomy, summary of 40 papers, 1952–2013

Effect	Increase	Decrease	No change	Variable	Undesirable effect on:
Dyspareunia	0	14	4	0	22
Vaginal lubrication	2	1	8	0	10
Libido	5	3	17	0	20
Orgasm frequency	2	4	9	0	12
Orgasm intensity	2	0	5	1	5
Sexual function	4	3	4	0	4
Sexual activity	4	1	18	3	14

vaginal hysterectomy [40]. Serati et al. found that laparoscopic radical hysterectomy did not show any benefit on women's sexuality over the open abdominal surgery for cervical cancer [41].

With recent advances in robotic surgery, this modality has been used for hysterectomy (benign and radical). Laparoscopic robotic-assisted radical hysterectomy with nerve sparing technique for bowel and bladder is proposed to be an attractive surgical approach for early invasive cervical cancer. However, effect on sexuality has not been studied to date and needs further exploration [42].

Kupperman et al. [43] conducted a randomized trial of 135women (67 TAH and 68 STAH) for benign conditions with a 2 year follow up. Sexual functioning and quality of life variables were measured with a telephone and clinic interviews. Both groups reported improvement in most measures of sexual functioning. The study by Thakar et al. [44] of 279 women (146 TAH and 133 STAH) was the only double-blind RCT. Each woman was followed for 1 year. A short-form, previously validated 36-question health survey (SF-36) and psychological outcome measure (GHQ: general health questionnaire) were used preoperatively and at 6 and 12 months postoperatively (0–100 scale). No statistical difference was found between the 2 groups before and after surgery. The frequency of intercourse, desire for intercourse, orgasm, and initiation of intercourse did not differ significantly between the groups. There was also a significant increase in the frequency of intercourse in both groups after surgery ($P = 0.01$). Deep dyspareunia was reduced significantly in both groups (46.2–6.6 % STAH and 39.3–14.3 % TAH) at 12 months ($P < 0.001$), but there was no statistical difference between groups. Zobbe et al. [29] conducted a randomized trial of 319 women (158 TAH and 161 SCH) with a one year follow-up and found no statistical difference between the 2 intervention groups regarding frequency of sexual desire, intercourse, masturbation, and orgasm, as well as quality of orgasm, vaginal lubrication, or satisfaction with sexual life ($P > 0.05$). Dyspareunia decreased significantly in both groups (89 women pre surgery and 22 post surgery $P = 0.009$). A multivariate logistic regression analysis identified preoperative satisfaction with sexual life, good relationship with partner, chronic disease, and use of hormone therapy as significant predictors of postoperative satisfaction with sexual life. Flory et al. [45] conducted a randomized trial of 63 women (32 LAVH and 31 laparoscopic subtotal hysterectomy) with a 7 month follow up. There were no differences in sexual functioning overall ($P > 0.05$).

Table 9.1 gives a summary of findings reported in the papers regarding the variably reported outcomes of hysterectomy. Any individual study reporting on at least some women who experienced deleterious effects after hysterectomy, whether or not statistically significant, was included in the last column of the table – "Undesirable Effects On:" It is important to identify and report incidence of deleterious effects of hysterectomy on any individuals. Since very few papers elaborated on these deleterious effects, we could not distinguish whether the women who, for example, experienced dyspareunia after hysterectomy developed this condition after the surgery or if the condition was present preoperatively but not treated with surgery.

Conclusion

The research on the effect of hysterectomy on sexual function that has been performed to date is not conclusive. There are discrepancies in the literature as to whether hysterectomy improves or attenuates sexuality. Hysterectomy may alleviate the discomfort of pain and bleeding, resulting in positive psychological factors such as elimination of anxiety over unwanted pregnancy and cancer risk. Symptom relief may have led to increased sexual enjoyment and increased orgasm frequency. While women report an improvement of sexual functioning after hysterectomy, this may be the result of the relief of symptoms (such as vaginal bleeding and dyspareunia) from the uterus, some women develop sexual dysfunction as a result of hysterectomy. More research is needed to clarify the issue of the effect of hysterectomy on sexual response.

Tips for the Reader

It is imperative that sexual function/dysfunction should be addressed in counseling women undergoing hysterectomy. The evaluation process for women with sexual dysfunction includes identification of the dysfunction, patient education

and modification of reversible factors. The history should include a sexual function history, medical history and psychosocial history. The examination should include both an external and internal physical exam. A multidisciplinary approach with involvement of gynaecologist, vulval pain specialist and a psychosexual counselor should be used, where indicated.

Treatment for physical causes may include the use of vaginal estrogen pessaries especially in presence of vaginal atrophy. Testosterone therapy also converts to estrogen so women in transition from peri-menopause to menopause who have vasomotor symptoms (hot flashes, night sweats) and low androgens may need to take additional estrogen in conjunction with androgens. Other treatments include Dehydroepiandrosterone (DHEA), which may result in enhanced androstenedione and testosterone levels and improvement of sexual symptoms including better Female Sexual Function Index (FSFI) and Sexual Dysfunction Score (SDS). Considering the low incidence of the adverse effect of hysterectomy on sexual function psychosexual counseling and therapy is an integral part of treatment of patients with sexual problems after hysterectomy.

Guidelines and Recommendations of Scientific Societies and Associations for Hysterectomy

10

Klaus Neis and Felix Neis

Hysterectomy represents the second most performed surgery in gynecology after the Cesarean Section. In Germany there are 100,000 hysterectomies performed a year in case of benign indication. 27 % of these are prolapse surgeries. Thus, there remain 75,000 hysterectomies due to benign diagnostic findings in 2012 [1]. Worldwide most of the hysterectomies of this group are performed abdominally. Only in Germany, Austria and Switzerland a lower rate could be found. As in the USA 64 % of the hysterectomies are performed abdominally, in Canada 60 %, Austria 29.6 %, Switzerland 26.0 % and in Germany 17.5 % [2].

At the beginning of the 90s, when the laparoscopic surgery has been introduced for hysterectomy, the aim was to reduce the number of abdominal hysterectomies. In individual hospitals which decided to specialize in this field, this could be realized in an impressive way. [3]. Regarding however the national statistics this development has only lead to moderate adjustments [4]. For example declined the rate of abdominal hysterectomy in the USA from 66.1 % in 2003 [4] to 54.2 % in 2010 [5].

Two Cochrane Analysis, in which the different methods of hysterectomy have been evaluated, showed however that the vaginal hysterectomy is the method of the lowest rate of complications, the lowest blood loss and also the shortest time of surgery. Additionally, cost analyses demonstrate that the vaginal hysterectomy represents the most economical method by far in the whole range of hysterectomies [6, 7].

In Germany the rate of vaginal hysterectomies lies at about 50 %, in Austria at 46.2 %, in Switzerland at 41 %. In the USA the rate of vaginal hysterectomies lies at only 20 % [8–11].

In 2009 this had been the reason for the American College of Obstetricians and Gynecologists (ACOG) to publish a statement, in which the vaginal hysterectomy was recommended as first option. In cases where a vaginal hysterectomy seems not to be viable the possibility of laparoscopic hysterectomy should be investigated. If both options are unviable then there is given an indication for abdominal hysterectomy [12].

Analogously there is also the recommendation of the AAGL (American Association of Gynecologic Laparoscopists) of 2011. In the meantime a working group in the AAGL is established where colleagues with special interests in vaginal surgeries are united [13].

Meanwhile also the insurance companies suggest that the vaginal hysterectomy should be the method of first choice. They justify their suggestion as they want to offer their insurants the method of least complications. The fact, that this method is the most economical one at the same time, may probably be also an important point for an insurance company.

In 2010, a group under the auspices of K.J. Neis and K. Schwerdtfeger has been authorized by the German Society of Gynecology and Obstetrics (Deutsche Gesellschaft für Gynäkologie und Geburtshilfe e.V. ‚DGGG) to develop in Germany a guideline for indication and methodology of hysterectomy. The guideline was compiled by 24 scientifically and clinically operating colleagues and was available in 2012. It reflects the situation in Germany, Austria and Switzerland, where the vaginal hysterectomy is preferred traditionally and where today the laparoscopic surgeries are integrated to the greatest possible extent into the range of surgeries for hysterectomy.

When compiling the individual chapters it became more and more clear, that also the alternative methods as hysteroscopy, the systemic und local hormone therapy or Uterine artery embolization (UAE) are all effectible. However, the most satisfied women are to be found in the group of patients who underwent a hysterectomy (Table 10.1).

Table 10.1 Comparison of satisfaction rates of women who underwent hysterectomy, endometrial ablation or the levonorgestrel-releasing intrauterine system (LNG-IUS)

	Hysterectomy	Endometrial ablation	LNG-IUS
Control of bleeding symptoms	+++	++(+)	++
Rate of reinterventions within 5 years	<5 %	10–36 %	42 %
Quality of life	++++	+++(+)	+++
Chance of success Length of uterine cavity >8 cm	+++	+	+

+ = degree of satisfaction

Due to the highly sociopolitical importance the board of DGGG had decided to subordinate these already compiled statements to an evidence analysis. This analysis had been executed by Dr. M. Nothacker, an employee of AWMF (Arbeitsgemeinschaft der Wissenschaftlichen Medizinischen Fachgesellschaften e.V.) especially skilled in this field.

The evidence, which includes the present literature until 12/2014, leads fortunately to the same results and recommendations as the primary 2 k-guideline. Thus, all predications, recommendations and statements are supported objectively. Accordingly, the guideline was upgraded to the highest scientific level S3.

The full text of the German guideline and the report of evidence, inclusive the list of authors, is available at http://www.awmf.org/leitlinien/detail/ll/015-070.html.

The recommendations of this guideline concerning the preference of the methods are:

Evidence Based Recommendations

Evidence Grade **1a**	*Recommendation Grade* **A**	*Consensus Level* **+++**

If possible the vaginal hysterectomy shall be preferred to the abdominal hysterectomy.

Evidence Grade **1a**	*Recommendation Grade* **B**	*Consensus Level* **+++**

If the vaginal hysterectomy is not viable, the possibility of a laparoscopic hysterectomy shall be investigated.

Evidence Grade **1a**	Recommendation *Grade* **0**	*Consensus Level* **+++**

The LASH can be performed alternatively to the abdominal hysterectomy as well as to the vaginal hysterectomy.

Consensus Based Statement

Expert Consensus	*Consensus Level* **+++**

However, the recorded data does not allow at present to differ exactly between the various laparoscopic techniques.

Consensus Based Recommendation

Expert Consensus	*Consensus Level* **+++**

The abdominal hysterectomy should only be performed in case of special indication.

Quality of Life

The patient's question, whether the disorders impairing her quality of life will really be improved by hysterectomy, represent a very central point within the medical counseling.

There exist numerous investigations to this question and all of them show the result that quality of life will be considerably improved after hysterectomy [14–16].

Thus, an evidence based recommendation could be compiled:

Evidence Grade **1a**	Recommendation Grade **B**	*Consensus Level* **+++**

The patients should be informed that they can expect predominantly an improvement of quality of life and sexuality after an indicated hysterectomy compared to their pre-operative situation.

Alternatives to Hysterectomy and Counseling

When evaluating the different operative and non-operative alternatives to hysterectomy it can be stated that all of them are effective at the end. Though, due to the fact that the uterus is conserved, the alternative methods naturally have a risk of recurrence respectively a failure rate which then requires after all in lots of cases still a hysterectomy.

Thus, the hysterectomy is at least the most effective method to eliminate the disorders.

Independent of this, in each individual case it has to be examined whether the medically most reasonable method is also the best method for the patient.

So, the latent desire to have children independent of the age represents always a contra indication against hysterectomy. The same is valid for women who occupied their uterus with very important personal feelings. For those the loss of the uterus may be technically the perfect solution, but emotionally they would suffer.

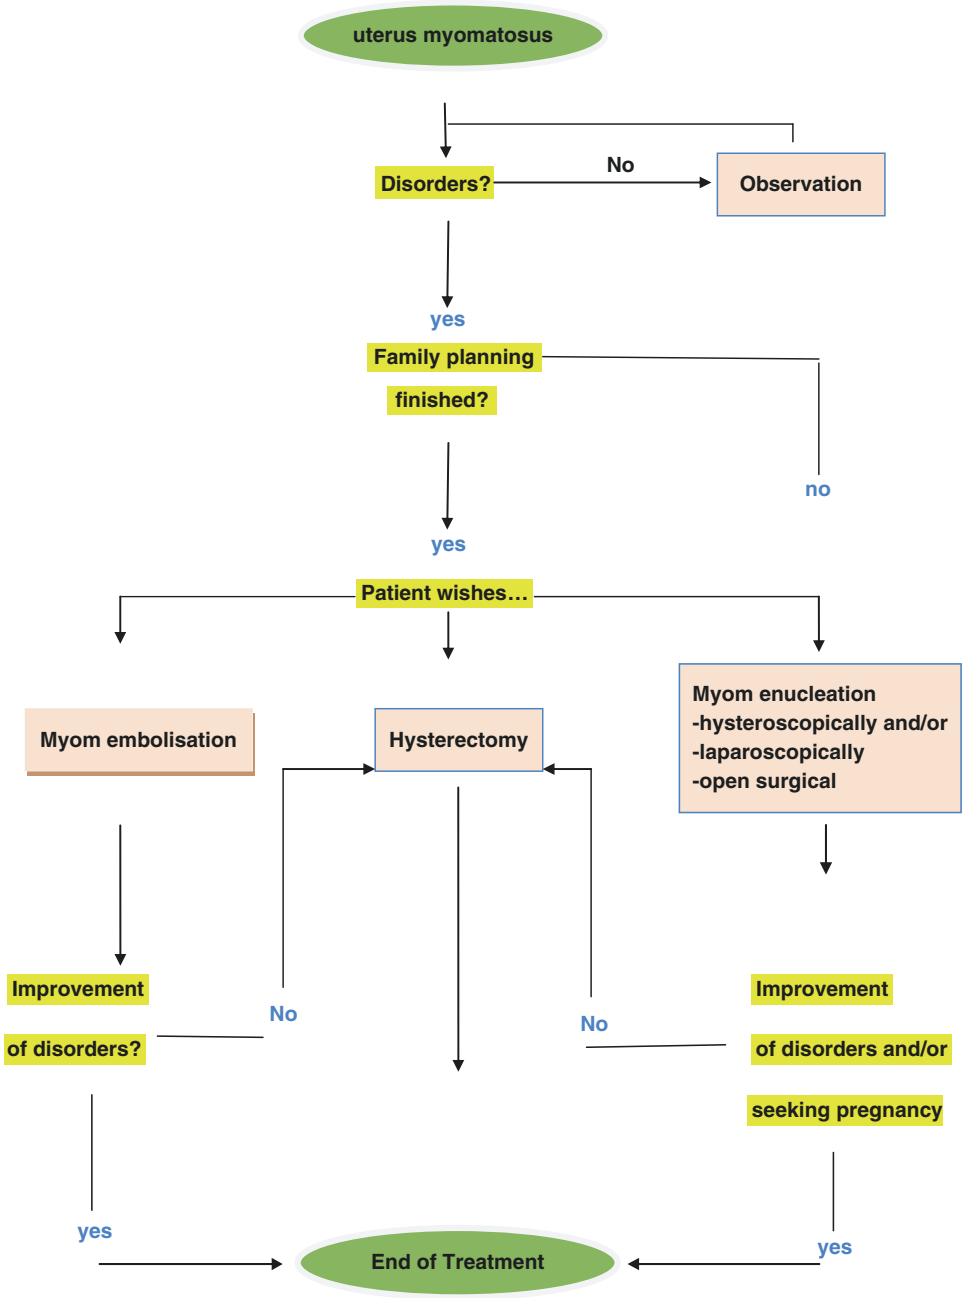

Fig. 10.1 Algorithm: alternatives to hysterectomy

Those women have to be identified and selected within an intensive talk before surgery. In order to guarantee that a complete and highly-qualified counseling is made it is recommended to follow the algorithms compiled by the guideline group (for example, uterus myomatosus shown in Fig. 10.1). That way the patient can realize at a glance the complete range of her possibilities.

The discussion of the individual steps, explaining the advantages and disadvantages of the different possibilities, require however a special education in the field of hysterectomy and its alternatives. As also the alternatives have indications and contra-indications and the probability that the success hoped for is different due to various medical findings and varying anamnesis, the consultant physician should have qualified for this field by advanced training.

It is the aim of the counseling, that on one side transparency is shown, but on the other side, the evidence situation of the individual contemplable methods has to be presented that way that the woman knowing her different possibilities is able to choose that therapy option of which she believes it suits the best to her and her situation of life.

The experience shows that women who are used to take responsibility in their lives are also able to take a decision

quickly, or that they already have made a decision for themselves based on their own research before the counseling.

Even in those cases the patient should be informed again in order to assure that really all aspects were considered for the decision making.

Hesitant women are never to be urged in one or another direction. If there is no imminent danger, as e.g. an anemiating bleeding disorder, the woman can take the time to deal in detail with her disorders and her psychological strain.

Frequently, she will seek medical advice also somewhere else, where she hopefully will be advised just as qualified, transparent, evident and impartial.

When comparing the possibilities we have today with those given 100 years before, as the hysterectomy has been a surgery with high mortality and morbidity and which therefore only has been performed in exactly justified individual cases, with the broad range which we have today as well in the field of hysterectomy as in the field of uterus conserving alternatives, so it is possible today to offer each woman an effective method individually specific to her, so that she can regain the lost quality of life.

The woman always should decide by herself which way to go. In our opinion, with a qualified patient information each woman independent of the primary educational level is able to make her own decision at the end with which she is satisfied also years thereafter.

In summary it can be stated that at present there is generated one standard worldwide concerning the method of hysterectomy. The first option is and will be the vaginal hysterectomy. The second option represents the laparoscopic surgeries which differ decreasingly in their complication rate, so that it is recommended here to choose the method which can be performed best by the surgeon. Then, there are only a few indications remaining for the abdominal hysterectomy. In the meantime, the organ conserving alternatives also have a fixed significance. Their presentation is an essential part of the patient information today.

Choosing the Correct Hysterectomy Technique

11

Linda-Dalal J. Shiber and Resad Pasic

Introduction

In 2009, a systematic review of all randomized control trials comparing surgical approach to hysterectomy for benign disease was published. The objective of this review was to determine the 'most beneficial and least harmful surgical approach to hysterectomy' [1]. The conclusion was that, based on cumulative outcomes of time to recovery, complication rates and length of hospital stay, vaginal hysterectomy should be performed preferentially to abdominal hysterectomy and, when vaginal hysterectomy is not possible, laparoscopic approaches should be considered over the abdominal route.

Existing data clearly indicates that vaginal approach to hysterectomy is associated with fewer complications, faster recovery and lower healthcare costs than abdominal hysterectomy and shorter operative time than laparoscopic hysterectomy (Table 11.1) [1, 2]. Comparisons between vaginal hysterectomy and laparoscopic hysterectomy typically indicate longer operative time with the laparoscopic approach. Some studies have suggested increased complication rates with laparoscopic hysterectomy, namely urinary tract injury [2, 3]. Others have found no significant increase in such complications [4, 5].

Position statements from the American College of Obstetricians and Gynecologists (ACOG) and the American Association of Gynecologic Laparoscopists (AAGL) echo the above recommendations [6, 7]. The concept seems simple-i.e., vaginal hysterectomy is preferable, followed by laparoscopic approach, followed by laparotomy. In reality, however, selecting the route for hysterectomy is a complex task that requires consideration of patient preference, surgical indications, patient characteristics, available resources/procedural costs and surgeon skills and limitations. Perhaps the better way to address this chapter is to ask the question–how do we identify women who are *not* candidates for vaginal hysterectomy? And, of these women, how do we choose who undergoes abdominal hysterectomy over laparoscopic hysterectomy?

Note: For the purpose of this discussion, robotic-assisted laparoscopy will be considered to be within the category of laparoscopic techniques unless otherwise specified.

Operative Indication

In benign gynecologic practice, the most common indication for hysterectomy is symptomatic uterine fibroids, followed by abnormal uterine bleeding. A plethora of other indications exist, including pelvic organ prolapse, endometriosis, pelvic pain and prophylaxis against reproductive system cancers in high-risk women [8].

Selecting the surgical route for hysterectomy is intimately linked with the indication for surgery (Fig. 11.1). The surgical management of gynecologic malignancies is beyond the scope of this chapter and will be considered separately.

For women who present with pelvic pain symptoms or a definite indication for adnexectomy, it is most reasonable to offer a surgical approach that allows a systematic inspection of the pelvic peritoneum, the abdominal contents and the adnexa. Vaginal hysterectomy does not provide a reliable or global survey of the pelvis in these women and does not consistently allow for identification and resection of disease such as endometriotic lesions, adnexal masses or other abnormalities that may contribute to pelvic pain. Though underpowered, a 2004 study found that despite the inherent advantages of vaginal hysterectomy in many women, laparoscopic route to hysterectomy was associated with a higher incidence of detecting unexpected pathology [9]. Certainly, for women who seek hysterectomy for pain

[c]As compared with laparoscopic and vaginal hysterectomy

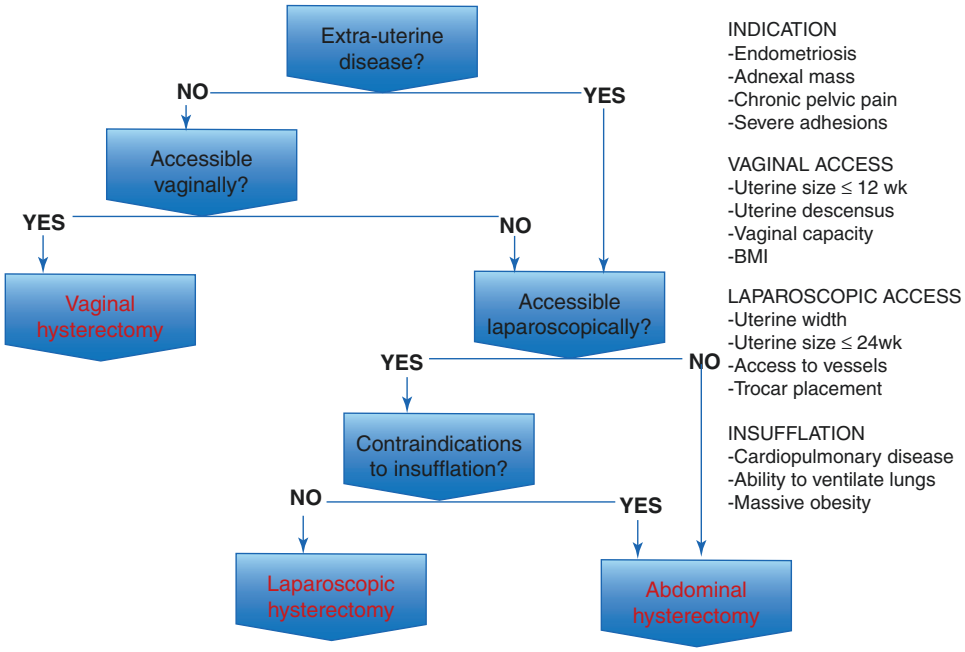

Fig. 11.1 Choosing the route of hysterectomy

symptoms, it is imperative that inspection of the abdominopelvic contents occurs. This should preferentially occur via laparoscopy rather than laparotomy. Though salpingo-oophorectomy is often performed at the time of vaginal hysterectomy, there is no guarantee that adnexal structures will be visible or mobilized from below. Again, in a patient who has adnexal pathology or desires risk-reducing BSO, the laparoscopic approach is most reliable and appropriate.

Concomitant, planned procedures must also be considered when selecting the route of hysterectomy. In women with pelvic organ prolapse who are candidates for vaginal repair, the vaginal route to hysterectomy is most logical. However, in women who require sacro-colpopexy, a laparoscopic or robotic route is preferable to laparotomy.

Co-morbid Conditions: Obesity and Cardiopulmonary Disease

As the obese patient population grows, surgical complication rates and post-operative morbidity increase. It is important to offer these high-risk patients a minimally invasive approach to hysterectomy [10, 11]. Obese patients may have poorer wound healing with higher rates of wound infection and postoperative complications such as venous thromboembolic events. Providing surgical options that minimize hospital stay and immobility is key. Abdominal hysterectomy should therefore be avoided in most scenarios. In a parous patient without indication for abdominopelvic survey and with a uterus of feasible size, vaginal hysterectomy is preferable.

Devices such as the vaginal Bookwalter retractor may aid with visualization and completion of surgery.

If vaginal access is not possible, if the patient suffers from pelvic pain or if the uterus is very enlarged, laparoscopic approaches to hysterectomy are ideal and offer equivalent benefits. However, it is important to counsel the super obese patient considering a laparoscopic or robotic hysterectomy that steep Trendelenburg position and abdominal insufflation may not be tolerated, resulting in laparotomy.

The role of robotic-assisted laparoscopic hysterectomy in the obese patient remains unclear. Anecdotally, the robot may aid with minimizing surgeon fatigue and optimizing visualization during minimally invasive hysterectomy and is certainly preferable to laparotomy in terms of decreasing hospital stay [12]. Randomized control trials comparing surgical outcomes for robotic hysterectomy to laparoscopic and vaginal hysterectomy in obese women are not currently available. One study comparing surgical outcomes of robotic hysterectomy in morbidly obese (body mass index (BMI) > 35) patients versus patients with BMI < 35 found equivalent outcomes but increased operative time for these heavier patients [13]. Regarding the general population, a recent Cochrane systematic review found limited evidence that robotic assisted laparoscopy affords benefit in benign disease [14] and it is well accepted that the robotic approach is more costly [15, 16].

Patients with certain types of heart failure or severe pulmonary conditions such as chronic obstructive pulmonary disease and obstructive sleep apnea may not tolerate the increased intra-peritoneal pressures created by carbon dioxide insufflation during laparoscopy. Deep trendelenburg position, necessary for pelvic surgery in these patients, may not be possible either. Depending on the co-morbid condition present, evaluation of pulmonary and cardiac function is necessary prior to surgery. Consultation with cardiology, pulmonology and anesthesia services is of great importance to surgical planning. These patients should be offered vaginal hysterectomy if possible, but unfortunately may require laparotomy for safe completion of surgery (Fig. 11.1).

Surgical History

In women with multiple abdominal surgeries, adhesion formation is common. Levrant et al. found the incidence of adhesions to be 59 % in women with a prior vertical midline incision versus 28 % in women with a prior Pfannenstiel incision [17]. In women with multiple laparotomies or prior pelvic infections, the likelihood of pelvic and anterior abdominal wall adhesions involving bowel increases. This may preclude safe vaginal hysterectomy. In addition, with the increased rates of cesarean sections in the US and certain other countries, severe vesicouterine adhesions may be present, making bladder dissection from below challenging and dangerous. Although one prior cesarean delivery is certainly not a contraindication to vaginal hysterectomy, clinical judgement must be used. In a patient who is high risk for severe pelvic adhesions, the laparoscopic route to hysterectomy is recommended and laparotomy may ultimately be required to complete the procedure safely.

Parity, Pelvis, Uterine Size

The obstetrician within every gynecologic surgeon must consider the anatomic feasibility of removing the uterus vaginally. When considering vaginal hysterectomy, it is important to assess the vaginal capacity, the uterine size and degree of uterine descensus [18]. For experienced vaginal surgeons, the upper limit of uterine size when considering vaginal route to hysterectomy may approach 16–18 week size. However, in an era when the typical OB/GYN resident is finishing training with fewer vaginal hysterectomies, this is neither a safe nor acceptable parameter. Typically, for uteri larger than 10–12 week size, a laparoscopic or robotic approach allows easier visualization of upper pedicles and even the uterine vasculature. For very large uteri or even uteri >12 week size with an inexperienced laparoscopic surgeon, the abdominal route to hysterectomy may be indicated. In women with rapidly growing fibroids or strong suspicion for malignancy, laparotomy is indicated.

In addition to uterine size, consideration of the shape of the uterus and mapping of fibroids is imperative to surgical planning. For women who have large lower uterine segment fibroids precluding peritoneal access from below, vaginal hysterectomy may not be possible.

Nulliparity and limitations posed by the bony pelvis (i.e., narrow pubic arch) are other important considerations when assessing candidacy for vaginal hysterectomy. Vaginal hysterectomy may be challenging in these women as descensus may not be present and visualization may be very difficult. An important point, however, is that if the patient is otherwise an appropriate candidate for TVH, it may be appropriate to attempt vaginal surgery with preoperative counseling that a laparoscopic approach may be necessary if that fails.

Surgeon Skills/Strengths/Limitation

Despite recommendations set forth by professional societies, it is important to critically assess one's surgical skill set prior to consenting a patient for a particular route of hysterectomy. For surgeons who are inexperienced in *any* approach, the rate of complications and intra/post-operative morbidity increases exponentially for that approach despite purported benefits [18–20].

Decreasing surgical numbers during residency training and a paucity of hysterectomy cases per year of practice have contributed to continued, widespread use of the abdominal route for benign hysterectomy, even in women who would be candidates for TVH or TLH in more experienced hands [21–23]. Surgeons who identify a candidate for MIS hysterectomy but who do not possess the skill set to perform such procedures should actively seek consultation from surgical specialists who can provide optimal hysterectomy care for their patients.

Cost Considerations, Resources

With regard to healthcare costs, vaginal hysterectomy is the most cost-effective approach with robotic hysterectomy accruing the highest costs, both in operating room time and equipment/maintenance, etc. [14–16, 24–27]. In a world recognizing the importance of evidence-based, cost-conscious and high-quality healthcare, the use of expensive robotic technology in benign gynecology is not justifiable.

Patient Preference

Ultimately, after clinical considerations have been outlined and the objective risks and benefits of each approach to hysterectomy detailed to the patient, her informed opinion regarding which technique she prefers must be taken into consideration.

With recent debates in the United States on tissue extraction, many women are declining even vaginal morcellation of tissue and requesting laparotomy. Some women concerned for cosmesis allow this to govern their decision regarding surgery. One study surveyed 100 women and found that the majority preferred a suprapubic mini-laparotomy incision or single-site laparoscopy incisions over laparoscopic, pfannenstiel and robotic incisions [28]. In addition, despite data that has suggested supracervical hysterectomy affords no long-term benefit to sexual function or post-operative outcomes and quality of life [29, 30], some women desire to retain the cervix and this request must be honored in the medically appropriate patient.

In conclusion, selecting the route of hysterectomy for benign gynecologic disease is a complex task that requires consideration of patient preference, surgical indications, patient characteristics, available resources/procedural costs and surgeon skills and limitations. As existing data on surgical outcomes, benefits, limitations and costs continues to evolve, it is important to incorporate these new findings in the patient counseling process.

Indications for Salpingectomy

12

Roberta Venturella

Anatomical and Functional Considerations

The uterine tubes (Fallopian Tubes, FT) are two hollow muscle-mucosal organs, about 10–12 cm long, divided into three portions: the intramural, the isthmic and the ampullary ones. This last portion terminates in an enlarged end, called infundibulum, with some protrusions called fimbriae. The ovarian fimbria, in particular, is connected through the mesosalpinx to the ovary. The tubal ostium, laterally, is the site where the tubal canal meets the pelvic cavity, while the uterine opening of the FT is the entrance into the uterine cavity, the utero-tubal junction (Fig. 12.1).

As the cervix and endometrium, also the FT are derived from the müllerian ducts. The wall of the tube has a mucous layer and a muscle one, thicker in the medial part of the tube. The contraction of the muscle bundles allows the tubes having their own peristaltic motility. The mucosal layer is covered with cells, some of which ciliated, that determine a bidirectional internal movement of fluids and cells, both to the uterus and towards the pelvis. The production of cilia on these cells is increased by Estrogens. Scattered between the ciliated cells are secretory cells, which contain apical granules and produce the tubular fluid. The number of these cells is increased by Progesterone, while Estrogens increase their secretory activity. The tubal fluid contains nutrients as lipids and glycogen for spermatozoa, oocytes, and zygotes and also promote capacitation of the sperm.

After ovulation, physiologically, the oocyte is caught by the fimbriated end and travels to the ampulla of the uterine tube where the sperm are met and fertilization occurs. The fertilized ovum, now a zygote, comes towards the uterus thanks to the activity of tubal cilia and muscle. After four to five days the embryo reachs the uterine cavity and on about the sixth day implants on the wall of the fundus of the uterus.

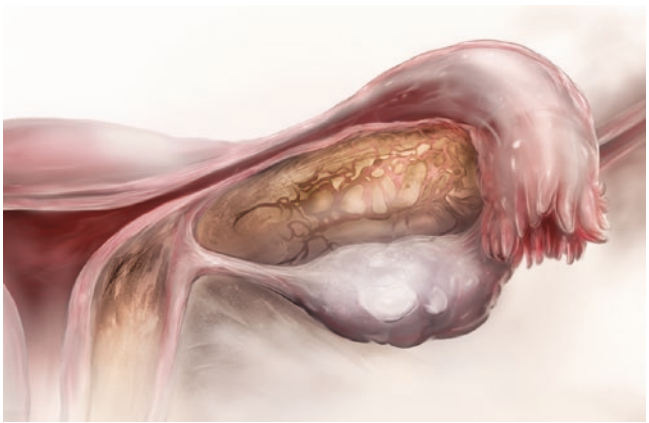

Fig. 12.1 Normal tubal anatomy

Given their bidirectional motility, moreover, the FT are able to let cells, pathogens, blood and substances from the vagina, the cervix and the endometrium to reach the abdomino-pelvic cavity.

Benign Tubal Pathologies as Indication to Salpingectomy

Inflammatory diseases are the most important tubal disorders, due to their frequency and their consequences, sometimes serious [1].

FT indeed, placed between the uterus and ovaries, are frequently infected by one of these two organs. The communication with the peritoneal cavity, moreover, exposes the tube also to any abdominal infection. Appendicitis is a frequent source of descending infection. Rarely, the tubal infection is transmitted by blood, as in the case of tuberculous salpingitis.

More often, the infectious processes ascending from the lower genital tract extend to the tube and reach the peritoneal cavity, leading to Pelvic Inflammatory Disease (PID) [1].

The narrow tubal lumen undergoes important consequences in case of inflammation. The mucosal edema can completely occlude the utero-tubal junction, preventing drainage of inflammatory secretions in the uterine cavity. This causes the onset of acute salpingitis, in which the tube is red, swollen, tortuous, with thickened wall and the lumen filled with pus. The progress of each salpingitis is very slow. Exceptionally acute inflammation can heal spontaneously and the restoration of tubal anatomy and function occurs. Usually, however, the infection becomes chronic and causes permanent tubal occlusion (Fig. 12.2). The tube becomes more dilated, takes the form of a sausage and is filled with pus, leukocytes or plasma-cells (pyosalpinx). The drainage of this infected tube into abdominal cavity can cause the insurgence of peritonitis.

The purulent content may gradually melt turning into a serous or sero-hematic fluid (hydrosalpinx or hematosalpinx). This conditions can remain asymptomatic for a long time, and the diagnosis is often difficult or accidental. When salpingitis becomes chronic, the peritoneal adhesions surrounding the tube and ovaries distort the course of the FT and cause infertility.

In tubal factor infertility, when the cause is bilateral hydrosalpinx, in vitro fertilization (IVF) is now considering the first option rather than attempting to restore tubal function [2]. The hydrosalpinges themselves, however, adversely affect IVF outcomes, reducing the implantation rate and increasing the risk of miscarriage [3]. Among the pathogenic mechanisms proposed, embryotoxic effects, mechanical flushing and changes in endometrial receptivity are the most shared by reproductive gynecologists [3]. The hydrosalpinx fluid, indeed, is able to reach the uterine cavity, in which embryos try to implant, and exerts a toxic effect on this delicate phase of pregnancy.

Fig. 12.2 Hysterosalpingografic image suggestive of right hydrosalpinx

Laparoscopic salpingectomy has been demonstrated to be an effective option for avoiding this negative reproductive interference, improving pregnancy rates and removing the risk of PID and ectopic pregnancies. Whenever laparoscopy is not recommended due to the presence of dense pelvic adhesions, hysteroscopic insertion of device seems a very effective option for management of hydrosalpinx before IVF [4].

Recently, a systematic review and meta-analysis of studies comparing the pregnancy outcomes in hydrosalpinx patients treated with salpingectomy versus those treated with proximal tubal occlusion prior to IVF has been published [5]. In this study, comparable responses to controlled ovarian hyperstimulation and pregnancy outcome were observed between groups, demonstrating that salpingectomy does not worsen reproductive prognosis of patients in which excisional surgery is chosen.

Hydrosalpinx is also the most frequent (35.5 %) complication of the blind-ended remnants of the FT in patients undergoing hysterectomy with tubal preservation [6]. Others pathologies that may emerge from retained FT are tube prolapse, torsion, PID, benign and malignant Fallopian Tube tumors.

Other frequent causes of peritoneal adhesions, responsible of anatomical and functional FT alterations, are previous pelvic and abdominal surgeries, especially if performed by laparotomy. Caesarean sections, surgeries for uterine myomas or ovarian cysts, but especially the presence of peritoneal or ovarian endometriosis are well-known risk factors for tubal alterations and occlusion.

Many variables have to be considered when counseling patients with tubal alterations regarding corrective surgery or direct IVF. The chronological and ovarian age of the woman, the site and extent of tubal pathology, the semen analysis of the male partner, the presence of other infertility factors (such as ovarian endometriosis), the experience of the surgeon and the quality and success rate of the referring IVF center are the most important. Given the costs and benefits associated to both surgery and IVF, the ideal candidate for surgical tubal restoration is probably a young woman, with no other infertility factors, a partner with a normal semen analysis and a tubal anatomy amenable to repair. Conversely, patients with extensive omolateral dense peritubal adhesions from endometriosis and/or dilated tubes (>3 cm) with thick fibrotic walls have poor prognosis: in all these cases the tube is usually damaged beyond repair and omolateral salpingectomy is indicated when pregnancy can be achieved by spontaneous attempts. In patients with tubal factor infertility, however, IVF has a higher pregnancy rate per cycle and this

information need to be discussed with the patient to provide assistance in her decision making.

The second most frequent benign condition affecting the FT is the ectopic pregnancy (EP). Between 1 and 2 % of live births in developed countries, and as high as 4 % of pregnancies involving assisted reproductive technology [7] are complicated by EP, in which the embryo is implanted outside the uterine cavity.

At least 93 % of ectopic pregnancies are located in a FT (Fig. 12.3) [8]. Of these, 75 % are located in the ampullar portion, 13 % are located in the isthmus, and 12 % in the fimbriae [7] but ectopic implantation can also occur in the cervix, ovaries, and abdomen.

EP can be a life-threatening condition as it is responsible for 6 % of maternal deaths during the first trimester of pregnancy [8].

In a typical tubal pregnancy, the embryo adheres to the lining of the FT and burrows into the tubal wall. Commonly, it invades vessels and causes intratubal bleeding, which may discharges the implanted embryo out of the tube as a tubal abortion. Sometimes this bleeding might be heavy enough to threaten the life of the woman, even if, in developed countries, this event is today luckily rare.

Identified risk factors for EP include: PID, infertility, use of an intrauterine device (IUD), previous exposure to toxicants, tubal or intrauterine surgery (e.g. D&C), smoking, previous EP, and tubal ligation [9].

Fertility following EP is dependent from several factors, the most important of which is a prior history of infertility [10]. The treatment choice seems not to play a great role. A recent randomized study concluded that the rates of intrauterine pregnancy two years after treatment of EP are approximately 64 % with excisional surgery, 67 % with methotrexate, and 70 % with conservative surgery (salpingotomy) [11].

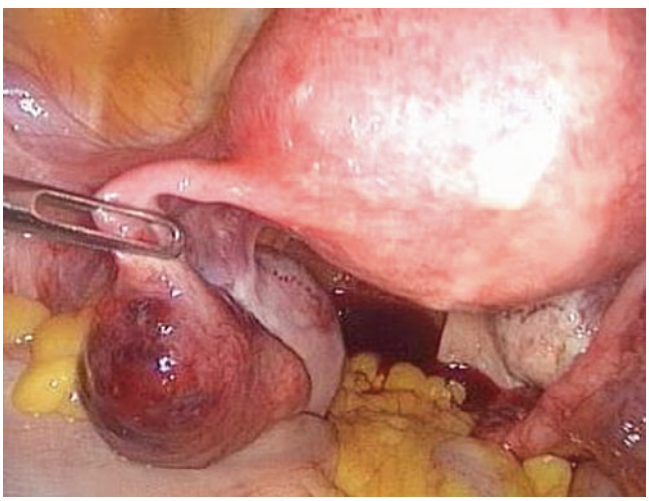

Fig. 12.3 Laparoscopic view of a left tubal ectopic pregnancy

In 2014, in a new open-label, multicentre, international, randomised controlled trial, women aged 18 years and older with a laparoscopically confirmed tubal pregnancy and a healthy contralateral tube were randomly assigned to receive salpingotomy or salpingectomy [12]. In this study, the cumulative ongoing pregnancy rate was 60.7 % after salpingotomy and 56.2 % after salpingectomy (difference not significant between groups). Persistent trophoblast, however, occurred more frequently in the salpingotomy group than in the salpingectomy group (7 % vs < 1 %). Repeat ectopic pregnancy occurred in 8 % of women in the salpingotomy group and 5 % of those in the salpingectomy group. The number of ongoing pregnancies after ovulation induction, intrauterine insemination, or IVF did not differ significantly between the groups.

Meta-analysis of data substantiated the results of the trial so that authors concluded that in women with a tubal EP and a healthy contralateral tube, salpingotomy does not significantly improve fertility prospects compared with salpingectomy.

Malignant and Pre-neoplastic Tubal Pathologies as Indication to Salpingectomy

Historically, primitive tumors of the FT were described as rare [13]. In women with advanced peritoneal carcinoma, the involvement of the ovary usually hides and incorporates the fallopian tube, drawing the attention of surgeons and pathologists and resulting in a diagnosis of ovarian primary carcinoma. In those cases, however, salpingectomy is only a little part of the more radical surgical procedure that is total hysterectomy plus bilateral salpingo-oophorectomy, with pelvic and aortic lymph node dissection when indicated.

Recently, however, morphologic, immune-histochemical and molecular studies [14, 15] have led to the development of a new theory on the pathogenesis of Epithelial Ovarian Carcinomas (EOCs) based on a dualistic model of carcinogenesis [15], which identifies type II neoplasia (high-grade serous (HGSC), high-grade endometrioid, malignant mixed mesodermal tumours and undifferentiated carcinomas) as cancers typically genetically unstable, aggressive and presented in advanced stages [15]. Among these, HGSC is the most common Ovarian Cancer (OC), responsible for the higher death rate among the others types.

Interestingly, the new proposed theory shifts the early events of carcinogenesis to the FT instead of the ovary [15], suggesting that types II tumors derive from the epithelium of the Fallopian tube, whereas clear cell and endometrioid tumors derive from endometrial tissue that migrate to the ovary by retrograde menstruation [14].

These observations have been mainly collected from women carrying BRCA1/2 mutations and undergoing

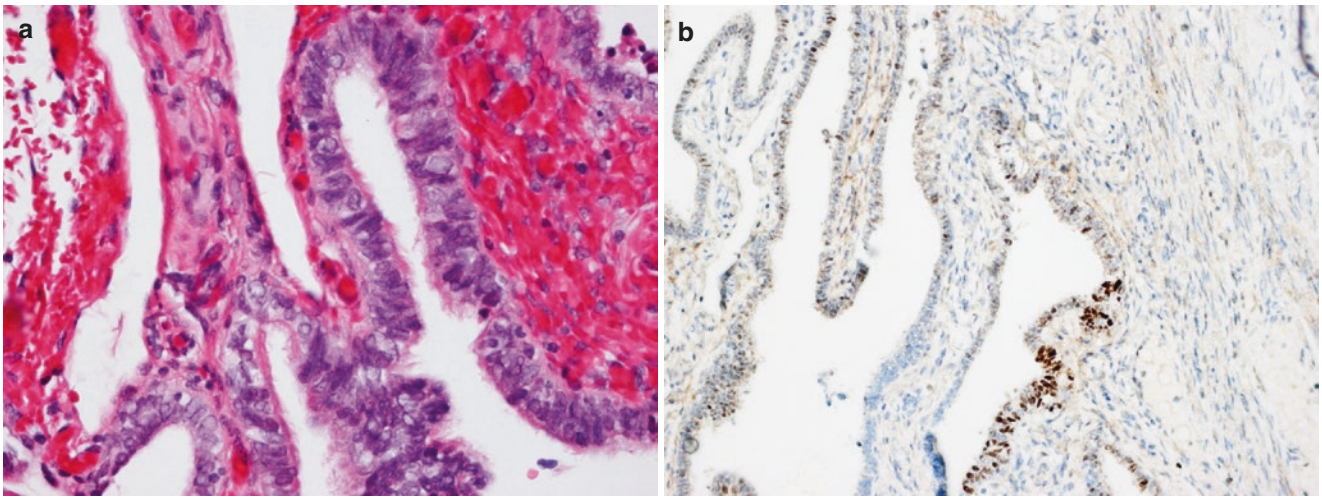

Fig. 12.4 Histologic view of a serous intraepithelial tubal cancer (STIC). In this H&E staining, (**a**) the STIC cells show polymorphic nuclei and a multilayer epithelium, compared with normal tubal epithelium (**b**), in which a distinct transition from normal tubal epithelium to p53 positive STIC (p53 immunohistochemistry) is also shown

prophylactic salpingo-oophorectomy, in which most of the incidentally diagnosed in situ carcinomas or intraepithelial precursors of cancers (STIC) were detected not in the ovary but in the fimbrial end of the FT [16–18] (Fig. 12.4). STIC were also subsequently diagnosed in many women not carrying BRCA mutations, thanks to an extended protocol of pathologic examination of the Fallopian Tubes (SEE-FIM) of patients operated for sporadic HGSC [19–22].

Based on these evidences, prophylactic bilateral salpingectomy (PBS) without ovariectomy has been proposed as a new preventive approach to reduce the risk of sporadic neoplasia [23, 24] in women at population risk of ovarian cancer (i.e. those not carrying BRCA 1/2 mutations) [25], without exposing these patients to the adverse effects of iatrogenic premature menopause.

Even if opinions vary regarding short and long term outcomes of PBS [26, 27], consistent preliminary data demonstrated its safety both in term of ovarian reserve preservation and surgical complication [28, 29]; moreover, several authors have shown a significant reduction in OC risk among women with previous bilateral salpingectomy compared to tubal preservation [30, 31] or unilateral salpingectomy [31].

Therefore, a 2011 position paper by the Society of Gynaecologic Oncology of Canada [25] encouraged physicians to discuss the risks and benefits of PBS at the time of hysterectomy or tubal ligation with women at population risk for OC and this recommendation has been confirmed in 2015 by the American College of Obstetricians and Gynaecologists [32].

The advantage of PBS has been estimated also in term of cost-effectiveness. A recent analysis on PBS (elective salpingectomy at hysterectomy or instead of tubal ligation), showed as salpingectomy with hysterectomy for benign conditions will reduce ovarian cancer risk at acceptable cost and is a cost-effective alternative to tubal ligation for sterilization [33].

Concerning BRCA women, current recommendations include bilateral salpingo- oophorectomy (PBSO) by the age of 40 years or on completion of childbearing to reduce their risk of both ovarian and breast cancers. In these women, indeed, PBS might reduce risk of OC and premature death secondary to cardiovascular disease, but it would not reduce breast cancer risk; conversely, PBSO is able to decrease the risk of OC and breast cancer by approximately 80–90 % and 50 %, respectively.

Permanent Contraception as Indication to Salpingectomy

Surgical sterilization is the most used method worldwide [34] involving 8.1 % of the 15-to 49-year-old married women in developed countries, and 22.3 % of women of reproductive age in less-developed countries [35].

Surgical sterilization it is often achieved by resection (i.e. during a Caesarean section) or laparoscopic coagulation of the isthmic portion of the FT. The remnant segment of the transected tube, however, frequently exhibits histological modifications that let unsuccessful the micro-reanastomotic procedures [36]; the most successful contraception, moreover, is recognized to be obtained by total salpingectomy [37].

For those of women(1–2 %) who revise the previous decision for sterilization for any reason, it was demonstrated that the best method to obtain a pregnancy would be IVF [38], so that bilateral salpingectomy doesn't have any disadvantages

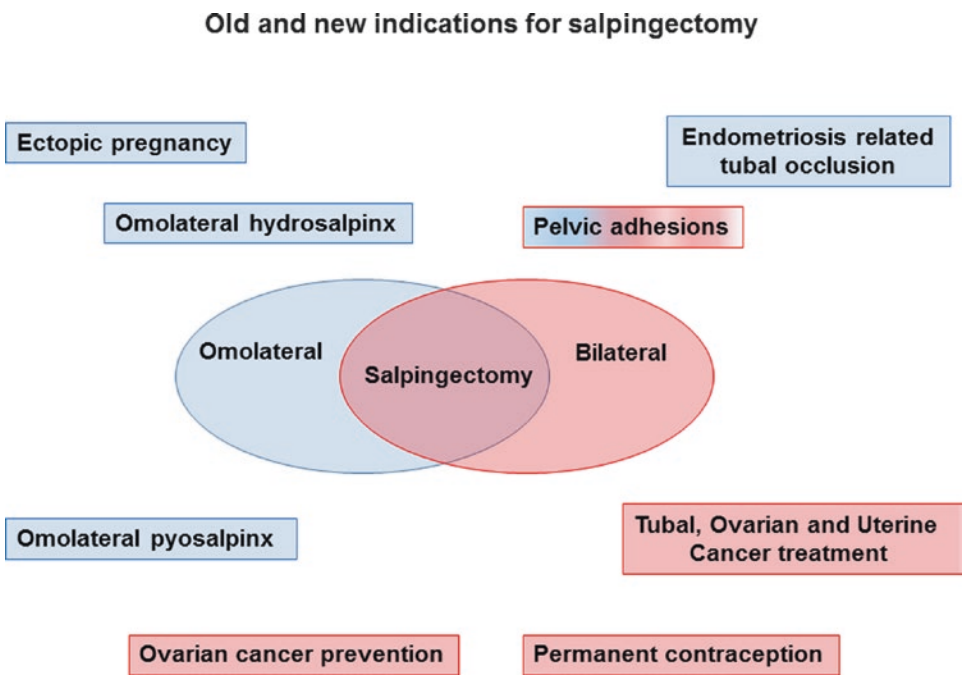

Fig. 12.5 Old and new indication for salpingectomy

in this population of women, while tubal preservation with subsequent tubal disease, definitively impair the implantation of transferred embryos [39].

Hysteroscopic sterilization was recently introduced as an attempt to provide a less invasive but similarly effective alternative to the abdominal approach. Current methodologies, unfortunately, have limitations that make the procedure less promising than expected [40].

Considering the new theory on OC pathogenesis, even if also tubal ligation seems to reduce the risk of EOC of 33 % both in no-BRCA1 [41] and BRCA1 carriers [42, 43], recent data demonstrated that excisional tubal sterilization confers greater risk reduction (64 %) than other methods [44], thus representing the more advisable sterilization procedure to be adopted in the clinical practice.

Bilateral salpingectomy, indeed, would offer to those women requesting for permanent contraception not only the absolute prevention of intrauterine pregnancies and the almost complete elimination of tubal pregnancies, but also protection against EOCs, further providing the chance to assess, along the years, the efficacy of this risk-reducing procedure [35] (Fig. 12.5).

Indications for Oophorectomy and Adnexectomy

13

William H. Parker

The continued hormonal function of the ovaries after menopause has been well established and the current understanding of the health-related long-term effects of removal of the ovaries has effected a change in the indications for oophorectomy. While adnexectomy is presently indicated for women with an adnexal mass suspicious for cancer, increased risk of ovarian/tubal cancer due to genetic mutations, or for some women with severe symptomatic endometriosis, conservation of the ovaries should be considered for most other women without these conditions.

Benefits of Ovarian Conservation

Prophylactic oophorectomy in order to prevent the subsequent development of ovarian cancer was first proposed in the 1970s. This proposal leads to approximately 250,000 US women having normal ovaries removed at the time of hysterectomy for benign disease every year.

However, endocrine studies first performed in the 1970s and subsequently confirmed, showed that the ovaries continue to produce androgens which are converted to estrone throughout a woman's lifetime [1, 2]. Studies showing the potential benefits of endogenous estrogen exposure on long-term women's health outcomes led to a 2005 Markov model constructed from previously published studies [3]. This model suggested that the health benefits of ovarian conservation outweighed the very small risk of ovarian cancer.

In 2013, an analysis of the Nurses' Health Study cohort examined health outcomes after 28 years of follow-up for 16,873 (56.3 %) women who had a hysterectomy with bilateral oophorectomy for benign disease and 13,113 (43.7 %) women who had a hysterectomy with ovarian conservation [4]. Although oophorectomy was associated with a much lower mortality from ovarian cancer, less than 1 % of the women with ovarian conservation died of ovarian cancer. In contrast, more women who had bilateral oophorectomy died from lung cancer (HR = 1.32), colorectal cancer (HR = 1.56), total cancers (HR = 1.18) and coronary heart disease (HR = 1.26) when compared with women who had ovarian conservation. Importantly, at no age was oophorectomy associated with an increased survival.

Studies from the Mayo Clinic had similar findings ; women who had bilateral oophorectomy before age 45 had a 44 % increased risk of cardiovascular mortality [5]. Other Mayo studies showed higher risks of anxiety/depression, dementia/cognitive impairment and Parkinsonism in women who had their ovaries removed [6]. In addition, after oophorectomy about 90 % of premenopausal women will have vasomotor symptoms and many women will also experience mood changes, a decline in well-being, a decrease in sexual desire, sleep disturbances, and headaches [7, 8]. Additionally, vaginal dryness, painful intercourse, bladder dysfunction, and symptoms of depression may occur [9, 10].

In both the NHS and Mayo studies, these detrimental effects on health outcomes were not seen in women who took estrogen following oophorectomy. Therefore, some gynecologists have suggested that oophorectomy be performed at the time of hysterectomy for benign disease and these women be given prescriptions for menopausal hormone therapy and statins to ward off harmful cardiovascular effects. But studies show that within 5 years of a first prescription, only 17 % of women continue to take estrogen and fewer than 18 % are still taking statins [11]. And, these numbers are overstated since they do not include women who never see a doctor, see a doctor but don't get a prescription or women who get a first prescription but never fill it. Consequently, removing ovaries and prescribing medication to prevent the health consequences is not likely to be effective.

Medical ethics suggests that prophylactic procedures should follow two guidelines: there is a reasonable expectation that the procedure will result in a net benefit to the patient; and, without the intervention the individual would be

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_13

at high risk of developing the disease. Therefore, the evidence suggests that removal of healthy ovaries does not meet the definition of a prophylactic intervention. Therefore, prophylactic oophorectomy, in women at average risk of ovarian cancer, should be approached with caution.

Tubal Cancer and Salpingectomy

Recently, the origin of "epithelial ovarian cancer" has been questioned. Interestingly, the ovary contains no epithelial cells and metaplasia of surface mullerian cells to epithelial cells has been hypothethized to explain the types of epithelial ovarian cancer: serous, mucinous and endometriod. Recently, with careful pathologic analysis of ovaries and tubes removed from BRCA positive women, precursor lesions called serous tubal intra-epithelial cancer (STIC) have been found in the fallopian tubes, but no such precursor lesions have been found in the ovary. STIC lesions have the same p53 mutations found in high-grade serous "ovarian" cancers. The more indolent and treatable Stage I low grade cancers, found rarely inside the ovary do not have these p53 mutations. Astonishingly, the deadly form of ovarian cancer does not come from the ovary; most aggressive "ovarian" cancers are, in fact, tubal cancers [12].

Bilateral salpingectomy has been proposed as an alternative to oophorectomy, as it removes the source of aggressive cancers but conserves functioning ovaries. Interestingly, a recent study found that women having hysterectomy and salpingectomy had similar sonographically measured antral follicle counts, mean ovarian diameters and similar blood levels of AMH and FSH. Therefore, it appears that the ovaries function normally after salpingectomy. Based on all of the evidence, and following the lead of the Society of Gynecologic Oncologists of Canada, the Society of Gynecologic Oncologists recently published practice guidelines suggesting that for women at average risk for ovarian cancer, salpingectomy should be considered at the time of hysterectomy, in lieu of tubal ligation, and also at the time of other pelvic surgery (after completion of childbearing) [13]. This strategy is being closely studied in Canada.

It appears that there is now a convergence of ideas: aggressive "ovarian" cancer appears to be "tubal" cancer and salpingectomy may prevent many of these horrible deaths; oophorectomy has adverse long-term health consequences for women and ovarian conservation should be encouraged.

Oophorectomy Not Indicated for Most Ovarian Cysts

Benign ovarian cysts are a common finding in women. In asymptomatic women aged 25–40, 8 % are found to have ovarian cysts larger than 2.5 cm [1] and a study of women age 50 or older found 18 % had unilocular cysts less than 10 cm. However, most ovarian cysts will resolve, even in post-menopausal women. The University of Kentucky Ovarian Cancer Screening Program monitored 39,337 women with baseline and subsequent transvaginal ultrasonography over 25 years of follow-up [14]. Abnormal sonograms were found in 6807 women (17.3 %) over this time. Ovarian cysts were commonly found: in premenopausal women the prevalence was 34.9 % and the incidence was 15.3 %; in postmenopausal women the prevalence was 17.0 % and the incidence was 8.2 %. For the group having an initial abnormal transvaginal sonogram, 63.2 % resolved on subsequent sonograms. The abnormal findings were classified: unilocular cysts (11.5 %), cysts with septations (9.8 %), cysts with solid areas (7.1 %), and solid masses (1.8 %). Surgery was performed on 557 women with the findings of 472 benign cysts and 85 ovarian malignancies. Serial sonography found that many ovarian abnormalities resolved, even if the initial appearance is complex, solid, or bilateral. Cysts considered low risk for malignancy (unilocular and cysts with septations) had a median time to resolution of 12 months. Interestingly, cysts considered higher risk for malignancy (cysts with solid areas or predominantly solid masses) had a shorter median time to resolution – 2 months. Although many cysts resolved in less than 6–12 months, some cysts took longer and, when documented to be stable, these cysts were then followed on an annual basis. However, after 6–12 weeks, cysts that increased in complexity or size were more likely to be malignant and the authors recommended surgery [15]. Using this strategy of serial sonographic monitoring was associated with a positive predictive value of 25 %. Therefore, the authors recommended avoiding a single sonographic abnormality as the sole indication for surgery and they recommended using serial sonograms to reduce false-positive results and unnecessary surgery.

When evaluating women with an adnexal mass, it is a good idea to view the images yourself. Many radiologists use the descriptive term "complex" to denote any cyst other than entirely clear simple cysts. However, "complex" cysts include many benign etiologies: dermoid cysts, endometriomas, hemorrhagic cysts and cystadenomas. Very young women are at risk for developing germ cell tumors, which may produce BHCG or Alpha feto-protein, so these tumor markers should also be considered. Tumor markers, such as CA-125, are rarely helpful in determining the management of cysts in premenopausal women since the chance of a false positive is about 70 %. Endometriosis, functional cysts, fibroids or adenomyosis, cyclic elevations associated with the menstrual cycle, pelvic infection and pregnancy, all common conditions in premenopausal women, have all been associated with abnormally high CA-125 values. Also, 50 % of women with stage I ovarian cancer will have a negative test. Therefore, this test should be avoided in premenopausal women.

Careful scrutiny of the images and serial sonography will often be indicated and, at times, other imaging studies can often help determine the most likely diagnosis and help guide management. Suspected dermoid cysts can often be confirmed by limited CT scan, when fat (sebaceous material), teeth or bone is seen within the ovary. If a hemorrhagic cyst is present, a follow-up sonogram about two weeks later may show either a smaller cyst or changes in the internal echoes consistent with organizing clot.

One study showed that surgery for adnexal masses found during cancer screening does not decrease the death rate from ovarian cancer and subjects some women to the risks of unnecessary surgery. The Prostate, Lung, Colorectal and Ovarian (PLCO) Cancer Screening Randomized Controlled Trial randomized 78,216 women ages 55–74 to a study group screened with annual CA-125 and transvaginal ultrasonography and a control group who received usual medical care [16]. The women were followed for 11–13 years and managed based on the findings.

In the study group, 212 women were found to have ovarian cancer and 118 women died from ovarian cancer (3.1 per 10,000 person-years); in the usual care group 176 women were found to have ovarian cancer and 100 women died from ovarian cancer (2.6 per 10,000 person-years). The risk of death was statistically no higher in the screened group (mortality RR, 1.18; 95 % CI, 0.82–1.71). However, 3285 women had false-positive screening results and 1080 of these women underwent oophorectomy for the findings. Importantly, 163 of these women (15 %) had at least one serious complication occur as the result of unnecessary surgery for an adnexal mass.

Detorsion Rather than Adnexectomy for Adnexal Torsion

Especially in pre-menopausal women, detorsion of the adnexa even in apparently severely injured ovaries can be accomplished with good recovery of ovarian follicles and hormonal function. The not infrequent black-blue appearance of a torsed adnexa results from venous and lymphatic stasis, but some blood supply continues from the ovarian or uterine artery [17]. Some studies suggest that time from the onset of pain to de-torsion best predicts viability of the ovary. One study found evidence of necrosis on microscopy only after 48 h following the onset of pelvic pain [18]. Eighteen young women, ages 23–35, undergoing in-vitro fertilization and ovarian stimulation, were studied with sonography following detorsion of the adnexa [19]. There was no difference in mean antral follicle counts when the de-torsed ovary was compared with the contra-lateral ovary at 6 months following surgery.

Due to the edema caused by torsion, some authors recommend detorsion of the ovary and postoperative follow-up with serial ultrasounds to determine cyst resolution [20]. Cystectomy at time of detorsion may be difficult due to the edema and loss of tissue planes. Additionally, one study found that in 3 of 4 women treated with cystectomy at the time of de-torsion, loss of ovarian function was found in follow-up sonograms 6 months later [21].

However, if the cyst is not removed, there is risk of re-torsion and need for another operation. One study found higher rates of recurrence among 40 women managed with detorsion or detorsion and cyst aspiration, compared with detorsion with cystectomy or salpingo-oophorectomy [22] Malignancy is present in 2 % of women with adnexal torsion, and oophorectomy should be considered in postmenopausal women. However, in pre- menopausal women, detorsion and ovarian conservation should be strongly considered.

When Adnexectomy Is Warranted

Oophorectomy is indicated when the mass is considered suspicious for a neoplastic lesion. Criteria for suspicious lesions include a high initial morphology index, increasing size or complexity on serial sonography over a 6–12 week time period, or an elevated CA-125 in a postmenopausal woman. The University of Kentucky developed a morphology index (MI) in a cohort of post-menopausal women, which can be helpful in predicting the likelihood of malignancy for ovarian tumors (Fig. 13.1) [15].

The MI calculates a score between 0 and 10, using sonographically determined volume and morphologic complexity, with complexity having twice the weight of volume. A score of 0–4 implies that the cyst is likely benign; 5–10 implies that the cyst is likely malignant. Eighty-five percent of all cancers had a MI score ≥ 5. Of the 38,983 women in the study cohort, 472 women had surgery and 74 women were found to have ovarian cancer. The risk of malignancy based on the calculated MI was: MI = 5 (3 %); MI = 6 (3.7 %); MI = 7 (12.6 %); MI = 8 (26.7 %); MI = 9 (27.8 %); and, MI = 10 (33.3 %).

The best predictive values for malignancy were achieved with serial sonographic evaluation at 6–12 week intervals. The mean increase in MI for tumors found to be malignant was 1.6 per month. Women who were found to have benign tumors at surgery had a mean decrease of the MI of −0.3 per month. Tumors that resolved over time had a mean decrease MI of −1.0 compared to tumors subjected to surgery.

This study is very helpful to show that most ovarian tumors, even those with morphologic complexity, resolve over time. However, tumors that have an increase in MI over time should be considered for surgical exploration, oophorectomy, frozen section and surgical staging if malignancy is found.

Risk-Reducing Adnexectomy for BRCA, Lynch

Women with BRCA 1 have 40 % risk of having ovarian cancer in their lifetime and BRCA 2 confers a 20 % lifetime risk. Women with a BRCA 1 mutation have an increased risk of ovarian/tubal cancer as early as age 35, and 2–3 % of these women will develop ovarian cancer by age 40. The risk of women with the BRCA2 mutation developing ovarian/tubal cancer occurs about one decade later [23]. Women with Lynch Syndrome, especially those with the MSH2 gene, have a lifetime risk of ovarian cancer of 33 % and they also have a 40–60 % risk of developing endometrial cancer.

In a BRCA positive woman, oophorectomy, or more correctly, adnexectomy, reduces the risks of ovarian/tubal cancer to less than 3 %. Current recommendations suggest adnexectomy at the completion of child-bearing or: for BRCA 1, before age 35–40; for BRCA 2, before age 50; for Lynch Syndrome, adnexectomy and hysterectomy before age 40 [24].

Endometriosis and Oophorectomy

For women with severe, symptomatic endometriosis unresponsive to conservative management, bilateral oophorectomy concurrent with hysterectomy may decrease recurrent or persistent symptoms and the need for reoperation [25]. One study of women with symptomatic endometriosis compared outcomes between women who had a hysterectomy with ovarian conservation and women who had a hysterectomy with concurrent bilateral oophorectomy [26]. For the women who had ovarian conservation, 18/29 (62 %) had recurrent pain and 9/29 (31 %) required reoperation. For the women who had both ovaries removed, 11/109 (10 %) had recurrent pain and 4/109 (4 %) required reoperation.

Another study of women with endometriosis found that of the 47 women who had a hysterectomy with ovarian conservation, 9 (19 %) required further surgery over the 7 years of follow-up [27]. Of the 50 women who had a hysterectomy with bilateral oophorectomy, only 4 (8 %) required reoperation. Preservation of both ovaries doubled the risk of reoperation regardless of the patient's age. Nevertheless, given the problems associated with early menopause, the authors recommended that for women younger than 40 years, hysterectomy with ovarian conservation should be considered.

Large Masses

Some women may be symptomatic from larger cysts, or they may not be comfortable with, or available for, close follow-up. For these women, surgery may be indicated. There is some evidence for removal of endometriomas, that ovarian function decreases after removal of cysts >4 cm when compared with cystectomy for cysts smaller than 4 cm [28]. However, a review of the literature found no studies showing

loss of ovarian function related to the size of cyst removed. It may be prudent to conserve ovarian tissue even in large cysts clearly thought to be benign.

Summary

Oophorectomy is associated with decreased long-term health outcomes and ovarian conservation should be considered in many woman having pelvic surgery. Salpingectomy may be the procedure of choice for "ovarian/tubal" cancer prophylaxis. Oophorectomy is indicated for women with an adnexal mass that is suspicious for malignancy or for a mass that increases in size or complexity when monitored with serial sonography. Adnexal torsion can usually be treated with detorsion rather than adnexectomy. Oophorectomy decreases the likelihood of repeat surgery in women with severe, symptomatic endometriosis, but ovarian conservation should be considered in those women who are younger than age 40, since conservation avoids early surgical menopause.

Leiomyosarcoma

Epidemiology, Etiology, Pathogenesis, Staging

In Germany and Norway, LMSs constitute 47 [143] resp. 68 % [2] of all uterine sarcomas. The annual incidence rate is 0.55/100,000 among white women and 0.92/100,000 for black women [283]. In northern Europe, with around 0.4 cases/100,000 women of all age groups, the highest incidence rates could be observed among women aged between 45 and 59 [155]. The median and mean ages of disease onset are 53

Table 14.1 Staging for uterine leiomyosarcomas and stromal sarcomas, according to FIGO and UICC 2009 [291]

TNM	FIGO	Definition
T1	I	Tumor limited to uterus
T1a	IA	Tumor 5 cm or less in largest dimension
T1b	IB	Tumor >5 cm
T2	II	Tumor extends beyond the uterus to the lesser pelvis
T2a	IIA	Adnexal involvement
T2b	IIB	Involvement of other pelvic tissues/structures
T3	III	Tumor invades abdominal tissues
T3a	IIIA	One site
T3b	IIIB	>one site
N1	IIIC	Metastasis to pelvic and/or para-aortic lymph nodes
T4	IVA	Tumor invades bladder and/or rectum
M1	IVB	Distant metastasis

and 54 years, respectively (min. 31, max. 90 years) [143]. Other sources point to a median age of 48–57 years [2, 6, 116, 168, 231, 223, 247]. According to data from the German Clinical Center of Excellence for Genital Sarcomas and Mixed Tumors (Deutsches klinisches Kompetenzzentrum für genitale Sarkome und Mischtumoren, DKSM), 64.9 % of women are postmenopausal and 64.0 % are aged older than 50 [143] (Table 14.8). Only 5 to 13 % of LMSs primarily originate in the cervix, tubal LMS are the exception [23, 124, 143]. Medical histories have increasingly revealed a previous exposure to tamoxifen [298].

LMSs arise primarily in the wall of the uterus. Progression of an LMS from an LM is regarded as the exception, and is in fact widely rejected due to the differing gene expression profiles of LMs and LMSs [230, 290]. On the basis of genetics and morphology, it appears highly probable that a smooth muscle tumor of uncertain malignant potential (STUMP) can progress into an LMS [193, 194]. This is further suggested by the fact that the median and mean ages for STUMPs are 5 years lower [143] and that these tumors can also metastasize as LMS (see subchapter STUMP). LMS-growth is regarded as being estrogen-independent (see also prognostic factors).

New binding FIGO-staging [83, 264] for uterine LMSs and stromal sarcomas was released in 2009 (Table 14.1). Current staging takes tumor size into consideration as well as the fact that LMSs can also primarily develop in the cervix, which need not necessarily imply a higher stage or justify a different course of therapy.

Macroscopical and Microscopical Findings

LMSs are mostly intramural. They initially displace the cavum, then break into it and fill it with tumor masses which can subsequently protrude into the vagina via the cervix. Myometrial invasion can be so comprehensive that the myometrium is only covered by the serosa (Figs. 14.1a–f and 14.3a). It is not uncommon for the serosa to rupture. Tumor size ranges between 0.7 and 30 cm, and in 50 % of cases the tumor is solitary [143]. The presence of multiple "myomas" bears the general risk that an LMS may not be recognized as such. In 94 % of such cases, however, the LMS constitutes the largest "LM" [143]. Gross appearance and the cut surface can be strongly reminiscent of an LM (Fig. 14.2a, b). However, the whorled structure that is typical for LMs is missing in most cases (Figs. 14.3a, b and 14.4a). The tumor usually has a rosy, yellowish or grayish-white, "dirty" color. The macroscopic appearance can be markedly pleomorphous, with numerous haemorrhagia, decomposed greenish-yellowish necrotic tissue, and blood-filled cysts (Figs. 14.1d, 14.3a, b, and 14.4a). What usually results is a noticeably soft consistency. In actual fact, what appear to be "capsules" in fact virtually always consist of compressed tumor tissue (Fig. 14.4a). Thus the margins to surrounding tissue are usually poorly defined. The soft consistency of the tumors and the absence of a capsule frequently result in intraoperative tumor perforations (Fig. 14.4b, c). Accordingly, unlike LMs, LMSs cannot be enucleated or abraded ("shelled-out"). Ultimately, the spectrum of gross macroscopic appearance ranges from myoma-like aspects to almost entirely decomposed tumors. Epithelioid LMSs can barely be differentiated from typical LMSs on gross observation. Myxoid LMSs, by contrast, have a more or less gelatinous, shiny surface (Fig. 14.3a, b).

At the microscopic level, LMSs are categorized into spindle cell, epithelioid, and myxoid types [201]. Spindle cell LMSs are much more common than the other variants. They usually have a high degree of cellularity and consist of intersecting bundles of spindle cells and/or pleomorphic cells with eosinophilic cytoplasm. However, cell count is not relevant when seeking to categorize an LMS as such. Destructive myometrial invasion is common. The presence of vascular invasions is characteristic and can be found in 30–34 % of non-epithelioid and non-myxoid LMSs [2, 61]. The decisive

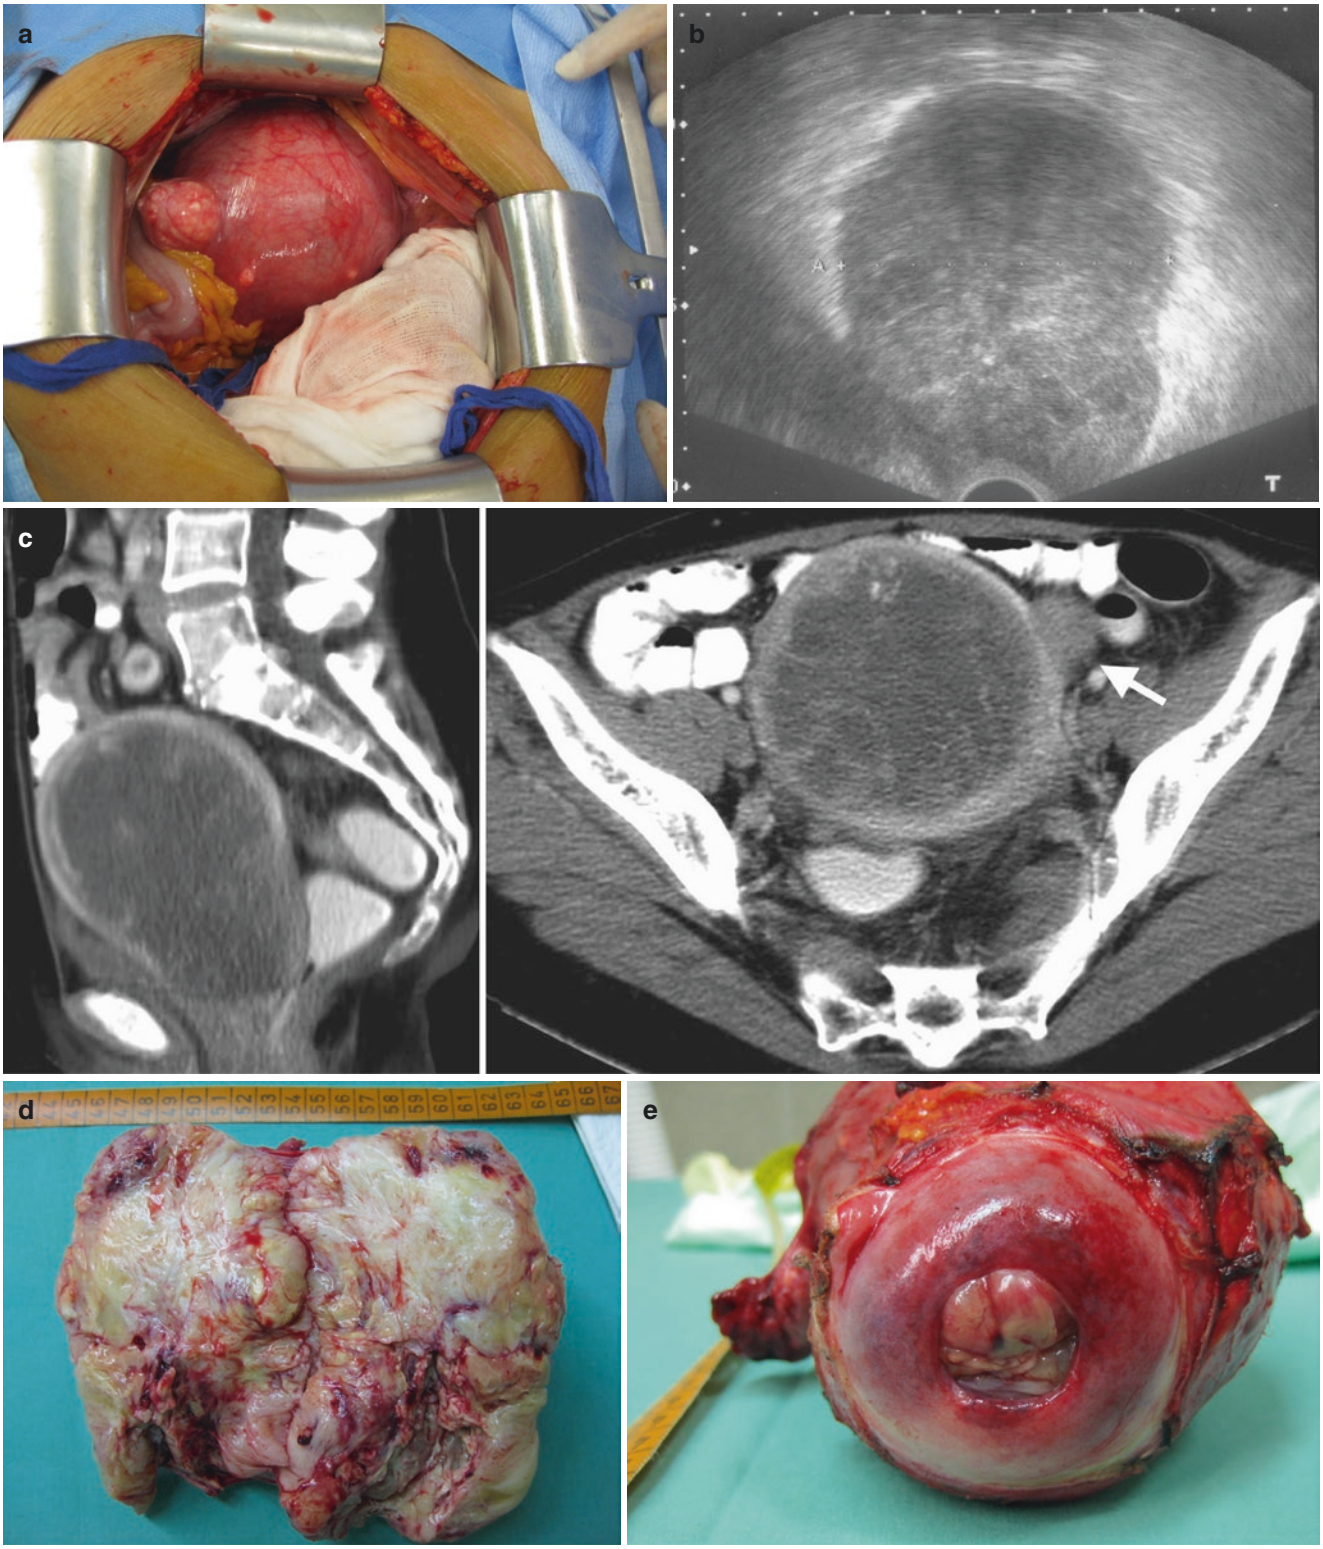

Fig. 14.1 Leiomyosarcoma. (**a**) Looking at the left of the uterine fundus, an LMS has visibly grown into the abdominal cavity, but still remains covered by the serosa; (**b**) in axial sonography, the uterine structures have disappeared and the LMS is practically only surrounded by the serosa; (**c**) both sagittal (*left*) and axial (*right*) CT clearly show that the distinguishability between different tissue layers has been entirely compromised by hypodense tumor masses that are pervaded by enhancing septa. The protrusion of the tumor into the cavity as described under A is clearly visible in the axial CT image (*arrow*); (**d**) macroscopic observation of the opened uterus served to confirm the findings from imaging diagnostics; (**e**) the strong pressure generated by its rapid rate of growth caused the tumor depicted in A–D to protrude through and from the cervix; (**f**) this monstrous cervical LMS appeared to be an LM both clinically and in LSC (With permission of Köhler et al. [145], Fig. 1.2–1a–f)

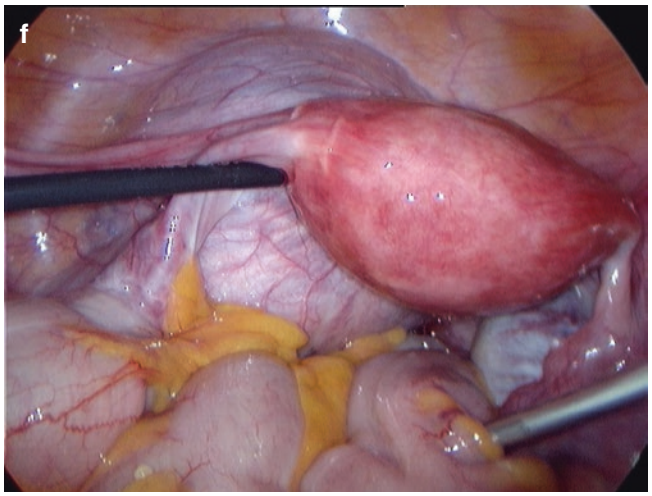

Fig. 14.1 (continued)

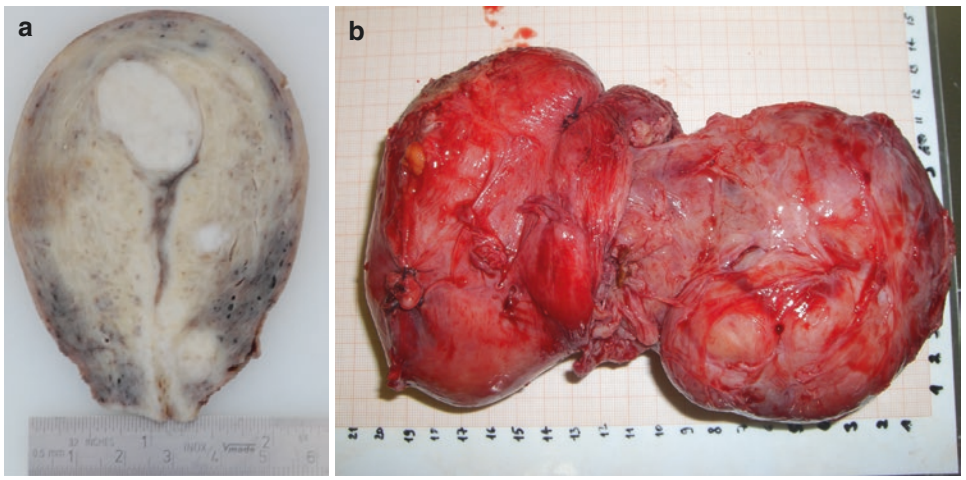

Fig. 14.2 Leiomyosarcoma. (**a**) This LMS, incidentally detected post-operatively following supracervical HE, was the largest of four lesions. The three smaller tumors were ordinary LMs that barely differed from LMS on gross observation; (**b**) even during supracervical HE, this monstrous LMS gave the impression of being an LM (With permission of Köhler et al. [145], Fig. 1.2–2a, b)

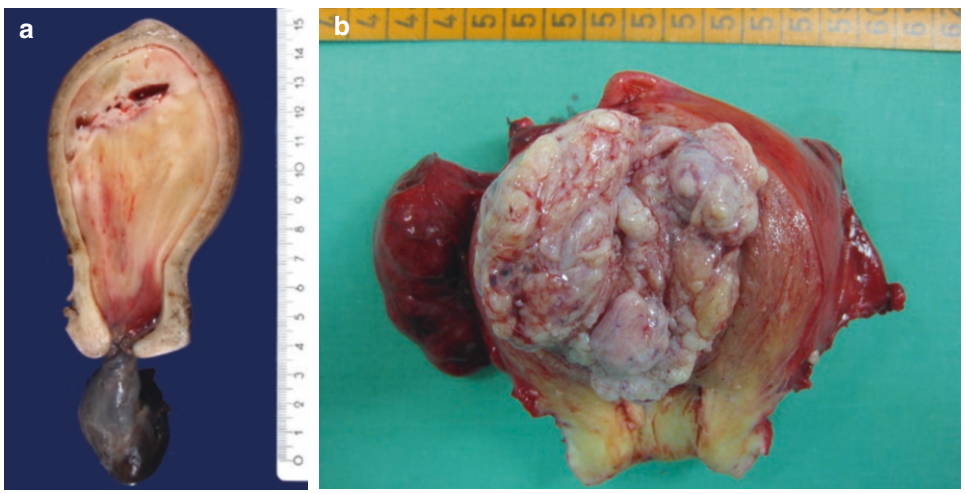

Fig. 14.3 Leiomyosarcoma. (**a**) The very smooth, almost hyaline cut surface, featuring several hemorrhages and cysts, is already a first macroscopic characteristic suggestive of myxoid LMS; (**b**) what is particularly noteworthy about these myxoid LMSs, besides their visible degree of macroscopical pleomorphism, is their hyaline, greasy appearance (With permission of Köhler et al. [145], Fig. 1.2–4a, b)

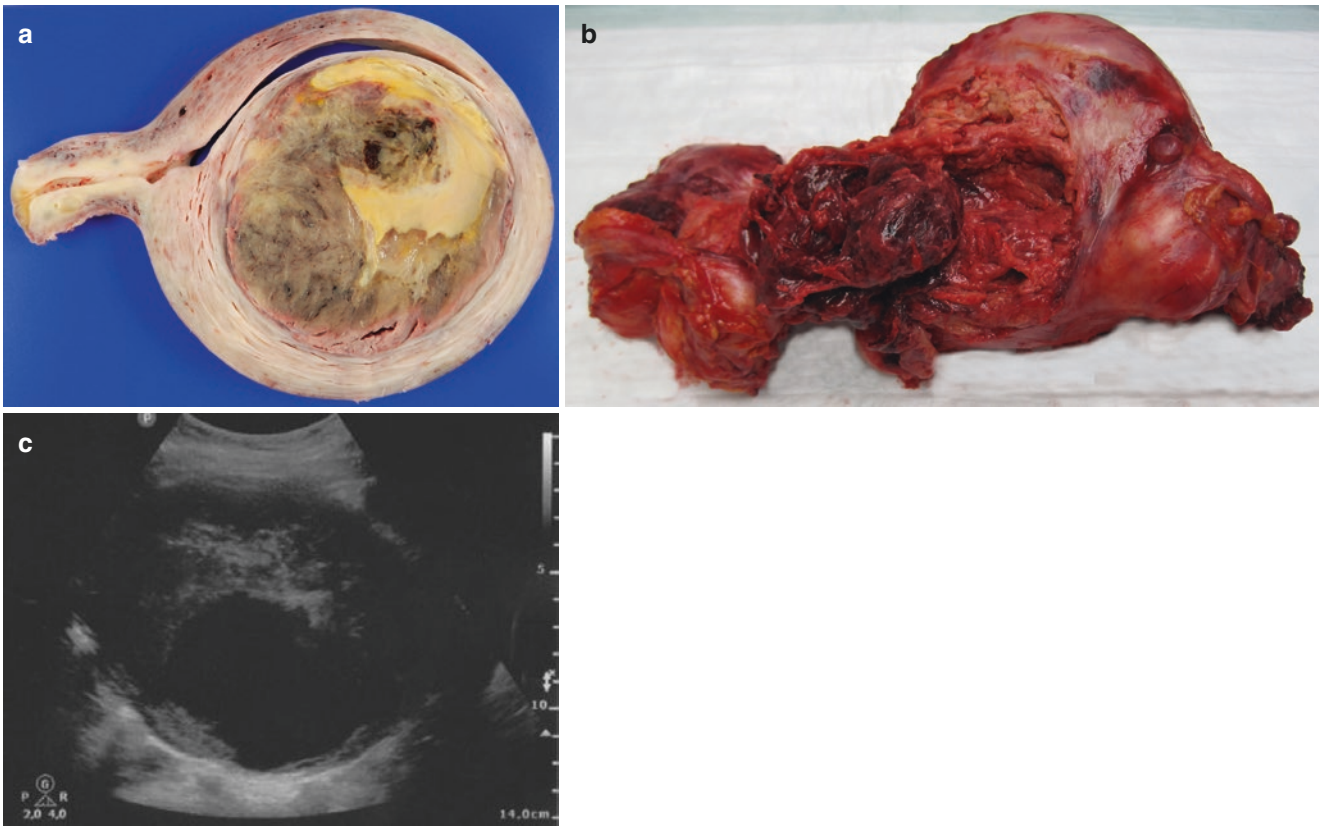

Fig. 14.4 Leiomyosarcoma. (**a**) The LMS is contained within the myometrium and has strongly distended the cavum, however without having broken through or ruptured it. The "capsule" is in fact merely a pseudo-capsule that consists of a mixture of myometrial and tumor tissue that directly merges into the tumor. The *yellow* areas are necroses; (**b**) this LMS was extremely soft, hemorrhagic, and was located immediately beneath the serosa. The attempt to lift the uterus from the pelvis by hand was already enough to cause perforation to the tumor; (**c**) sonography of the same tumor clearly shows that the cystic necrotic tumor was covered only by the serosa (With permission of Köhler et al. [145], Fig. 1.2–12, 1.2–2d, e)

3 factors for classifying a lesion as an LMS are: the presence of TCN, mitotic activity, and nuclear and cytologic atypia [28, 57, 207, 282].

TCN (synonyms: geographic or coagulative necrosis) usually occurs multifocally and is characterized by irregular, well-defined margins to surrounding vital tissue. Differentiating TCN from hyaline necrosis, which also frequently occurs in LMSs, can be challenging. Necroses for which such a clear differentiation is not possible are termed uncertain necroses or questionable TCNs.

MI constitutes the second diagnostic pillar and is measured as the mean number of mitoses per 10 HPF. Mitoses usually occur in so-called "hot spots" (i.e. areas with the most mitoses). Only measuring MI in randomly selected areas of the tumor should thus be avoided, a recommendation that can often not be fulfilled when opting for punch biopsy.

Significant diffuse or multifocal moderate-to-severe nuclear and cellular atypia provide the third diagnostic criterion for LMSs. .

In order to come to the diagnosis "LMS", at least 2 of the following characteristics must be fulfilled:

- TCN;
- an MI of ≥10 M/10 HPF (significantly lower in epithelioid and myxoid LMS);
- significant diffuse or multifocal moderate-to-severe atypia.

Where TCNs have been identified beyond doubt and there is any degree of mitotic activity, i. e. any MI, the diagnosis must be LMS, even in the absence of nuclear and cellular atypia. If the typical necroses are absent, then the MI must be ≥10 M/10 HPF and, additionally (!), there must also be diffuse or multifocal moderate-to-severe atypia in order to allow the tumor to be classified as LMS. Even when the diagnosis is already clear on the basis of the necroses and atypia, the MI should nonetheless always be noted so as to be able to determine prognosis according to the overall survival probability prediction tool for LMSs [308].

ER-expression is positive in 63 % of LMS patients, while the PRs are positive in 50 %; 29 % of tumors are negative in terms of both ER and PR-expression [112]. Other sources have measured positive ER and PR-expression in 20–60 % of LMSs. However, receptors were said to be focally localized in the majority of cases [5, 34, 204].

Myogenic markers, such as desmin and H-caldesmon, are normally well-expressed. LMSs show diffuse moderate Ki-67 (or MIB-1) staining and a moderate-to-strong expression of p53 and p16 [50, 61, 213]. The tumor suppressor protein p16 was in fact immunologically substantiated in 100 % of LMSs [50, 190]. The particulars of the very rare epithelioid and myxoid LMSs are described in great detail in the respective specialist literature [145].

No consensually accepted grading for uterine LMSs currently exists. Current UICC-TNM-classification provides no grading for uterine sarcomas [212, 291].

A re-evaluation of LMSs revealed that one third of lesions that had previously been classified as low-grade LMSs were in fact STUMPs [99] (s. a. section on STUMP). In a further study [287], only 31 % of low-grade LMSs actually fulfilled the LMS criteria.

Symptoms, Clinical Presentation, Clinical Diagnostics, Imaging, Differential Diagnosis

Abnormal vaginal bleeding is the most important symptom of LMS, present in 43–53 % of cases. It occurs as abnormal bleeding in form of intermenstrual bleeding and/or heavy, and/or prolonged, and/or irregular and postmenopausal bleeding [143, 168]. Hemorrhaging is observed in 54 % of postmenopausal women [143]. Compared to endometrial carcinoma and AS originating in the endometrium, in LMS and LG-ESS patients, such bleeding only occurs once the tumor has broken into the cavum. Uterine or lower abdominal pains as well as increased urinary urgency without any signs of bladder inflammation have also been observed [143, 168]. Overall, 86 % of patients show symptoms or report complaints of any sort in the course of tumor development. Symptoms that are independent of a patient's menstrual cycle are, in most cases, a result of the high rate of tumor growth. Said growth also causes the cervix to dilate (accompanied by labor-like pains) and tumor masses to protrude out of the cervical canal. An "LM" is particularly suspicious of being sarcoma when the tumor has developed *de novo* or grown during postmenopause, and when such patients' first symptoms or abnormal bleedings occur postmenopausally. Symptoms normally arise relatively late, with the consequence that the tumors have often already grown to a considerable size by the time they are initially diagnosed (see above and Table 14.8).

Continued LM growth or persistently symptomatic LMs within 12 Mo of embolization, high frequency ultrasound therapy, cryoablation, electromyolisis, or treatment with GnRH-analogues are all factors suggestive of an LMS [85, 101, 117, 191, 215, 289]. A lack of regression following embolization and/or the recurrence of vaginal bleeding are first signs for a primary misdiagnosis [43].

Gynecological examination reveals a relatively soft tumor in the majority of cases. This noticeable "softness" is also frequently stated as an intraoperative finding (Tables 14.4 and 14.11). LMSs have median and mean diameters of 8.0 cm and 9.5 cm, respectively [143]. According to other sources, 67–74 % of LMSs are >5 cm and 25–34.3 % are >10 cm in size [2, 234] (s. a. last section). The data from the DKSM [143] are presented in Table 14.8. The true significance of rapid uterine or myometrial growth for properly diagnosing LMSs has long been, and remains, a highly debated issue. One essential facet of this problem is that there are at least four definitions of what actually constitutes "rapid growth" [21, 41, 219, 222]. This overall lack of certainty needs to be borne in mind if one wishes to draw on rapid growth as a factor for discriminating between LMSs and LMs. Ultimately, one will have to rely on the expertise of the attending gynecologist. Rapid uterine growth was observed in 36 % of LMSs in the materials of the DKSM [143]. A recent report states, albeit anecdotally and without providing exact figures, that LMSs are strongly associated with a rapid increase in tumor size [130]. The issue of rapid growth, pertaining in particular to the differentiation between LMSs and LMs, is discussed below under DD.

Performing an HSC in combination with fractional curettage is indicated when patients present with abnormal uterine or postmenopausal bleeding. However, since LMSs remain in the myometrium for a relatively long time, they are correctly recognized as such on the basis of the curettage specimen in only 25 % of cases (i.e. a false-negative rate of 75 %) [143]. Curettage is thus not indicated when there is no abnormal uterine bleeding and where intracavitary sonography yields no suspicious findings – current NCCN-guidelines deem curettage inappropriate in such cases [191]. In postmenopausal patients, or patients who are premenopausal with suspicious clinical and/or sonographic findings, and who complain of uterine bleeding, unsuspicious findings resulting from analysis of curettage tissue specimens should not be blindly trusted or assumed to be correct. Likewise, the results from HSC could lead to an LMS being mistaken for an LM. Dilated, irregular and crossed vessels with diameter fluctuations could be suggestive of a malignancy and thus give rise to performing a deeper hysteroscopical biopsy and/or more intensive diagnostics.

It often only becomes evident intraoperatively – usually following morcellation – that a removed LM exhibits further unusual or uncharacteristic features, for instance serous or

hemorrhagic cysts and/or decomposing or necrotic tissue in the absence of a capsule (Fig. 14.4a–c, Table 14.11).

Diagnoses reached via frozen section are correct in only 19–28 % of cases [251], though it should be pointed out that these data are somewhat dated. The occurrence of mitoses, TCN and atypia in so-called "hot spots" further exacerbates these insecurities. Myomectomies are also known to have yielded misdiagnoses [263]. The difficult DD between benign, semi-malignant and malignant smooth muscle (!) tumors makes pathologico-anatomical diagnostics based on tissue removed via morcellation particularly challenging. The intraoperative findings presented in Table 14.11 however, provide clinicians with important pointers suggestive of a potentially non-ordinary LM.

While there are no specific tumor markers for LMSs, they do produce LDH and its isoenzymes. LDH-levels are known to have been elevated in up to 80 % of LMSs, but also in STUMPs and occasionally in LMs and degenerated LMs [103, 250]. According to DKSM data, even in recurring or metastasized LMSs, the LDH-values reach pathological levels in about 50 % of cases [143]. LDH-values are not suitable for screening due to their relatively low sensitivity. Notwithstanding, they can indeed be helpful in the context of differential diagnosis, if clinical assessment and symptoms are unclear or inconclusive and/or imaging reveals suspicious findings [58, 103, 187].

Sonography nearly always reveals findings suggestive of an LMS. What makes sonography so valuable is that it serves to provide results that point to an LMS even when clinical diagnostics do not. Such findings make further diagnostic measures necessary, or at the very least require the therapeutic approach opted for to be re-evaluated. Currently, 47 % of LMSs sonographically present and are subsequently described as unclear tumors (though not LM). A further 30 % appear to be suspicious LMs in sonography, while only 10 % are described as sarcomas [143]. In other sources, 30 % of LMSs are classified as unsuspicious findings following sonography, while 45 % are deemed abnormal [251]. As also applies to morphological diagnostics, in general, the largest mass should always be subjected to particularly close examination. The combination (!) of clear rapid tumor growth between successive sonographic examinations with an age of >45 years or present clinical symptoms is suggestive of a malignant or semi-malignant tumor. Solitary tumors with a diameter of ≥5–8 cm are generally to be suspected to be LMSs (see also flow chart) [143]. LMSs occur as solitary tumors ≥8 cm in 56.5 % of cases, compared to 9.1 % among LMs [143].

Changed echogenicity compared to myometrium is an important factor suggestive of an LMS or a malignant mesenchymal tumor. Furthermore, characteristic sonographic findings include: derounded tumors with, in part, bizarre and poorly defined margins to the myometrium; irregular cystic structures with and without hemorrhagic content; necroses. The septa between the cysts usually differ in thickness. The necroses and/or cystic structures usually have bizarre margins. This also applies to the interfaces between zones of differing echogenicity. In particular, numerous central and peripheral hypoechoic spaces can be observed in the tumor that usually reflect abundant vascularity, but also small cysts and necroses. The vessels can often be identified relatively easily due to their narrow hyperechoic rim. They reflect the presence of central hypervascularity, a typical characteristic of all uterine sarcomas. Tumors are highly suspicious of being malignant if they have ruptured the serosa and protrude through it (Figs. 14.1b, 14.4c, and 14.5c, d). Transvaginal sonography should be supplemented with transabdominal sonography in cases in which the former cannot sufficiently visualize the tumor due to its size.

Suspicious or unclear/ambiguous sonographic findings should be followed up by a Doppler examination, unless a primary total HE is already planned. Doppler- or color Doppler sonography usually reveal elevated levels of peripheral and intratumoral vascularity (Fig. 14.5b) [78, 225]. While LMSs are characterized by irregular or incidental vascularity, in LMs the vessels are predominantly peripheral and in a circular pattern. Vascularization of the septa between the cystic regions is also typical for LMSs [75]. A sensitivity of 88, a specificity of 96 and a PPV of 44 % are achieved when only the presence of marked central vascularity in LMSs is considered. The combination of a solitary intramural lesion, a diameter of >8 cm, central vascularity, and the presence of cystic areas is associated with a specificity of 99 % and a PPV of 57 %, albeit with a low sensitivity of 50 % [75]. Central vascularity can also be absent and thus promote a misdiagnosis as an LM. The RI can provide important information suggestive of sarcoma. The mean RI in cases of LM is 0.58, which is lower than in normal myometrium and in adenomyosis (mean: 0.67). RI in LMSs, with a mean of 0.31, is significantly lower than in LMs [161]. Another study has revealed that the median RIs in LMs (0.59) and LMSs (0.49) do not differ to any degree of statistical significance. The authors, however, go on to state that this could be a consequence of the small number of LMS-cases included in their study [19]. Overall, RI is highest in the myometrium, lower in LMs and at its lowest (relatively) in sarcomas. Setting a cut-off value of 0.4 for the RI is reported as being highly appropriate for distinguishing between benign and malignant lesions, i. e. for diagnosing malignant smooth muscle tumors, with a sensitivity of 90.9 and a specificity of 99.8 % (PPV 71.4 %, NPV 99.96 %) [160, 162, 225]. Applying an RI cut-off value of 0.5 yields a detection rate for LMSs of 67 %, with a false-positive rate of 11.8 % [270]. In principle, it is legitimate to assume that an RI < 0.4 is associated with a malignancy, while an RI > 0.7 is reliably suggestive of a benign condition. Further clarification via

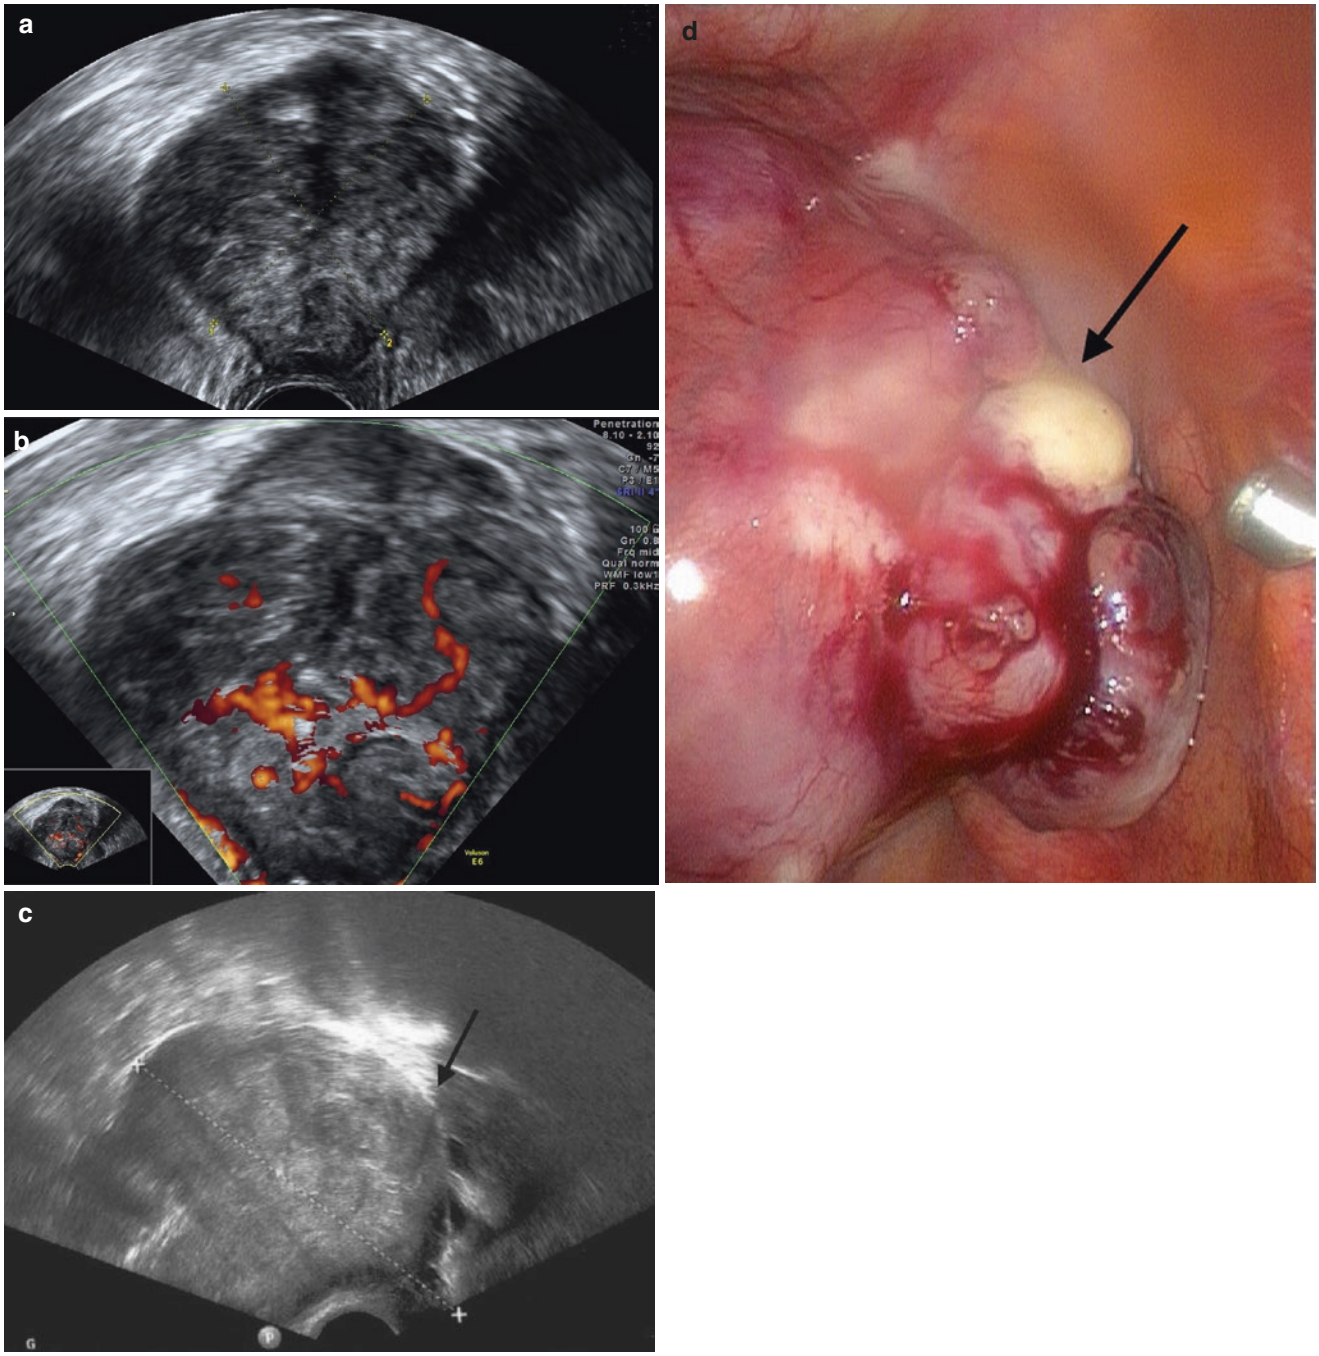

Fig. 14.5 Leiomyosarcoma. (**a**) This ultrasound image bears numerous characteristics that are suggestive of a malignant mesenchymal tumor; (**b**) color Doppler sonography confirmed this suspicion by showing up strong irregular vascularization that in part corresponded to the signal voids; (**c**) tumor with unobtrusively heterogeneous echogenicity that has broken through the serosa in the fundus region; (**d**) endoscopy confirmed that the tumor had broken through the serosa (*arrow*). The visible *yellow* mass was in fact necrotic tissue. The signal voids apparently correspond to the widened atypical vessels that are clearly visible on gross observation (With permission of Köhler et al. [145], Fig. 1.2–8d, e, 1.2–7i, j)

MRT should be sought in doubtful or questionable cases. Typical sonographic characteristics of LMSs are summarized in Table 14.2. The more criteria that are fulfilled, the greater the risk of a malignant mesenchymal tumor or another uterine sarcoma. Even if only one such criterion is fulfilled, diagnostics must be conducted in strict accordance with the flowchart depicted in Fig. 14.22, and/or any planned organ-preserving/sparing surgical procedures or interventional measures should be dispensed with. This equally applies when sonographic findings are unclear or difficult to assess.

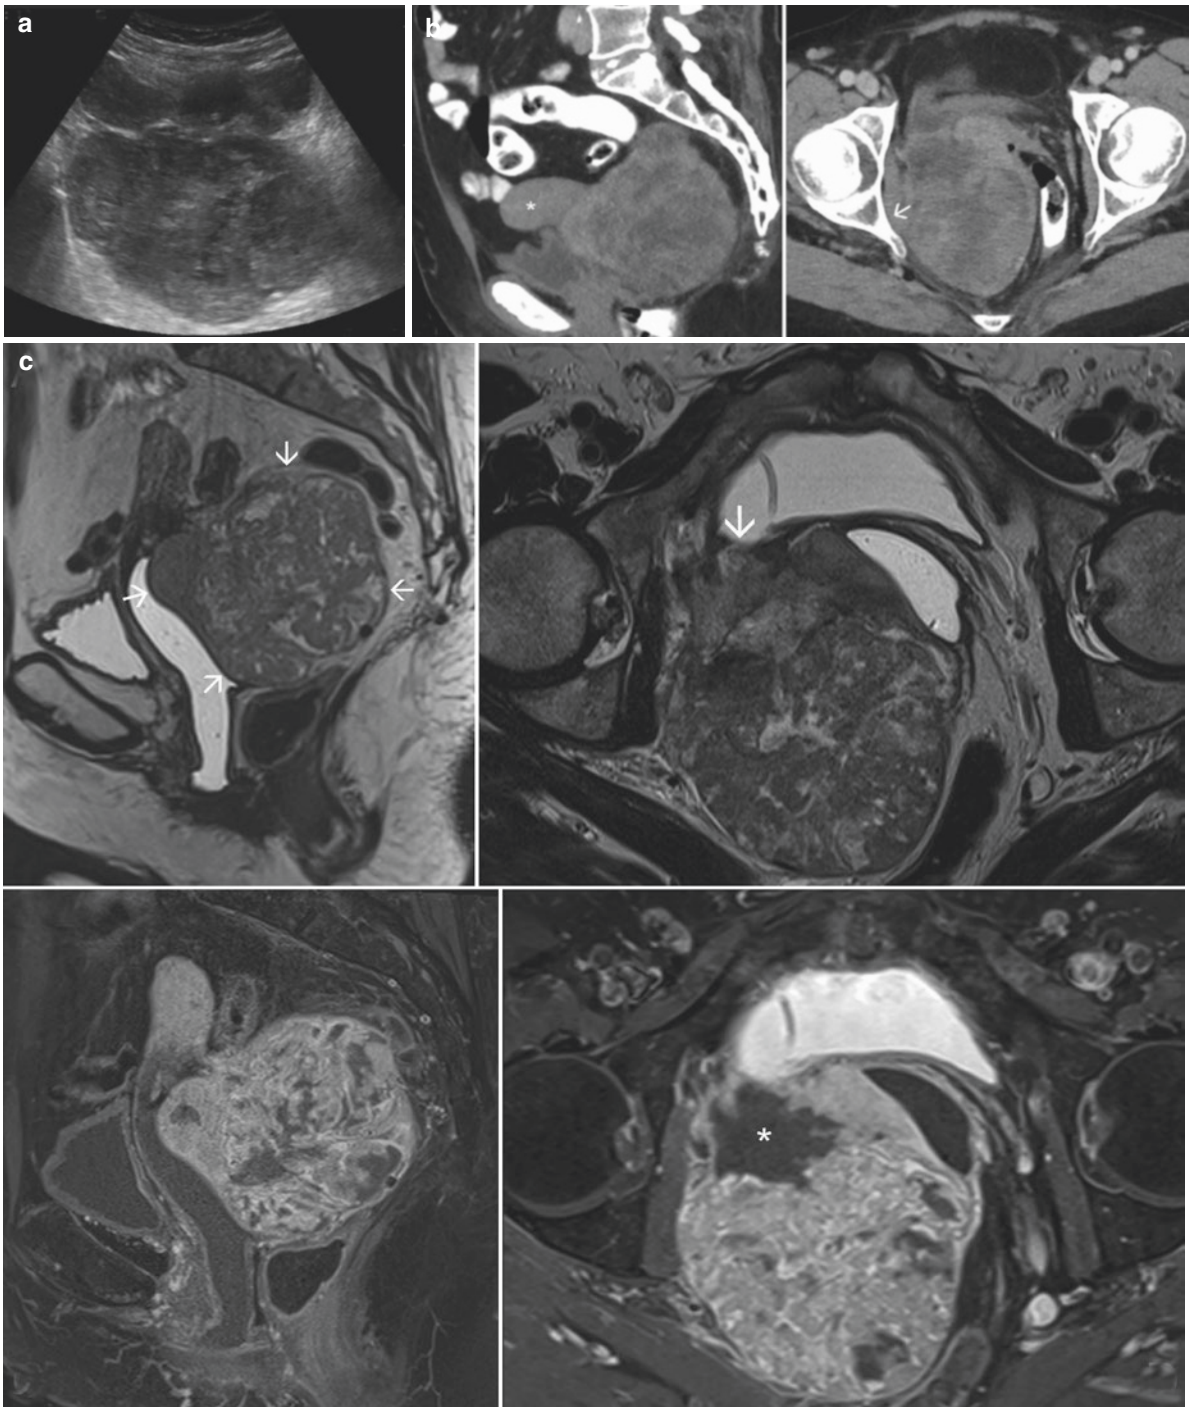

Fig. 14.6 Leiomyosarcoma. Sonographic (**a**), CECT (**b**) and MRT-image (**c**) of a large cervical LMS; (**a**) abdominal sonography shows a tumor with heterogeneous echogenicity that apparently contains numerous necroses with bizarre margins; (**b**) sagittal (*left*) and axial (*right*) CT findings of a large heterogeneously dense tumor in the Douglas that borders the pelvic wall on the patient's right (*arrow*). The corpus uteri (*asterisk*) is anteflected. Most of the hypodense areas are necroses with irregular margins, which corresponds with the findings from sonography and MRI; (**c**) in sagittal and axial T2 W-MRT (*left* and *right*, *top*), the LMS (boundaries marked with *small arrows*) appears as an inhomogeneous hypointense mass that is interspersed with hyperintense areas. A fistula to the bladder (*vertical arrow*) has already developed. Below the *arrow*, a predominantly hyperintense necrosis is recognizable. In sagittal and axial T1 W-MR images (*left* and *right*, *bottom*), upon application of the contrast agent and fat suppression, the LMS shows clearly inhomogeneous enhancement with several non-enhancing tumor necroses (*asterisk*). The latter correspond to the hyperintense mass revealed in T2 W (*top right*) and to the hypodense areas shown in axial CECT (With permission of Köhler et al. [145], Fig. 1.2–10a–c)

Table 14.2 Sonographic characteristics of uterine leiomyosarcomas

Boundaries to the myometrium are poorly defined, derounded, often bizarre or with pointed, tapered extensions
Tumor has clear heterogeneous echogenicity with larger areas of strong hyperechogenicity
Patchy or predominating hypo- to anechoic regions across the entire tumor
Margins between areas of differing echogenicity are derounded, often bizarre or with pointed, tapered extensions
Serosa reached or ruptured
Marked peripheral and irregular central hypervascularity
Central vascularity plus cystic sections plus tumor >8 cm
RI < 0.4

Köhler et al. [145]

Table 14.3 Characteristics of leiomyosarcomas in MRI

T1 W	Tumor with intermediate SI or low (cystic necroses in particular) SI, scattered areas of high SI (hemorrhages in particular)
T2 W	SI primarily intermediate, with heterogeneous hypo- (hemorrhages) and hyperintense SI, some sections with very high SI (necroses, cysts)
T1 WC	Tumor with heterogeneous enhancement
	Weaker enhancement than the homogeneously enhancing myometrium
	Necroses and cysts show no enhancement, often irregular margins

Köhler et al. [145]

Analogous to MRT, determining the LDH-value can be a useful means for further narrowing down the diagnostic options in cases of suspicious sonographic findings as well. It is, therefore, essential that, whenever an LM is suspected, sonography be performed prior to any projected surgical or interventional therapeutic measures – both as a means of preventing inappropriate therapy, and also on grounds of legal certainty.

Expanding imaging diagnostics to include MRT is indicated when sonography and Doppler sonography plus LDH-testing cannot provide sufficient clarification, but organ-sparing surgery and/or morcellation or interventional measures (embolization, high-frequency ultrasound destruction) are planned (see Fig. 14.22). A CT would be inadequate for resolving such issues, but could be a sensible option for determining disease spread when an LMS has been histologically verified (Fig. 14.6b). Taking into consideration that performing an LNE has yet to be scientifically proven as beneficial for almost all types of genital sarcoma, resorting to imaging diagnostics to determine nodal status is generally questionable. One study revealed a sensitivity and specificity of 40–60 % and 80–90 %, respectively, for pelvic LN involvement [296]. The values for para-aortic metastases were 43 % and 91 %, respectively.

MRI (Table 14.3) is better suited than CT for assessing the resectability of locally spread tumors, in particular in relation to neighboring organs, due to its high level of tissue resolution. In terms of LN-involvement, the same statements apply as have already been made regarding CT. 7.5 % of MRT-findings pertaining to LMSs are classified as normal findings, while 30 % are abnormal findings. No clear specification is made for the remaining 62.5 % of LMSs [247].

In T2-weighted MRT images, a high SI, irregular tumor structures, and cystic and necrotic areas (high SI) in combination with ill-defined tumor margins generally are important signs for a malignancy. An SI of >50 % in T2-weighted images together with the mere presence of high SI in T1-weighted MRT images and non-enhancing signal voids in T1 WC are strongly suggestive of a STUMP or an LMS. There have been accounts of LMSs showing homogeneous hypointense SI in T1 W [259, 285]. In T1 WC MRT with gadolinium, LMSs exhibited rapid contrast agent enhancement within 20–90 s, while LMs and the myometrium showed a delayed and gradual enhancement [103]. The necroses and cysts, with their irregular margins, do not enhance (Fig. 14.6c). Degenerated LMs and STUMPs can exhibit similar behavior in MRT [118].

The highest degree of diagnostic accuracy is achieved when there is a combination of the following findings: >50 % high SI on T2 W images plus hyperintense areas on T1 W images and well-defined areas of non-enhancement on T1 WC images [59, 277]. Respective findings also apply to STUMPs, however [277]. Despite the characteristic MRT images with their high specificity, and due to the low sensitivity of all of the findings, no statistically significant objective criteria exist that are associated with the presence or absence of an LMS or a STUMP. Combining the most important criteria [59] with sonography offers a sensitivity of 17–56 % and a specificity of 80–100 % for correctly identifying an LMS, which constitutes a far superior likelihood than can be achieved using purely clinical methods. Performing additional LDH-testing can serve to substantially narrow down the possible diagnoses. Combining MRT findings with elevated LDH-values is said to have a

sensitivity of 100 % for diagnosing LMSs. In one study [103], the specificity, PPV, and NPV as well as diagnostic accuracy associated with stand-alone MRI diagnostics were 93.1 %, 52.6 %, 100 % and 93.1 %, respectively. Combining MRI with LDH-testing served to raise all four of these figures to 100 %. It is important to note, however, that, in more than 50 % of LMSs, the LDH-values are within the normal range [143].

Degenerated LMs are the most important diagnostic pitfall, both clinically and in the context of imaging diagnostics. Differentiating between malignant tumors with cystic structures and degenerated LMs is somewhat simplified by the fact that, in the case of the latter, the cysts are located in an otherwise unsuspicious myometrial environment, exceptionally have bizarre margins, and women with degenerated LMs tend to be younger [230]. Cellular LMs can bear marked similarity to LMSs, both in T2 W and T1 WC images [199].

Performing an FDG-PET-CT can be indicated in exceptional cases (f. ex. in the case of an urgent desire to preserve fertility) when uncertain MRT results leave a need for further clarification [70]. PET-CT is said to have a diagnostic accuracy of 100 % when combined with LDH-testing [200]. There is currently no scientific justification for performing primary PET-CT [235].

Currently, the most substantial problem with LMSs lies in the fact that they are frequently not recognized as such, both before and during surgery, and that 51–68 % of LMSs are operated on under the indication of LM [143, 247]. LM is thus the most important and significant DD for LMS. The median age of women with LMs is 35.5 years at the time of initial presentation [38]. Decisively, however, the median age of women at the time at which LM-surgery is indicated is 45 years, according to the results from two DKSM working groups [143]. LMs are thus subjected to surgery 6–8 years earlier than LMSs are. LMs are predominantly associated with cycle-related pains (dysmenorrhea or hypermenorrhea and menorrhagia), while LMS-patients are more likely to complain of cycle-unrelated symptoms. Symptoms like *de novo* urinary urgency without signs of bladder inflammation or sensations of pressure are generally characteristic of larger tumors. Accompanying symptoms are somewhat more common in LMS than in LM patients. These findings notwithstanding, 14–31 % of LMS-patients show no clinical symptoms [143]. For contrast, 4–80 % of women with LMs are symptom-free [64, 199].

LMSs have median and mean diameters of 8.0 cm and 9.5 cm, respectively. A more detailed breakdown reveals that 85.6 % are ≥5 cm, 55.6 % are ≥8 cm, and 38.5 % are ≥10 cm in their largest dimension [143]. By contrast, according to two separate DKSM-analyses, only 55.2 % resp. 16.9 % of LMs have diameters of ≥5 cm to ≥8 cm [143] (Table 14.8). A further study [64] revealed a respective share of 13.5 % for the latter. A tumor size of ≥5 cm, and even more so tumors with a diameter of ≥8 cm, can be regarded as a criterion for differentiating LMSs from LMs.

According to DKSM-data, LMSs occur as solitary tumors in 50 % of cases [143]. Two separate DKSM studies have shown that 40.1 % of LMs are solitary lesions [143]. On its own, the fact that the tumor is solitary is insufficient for safely differentiating an LM from an LMS. When the two differentiation criteria "diameter ≥8 cm" and "solitary tumor" are combined, however, the differences in frequency become more apparent: while 9.1 % of LMs fulfill both criteria, the respective share among LMSs is significantly greater, at 25.5 % [143]. A solitary tumor with a diameter of ≥8 cm should thus be interpreted as being suggestive of LMS. The aforementioned data are considered in the diagnostics flowchart for preventing inappropriate surgery below (Fig. 14.22).

Two DKSM working groups revealed that 13.3 % of ordinary LMs and 26.0 % of LMSs exhibited rapid growth [143]. Other sources have observed rapid growth in up to 31 % of LMs [64]. In one prospective study, 26.7 % of LMs showed volume gains of 30 % within 1 year. In 26 % of those cases, a 30 % increase in volume was observed within just 3 Mo. There were no accounts of an LMS developing in that study. Interestingly, short-term growth spurts were less common or extensive in LMs that had a diameter of 5 cm or more at the time of initial observation [21, 64]. A further DKSM-analysis revealed that 13.3 % of LMs with a diameter of ≥5 cm exhibited rapid growth, compared to 26.0 % of LMSs. In a further prospective study, 34 % of LMs were rapidly growing. The study also revealed that the rapidity of growth declined dramatically as age increased – rapid LM growth in women aged 45 and above was the exception in the study [222]. It is currently contested whether rapid uterus growth in premenopausal women without accompanying symptoms should be regarded as a warning sign [64]. Besides the fact that LMSs exhibit rapid growth twice as frequently as LMs do, the DKSM-results and studies mentioned above [21, 222] also imply, however, that an LMS should be seriously considered in cases in which tumors with an initial diameter of ≥5 cm exhibit rapid growth and/or when there is rapid tumor growth in women aged 45 and above. At least one of the symptoms stated at the beginning of this section was present in 68 % of LMSs that exhibited rapid growth [143]. Reversely, this also implies that 32 % of patients with rapidly growing LMSs do not complain of any symptoms. According to a further study, asymptomatic, rapidly growing LMs up to a size of 16 WOP with and without rapid growth do not require any special measures to be taken – tumors beyond that size should be subjected to more intensive examination [78]. The clinical criteria that can be suggestive of an LMS as well as other uterine sarcomas are presented in Tables 14.4 and 14.8, and are also considered in the diagnostic flowchart (Fig. 14.22) below.

Table 14.4. Risk factors, symptoms, and clinical findings of uterine sarcomas in particular leiomyosarcoma suitable as selection criteria for preventing or excluding inappropriate sarcoma operations under the indication of a leiomyoma

Tamoxifen exposure
Suspicious sonography in particular in combination with elevated LDH-values
Newly occurring or growing "myoma" in women ≥50 years in particular during postmenopause
"Myoma" turns symptomatic postmenopausally (in particular bleeding)
Tumor diameter ≥8 cm in particular in solitary tumors
Myoma growth under medication therapy
Rapid growth from a starting diameter of ≥5 cm and/or with newly arising symptoms and/or aged >45 years
Myoma with abnormal uterine bleeding (beyond menses)
Very soft tumor

Modified from Köhler et al. [145]

Determining the GDF-15 factor and the unspecific N/L--ratio can be helpful in diagnostically differentiating an LMS from an LM [141, 284].

Both during and after surgery, an LMS need not necessarily be macroscopically discernible as such from other LMs alongside which it has developed. In 94.4 % of cases in which LMSs and LMs occur simultaneously, the former constitutes the largest lesion [143], the soft consistency of which is usually another factor strongly suggestive of it being an LMS. LMs are relatively solid and rough, and show a whorled structure on the cut surface. They have well-defined margins compared to LMSs and a discernible pseudo-capsule is present, out of which they can normally be easily enucleated.

STUMPs constitute the biggest challenge for DD at the histological level. They are difficult to discern – clinically, pathoanatomically and in imaging – from both LMSs and LMs. TCN, MI, and atypia are the pivotal histologic differentiation criteria. The particularities in this regard are discussed in the section on STUMPs. For more detail pertaining to histological appearance in the context of DD, reference should be had to the specialist literature [144]. The same applies to information on the diagnostic differentiation of LMSs from PEComs (perivascular epithelioid cell tumors) [152].

If the results from all imaging and laboratory-chemical options as well as curettage and HSC (where necessary due to abnormal uterine bleeding) provide no clarification, and the patient insists on a conservative strategy, a transcervical punch biopsy can be performed under ultrasound guidance. Experiences with this approach have been surprisingly positive. In one study, transcervical punch biopsies were taken from 453 women whose tumors were LMS-suspicious (high SI in T1/2 W MRT and/or high LDH-values and/or rapidly growing tumor with threefold gain in volume within 1 year) [135]. Among 372 eligible cases, only 7 sarcomas were found. In no case in which histologic examination revealed no suspicious findings (atypia, mitoses, TCN, infiltrations, vascular invasions, epithelioid or myxoid components) was an LMS subsequently revealed in the further course. Examinations performed on 312 women showed that a transcervical punch biopsy under ultrasound guidance is in fact less burdensome for/on patients than curettage [136]. Nonetheless, false-negative results need to be reckoned with, for spindle-cell sarcomas in particular [96]. One reason for this is because mitoses, atypia, and necroses can in fact be concentrated in so-called "hot spots". There is a real risk of missing these hot spots using punch biopsy, so that, essentially, only positive findings can be truly relied on. There are reports that measuring the CD34 and Ki-67 indexes can serve to minimize that risk [300]. The authors defined a case as positive when the measured Ki-67 index was ≥ 15 % [300]. Nonetheless, the Ki-67 index does not constitute a histological criterion for correctly diagnosing an LMS as such (!) (see section on STUMP). Due to the stated problems, biopsy should not be performed at the time of definitive surgery. The described problems and pitfalls notwithstanding, in a further study, the results from performing sonography-assisted trans- or intraabdominal needle biopsies (18-gauge needle) on suspicious lesions with high SI in T2-weighted images were greatly beneficial. Malignant tumors were found in 12 of 63 cases (19 %) (11 LMSs, one LG-ESS). Among the remaining 81 % (n = 51) that were classed as benign, surgery revealed only one LG-ESS. The other 50 lesions were LMs, 27 of which were surgically removed. The remaining 23 tumors exhibited no signs of malignancy in a median follow-up period of 32 Mo. The results are a specificity of 100 % and a sensitivity of 91.7 %, with positive and negative predictive values of 100 and 96.2 %, respectively [276]. The positive morphological results notwithstanding, the risks associated with intraabdominal (!) biopsy suffice to regard the procedure as a counter-indication. The high growth-related pressure within the tumor, that, in turn, is thus frequently pressed up against the serosa (Fig. 14.1a–d), can cause tumor cells to ooze out of the puncture point and subsequently disseminate within the abdominal cavity. Furthermore, tumor perforation cannot be ruled out (Fig. 14.4b, c). These risks are knowingly condoned when intraperitoneal biopsy is performed, and can be avoided by instead opting for a transcervical punch biopsy.

Clinical Course and Prognostic Factors Relevant to Therapy

With reference to the current staging system, median OS for stages I, II, III and IV is 75, 66, 34 and 20 Mo, respectively [232], while mean OS is 45.2, 28.1, 37.6 and 34.3 Mo, respectively [176].

Disease stage is regarded as the most significant prognostic factor, independent of patient age [6, 93]. 42.6–55 % of patients have stage I disease, 4–4.3 % have stage II, 11–12.1 % have stage III, and 30–40.9 % have stage IV disease at initial presentation [232, 233]. Tumor size is also a strong independent prognostic factor in multivariate analysis [2, 95, 232]. According to recent data, stage I disease has a 3 and 5 year OS of 64 % and 38 %, respectively, while OS remains stable at around 30 % in patients with stage II–IV disease. The median time to recurrence is 19.7 Mo across all stages [93].

An MI beyond 20 M/10 HPF is related to a significantly shorter RFI [182]. For instance, 5-year OS for patients with an MI of 6–10 is 60 %, and 23 % for an MI of >20/10 HPF [2]. More recent findings suggest that, in multivariate analysis, an MI of 12 M/10 HPF and above is already significantly associated with a higher rate of recurrence [93]. Ki-67 expression is said to have no influence on recurrence, i. e. it is of no predictive value [93].

Overall, the following pathoanatomical characteristics are said to be associated with poorer survival: size ≥5 cm, unclear gross margins, an MI of >20 M/10 HPF, epithelioid or myxoid components, extensive TCNs, diffuse severe atypia, lymphatic invasion, p53 positivity, and an absence of ER and PR-expression [57].

Most recent analyses suggest that the number of M/10 HPF alone (<25 vs. ≥25 M/10 HPF) constitutes the most important predictive factor for OS [233]. MI and tumor size as well as patient age and the presence of extrauterine spread are the most important factors in calculating prognostic scores according to Zivanovic [308]. The lymphocyte/monocyte ratio, a new independent prognostic variable for soft tissue sarcomas, including LMSs, is significantly associated with RFI and tumor-specific OS in both uni- and multivariate analyses. Preoperative values < 2.85 are associated with an inferior prognosis [271].

LMSs predominantly metastasize hematogenously, while lymphogenous spread plays only a subordinate role. LMSs have a propensity to metastasize to the lungs (65 %) and the liver (23 %) [233]. Overall, 56 % of disease recurrences involved hematogenous metastases, while pelvic metastases were found in only 7 % of cases [182]. According to other sources, up to 31 % of recurrences are solely distant metastases; 73 % are distant metastases plus pelvic recurrences [89].

Metastases to the ovaries occur in only 3.5 % of cases of stage I disease [187], and are almost always observed in connection with further extrauterine spread [57, 100, 168]. At the time of primary diagnosis, no metastases could be found in the ovaries of 202 DKSM-cases of LMSs of all stages [143]. It has yet to be proven that not performing a BSO has a negative impact on prognosis [106]. According to a case-control study [98] and a SEER-analysis [134], whether the ovaries are removed or left during premenopause has no effect on prognosis. A further study has shown that performing a BSO in fact has negative effects on disease-specific survival [95, 98]. This is in line with data that suggest that patients aged up to 55 years have a more promising prognosis than older women [95, 123], and that OS progressively worsens from age 55 onwards [6]. Other studies suggest that ER and PR-expression are not correlated with patient age, stage of disease, vascular invasion, and relapse rate, and have no influence on PFI and OS [33, 61, 93].

In a SEER-analysis, all lymph node-positive patients had stage IIIB or stage IV disease [134]. Nodal positivity was observed in 6.6 % of stage I–IV cases; positive LNs without extrauterine spread were observed in only 3.5 % [168, 182]. In a sample of 884 LMSs of all stages, positive LNs were found in only 3.3 % of cases. Similarly, nodal involvement was found in only 4 % of all LMS-cases included in the DKSM material database [143]. In all of these cases, positive LNs were accompanied by simultaneous extrauterine involvement. Positive LNs were not found in any of the cases of cervical LMS [24]. Accordingly, it has yet to be proven that performing an LNE has beneficial effects on RFI and OS [4, 60, 134, 154, 156]. This is in line with the findings that the number of distant metastases clearly exceeds the number of pelvic recurrences, that LN-involvement is usually accompanied by other extrauterine spread, and that recurrences are common despite patients being lymph node-negative.

The increased demand for conservative modes of treatment has been accompanied by parallel rise in the frequency of reports of surgical procedures being performed that are inadequate/inappropriate for LMSs [1, 87, 117, 201, 215, 226, 289]. An analysis of retroperitoneal sarcomas, including LMSs, identified R1/R2 resections and tumor ruptures as significant independent predictors for worsened OS [37]. These data can be regarded as surrogate evidence for the negative impact of tumor injury occurring in the course of surgical procedures that are inappropriate for uterine sarcomas. A negative impact on patient prognosis should always be expected whenever an LMS is subjected to morcellation [72, 223]. First studies have shown that morcellation only results in a slight increase in the rate of disease recurrence without any measurable impact on OS [197]. Three further studies have revealed a significantly shorter RFI for LMS and LG-ESS patients subjected to morcellation, as well as shorter OS among LMS patients, even though the women were younger and the tumors were smaller than in women who

underwent appropriate surgery [97, 199, 217, 225, 254]. A recent analysis compared the effects of morcellation and total abdominal HE on patient prognosis [97]. The study revealed a four-fold reduction in RFI when morcellation was performed (10.9 vs. 39.6 Mo for total abdominal HE) accompanied by a doubling of mortality risk. Endoscopic follow-up examinations of LG-ESS, STUMP and LMS patients who underwent morcellation revealed intraperitoneal tumor dissemination in 64 % of cases that occurred within 3 Mo in 43 % of cases, and that had not been present at the time of primary surgery. Follow-ups on 2 LMS patients originally subjected to conservative morcellation revealed that extensive metastasization had occurred within one Mo [104]. 75 % of LMS patients in whom there was peritoneal dissemination following morcellation succumbed to their disease within 8.4–40.3 Mo [210, 254]. The causal connection between morcellation and a shorter RFI is further supported by the fact that, in these cases, locoregional and intraabdominal recurrences were considerably more frequent than in LMS-patients who underwent appropriate surgical procedures [188, 217]. A recent meta-analysis covering morcellated vs. non-morcellated LMSs revealed an odds-ratio of 3.16 for all recurrences, 4.11 for intraabdominal recurrences and 2.42 for the death rate. The cumulative extraabdominal relapse rate was not elevated [35]. The higher relapse risk associated with endoscopic morcellation [217] might be due to changes in pathophysiological conditions during LSC. Experimental studies appear to be supportive of this assumption [221]. Another reason is seen in the use of electric morcellators during LSC that apparently propel tumor cells into the abdominal cavity [68, 247]. That would certainly help to explain why tumor cell dissemination seems to occur less frequently when a scalpel or other cutting instrument is used during open surgery. At 0.16–1.18 %, the very low rate of port-site metastases for endoscopic gynecologic carcinoma surgery [179, 185, 307] thus does not necessarily speak against there being an elevated risk of recurrence in performing endoscopic morcellation or the enucleation of sarcomas. What is more, intraperitoneal tumor implants cannot be equated to port-site metastases and, overall, sarcomas and carcinomas behave differently in general. However, the risk of port-site metastases is nonetheless regarded as also being elevated in cases of gynecologic high-risk neoplasms. In such cases, robot-assisted LSC should be avoided [179]. In the meantime, the AAGL and the FDA have issued warnings against using electric morcellators [1, 80].

Besides morcellation, tumor injury and positive surgical margins <1 mm are further independent risk factors that have been significantly associated with local disease recurrence and poorer OS. According to one study [292], local recurrence was in fact 5.6-fold more likely. For these reasons, tumor enucleation, too, is to be viewed critically from a prognostic perspective. There is generally no indication for performing tumor enucleation on LMS patients [74]. LMSs have no capsule, or rather appear to have a pseudo-capsule consisting of compressed tumor tissue, making it inevitable that only R1 (or at least RX) resection margins can be achieved. A recent study revealed a significant RFI-reduction compared to total abdominal HE (8.2 Mo for myomectomies, vs. 46.6 Mo for total abdominal HE) [130].

There is the risk that intravascular or myometrial infiltrations remain in the uterine stump following laparoscopic and abdominal supracervical HEs. Therefore, from a clinical perspective, even when R0-resection margins have been described, an RX-situation should always be assumed. Early disease recurrences within 3 Mo of such operations have been reported [14]. The situation appears to be similar when the uterus is injured with a sharp instrument. In fact, supracervical HE and other uterus disruptions resulted in a 2.8-fold increase in mortality-risk with simultaneous decreases in RFI and OS [223]. In the DKSM-sample, the rate of relapse after inappropriate operations (any form of tumor and uterus injury) is 28.3 %, compared to 27.7 % among patients subjected to appropriate surgical procedures. It needs to be noted, though, that the women who underwent appropriate surgery (n = 101), with a mean age of 55 years and an average tumor diameter of 9 cm, had a poorer primary prognosis than the patients who were subjected to inadequate surgical procedures (mean age of 47 years, tumor diameter of 6.5 cm) [143].

Two studies [246, 260] have shown that death due to LMS was more common in endoscopic HE with morcellation versus open abdominal HE. However, estimated overall (!) deaths were lower in the former. The authors state that the risk of LMS morcellation is balanced by complications that are associated with laparotomy, including death. Better quality of life and lower costs were further highlighted as advantages of endoscopic procedures. Such statements interfere with efforts to avoid inadequate LMS surgery, and to improve diagnostics for these tumors.

Surgical Therapy and Problems

The prognostic data unambiguously show that uterine sarcomas have to be resected in a manner that doubtlessly leaves R0 resection margins and that causes no injury to the tumor whatsoever. What this implies for uterine LMSs is that such tumors have to be removed together with their compartment “uterus” without injuring or damaging it. Total HE without injuring the uterus is thus to be regarded as the standard surgical procedure for LMSs, too [113, 172]. There is no indication for a primarily vaginal approach due to the risk of causing injury to the uterus that this procedure entails, as well as the lack of possibilities for exploring the abdominal

cavity. When opting for laparoscopically assisted vaginal HE or total endoscopic HE, neither the tumor nor the uterus are allowed to sustain injury. There are no data to confirm that performing such surgeries without injuring the uterus leads to less-promising results than would be achieved via open surgery. Intrauterine manipulators should not be used when endoscopic procedures are performed. In the USA and in Germany, 89.4 resp. 64 % of LMS patients undergo total abdominal or total laparoscopic HE [143, 233]. Since supracervical HEs always go hand in hand with injuries to the uterus (potential opening of microscopic invasion routes), they must be classified as inappropriate operations, not least because – as endoscopic procedures – they are virtually always performed in connection with morcellation. The prognostic consequences that could potentially result have been described in the subsection on prognosis. According to the current NCCN-guidelines, the GCIG consensus, the AAGL-recommendations, and the position paper of the German Society for Gynecology and Obstetrics (Deutsche Gesellschaft für Gynäkologie und Geburtshilfe, DGGG), morcellation should always be avoided when an LMS is suspected [1, 27, 113, 202].

Due to the impact that tumor and uterus injuries have on prognosis [204, 217, 223], intraabdominal *in vivo* excisional and punch biopsies as well as tumor enucleation (see prognosis) should not be performed when an LMS is suspected.

Based on the prognostic analyses (see prognosis), there is no indication for performing a BSO on LMSs that are confined to the uterus when the ovaries are unsuspicious from a clinical standpoint. Likewise, a BSO is not necessary according to the ESMO-guidelines [74]. The NCCN-guidelines and the current GCIG consensus [113, 202] state that a BSO can be performed on an individualized, i.e. case-specific basis, bearing in mind the age of the patient. The AAGL [1] recommends a BSO for premenopausal women who do not wish to preserve fertility, albeit without providing any scientific justification. The Japanese guidelines, too, do not back up their recommendation to perform a BSO with any scientific evidence [201]. Whether or not a BSO is indicated is thus dependent on the will of the patient, her menopausal status and the surgical conditions. Overall, in Germany, a BSO is performed on 67 % of LMS patients [143], in the USA this applies to 99.2 % [233]. The fact that at least 50 % of LMS-patients are postmenopausal could also help, at least in part, to explain the high frequency to which BSOs are performed.

According to the current NCCN-, ESMO- and Japanese guidelines as well as the GCIG-consensus, an LNE is not routinely necessary [74, 113, 201]. This takes into consideration that, currently, it has yet to be proven that performing an LNE would have any effect on RFI and OS (see also prognosis) [4, 60, 95, 134, 154, 156]. Furthermore, whether the LNs test positively or negatively does not allow for any further therapeutic consequences to be deduced. There has thus yet been no indication for routinely performing systematic and selective LNEs on patients with LMSs for some time now [91, 134]. Nor is an LNE recommended for cervical LMSs [24]. It remains unproven whether performing a selective LNE on enlarged or suspicious nodes offers any benefits [113], but such course of action can nonetheless be taken according to the GCIG-consensus [113]. Regional LNE does not fall within the surgical spectrum envisaged for retroperitoneal soft tissue sarcomas and LMSs [37, 85, 106]. Nonetheless, LNE in some form is performed in 27–30 % of LMS patients [143, 231, 233].

Omentectomy is not indicated unless there is omental disease involvement [202]. In the DKSM materials, omentectomies accounted for 13 % of 158 LMS-operations, and omental involvement was identified in 15.2 % of those cases. However, in all of those cases, said involvement was accompanied by other extrauterine spread [143]. Cytological smear testing of the abdominal cavity has no implications for therapy, as the resulting findings have not yet been proven to be of prognostic significance.

The poor overall prognosis (!) and the aforementioned risks (see prognosis) associated with certain surgical methods and procedures serve as a counter-indication against performing tumor extirpation on lesions that have been identified as LMSs. The RX-resection as the overriding problem with which tumor extirpation mostly because of the missing capsule (Fig. 14.4a–c) is associated cannot be remedied by using an extraction bag. The same applies to morcellating the tumor inside an extraction bag. A critical review of the literature reveals that a significant share of the conservative operations that resulted in favorable outcomes was in fact performed on so-called low-grade LMSs, that are in fact mainly classified as STUMPs nowadays [170, 248]. The promising courses and outcomes thus need to be treated and interpreted with caution. Should identified LMSs nonetheless be subjected to tumor extirpation in absolutely exceptional cases, the tumor should be no larger than 5 cm and R0 resection margins must be achieved without doubt. Overall, subjecting an LMS to conservative surgery is currently regarded as an inappropriate measure [91]. Should a patient who has been correctly diagnosed with an LMS wish to preserve her fertility and thus insist on conservative surgery, she must be insistently informed that such surgery will further worsen an already very poor overall prognosis, and follow-up LSC (see below) as well as total HE once the desire for fertility-preservation ceases (i.e. upon child birth) should be urgently recommended.

For the risks associated with incidentally inappropriate surgery, see the final section below.

If an LMS is diagnosed post-operatively following conservative primary surgical procedures, including supracervical HE, the residual uterus/cervix as well as all tumor masses

should be fully resected in any case [1, 27, 202], notwithstanding that having undergone inappropriate primary surgery will have already increased the risk of recurrence. The possibility of residual tumors remaining in the uterus and/or its lymphatic vessels is the primary motivation behind this course of action. In one study, 15 % of re-operated patients were upstaged [72]. Drawing on the experiences reported by the DKSM and more recent literature [143, 210], in these cases, the tumor stage was not primarily incorrectly assessed – rather, new tumor residuals or occurrences had arisen/developed. In a total of 12 DKSM-cases involving LMSs and LG-ESSs, metastases that had previously not been detectable were identified in the 2–4 weeks following primary surgery [143]. It is thus urgently recommended that patients who undergo morcellations or "myoma enucleations" be subjected to endoscopic follow-up or re-operation/completion surgery within 3 to 6 Mo [202, 210, 254]. The AAGL, too, recommends re-operation or LSC as means for follow-up, and to remove any suspicious tissue [1]. Where the aforementioned measures are not performed, following-up via imaging techniques is strongly advised [177, 202].

The surgical management of advanced LMSs applies to all LMSs that have spread beyond the uterus. Locally advanced LMSs are predominantly accompanied by dissemination to the abdominal cavity. Simultaneous distant metastasization, in particular to the lungs, is also common. If the LMS is confined to the pelvis or the abdominal cavity, and no distant metastatic disease is present, then maximal debulking should be aspired to. Aggressive cytoreduction can apparently serve to prolong survival even when only R1-resection margins have been achieved [66]. It is also possible to perform intra- and extraperitoneal interventions (the latter in the lung in particular) when conditions are favorable [169]. Absence of clinical post-operative residual disease was associated with a significantly improved RFI as well as improved OS. While the benefits for OS were not statistically significant, the median OS in such cases was still a remarkable 31.9 Mo [169]. Currently, in light of the few applicable chemotherapeutic agents available, and their poor response rates and very short PFIs, subjecting patients with advanced disease to remedial surgery should be the therapeutic strategy of choice. Accordingly, the current NCCN-guidelines and the GCIG-consensus [113, 202] both strongly prioritize the surgical resection of all metastases, depending on their resectability and the extent of disease. Where metastasization is extensive, a palliative HE is always indicated if uterine bleeding cannot be controlled by other means [113].

Follow-up and aftercare should entail gynecological and general examinations that are clinically guided by the presenting symptoms. Follow-up examinations should be conducted every 3 Mo for the first 2 years, every 6 Mo in the following 3 years, and every 12 Mo thereafter. The current NCCN-guidelines make a 2A–recommendation to consider running a CT on the thorax, the abdomen, and the pelvis at these follow-up examinations. MRI or PET and further diagnostic procedures should be reserved for when there are suspicious findings or when patients show clinical symptoms [202]. It remains unclear, however, what course of action should be taken when imaging diagnostics yield positive findings in symptom-free patients. Benefits for survival resulting from complex laboratory-chemical and instrument examinations have yet to be scientifically substantiated. Clinical examination should always be combined with vaginal sonography, and abdominal sonography where deemed necessary. This applies in particular to cases in which patients have undergone primary surgical procedures that are associated with increased risk of locoregional disease recurrence.

There are no indications for adjuvant or postoperative chemo- and/or radiation therapy. More detailed information, including data pertaining to the therapeutic approach for metastases, should be taken from the specialist literature [145].

Atypical Smooth Muscle Tumors (Smooth Muscle Tumors with Uncertain Malignant Potential, STUMP)

Epidemiology, Etiology, Pathogenesis

The term "atypical smooth muscle tumor" has come to be increasingly used in place of the term STUMP. Current WHO-classification [212] defines a STUMP as a smooth muscle tumor with characteristics that clearly preclude a diagnosis as an LMS, while at the same time not fulfilling the criteria for being classified as an LM or one of its variants. The common characteristic of these heterogeneous tumors (that are too rare to be able to definitively predict their behavior) is their metastatic potential, which is very low, and much lower than that of an LMS. The current nomenclature "atypical smooth muscle tumor" includes such tumors that had previously been termed 'atypical LM'.

STUMPs are observed in women with a mean age of 35 to 42 years, in an age range from 25 to 77 years [227, 277]. According to DKSM data, the median and mean ages are 46 and 44.9 years, respectively [143]. Thus, they occur roughly 7–9 years earlier than LMSs and can consequently be regarded as a kind of precursor or forerunner. In clear contrast to LMSs, only 20 % of women with STUMPs are postmenopausal and 28 % are $\geq$ 50 years old. Calculations conducted by two DKSM working groups revealed in summary that STUMPs account for 0.153 % (6 of 3920, 1:653) women who underwent any form of LM surgery (*14334*). Atypical LMs differ from LMs in that they can have proven chromosome-p1-deletions, which are suggestive of an independent etiology [53].

Macroscopic and Microscopic Appearance

According to DKSM data, STUMPs have median and mean diameters of 6 resp. 6.8 cm [143]. STUMPs are occasionally observed side by side with LMSs [164]. Cutting open the surgical specimen often reveals macroscopic characteristics that differ from those of ordinary LMs, for instance the absence of the whorled structure, and a more fleshy gross appearance. Necroses, hemorrhages and cystic sections can be present (Fig. 14.7a, b). It sometimes occurs that final diagnosis as a STUMP is only reached upon specimen re-examination on the occasion of a patient presenting with disease recurrence.

The histological criteria for categorizing an atypical smooth muscle tumor as such are the MI, the presence of cellular and nuclear atypia, and an absence of clear TCN (s. section on LMS). The lack of unambiguous TCN is the most important histological difference to an LMS. TCN needs to be distinguished from so-called hyaline (infarct-like) necrosis, which occurs relatively frequently in normal LMs as a spontaneous regression phenomenon. Necroses that cannot be reliably categorized as either TCN or hyaline necrosis are termed questionable or uncertain necroses, and constitute an important criterion for diagnostically classifying a STUMP as such.

According to the current WHO-classification [212], lesions are to be classified as atypical smooth muscle tumors or STUMPs if they fulfill the following histological characteristics [28, 57, 119, 120, 121, 212]:

- MI of > 15 M/10 HPF without TCNs and without atypia,
- focal/multifocal moderate to severe atypia with an MI of 3–5 M/10 HPF,
- diffuse moderate to severe atypia with an MI of 2–9 M/10 HPF,
- uncertain necroses or isolated/sporadic TCNs without mitoses and without atypia.

Opinion is divided on TCN in this context. While some hold the view that only uncertain necroses are eligible as a criterion [181, 207], others state that it is also sufficient if there are isolated/sporadic necroses coupled with no more than a low MI and mild atypia [62, 212]. The presence of multiple TCNs that have been reliably identified as such, however, is a criterion that clearly points towards LMS. Histologically, around 20 % of STUMPs exhibit hyaline necroses [181]. Hyaline necroses and areas of edema showed more frequently in atypical LMs treated prior with hormonal therapy. Microscopic examination demonstrated that 46 of 51 cases had pushing margins, i.e. margins penetrating the myometrium [181].

In one study, 100 % of atypical LMs exhibited strong PR-expression, and 10 of 13 tumors had moderate to strong ER-expression [269]. In other studies, ER and PR-expression tested positive in around 50 resp. 70–100 % of cases [34, 192, 305]. Measured ER-expression levels closely resemble those of LMSs and differ significantly from levels found in ordinary LMs. By contrast, PR expression is significantly higher than is the case in LMSs. These findings underline the special position that STUMP holds between LM and LMS, and serve to clarify the importance

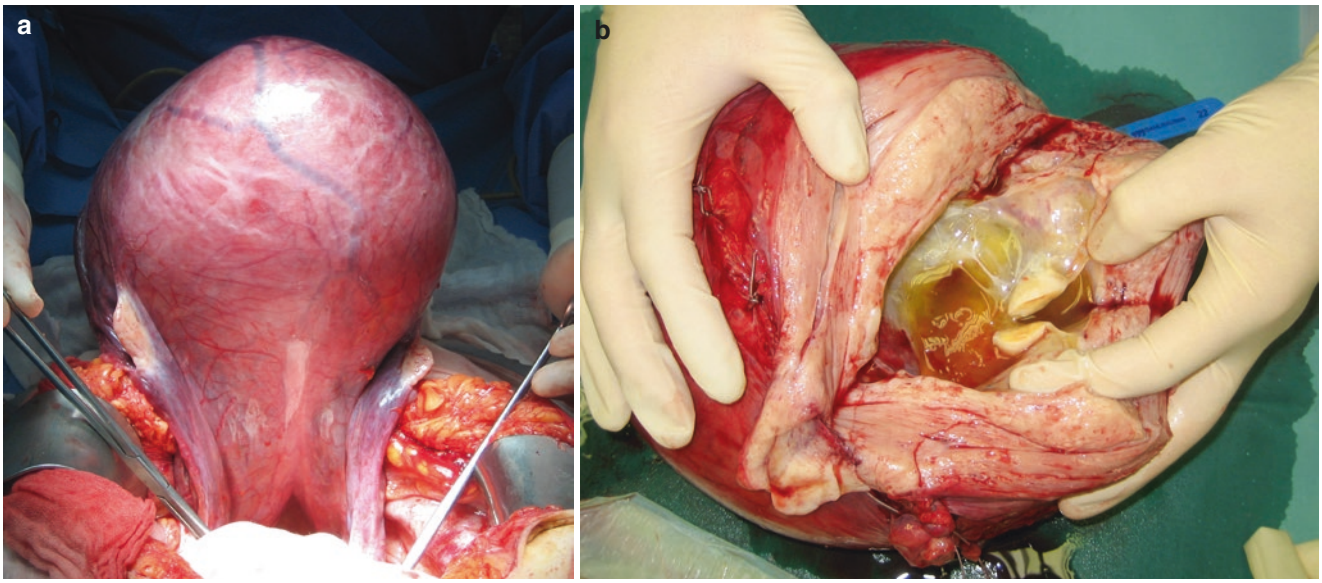

Fig. 14.7 Atypical smooth-muscle tumor (STUMP). AB: this 52 y.o. patient is a prime example for the fact that these tumors have often already grown to quite a size at the time of primary diagnosis. Compared to ordinary LMs, they are usually softer, less fascicular, and often inhomogeneously colored. Additional gelatinous components and cystic structures are not uncommon. (With permission of Köhler et al. [144], Fig. 1.1–15a, b)

of PR-expression as a factor for differentiating a STUMP from an LMS.

The Ki67-index of atypical LMs fluctuates between 0 and 25 % (mean 2 %). Since LMSs have a Ki67-index of between 6 and 50 % (mean: 25 %), said index can only be used with caution as a means for differentiating between LM and LMS. 84.6 resp. 38.5 % of atypical LMs show a strong immune reaction to p16 and p53 [269]. A further study [50] revealed a mediate-to-strong diffuse p16 staining pattern in 100 % of LMSs and STUMPs (WHO-classification pre-2014). STUMPs with diffuse p16 staining and TCN should be classified as LMSs [18, 142]. Diffuse p16 and/or p53 staining is regarded as the most important indicator for an increased risk of recurrence [57]. Overall, drawing a line and differentiating between STUMPs and LMSs is remarkably difficult. For more detailed information, also on the extremely rare myxoid and epithelioid STUMPs, reference should be had to the specialist literature [144].

Symptoms, Clinical Presentation, Diagnostics, Imaging, Differential Diagnosis

The symptomatology associated with STUMPs largely corresponds to that of ordinary LMs, and also that of LMSs, featuring heavy menstrual and prolonged bleeding, menorrhagia, dysmenorrhea, and premenstrual pains. The same can be said of their clinical presentation. STUMPs often exhibit a rapid rate of growth, in young women in particular [143]. Postmenopausal LM-growth points to a STUMP or an LMS. Lack of remission following treatment with GnRH-analogues or UPA, or continued LM-growth, are also suspicious. On palpation, STUMPs often feel softer than ordinary LMs, a finding that is reported almost without exception in surgery reports [143]. During surgery in which the tumor remains *in situ* or is not cut open, the differences to ordinary LMs are often only implied, or are not even visible and discernible at all. In opened tumors, however, hemorrhaging, gross necroses, or cystic areas are not uncommon. When in doubt, a frozen section can be performed. However, such practice can often not provide definitive clarification if not accompanied by immunohistochemical testing. The problems and difficulties that frozen section procedures entail are referred to in the chapters on LMS and LG-ESS. What can be said at this point is that frozen section procedures should only be performed on fully excised tumors (excisional biopsy), since otherwise, as with morcellation, tumor cell conveyance is virtually unavoidable.

STUMPs have a polymorphic sonographic appearance that can be similar to that of ordinary/degenerated LMs and LMSs. Heterogeneous echogenicity and the presence of anechoic regions, in the form of cysts and necroses that are usually an expression of cystic degeneration or hyaline necroses, could be suggestive of a STUMP (Fig. 14.8a) [180]. Narrow anechogenic areas usually correspond to dilated vessels. STUMPs thus cannot be differentiated from ordinary, degenerated and cellular LMs or from LMSs solely on the basis of cystic structures being present. However, the presence of bizarre margins between the individual echogenic and anechoic regions constitutes an important criterion for differentiating STUMPs from LMs. Doppler sonography reveals that STUMPs have a significantly higher degree of central vascularity than both cellular LMs and ordinary LMs (Fig. 14.8b) [75]. STUMPs have an RI between those of

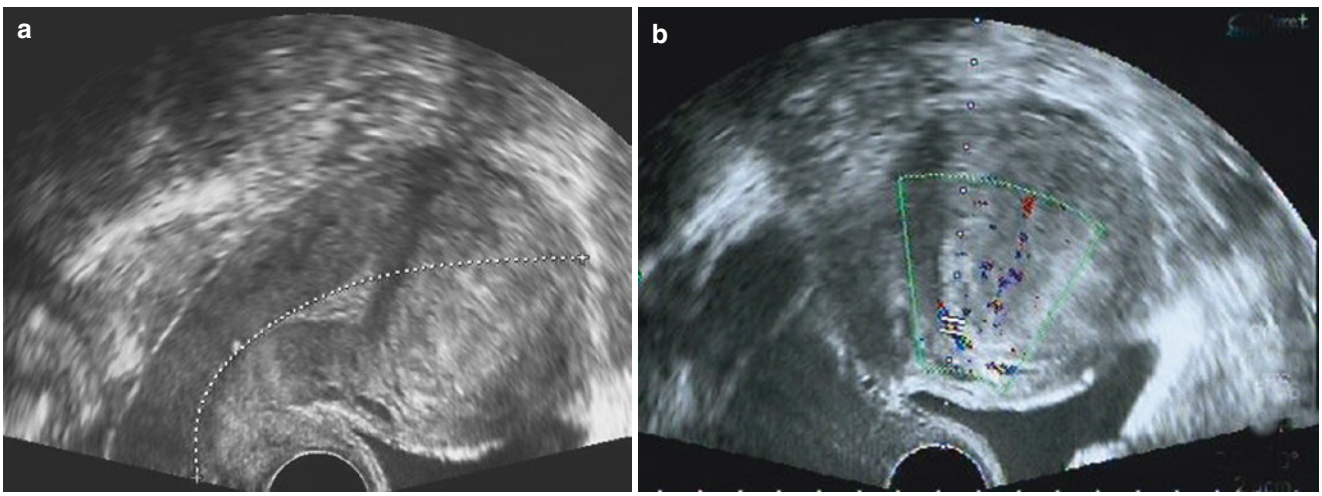

Fig. 14.8 Atypical smooth-muscle tumor (STUMP). (**a**) Closer observation of this predominantly hyperechoic tumor shows margins between the different echogenicities that are bizarre in part. The anechoic voids just above the bladder, with their hyperechoic margins, correspond to dilated vessels, as confirmed in Doppler sonography (B); (**b**) color Doppler sonography of the same tumor also reveals the tumor's central but weak vascularization that in turn speaks less likely for an LMS. The RI of 0.58 lies between those of ordinary LMs and LMSs (With permission of Köhler et al. [144], Fig. 1.1–18a, b)

Table 14.5 Variants of leiomyomas and smooth muscle tumors of uncertain malignant potential

Variant	Tumor cell necroses	Mitotic rate/10 HPF	Atypia or other criteria
Cellular leiomyoma[a]	Missing	<4	Missing or light, but cellular
Leiomyoma with bizarre nuclei	Missing	Missing or low	Bizarre cells and nuclei diffuse p16 and/or p53 staining possible [2]
Mitotically active leiomyoma	Missing	≥5 (10) and ≤15	Missing
Atypical smooth muscle tumor (STUMP [4])	Few present or questionable [3]	none	None
	Missing	>15	Missing
	Missing	3–5	Moderate to severe, focal or multifocal
	Missing	2–9	Moderate to severe, diffuse

Modified from Köhler et al. [144]

[a]Particularly when chromosome p1-deletions are positive, cellular leiomyomas exhibit the prognostic behavior of STUMPs [2], classification as STUMP when there is diffuse p16 and/or p53 staining [3], when hyaline necroses and TCN cannot be clearly discerned from one another [4], elevated risk of recurrence for all STUMPs in case of diffuse p16 and p53 expression

LMs and LMSs in most cases (0.4–0.7). More detailed particularities are described in the chapter on LMSs.

CT does not allow for a specific diagnosis to be reached. As is also the case with LMs, for STUMPs, in many cases T2 W MRI reveals a homogeneous hypointense mass [257, 277]. Differentiation from an ordinary LM is not possible in such cases. However, as is the case with LMS, T2 Ws can also reveal hyperintense tumor sections or cysts. The non-enhancing cystic regions and necroses within the enhancing tumor are easily discernible in T1 WC images. A clear differentiation from an LMS is often not possible [257, 277]. Despite remaining uncertainties, the probability of identifying an LMS or a STUMP is very high (with an accuracy of 87 %, a sensitivity of 72.7 %, and a specificity of 100 %), if >50 % of the tumor has a high SI in T2 W images, smaller sections have a high SI in T1 W images, and several non-enhancing pockets are recognizable in T1 WC images.

In terms of DD, the greatest histological challenges are posed by cases that are borderline between STUMP and LMS. Due to the frequent localization of mitoses, atypia, and necroses in so-called 'hot spots', results from frozen section examinations that are suggestive of a STUMP are to be deemed uncertain unless there is a clear and unambiguous LMS-diagnosis. Moreover, MI is elevated during progestin therapy and pregnancy. The pathologist must be provided with such information where present, so as to prevent false diagnoses that otherwise have been avoidable. Analyzing mast cell count in the tumor can be helpful for differentiating between a STUMP and an LMS. Mast cell counts are significantly lower in LMSs than in cellular and atypical LMs [214, 297]. The cut-off value is 16 mast cells per HPF [214], with a sensitivity of 100 % and a specificity of 96 % [214]. In uncertain cases, p16 expression should be taken into account – where p16 expression is diffuse, then a diagnosis of LMS should rather be opted for [18]. According to a different source, immunohistochemically determining p16, p53, and Ki67-indexes is not suitable for differentiating between LMSs and STUMPs. It should be borne in mind that p16-expression does not constitute an independent diagnostic criterion for LMSs. Histologically differentiating STUMPs from mitotically active LMs, from LMs with bizarre nuclei, as well as from cellular LMs can be challenging (Table 14.5). Differentiating the very rare epithelioid and myxoid STUMPs from the respective LM and LMS variants is particularly difficult. For more detail, reference should be had to the specialist literature [144].

Clinical Course, Prognostic Factors Relevant for Therapy

As a general rule, the different STUMP variants are all benign lesions. Recurrence and metastasis usually occur within the uterus, the pelvis, the abdominal cavity, the retroperitoneal region, the lung, the liver, in the bones, and the LNs. Distant metastases usually occur in the lungs [31, 108, 227]. There have also been accounts of metastasis in the deep soft tissue of the neck, the posterior mediastinum, and the paravertebral region [51, 245]. Interestingly, with a mean age of 34 years, women with recurring disease are roughly 10 years younger than women without recurrence [108, 119]. There are only few morphological criteria that serve to predict the risk of disease recurrence and the sites of recurrence and metastasis. There have been accounts of recurrences of atypical LMs with entirely absent MI or an MI < 2 M/10 HPF. From an immunohistochemical and molecular genetic perspective, diffuse immunoreactivity for p16 and/or p53 is regarded as a strong predictive factor for recurrence or metastasis in STUMPs [18, 50, 119, 121]. Even the presence of only minimal TCN is apparently associated with an elevated risk of disease recurrence [10], though it should be noted that, in these cases, the differences to LMSs are not stark or overly blatant. Estrogen and progesterone receptor expression are of no prognostic significance [31, 34].

According to different sources, the rate of recurrence in STUMPs is between 7.7 and 26.7 % [108, 121, 224, 270], and thus markedly lower than for LMSs. Another study comes to the conclusion that recurrences and metastases occur after a mean period of 46.9 Mo (15–108 Mo). Median OS in these cases was 63.9 Mo (40–108 Mo) [121]. Even after 20 years, the risk of recurrence cannot be entirely ruled out. The majority of disease-specific deaths occur 6–11 years after diagnosis [99]. Accordingly, the disease-specific 5, 10, and 15-year survival rates are 100, 88, and 81 %, respectively [99]. A considerable share of STUMPs also recurs and metastasizes as LMSs [10, 107, 108, 227, 258]. Of the 12 STUMPs in the DKSM material that developed metastases, 42 % did so as STUMP, while in the remaining 58 % disease metastasized as LMS [143]. Given the current data situation, the transformation of a STUMP into an LMS should be deemed a serious possibility, not least because STUMPs generally provide the necessary genetic and microbiological preconditions.

Recurrences and metastases only seem to occur following conservative "myoma therapies" and abdominal or endoscopic supracervical HE (Fig. 14.9) [3, 31, 258, 269]. It cannot be safely deduced from the merely occasional accounts of recurrences occurring following total HE that a morcellation was not performed in those cases [108, 181]. Performing morcellation on smooth muscle tumors has increasingly come to constitute a special risk factor, not least due to the danger of spreading cellular tumor material. There have been accounts of STUMP-recurrences occurring within only a few weeks [143]. The problems associated with morcellation are addressed in detail in the chapter on LMSs. In order to prevent morcellation being performed on the wrong object, when clinical and sonographic findings are suspicious, more intensive diagnostics should be conducted, in particular prior to organ-sparing surgery. Due to the numerous clinical and sonographic commonalities between STUMPs and LMSs, the diagnostics-flow chart (Fig. 14.22) presented in the chapter "risk and prevention of inadequate surgery" should be consulted as a decision-making aid.

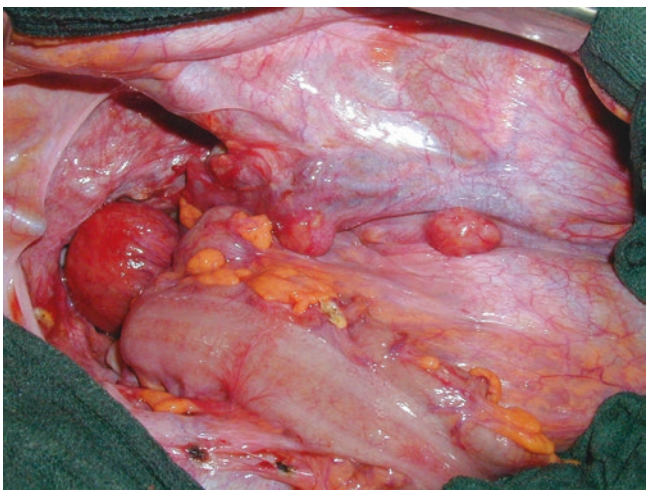

Fig. 14.9 Atypical smooth-muscle tumor (STUMP). Peritoneal metastases of an atypical smooth muscle tumor that was incidentally discovered post-operatively following endoscopic supracervical HE with morcellation, 22 months after primary surgery (With permission of Köhler et al. [144], Fig. 1.1–20a)

Overall, total HE without injuring the tumor is the best method for preventing recurrence. In 3 of 51 cases (34 HE, 17 myomectomies), subsequent HE resp. Myomectomy revealed two atypical LMs in the residual uterus and one atypical LM in the retroperitoneum. Interestingly, in the latter case, the recurrent tumor had been preceded by a total HE, probably in combination with laparoscopic morcellation [181]. It in fact currently remains difficult to assess whether performing laparoscopic myomectomy on STUMPs results in more intrauterine recurrent disease than in ordinary LMs [181]. The cumulative risk of intrauterine recurrence following laparoscopic myomectomy of ordinary LMs is at around 51 % [203]. This rate is possibly no lower than that for recurrence following myomectomies performed on STUMP patients. What is decisive, though, is that recurring tumors and metastases of STUMPs need to be assessed differently than LMs in terms of whether or not they are malignant, and that transformation into an LMS is a possibility that should be reckoned with.

Surgical Therapy and Problems

According to the current literature, total HE is the standard surgical procedure for STUMPs [181]. Surgery should be performed without injuring the tumor (morcellation, sharp clamping). There is no indication for a systematic and/or selective LNE. Recurrences are known to occur both in cases in which a BSO has been performed, as well as in such in which it has not [31]. One analysis found that having undergone BSO has no influence on the rate of disease recurrence [108]. Data pertaining to LMSs suggest that a BSO has no influence on the further course of disease [134]. A case has been reported in which a STUMP patient developed LMS metastases following a supracervical abdominal HE with BSO [258]. BSO can thus be indicated on the basis of the patient's wishes, her menopausal status, or other circumstances that give rise to an independent indication for such surgery. There is no indication for performing a BSO *ex post*.

Where a STUMP has been diagnosed, in exceptional cases – for instance where the patient has an urgent and pressing desire to have children [121] – conservative uterus-sparing surgery can be considered [181]. In doing so, the tumor must not be injured during resection, and the cut must be made outside the pseudocapsule in tissue that is definitely

disease-free. Since disease recurrences and metastases almost exclusively occur after conservative procedures, patients must be insistently informed of the increased risk of recurrence and the danger of a possible transformation into an LMS. It is strongly recommended that patients undergo a total HE once their desire to have children has been fulfilled, i.e. following pregnancy and childbirth [121].

Whether or not a subsequent HE should be recommended upon the incidental finding of an R0-enucleated STUMP can be decided based on the immune reaction to p16 and p53, as well as the presence of coagulative or questionable necroses. From a pathological-anatomical perspective, it is urgently advised to perform the HE in all cases in which there is no certainty of tumor benignity (f. ex. questionable necroses, size, atypia, the presence of any mitotic activity) [207]. Whether or not performing a gasless endoscopic myomectomy in STUMP patients, as is recommended by some authors [274], should indeed be regarded as innocuous in terms of recurrence risk, remains unproven and rather unlikely. R1/2 resections should be followed by a follow-up resection, or even better by HE.

Cases of very early post-surgery tumor dissemination following morcellation of a STUMP have been reported [210]. The recent literature [198, 210, 254] recommends a follow-up LSC within 3–6 months of performed myomectomy, morcellation/tumor injury, and unclear resection margins, unless a subsequent total HE is planned [210, 254]. Possible tumor deposits should be R0 resected in the course of these procedures. Total HE is indicated for cases in which patients have no desire to preserve fertility.

Due to the problems associated with determining and specifying the MI, as well as the possibility of overlooking a STUMP or (in the worst case) an LMS as a consequence thereof, conservative surgery should rather not be considered for lesions classified as myxoid or epithelioid LMs or STUMPs. For more detail, reference should be had to the specialist literature [144].

Clinical aftercare should be designed according to the symptoms shown and can be roughly adapted to aftercare for LMS patients. There are no indications for post-operative chemo, hormone, or radiation therapy. There are no known contraindications for hormone replacement therapy.

Low-Grade Endometrial Stromal Sarcomas (LG-ESS)

Epidemiology, Etiology, Pathogenesis, Staging

In Germany and Norway, LG-ESSs account for 26.9 resp. 20 % of all uterine sarcomas, excluding carcinosarcomas [2, 143]. Incidence of LG-ESSs in Southern and Northern Europe is at around 0.23 resp. 0.3 cases/100,000 women [155, 186]. According to various sources, the age of affected women ranges from 15 to 96 years. Median age is 42–52 years; 50 % to 88 % of LG-ESSs arise prior to menopause [20, 47, 299]. The age range in Germany is 18–80 years according to DKSM-data [143], median age is 46 years, and only 18 % of presenting women are postmenopausal.

LG-ESSs exhibit t(7;17) translocations and consecutive fusions of the JAZF1- and SUZ12- (previously: JJAZ1) genes as well as t(6;7) translocations (JAZF1/SUZ12-gene fusion), which are typical genetic abnormalities [206]. t(7;17)(p15;q21) translocation is an early genetic aberration in the development of LG-ESSs. Interestingly, this translocation can also be observed in LG-ESSs that exhibit a focal smooth-muscle differentiation, which allows the conclusion that such tumors originate from a pluripotential mesenchymal precursor cell (progenitor cell) [32, 206, 211]. Identical genetic aberrations are also found in so-called endometrial stromal nodules (ESN), which are regarded as a precursor of LG-ESSs [157].

ER, PR, and aromatase expression as well as association with pregnancy and endometriosis allow the assumption that estrogens are involved in the etiology, pathogenesis, and progression of LG-ESSs [236–241]. Previous or ongoing tamoxifen or toremifen therapy is regarded as another etiological factor [15, 111, 115].

Since 2009, FIGO-staging and UICC-TNM-classification for stromal sarcomas and LMSs have applied (Table 14.1) [83, 217, 264].

Macroscopic and Microscopic Findings

LG-ESSs predominantly have the appearance of an intramural nodulated tumor with strong similarities to an LM or the rare ESNs. LG-ESSs can expand into the cavum and protrude through the cervix when growth persists (Fig. 14.10a–c). They have a median size of 5.5 to 5–8 cm [94, 143]. Compared to LMs, LG-ESSs almost always have a softer consistency. Like with LMs, the cut surface may exhibit whorled structures, but is usually significantly smoother. Like ESNs, the opened tumor often has a yellowish to tan-yellow, sometimes light reddish appearance. On gross examination, intramural tumors can appear well circumscribed and can displace the surrounding myometrium and endometrium. Compressed tumor and surrounding tissue can form a kind of pseudocapsule (Fig. 14.11). Macroscopically visible finger-, worm- or tongue-like infiltrations, when present, are a typical gross characteristic.

Cystic structures, necroses, and focal hemorrhages are present to varying degrees (Fig. 14.13a). LG-ESSs can also exhibit a less common growth pattern in which diffuse myometrial infiltration forces the myometrium apart/separates it. In such cases, the wall of the uterus appears enlarged and

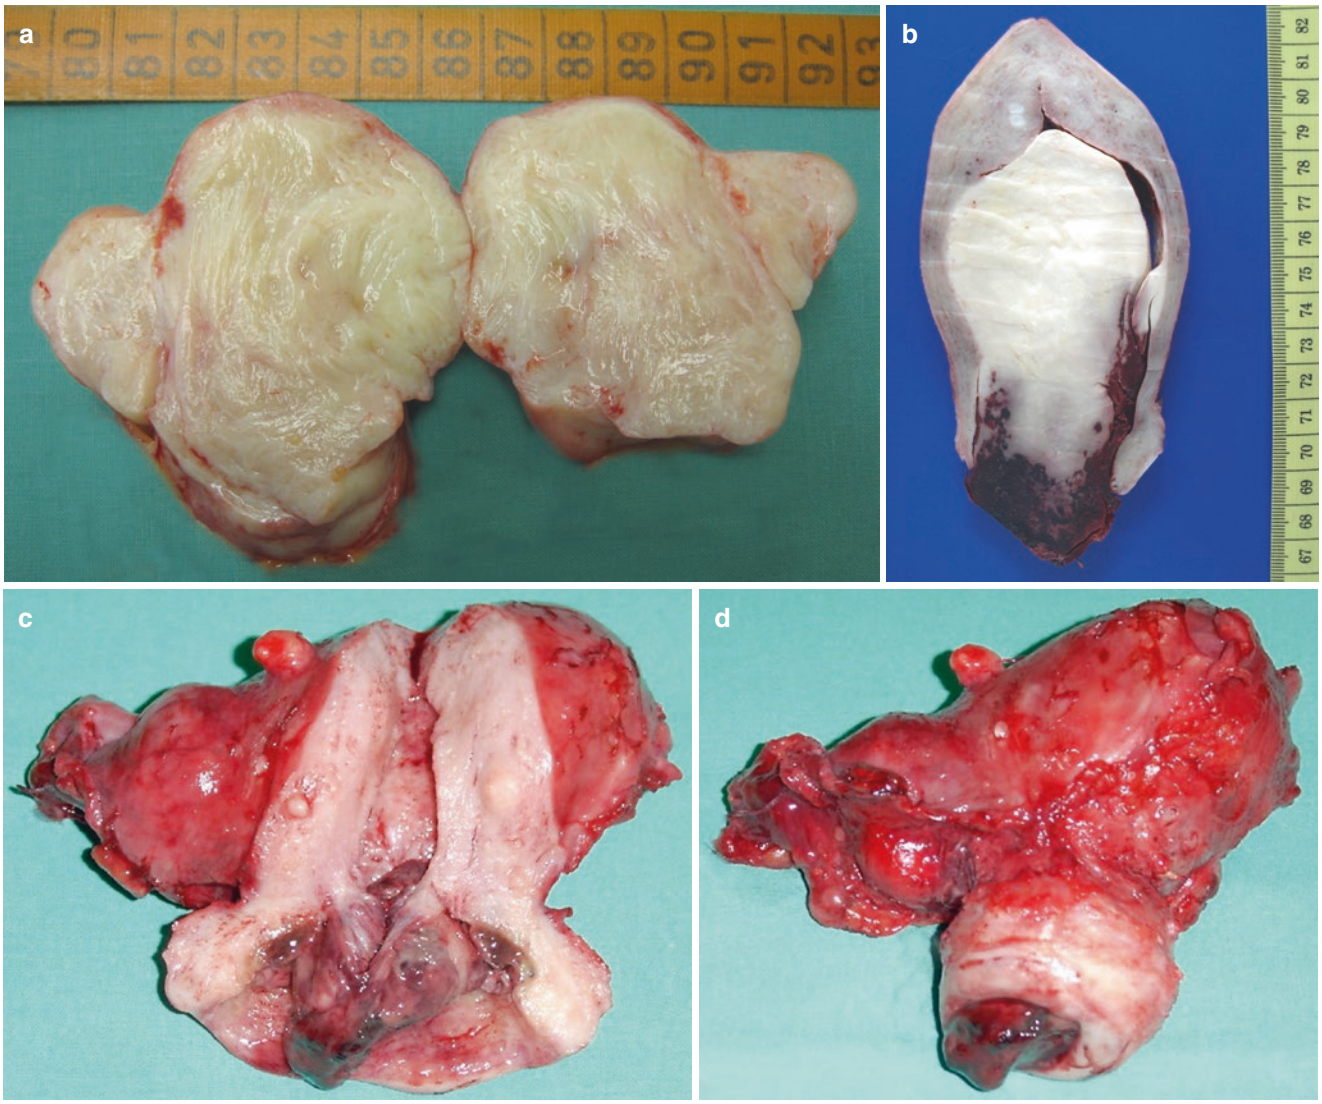

Fig. 14.10 Low-grade endometrial stromal sarcoma. (**a**) Knotty tumor that can barely be macroscopically discerned from an LM; (**b**) large smooth formalin-fixated LG-ESS that had filled out the entire cavum uteri; (**c**, **d**): pedunculated tumor macroscopically similar to an LM that is protruding from and through the cervix (With permission of Köhler et al. [147], Fig. 2.2–1a–d)

thickened, with a certain degree of nodulation. LG-ESSs occasionally also originate primarily in the cervix.

Overall, an LG-ESS consists of cells that are reminiscent of endometrial stroma in the proliferation phase. The cells cannot be morphologically discerned from ESNs. Microscopically, LG-ESSs are characterized by opulent small uniform cells with oval nuclei, small or absent nucleoli, scant cytoplasm, and poorly defined cytoplasm boundaries. Significant atypia are absent by definition [195]. Accordingly, the microscopic appearance is monotonous and bland. Necroses and hemorrhages also occur in LG-ESSs [286]. The MI does not correlate with diagnosis and prognosis, and is usually measured at around <5 M/10 HPF, but can also exceed 10 M/10 HPF. Atypical mitoses are rare, and true TCNs hardly ever occur. The vessels most closely resemble uniformly distributed endometrial spiral arteries. Lymphatic and blood vessel invasion are observed in 19.1–26.6 [20, 143] resp. 30.8 % of cases [143].

Fig. 14.11 Low-grade endometrial stromal sarcoma. Cut-open LG-ESS specimen with what appears to be a capsule – in the left of the image – that gradually diminishes (or fades) towards the cut base and crosses over into infiltration on the opposite side that is clearly visible on gross observation (With permission of Köhler et al. [147])

LG-ESSs typically have a strong expression of ER and PR (in 71–95 % of cases) [22, 54, 118, 237]. Missing ER and PR-expressions have been reported, albeit with ER being negative more frequently than PR [286, 299]. LG-ESSs can contain aromatases and can thus synthesize estrogens themselves [237]. CD10 expression is characteristical of LG-ESSs, though not specific to them.

Symptoms, Clinical Presentation, Diagnostics, Imaging, Differential Diagnosis

In about 70 % of cases, LG-ESS is an incidental finding during or after HE that is performed on the basis of an LM diagnosis [20, 143, 247, 299]. Forty-eight to seventy-two percent of all patients present with abnormal uterine bleeding in form of intermenstral bleeding and/or heavy und prolonged menstrual, or postmenopausal bleeding. Abnormal uterine bleeding, while it may be absent in some patients, thus constitutes the most common symptom [20, 143, 299]. Tumor growth causes diffuse enlargement of the uterus and is linked with lower abdominal pains in around 20 % of cases. Feelings of satiation and pressure are also occasionally reported [143, 299]. Palpation reveals a noticeably soft, fleshy consistency and/or a lumpy surface on the (usually enlarged) uterus or the palpated "LM". A soft consistency is generally to be taken as suggestive of a malignant or semi-malignant mesenchymal tumor. On average, LG-ESSs are said not to be larger than ordinary LMs [59]. Among the DKSM materials [143], and according to a further source, the median size of LG-ESSs is 5.5 resp. 5.8 cm [94, 143]. Data from a further study revealed a mean tumor size of 6.2 cm (0.3–18 cm), with 58.8 % being ≤5 cm [20]. Rapid growth of an "LM" or a rapidly growing uterus during pubescence is not a common clinical finding in women with LG-ESSs, and is observed in only 6.5 % of cases [20]. By contrast, 30 % of all ordinary LMs occurring during pubescence are rapidly growing tumors [64]. Compared to LMSs and UUSs, symptoms associated with rapid tumor growth, like lower abdominal pains and uresiesthesis, are rather less common in LG-ESS patients. Nonetheless, uterine growth or "myoma growth", especially when postmenopausal, is to be regarded as strongly suggestive of a malignant or semi-malignant mesenchymal uterine tumor.

It is essential that conventional clinico-gynecological examination be accompanied by sonographic examination. Abnormal and postmenopausal uterine bleeding most commonly suggest that the LG-ESS has developed into the cavum of the uterus. Hysteroscopy and fractional curettage are always indicated in such cases. The hysteroscopic appearance shall bear similarity either to a pedunculated LM or a polypoid tumor. Since LG-ESSs are frequently located intramurally, curettage will yield unsuspicious findings or a wrong diagnosis in 50–59 % of cases [23, 143, 269]. It is thus unavoidable that hysteroscopy and/or curettage result in misdiagnoses, a typical diagnostic pitfall.

Analogous to gross appearance, sonography, too, predominantly reveals LG-ESSs within the myometrium. Depending on the extent and depth of infiltration, the tumor margins appear either well-defined or poorly defined/irregular in sonography. According to the literature, solid lesions are generally homogeneously or heterogeneously hypoechoic or intermediately echoic [139, 165, 281]. Hypoechogenicity can correspond to that found in LMs and can apply to the entire tumor. There are also accounts of masses being isoechogenic to the myometrium [44]. Differentiation from an LM can be particularly difficult in such cases. A heterogeneous echogenicity, with anechoic regions and strongly hypoechogenic sections separated by washy or bizarre margins, is most commonly encountered, as is also confirmed by DKSM research [143]. LG-ESSs usually clearly displace the hyperechoic endometrium. Growth of the tumor into the cavum usually interrupts the endometrial layer [165]. It is often the case that anechoic clefts or small cysts are visible, either solitary or spread across the entire tumor, that in part correspond to dilated vessels [122], cystic areas, or necroses. The vessels usually have very small hyperechoic edges (Figs. 14.12a, and 14.13b). A diffuse heterogeneous echogenic thickening of the myometrium with partially nodular components is not an uncommon sonographic correlate for diffusely growing LG-ESSs [139, 242].

Between 68 % and 71 % of cases, sonography yields a diagnosis of LM [143, 265], with substantial consequences for surgery indication and surgical procedure (see also the section on risk and prevention of inadequate surgery). Only 18 % of findings are described as malignant tumors, and overall, 17.9 % are classified as suspicious tumors [143].

In Doppler sonography, LG-ESSs show a strong degree of irregularly and focally distributed vascularity in combination with a low RI of 0.21–0.42 and a PI of 0.2–0.49 [46, 49, 126, 139, 162, 242]. The RI cut-off value of 0.4, with a sensitivity of 90.9 % and a specificity of 99.8 %, is largely adequate for differentiating between benign and malignant lesions, or for classifying a tumor as highly suspicious. In Doppler sonography, visible cysts are surrounded by numerous vessels (Fig. 14.12b) [259]. These findings, however, are by no means unique or specific to LG-ESSs, and in fact also apply to other sarcomas. Nonetheless, they serve as a useful criterion for distinguishing malignant lesions from LMs [153]. It can occasionally so occur that color Doppler sonography provides a visual appearance typical of an LM. Should the suspicion of a malignant mesenchymal tumor prevail in light of the patient's medical history and the clinical findings, and should the patient desire organ-preserving/sparing surgery, then adherence to the diagnostic flowchart (Fig. 14.22) (sec-

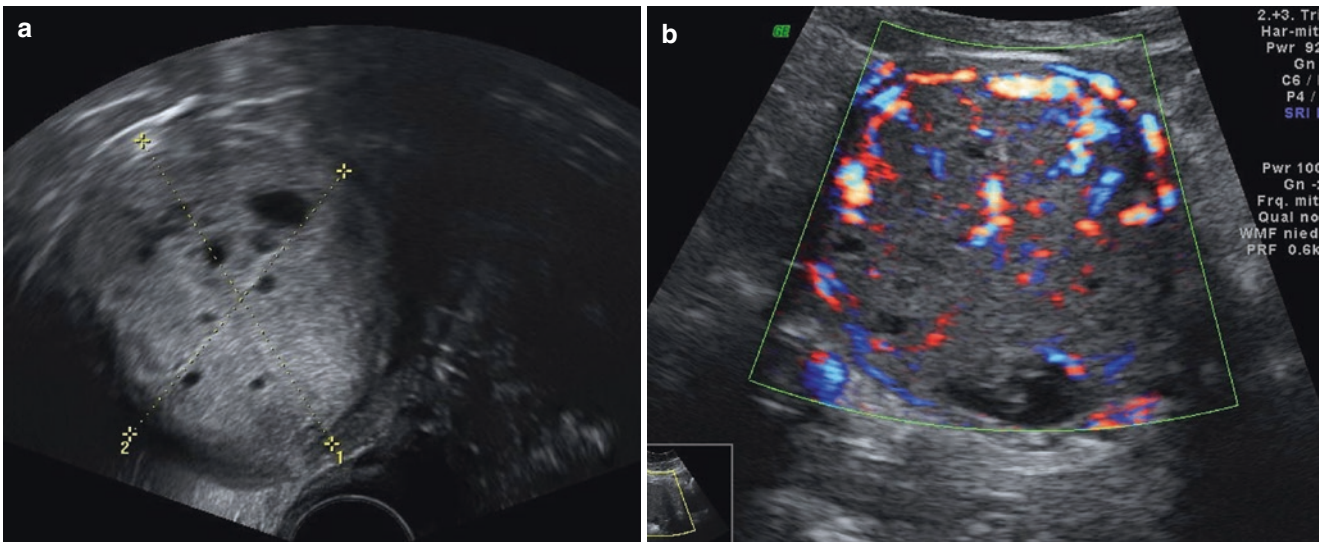

Fig. 14.12 Low-grade endometrial stromal sarcoma. (**a**) Gray scale sonography showing a tumor with heterogeneous echogenicity containing numerous anechoic spaces and gaps. The larger anechoic spaces most likely correspond to necroses with bizarre margins; (**b**) color Doppler sonography revealed that many of the anechoic gaps corresponded to vessels. The strong degree of irregular central vascularity is suggestive of a malignancy (With permission of Köhler et al. [147], Fig. 2.2–9c, d)

tion: risk and prevention of inadequate surgery) is strongly indicated.

Regarding CT, the same applies as previously described for LMSs.

In the majority of cases, MRT images show LG-ESSs as lesions within the myometrium (Fig. 14.13c, d). T1-weighted images typically show a predominantly heterogeneous SI that is hypo- to isointense (and occasionally hyperintense) compared to the myometrium. Signal-free regions are usually necroses or cystic areas that show no enhancement in T1 WC images, but strong hyperintense enhancement in T2 W images. In T1 and T2-weighted images, the tumor is delimited from the surrounding areas by a hypointense layer or rim that can be interrupted by tumor infiltrations. Enhancement in T1 WC-images is predominantly intense (occasionally mild) and heterogeneous (occasionally also homogeneous). Here, too, there is a recognizable band of enhancement that is weaker compared to the rest of the tumor and the myometrium, and that corresponds to the hypointense margin visualized in T1/2 W MRI images. T2-weighted images show a recognizably homogeneous or heterogeneous, sometimes intermediate SI that is higher than that of the myometrium and the skeletal muscles. Cystic structures that appear hypointense in T1 W imaging, but show no enhancement in T1 WC images, are strongly hyperintense in T2 W [88, 259]. In tumors with myometrial involvement, i. e. muscle infiltration/invasion, preserved bundles of muscle fibers are recognizable as bands of low signal intensity (hypointense) within the myometrium in T2-weighted images. This imaging feature is regarded as one of the most important criteria suggestive of an LG-ESS (Table 14.6) [138, 158, 242, 257, 259, 281].

The definitively benign ESN is the most important macroscopic and microscopic DD for LG-ESSs. ESNs and LG-ESSs have identical cytological pictures, so that they only really differ in that, in case of the former, there is no lymphovascular, vascular, or myometrial invasion [268]. Differentiating between ESNs and LG-ESSs on the basis of the tissue specimens gathered via curettage or morcellation without bordering neighboring tissue can thus be very difficult, or even impossible. The attending clinician must be aware of this problem and, where such cases arise, bear the real possibility of an LG-ESS in mind and inform the patient of that possibility and what it implies.

Since LG-ESSs bear great similarity to LMs, both clinically and macroscopically, and predominantly occur prior to menopause, successfully differentiating them from LMs is of particular importance. Accordingly, LG-ESSs are operated under the indication of an LM in 69–78 % of cases [20, 143, 216, 247, 299]. Thus, the majority of LG-ESSs are incidentally diagnosed as such either during or post-surgery. The risk of encountering an LMS or an LG-ESS during HE, regardless of the indication on the basis of which it is performed, is addressed in detail in the section on the risk and prevention of inadequate surgery.

Successfully histologically differentiating LG-ESSs from cellular LMs is by far the greatest differential diagnostic challenge, since both tumors express ER and PR as well as SMA and desmin (the latter albeit rarely among LG-ESSs). Measuring CD10 expression (which, unfortunately, is not seldom positive in LMs and LMSs), especially in combination with H-Caldesmon-expression, can be helpful in this regard [178, 306]. The attending clinician must be aware of the fact that successfully differentiating

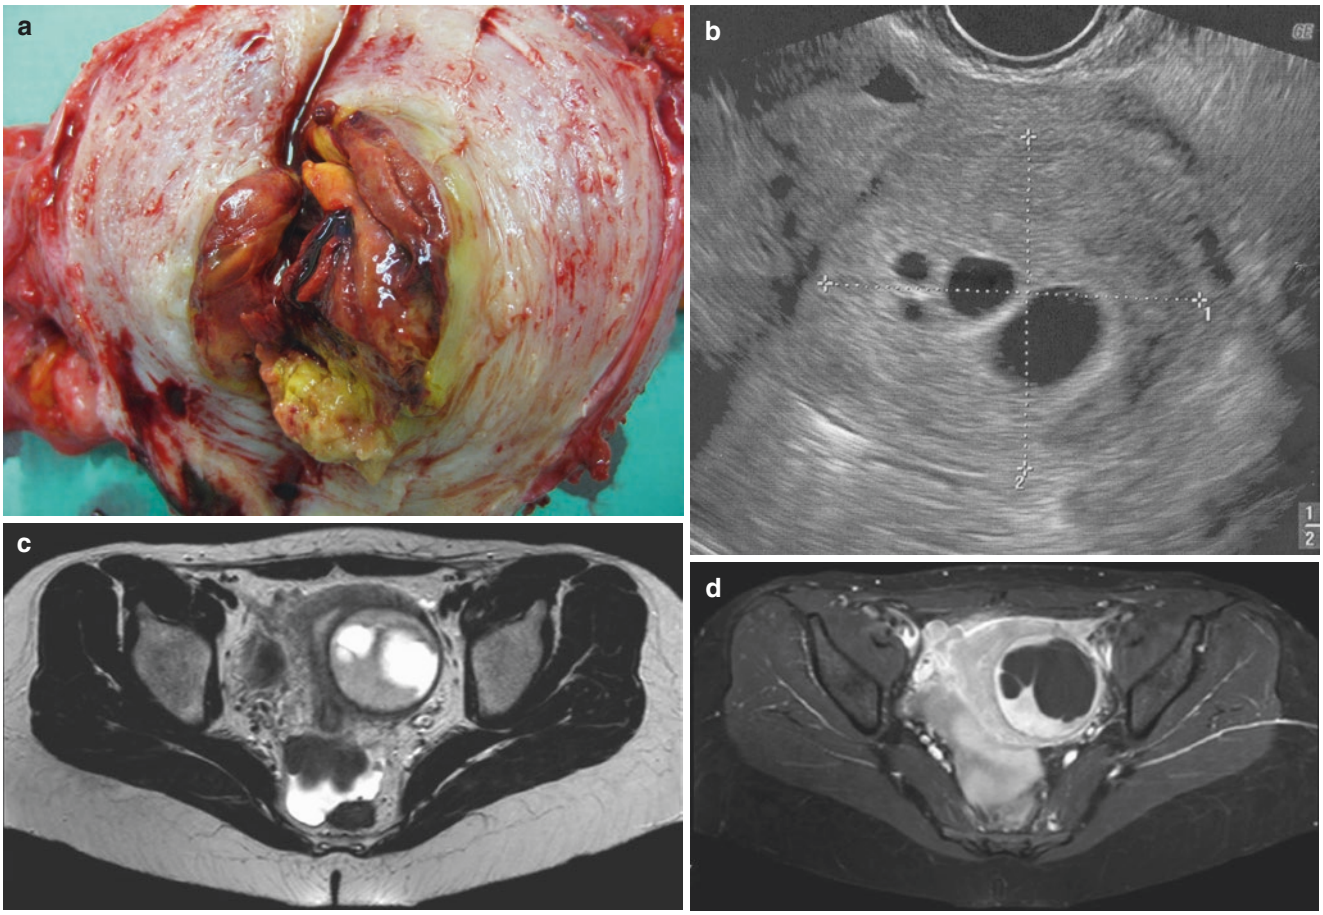

Fig. 14.13 Low-grade endometrial stromal sarcoma. (**a**) Intramurally located LG-ESS with predominantly necrotic (*yellow color*) and cystic components; (**b**) the necrotic and cystic regions of the same tumor showed as anechoic areas in abdominal sonography; (**c**) results from axial T2 W MRI correlated very well to the sonographic findings. The necroses showed typically high levels of signal intensity. The LG-ESS is intramurally located and has visibly displaced the endometrium and the cavum. The typical intratumoral hypointense bands are only barely discernible; (**d**) T1 W contrast-MRI with fat suppression confirmed the necroses as such – they showed no enhancement and showed up as signal free sections. The hypodense rim at the margins is recognizable in all of these images (With permission of Köhler et al. [147], Fig. 2.2–3a, 2.2–11a, c, e)

Table 14.6 Characteristics of low-grade endometrial stromal sarcomas in MRI

T1 W	Tumor with intermediate SI and low (necroses, cysts) SI, scattered areas with high SI (hemorrhages in particular), hypointense rim
T2 W	Predominantly intermediate to hyperintense SI with intratumoral hypointense bands, in part sections with very high SI (necroses, cysts), hypointense rim
T1 WC	intensive homogeneous enhancement, up to heterogeneous enhancement compared to the homogeneously enhancing myometrium
	Rim with weaker enhancement compared to tumor and myometrium
	hyperintense necroses and cysts show no enhancement in T2 W

From Köhler et al. [147]

LG-ESSs from cellular LMs on the basis of frozen section specimens without accompanying immunohistochemical testing can be difficult to impossible. Any diagnosis of a cellular LM that is based solely on photo-optical observation of the biopsy or curettage specimen, and without immunohistochemical testing, should be subjected to critical scrutiny.

Clinical Course and Prognostic Factors Relevant to Therapy

Stage of disease is also the most important prognostic factor for LG-ESSs [6, 94]. Prognosis for tumors >10 cm is apparently no worse than for such that are 5.1–10 cm in size [2, 94]. Prognosis worsens as age progresses [20, 47, 94, 256]

and is significantly less promising in postmenopausal than in premenopausal women. Drawing on numerous accounts, the median time to first recurrence is 36–130 Mo for Stage I, 3 years for Stage I/II and only 9 Mo for stages III/IV (FIGO pre 2009) [7, 48, 129, 140]. Nonetheless, the occurrence of late relapses after more than 10–30 years is distinctive. SEER-data (FIGO pre-2009), calculated for a sample of 356 cases, have revealed a 5-year OS of 96 % for stages I and II, 89 % for stages III and IV, and 92 % for stages I–IV [256]. Two larger retrospective studies measured a 10-year-OS of 87.1–95.8 % and a 10-year RFI of 49.6–52.1 % [20, 299]. LG-ESSs can thus be considered tumors with a relatively promising prognosis. Even relapsed LG-ESSs remain local for a long time and only develop distant metastases relatively late.

Positive pelvic and/or para-aortic LNs are found in 2.6–17 % of women with stage I-IV disease [143, 162, 299] and in 10 % [69] of cases in which the LG-ESS is confined to the uterus. According to SEER-data [256], LNs test positive in 7 % of cases (mean number of removed LNs: 12; 63 % of stage I/II tumors, acc. to FIGO pre-2009). It is thus apparent that positive LNs do not correlate to distant metastasis and disease recurrence in the context of LG-ESSs that are confined to the uterus, while, however, being linked to simultaneous extrauterine spread in the majority of cases [69]. Whether performing an LNE has any effect on prognosis remains unproven. A SEER-analysis compared 100 women who underwent an LNE with 283 patients who did not, and revealed no differences in terms of OS [256]. Benefits could not even be identified for cases in which LNs tested positive. Further SEER-analyses covering 310 and 1010 LG-ESSs, respectively, as well as a smaller and a larger retrospective study, all came to the unanimous conclusion that undergoing an LNE effects no change in OS [11, 20, 25, 94, 261, 299]. Recurrences occurred entirely locoregionally in 40–42 % of cases, albeit without any marked preference for the draining lymphovascular spaces or nodes [20, 143]. The remaining 60 % of cases were comprised of intraabdominal recurrences, distant metastases, or a combination of all forms of dissemination [140]. Distant metastasization occurs to the lungs in particular, though bone metastases have also been reported in isolated cases [20, 299].

Metastatic dissemination to the ovaries is known to occur – in the DKSM-materials, such spread, without involvement of other organs, occurs in 2.4 % of cases [143, 302]. Adnexal involvement has been observed in 9.5 % of cases, and almost uniformly goes hand in hand with further extrauterine dissemination [69]. Despite the fact that HRs usually test positive, the benefits of performing a BSO for both OS and disease-free survival are highly contested. Retrospective studies suggest that sparing the ovaries in premenopausal women increases the risk of recurrence without having any effect on OS [11, 20, 26, 29, 129, 174, 299]. One study determined a median RFI of 5 years for patients who did not undergo BSO, compared to 2 years when the ovaries were left *in situ* [73]. A more recent study concludes that ovarian preservation constitutes a "high-level risk factor" for recurrence [82]. What stands out in this study, besides the relatively small sample size (61 with vs. 7 without BSO), is the relatively low median age of women who did (35.4 years) or did not (43 years) undergo a BSO. Since the surgical methods applied are not described anywhere in the study, it is rather likely that organ-sparing surgical techniques were performed in these cases that in turn are associated with an increased risk of recurrence. In two further studies, leaving the ovaries *in situ* was associated with an increased rate of recurrence (87.5–95.5 resp. 27.4–59.6 %) and a shorter RFI however without being statistically significant [20, 299]. In one of these studies, however, almost without exception, the women on whom BSO was not performed underwent a myomectomy [20]. In practice, the ovaries remain *in situ* significantly more often when conservative surgery is performed [20, 143, 216]. The actual effects of a BSO on RFI thus remain unclear. However, in all analyses stated, myomectomy and sparing the ovaries, notwithstanding the shorter RFI had no influence on OS [20]. Other studies observed identical OS and RFI both with and without BSO being performed [140, 174, 218]. The relatively extensive SEER-data also suggest that leaving the ovaries *in situ* in premenopausal women has no negative effects on OS [122, 256]. Despite their inherent bias, all larger retrospective studies [140, 174, 256] allude that retaining the ovaries is relatively unobjectionable. However, the ovaries are still removed in 46.5–49.4 % of all cases [143, 299]. Overall, and in summary, to date, evidence has yet to be presented that leaving the ovaries *in situ* has a negative effect on patients' OS. However, a potentially elevated risk of recurrence cannot be ruled out entirely.

The surgical techniques applied have a crucial influence on prognosis. The fact that 69–78 % of LS-ESSs are operated under the primary diagnosis of an LM [20, 143, 216, 247, 299] subsequently results in a large number of inadequate surgical procedures being performed. At present, in Germany, 23 % of all women with an LG-ESS undergo tumor enucleation, and laparoscopic or abdominal supracervical HE is performed in 13.2 % of cases. 42 % of the different surgical procedures include morcellation [143]. Other sources report that myomectomies are performed in 12.4 % of cases, all of which are connected with foregoing a BSO [20]. In 0.28 % of cases in which morcellation was performed under the diagnosis of an LM, an LG-ESS was revealed as an incidental finding [71]. Since LG-ESSs, like LMSs, do not have a capsule or pseudocapsule, every enucleation poses a high risk of achieving only R1-resection margins (at the very least RX-resection margins). Accordingly, tumor extirpation bears a significantly higher

risk of recurrence (78.9 %) than total HE (25.4 %). Resection margins that are not definitely tumor free are equally associated with increased rates of recurrence. Not one patient remained relapse-free within the five years following tumor enucleation, however without differences in terms of OS [20]. There have been multiple accounts of (sometimes extensive) intraperitoneal deposits being observed within 1–3 Mo of endoscopic morcellation or tumor enucleation [65, 143, 221, 223]. A further study compared outcomes of LG-ESS patients who underwent morcellation during abdominal tumor enucleation, total abdominal HE, or a laparoscopy-assisted vaginal HE with outcomes of patients on whom total abdominal HE was performed without morcellation [216]. The results show that both 5-year PFS and abdominopelvic PFS were significantly poorer in the group of morcellation patients, of whom the majority had undergone endoscopic procedures. The problems pertaining to elevated risk of recurrence following morcellation are elaborated in greater detail in the chapter on LMSs.

Generally, laparoscopic or abdominal supracervical HE bears the danger of residual intravascular or myometrial infiltrations in the uterine stump. Moreover, in practice, supracervical laparoscopic HE is virtually always performed in connection with morcellation. Even if an R1-resection cannot be observed, from a clinical perspective, an RX-situation should be assumed. There have been accounts of early tumor deposits occurring within three months of such procedures being performed (Fig. 14.14a, b) [143]. Any form of supracervical HE should thus be classified as inadequate procedure until proven otherwise. An increased risk of tumor cell spillage should apparently also be assumed even if the uterus has only been damaged with a sharp instrument. Therefore, the uterus must not be subjected to any clawing with sharp instruments whenever an LG-ESS has been unambiguously identified as such or is even suspected. DKSM-data reveal a median time to first recurrence of 17 and 7 Mo following adequate and inadequate operations, respectively [143].

In summary, tumor enucleation and/or R1-resection are regarded as independent risk factors for locoregional and intraabdominal disease recurrence, but have no influence on OS. The fact that OS remains unaffected, in contrast to the encountered reduction in RFI, can evidently be accounted for by the good level of surgical tumor control achieved in 63.6 % of LG-ESS recurrences [20] and can help to explain the high response rates to HT that have been known to last for several years in some cases. To date, no cases have been reported in which LG-ESS patients with local recurrence have succumbed to their disease [20].

The negative prognostic impact of BSOs performed during adequate (!) surgical procedures, as is claimed by some authors (see above), remains highly questionable.

No valid, reliable RFI or OS-related data exist to date that militate against operating LG-ESSs endoscopically, so long as tumors and/or the uterus remain uninjured in the process.

Surgical Therapy and Problems

Total HE and BSO without causing injury to the tumor and/or the uterus is the generally accepted standard for patients with LG-ESSs. Opting for a primarily vaginal approach is

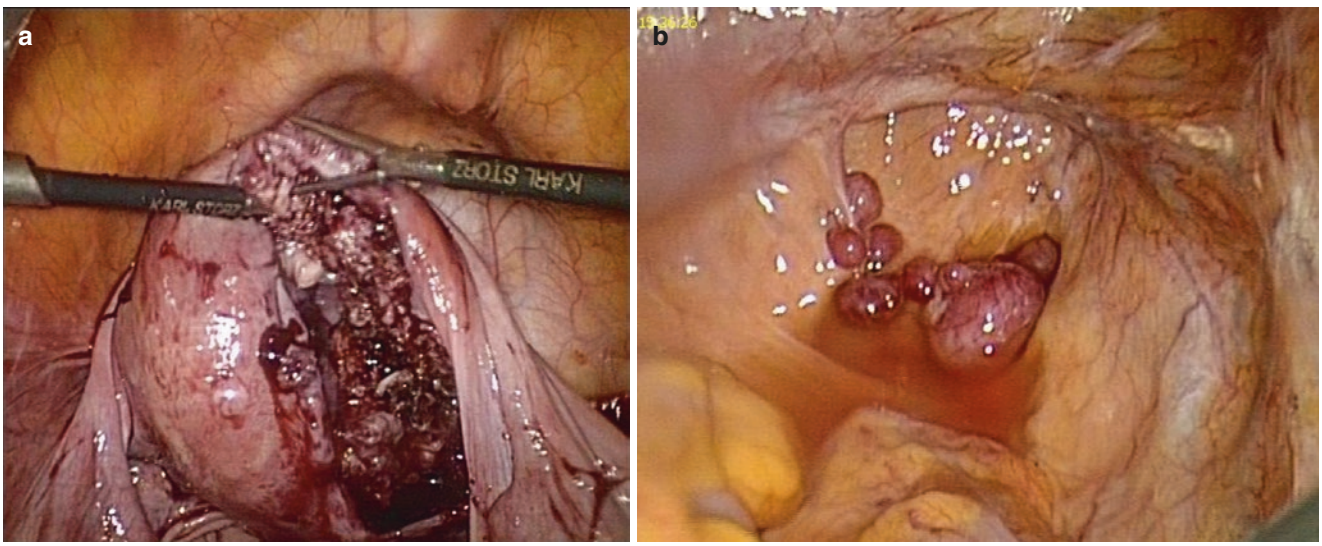

Fig. 14.14 Low-grade endometrial stromal sarcoma. Despite the presence of suspicious results from imaging diagnostics, the patient insisted on undergoing endoscopic myoma enucleation; (**a**) the shown tumor had no capsule, and cutting open the wall of the uterus caused it to immediately expand (or virtually "jump") out of its "bed"; (**b**) despite having undergone subsequent HE with BSO, within a short period of time the patient developed comprehensive local recurrence (With permission of Köhler et al. [147], Fig. 2.2–12a, d)

not indicated due to the risk of damaging the uterus and the lack of possibilities for abdominal exploration. Laparoscopy-assisted vaginal HE must be performed without injuring the tumor or the uterus. Subjecting an intact uterus retrieved via laparoscopy-assisted HE to vaginal morcellation inside a vaginally inserted protective pouch/endobag can be an acceptable solution for achieving this [79].

The benefits of a BSO are contested and have been described in great detail in the subchapter on prognosis. In light of the rarity of isolated ovarian metastases, a respective surgical procedure need not be necessarily justified when the ovaries are unsuspicious on gross examination. According to the current NCCN-recommendations and the GCIG-consensus, decisions for or against a BSO can be made on a case-specific basis dependent on the patient's reproductive age and/or desire to preserve fertility [12, 202]. The ESMO-guidelines – while not making a respective recommendation – merely draw attention to the fact that BSOs are performed in practice *per se* [74]. Taking all data pertaining to prognostic consequences together, preserving the ovaries cannot be deemed erroneous practice, and subsequent i.e. later extirpation can be foregone if the LG-ESS was subjected to adequate primary surgery. Patients should be informed of the potentially increased risk of recurrence, albeit without any consequences for OS, when deciding whether or not the ovaries should be preserved. The consensus [11, 29, 81, 82, 91, 174] that had existed previously, namely that a BSO is indicated for premenopausal women due to the high levels of HR-expression found in LG-ESSs, can no longer be sustained. A BSO is nonetheless performed in 71.2–78.4 % of cases [20, 94]. In Germany, the respective rate is 47 % [143].

There are recommendations for performing at least selective pelvic and para-aortic LNE in patients with enlarged LNs so long as such course of action can reasonably be expected of them [196]. Such a recommendation, however, cannot be made on the basis of the recurrence and metastasization patterns described in the subsection on prognosis above. The NCCN-guidelines no longer make any mention of performing LNE alongside total HE with or without BSO [202]. Likewise, the ESMO-guidelines and the GCIG-consensus do not recommend systematic LNE, as such course of action has yet to be proven to be beneficial [12, 74]. The aforementioned publications do, however, suggest that LNs that appear enlarged, either clinically or via imaging diagnostics, be subjected to cytoreductive resection (debulking). The NCCN-recommendation is somewhat confusing, since it assumes in its commentary that surgical staging be performed in accordance with staging for endometrial carcinoma. A holistic observation of all the available data reveals that, currently, the scientific basis is insufficient to support an indication for conducting systematic LNE. Accordingly, systematic LNE cannot be defined as standard practice. Moreover, the findings currently have no ramifications for the further course of therapy, even when the LNs are positive. This does not mandatorily preclude that clinically suspicious LNs can be resected in the absence of evidence that doing so bears any benefits. However, an LNE is nonetheless performed in 26.4–39.5 % of cases [20, 94, 143, 299].

There is no indication for an omentectomy if the omentum appears tumor-free, i.e. there is no omental involvement, on gross examination.

Taking all available data into account, there is no indication that patients with LG-ESSs should undergo an organ-preserving extirpation. One exception could be cases in which young women, upon extensive elucidation, wish to preserve fertility and their physical ability to have children [67, 267]. In such cases, the tumor must be R0-resected. As the pseudo-capsule usually consists of compressed tumor material (Fig. 14.14a), it not seldom occurs that the tumor is damaged or injured during surgery.

A subsequent pregnancy will obviously have a negative impact on prognosis and further exacerbate the risk of recurrence that is already elevated due to having undergone inadequate primary surgery. Patients must be unequivocally informed of these circumstances. Reference should be had to the respective specialist literature [309] for more detailed information.

The problem of inadequate surgery and means of preventing it, which apply in equal measure to both LG-ESSs and LMSs, are discussed at length in the chapter "risk and prevention of inadequate surgery", together with the diagnostic flow-chart (Fig. 14.22).

As is also the case for LMSs, surgical procedures that preserve or spare organs either wholly or partially should be followed up by total HE or a resection of the residual uterus. Additional BSO is recommended in these cases. Such course of action also corresponds to current recommendations of the AAGL, the DGGG and the NCCN [1, 27, 72, 202, 254]. Should the patient decline such course of action, then at the very least an endoscopic follow-up examination/countercheck should be sought within 3–6 months [198] (see also section on LMS), and postoperative hormone therapy should be given serious consideration [1, 254].

Taking the patient's general state of health and overall condition into account, maximal debulking should be performed in cases of LG-ESSs that have spread in the pelvis and abdominal cavity. Systematic LNE is not indicated and thus not deemed sensible [91, 202]. No data are available to underline that performing a selective LNE on enlarged LNs when an intraabdominal R0-resection has been achieved is in fact beneficial. Overall, as is also the case for soft tissue sarcomas, having 'no macroscopic tumor-burden' and 'clear resection margins' are regarded as the most important prognostic factors [13, 114, 205]. Even for LG-ESS patients who have undergone surgery on metastases and/or

disease recurrences with or without gross residual tumor burden, the 5-year PFS rates were 65 % and 100 %, respectively [20]. The available data, therefore, suggest that maximal debulking is the gold standard to be aspired to in cases of advanced disease. The same results might also be achieved with HT. Since recurrences remain in the abdomen for a long time and remissions are known to occur years later, even after an R1-resection with subsequent HT [20, 143], surgical intervention should always be prioritized.

Aftercare corresponds to what has been described for LMSs. Regarding indications for a thorax CT in the context of LG-ESS, both the implications of radiation exposure and the relative rarity of lung metastases need to be taken into consideration. There are no indications for adjuvant or postoperative chemo- and/or radiation therapy. Particularities in this regard, as well as more details pertaining to the necessity for postoperative hormone therapy following inadequate operations, can be found in the specialist literature [147].

High-Grade Endometrial Stromal Sarcoma and Undifferentiated Uterine Sarcoma

Epidemiology, Etiology, Pathogenesis, Staging

HG-ESSs and UUSs need to be clearly pathogenetically, morphologically, clinically, and prognostically distinguished from LG-ESSs. The data situation pertaining to HG-ESSs and UUSs is extremely poor, particularly in terms of the therapeutic approach to be followed. Recommendations are mainly based on individual case reports and retrospective studies with relatively small sample sizes and often include all stages of disease. HG-ESSs and UUSs account for 10.1 % and 3.7 %, respectively, of all uterine sarcomas [143]. Women with HG-ESSs and UUSs have a median age of 58 and 63 years, respectively, and are thus noticeably older than LG-ESS patients [143]. These tumors thus occur in postmenopausal women in the majority of cases.

HG-ESSs and LG-ESSs both derive from the endometrial stroma [57, 163, 212]. This commonality notwithstanding, they are nonetheless pathogenetically independent of one another. A fusion of the YWHAE and NUTM2 genes (YWHAE-FAM22), a result of chromosomal translocation of t(10;17) (q22;p13), can be found in HG-ESSs. In LG-ESSs, by contrast, JAZF1-SUZ12 is the most characteristic gene fusion (see the section on LG-ESS) [105, 166, 167]. The fact that HG-ESSs and LG-ESSs exhibit differing fusion genes suggests that an HG-ESS does not usually develop from an LG-ESS [252]. The principal difference between HG-ESSs and UUSs lies in the fact that the cytological criteria of the former resemble endometrial stroma *to any degree* [252]. These cytological criteria as well as the fusion genes found in LG-ESSs and HG-ESSs are absent in UUSs [105, 160, 163, 166]. In contrast, UUSs exhibit complex chromosomal aberrations, with gains on 2q, 4q, 6q, 7p, 9q, and 20q, and losses/deletions on 3q, 10p, 14q [109]. UUSs generally exhibit no specific type of differentiation, and their histogenesis remains unclear [212]. UUSs thus constitute an independent type of neoplasm. There have been accounts of cases in which HG-ESSs and UUSs have developed from or alongside an LG-ESS [90, 133, 160, 212]. Significant associations between HG-ESSs/UUSs and tamoxifen therapy are considerably rarer than is the case for LG-ESSs and LMSs [111, 255].

FIGO-staging and UICC-TNM-classification correspond to those provided for LMSs (Table 14.1).

Macroscopic and Microscopic Appearance

Gross examination of HG-ESSs/UUSs often reveals polypous fleshy masses in the cavity of the uterus that are yellowish, yellowish-gray, or grayish-white in color, and which are characterized by hemorrhages and necroses as well as extensive myometrial invasion in some cases. Decomposed necrotic masses can make up up to 90 % of the tumor. HG-ESSs/UUSs generally exhibit rapid growth, quickly fill the entire uterine cavity, and are associated with a rapid increase in the size of the uterus. The borders of the uterus are often exceeded within a very short period of time (Figs. 14.15a–c, 14.16a, and 14.17a). Due to their rapid growth rate, HG-ESSs already have mean and median diameters of 8.0 cm and 7.5 cm, respectively, at the time of initial diagnosis (min.: 1.7 cm; max.: 15 cm) [143]. UUSs have mean and median sizes of 12.2 cm and 11 cm (min.: 2.6 cm; max.: 24 cm), respectively [143]. The fact that UUSs are generally larger at the time of initial diagnosis strongly underlines their higher degree of malignancy compared to HG-ESSs. The low-grade component of HG-ESSs can sometimes be easy to discern on gross observation, and bears resemblance to the low-grade component found in LG-ESS [252].

HG-ESSs and UUSs are highly pleomorphic and thus can already be clearly discerned from the more knotty, nodal, and uniform LG-ESSs on the basis of gross macroscopic appearance.

Within HG-ESSs, there is a coexistence of areas of low-grade structures with a close resemblance to LG-ESS on the one hand, and (usually predominating) high-grade areas on the other. The low-grade component is characterized by uniform low-grade spindle cells with visible cytological connections to the endometrial stroma, and finger or worm-like (permeative) myometrial infiltrations. The high-grade areas, in contrast, exhibit higher degrees of nuclear atypia, ample TCNs, a usually clearly elevated MI (>10 M/10 HPF), lymphovascular invasions, and destruc-

Fig. 14.15 Undifferentiated uterine sarcoma. (**a**) Necrotic tissue accounts for almost 90 % of the depicted UUS. The immense pressure generated by strong tumor growth has distended the cervix; (**b**) in this case, the uterine cavity is completely filled by a predominantly necrotic UUS that has prolapsed through the cervix. Moreover, metastases were found on the peritoneum of the bladder and in the left adnex; (**c**) due to their extremely rapid rate of growth, UUSs are often found to have perforated the wall of the uterus (With permission of Köhler et al. [148], Fig. 2.3–1a–c)

tive myometrial invasions. This coexistence of differing cytological criteria is also associated with variations in CD10-, ER-, and PR-expressions within the tumor [160, 207, 212, 252]. Diffuse and strong CD10-, ER-, and PR-expression can be found in the low-grade component in particular. It is thus by all means appropriate to conduct HR testing at least in HG-ESSs with a view to potential HT. By contrast, the high-grade component is characterized by ER-, PR-, and CD10-negativity [252]. These findings correlate with diffuse and strong cyclin D1-positivity. Cyclin D1 is regarded as a marker for the fusion gene YWHAE-FAM22 [163, 166] that is only found in the high-grade component of HG-ESSs. While this fusion gene may not be traceable in some cases, it nonetheless remains an important characteristic of HG-ESSs that does not or only in a few exceptions occur in LG-ESSs or UUSs. Overall, the simultaneous presence of positive, negative or heterogeneous ER-, PR-, CD10-, and cyclin D1-expression, and of the YWHAE-FAM22 and JAZF1 and JJAZ1 fusion genes shows that both HG-ESSs and LG-ESSs derive from

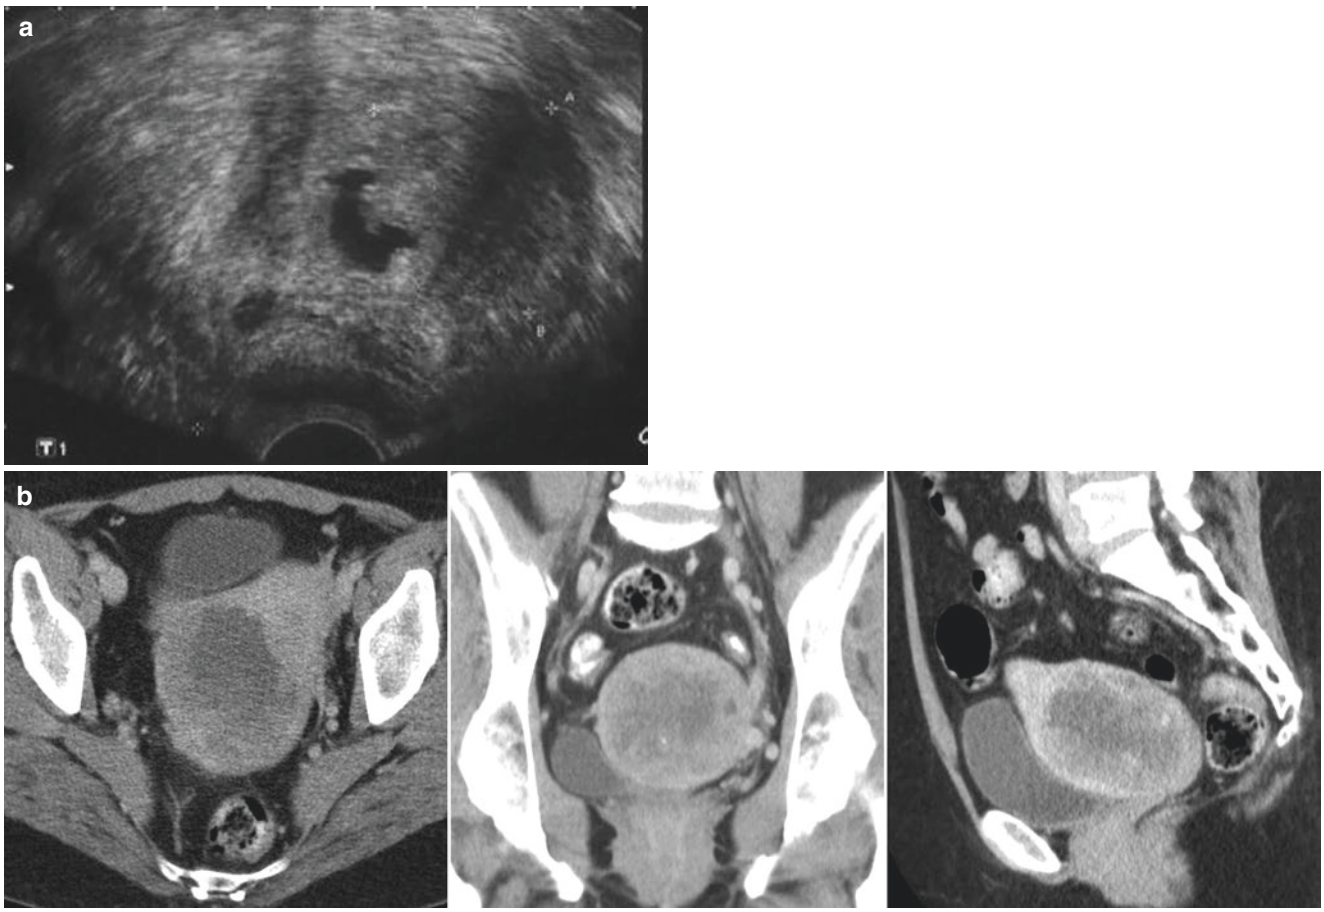

Fig. 14.16 Undifferentiated uterine sarcoma. (**a**) This UUS shows heterogeneous echogenicity in axial sonography, with the exception of some signal voids that correspond to necroses. The tumor fills out the entire cavum. The narrow hyerechoic endometrial rim that is primarily indicated in the right half of the image serves to visibly delimit the UUS from its surroundings there. Said demarcation decreases and is gradually lost as we move to the opposite side of the image; (**b**) the tumor enhances homogeneously in the axial CECT image (*left*) which, analogous to the sonographic findings, recognizably shows that the tumor margins are not clear and sharp throughout. The extent to which the notably enlarged uterus has been infiltrated becomes clear in the coronal (*center*) and sagittal (*right*) planes. Enhancement was heterogeneous in these images. The remainder of the myometrium has been compressed and reduced to a narrow seam (With permission of Köhler et al. [148], Fig. 2.3–6a, b)

the endometrial stroma. The observation that an HG-ESS is reminiscent of or bears resemblance to the endometrial stroma in any way is a decisive diagnostic factor that clearly delineates such neoplasms from UUSs [252].

UUSs exhibit such extensive dedifferentiation that it can often no longer be discerned that (or whether) they originated from the endometrial stroma or the myometrium. The cells are characterized by clear aneuploidy, marked cellular and nuclear pleomorphism including prominent nucleoli and bizarre polynuclear giant cells, and no specific type of differentiation. Expansive foci of coagulative necrosis and high rates of often atypical mitoses are typical characteristics of UUSs [160, 212, 304]. The MI usually clearly exceeds 10 M/10 HPF. Destructive myometrial invasion is already visible on gross observation. Furthermore, early and extensive lymphovascular and blood vessel invasion is observed in 47 % and 48 % of cases, respectively [143]. UUSs exhibit no (or occasionally weak) HR- and CD10-expression [61, 125, 160, 212]. Desmin, SMA, or cytokeratins have also been traced in UUSs in some cases [160, 278]. P53-positivity is detected in 57 % of UUSs [125]. Ultimately, immunohistochemical analyses of UUSs are very unreliable, as these dedifferentiated tumors have already lost their reactivity to numerous antigens [295]. Taken together, the evidence underlines that, unlike LG-ESSs and HG-ESSs, and bar a few exceptional cases, UUSs do not derive from the endometrial stroma.

The most evident commonality between UUSs and HG-ESSs is the fact that both are highly aggressive neoplasms.

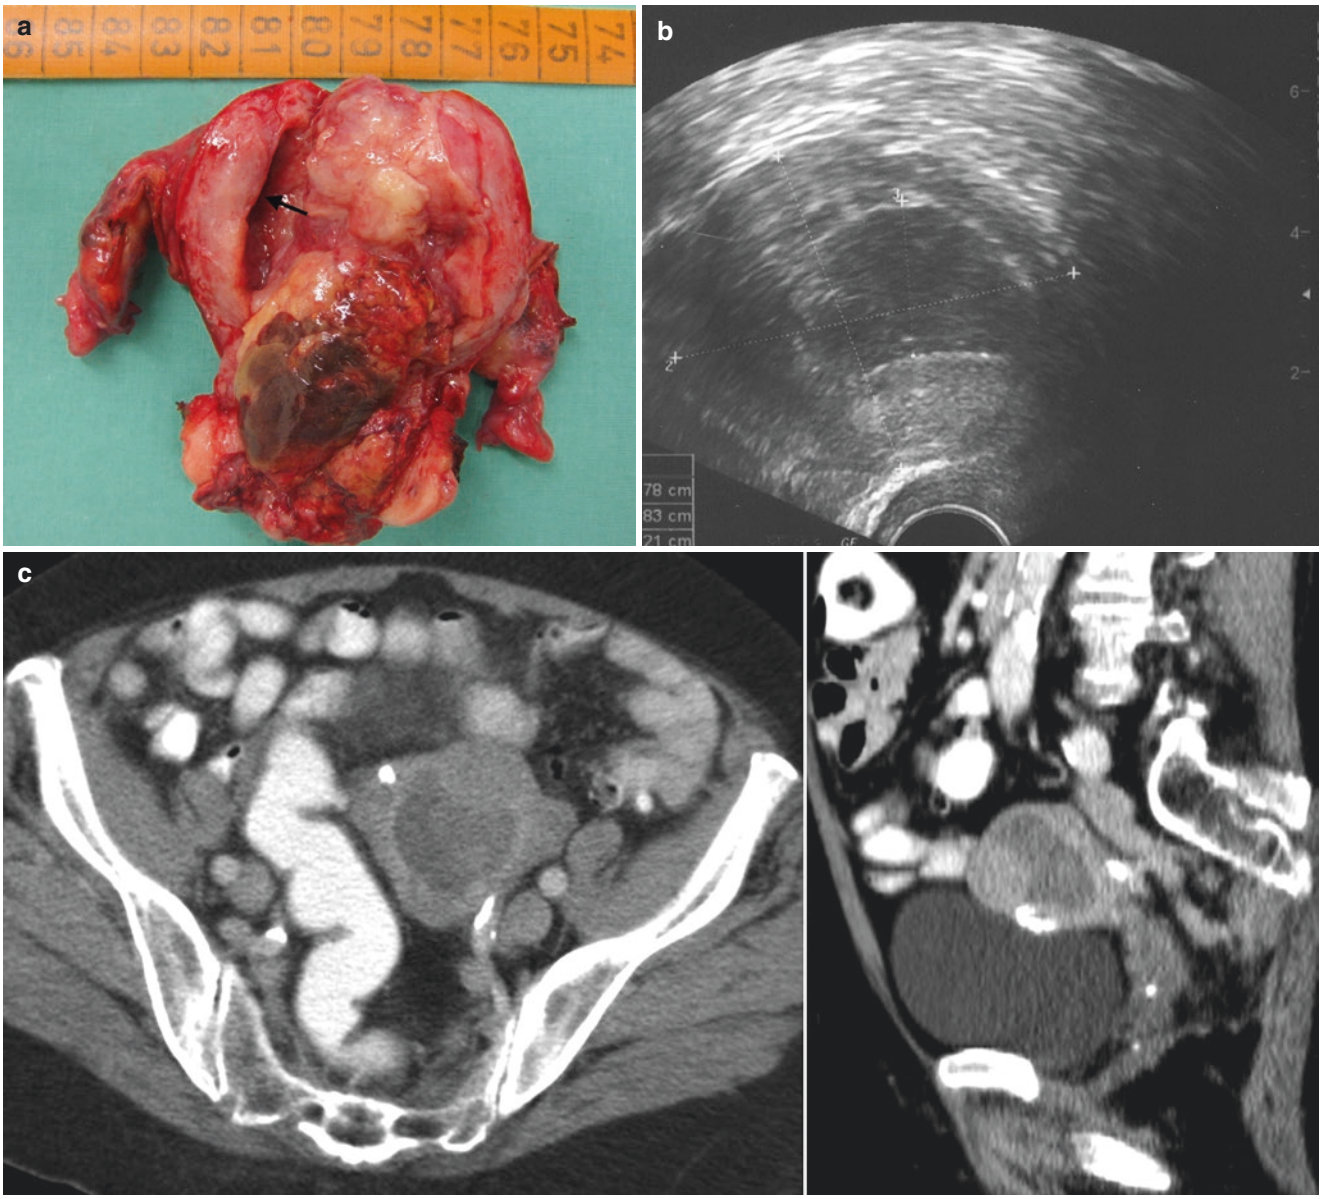

Fig. 14.17 High-grade endometrial stromal sarcoma. (**a**) Macroscopic appearance of an HG-ESS that originated in the anterior wall of the fundus and subsequently filled out the entire cavum. The endometrium is still visibly intact (*arrow*); (**b**) in sonography, the heterogeneous, predominantly hypoechoic HG-ESS is recognizably located within the endometrial hyperechoic band. The image also shows that the tumor interupts the endometrial band towards the fundus (*left side* of the image). The visible round finding with an echogenicity even lower than that of the surrounding tumor tissue, with dull interior echoes, most likely corresponds to a pathological-anatomically verified necrosis; (**c**) axial and sagittal CECT images show that the HG-ESS – with an enhancement weaker than that of the endometrium and the myometrium – is mostly located in the distended cavum of the uterus. As a secondary finding, an LM can be seen in the anterior wall of the uterus. This LM is also clearly visible when observing the macroscopic specimen (With permission of Köhler et al. [148], Fig. 2.3–17a, b, d)

Symptoms, Clinical Presentation, Clinical Diagnostics, Imaging, Differential Diagnosis

Postmenopausal bleeding is the pivotal symptom of HG-ESSs/USSs. Premenopausal women usually present with abnormal uterine or irregular menstrual bleeding. Rapid tumor growth results in marked, usually irregular enlargement of the uterus, and is usually associated with lower abdominal pains and uresiesthesis. Postmenopausal growth of the uterus is generally an observation that serves to arouse suspicion of sarcoma. HG-ESSs/USSs have a predominantly soft consistency. The rapid growth of the tumor can cause tumor masses to protrude from the cervix at a very early stage (Fig. 14.15a, b). Distant metastatic disease occurs very early. It is thus not seldom the case that HG-ESSs/UUSs are primarily discovered upon detection of their metastases.

Diagnostics largely correspond to the procedure followed for LMSs. Since up to 90 % of the tumor can consist of necrotic tissue, it can so occur that performing multiple curettages still fails to yield any actual tumor tissue. HG-ESSs/UUSs or malignant neoplasms are correctly diagnosed as such on the basis of curettage specimen analysis in only 35–65 % of cases [143, 278]. As metastatic spread to the abdominal cavity and the lungs is already present in up to 52 % of cases at the time of primary diagnosis [278], the pelvis, the abdomen, and the thorax should be subjected to imaging-based staging using CT or MRI after receipt of the histological diagnosis.

The sonographic picture correlates with the tumor's polymorphous gross appearance, characterized by decomposing tumor tissue, necroses, cysts, and dilated vessels alongside solid areas with high cell counts. Sonography, too, shows that the tumor usually fills the entire cavity of the uterus with clearly discernible myometrial invasion. As long as the tumor is predominantly located in the cavum, the endometrium is usually recognizable as a thin hyperechoic layer or band. It can be punctured or interrupted by the tumor in one or numerous locations, and is known to have been entirely consumed in some cases. Both HG-ESSs and UUSs are almost exclusively heterogeneously echogenic and are predominated by areas of hypoechoicity in the majority of cases. Tumors can also be predominantly hyperechoic in some cases. Anechoic areas, resembling larger cysts or wide seams/clefts, can be found in both the hypoechoic and the hyperechoic areas of virtually all such tumors. Narrow seams or signal voids often resemble vessels, while large hypoechoic areas resemble necroses or cystic structures. The borders between the hyperechoic and hypoechoic areas are virtually always derounded, with, in part, bizarrely frayed, ragged margins (Figs. 14.16a and 14.17b).

As is also the case for the other types of uterine sarcoma, Doppler sonography shows a highly hypervascular tumor, with an RI of 0.27 [208]. Despite noticeable conspicuous features, 56 % of HG-ESSs are assessed in sonography as being LMs, and 34.6 % are also subjected to surgery under that indication [143]. While 26.1 % of UUSs are operated on under the indication of an LM, to date, no UUSs are reported to have been sonographically classified as an LM [143].

CT is not suitable for precisely diagnosing or classifying HG-ESSs/UUSs, but is a useful method for staging diagnostics (Figs. 14.16b and 14.17c). Only very few data are available pertaining to the MRI-characteristics of these tumors. The absence of low SI in T2-weighted images (100 %), an inhomogeneous SI in T1-weighted images (88 %), and the presence of necroses (69 %) have the highest sensitivities in this regard, with respective specificities of 26, 42, and 98 %. There have been accounts in which adjacent regions of both high and low SI within the same tumor have been described [259]. Necroses and hemorrhagic areas are more common than in LG-ESSs, and the hypointense bands with low SI, that are typical of LG-ESSs, are absent in T2-weighted images [111, 158, 234]. Numerous signal voids can be observed within the areas of myometrial involvement that reflect the hypervascular nature of the tumors [158, 259]. There are accounts of normal myometrium having a clearly stronger enhancement than tumor tissue in T1C-weighted images [272]. There are also reports of iso- or hyperintense contrast enhancement compared with normal myometrium that can help in differentiating from endometrial carcinomas [249].

While both LG-ESSs and LMSs are primarily intramurally localised, clinical and imaging diagnostics usually reveal that HG-ESSs/UUSs are predominantly located within the cavity. In contrast to LG-ESSs, HG-ESSs/UUSs have a noticeably pleomorphic macroscopic appearance, with numerous necroses and hemorrhages that are not seldom accompanied by a pyometra.

HG-ESSs and UUSs do differ in terms of their microscopic appearance. In contrast to HG-ESSs, most UUSs exhibit no specific type of differentiation, both cytologically and immunohistochemically. HG-ESSs can be differentiated from UUSs by measuring cyclin-D1, CD10, and possibly ER- and PR-expression, all of which are negative in UUSs. Histologically discerning HG-ESSs/UUSs from LG-ESSs is usually unproblematic. Complications can arise when doing so solely on the basis of tissue specimens gathered via curettage or biopsy, since HG-ESSs can contain focal areas consisting of LG-ESS. Special attention needs to be devoted to identifying possible epithelial structures during microscopic examination so as not to overlook an AS or a carcinosarcoma.

Clinical Course, Prognostic Factors Relevant for Therapy

Both HG-ESSs and UUSs have a substantially poorer prognosis than LG-ESSs [163, 166]. Prognosis for HG-ESS/UUS worsens as patient age increases, and is especially unfavorable for women of particularly advanced aged [6, 47, 94]. Stage of disease is the most important prognostic factor [6]. Fifty-two to seventy-two percent of cases already exhibit primary involvement of the abdominal cavity [183, 278]. Overall, UUSs have an even worse prognosis than HG-ESSs [105, 160, 228]. Twenty percent of HG-ESS patients present with stage IA disease at the time of initial diagnosis, compared to only 12 % of UUS patients [143]. Moreover, among UUS patients, 32 resp. 28 % presented with FIGO-stage IVa resp. IVb disease at the time of initial diagnosis. For HG-ESS patients, the rate was 10 % both for stage IVa and stage IVb.

Metastases predominantly occur in the lung, the abdomen, the liver, and sometimes in the bones [183, 278]. There

is significant variation in the data pertaining to regional LN involvement. An analysis of stage I-IV primary HG-ESSs and UUSs revealed positive pelvic and para-aortic LNs in 18 % resp. 15 % of cases [163]. A further study revealed an incidence of pelvic and/or para-aortic LN involvement of 44.4 % [183]. SEER-data [47], covering 143 patients with stage I-IV disease, revealed positive LNs in 18 % of cases, with a mean number of 12 removed LNs. Within the DKSM sample, positive LNs were found in 25 % of UUSs and only 7.7 % of HG-ESSs [143]. Positive LNs are a clear sign of a particularly poor prognosis. This evidently has to do with the fact that positive LNs are virtually always found in patients in whom disease has also spread to other extrauterine sites [183]. In light of research findings, according to which extrapelvic metastases with simultaneous pelvic disease recurrence are found in 75 % of cases [91], and isolated distant metastases occur in 67 % of cases [143], survival appears to be mainly determined by extrapelvic sites of recurrence or metastasization [183]. The ineffectiveness of LNE is thus primarily footed in the fact that disease is frequently already so extensive at the time of primary diagnosis. Accordingly, despite their intrinsic bias, the few available retrospective studies, including the SEER-data, have been unable to verify that performing an LNE on HG-ESS/UUS patients has any beneficial effects on survival [94, 154, 185, 256].

Removing or preserving the ovaries has no influence on survival, neither for HG-ESSs nor for UUSs [94, 257].

Median RFI and OS for all cases is 5–11 resp. 11.8 Mo [129, 143, 163]. Among other factors, the median RFI is strongly dependent on the type of surgery performed – 8 Mo for cases of adequate surgery, and 3 Mo for inadequate operations [143]. In contrast to LG-ESS, R2-resection margins, in particular, are associated with an extremely negative prognosis [163, 183]. It more than seldom occurs that recurrences become clinically evident within only a few weeks of primary diagnosis [278].

Surgical Therapy and Problems

Total abdominal HE with BSO is regarded as the generally accepted surgical standard for HG-ESSs/UUSs. Since steroid receptor expression is nearly always negative in UUSs, resection of the adnexa is not absolutely necessary in premenopausal women. Given that HG-ESSs and UUSs are said to metastasize to the ovaries rather frequently [302], performing a BSO by all means seems to be appropriate. However, it remains scientifically unproven that performing such surgery offers any benefits in cases in which the ovaries are clinically tumor-free. The current NCCN-guidelines, accordingly, state that decisions to leave the ovaries *in situ* should be made on an individualized case-by-case basis that takes reproductive age into account [202]. Clinically tumor-free ovaries need not be removed, according to the ESMO-guidelines [74]. HG-ESSs that express ER- and/or PR-positivity should be subjected to surgical therapy as described for LG-ESSs.

Since the number of extrapelvic recurrences and distant metastases clearly exceeds the incidence of local disease recurrence, the degree to which performing a systematic LNE can be deemed appropriate is both questionable and strongly debated (see prognosis for details). Isolated LN-metastases only rarely occur postoperatively [183, 278]. LNE has not been included as a surgical measure in the current NCCN-guidelines [202], and well-researched reviews [91] as well as the current ESMO-guidelines do not recommend it [74]. The Japanese guidelines state that pelvic and para-aortic LNE can nonetheless be considered, but simultaneously draw attention to the absence of scientifically proven therapeutic benefits [201]. The aforementioned guidelines go on to state that LNs can be resected in order to reduce tumor burden when they are radiologically or clinically suspicious. The GCIG-consensus does not recommend performing a systematic LNE unless there is a radiological or clinical suspicion of nodal involvement [220]. However, no statement is made in the guidelines as to the benefits of such practice.

Overall, all forms of LNE currently lack an adequate and sufficing scientific evidence base and thus cannot be defined as standard practice. Where this procedure is nonetheless opted for, it must be borne in mind that no therapeutic consequences can be deduced from the findings resulting from said course of action, even in cases of LN-positivity.

The risks associated with tumor enucleation, supracervical HE, and injuring the uterus or the tumor are addressed in detail in the sections on LMSs and LG-ESSs. 35.7 % of HG-ESSs and 36.4 % of UUSs are subjected to inadequate surgical procedures. While these rates are lower than those measured for LG-ESSs, from a prognostic perspective, they are still too high [143]. Adhering to the diagnostics flowchart (Fig. 14.22) presented in the section “risks and prevention of inadequate surgery” can contribute significantly to preventing inadequate operations being performed, as the criteria described there equally apply to HG-ESSs/UUSs.

HG-ESSs/UUSs that have invaded the abdominal cavity (stage III) should be subjected to maximal cytoreductive surgery. According to retrospective studies pertaining to all uterine sarcomas, and a retrospective study on HG-ESSs/UUSs [163], maximal debulking is evidently associated with improved survival. Complete macroscopic resection was achieved in 60–86 % of patients, though it should be noted that these figures also include intestinal resections [183, 272]. However, due to the fact that these tumors are highly malignant, rapid progression is still identified in 61 % of cases despite having achieved complete gross (R0) resection [278]. Overall, free resection margins are regarded as the most important prognostic factor [205]. Compared to

incomplete macroscopic resection, maximal cytoreduction is associated with significantly improved OS [183]. Some studies suggest that cytoreductive surgery generally has no influence on OS [280]. According to the current NCCN-2A-recommendations and the Japanese guidelines, the decision to surgically resect all tumor tissue can be made on an individualized i.e. case-specific basis, depending on symptoms, extent of disease, and resectability [201, 202]. The GCIG-consensus [220] points out that debulking apparently (though not significantly) improves OS, albeit without making a formal recommendation to that end. An LNE is deemed inappropriate when there is evidence of extrauterine disease [202]. Selective resection of affected enlarged LNs could be appropriate, if it has also been achieved that the patient is intrabdominally tumor free. Overall, the available data pertaining to such cases are very slim at best.

Regarding aftercare, reference should be had to what is stated for LMSs. There is no indication for adjuvant/postoperative chemo- and/or radiotherapy. For more detailed information, reference should be had to the specialist literature [148].

Adenosarcoma

Epidemiology, Etiology, Pathogenesis, Staging

AS is a mixed tumor that consists of a benign epithelial and a malignant mesenchymal (stromal) component. ASs occur with and without SO (sarcomatous overgrowth, see below). Due to the rarity of this variety of tumor, there are currently no "evidence based" therapeutic strategies. The NCCN-guidelines for uterine sarcomas make no reference to ASs. Studies that are devoted solely to ASs are, without exception, retrospective case studies with relatively small sample sizes on average.

When carcinosarcomas are excluded, ASs account for 8.9 % of all uterine sarcomas [143]. More detailed information pertaining to AS prevalence rates are generally non-existent. The majority of AS-patients are aged 50–70 years, with a median age of 54–58 years [45]. Patients covered in the DKSM material database are aged between 22 and 82 years (mean: 55.6, median: 56 years) [143]. There are clear age differences between AS-patients with and without SO: according to the literature, the median age of patients without SO is 58 years (29–87 years), compared to 67 years [38–94] among patients with SO [24]. According to DKSM-data, the median ages are 56 and 55 years, respectively [143]. ASs thus occur in postmenopausal women in the majority of cases.

Uterine ASs develop in the endometrium in more than 90 % of cases. ASs that originate in the myometrium are likely to have developed from an adenomyosis [102, 209]. There are accounts of ASs primarily originating in the cervix [24, 184]. Likewise, cases in which ASs have developed from adenofibromas are long known to exist. AS-patients often exhibit a previous medical history of cervical or corporal polyps. It is likely that ASs or adenofibromas were not primarily recognized as such in these cases. There are multiple reports pertaining to the existence of a connection between AS and tamoxifen exposure [17, 52, 56, 77, 127].

Since 2009, new binding FIGO-staging and UICC-classifications [83, 264] have been in place for ASs that differ from those provided for pure uterine sarcomas (Table 14.7), and that take into consideration the fact that ASs generally originate in the endometrium in 90 % of cases.

Macroscopic and Microscopic Appearance

ASs are usually polypoid or papillary, often broad-based pedunculated masses that frequently fill the endometrial cavity (Figs. 14.18a, b and 14.21a, c, e). ASs can grow to a considerable size. Diameters of up to 20 cm have been described in the literature [92]. In most cases, the tumor forces the myometrium apart. Myometrial infiltration only rarely occurs in cases of ASs without SO. ASs contain epithelial

Table 14.7 FIGO staging for adenosarcomas [291]

I	**Tumor limited to uterus**
IA	Tumor limited to endometrium/endocervix with no myometrial invasion
IB	Less than or equal to half myometrial invasion
IC	More than half myometrial invasion
II	**Tumor extends to the pelvis**
IIA	Adnexal involvement
IIB	Tumor extends to extrauterine pelvic tissue
III	**Tumor invades abdominal tissues**
IIIA	One site/organ
IIIB	> one site/organ
IIIC	Metastasis to pelvic and/or para-aortic lymph nodes
IV	**Tumor invades bladder and/or rectum and/or distant metastasis**
IVA	Tumor invades bladder and/or rectum
IVB	Distant metastasis

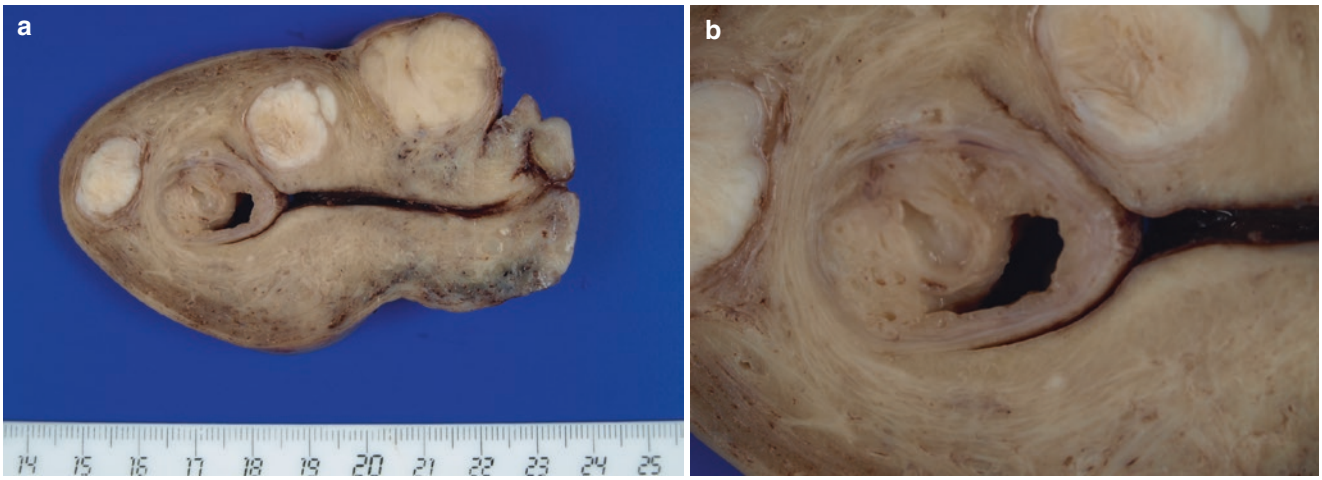

Fig. 14.18 Adenosarcoma. (**a**) An AS alongside several LMs in the fundus of the uterus; (**b**) it becomes apparent upon magnification that the AS developed from the endometrium and subsequently advanced into the cavum like a broad-based polyp. Numerous smaller and larger cysts are recognizable within tumor. They usually correspond to dilated endometrial glands and can be easily visualized via imaging diagnostics (With permission of Köhler et al. [153], Fig. 3.2–1a, b)

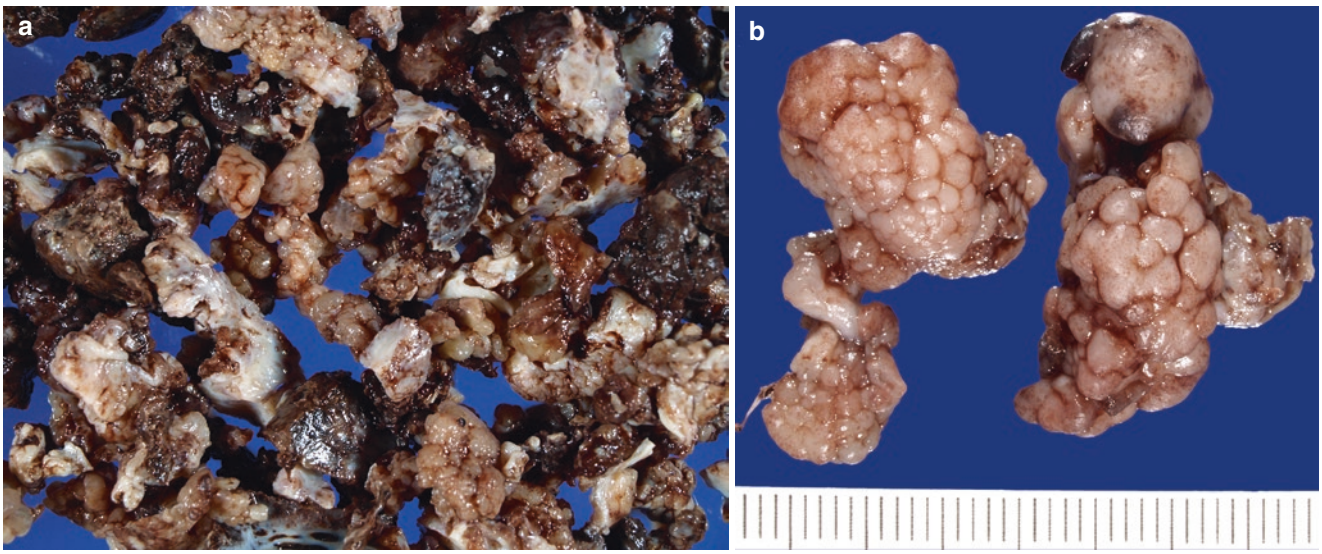

Fig. 14.19 Adenosarcoma without sarcomatous overgrowth. (**a**, **b**) The AS specimens obtained via curettage have a noticeable grape-like appearance that becomes even more apparent when magnified (**b**) (With permission of Köhler et al. [153], Fig. 3.2–2a, b)

cysts that vary in size and that effect a spongy appearance on the cut surface. Grape-shaped tumor masses are also typical in this context (Fig. 14.19a, b). The yellowish to brownish, pink or white to gray tumor is usually also macroscopically well differentiated from the myometrium. Outside the cystic areas, the tumor can be of a solid or fleshy, but also a soft and gelatinous consistency. Grossly visible necroses and hemorrhages can be observed in roughly one quarter of all cases.

An AS is classified as homologous when the sarcomatous component is of uterine origin (endometrial stroma, myometrium, connective tissue, vessels). Said component is comprised of an LG-ESS, an HG-ESS, a UUS, or an LMS in the vast majority of such cases. Roughly 75–80 % of ASs are homologous tumors [55, 92]. By contrast, an AS is heterologous if the sarcomatous component derives from extrauterine tissue. In those cases, the mesenchymal component usually consists of rhabdomyosarcoma or chondrosarcoma, or osteosarcoma, liposarcoma, or another form of sarcoma in rarer cases.

Classification of ASs into tumors with or without SO is of considerable clinical and prognostic importance. An AS is classified as having SO when more than 25 % of the tumor volume is composed of pure (i. e. epithelium-free) sarcoma [178]. AS without SO is regarded as the “classical” or “typical” variant of AS. Unfortunately, numerous studies and publications make no precise distinction between these two

AS-variants. A look at the histological appearance of ASs reveals an eye-catching phylloid, leaf-like, or papillary growth pattern. Epithelium-lined clefts and cysts of varying size, combined with papillary protrusions of cellular stroma into these cysts, serve to generate this appearance.

The epithelium is distributed across the entire tumor, usually in the form of benign glandular isles, however without fostering an impression of infiltration. In most cases, the epithelium is atrophic/inactive or resembles the normal phase of proliferation. The presence of malignant epithelial cells is indicative of carcinosarcoma.

The characteristic abounding, collar-like growth of stroma cells around the benign glands has resulted in the coining of the term "cuffing", a phenomenon that is strongly suggestive of an AS both in diagnostics and DD. The fact that ASs are closely related to adenofibromas is also more than apparent at the microscopic level. Prime criteria for distinguishing ASs from adenofibromas are: an MI ≥ 2 M/10 HPF, marked stromal hypercellularity with periglandular or subepithelial stroma cell congestions (collar, cuff), and significant stromal cell atypia. The mitotic rate is usually between 2–4 M/10 HPF. However, the mean mitotic rate across the whole tumor is only 2.2 M/10 HPF [266]. Nuclear atypia are predominantly mild-to-moderate. The majority of ASs without SO are confined to the cavity of the uterus or to the endometrium. Myometrial invasions are rare and non-destructive. They occurre in roughly 20 % (16–42 %) of cases, and usually reach only a few millimeters deep [55, 92]. Lymphovascular invasion is reported in only 7 % of cases [131]. Analogous to LG-ESSs, ASs without SO are characterized by high levels of HR-expression: in one study, ER- resp. PR-positivity were measured in the epithelial component of 85 resp. 65 %, while the stromal component was ER- resp. PR-positive in 80 resp. 60 % of cases. Both ER- and PR-positivity were detected in 90 % of cases [8]. Analogous to LG-ESSs, CD10 expression tests positively in 81–100 % of ASs without SO. Moreover, immunohistochemical testing has verified a smooth muscle differentiation in numerous cases (smooth muscle actin, desmin) [8, 189, 266]. Overall, ASs without SO and LG-ESSs share numerous morphological and immunophenotypical commonalities.

ASs with SO differ from the aforementioned typical or classic ASs in numerous aspects. The literature suggests a rather wide range of frequency, from 8 to 60 % of all ASs. The majority of studies narrow their share down to 20 to 48 % [45, 55, 92, 131, 178, 253, 266, 279]. 35.1 % of all ASs in the DKSM-materials exhibited SO [143]. While no significant differences between ASs with and without SO are discernible in the epithelial component of the tumor, the sarcomatous component of ASs with SO usually consists of an HG-ESS, a UUS, or another high-grade sarcoma, for instance rhabdomyosarcoma or angiosarcoma. With an MI of up to 115 M/10 HPF and a mean MI of 13.5 M/10 HPF, the number of mitoses is significantly higher in ASs with SO compared to ASs without SO [55, 92, 266]. Myometrial invasion is observed in 53–60 % of cases [92, 159] and often borders on the serosa. Lymphovascular invasion is verified in up to 24 % of cases. Hemorrhaging, necroses, and heterologous components are much more frequent in this neoplasm than in its counterpart without SO [131]. Analogous to HG-ESSs and UUSs, and in contrast to LG-ESSs, ER- and PR-expression are very low or non-existent. The epithelial component has shown ER- and PR-positivity in 50 % resp. 25 %, while the stromal component has shown ER-positivity in 0 % and PR-positivity in only 0–12 % of cases [9, 92]. CD10-expression is positively measured in the sarcomatous component of no more than 28 % of ASs with SO [8, 92, 255].

Symptoms, Clinical Presentation, Clinical Diagnostics, Imaging, Differential Diagnosis

Since ASs originate in the endometrium or the cervix, abnormal vaginal bleeding or postmenopausal bleeding are the most commonly presenting symptoms. Overall, the symptoms correspond to those of endometrial carcinomas. Like for the other uterine sarcomas, a broad-based, usually polypoid tumor protruding from the cervix is a commonly reported finding (Fig. 14.20a–c). Especially in very young patients, such tumors usually turn out to be cervical ASs. Lower abdominal pain is a frequent symptom resulting from rapid tumor growth, which in turn causes the uterus to expand and/or the cervix to dilate. Performing an HSC and/or fractional curettage is indicated when patients present with abnormal/postmenopausal bleeding (Fig. 14.20c, d). ASs can primarily originate in the myometrium; however, this is only rarely known to have occurred. Notwithstanding, in such cases, the AS might not be traceable in tissue specimens retrieved via curettage.

Since ASs originate in the endometrium in more than 90 % of cases, in contrast to both LG-ESSs and LMSs, sonography, too, shows that they are limited to the endometrium or primarily centrally located. The tumor often fills the endometrial cavity. In contrast to polyps, which constitute an important DD for ASs, sonography reveals a broad-based connection to the endometrium almost without exception.

The AS has a higher echogenicity than the surrounding myometrium and is thus well differentiated from it. ASs are heterogeneously echogenic in the majority of cases [273] and thus essentially correspond the echogenic texture of the endometrium [52]. Analogous to the macroscopic and microscopic appearance that is characterized by cystically dilated glands, sonography, too, reveals an internal structure that comprises numerous anechoic areas that represent said

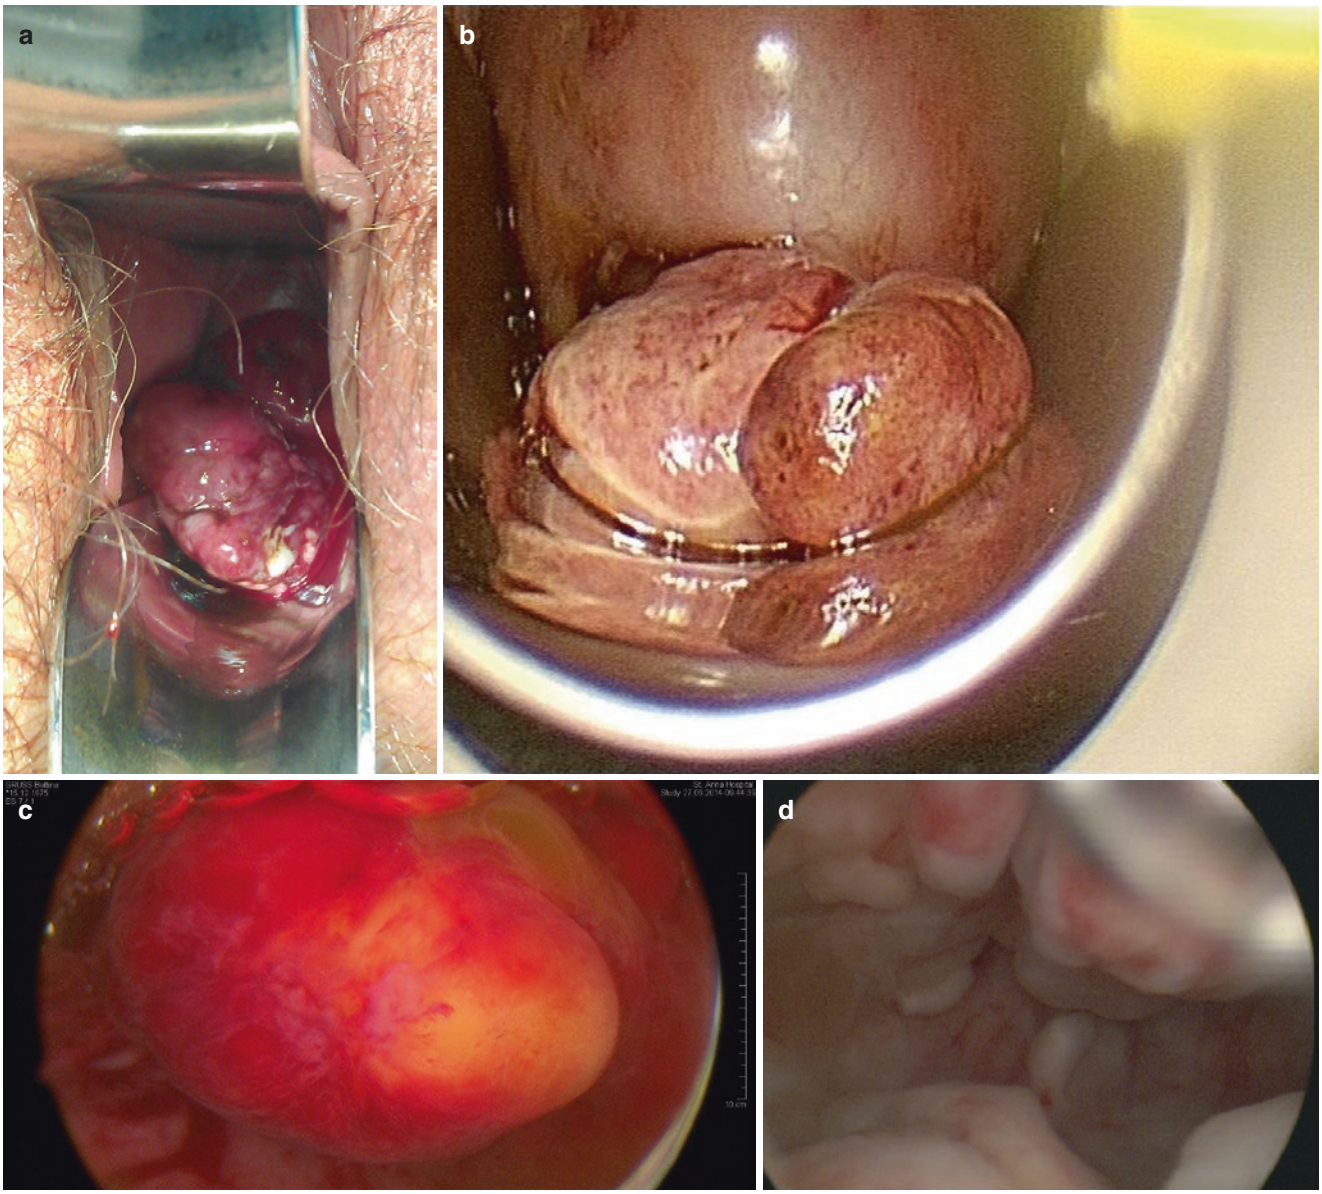

Fig. 14.20 Adenosarcoma with and without sarcomatous overgrowth. (**a**) AS without SO that has prolapsed into the vagina, the cystic-polypoid structure is clearly recognizable on close observation; (**b**) two polyps removed via hysteroscopic resection that turned out to be AS with SO. The presence of only very few barely discernible cysts is a typical feature; (**c**) hysteroscopic finding of a relatively smooth intracavitary tumor the macroscopic observation of which yielded no suspicions of AS; (**d**) typical HSC-image depicting grape-like AS without SO in a 21 y.o. patient (With permission of Köhler et al. [153], Fig. 3.2–6a–d)

glands [52]. The resulting respective visual appearance is of seminal importance for arriving at the proper diagnosis. The phylloid growth pattern can also be clearly recognizable in fortunate cases (Fig. 14.21a). Nonetheless, the location of these tumors within the cavity and their predominantly hyperechogenic texture make them difficult to differentiate from carcinosarcomas and endometrial carcinomas.

Doppler-sonographic criteria correspond to those for LG-ESSs and LMSs, characterized in particular by strong irregular central vascularity. One marked difference, however, lies in the fact that, in ASs, the numerous differently sized cysts are easily recognizable alongside the visible vessels (Fig. 14.21b).

CT is not suitable for precisely diagnosing or classifying tumors, but is a useful method for spread-related diagnostics and staging. However, the presence of numerous intratumoral cysts with a density equal to that of water (Hounsfield-unit 0) could be suggestive of an AS (Fig. 14.21c). T1 W MR-images reveal a heterogeneous tumor with intermediate SI that is usually isointense to the myometrium. Hemorrhagic areas are characterized by areas of high SI, while the (usually numerous) cystic areas of varying size have low SI on

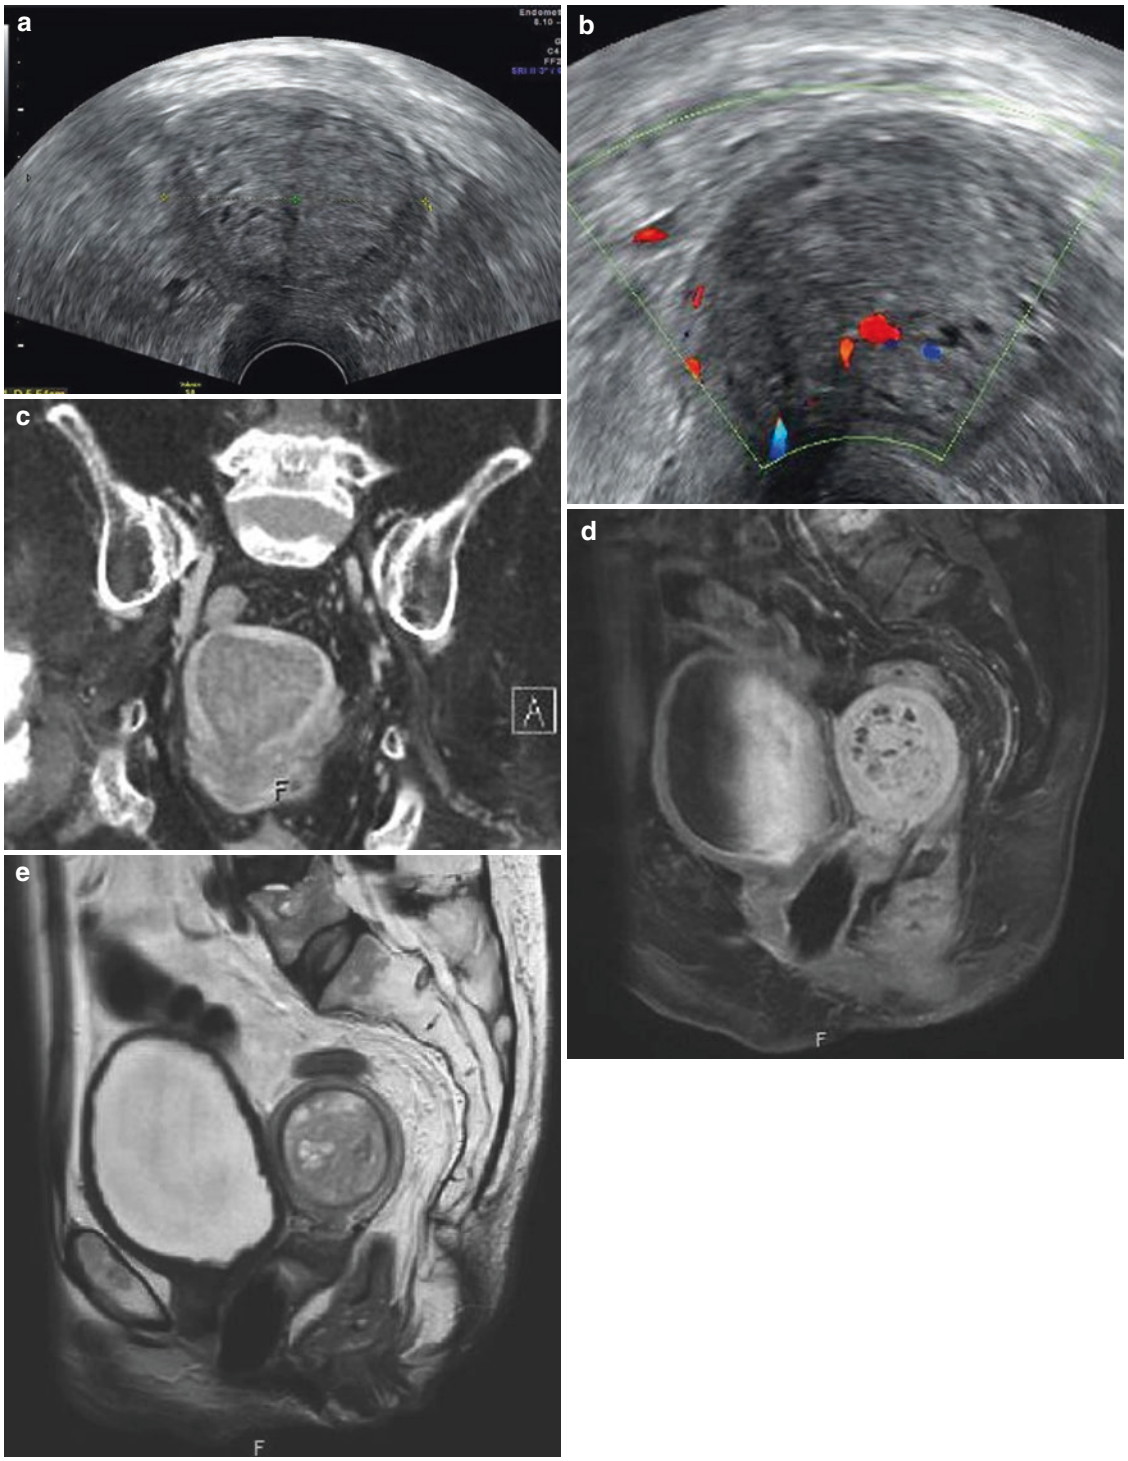

Fig. 14.21 Adenosarcoma without sarcomatous overgrowth. (**a**) Gray-scale sonography of an AS without SO with a mesenchymal component resembling LG-ESS shows a tumor with irregular bizarre margins that is hyperechoic to normal myometrium, that fills the entire cavum, and that has inflitrated the myometrium in multiple locations. Numerous anechoic areas are visible that correspond to vessels and dilated endometrial glands; (**b**) color Doppler sonography reveals some of these anechoic spaces to be dilated vessels; (**c**) the findings from CECT correspond to those from sonography, the non-enhancing areas correspond to dilated glands; infiltrations of the more hyperdense myometrium are clearly recognizable; (**d**) AS shows a similar enhancement to normal myometrium in T1 W-contrast MRT with fat suppression. As is also the case in T2 W, here, too, there is a discernible margin (albeit with a lesser degree of hypointensity at the bottom of the tumor) that is interrupted in several places (as is also recognizable in **e**). The non-enhancing hypointense sections correspond to the hyperintense areas in T2 W; (**e**) analogous to LG-ESS, this T2 W images show a clear hypointense rim or margin that is breached in the lower part of the uterus, where it most likely corresponds to myometrial infiltration. The strongly hyperintense sections predominantly correspond to the greatly dilated, fluid-filled glands (With permission of Köhler et al. [153], Fig. 6–8a–d, f)

T1-weighted images [52, 301]. ASs have heterogeneous SI on T2 W-images with hypointense, intermediate, and hyperintense areas. The multitudinous hyperintense regions represent the cystic components, while the areas of low-to-intermediate SI correspond to the solid components of the tumor [272, 273, 275, 281]. Clustered cystic components with strong SI are regarded as a key finding. The tumor components that are hypointense in T2 W-images show a strong enhancement in T1 WC images [272]. There are accounts of cases in which the myometrium has a stronger enhancement than the tumor, which makes tumor invasions easy to recognize, as well as of SIs that appear isointense compared to the myometrium [301]. The enhancing solid tumor components, as well as the enhancing septa between the non-enhancing cystic areas, often generate a lattice- or truss-like overall visual impression [52, 275, 301] (Fig. 14.21d, e).

It is barely possible to grossly differentiate an AS from endometrial carcinoma, carcinosarcoma, adenofibroma, stromal sarcomas as well as from large necrotic endometrial polyps solely on the basis of macroscopic observation of the resected and opened uterus. Real polyps usually have a tapered, gradually narrowing stem and a generally smooth appearance. ASs, by contrast, usually have a broad-based connection to the corpus or the cervix. Multitudinous cystic structures or a grape-like appearance are suggestive of an AS, but are also characteristics of botryoid rhabdomyosarcoma.

Adenofibroma constitutes the most difficult and challenging DD, since the histological transition from adenofibroma to adenosarcoma is a continuous, gradual one [55, 92]. ASs without SO are generally difficult to differentiate from LG-ESSs, since these two tumor types are largely identical in terms of their morphology and immunophenotypic profiles [266]. In particular, basing diagnostic decisions and conclusions on a relatively small amount of tissue, for example such stemming from a frozen section or curettage, bears numerous trap doors and much room for potential misinterpretation. In such cases, the specimens might omit the epithelial components or facilitate them being overlooked, thus making misdiagnoses as pure sarcomas more likely. Within the DKSM-materials, on the basis of the curettage specimens alone, 17.6 % of all ASs were primarily diagnosed as purely homologous or heterologous sarcomas (LG-ESS, HG-ESS, UUS, LMS, rhabdomyosarcoma) [143]. Final diagnosis is thus frequently only reached upon examination of the surgical specimen.

Clinical Course, Prognostic Factors Relevant for Therapy

Generally speaking, stage of disease is the most important prognostic factor for both AS-types [2]. There is apparently no correlation between MI-levels and rates of recurrence [131]. Deep myometrial invasion and lymphovascular invasion are regarded as predictors of recurrence and metastasis [92, 131].

According to DKSM findings and the majority of other studies, metastatic spread to the ovaries is not observed at the time of primary diagnosis [16, 30, 143, 279]. One further study reported ovarian involvement at the time of primary therapy in 8 % of cases. Metastases were not visible on gross observation in 2 of 5 cases [45].

Only limited data are available pertaining to the rate to which LNs test positive in cases of AS with and without SO. According to one study covering 262 cases of AS, nodal metastases were found in only 3.1 % of cases of AS (all stages) with and without SO [16]. A further study [45] identified positive LNs in only one case of AS with SO, accompanied by further extrauterine spread. Within the DKSM materials, LN-metastases could be verified for 33 % of ASs with SO and 11 % of ASs without SO. Interestingly, recurrences only occurred in patients with negative LNs. 25 % of distant metastases occurred in patients with positive LNs, while the LNs of the remaining 75 % of patients who developed distant metastatic disease tested negative [143]. Accordingly, the prognostic value of positive LNs is indeed questionable. Data stemming from some smaller research series suggest that performing an LNE may well serve to reduce the number of pelvic recurrences [244, 280]. These findings notwithstanding, according to SEER-data, performing an LNE does not seem to affect OS beneficially, even in cases of positive lymph node metastasis [256]. Further retrospective studies, too, have confirmed that, to date, performing an LNE apparently serves to provide no benefits in terms of OS [30, 154].

The typical (classical) AS-variant – AS without SO – is associated with a relatively favorable prognosis (analogous to LG-ESS) and is often cited as a tumor with low malignant potential [92, 131, 228, 293]. In actual fact, up to 96 % of AS patients initially present with stage I disease [30]. Tumor growth is relatively slow and recurrences usually occur in the form of late recurrences in the vagina, the lesser pelvis, and the abdomen. Reported rates of recurrence range from 7–14 % [30, 55, 131, 279]. Distant metastasis has been described in up to 50 % of cases [30], with a median time to recurrence of 21.3 Mo (10.4–60.9 Mo) [30].

Presence of SO is significantly statistically associated with less favorable OS and is regarded as an independent prognostic determinant *per se* [42, 92, 288]. Thirty to forty percent of ASs with OS are already at an advanced stage of disease at the time of initial diagnosis [30, 159]. Overall, rapid tumor growth and early recurrence and/or metastasization should be expected when SO is present. Recurrence rates for ASs with SO have been measured at 44–80 % [30, 55, 131, 279] and distant metastases occur in up to 90 % of cases [30]. In 30 % of cases overall, lung metastases arise

without local recurrences or metastases in the abdominal cavity [30]. The risk of recurrence is roughly 3.2 times higher than for classic ASs [131]. The median period of time until the occurrence of first tumor recurrence is 21.3 Mo (2.1–87.8 Mo) [30]. Overall, the presence of SO and/or predominantly myometrial invasion as well as lymphovascular invasion are regarded as the most reliable histological predictors for recurrence of AS [45, 110, 266].

Taking both AS variants together, the time period until first recurrence is around 3.4–5 years; 38–40 % of first recurrences occur after 5 years or more. There are accounts of dramatic courses in which tumors recurred within just 2 weeks [76]. Isolated recurrences in the vagina and the pelvis are observed in 33 % and 28 % of cases, respectively. Roughly 38 % of recurrences occur in the abdomen and the pelvis with and without distant metastases. By contrast, isolated (!) distant metastases are observed in only 5–9 % of all AS patients. Hematogenous metastatic spread is rather the exception and practically only occurs in AS-patients with SO [55, 303]. A recent analysis [45] measured a median RFI and a median OS of 29.4 resp. 55.4 Mo for ASs with SO, compared to 105.9 resp. 112.4 Mo for ASs without SO. Among stage I disease patients, 77 % with SO and 22 % of patients without SO showed recurrence. The difference was statistically significant.

Thus, ASs with SO and ASs without SO differ significantly in terms of their prognosis. The former exhibits clinical and prognostic behavior and characteristics more reminiscent of HG-ESSs and other high-grade sarcomas, while the latter more closely resembles LG-ESSs from a clinical and prognostic perspective.

Surgical Therapy and Problems

Since ASs are rare malignancies, there are currently no therapeutic studies that are devoted solely to this form of tumor. Accordingly, there are no recommendations that fulfill the criteria for "evidence based medicine". The NCCN-guidelines [202] contain no provisions pertaining to ASs. The situation is even more unsatisfactory if one differentiates between ASs with and without SO. Therapeutic decision-making is made somewhat easier, however, by the fact that ASs and stromal sarcomas share certain clinical, microscopic, biochemical, and prognostic commonalities [266]: AS without SO is more reminiscent of LG-ESS, while AS with SO more closely resembles HG-ESS or other high-grade sarcomas, not least because, in ASs, prognosis is primarily influenced by or dependent on the mesenchymal component. Procedure should or can thus be guided by the procedure applied to the sarcomas to which the different AS variants bear close resemblance [86, 266, 288]. One exception is when the sarcomatous component consists of a rhabdomyosarcoma, in which case the tumor should not be approached as if it were a rhabdomyosarcoma, but instead analogous to the other high-grade sarcomas.

In accordance with the current NCCN-guidelines for LG-ESSs and HG-ESSs and the GCIG-consensus [86, 202], total HE without injuring the uterus with accompanying BSO is regarded as the adequate surgical approach to be applied, and thus as accepted standard practice. There is no indication for performing total vaginal HE when an AS has been diagnosed, due to the risk of injuring the uterus and the fact that this procedure does not allow for abdominal exploration. Laparoscopically assisted vaginal HE or total laparoscopic HE, when opted for, must be performed without causing injury to the uterus.

The SEER-analyses and the lack of scientific evidence notwithstanding, there is nonetheless consensus among several studies that a BSO is more likely indicated when the tumor expresses HR positivity [11, 29, 91, 174]. The data, when taken together, suggest that preserving the adnexa is at least a possibility, i.e. that a subsequent extirpation can be forgone. According to the NCCN-guidelines, in referring to LG-ESS, decisions for or against performing a BSO can be made on an individualized basis under consideration of patients' reproductive age or desire for fertility preservation [202]. This statement is supported by the current GCIG-consensus [86]. Patients with HR-positive ASs should, however, be informed of the potentially elevated risk of recurrence that is associated with ovarian preservation. Said risk obviously only applies to uterus-preserving surgical procedures. This issue is discussed in more detail in the section on LG-ESSs. Since ASs with SO are usually HR-negative, a BSO is not indicated when the ovaries are unsuspicious.

It is currently contested whether or not performing an LNE is necessary [131], not least because the share of cases with nodal involvement is low (see prognosis). In the current NCCN-guidelines, LNE has been removed from the recommendations for all uterine sarcomas [202]. Likewise, according to the current GCIG-consensus, the benefits of an LNE have yet to be scientifically proven. Routinely performing a systematic LNE is thus not recommended [86]. However, the guidelines do indeed recommend the removal of all metastatic masses, which can be interpreted as a recommendation for performing selective LNE on enlarged LNs on an individualized basis. It needs to be reiterated that the preceding statement is not supported by evidence-based data, and that it has yet to be scientifically proven to any degree that performing any form of LNE is beneficial for prognosis.

In summary, systematic LNE or LN-sampling currently lack a sufficing and adequate scientific basis, and can thus not be defined as standard practice [45, 86, 91, 256]. Sampling enlarged LNs is currently deemed a justifiable compromise. If an LNE of any type is opted for, it must be borne in mind that no therapeutic consequences can be

deduced from the findings resulting from said course of action, even when the LNs test positive. Overall, therefore, not performing an LNE cannot be regarded as erroneous practice.

Stand-alone tumor extirpation, any form of morcellation, and any form of supracervical HE all constitute inadequate surgical procedures for ASs. As also applies for LG-ESSs, HG-ESSs, UUSs, and LMSs, a negative impact on the prognosis has to be expected when such procedures are performed [72]. However, 19 % of all ASs are still operated on under the indication of an LM [143]. The problems connected with and arising from inadequate surgical procedures, including morcellation in particular, are elaborated in detail in the section on LMS, while strategies for preventing inadequate surgery are discussed in the section on "risk and prevention of inadequate surgery" using a diagnostic flowchart (Fig. 14.22).

Local resection appears to be an option in exceptional cases of young women who urgently desire fertility-preservation and in whom the AS without SO is conveniently located within and confined to the uterus [55, 110, 184, 267]. It is necessary that R0-resection margins are achieved beyond doubt. One study revealed that one patient who underwent curettage alone, and two patients who underwent supracervical HE, had no recurrences [30]. According to two further studies [42, 84], among 7 adolescents who underwent organ-sparing surgery for cervical ASs, 5 developed recurrences. Conservative procedures are best suited for pedunculated tumors confined to the endometrium, under the condition that R0-resection is achieved [110]. In general, organ-sparing surgery, including supracervical HE, should nonetheless be classified as inadequate procedure and should thus not be recommended by physicians. Should the patient insist on such surgery, she must be thoroughly informed of the implications of such course of action, not least because preserving the ovaries when an HR-positive AS has been subjected to inadequate surgery could potentially promote recurrence (as also applies to LG-ESSs). A case has been reported in which adnexal preservation was not accompanied by recurrence in the follow-up period [184].

ASs that have spread within the pelvis and the abdominal cavity should be subjected to maximal cytoreductive surgery. Retrospective studies, albeit referring to all uterine sarcomas, suggest that such procedure is associated with improved OS [91]. There is an account of a patient with an AS with SO that had spread to and within the pelvis, who underwent a total of three cytoreductive operations following total HE with BSO plus cytoreduction plus hyperthermic intraperitoneal CHT with 50 mg/m^2 melphalan. The patient was still alive with disease after 55 months [128]. However, it remains unclear in this case whether hyperthermic CHT actually had any effects. Drawing on findings relating to LG-ESSs, it can be assumed that performing maximal cytoreductive surgery in cases of ASs without SO allows improvements in OS to be expected [280]. "Removal of all tumor" and "free resection margins" are deemed the most important prognostic factors [205]. For ASs with SO, analogous to HG-ESSs, due to the absence of effective alternatives, maximal cytoreductive surgery should also be considered. According to the current NCCN-2A-recommendations (that refer to all uterine sarcomas), the decision to surgically resect all tumor tissue can be made on an individualized i.e. case-specific basis, depending on symptoms, extent of disease, and resectability. LNE is deemed inadequate where there is extrauterine spread [202]. There are currently no data available pertaining to the potential benefits of performing a selective LNE, even when R0 resection margins have been achieved.

More extensive surgical procedures, for example exenterations, are generally rejected on the grounds of the substantial complications that can arise and in light of the poor prognosis with which sarcomas with exception of LG-ESS are generally associated. Pelvic exenteration should only be considered in exceptional cases, in which R0-resection (i.e. resection with clear margins) can be achieved and the patient is young and in a good general state of health [137].

Aftercare should be managed in accordance to what has been stated for LMSs and LG-ESSs. There is no indication for adjuvant/postoperative chemo- and/or radiotherapy. For detailed information in this regard, as well as for information pertaining to potential postoperative HT in cases of HR-positive ASs that have been subjected to inadequate surgical procedures, reference should be had to the specialist literature [153].

Other Uterine Sarcomas and Rare Mesenchymal Tumors

Angiosarcomas and liposarcomas also occasionally occur in the uterus. Regarding the different variants of liposarcoma, only the dedifferentiated, myxoid-round cell, and pleomorphic variants are known to occur in the uterus, while well-differentiated liposarcoma does not. Liposarcomas stand out for their imaging characteristics in particular. The tumor component containing adipocytes is typically hyperechoic in sonography. The lipogenic components show hyperintense SI in T1 and T2-weighted MR images. By contrast, fat suppression results in a complete loss of signal intensity. Combining the findings from these two imaging methods is expedient for diagnosing liposarcomas or lipogenic tumors. Analogous to LMSs, angiosarcomas and liposarcomas are treated with total HE without injuring the uterus. No adjuvant therapeutic measures have yet been established in practice.

There are also occasional accounts of embryonic, alveolar, and pleomorphic rhabdomyosarcomas occurring in the uterus in adult women (1.8 % of DKSM cases, 143). While the surgical management of pleomorphic rhabdomyosarcomas resembles that of LMSs, performing surgical therapy with and without LNE on the other two variants constitutes only one aspect of a multimodal therapeutic strategy that – depending on which of the pre-defined risk groups is at hand in the individual case – usually includes radiotherapy and chemotherapy. Particularities pertaining to PEComs (perivascular epithelioid cell tumors), endometrial stromal tumors with sex cord-like elements (ESTSCLEs), and uterine tumors resembling ovarian sex cord/stromal tumors (UTROSCTs) can be found in the specialist literature [146, 149–152].

Risk and Prevention of Inadequate Surgery

The central problem for diagnosing and adequately treating uterine sarcomas is that, in many cases, they are incidental or unexpected diagnoses that are reached intra- or postoperatively. Due to the frequent absence of specific symptoms, but also due to clinical, sonographic, and anamnestic clues or risk factors being overlooked, 68 % of all LG-ESSs and 51 % of all LMSs in the DKSM-materials were operated under the indication of an LM [143]. Unfortunately, the same applies to 19 %, 26 %, and 35 % of ASs, UUSs, and HG-ESSs, respectively (Table 14.8) [143].

The likelihood of encountering an LMS or an LG-ESS in the course of or following HE, regardless of the indication under which it was performed, is 0.14 % (LMS: 0.07 %; LG-ESS: 0.07 %) [132]. Among patients operated on under the indication of an LM, the risk is 0.23 % (LMS 0.08, LG-ESS 0.15 %) [171, 219]. Other studies have reported likelihoods of 0.09 % [263] and 0.39 % [262] for encountering unexpected LMSs during or following sole LM-enucleation. In 1.2 % of cases, LM-morcellation (1091 instances) reveals unexpected LMSs (0.09 %), LG-ESSs (0.09 %), or STUMPSs [243]. However, the risk of incidentally diagnosing an LMS in patients subjected to HE for symptomatic LMs is substantially higher, at 0.49 %, and increases from 0.2 % at age 36 to 1.4 % beyond the age of 50, and 1.7 % from the age of 62 [172]. Further analyses report a 0.22 % likelihood of discovering an occult LMS or LG-ESS on morcellated specimens taken under any indication [104]. The aforementioned data are, however, all based on relatively small samples. A more recent and extensive study of 41,777 women who underwent a myomectomy with or without power morcellation revealed an 0.18 % chance of encountering occult uterine sarcomas and (!) endometrial carcinomas (codified as ICD-9-codes 179 and 182). This corresponds to 1 tumor per 550 cases. The ratio changes to 1 tumor per 161 cases in women aged 50 and older. The rate for patients who underwent power morcellation was 0.09 % [294].

In a recent German analysis, the rate of all occult sarcoma (LMS and LG-ESS) among 10,731 women who underwent supracervical laparoscopic HE was 1:1788 (LMS 1:5365, LG-ESS 1:2683) [36]. Two separate analyses were conducted by cooperation partners of the DKSM [143] in 2015. The first (143) revealed an 0.22 % chance (1:455) of incidental uterine sarcoma (1 LMS, 6 LG-ESS, 1 AS), but only an 0.027 chance (1:3703) of LMS in 3717 women who underwent any form of LM surgery. The second study (143) revealed a risk of 0.06 % (1:1666) of finding occult uterine sarcomas (LMS, LG-ESS, carcinosarcoma) among 31,227 patients who were subjected to LM-surgery. This risk was significantly higher among postmenopausal women (1:100). The risk for LMS and LG-ESS was 0.05 % (1:2000) and 0,006 % (1:16,666), respectively. A review of the available literature suggests that the prevalence of unexpected sarcomas in cases of suspected LM is roughly 0.14 % (1:700) [40]. Taking the more recent German studies with their larger respective cohorts into consideration, it is justifiable to assume that the prevalence rate is closer to 1:1000 for all uterine sarcomas and from 1300 up to 1:5000 for LMS. In an up-to date meta-analysis [229], 134 studies (without the German analysis (31)) were analyzed, covering 30,193 women in whom fibroid related indications were the primary reason for an HE or a myomectomy. The analyses of 64 prospective studies revealed an estimated prevalence of LMS of 0.12 per 1000 surgeries (1:8300). When restricted to the retrospective analyses, the estimated prevalence was 0.57 per 1000 surgeries (1:1700). Meta-analyses of all 134 studies estimated prevalence to be 0.57 per 1000 surgeries (approximately 1 LMS for every 2000 procedures). The latter is similar to the results of the DKSM-study [143].

In the DKSM database [143], of the LMS patients who were operated on under the indication of an LM, 5 % were subjected to myoma enucleation, 27 % underwent morcellation, and a total of 66 % received inadequate surgery (all techniques that cause injury to the tumor and/or the uterus, including supracervical abdominal or endoscopic HE). The figures are significantly higher for LG-ESSs, at 23 %, 41 %, and 70 %, respectively. What this implies in terms of patient prognosis has already been elaborated in detail in the respective subsections. The situation is similar for uterine ASs, HG-ESSs, and UUSs, albeit with significantly smaller shares of these tumors being operated on under the indication of an LM (Table 14.8). Pre-therapeutic and intraoperative selection thus requires vast improvement, and more thought and consideration need to be devoted to indications for surgery. The fact that the risk of 1 sarcoma per 1000 LM-operations is rather low by comparison should not serve to distract from that need.

The AAGL [1] recommends that morcellation should only be considered when appropriate examinations of the myome-

Table 14.8 Epidemiological and clinical characteristics and primary indication for surgery of 1132 uterine sarcomas and 3920 leiomyomas covered by the Doctoral Research Group (Promotions- und Forschungsgruppe) of the DKSM [143]

Diameter ≥8 cm and solitary	9,1	28.0

trium, the cervix, and the endometrium have revealed no suspicious findings. When the pre-operative findings are suggestive of a malignancy and/or the patient is postmenopausal, alternative measures, including laparotomy, should be opted for. At the same time, morcellation should not be performed when examinations have revealed malignant or premalignant findings. This view is also reflected in the most recent recommendations of the DGGG as well as the current NCCN-guidelines [27, 202]. Whenever electric morcellation is being seriously considered, the specific risks associated with performing the procedure on benign (!) LMs (for instance provocation of a disseminated peritoneal leiomyomatosis or benign metastasizing LM) need to be explicitly discussed with the patient. Particularities pertaining to these clinical situations should be sought in the specialist literature [145].

Consistently having regard to the anamnestic, clinical, and sonographic criteria and risk factors that are suggestive of uterine sarcoma (Tables 14.2, 14.4, 14.8, and 14.9), while consistently adhering to a respective diagnostic flowchart (Fig. 14.22) prior to every LM-operation, can rather easily serve to protect uterine sarcoma patients from being subjected to inappropriate therapeutic procedures in the majority of cases.

In women aged 50 and older, the chance of encountering unexpected uterine sarcomas during LM-surgery is 0.62 % (1:116). The risk increases to 3.4 % in patients aged ≥60 years (1:29). In contrast, for women aged <40 years, the likelihood is only 0.04 % [293]. Overall, about 66 % of LMSs occur in women aged 50 and above, and about 62 % are found in postmenopausal patients [8, 9] [143]. Currently, 64.2 % of all LMSs are subjected to inappropriate surgical treatment [143]. If one were to exclude all women aged 50 and above as well as all postmenopausal patients from inappropriate surgery or advise against undergoing such surgery, as is recommended by the AAGL [1], then such inappropriate surgery would be prevented in well more than 50 % of LMS-cases. For ASs, HG-ESSs, and UUSs, the proportion of patients aged ≥50 is 64.3 %, 80.4 %, and 84 % (!), respectively (see Table 14.8). In order to better protect LG-ESS patients from being subjected to inadequate surgery, it is sensible to set the upper age threshold for organ-sparing surgery to 50 years, not least because LG-ESS patients have a median age of 46 years and only 18 % of these tumors occur postmenopausally (see also the section on LG-ESS).

For premenopausal patients (even better, patients aged <50) who desire organ sparing surgery (including supracervical HE), following anamnesis and clinical examination, selection must be based on the results from sonographic examination (and from curettage and HSC in cases of abnor-

mal bleeding). Should gray-scale sonography reveal findings that are suspicious of sarcoma (Table 14.2) or other suggestive findings (Tables 14.4, 14.8, and 14.9), then total HE without injuring the uterus should be the primary surgical course of action. Otherwise, further diagnostic measures are necessary.

According to the data from the DKSM [143] factors (Table 14.9) suggestive of sarcoma are, in particular, rapid tumor growth in women aged ≥45 years (24 % in LMS and 9.4 % in LM) and/or in combination with newly arising symptoms (17.3 % in LMS and 8.7 % in LM). Of all LMs ≥5 cm 13.4 % exhibit rapid growth, compared to 26.7 % of LMSs of the same size. Tumors with a diameter of ≥8 cm (60.2 % in LMS, 16.7 % in LMs) are particularly suspicious of being sarcomas, especially when they are solitary tumors or are noticeably soft. Only 9.1 % of ordinary LMs are solitary tumors with a diameter of ≥8 cm, while 28.0 % of LMSs fulfill these criteria. So the fact that LMSs have a median diameter of 8.0 cm would in itself serve to avoid inadequate surgery for at least 50 % of all LMSs, regardless of patient age, symptoms and rapid growth (Table 14.9).

Lowering the threshold for critical tumor size from 8 to 5 cm would be particularly helpful from the perspective of advanced diagnostics. Doing so would bring more than 50 % of all LG-ESSs and ASs within the remit of the selection criteria, bearing in mind that LG-ESSs and ASs have a median diameter of 5.5 cm at the time of initial presentation. The share of LMSs that would thus be covered by the criteria would be 85.6 %. Moreover, in the DKSM database, 69.2 % of LG-ESSs that were described as LMs in clinical examination and/or sonography and that were subsequently operated on as such were ≥5 cm in diameter, and 87.5 % of them were morcellated [143]. Expanding the diagnostic criteria to include all tumors with diameters of ≥5 cm would have been extraordinarily helpful in these cases. While changing the diagnostic criteria to this end would indeed entail that a larger proportion of

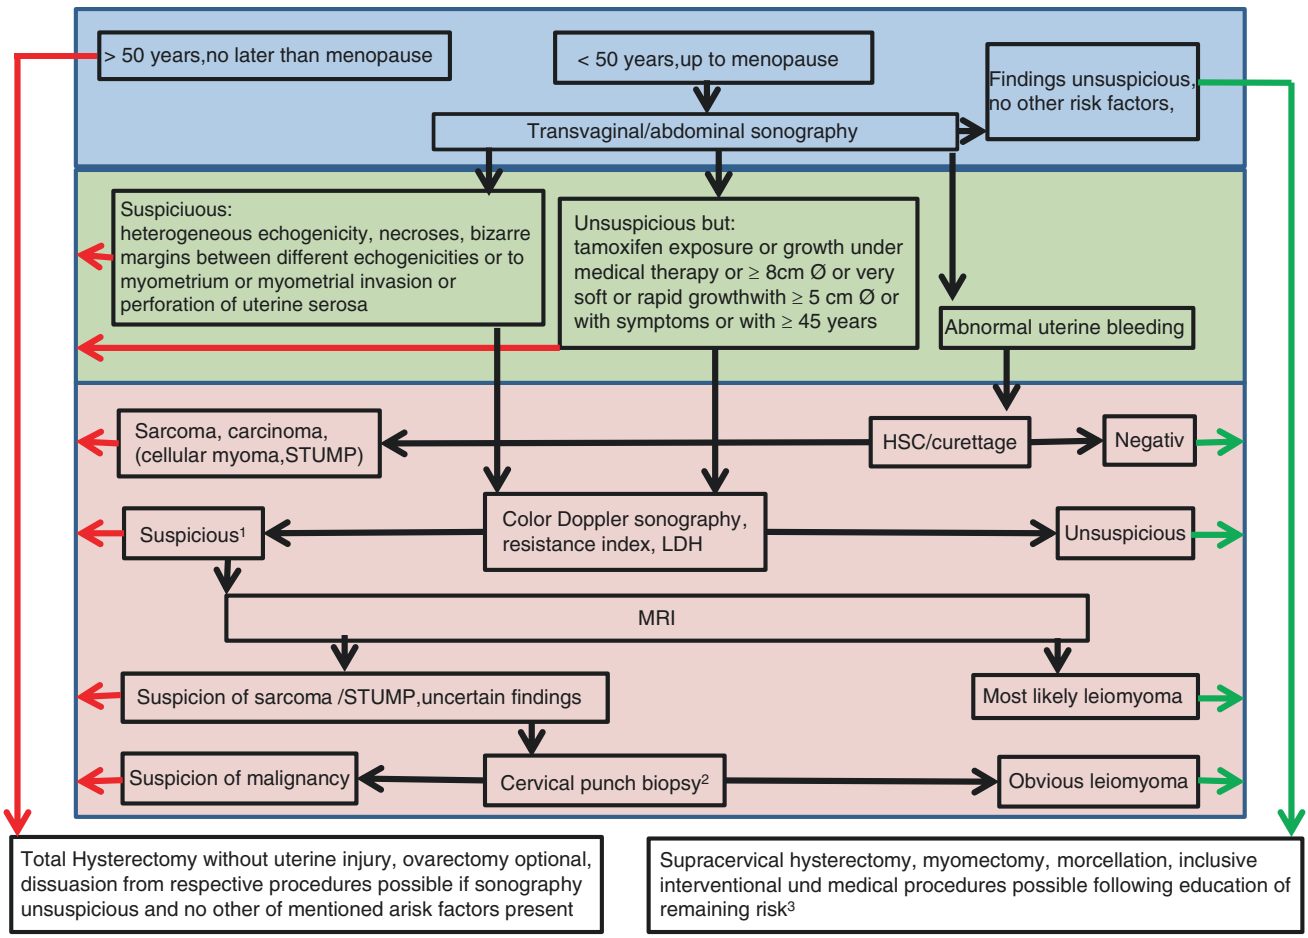

Fig. 14.22 Flowchart for preventing inappropriate surgery being performed on uterine sarcomas operated on under the assumption of a leiomyoma (With permission of Köhler et al. [144], Fig. 1.2–13)

Table 14.10 Results of the flowchart, if used prior to surgical procedure according to the data from the DKSM [143]

	LMS	Proven risk factors	
Surgical procedure	n	n	%
Inadequate surgery	129	122	94.6
Adequate surgery	72	71	98.6

patients would be subjected to Doppler sonography, at the same time, it would also imply that inappropriate surgical procedures could be prevented for up to 85.6 % of LMS, 83.3 %, of UUS and 90 % of HG-ESS patients. However, adapting the diagnostic criteria in the flowchart below to include tumors with a diameter of ≥5 cm with (apparently) unsuspicious results from gray-scale sonography inevitably has a negative impact on sensitivity, as 55.2 % of regular LMs and have a diameter of ≥5 (LMS in 85.6 %) (Table 14.8) [143].

The resulting decrease in sensitivity notwithstanding, tumors with a diameter of ≥5 cm should be included in the scope of expanded diagnostic criteria so as to improve diagnostic security and accuracy.

A medical history of exposure to tamoxifen is also among the risk factors that need to be clarified prior to performing surgery (see pathogenesis for all uterine sarcomas).

Should a patient request surgery that is either entirely or partially organ-sparing, even though one or more risk factors for a sarcoma are fulfilled (Table 14.4), then subsequent diagnostic measures must be initiated. Besides performing curettage and/or HSC in cases of abnormal vaginal bleeding, the patient should undergo a Doppler sonography examination, ideally in combination with LDH-testing. Both of these measures have been discussed in detail in the respective subchapters on the different sarcoma types. Where results from these procedures are likewise suspicious or pathological, and the patient continues (!) to request conservative surgery, an MRT examination should be performed. If the MRT results (for details, see the respective subsections) are suspicious or unclear, especially in combination with elevated LDH-levels (reference value × 1.2), and the patient continues to reject total HE in the course of which the uterus would not sustain injury, then performing a transcervical punch biopsy is the last available option. The potential pitfalls and risks associated with this procedure have been elaborated in detail in the differential diagnosis subsection for LMSs.

Overall, the diagnostic flowchart (Fig. 14.22) generally implies that sonographic examination has been performed prior to any LM-operation. Routinely subjecting patients with anamnestically, clinically, and sonographically unsuspicious LMs to curettage and/or HSC, color Doppler sonography, and/or MRT is not necessary according to the current state of information. Nonetheless, even when the flowchart is applied, incidental discoveries of uterine sarcomas and STUMPs cannot be entirely ruled out. Patients must be informed of this remaining risk.

Even in cases with ordinary LM patients must be informed of the fact that performing enucleation or morcellation can increase the risk of disseminated peritoneal leiomyomatosis and benign metastasizing LM.

When considering interventional therapy (embolization, ultrasound-guided destruction) for LM-patients, it must be borne in mind that the object on which such therapy is to be performed might well be inappropriate for such course of action [226]. However, in the DKSM-sample, embolizations accounted for only 1.2 % of all primary LMS-operations [143]. In contrast to older publications [63], more recent analyses and meta-analyses on LM-embolization lack any reference to potential sarcoma risk. Attending physicians should, however, not interpret this state of affairs as absolving them from the need to inform their patients of this risk, nor from taking further respective diagnostic steps to minimize it.

5.4 % of the 129 inadequate LMS surgeries covered in the DKSM materials [143] exhibited none of the risk factors described above (Table 14.9 and Fig. 14.22). Consequently, 94.6 % of these operations could have been prevented by referring to the flow chart (Table 14.10). Among the 72 adequate LMS operations performed, only 1.4 % of LMSs would have been missed as a consequence of adhering to the diagnostic chart. This (albeit minor) difference can be explained by the fact that total HE without injury to the uterus was often performed in cases in which an LMS had already been primarily diagnosed or suspected. In a further study [175] 4791 patients were referred to surgery under the indication of an LM. Among them, a total of 26 LMSs (1:183) were discovered. 20 LMSs could be successfully identified as such and referred to adequate surgery on the basis of diagnostics (curettage) or arising clinical suspicions of malignancy (tumor size). Only 6 cases (1:799) thus remained undetected. Ultimately, the share of LMSs that are detected incidentally during or following LM operations can be decreased dramatically if suspected LMs are subjected to more critical assessment prior to surgery.

This notwithstanding, an analysis conducted by the cooperation partners of the DKSM [143] revealed that, among 3920 ordinary LMs, 1739 (44.4 %) exhibited at least one of the risk factors stated above. However, only those patients who decline primary total HE need to be subjected to further diagnostics (yes when HSC/curettage and/or color Doppler sonography yield findings).

Therefore, seeking to prevent subjecting uterine sarcomas to inadequate surgery under the indication of an LM would not entail much effort, not least because, in its flow chart, the

Table 14.11 Descriptive accounts of uterine sarcomas, rendered either intraoperatively or immediately following surgery, based on 804 DKSM-surgical reports [143]

Intraoperative
Tumor very soft
Tumor primarily ruptured
Tumor extremely fragile (ruptures upon slight pressure)
Protrusion/outpour of hemorrhagic, marrowy, cauliflower-like, degrading or liquefied material upon cutting/dissection
Resected, opened tumor
If present, pseudo-capsule consists mostly of compressed tumor tissue
Hemorrhagic tumor, cystic structures, necrotic components
Entirely or partially gray, greenish-gray, dirty, intense yellow color
Very smooth cut surface, either partially or overall

ESGE [40] already regards color Doppler sonography as a precondition for conservative myoma surgery.

The performance of inappropriate modes of surgery on patients with sarcoma types not covered in the flowchart can nonetheless be prevented, if the attending physicians bear the factors suggestive of sarcomas (Table 14.11) in mind both during and immediately after surgery. The surgical approach should be reconsidered and/or a frozen section should be performed in respectively appropriate cases. The problems and pitfalls associated with frozen section procedures have to be taken into consideration (see LMS).

When findings are deemed unsuspicious according to the flowchart, and no intraoperative suspicions arise, there is currently no sound reason to deviate from tried and tested interventional and conservative surgical procedures for LMs, or to refrain from performing endoscopic procedures or morcellation where necessary. Notwithstanding, the patient must nonetheless be informed of the risks associated with morcellation (disseminated peritoneal leiomyomatosis and benign metastasizing LM). Electric morcellation should currently not be resorted to due to the large number of unresolved questions pertaining to the procedure. In their flowchart, the European Society of Gynaecological Endoscopy prioritizes performing a Doppler sonography examination as the primary method for verifying indications for surgery, a demand that is currently unrealistic context. The aforementioned chart [40] also demonstrates a number of other weaknesses and unclear, in part ambiguous wordings.

A real LMS risk score will be published soon by the DKSM.

Conclusions

LMs shall not be subjected to surgery without prior sonographic examination

Consistent application of the diagnostics flowchart

Consistent consideration of suspicious findings arising intraoperatively

Patients to be informed that, despite appropriate diagnostics, additional surgical procedures could be necessary if a finding of a malignancy arises

Patients to be informed that performing enucleation or morcellation on unsuspicious, ordinary LMs can result in disseminated peritoneal leiomyomatosis or a benign metastasizing LM.

Uterine Morcellation

15

Courtney J. Steller and Charles E. Miller

Minimally invasive surgical techniques have been proven to lead to decreased post operative pain, decreased morbidity, and faster recovery times when compared to open abdominal procedures [1]. According to committee opinions from ACOG and the AAGL, the preferred route for hysterectomy is a minimally invasive approach, including a laparoscopic or vaginal approach when feasible [2]. Fibroids are the most common indication for a hysterectomy (40.7 %) [3] which in turn makes specimen removal difficult as the specimen size is often larger than the abdominal or vaginal incisions made during surgery. As stated by Wright et al., patients who are nulliparous or have a large uterine size are at higher risk of requiring alternate methods of specimen removal such as morcellation [4]. Morcellation is defined as "division and removal in small pieces" in the Merriam-Webster dictionary. In addition, a similar challenge arises when removing tissue in the absence of a colpotomy, as in a supracervical hysterectomy or myomectomy.

History

Dr. Kurt Semm in Kiel, Germany originally developed a solution to the problem of specimen removal when he introduced a hand held manual morcellator in 1973. This hand-activated morcellator was produced by WISAP and resulted in a procedure that was very time consuming, arduous and painful for the surgeon. In order to avoid these issues, he developed a battery driven power morcellator in 1984 which was called the S.E.M.M. (serrated-edge macro morcellator). Then, in 1991 this was replaced by a completely electrically driven power morcellator [5]. This new S.E.M.M. worked by punching out tissue cylinders up to 1.5 cm in diameter. If used together with a myoma drill, large holes could be punched into the specimen, making them easily removable [6].

Dr. Rolf A. Steiner out of Zurich, Switzerland developed the first power morcellator, which was FDA approved in 1995. Utilizing a rotating knife driven by an electric micro-engine and controlled via foot pedal, the function was, again, to cut tissue in cylinder-shaped pieces. The cutting cylinder, which was 13 mm in diameter and 25 cm long, was placed in a 14 mm trocar sleeve and protruded a few millimeters past the sleeve of the trocar into the abdomen. Outside the abdomen was a gearbox, by which the electrical micro-engine produced the turning motion. A 10 mm grasping forceps was used through the cutting cylinder to grasp the tissue and a rubber ring ensured an airtight seal. In his paper, Steiner stated that the transmission of power was sufficient to cut almost any type of tissue. He originally performed this technique with uterine fibroids or ovaries, reporting 11 successful cases with mean specimen removal times of 6.5 min for fibroids and 4.5 min for ovaries, as compared to the "conventional technique" which he reported at 30 min [7].

Carter JE, et al. published a time and cost analysis of power vs. manual morcellation in 1997. He demonstrated that electromechanical morcellation reduced the average time for extraction of specimen <100 g by 15 min and of specimen weighing 401–500 g by 150 min. This also led to a significant cost reduction despite the more expensive nature of the electromechanical morcellators [8]. Electromechanical ("power") morcellators began to gain significant popularity and several new developments and models were created.

Modern Morcellators

The general engineering of the modern electromechanical morcellator is similar to that described by Steiner. The ideal morcellator is easy to handle, ergonomic, maintains pneumoperitoneum, and enables constant visualization of the rotating knife with minimal operator effort [9].

The Morcellator Knife was developed in 2000. It was a classic lancet with an interchangeable blade that was inserted through at 10 mm trocar and used to cut a specimen as it was held between two forceps. A posterior culdotomy was made to remove the small pieces of the specimen [10]. The Sawalhe morcellator, developed by Karl Storz, modified the Steiner model and enabled removal morcellated tissue from the abdominal cavity via the sleeve, obviating the need for a posterior culdotomy that was necessary with the Morcellator Knife [9].

Karl Storz then developed an even more competitive morcellator in 2007 called the Rotocut G1 morcellator (Fig. 15.1). In comparison to the existing Sawalhe model in a study published in 2007, the Rotocut G1 device accomplished significantly shorter morcellation time, operative time and duration of anesthesia. It also created fewer and longer pieces of tissue due to a more effective power output and drive transmission. In this model, the generator is located in the hand piece and is activated by a foot pedal.

The Gynecare Morcellex tissue morcellator developed by Ethicon, Inc. is another popular power morcellator (Fig. 15.2). Unlike the Rotocut G1, the Gynecare Morcellex does not require a foot pedal. In 2009, a randomized controlled trial was initiated to compare the two popular models, the Gynecare Morcellex and the Rotocut G1. There was no statistical difference between the two groups in regards to operative time, morcellation time, weight of excised pieces, blood loss/blood transfusion, intra or post operative complications, post operative pain, hospitalization or time to return to full activity. The two morcellators were evaluated by the surgeon using a VAS score ranging from 0 (low handling, easy) to 10 (high handling, difficult). There was a significant difference in ease of use, with the Gynecare Morcellex having a higher handling score (average 7.0 for supracervical hysterectomy and 7.2 for myomectomy). Also noted in this study, since the Rotocut G1 morcellator is reusable, it was more cost effective in large volume hospitals where laparoscopy is performed routinely. However, in hospitals where laparoscopy is not performed routinely, the Gynecare Morcellex was more cost-effective since more than 30 laparoscopic procedures requiring morcellation are needed to reach the cost of the Rotocut G1 [11]. The Gynecare Morcellex was voluntarily withdrawn from the market by Johnson and Johnson in late July, 2014 after a statement discouraging the use of power morcellators was released by the FDA. See "Updated FDA Recommendations under Complications" for further details.

There is also a morcellator currently on the market developed by Olympus Gyrus that uses purely bipolar technology and does not have a bladed system. The device, known as the PKS PlasmaSORD (Solid Organ Removal Device), utilizes bipolar energy to morcellate the tissue instead of sharp blades (Fig. 15.3). Theoretically, this creates fewer tissue fragments. It connects to a standard bipolar generator (Fig. 15.4), requires minimal set up, is lightweight and is ergonomical. There have been reports of successful morcellation

of large uteri using this device [12] but few studies have been performed comparing this bipolar technology with the standard bladed technique. Reported injuries have been related to limited visualization due to electrosurgical smoke and skin burns due to the bipolar system [13].

A comparison of these and other current models of morcellators is listed in Table 15.1.

Use

The use of most power morcellators is similar amongst manufacturers. Figure 15.5 shows the various pieces of the Storz Rotocut G1 Morcellator. The technique is historically done with the power morcellator placed in the abdominal wall. First, the largest trocar is removed from the abdominal wall. The incision is extended to the appropriate diameter, usually by dilators, under direct visualization. Once the appropriate diameter is reached, the morcellator cannula with obturator is inserted through this incision under direct visualization (Fig. 15.6). The obturator is removed and the blade is placed into the cannula (Fig. 15.7). A grasper, usually a 10 mm-diameter tenaculum or spoon, is then inserted through this cannula/blade and the tissue to be morcellated is grasped (Fig. 15.8). The cannula should contain a seal in order to maintain pneumoperitoneum. The tissue is brought up flush with the morcellator blade. Care should be taken to bring the specimen to the morcellator, not the morcellator to the specimen. The motor is then activated and the blade rotates while an upward force is exerted by the surgeon to allow the blade

Fig. 15.5 Separate pieces of the Rotocut G1 Morcellator. Pieces include (from left to right): obturator, sleeve (12 or 15 mm), blade, motor with power cord, motor valve, blade handle, sealing cap, and tenaculum (©2015 Photo Courtesy of KARL STORZ Endoscopy-America, Inc.)

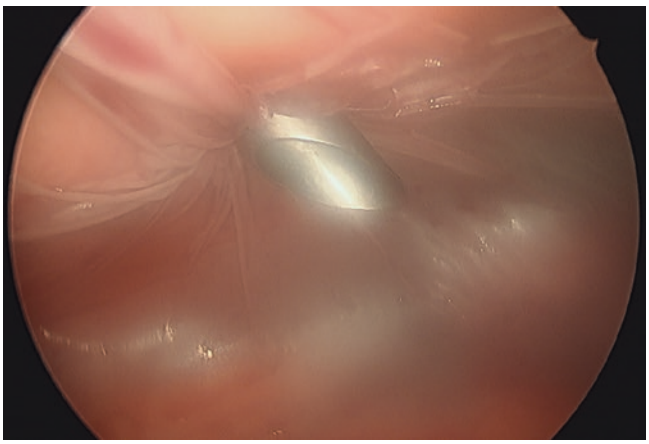

Fig. 15.6 The morcellator cannula inside the abdomen. Dilate the incision to the appropriate size prior to placement. Take care to have the long arm of the cannula bevel anterior

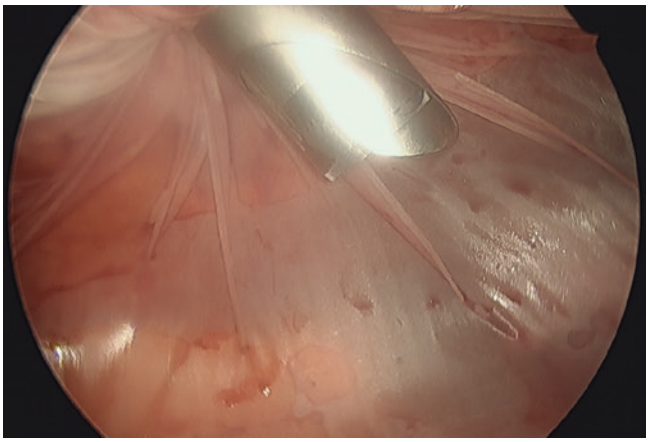

Fig. 15.7 The morcellator blade is now inserted through the cannula. Always aim towards the pelvis

Fig. 15.8 Using the Rotocut G1 Morcellator: one hand holds the morcellator steady while the other hand uses the tenaculum to grasp the tissue. This hand then pulls the tissue against the blade, the blade is activated, and morcellation ensues (©2015 Photo Courtesy of KARL STORZ Endoscopy-America, Inc.)

to cut through the tissue. This action cuts the tissue into cylindrical strips and allows for its removal through the cannula. The long arm of the bevel of the cannula should be anterior to allow a "coring" of the tissue, like peeling an apple [14]. The blade should be pointed away from the abdominal organs toward the pelvis with the cannula close to the abdominal wall (Fig. 15.9). When the tissue breaks, the activation of the morcellator should be stopped until a new piece of tissue is grasped. This is repeated until the entire specimen is able to be removed. Visualization should be maintained throughout the entire procedure and the end of the blade should be constantly seen by the surgeon. During this process, small pieces of the tissue may be separated from the specimen and dispersed throughout the abdominal cavity (Fig. 15.10). Careful inspection of the cavity should be performed and all small pieces removed prior to terminating the morcellation procedure. Small pieces should be removed by a spoon rather than a tenaculum [14].

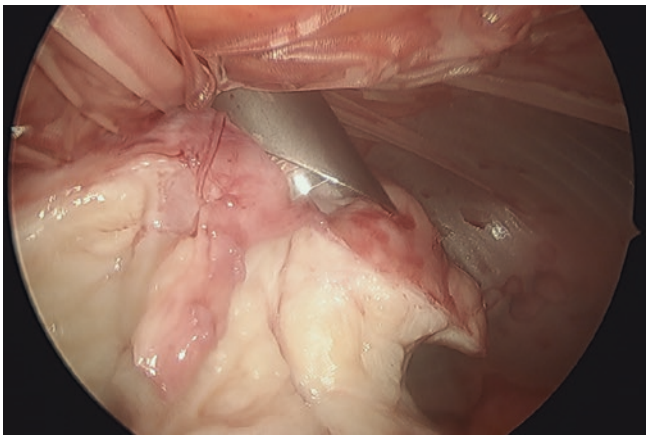

Fig. 15.9 Morcellating the specimen. Grasp specimen with a tenaculum or spoon and pull towards the morcellator until flush against morcellator. Point morcellator towards the pelvis. Pull back on the specimen while activating the blade. Use a "coring" technique to morcellate

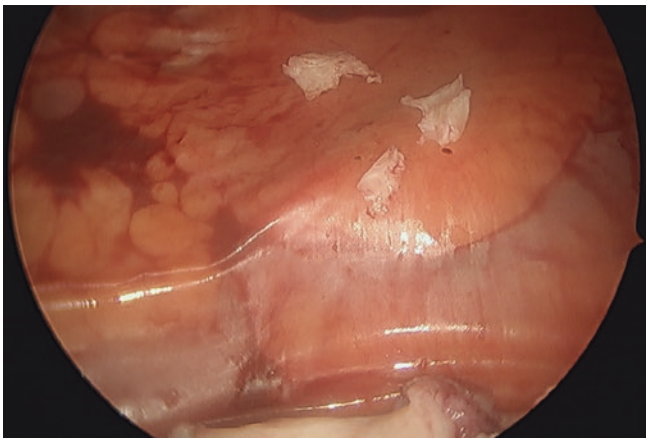

Fig. 15.10 Small fragments of tissue that may be dispersed after morcellation. Take care to remove all small pieces

Transcervical Morcellation

Morcellation has also been described using a transcervical approach after a supracervical hysterectomy. The steps are essentially the same; however, instead of extending an abdominal wall incision by dilation, the cervical canal is dilated until the morcellator cannula can be inserted. A longer cannula and blade must be used to traverse the vaginal canal. Morcellation is then completed in the same manner and the dilated cervical so may be closed using a single stitch laparoscopically. This technique allows the surgeon to avoid making a large abdominal wall incision and thus decreases the risk of future herniation. This technique was first reported in the literature by Rosenblatt et al. in 2010 [15].

At our institution, we have successfully performed transcervical morcellation after supracervical hysterectomy in several patients. We utilize the 12 mm Rotocut G1 Morcellator with the extra-long cannula. However, we have recently abandoned this method in order to routinely utilize contained in-bag morcellation which, at this time, can only be performed trans-abdominally and trans-vaginally. See "Updated FDA Recommendations under Complications" and "Contained Morcellation" for more details.

Manual Morcellation

An alternative form of morcellation can be performed by hand. This historically is performed vaginally, using a scalpel or scissors to cut a large specimen into smaller, retrievable pieces. It can also be performed abdominally through a small incision. In a study published in 2006 by Wang, et al., extraction of uterine myomas by culdotomy with hand morcellation vs. power morcellation was compared. The time for specimen removal with power morcellation was significantly less and there were no differences in myoma weight, size, number removed, blood loss or post-operative stay and no major complications occurred [16].

Complications

As morcellators have become more common place in laparoscopic surgery, morcellator-related injuries have also increased. These injuries range from direct surgical risks resulting in immediate complications to sequelae of morcellated tissue fragments and morcellation of undiagnosed malignancy resulting in more long term complications.

Immediate Complications

Immediate complications inherent in morcellation are generally caused by the sharp blade that is placed in the abdomen. Several advances have been made to decrease the incidence of these injuries, such as improved visualization of the blade due to a beveled trocar, completely covered blades and improved maintenance of pneumoperitonum. Some morcellators, such as Xcise, have different settings allowing the blade to protrude by different lengths. Despite these advances, adverse events can still occur. Milad et al. performed a systematic review using a literature search and a search of the FDA Medical Device Reporting (MDR) and Manufacturer and User Facility Device Experience (MAUDE) databases to determine the frequency of immediate morcellator injuries from 1992 to 2012 [13]. This study examined morcellation after hysterectomy, myomectomy, nephrectomy, splenectomy, and "other." He found a total of 55 complications, specifically including injuries to the small

and large bowels (n = 31), vascular system (n = 27), kidney (n = 3), ureter (n = 3), bladder (n = 1) and diaphragm (n = 1). Most (66 %) of these injuries were identified intraoperatively. Six patients died of morcellator related complications. No single manufacturer was solely associated with visceral or vascular injuries. The most common contributing factor for the injuries was lack of surgeon experience (n = 16) followed by lack of visualization (n = 4) and device malfunction (n = 4). Therefore, it is imperative that surgeons planning on performing power morcellation undergo training to gain experience and understand how to use, put together, operate and troubleshoot the device they plan to use. Other tips to reduce the surgical risk of morcellator use include:

1. Use the beveled tip of the morcellator anteriorly to allow an "apple peeling" technique.
2. Make sure, prior to activating the morcellator, that only the specimen is grasped and that the specimen is away from underlying bowel which may incidentally be grasped.
3. Only morcellate when the blade tip is visible
4. Never bring the morcellator to the specimen; instead, bring the specimen to the morcellator.
5. Always ensure adequate visualization is obtained prior to morcellation.

Long-Term Complications

Long term complications of morcellation include retained or parasitic tissue, leiomyomatosis or dissemination of undiagnosed malignancy. The term "iatrogenic parasitic myoma" has been developed to describe the formation of new myomas that are not attached to the uterus presenting after uterine or myoma morcellation. This is thought to occur when fragments of myomas are left behind following morcellation and become implanted in normal tissue in the abdominal cavity. The morcellated fragments are then able to grow via neovascularization from the peritoneum or adjacent tissue. Although Donnez et al. estimated the incidence to be 0.57 % of subtotal hysterectomies, the true incidence of retained uterine fragments is unknown. There are several case reports and literature reviews documenting the development of iatrogenic parasitic myomas but the numbers are too low to justify any substantial conclusions or to determine the incidence. In 2010, Larrain et al. reported a series of four cases of parasitic myomas diagnosed after prior morcellation at their institution. They also reviewed the literature, revealing 14 different reported cases or series of iatrogenic parasitic myomas at that time [17]. In 2011, Cucinella et al. reviewed four cases of parasitic myomas over a three year study period, giving an incidence of 0.9 % in their institution [18]. Finally, in 2012, a review out of Scandinavia reported three cases of parasitic myomas between 2004–2011, making their reported incidence of parasitic myomas only 0.12 % [19]. These lesions are usually confined to the pelvis, especially in the paravesical, pararectal, and rectovaginal spaces [18, 20, 21] however, reports exist of parasitic myomas found in the upper abdomen, anterior abdominal wall and port sites as well [9, 22–25]. Symptoms of parasitic myomas are not specific and patients are often asymptomatic. Palpable masses have also been described, as well as pelvic pain dyspareunia and abnormal vaginal bleeding [17, 26]. Treatment is surgical removal.

Disseminated peritoneal leiomyomatosis is another condition that has been reported after morcellation of leiomyoma. It is a rare hormonally dependent condition in which multiple nodules stud the pelvic and peritoneal surfaces, often giving the appearance of metastatic ovarian or peritoneal carcinoma [27]. There are approximately 150 cases reported in the literature since the first report in 1952 [28, 29]. Complete or partial smooth muscle differentiation in the absence of cytologic atypia is seen on morphologic, immunohistochemical evaluation. It is generally a benign condition but there are rare reports of malignant transformation. Patients can be asymptomatic and therefore, the condition is often diagnosed incidentally. However, abdominopelvic pain or palpable masses, dysmenorrhea, menorrhagia and intestinal obstruction have all been reported as presenting symptoms. If suspected, surgical exploration is indicated for diagnostic and therapeutic purposes with removal of the masses. This has been successfully reported by the laparoscopic approach [30]. Recent reports of successful treatment with GnRH agonists [31] or aromatase inhibitors [32] are documented as well.

Iatrogenic endometriosis has been reported to occur after uterine morcellation, but not all of the literature is consistent. A case report by Sepilian demonstrated widespread endometriosis and symptoms of cyclic pelvic pain six months following morcellation after a supracervical hysterectomy performed for uterine fibroids with an absence of endometriosis [33]. Implants have also been reported in the abdomen, pelvis and port sites [33–35]. One proposed theory is that viable endometrial tissue can seed the pelvis and peritoneum during hysterectomy and uterine morcellation. This would lead to implantation and proliferation of this endometrial tissue, leading to endometriosis formation. Other possible causes include retrograde flow from remaining endometrial tissue in a cervical stump or the presence of endometriosis that was not visualized on initial procedure [33, 36]. However, a case control study reported by Schuster et al. showed no difference (p = 0.998, n = 464) in new-onset endometriosis in patients after hysterectomy with morcellation compared to hysterectomy without morcellation [36]. Therefore, despite some case reports, uterine morcellation does not seem to increase the risk of a subsequent diagnosis of endometriosis.

In a systematic review analyzing 66 patients between 1990 and 2014 who underwent reoperation after morcellation during laparoscopic hysterectomy or myomectomy, the most common reason for reoperation was parasitic leiomyomata (33.3 %). The majority of the reoperations were due to new clinical symptoms, 60 % in the myomectomy group and 60 % in the hysterectomy group. The remaining reoperations were performed due to unsuspected malignancy, and the majority of these malignancies were leiomyosarcomas (24 %) [37].

Disseminated Malignancy

The biggest concern in regards to dissemination of tissue during morcellation is the inadvertent dissemination of malignancy.

Endometrial Adenocarcinoma

Morcellation of endometrial adenocarcinoma can cause cancerous tissue to be spread throughout the abdomen and lead to possible upstaging of an existing malignancy. Morcellation of endometrial adenocarcinoma can usually be avoided by appropriate pre-operative evaluation with endometrial biopsy or dilation and curettage; however, this is not always accurate. In symptomatic patients with confirmed endometrial malignancies, cancer detection rates are as high as 95 % with office based endometrial biopsy. However, in women undergoing hysterectomy without these symptoms, office sampling is much less effective [38]. In addition, curettage may be preferred over biopsy for endometrial sampling in certain situations. Studies have shown a discrepancy of 10–16 % in histologic diagnosis with endometrial biopsy or curettage when compared to hysterectomy [39]. A recent study out of Europe showed a concordance rate of only 62 % and 67 % of endometrial biopsy and curettage (respectively) when compared to hysterectomy [40].

Although the exact guidelines vary by source, it is always necessary to undergo appropriate preoperative evaluation. In patients with abnormal uterine bleeding, endometrial evaluation with ultrasound and endometrial biopsy should always be performed. If the endometrial lining is thickened, sonohysterogram should be considered to evaluate for polyps or intracavitary fibroids. Abnormally thickened endometrium is defined as thickness > 4 mm in post-menopausal women or >5 mm on days 3–5 of the menstrual cycle of a pre-menopausal women. If, after sonohysterogram and biopsy, there is no evidence of intracavatary pathology and the biopsy is negative, uterine curettage may be warranted. In patients without abnormal uterine bleeding, ultrasound should still be performed for operative planning. Although there are no strict guidelines, it may be beneficial to proceed with endometrial sampling for abnormally thickened endometrium in these patients as well, especially when morcellation is anticipated. In our practice, we perform a routine hysterosonogram and endometrial biopsy prior to any case that may undergo uterine or fibroid morcellation regardless of their presenting symptoms.

Yet, even with appropriate pre-operative evaluation, an endometrial cancer can remain undetected and inadvertent morcellation and dissemination of malignancy can, rarely, occur. In a study evaluating 708 women undergoing hysterectomy for pelvic organ prolapse (i.e. benign disease), five patients had pathologic diagnosis of endometrial cancer (0.6 %) and 4/5 of these cases had normal preoperative screening [41]. Finally, a case report out of Duke University Medical Center in 2013 describes a case where laparoscopic hysterectomy was performed with morcellation after an endometrial curettage with frozen section was negative for malignancy. The morcellated specimen was evaluated by pathology and was also found to be negative for malignancy. Fourteen months later, the patient had left lower quadrant pain and a persistent cough and was found to have evidence of metastatic disease on PET-CT. Biopsy showed grade three endometrioid adenocarcinoma. The differential included unrecognized malignancy at the time of initial hysterectomy or malignant transformation of retained endometrial tissue or endometriosis after morcellation [42]. Despite these anecdotal examples, it is imperative to undergo strict and standardized pre-operative evaluation with all patients, especially when uterine morcellation is planned.

Other Tumors

Case reports of rare undiagnosed tumors that were morcellated have been reported as well. Upstaging of these tumors is possible, but due to low number, no incidence can be determined. In a case series out of the University of Pennsylvania, a series of 101 patients undergoing laparoscopic hysterectomy with morcellation was reviewed. In this series, one case was noted to have an atypical trophoblastic nodule with necrosis and myometrial infiltration, suspected to represent epithelioid trophoblastic tumor [43]. A case reported out of Drexel University revealed morcellation of a low-grade endometrial stromal sarcoma after laparoscopic supracervical hysterectomy for abnormal uterine bleeding. This patient had a benign pre-operative dilation and curettage. She was transferred to a gynecologic oncologist who performed a laparotomy, bilateral salpingo-oophorectomy and removal of the cervical stump as well as debulking of extensive sarcoma throughout the pelvis that was not seen on initial laparoscopy. The authors concluded that morcellation of the tissue likely accelerated the spread of the disease [44]. It must be recognized that these are anecdotal cases. While in discussion with patients, the risks must be noted but it should

be recognized that the likelihood of morcellation of these tumors is rare, especially if age stratification is recognized and the patient is properly evaluated.

Leiomyosarcoma

Of greatest concern is the inadvertent morcellation of a leiomyosarcoma. Leiomyosarcoma is the most common malignant nonepithelial tumor of the uterus [45] representing 1–2 % of all uterine malignancies [46]. It is an aggressive malignancy with 5-year survival rate of 18.8–65 %. It typically affects women in the perimenopausal years with a median age of 52 years and is very rare in women below the age of 40. Leiomyosarcoma presents as a solitary, fleshy and necrotic intramural tumor [47] in patients noting uterine enlargement, pain, a sensation of pressure, abnormal uterine bleeding or a lower abdominal mass. The classic sign of this malignancy is a rapidly growing uterus; however, because it is uncommon, only 0.23 % of patients with this finding will have leiomyosarcoma [48]. Preoperative diagnosis is challenging because the symptoms and the clinical appearance associated with leiomyosarcoma are nearly identical to benign leiomyoma. MRI with diffusion-weighted imaging and PET/CT with F-FDG have both been evaluated in the pre-operative diagnosis of leiomyosarcoma [49, 50]; however, neither has been sufficiently proven to offer accurate diagnosis. Utilizing serum lactate dehydrogenase (LDH) and its isoenzymes, especially isozyme type 3, has also been utilized to distinguish leiomyosarcoma from benign leiomyoma and is a promising technique. The correlation was first seen in a series of 1886 patients who underwent hysterectomy for uterine myomas, 7 of which were found to have leiomyosarcoma. Three of these 7 patients had an elevated LDH and these 3 patients had tumors with worse prognostic factors [51]. In a follow up study evaluating 10 patients with leiomyosarcoma and 130 patients with degenerated leiomyoma, all patients with leiomyosarcoma had elevated total LDH and LDH isozyme type 3. When LDH was combined with MRI, the specificity, positive predictive value and negative predictive value were all 100 % in this particular study [52].

Despite these findings, there is no formal recommendation to use specific labs or imaging to pre-operatively diagnose leiomyosarcoma. At this time the only way to accurately distinguish a leiomyosarcoma from a benign leiomyoma is through histologic evaluation with leiomyosarcomas revealing coagulative tumor cell necrosis, moderate to severe cytologic atypia and numerous mitotic figures [47]. However, in our practice we will utilize serum LDH and/or MRI based on individual patient findings. We do not obtain them on all patients with fibroids; however, if a patient is at an increased risk for a leiomyosarcoma, we may consider using these diagnostic modalities. High risk patients include perimenopausal patients with any sized fibroid, a fibroid that is rapidly growing or has been present for an unknown amount of time, or a fibroid that looks suspicious on ultrasonography. Of note, in the few patients in our practice that had elevated LDH and LDH3 levels pre-operatively, the final pathology was benign.

An updated series on uterine leiomyosarcomas was published in 2013. In 198 patients with leiomyosarcomas over 10 years the presenting symptoms varied. Eight percent were incidental, 29 % of patients had menorrhagia or abnormal uterine bleeding, 25 % had pelvic pain, 17 % had postmenopausal bleeding, 19 % had abdominal fullness and 4 % had an unknown presenting symptom. Of the patients who had preoperative endometrial sampling, only 46 % were suggestive of leiomyosarcoma. The mean tumor size was 10 cm. The median disease free survival and median overall survival for women with stage 1 were 37 and 75 months, stage 2 were 23 and 66 months, stage 3 were 10 and 34 months and stage 4 were 3 and 20 months respectively [46].

There are currently nine studies in the literature on unsuspected leiomyosarcomas in patients who had a hysterectomy or myomectomy for presumed benign disease [52]. The rate of leiomyosarcoma in these studies ranges from 0 to 0.49 % with the average being 0.18 % [53]. The FDA recently released a statement quoting the incidence to be 1 per 350 or 0.29 % [54]. This incidence has been challenged by Elizabeth Pritts, et al. at the FDA meeting. Her more extensive evaluation of the literature was correlated to a much lower risk of leiomyosarcoma.

Morcellating these unsuspected malignancies can result in upstaging and a worse prognosis [55, 56]. In a comparison of 56 patients with LMS, 25 with and 31 without morcellation, tumor morcellation was significantly associated with poorer disease free survival ($p = 0.043$), higher stage (I vs. II, $p = 0.037$) and poorer overall survival (0.040). It was also found that the percentage of patients with abdominopelvic dissemination was significantly greater in patients with tumor morcellation (44 % vs. 12.9 %) [55]. Of course, one must always question whether the patients were originally staged adequately. In a review out of Sloan Kettering, four patients who underwent completion operations after laparoscopic morcellation of an unknown malignancy were evaluated. One patient had uterine endometrioid cancer and three had uterine leiomyosarcomas. Two of the three leiomyosarcoma patients were upstaged from stage one to stage three. The patient with uterine endometrioid cancer with stage 1B disease was not upstaged at reoperation [56]. Another retrospective study of 58 patients, 19 of whom underwent morcellation, showed a significant increase in the risk of abdominal/pelvic recurrences and shorter median recurrence-free survival in patients with unsuspected leiomyosarcomas who underwent intraperitoneal morcellation [57]. Oduyebo et al. reviewed 21 patients with the diagnosis of leiomyosarcoma or uterine smooth muscle tumors of uncertain malignant potential (STUMP) after morcellation. Twelve of these

patients had re-exploration surgery and 28.5 % of the leiomyosarcoma patients and 25 % of the STUMP patients had findings of disseminated intraperitoneal disease [58]. Yet, despite these reports, this data is still limited and controversial. In a systematic review of six studies, data seemed to be highly biased and of poor quality, resulting in the author's conclusion that there is no reliable evidence that morcellation significantly results in tumor upstaging or in poorer patient outcome. There is also no evidence from these studies that power morcellation affects patient outcomes differently than any other type of morcellation, or even simple myomectomy [59]. Finally, in a decision-tree analysis using base-case estimates, a lower overall mortality rate is seen with laparoscopic hysterectomy with morcellation versus abdominal hysterectomy for the treatment of presumed fibroid uterus in premenopausal women. Although there were more deaths from leiomyosarcoma after laparoscopic hysterectomy, there were more hysterectomy-related deaths with abdominal hysterectomy as well as higher rates of transfusion, infection, thromboembolism and hernia [60].

Updated FDA Recommendations

Due to these controversial findings and reports, the FDA put out a statement discouraging the use of power morcellators, citing safety concerns, mostly the inadvertent dissemination for occult uterine cancer in patients undergoing hysterectomy and myomectomy for presumed leiomyomata. They state that morcellation is contraindicated in peri- or postmenopausal women or in anyone where an alternative form of specimen removal can be performed [54]. According to the SGO, morcellation is contraindicated in the presence of a documented or highly suspected malignancy and may be inadvisable in premalignant conditions or risk-reducing surgery. They quote other options to intracorporeal morcellation including removing the uterus through a mini-laparotomy or morcellating the uterus inside a laparoscopic bag [61]. The AAGL states that when comparing the risks involved in open hysterectomy versus those of power morcellation, gynecologists should improve but not abandon power morcellation, and that power morcellation with appropriate informed consent should remain available to appropriately screened, low risk women [62].

Contained Morcellation

Due to these recent reports, the method of morcellating in a laparoscopic specimen retrieval bag has been proposed. Cohen et al. released a feasibility study in September 2014 reporting 73 successful cases of morcellation of uteri or myomas with and insufflated bag. There were no complications in this report and no visual evidence of tissue dissemination outside of the isolation bag. The bag used in this case was developed by one of the authors specifically for this use [63].

At our institution, we have performed contained in-bag morcellation since May 2014. We use the EcoSac230 bag made by Espiner (Fig. 15.11). Our standard technique is as follows: the bag is inserted through the umbilical port (Fig. 15.12) and the specimen placed inside (Fig. 15.13). The cinched bag edge is pulled out through a 15 mm umbilical incision (Fig. 15.14) and a 12–15 mm trocar is replaced into the bag through the pulled-up bag edge (Fig. 15.15). The bag is insufflated to 25 mmHg allowing a bladed lateral trocar to be placed through the bag (Fig. 15.17). Ideally, this trocar should have balloon on the end, which is then inflated and pulled against the abdominal wall to prevent leakage of insufflation or tissue (Fig. 15.16). The 5 mm laparoscope is used through the lateral port for visualization. The umbilical trocar is removed and the morcellator is placed through this incision into the bag under direct visualization (Fig. 15.18).

Fig. 15.12 Inserting the Espiner EcoSac 230 bag through the umbilical port

Fig. 15.13 Specimen placed inside Espiner EcoSac230 bag. The bag is ultimately cinched closed and pulled up through the umbilical incision

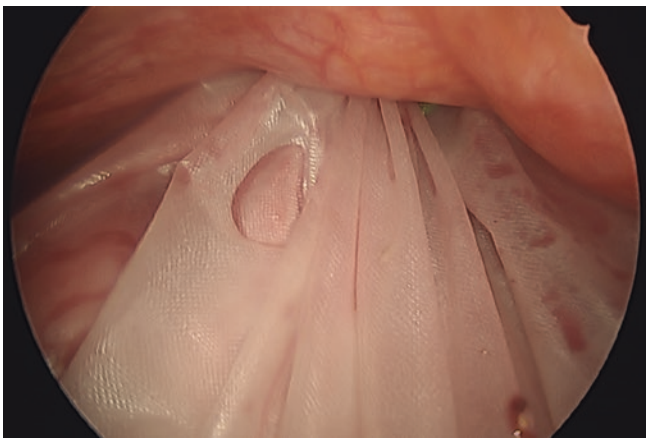

Fig. 15.14 The bag is cinched closed and pulled up through the umbilical incision

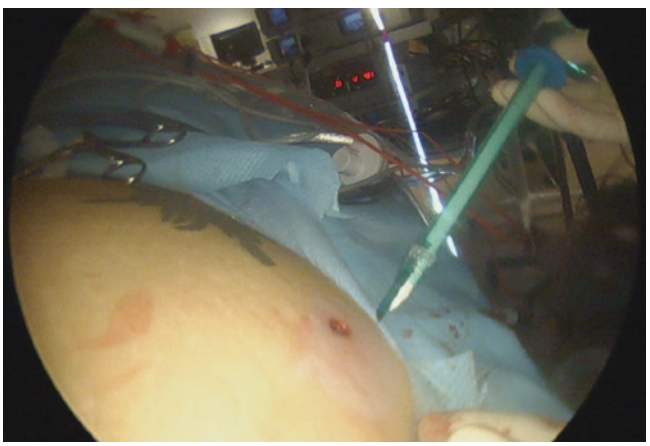

Fig. 15.16 A lateral trocar is placed inside EcoSac230 bag after bag is insufflated to 25 mmHg. This trocar should be bladed to allow adequate puncture of the bag. This is inserted under direct visualization through the umbilical trocar prior to placement of the morcellator

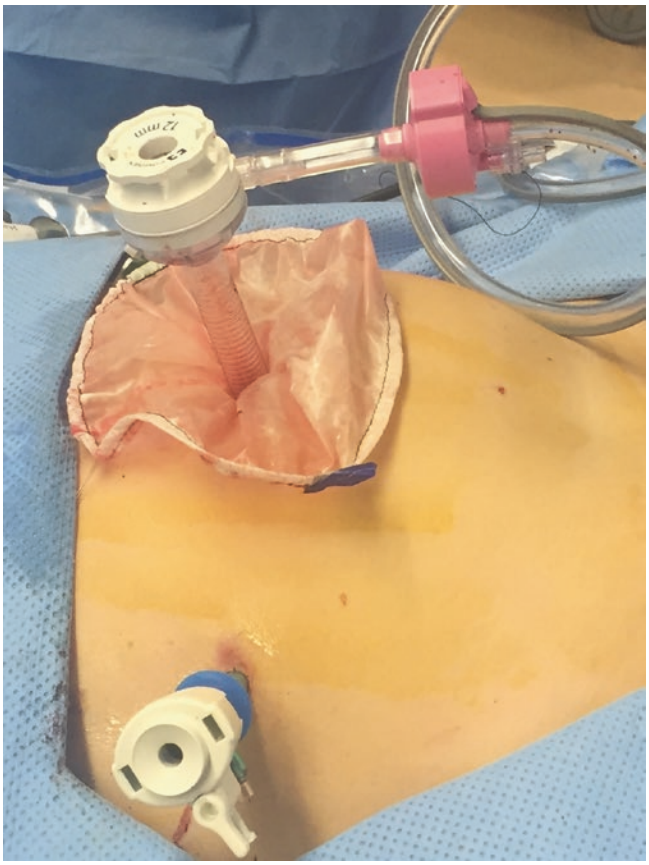

Fig. 15.15 The umbilical trocar is replaced into the bag through the pulled-up bag edge. Insufflation is then attached to this trocar and the bag is insufflated to 15 mmHg

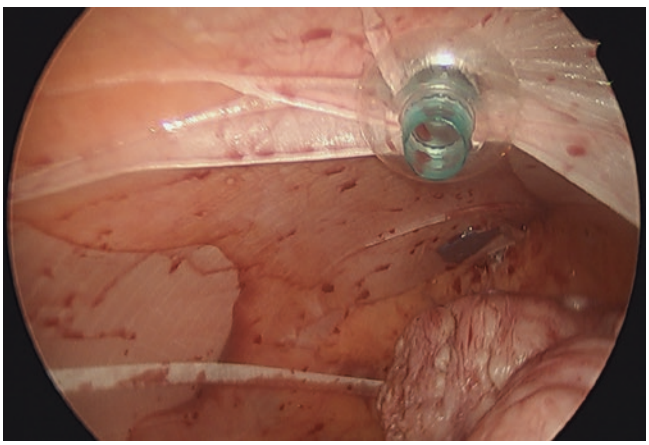

Fig. 15.17 The lateral trocar seen through the bag. The balloon on the end of the lateral trocar is inflated and pulled against the abdominal wall to prevent leakage. This trocar is now used for the laparoscope

Fig. 15.18 The umbilical trocar is removed and replaced with the morcellator. The morcellator is placed through the umbilical incision into the bag. This is done under direct visualization using the laparoscope in the lateral port

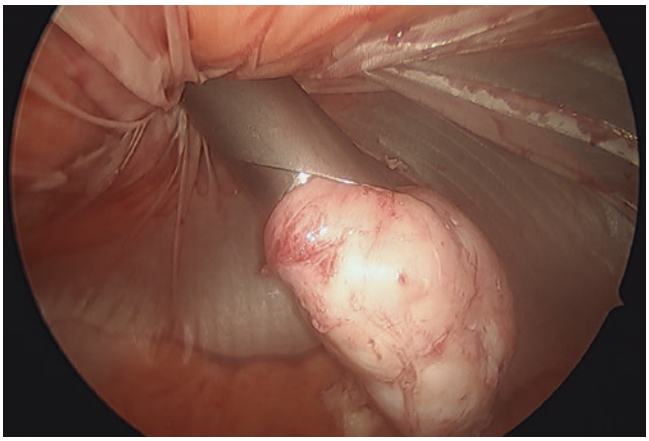

Fig. 15.19 Morcellation occurring with the Storz Rotocut G1 Morcellator. The 5 mm laparoscope is utilized for visualization from the lateral trocar

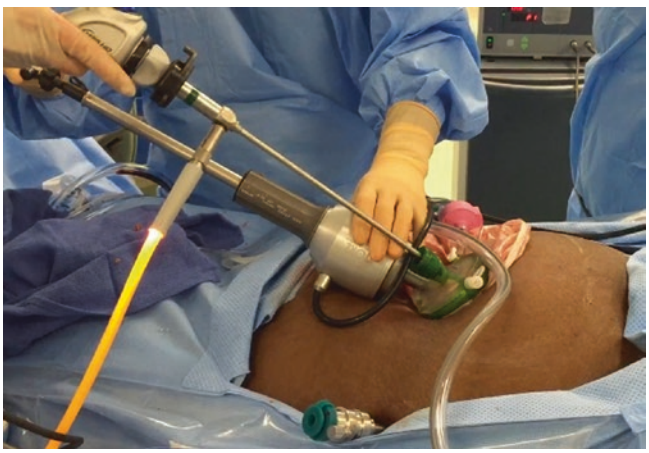

Fig. 15.20 Abdominal set-up of the GelPOINT Mini Advanced Access Platform with the 5 mm laparoscope and the Storz Rotocut G1 Morcellator

Morcellation is then performed through the umbilical incision (Fig. 15.19). We have successfully used this technique in over 90 patients, 27 % of which have been hysterectomies. Our average specimen weight was 288 g, with the largest specimen weighing 2134 g, proving the efficacy of this technique even with larger specimen.

In order to avoid puncturing the bag with a lateral trocar, we have developed another technique of contained in-bag morcellation utilizing the GelPOINT Mini Advanced Access Platform made by Applied Medical. This technique allows the EcoSac230 bag and the laparoscope to both be inserted through the GelPOINT platform simultaneously. It necessitates a slightly larger umbilical incision of 25 mm to allow insertion of the Platform, but prevents the creation of an extra hole in the bag for laparoscopic visualization (Fig. 15.20).

Other institutions are using previously manufactured specimen retrieval bags with insufflation for morcellation under direct visualization. Many studies regarding this new method of morcellation are currently in progress across the country. There are also new specimen bags being developed specifically for this purpose which are under investigation. No FDA approval on the use of specimen retrieval bags for morcellation has been obtained at this point.

Patient Counseling/Informed Consent

When considering morcellation in conjunction with hysterectomy, it is prudent to provide adequate patient counseling. The discussion with the patient should be open, honest and all questions should be answered. The technique of morcellation should be described as well as the reason for performing morcellation. It is important to discuss the risk of underlying malignancy tailored to the individual patient. In appropriate patients, the reasoning behind pre-operative evaluation can be reviewed. It is imperative to include the risk of leiomyosarcoma in this discussion. It should be

noted that the precise incidence of this malignancy is unknown but a risk estimate of 1/350 is quoted by the FDA [54]. The aggressive nature of the tumor as well as the possibility of upstaging due to morcellation leading to a worse prognosis should be reviewed. It may also be beneficial to discuss the recent decision-tree analysis concluding that there are fewer predicted overall deaths with laparoscopic hysterectomy with morcellation compared with abdominal hysterectomy [60]. The possibility of dissemination of benign tissue to should be included in the discussion as well. Once this discussion is complete, any methods to avoid complications involving uterine malignancy should be reviewed. This includes the possibility of morcellation in a bag. The patient should be aware that there is no literature proving the efficacy of contained morcellation at this time, but there are many studies in progress. If vaginal morcellation is feasible, this can be offered to the patient as well. The patient should also be offered an alternative to morcellation, which would be to create a mini-laparotomy, laparotomy or colpotomy to remove the specimen. The size the incision can vary based on the size of the specimen. With any larger incision, the patient should be aware that her recovery time will be longer, pain will be greater, and she will have a higher risk of infection and other morbidities. Once this discussion is complete, specific consent forms allowing for uterine morcellation should be reviewed and signed with the patient [64].

Conclusion and Recommendations

In conclusion, morcellation is an effective way of removing a large specimen via a minimally invasive approach. Manual morcellation can be performed vaginally, through a culdotomy or abdominally but is often time consuming and laborious for the surgeon. Power morcellation may improve surgeon ergonomics and spare time; however, it has controversial complications. Proper visualization of the blade and surrounding tissues should be employed at all times. Care should be taken to remove all morcellated fragments from the abdomen. When possible, the use of a laparoscopic bag may be beneficial during power morcellation to avoid dissemination of tissue. Other techniques to reduce complications include handing the tissue to the tenaculum as opposed to reaching with the tenaculum, using an atraumatic "spoon" forceps when retrieving small fragments, keeping the longer portion of the beveled sleeve more anterior and being sure to consistently maintain sufficient pneumoperitoneum [13]. Appropriate pre-operative work up is essential when planning on potential morcellation in order to exclude pre-existing uterine malignancy. If malignancy is found incidentally after morcellation, the patient should be immediately referred to a gynecologic oncologist [52]. Finally, patient counseling and education is prudent when planning on utilizing the benefits of morcellation. Informed consent should always be addressed and any patient concerns or questions should be attended to in detail. Most importantly, surgeons should always have proper training and sufficient surgical experience prior to entering a case with the potential need for power morcellation.

Surgical Education and Training

Learning by Doing: How to Teach Hysterectomy

16

Carolin Spüntrup, Marc Banerjee, and Elmar Spüntrup

The Hippocratic oath reminds since more than 2000 years to heal patients to the best of knowledge and to impart knowledge to the next generation. Over centuries history showed that individual ethically and morally understanding as well as motivation for education are adapted to external factors – advantaged by base motives as personal professional advancement or the uncritical acceptance of specific ideologies. Dreadful experiments using living human being were performed and legitimated by the pretended scientific benefit.

Following the ideals medicines should hold for: Medical knowledge is common knowledge – it should be denied neither patients nor younger colleagues. Medical education of younger colleagues must be carried out in an ethically and morally acceptable way and always with the focus on the benefit of patients.

Introduction

For century's surgical education based on a learning-by-doing apprenticeship model using a high patient volume to teach the residency step by step certain surgical skills under various levels of supervision. Mistakes and costs resulting from the trainee's learning curve were accepted by the society [1].

Today a couple of factors limit this traditional model: surgical procedures have become more complex and specified resulting in a reduced patient volume for certain operation morally and ethical aspects came into focus, the acceptance of the society concerning medical mistakes has changed and finally financial aspects especially concerning operation time, complication rate as well as time and costs for a surgical education came more into focus of both, society as well as surgeons (Fig. 16.1) [1].

Several studies analysed the influence of repetition of specific interventions to iatrogenic injury and found an association between number of repetitions and declining injury rate (Fig. 16.2). But also other associations were found correlating to repetition such as operative time, operative result etc. This indicates that repetition is a central factor for the surgeons learning curve and how complex and multifactorial the process of operative learning is.

Considering these factors it seemed likely to establish a new surgical education system which includes a repetitive step by step education of complex operations under ethical, morally and financially more acceptable conditions.

Educational Concepts

The idea to update the traditional apprenticeship-model is not new. Over the past century several proposals were reported how to innovate the traditional system [2]. The American Bord of surgeons complained in 1916 that the traditional apprenticeship model does not result in a broad and well-grounded surgical education respectively the operative quality [3]. To improve surgical education, some American universities introduced surgical education programs including refresher courses in anatomy, pathology, biochemistry and skill training using cadavers and animals before residents performed operations in real patients [3].

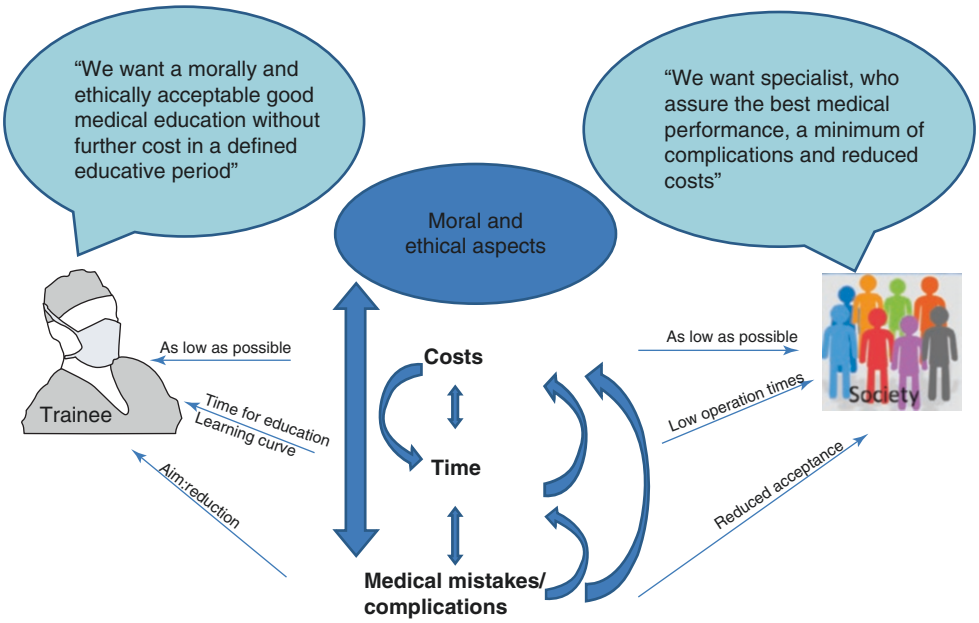

Fig. 16.1 The dilemma of surgical education

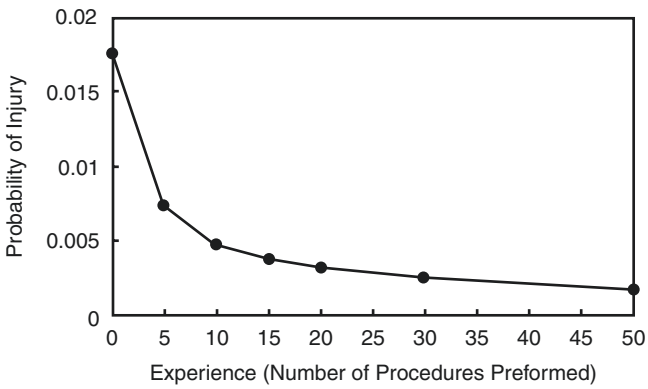

Fig. 16.2 Typical example for the decline of a learning curve. Instead of probability of injury also time for the performance of a specific task could be chosen (compare Fig. 16.4a) (From Rogers et al. [25])

With regard to the success of simulated training for pilots, surgical training in a simulated environment came more into focus and is meanwhile one of the central parts of innovative surgical trainings-models [4, 5]. In pilot trainings difficult situations, e.g. a clear defined storm of certain intensity hits the airplane and induces some damages. The pilot trainee learns how to handle this situation in a simulated, not life threatening environment. By repetition he will develop mental schemes and he will also increase psychic stability to manage these extreme situations in case of real occurrence. Modern findings of behavioral cognitive sciences describe a couple of modifications which can be used as variances to reach specific aims in such pilot trainings-schedules [6]. Theoretically similar schemes could be adopted for a surgeon to handle different situations e.g. the step-by-step training of a routine hysterectomy or a complication occurring during a hysterectomy. Technically it is already possible to simulate a couple of difficult intraoperative situations with some of the existing trainers presented later. In reality for a resident it is still not a routine to train such situations on a simulator [4, 5]. The main difference between education of pilots and surgeons is that pilots *must* undergo trainings units while surgeons do it optional. This is reflected in the fact that airlines bear the expenses for pilot training while surgeons often have to come up themselves for the costs. Surgical admission boards mostly do not demand a participation in simulated training to reach a certain educational level. The associated high costs for the trainees as well as the volunteer status of simulator training are probably reasons why still no widespread educational concept has been accomplished.

Behavioral Sciences and Surgical Training

Behavioral sciences analyzed the complexity of learning in several fields and defined specific terms for learning processes [7]. From a behavioral point of view experts are characterized by cognition in a certain field. Cognition itself is composed of several factors: perception, attention, information processing, information storage (including organization), and then retrieval from long-term memory at the appropriate time as "knowledge" which helps the individual make their decision [5, 8].

Gallagher emphasizes the value of attention for surgical learning [5]. Attention of an experienced surgeon will focus the intraoperative progress searching the best way of operation to minimize the individual patients risks and possible complications while the novices attention is focused –depending on his educational level- on basics, such as anatomical orientation or guiding his instruments etc. [5]. It has been proposed that simulators can help to reach the point where many of the psychomotor skills (e.g. hand-eye coordination) and spatial orientation have been automated. This process is called "shap-

ing" in a behavioral sciences sense. It generates new resources of attention for the trainee [5] and allows the trainee to focus more on learning of the operation steps itself or the management of complications [4, 5]. Figure 16.3 outlines behavioral aspects focusing the aims of surgical learning, the pathways of internalizing and mediums to optimize the processes.

Manual Dexterity

Teachers often subjectively report on talented surgical trainees and it must be contributed that even in the eyes of experienced surgeons some colleagues stick out by performing difficult procedures with a phenomenal ease. Talent in its usual sense meaning a pre-existing manual dexterity seems to be useful but not a precondition to become a good surgeon [4, 5]. For endoscopic knotting and suture techniques it was found that the influence of concomitant factors which might influence the talent of manual dexterity is of less importance (Fig. 16.4a, b) [9]. Only during the first five procedures individuals, who trained their bimanual dexterity before (e.g. by playing guitar, knitting or former endoscopic experience for more than 10 h) but were novices concerning self-performed endoscopic operations, had a significant advantage concerning knotting times. Learning curve improved most remarkably during the first five procedures. Afterwards a kind of steady state is reached without a further significant improvement of knotting time for the individual surgeon and an adaption of knotting times between all individuals is found (Fig. 16.4a, b) [9]. Thus it is proposed

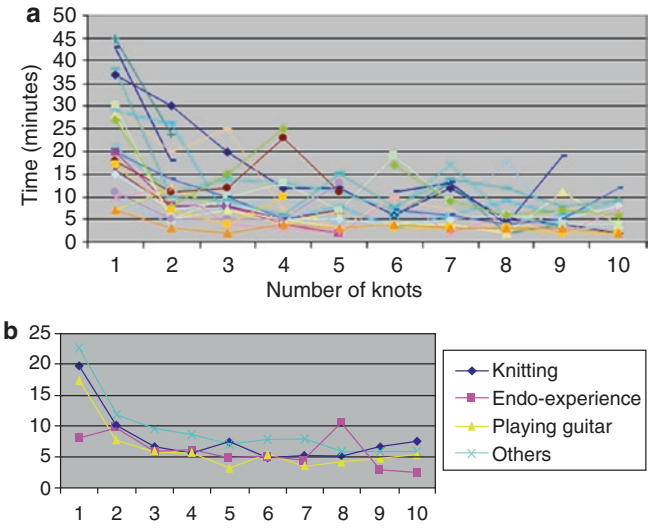

Fig. 16.4 (**a**) Repetions and times of the first 10 knots of novices (each *color lines* one novice). (**b**) Novices, who played guitar, had experience in endoscopic assistance or knitted started on a faster niveau of time for each knot. These findings adapted after 5 knots

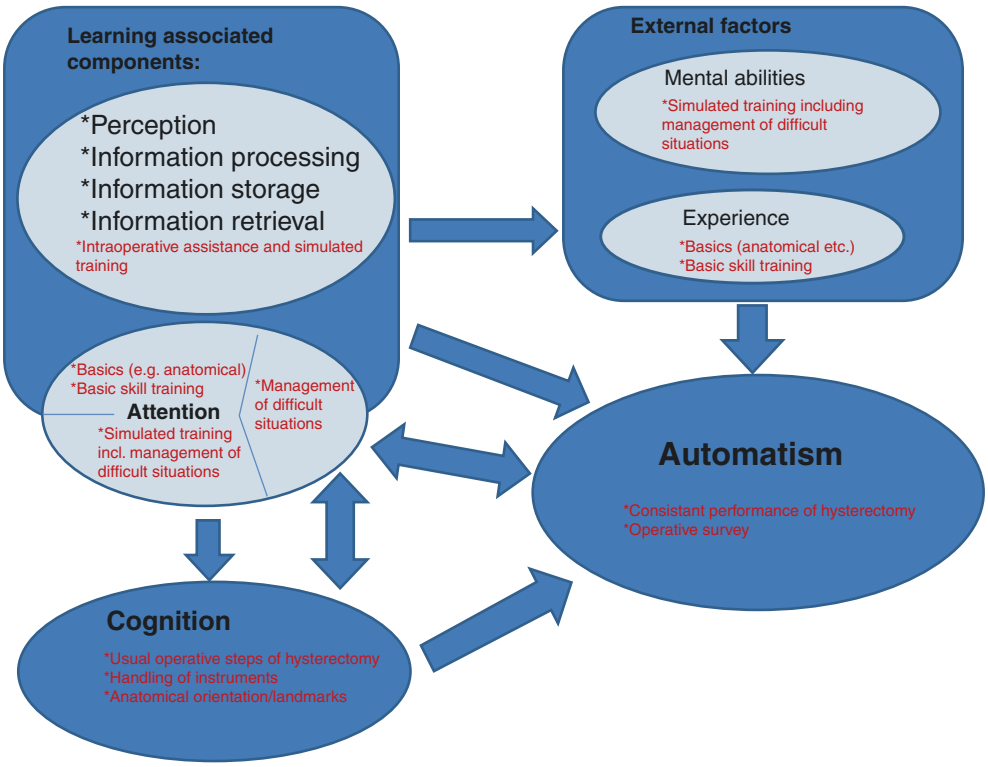

Fig. 16.3 Behavioral aspects of endoscopic learning. In a behavioral sense of learning, automatisms for a specific tasks are the designated learning aim. Several components influence the generation of automatisms. The graphic summarizes the influence of superior components (*black, bold face*), subitems (*black*) and related endocsopical trainings levels (*red*). Attention is a central point for developing automatisms and the focus of attention changes in correlation to the trainees educative level

that surgical manual dexterity concerning knotting is not a specific talent. It can be improved after a few repetitions and interindividual differences will adapt over time.

Gallager and Satana [10] reported about three trials on a virtual reality trainer comparing the surgical skills of novices (no experiences), juniors (10–100 operations) and experts (more than 100 operations). Also in this study surgical basic skills adapted after three trials, but novices and experts showed a very different behavior concerning the instrumental activity: while the experts used electrocoagulation rather conservative and situate adapted, the novices ignored alerts concerning thermic damages and did not change their behavior during the trials. Juniors tried to reduce the use of electrocoagulation after repeated alert [10].

Surgical Trainings-Aims

In accordance to these findings it has been estimated that the performance of a skillfull operation depends in 75 % percent in decision making and only in 25 % in manual dexterity [11]. Correct decisions require a good intraoperative survey and are compound by an excellent fact knowledge and other factors which are summarized under the behavioral scientific term "cognition". This weighting of the factor "decision making" changes former concepts of surgical skill training. Former concepts separated theoretical knowledge and practical skill training depending on individual trainings level. Theoretical knowledge included the theoretical knowledge of anatomic landmark, operative steps etc. The education of practical skills concentrated in exercises for the hand-eye coordination. Not before the performance of operations in living patients both components were united. Newer trainings programs allow focusing on the togetherness of components, fact knowledge and practical training [4, 5, 11, 12]. They respect the complete field that influences intraoperative decisions. Theoretical and practical aspects of operations are thus more joined even on an early educative level (Fig. 16.5).

Accordingly new trainings aims base on a entirety concept focusing both, operation specific practical knowledge (manual dexterity, guidance of instruments, intraoperative details etc.) and theoretical knowledge (anatomical, pathological, bio-

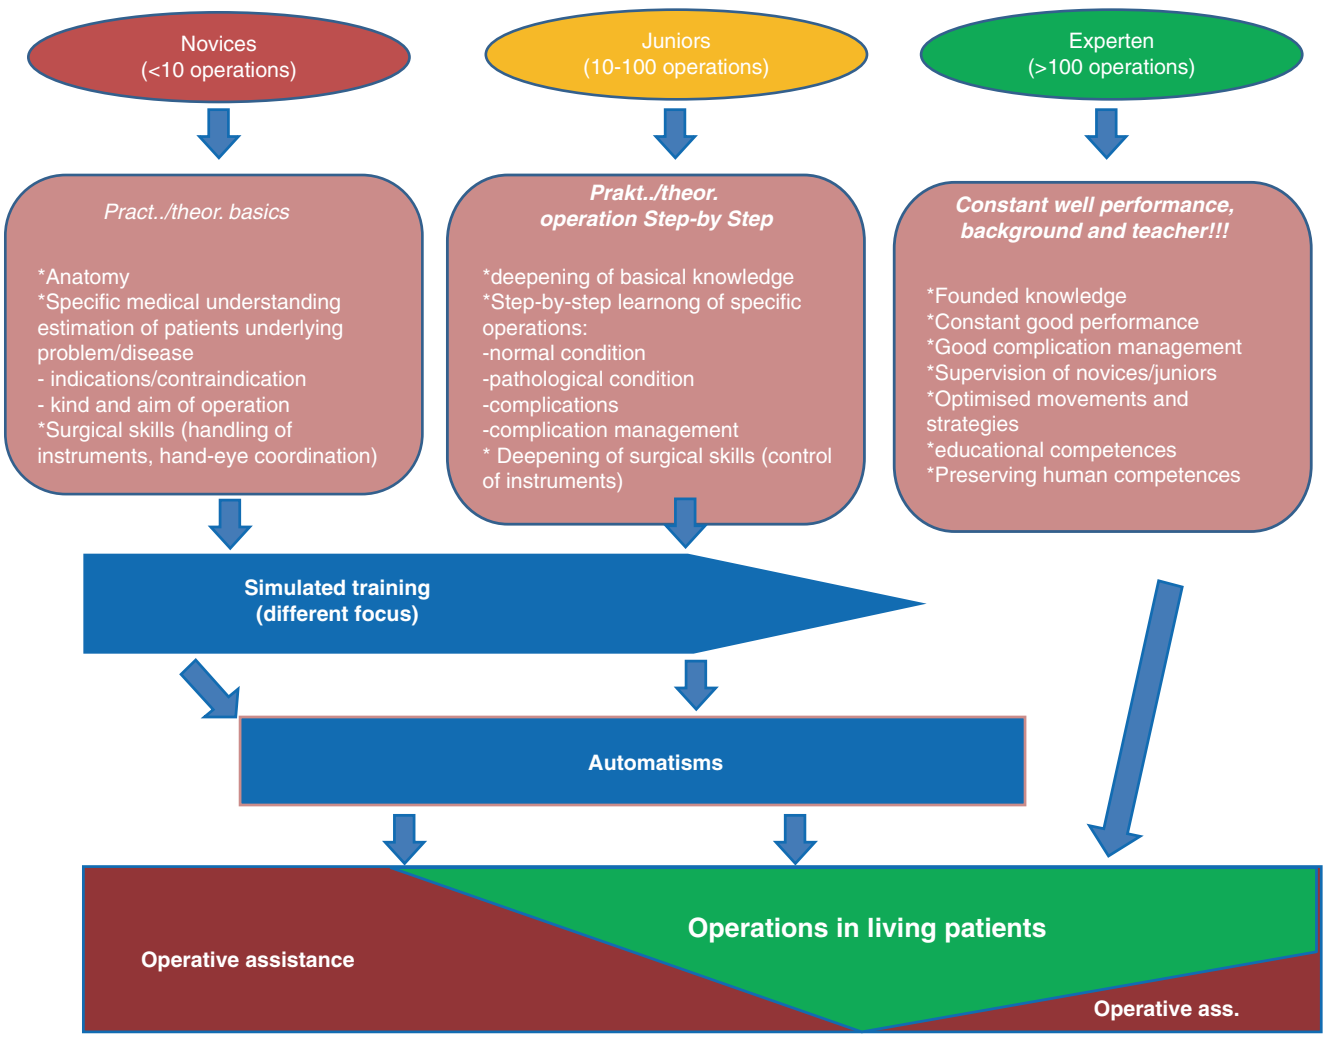

Fig. 16.5 Learning aims of novices, juniors and experts. Simulated training (with different trainings aims) decreases with rising trainings level and generation of automatisms

chemisty, theoretical knowledge on procedure etc). Trainings aims are correlated to the individual trainings level [2, 12–14]. The tripartitude into novices, juniors and experts is a recurrent classification in literature and seems suitable to summarize trainings aims for an entirety concept (Fig. 16.5) [5, 10, 13].

Novices are unexperienced in all respects. For novices trainings aims are the implementation of automatisms concerning basics: anatomical basics, intraoperative anatomical orientation, handling of the surgical instruments, understanding of the aim of the surgical procedure (that means why is the procedure done, how is it done and what is the final aim) [5, 10, 13].

Juniors are low experienced with a beginning survey on operative procedures. Defined subordinated targets can be accomplished. The trainings aims of juniors are the implementation of automatisms concerning the single steps of a certain operative procedure, internalizing specific subordinate targets and the control of instruments. With an increasing experience on the way to become an expert, juniors will also learn automatisms concerning pathological situation, complications and other difficult intraoperative situations [5, 10, 13].

Experts (more than 100 procedures) featured automatisms for operative basics, have a founded knowledge and internalized pathways for many intraoperative situations. Intraoperative movements and activities are optimized, with a clear defined final aim and several sub-ordinate targets, knowing and respecting the consequences of each movement and activity. In case of complications the expert acts more calm and stringent in order to return to the "normal" operative pathway. For the definition of trainings aim the priority aim should be to reach this expert level with optimized and constant performance as well as a reduction of errors [4, 5]. The aims of experts are finally to optimize the education of novices and juniors as well as to supervise operation in real patients and help in case of problems (Figs. 16.5 and 16.6) [4, 5, 12, 13].

Associated Factors for an Optimized Training and Opportunities for Efficiency Control

Concerning an optimized trainings scheme for the ideal implementation of trainings aims the distributed short interval training has been described as more effective than single long sessions. According to behavioral sciences the cognitively implementation of surgical skills is better consolidated, if an interval between training is realized [5, 15]. In practice this means that e.g. a splitted overnight training (afternoon session on one day and morning session on the next day) is more effective than a complete one day training (morning session and afternoon session on the same day).

Feedback mechanisms and similar control respectively test tools visualizing the success of simulated training seem to be useful. The trainee gets information whether he has reached the accomplished trainings aims. Depending on the system mistakes are pointed instantly and can be reduced by repeated training [8, 11].

Test systems additionally provide a good tool for the trainers to assess whether the trainee is able to reach the next level. This can be also used for the award of a certificate. Trainees who verify their ability of successful performance of a specific operation before they start performing supervised operations in real patients will reduce operation time and complication rate in an ethical acceptable way [1, 4, 5, 15]. For the daily routine this could ease the disposition of operators and maybe also benefits the mutual trust between patient and surgeon.

Several predictors have been tested as control systems for the estimation of learning success in simulated trainers. Time is not only influenced by experience but also by quality and is therefore as a single item not a good predictor [5, 16]. The number of required repetitions for a specific task is also not a good predictor. Basically surgical skills are reproductive acceptable after about three repetitions. Concerning more

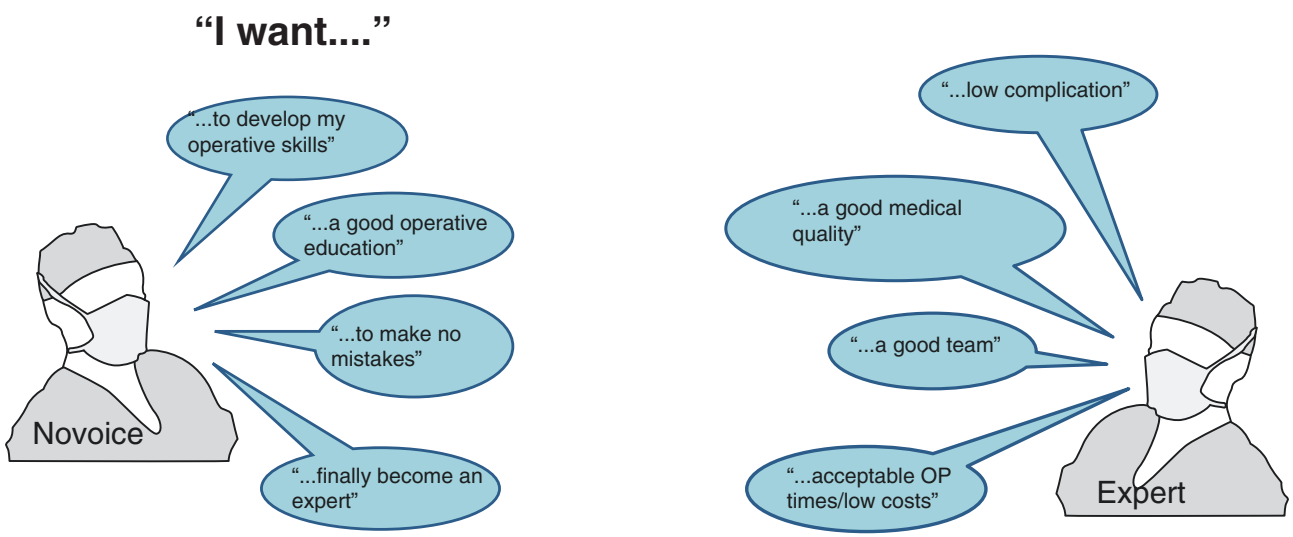

Fig. 16.6 Claims on surgical education from different points of view (pict.: pixabay)

complex tasks (e.g. a complete operative procedure with the need of a more distinguished efficiency control) the number of necessary repetitions depends on the individual trainee and does not reflect the quality of performance in detail. For those complex tasks the achievement of a certain degree of proficiency including a constantly well performance or the evaluation of relevant single items including mistakes is provided to be more useful [5, 13, 17]. Several factors such as the relation between time and accuracy or knowledge and manual dexterity influence the operative result. These factors are difficult to estimate objectively. For that reason predictors ideally should be measurable in any way. For the objective assessment of technical skills performance the economy of hand movements using an electromagnetically tracking system (ICSAD) [18] seems to be appropriate to differ between very experienced surgeons and less experienced surgeons. The system can be also used for open approaches. Other control instruments use more metric systems to objectify the trainee's performance, e.g. measuring the difference between the ideal puncture of a suture and the actual puncture. In combination with other factors (time etc.) a points-based system can be used for evaluation.

Trainings Concepts for Hysterectomy

In accordance to former surgical training systems and respecting behavioral findings concerning cognition, the adoption of an educational system with three levels (surgical basics, practical training on simulators and final education schedules in real patients) seems suitable [5]. The three levels are overlapping and respect the different start levels of trainees [novice, juniors (non-experienced and experienced), expert].

In detail the implementation of levels for a structured hysterectomy education comprises:

Surgical Basics

This educational stadium should be hallmarked by the aims of deepening anatomical, topographical and pathological knowledge of the pelvis minor and adjacent structures, an understanding of biochemical processes, knowledge about correct indications/contraindication for a hysterectomy including judicial consequences, basically management of complications (kind of possible complications, perception of complications, adequate therapy of complications, strategies to avoid complications) and a broad knowledge about the postoperative sequence in general. This stadium should be more than only a recapitulation of students-knowledge. Especially anatomical and topographical knowledge should be specifically considered under the operative aspect, e.g. using certain structures as landmarks, acquire a 3-dimensional idea of the course of the ureter and other structures etc. These aims can be reached by practical assistance and hospitation during operations and indications, refreshing the literature including modern opportunities such as videos, video animations etc. and participation in special courses. Hand eye-coordination and first steps in instruments handling can be improved by the use of simulators.

The stadium of *surgical basics* will have its maximum learning effect during the first years of residency but in fact learning effect of this stadium will attend throughout a doctor's life with a lower intensity and changing focus than during the first few years of surgical education.

Simulated Hysterectomy

Modern surgical simulators can be used to achieve more or less the following trainings aims:

- improvement of manual dexterity (also concerning single steps, e.g. suture of the vagina)
- continuing enlarging experience and fact knowledge (active use of the basic knowledge of stadium I, e.g. concerning the course of the ureter or identification of leading structures)
- induction of schemes and strategies for the solution of difficult situations by repeated hysterectomies in a not life threatening surrounding (e.g. how to handle intraligamental myoma etc.)
- accomplishing the steady state of the learning curve concerning hysterectomy before continuing stadium three
- improvement of operative survey including the knowledge to make quick and correct decisions
- making correct valuations of intraoperative findings (e.g. the valuation of endometriosis)
- finding strategies concerning prevention respectively management of iatrogenic complications
- performing examinations to verify certain levels of certification

It becomes feasible that the differentiation into novice and junior is important for the trainings aims of this level. Simulators are an effective tool for both group, but with a different focus. While the novice can improve his knowledge concerning intraoperative anatomical orientation, control on the surgical instruments, understanding of the aim of the surgical procedure (that means why is the procedure done, how is it done and what is the final aim), juniors will deepen their

skills concerning the implementation of automatisms concerning the single steps of a certain operative procedure, pathological situation, complications and other difficult intraoperative situations.

Most hospitals possess on box trainers so trainees have the opportunity to learn certain steps such as knotting/ suturing as well as the handling in general. Anatomical models of the pelvis are also often available and partly even integrated in the box- trainers. These trainings tools allow an advanced anatomical and topographical education. The complete imitation of hysterectomies, ideally with a simulated sick uterus (e.g. uterus myomatosus), will be more a subject of courses in specialized training centers, but at present the costs of such courses must be mostly beared by the trainee himself. It is of high importance, that – according to the pilot training- these specified courses focus on clear defined education aims which can be realistically achieved by the trainee during the course. Otherwise courses will only lead to a certificate- without a real surgical use to the trainee or finally to the patient!

The participation of courses in such institutions should be integrated part of this stadium. Several courses concerning hysterectomy are available focusing on different educational aims, e.g. deepening hysterectomy-specific anatomical and topographical knowledge (human cadaver courses), training of hysterectomy steps in general (hysterectomy of living porcs), advanced training of hysterectomy with simulation of different uterine diseases (intraligamental myoma, large uterus myomatosus, endometriosis etc.; Realsimulator), test instruments for estimation of surgical skill level (computer assisted systems). The different trainings systems will be précised later.

Training in Patients

In this educational stadium the trainee will continue his surgical hysterectomy education in real patients. In contrast to the traditional system the trainee will start making hysterectomies on a higher education level. That means that he has reached already a certain steady state of his learning curve and his attention can be focused on the essentials of hysterectomy. Combined with the supervision of an experienced surgeon a preferably simple hysterectomy (normal weighted patients without expected adhesions or complications) can be chosen. In case of any complication the experienced surgeon can either guide the trainee throughout the operation or can take over the hysterectomy. According to trainings-degree supervision by an experienced surgeon can be reduced step by step and degree of difficulty of the sick uterus can be elevated step by step until the trainee has reached a level to take the full responsibility even for expected difficult hysterectomies.

Training Systems

Several training modules are available today and it is difficult to get an overview about all existing systems. According to Munro et al., the division into organic (that means human cadavers or animals) and inorganic trainers (others) is adopted here and complemented by combined organic/inorganic trainers [1].

Most trainings systems have been developed for unspecific surgical intervention such as hand-eye- coordination or suturing techniques. With a new focus on surgical survey and the induction of automatisms for intraoperative decision making as trainings aims, the simulation of complete operations seems useful. Such high complex training systems have been developed for open abdominal, vaginal or endoscopical approach opportunities and offer theoretically a couple of interventional possibilities [19, 20]. These training systems partly allow the performance of “complete” operative procedures, such as access to operative field, specific operations and reconstruction of abdominal/vaginal wall. In practice these simulators are very expensive and most of the patented simulators obviously have not been produced in a broad mass.

Other simulators consist on vessels as well as on nerve simulations, so even defined complications are possible. The operative procedure itself is mostly simulated by the use of animal organs. For the simulation of surgical operations porcine gall bladder or porcine intestine are common used trainings-objects [1, 4, 5]. Porcine gall bladder and adjacent structures allow a realistic simulation of gall bladder extirpation including preparation of bile duct etc. Porcine guts system is favorited as trainings –tool for a couple of surgical interventions (resections, enteroanastomosis, use of staplers, suturing and knotting, endoscopic resections etc.) [1, 4, 5]. Simulators which allow the use of animal organs offer special equipment for fixation of the focused structures.

As the organic simulators are associated with some disadvantages (unpleasant odor, explanation of organs, no planned pathologies) during the last decades inorganic trainings moduls came more into focus. Concerning hysterectomy such simulators are still rare.

In the following section we give an overview over the existing training systems, which can be used to improve surgical skills regarding hysterectomy. Also a short interpretation is given for which purpose or trainings aim the presented systems are fitting (Table 16.1).

Table 16.1 Characteristics of different endoscopic trainings and education levels

	Anatomical/pathological details	HE simulation	Hand eye coordination	Infectious	Ethical vote	costs	Proportion HE: trainee	Planned Pathologies	Tests for certificates
Human Cadavers	Very good	+ (o,e,v)	+	Risk	(Agreement of patient)	++	1:3	Not planned	No
Living pigs	Partly comparable	+ (o,e)	+	Low risk	Yes	+++	1:3	Not planned	No
Box trainers	Not at all	–	+	Low risk	No	(+)	–	–	Yes
Advanced Trainers	Partly comparable - good	+ (o,e)	+	No	No	++	1:1	Partly yes	Partly yes
VRT	Very good if programmed	+ (e)	+	No	No	++++	1:1	Yes	Yes
Real Simulator	Good	+ (o,e)	+	Very low risk	No	++	1:1	Yes	Yes

Organic Trainers

Organic simulators are in common human cadavers or animals.

Human cadavers have been used as a teaching tool for centuries. Learning aims of hysterectomy courses using human cadavers are focusing on a recapitulation and deepening of anatomical and topographical details around the operated field on the one hand and the possibility of performing the steps of a hysterectomy on the other hand. The simulation of a hysterectomy is possible in all variations (vaginal, open abdominal, endoscopical, supracervical or complete etc.). Operative access is comparable to living patients. In general two to three persons learn on one human cadaver. Therefor not all trainees will perform a complete hysterectomy during the courses. A vascular perfusion of the cadaver to imitate blood flow is in most cases not realized. Nevertheless coagulation, ligation, sutures, morcellations , incisions and other steps, which are important during hysterectomy are similar to a real hysterectomy. Pathologies in the operative field can be used as a welcome special challenge during the course, but they cannot be planned.

Formaldehyde-based fixation techniques are not appropriate due to the rigid consistency of pelvic organs and abdominal wall and, thus, have to be replaced either by alternative fixation methods or the use of fresh frozen cadavers. Fixation procedures providing good conditions to perform open abdominal or laparoscopic procedures include embalming techniques based on ethanol-glycerin or Thiel fixation [21, 22]. Although the tissue properties (e.g. color, water content, consistency, mobility) still differ from the in-vivo situation, virtually all surgical procedures including the use of electrocautery and ultrasound devices are feasible applying these alternative fixation methods. Decision making, acquire operative survey, guidance of assistance as well as single steps (appropriate use of coagulation, preparation, sutures, hand eye-coordination etc.) are trainings aims which can be learned using this setting. Disadvantages of the use of human cadavers are the risk of transferring certain infections during the procedure and the partly unpleasant odor. The transvaginal access is sometimes limited either by natural factors as the higher age at the time of death (associated with narrow and thin walled vagina) or by a certain disgust of the trainees.

Simulation on Animals

Animals, either living or death, were used for medical learning and education purposes since antiquity. Claudius Galenus performed a couple of sections in different animals (e.g. neurolysis in pigs, study of organs in elephants).

For hysterectomy trainings the uterus of pigs seems to be most qualified, as the size and adjacent structures are tolerably comparable to real patients. Operations on living pigs allow a perfusion of the uterus, which makes the operation more realistic. Haptic, color, admittance (at least open abdominal or endoscopic) are similar to operations in real patients. All intraoperative steps including admittance, complete steps of hysterectomy and closing the admittance are possible.

Decision making, acquire operative survey, guidance of assistance as well as single steps (appropriate use of coagulation, preparation, sutures, hand eye-coordination etc.) are trainings aims which can be learned using this system. In living pigs the trainee gets a comparable intraoperative feedback concerning his operative behavior (e.g. via the anesthesist etc).

Limiting factors are the necessity of a positive ethical votum for each course and the high costs of each pig. In living pigs for ethical reasons pigs must get a general anesthesia. In most courses two to three trainees will operate one pig, so not all participants will operate a complete hysterectomy themselves. In general, animals will die after operation. Pathologies cannot be planned. Anatomic and topographic details are only partly comparable to human beings. The risk of zoonosis exists, but is small.

Inorganic Trainers

Inorganic trainers can be divided into classical box trainers, advanced trainers and virtual reality systems (VRT) with the subgroup of robotic assisted VRT's. Most inorganic trainers refer more to the endoscopic approach, but also allow at least an open abdominal access. Some trainers are even equipped with a vagina.

Box Trainers (Fig. 16.7)

Classical box trainers are characterized by a kind of box covered by an exchangeable layer, which simulates the abdominal wall. The box includes possibilities for fixation of artificial layers, structures or even simulated organs. Box trainers are widespread trainings tool and are available in most hospitals. In general they are not associated to a certain operative field. Thus trainee can learn basic steps such as admittance, hand-eye coordination, instrument handling or knotting and suture techniques.

Fig. 16.7 Box Trainer and fitting inlay for hand-eye coordination and suture -knitting skills (By courtesy of Erler-Zimmer)

Advanced Trainers

Advanced (endoscopic) trainers allow the fixation of operative inlays for specific operations. Some endoscopic advanced trainers are additionally equipped with USB connections to overcome the problem of optical system. Genuine endoscopes are no longer necessary to learn on the simulator but it is possible to adapt the integrated camera e.g. to the own computer or laptop. Often a mannequin form is chosen with openings on the upper or lower abdomen. Access ports are either determined or can be chosen free on a complete flexible abdominal wall. Operative inlays consist on all important structures and landmarks which are necessary for specific operations. Inlays are rather expensive, but often two or three organs with pathologies (uterus, ovarian cyst, ectopic tubal pregnancy) are simulated. After operation(s) inlays must be rejected. They can be changed easily and are fixed by a kind of click-in system. They are made completely from inorganic material. This lightens storage.

Concerning hysterectomy very less simulators have been described using artificial tissue (e.g. a kind of special foam) to simulate organs and structures. Hysterectomy steps including preparation, cutting, sutures etc. are realistically possible to a certain degree. Some systems allow even the simulation of pathologies such as myoma etc.

Decision making, acquire operative survey, guidance of assistance as well as single steps (preparation, sutures, hand eye-coordination etc.) are trainings aims which can be learned using this system. The use of additional training success tool gives the trainee feedback concerning his operative behavior and allows also evaluating the success of learning.

Disadvantage of the systems is that they are not aligned for electrocoagulation or HF surgery. No coagulation of prefunded vessels or electric surgery procedures on tissue (monopolar cutting, sealing etc.) is possible. Additionally the systems are rather expensive for the daily clinical use and therefor more useful in courses.

Virtual Reality Trainers (Fig. 16.8)

During the last decade for endoscopic procedures a new generation of computed based simulator has been introduced. Simplified virtual reality trainers are comparable to a wii system, using detectors and microprocessors to convert the surgeon instruments movement into an imaginative movement on the monitor. The underlying imaginative computerized matrix is very realistic and bases on real happened cases.

In first systems sometimes leaps in time or mistakes in converting the surgeons movements occurred which were meanwhile reduced.

Virtual reality trainers have a large potential, as already every operation and complication can be simulated. Additionally operations can be performed only by the trainee without the need of assistance. Additionally specific hand eye coordination tools are available.

All procedures which are necessary during hysterectomy such as preparation, cutting, sutures, electrocoagulation, monopolar cutting, sealing etc. are theoretically possible, but must be implemented by the codes.

Decision making, acquire operative survey and single steps (appropriate use of coagulation, preparation, sutures, hand eye-coordination etc.) are trainings aims which can be learned using this system. The use of additional training success tool gives the trainee feedback concerning his operative behavior and allows also evaluating the success of learning.

A great problem is the lack of haptic. The development of a haptical feeling is a relevant factor for a trainee. Newer systems implemented codes for a kind of haptical feeling but there is still no solution to copy the original feeling in all situations during the operation.

A further disadvantage is that the coded systems only allow defined steps of the trainee. That means, that the system answers with a programmed displacement activity in

Fig. 16.8 Virtual Reality Systems: (**a**) LapSim® Haptic System, (**b**) LapSim® Non-Haptic System, (**c**) LapSim® virtual hysterectomy., LapSim® Laparoscopic Trainer (Source: LapSim®)

case of movements of the trainee, which have not been programmed. So an accidental injury of a gut during a hysterectomy is not possible and the gut evades, if the simulated operation has not been coded for the complication "injury of guts".

The fact that in some systems no further assistance is necessary seems to be positive on the first sight. Regarding the trainings aim of intraoperative survey it must be contributed that also the guidance of an intraoperative assistance is a relevant factor and should be trained.

Further disadvantages are the high costs for the systems, which are reasoned in the developing cost for the different tools.

Summarizing virtual reality trainers are at present not seen in the first line of simulated training for novices. They are rather used as control instruments of trainings success in specialized courses. If all "teething troubles" including the lack of haptic will be overcome and a really broad spectrum of intraoperative courses including spontaneous induced complications can be realistically simulated, this system could be the surgical counterpart of simulators for pilots.

Integrated Virtual Reality Trainers in Robotic Assisted Surgical Systems

During the last decade robotic assisted surgical systems have been introduced also for hysterectomy. The robotic assisted surgical systems are in general featured with an integrated virtual reality trainer. These "robotic" VRT's focus on the one hand in general skill training and on the other hand on a training to optimize the use of all function which are provided by the robotic system.

Moglia et al. published in 2015 a review comparing the different VRT's of robotic systems concerning general skill training and skill transfer to robotic operation.

They found in all analysed systems a realistic simulation, which made the tool usable and useful for the trainee, but trainings tools are not standardized at all [23]. Robotic VRT's are a useful tool for bimanual wristed manipulation, camera control, master clutching to manage hand position, use of third instrument arm, activating energy sources, appropriate depth perception, and awareness of forces applied by instruments for surgeons who intend to use robotic systems [24].

Concerning the items of general skill training and especially on simulated hysterectomy no additional facts than those of VRT's have been reported.

Combined Organic/Inorganic Trainers (Fig. 16.9)

Combined trainers are characterized by the combination of advantages of organic trainers such as the possibility of electrocoagulation or perfusion with advantages of inorganic trainers such as reproducible simulation of pathological conditions. By the combination of both components the realistic simulation of a couple of operative steps is optimized and l a realistic haptic is given [15]. Additional hand-eye-coordination tools are available.

In a certain way box trainers with the fixation possibility for organic parts of animals can be considered as precursor of combined trainers but the characteristic difference is that pathologies cannot be planned and that they are not exactly reproducible. In a real combined trainer organic structures are not used in its entity but only components of organic origin are processed to create reproducible artificial pathological organs. According to bionic sciences characteristics of organic material is analysed and useful components for each operative step are composed until a fully functional simulation of a certain operation is created. The organic parts are often by-products of vegetable, meat or fish processing.

The Gynecological Real Simulator (GRS) system is a combined trainings tool for frequent gynecological operations (hysterectomy, ovarian surgery, endoscopic descensus surgery and anti-incontinence procedures). The unit consists of three parts:

1. The Gynecological Real Simulator
2. Pelvic models
3. Operation-specific inlays

The Real Simulator imitates a female torso. It consists of a closable opening on the lower abdomen, a vaginal opening and smaller holes for connection of equipment (e.g. perfusion). Endoscopic equipment is introduced via four defined areas on the classical introduction places. The pelvic models are scaled to the GRS and are fixed by bolted connections. Pelvic models are specific for the simulation of defined operations so different pelvic models are available (hysterectomy model, ovarian cyst model, descensus model, anterior compartment model). An additional basic-skills model is available, using classical tools for hand eye-coordination and handling of instruments .

Pelvic models consist of all structures which are important landmarks for the specific operations. Depending on the trainings aim learning success tools as well as perfusion or the possibility for the use of electrocoagulative instruments are possible.

The operative area of the pelvic models is recessed for the according inlays and provides fixation mechanisms for the inlays. The inlays are the centerpiece of the simulated operations. They simulate specific operations as realistic as possible, can be changed easily by a click-in system and are thrown away after operation.

For a simulation of a hysterectomy using the GRS system additional to the GRS a hysterectomy model and appendant inlays are necessary. The hysterectomy model consists on the pelvic bone ring, a flexible pelvic floor, sigma and rectum, bladder, ovaries, tubes, Ligg. Suspensorium, ureters, fatty tissue and peritoneum. All structures are hardly inflammable and are resistant to a certain level of transmitted heat resulting by the use of common electrosurgical instruments. The model itself can be cleaned with water and a mild cleaning agent.

The hysterectomy inlays can be fixed easily by a click-in system. Perfusion lines must be connected. If monopolar instruments are intended to use, a neutral electrode must be fixed on the inlay. Different hysterectomy inlays with an increasing degree of difficulty are available (normal uterus, uterus with intraligamental myoma, large uterus myomatosus, attached gut/endometriosis). All inlays of one category (e.g. large uterus myomatosus) are exact reproducable. Hysterectomy inlays allow all relevant operative steps including preparation, coagulation, monopolar cuts, use of slings, sealing, morcellation, sutures etc. and are thrown away after operation. Decision making, acquire operative survey, guidance of assistance as well as single steps

Fig. 16.9 Combined System, Real Simulator (GRS): (**a**) Closed Real Simulator System; (**b**) Opened Real Simulator System with adapted pelvic model; (**c**–**g**) Hysterectomy inlay during a trainings session. (**c**) artificial hysterectomy trainings inlay, (**d**) dissection of round ligament, (**e**) separation of broad ligament layers and preparation, (**f**) exposure of uterine vessels, (**g**) dissected uterine vessels (after coagulation, not shown) (Courtesy of Pelvic School Saaarbuecken)

(appropriate use of coagulation, preparation, sutures, hand eye-coordination etc.) are trainings aims which can be learned using this system. The use of additional training success tool gives the trainee feedback concerning his operative behavior and allows also evaluating the success of learning.

Disadvantages are the necessity of unfreezing inlays before use. Connection of vessels, neutral etc. is associated with a lead time of about 15 min.

Outlook

An educational concept for hysterectomy basing on three levels (surgical basics-simulated training-hysterectomy in patients) seems suitable and complies ethical and morally requirements. It allows trainees to graduate their individual educational niveau and helps defining trainings aims which should be focused next. Concerning simulated training, trainings aims should be clearly defined in order to choose the optimal simulated trainer for the focused aim. The financial aspect of simulated training cannot be resolved finally. The costs of simulated training are high and correlate to the technical and scientifically effort. A structured education, at least for the second level, in trainings-centers seems more appropriate than an individual, self-ministered training in each hospital. Maybe the wide spread implementation of structured trainings-programs will help to come closer to a conceptual medical counterpart of pilot training.

Tools for learning success as a basis e.g. for a hysterectomy certificate are an interesting vision. A certificate verifying a defined trainings level as precondition for operation in real patients would give patients who undergo hysterectomy the feeling of security and could simplify the clinical daily routine for trainees and trainers.

Communicative and Ethical Aspects of the Doctor-Patient Relationship in Extreme Situations

17

Ibrahim Alkatout

Introduction

A doctor's actions constitute the very core of the medical profession. A doctor's actions are, by their very nature, unique, unrepeatable, and irrevocable. The element of irreversibility and constant contact with the patient's biological existence impose an enormous burden of responsibility on the doctor's actions [1]. The residual lack of safety and uncertainty, which cannot be eliminated despite most recent discoveries in medical science and technology, still make it almost impossible for the doctor to guarantee the success he/she intends to achieve [2]. The general purpose of a doctor's actions is to cure an ill person. This includes the prevention of disease as well as its cure, the patient's rehabilitation, palliation, the diagnostic procedures required for these measures, and their consequence, which is the treatment [2]. In order to ensure that the treatment addresses the specific disease as well as the patient's right to individual care, the patient must be viewed in his/her entirety at all times. A successful doctor-patient relationship can be learned and applied in all fields of medicine.

The Doctor-Patient Relationship Is the Basis of All Fields of Interaction

A positively perceived and productive relationship between the doctor and the patient is primarily based on the following three basic attitudes: *empathy* (sensitivity), *congruence* (authenticity) and absolute (unconditional) *esteem* [3].

Assuming that the diseased patient is a self-determined individual, his/her autonomy is in no way reduced by the loss of his/her physical integrity. The doctor and the patient are partners with equal rights; each of them has specific competences and responsibilities.

Empathy

Empathy may be defined as understanding the emotional and cognitive processes of another, the ability to recognize a person's conflicts, feelings and attitudes, and be able to experience the emotions of another [4].

The doctor should, in lieu of the patient, be able to put the latter's feelings into words and determine the patient's needs, which the patient himself/herself may not yet be fully aware of. These processes occur at the emotional and intuitive level in the form of empathy, as well as the cognitive level in the form of comprehension. The therapist's ability to identify himself/herself with the patient for a limited period of time enables the therapist to share the patient's experience. Gestures, facial expression, body posture, the speed of talking, the tone of voice, and other features of non-verbal communication trigger empathy in the interacting partner [5]. Thus, empathy is also an attempt to understand the reasons for another's actions and opinions, based on the latter's view of the world and horizon of experience (Fig. 17.1) [6].

Fig. 17.1 Authentic empathic setting in preoperative counseling based on congruence and esteem

Congruence (Authenticity)

Congruence (authenticity) refers to the therapist's attitude: he/she is entirely sincere towards the patient, without any deception of himself/herself or the patient. The doctor is aware of his feelings at all times and can communicate these to the patient if necessary [4].

Thus, the doctor-patient relationship incorporates the therapist's authentic communication towards the patient. Authenticity refers to everything the doctor feels and experiences, those parts of his/her feelings and experiences he/she is aware of, and those parts he/she eventually communicates. Thus the therapist is able to access his own thoughts and feelings towards the client and the therapy situation [7]. The therapy principle of authenticity makes it necessary for the doctor to render his identity (which differs from that of the patient) transparent to the patient, answer questions sincerely, and seek opportunities to face the patient and communicate with him/her [7, 8].

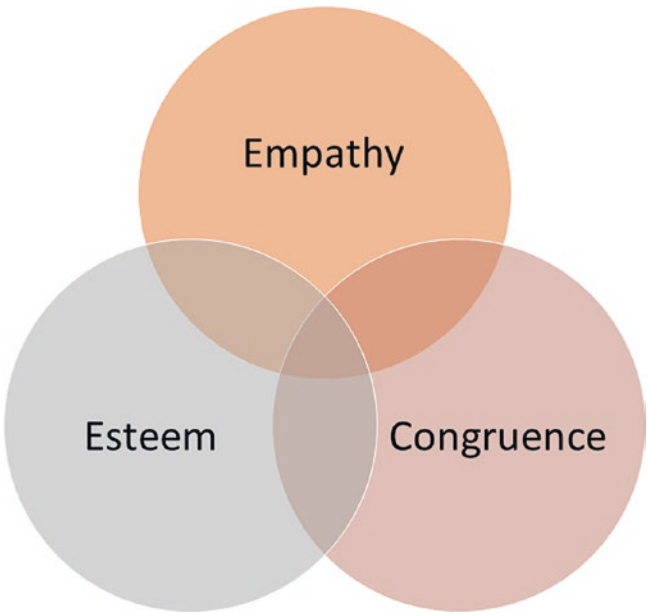

Fig. 17.2 The doctor-patient relationship is the basis of all fields of interaction. It is founded on the three cornerstones of empathy (sensitivity), congruence (authenticity), and absolute (unconditional) esteem

Unconditional Positive Esteem (Unreserved Acceptance)

A relationship of unconditional positive esteem is marked by trust, appreciation and respect; these qualities form the foundation of the doctor-patient relationship [8].

The patient is welcomed and accepted, independent of what he/she says and how he/she behaves at the present time. This unrestricted acceptance is incompatible with an attitude expressing judgment, dislike or disapproval, or even a selectively expressed esteem of another (depending on the contents of the conversation). Unconditional acceptance consolidates the therapeutic relationship, promotes one's experience of self-respect, and mobilizes the patient's own resources. The doctor focuses his entire attention on the patient and confirms the patient's ambitions by acknowledgement, encouragement, and expressions of solidarity and concern. The patient's communication is accepted exactly as expressed by the patient, and is not questioned further [8]. This gives the patient the certainty he/she needs in order to fully experience his/her feelings at the moment, although the therapist is still obliged to align his/her experience to his/her values [5] (Fig. 17.2).

Creating the Doctor-Patient Relationship

The doctor's professional rule of conduct has existed since the antique ages of medicine: *primum non nocere* (above all, you should do no harm).[1] The principle of *Nonmaleficience* or prevention of damage is, in addition to the *patient's autonomy*, the *patient's wellbeing* and *justice*, one of the four ethical guiding principles of decision-making by a doctor. The art of ethical judgement is derived from a balance of these four basic principles: dispensing with harmful interventions (*primum non nocere),* respecting the patient's self-determined decision (*voluntas aegroti*), ensuring that any medical measures serve the preservation and improvement of the patient's mental and physical health (*benevolence)*; and being just in one's actions (*fairness*) [9, 10]. The four principles incorporate a number of explicit, implicit and potential standards, which may contradict each other in many ways but result in a coherentistic approach in terms of application [9, 11, 12].

Self-Determined Decision (The Patient's Autonomy)

The term autonomy is derived from the Greek words *autos* (self) and *nomos* (law, rule), and means self-legislation or self-determination. It was initially used to express the self-determination and self-government of independent city states of the antique period. Kant regarded the autonomy of practical reason as the commitment of human will – driven by the legitimate categorical imperative – to assign greater importance to unconditional obligation than to primordial intentions.

Preconditions for autonomous decisions are the following:

1. *Awareness*: Being able to understand the issue in question
2. *Competence*: The ability to inspect, judge, and make decisions; in other words, to be competent
3. *Freedom*: To make one's decision without the controlling influence of another, and also implement one's decision.

In the medical context, autonomy is the ability to act freely in regard of one's own mental and physical matters. The contrary term *heteronomy* refers to dependence and external determination. Promotion and restoration of one's ability to exercise self-determinism is one of the major goals of medical action [13]. Respect for autonomy, in its minimal form, is expressed as respect for the basic rights of the patient. The relationship between the doctor and the patient must ensure asymmetry between action and suffering on the one hand, and symmetry of self-determinism and freedom of action on the other [14]. The doctor-patient relationship is outlined in three basic models: (1) *Paternalistic model*, (2) *Contractual or Client Model*, and (3) *Partnership model*. External influences exist due to secularization, economization, and technological developments in medicine on the one hand, and the changing values of our pluralistic society on the other. The diverse and variable *models of relationship* differ especially in regard of the criterion of trust and the actual degree of patient autonomy in the respective interaction. We are concerned with the communication requirements to be fulfilled by the doctor [15, 16].

Techniques of Conducting a Doctor's Conversation with the Patient from the Viewpoint of Autonomy

The core aspects of a successful conversation conducted by the doctor with the patient include, above all, active listening, determining the structure of the conversation, as well as identifying and resolving difficult patterns of interaction.

1. Active listening. Techniques of active listening are summarized in Table 17.1.
2. Determining the structure of the conversation. *Transparency* is a basic instrument for structuring the conversation and adhering to the time frame. This includes transparency of the elements of the conversation, such as providing information about the steps of the treatment, the necessary medical informatioin, and informing the patient as to why a step is being performed. The transparency of basic conditions includes informing the patient about potential disorders and the time frame of the conversation. Transparency concerning the individual phases of the conversation enables the patient to differentiate between doctor-centered and patient-centered sections of the conversation.

The conversation can be reflected on and corrected through *metacommunicative statements*. Metacommunicative statements concern the content of the conversation, the style of conversation, the positions of those conducting the conversation, and problems in the doctor-patient relationship.

3. Identifying and resolving complex patterns of interaction. Harmonious communication patterns are oriented to the anticipated reactions of one's counterpart. This calls for a

[1]The dictum is attributed to the Roman physician Scribonius Largus, court physician of the emperor Tiberius Claudius Nero Caesar Drusus who ruled Rome around 50 A.D. A similar phrase is also found in the Corpus Hippocraticum (Epidemics, Book I, Section XI).

Table 17.1 Techniques of active listening

Active listening	
Let the patient finish speaking	The first few minutes form the basis of the relationship. Active listening is encouraging and delivers valuable information
Ask open questions	Open questions yield comprehensive information, clarify associations, and provide background data beyond the actual facts of the case
Inquire	Problems of comprehension can be addressed immediately
Balance pros and cons	Helps to determine the patient's priorities or encourages him to think about them. Especially by explaining why a step is being given preferences
Pause	Short pauses (about 3 s) have a relieving effect. The patient thinks of data he/she had ignored until now
Encourage the patient to speak further	Echoing or nonverbal communication (nodding, eye contact, body facing the patient) signalizes one's presence
Paraphrase (repeat)	Focus on those parts of the patient's statements that are most significant (verbal accompaniment) and thus open new perspectives
Summarize what has been said	Agreement between the doctor and the patient by expressing longer portions of the conversation in one's own words
Reflect emotions	Address emotions verbally in the form of a suggestion

high degree of flexibility and thorough knowledge of role expectations. Interaction may be disrupted by inadequate social competence, fixation on oneself, or distorted perception of social behavior.

Individual Requirements of the Doctor in a Patient-Centered Doctor-Patient Relationship

A successful doctor-patient relationship is the foundation of any successful treatment and the breeding ground for sustained satisfaction in the professional existence of a doctor.

The action-guiding *obligations of a doctor* include the willingness to take responsibility, confidentiality, and authenticity. Action-guiding *virtues of a doctor* are patience, empathy, compassion, and the willingness to help. Finally, one needs to work out what the various optional decisions mean in terms of obligations towards third parties. In this context one needs to consider the patient's family members and close friends, as well as the entire community of the insured person [17].

Very urgent decisions and chronic diseases are the easiest to handle from the ethical point of view. In highly acute situations, such as emergencies, the responsibility of decisions is still handed over to the doctor without considering the patient's opinion (accepted paternalism). In this setting the patient is informed of the bare essentials, without disregarding the his/her right of self-determination. Even when the patient's ability to help himself/herself is on the decline and the patient needs help and care to an increasing extent, as in old age frailty and/or cognitive impairment, his/her modified autonomy should be accompanied by a high degree of empathy on the part of the doctor concerning the putative will of the patient. Chronic diseases differ from this approach in that a satisfactory outcome of care and the required degree of compliance can only be achieved cooperatively by the doctor and the patient. The less urgent the decision is, the more responsibility one may assign to the patient; in this setting decisions can be made in accordance with the *shared decision-making model* (Fig. 17.3) [18]. The degree of autonomy depends on the momentary and general condition of the individual patient (such as the patient's mental condition, degree of intellectual differentiation, severity of symptoms, severity of disease), and must be adapted to the current situation. The patient's values (estimation of the disease, will, concept of life) should be viewed along with the values of his environment (the patient's living environment, the treatment team) and the values of society (implicit values, institutionalized values). Even if the patient's living values are clear, there may be ambiguity concerning what is meaningful, appropriate, and beneficial for the patient.

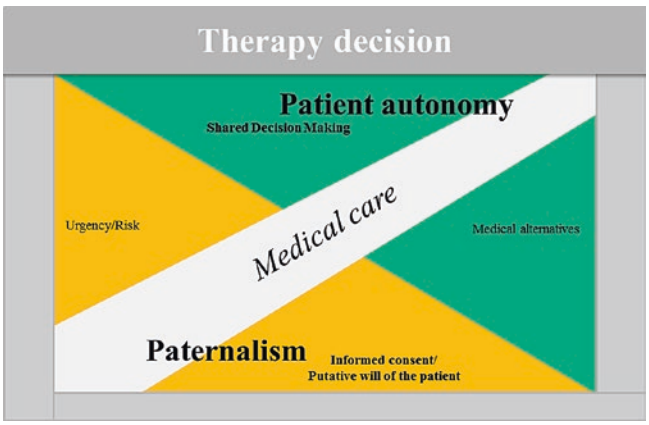

Fig. 17.3 Reciprocal flow diagram of paternalism and Informed Consent on the one hand, and patient autonomy and Shared Decision Making on the other. Dependent variables are medically equivalent alternatives and the medical urgency or risk for the patient. Medical care should respect the patient's wellbeing as well as his/her will

In many medical situations, the relationship between the doctor and the patient remains no more than an idealized behavior pattern. Many situations are rendered complex by the indefinite prognosis of acute diseases, especially when the initiated maximal therapy has not been successful and the doctor contemplates a change in the goals of treatment. However, particularly such extreme situations call for mastery over, and the application of, medico- ethical principles.

Borderline Situations in Dealing with Aged Patients and Those with Cognitive Impairment (Dementia)

The rising number of aged patients and those with cognitive impairment (dementia) permits complete patient autonomy in a very small number of cases. However, demographic developments necessitate the establishment of applicable concepts that will do justice to the altered spectrum of morbidity, which includes a rise in chronic diseases and multimorbid conditions. When coordinating the medical reports and other collected data with the individual patient's value system and also when considering the available resources in a specific case, the treatment team needs to employ a high degree of empathy and respect for the patient's autonomy. Again, it may be necessary to re-check and ensure congruency between the medical approach and the patient's concept of living, and make the respective putative decisions anew [19, 20].

Borderline Situations in Dealing with Psychiatric Patients, Young Children, and Mentally Challenged Persons

According to the principle of autonomy, young children, psychiatric patients and less gifted persons also have the right to be informed comprehensively. On the other hand, a comprehensive explanation may involve potential harm or delay in all three groups. Therefore, in the patient's interest many decisions about him/her are made on his/her behalf. When making serious decisions one must integrate the patient to the greatest possible degree. Consulting and including family members and caregivers is especially relevant in these situations. Showing empathy and sympathy for the patient and the family, answering questions, and explaining the medical treatment are highly valued aspects in this setting [21].

The Doctor-Patient Relationship in Oncology

Tumor patients are typical candidates for patient-centered doctor-patient communication. Cancer patients need a great deal of information about their disease, its consequences, and the available options. In many cases, the treating doctor and the patient share an intensive and long-term relationship. Therapy decisions are of long duration and have far-reaching consequences on the patient's quality of life and the prognosis of his/her disease. The doctor's task and responsibilities in providing medical assistance for cancer patients involves, to a much greater extent now than ever before, inviting the patient's active participation in decisions regarding treatment [22].

In 1819 Goethe wrote in *West-Östlichen Diwan (West-Eastern Divan)*: "What I thank Allah most for? That he has made a division between suffering and knowing. Any ill person would be desperate if he knew the disease as thoroughly as the doctor does".[2]

Slevin et al. were able to show that, in apparently hopeless situations, cancer patients are much more willing to undergo stressful chemotherapy with minimal chances of cure than the medical personnel in charge of their treatment would be willing to subject them to such treatment. Also with regard to the prolongation of overall survival and the improvement of quality of life, the acceptance threshold of severe side effects is highly underestimated (Table 17.2) [23]. Although many ill persons will accept a stressful treatment that prolongs their lives by a few months or provides brief symptomatic relief, some patients refuse to undergo a stressful therapy although the prognosis of their disease may be quite favorable [24]. Achievement of the goals of therapy, in this case, is not dependent on the effects or the efficacy of therapeutic measures alone, but is subject to a positive evaluation of the treatment by the patient [25].

Patient-centered medicine includes the ability to deliver bad news. Communications about impending death and statements about the significance of a disease or death are major challenges for the doctor and the patient. Empathy, congruence, and unrestrained respect for the patient when delivering bad news have culminated, for instance, in the SPIKES protocol described by Baile (Table 17.3) [26].

Questions to establish one's estimation of the patient's perception include, for instance, "What do you know about your medical situation so far?" or "What is your understanding of the reasons we wish to do the investigation?"

Table 17.2 The threshold likelihood (in percentage) of cure, prolongation of life, or symptomatic relief: the point from which patients are willing to accept chemotherapy associated with severe side effects and complications. This survey was conducted among cancer patients as well as a group of doctors and nursing staff [23]

	Patient	Therapist
Chances of cure	1 %	10–50 %
Prolongation of life	12 months	12–60 months
Alleviation of symptoms	10 %	50–70 %

[2]In: Johann Wolfgang von Goethe: *West-Östlicher Diwan*, Frankfurt am Main 1999, page 47.

Table 17.3 The SPIKES model. A six-step protocol for delivering bad news. This is a tool for obtaining information about the patient's current level of knowledge. He/she can also be informed about medical facts, depending on his/her need for information, support can be expressed, and suitable options can be rendered accessible. Finally, a treatment plan can be drafted in cooperation with the patient

S P I K E S	Steps	Contents
S	1. Setting up the interview	Arrange for some privacy Involve significant others Sit down Avoid interruptions
P	2. Assessing the patient's perception	Open questions to assess the patient's current perception (avoid misunderstandings early)
I	3. Obtaining the patient's invitation	Assess the patient's willingness to receive bad news Mention that the patient can speak to the doctor at a later point in time
K	4. Giving knowledge and information	Warning before delivering bad news Optimizing communication
E	5. Addressing the patient's emotions with empathic responses	Empathic statements express support
S	6. Strategy and Summary	Depends on level of wellbeing Discuss the next steps

To better estimate the ability of one's counterpart to receive bad news, it may be useful to ask questions like "How would you like me to give the information about the test results? Would you like me to give you all the information or sketch out the results and spend more time discussing the treatment plan?" To warn the patient before delivering bad news, one could try to steer the conversation, "Unfortunately I've got some bad news to tell you…" or "I'm sorry to tell you that …". While speaking to the patient, it would be advisable to make repeated and active attempts to optimize the conversation. This includes alignment of one's language to the patient's vocabulary and omitting specialized medical terms. Excessive directness should be avoided, and the required or desired information should be given in small units. The level of communication can be further improved by avoiding phrases like "There's nothing more we can do for you." Empathic statements in these exceptional situations express support. Specifically, the patient is helped when emotions are registered, named, and identified (such as grief, anger or shock). The patient is also helped when the doctor signalizes that the patient may express himself/herself. Agreeing upon a plan of treatment simultaneously makes the patient feel that his/her wishes are being taken into account; it also avoids misunderstanding, uncertainty and anxiety (Fig. 17.4).

The Doctor-Patient Relationship in Obstetrics from the Invasive Point of View

Obstetrics and prenatal medicine constitute an equally important part of our spectrum of activities. In contrast to gynecology, the doctor is called upon to bear responsibilities beyond the patient's scope of action. High-risk pregnancies have risen greatly in the last few years because of improved procedures in reproduction medicine. Maternal diseases may become consolidated or be exacerbated during pregnancy. The increasing complexity of this subject calls for interdisciplinary management and imposes the highest medico-ethical demands on our specialty.

In addition to the medico-ethical questions of the mother, the demands of the unborn child also must be taken into account. A crucial aspect of decision-making when dealing with the unborn child is the moral status an embryo must achieve in order to be granted specific rights – such as the right to live – as a practical subject. The fundamental rights granted to nascent life and the consequent legal protection that goes with these can be described in different ways [27].

1. *The species argument*: All members of the biological species known as *Homo sapiens* and, in fact, only this species, are entitled to human dignity and the comprehensive legal and moral protection that go with it.
2. *Potentiality argument*: The potential of entire human development is present in the primary cells. An embryo, which normally develops into a human being, is therefore worthy of protection and possesses the same moral characteristics as the fully developed human being.
3. *Identity argument*: The human embryo/fetus has the same rights as the persons they will become in the normal course of life, because the two are basically identical. The identity of the developed individual results from the composite of cells he/she evolves from.
4. *Continuity argument*: The process of development that starts with nidation is a continuous process with no sharp divisions and therefore does not permit any specific demarcation of the stages of development. Despite the

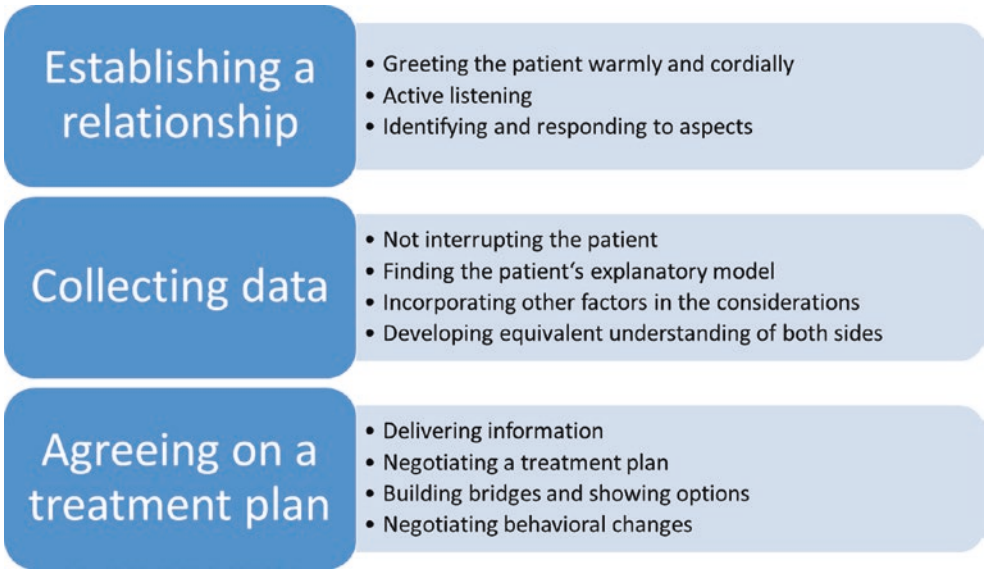

Fig. 17.4 Three functions of a doctor's consultation

continuity of human development from the very start, one can identifiy various stages of development whose demarcations, however, are blurred.

Fetomaternal conflicts result from the need to set priorities regarding the wellbeing of the expectant mother or the future child. Once the moral and ethical status of both parents and their right of self-determination have been established, it will be necessary to register the moral and ethical status of the unborn child. Any decision in favor of one would be accompanied by neglect of the other. Equal treatment of the interests and possessions of the unborn child and the future parents is practically impossible. Once the individuality of the embryo starts to take shape – which would be at the time of insemination or later – the individual possesses complete human dignity and must be protected accordingly. From this time on, the existence of the human being and his/her individuality is determined by the uniqueness of his/her genetic material. Based on the ethical principle of autonomy, one is obliged to justify any hindrance to self-determined life and protect the value of freedom. However, embryos and fetuses are unable to make competent decisions and are therefore incapable of moral, independent, and autonomous action or decisions – which, however, are essential for the self-determined decision-making process. Therefore, *competent representatives* have to make decisions on their behalf. The representative also has to align the child's value system with general ethical considerations in order to make appropriate decisions in keeping with the presumed life concept of the unborn child. Thus, a person who makes decisions for others is especially obliged to adhere to ethical principles, standards and criteria.

Given these facts, many prenatal diagnostic and obstetric situations pose a dilemma because it is impossible to act in the interests of the embryo or fetus as well as the expectant mother, not do them any harm, preserve their autonomy, and behave in a just manner. The options of action from the medico-ethical point of view would be quite clear if the unborn child's right to live would be ranked secondary to the expectant mother's. These questions are not, by any means, conclusively clarified at the present time.

Since parents are those who have to live with their decisions in favor of one of the courses of action and its respective dramatic consequences, they should be given all of the tools that enable them to make a sustainable decision. These include, in addition to the medical information provided by an interdisciplinary team of doctors (obstetrics, human genetics, prenatal diagnosis, neonatology, pediatrics), information about further decision-making aids and about tools for coping with the conflict-ridden situation.

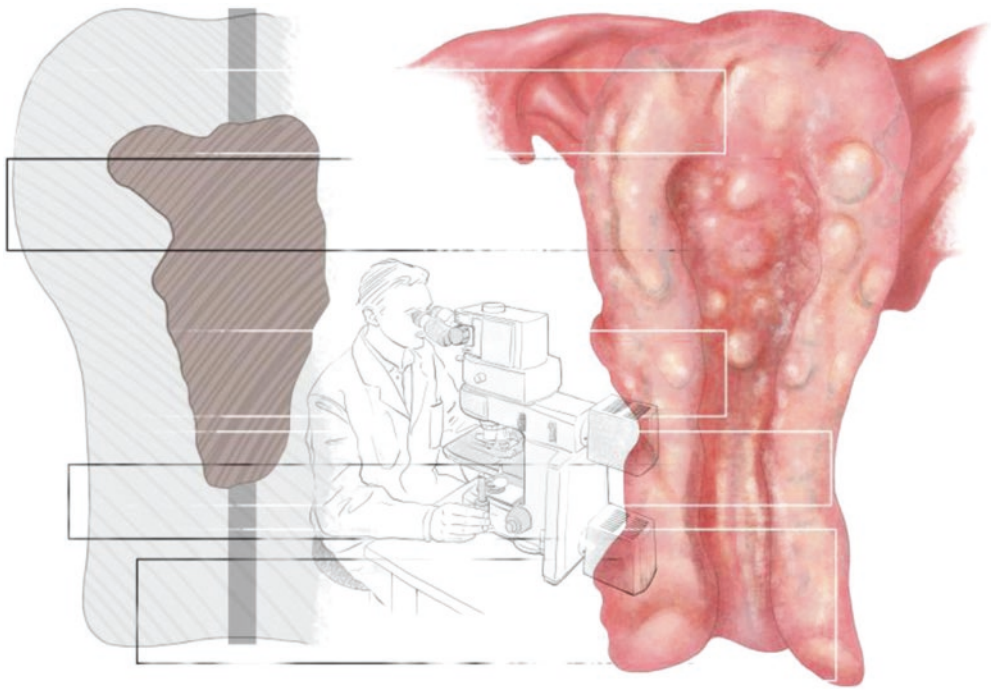
Endangerment of the Doctor-Patient Relationship

The atmosphere of trust created by both of these parties is currently at risk of being lost forever. Three factors are worthy of mention in this regard. *Increasing anonymity* is a result of increasingly complex infrastructures. The patient is compelled to surrender his relationship with his treating physician and share his existence as an ill person as well as his doctor (a confidant) with the entire institution. *Juridification*, by which the doctor-patient relationship is subject to an increasing degree of legal control. The third source of uncertainty is *probabilization*. Statements about the disease process can only be made with certain degrees of probability.

Industrialization and the enhancement of efficiency in the health care system through measurable performance have, in

many instances, reduced non-measurable medical services to a minimum. Higher-level optimization processes, technocracy and bureaucracy are culminating in an unsurmountable pressure of time, which is partly offset by specialized medical services such as those of psychologists, specialized nursing staff, or social workers.

Conclusions and Future Perspectives for Medical Practice



Decision-making in medical treatment is an individual process founded on ethics and can only be rendered possible by a well-functioning doctor-patient relationship. A prerequisite for the latter is communication based on empathy, congruence, and unconditional esteem. With a foundation of this nature, the patient and the doctor will be able to strive for the patient's wellbeing while preserving the patient's autonomy, avoid damage or injustice, and tread a common pathway, ideally as partners, which would lead to sustained satisfaction – also from the doctor's point of view – and render the two extremes of paternalism and contractual action unnecessary. In the majority of situations, the basic demands of the two parties must be weighed against each other and may not be achieved simultaneously. In the joint process of decision-making, it will be necessary to strike a compromise between the respective non-negotiable principles.

Part VI

Macroscopic and Microscopic Pathological Aspects

Processing and Histopathological Workup of Hysterectomy Specimens

18

Lars-Christian Horn and Anne K. Höhn

Introduction

The challenges of histopathology have been changed dramatically during the last years. The pathologist nowadays is a diagnostic oncologist and in the majority of the cases the management of patients is influenced by the histopathology report so, the surgical pathologist performs a "background treatment" of the patient.

The histopathologic report is one cornerstone and within the majority of cases the basement of quality control and decision making for adjuvant treatment and guides the selection of appropriate approach in additional treatment, especially in patients suffering malignant disease.

The gross description of a resection specimen is one important, if not the most important, part in several cases of the entire surgical pathology report.

The following chapter describes an approach of gross examination and the method of reporting the pathologic findings for benign and malignant gynaecologic diseases within hysterectomies, guided by the clinical principles of patient management, focussing on a concise report to guide the decision makings in multidisciplinary meetings.

Crosstalk Between Clinicians and Treating Pathologists

The surgical pathology report gives the final diagnosis and includes specific information about the success of surgical treatment and just in case about prognosis and treatment. So, the "treating pathologist" must have sufficient familiarity with the management of obstetric and gynaecologic disorders to assure that the report, as its major focus, communicates the clinically relevant information [143].

But, the quality of the histopathological report is mainly influenced by the available clinical information. Some important points of interaction between the clinicians and the surgical pathologist should be addressed.

The gynaecologic surgeon has seen the situation and the disease in vivo in conjunction with several anatomic landmarks. These landmarks cannot be reconstructed by the pathologist within the laboratory. So, it is absolutely necessary that the gynaecologist communicates important intraoperative findings on the requisition sheet. For proper orientation of the specimen in the lab, a marking of relevant structures/landmarks/resection margins on focus on the resection specimen (e.g. by sutures) is mandatory. Especially in complex resection specimens, special requirements of the gynaecologic surgeon, special intraoperative findings and a proper orientation of the specimen will directly influence how the pathologist will handle and process the specimen postoperatively at the cutting room. This is also the case during intraoperative frozen section analysis.

Intraoperative frozen section examination of a specimen should guide the operation procedure by evaluation the status of resection margins and the extent of the disease. Unnecessary frozen sections should be avoided to cut the costs and save manpower. It should be recognised that frozen section analysis present a preliminary method and is not as good as permanent sections from any tissue [37, 47]. The overall accuracy of frozen section analysis has tested and proved on numerous occasions, both in university and community hospitals with good results [121, 144]. A review, sponsored by the College of American Pathologists covering over 90,000 frozen sections, performed at 461 institutions showed a concordance rate with permanent sections of 98.6 % [144]. Given limited sampling, frequent paucity of clinical information and the various artifacts introduced by the freezing process, the technique is remarkable accurate but not perfect. So, the diagnosis of frozen section examina-

tion might be changed after examination of the whole specimen by permanent slides.

The surgical specimen will be examined and described at the cutting room. For frozen section analyses and the selection of tissue blocks for the histopathologic examination the tissue will be sliced and dissected. During the cutting of the specimen it will be distorted and a complete reconstruction in context with all structures removed will be impossible.

The examined tissue will be stored for several weeks. Then, the tissue will be discarded under the line of legal regulations. So, there is no way to return to the specimen for re-examination and/or additional embedding of tissue after that time. This means for the clinician to contact your pathologist as early as possible if there are any questions regarding the specimen and its histopathological report.

Proper fixation of surgical specimens is an absolutely prerequisite for adequate handling and processing of the tissue. Improper fixation causes problems in cutting the paraffin blocks, sadly influences the quality of H&E-staining (Fig. 18.1a, b) and may cause false-negative or false-positive results in immunohistochemical staining (Fig. 18.1d, e; [98, 140]). Improper fixation may also cause problems in molecularpathologic analyses [98, 120]. Formalin-based fixatives are most commonly used today. For proper fixation 10 % buffered formalin should be used. The relationship between specimen size and the amount of formalin used should be 1:10.

In therapeutic resections a larger amount of tissue will be resected within each individual specimen. The formalin-based fixation works by the penetration of the formalin in the tissue from the periphery to its centre with a speed of ~0.1 cm per hour [29]. So, a minimum of about 12 h for medium sized specimens (simple hysterectomy) and a minimum of 24 h for larger specimens (e.g. radical hysterectomies, exenteration specimens) will be needed for proper fixation. The processing of the specimen and its histopathological interpretation (without additional immunohistochemical stains) needs about 24–48 h. This timeline (Fig. 18.2) should be kept in mind by the clinician for proper information of the patient. In complex therapeutic resections, some information will be available earlier as the result from frozen section examination (e.g. status of the resection margins, dignity of the lesion). Additionally, some patients will need intensive or intermediate-care after operation procedure. So, in almost all cases with extended gynaecologic surgery there will be no need to rush up the pathologist. The major points of the crosstalk between pathologists and clinicians are summarised in Table 18.1.

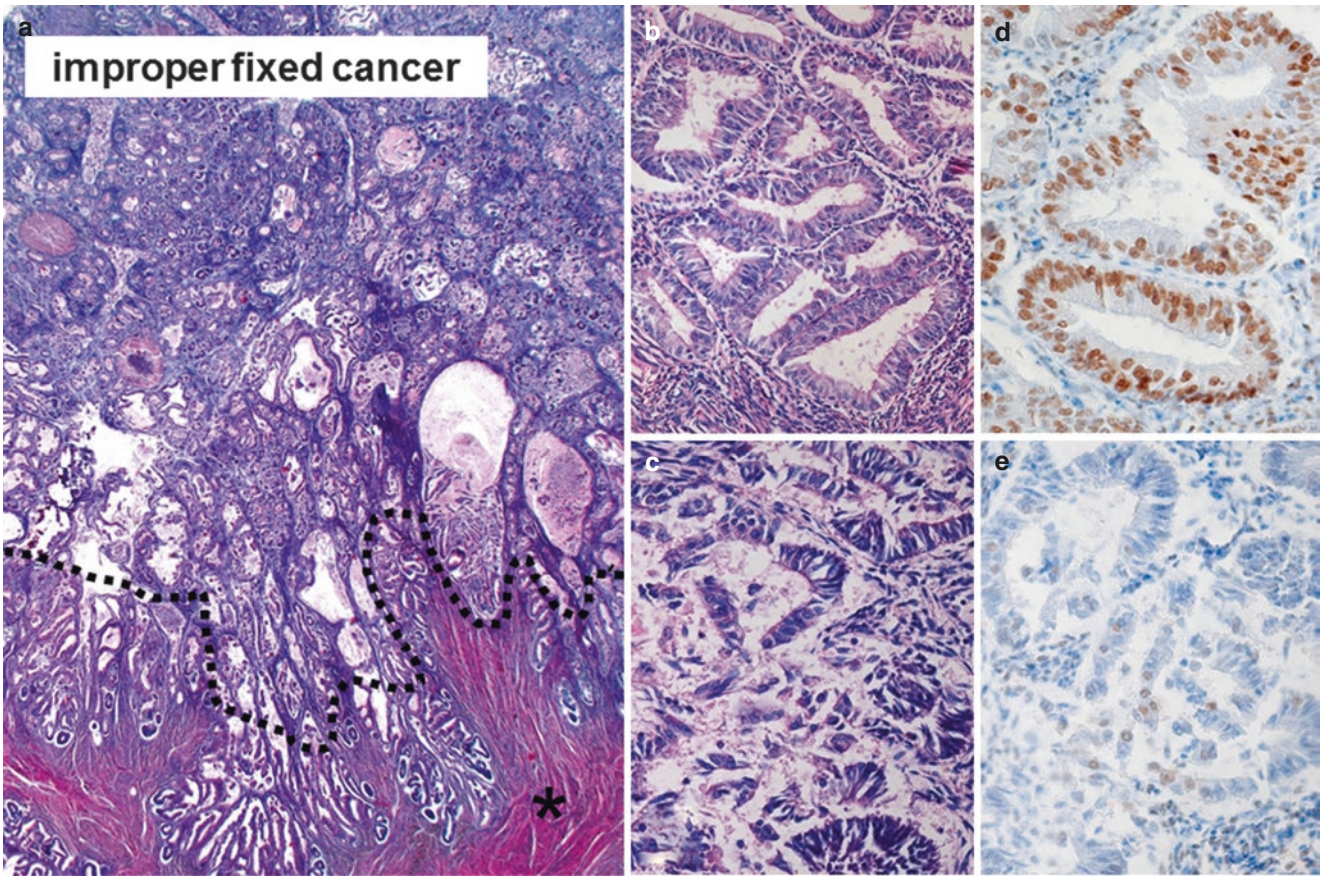

Fig. 18.1 Impact of fixation on morphology. (**a**) Poorly fixed endometrioid adenocarcinoma within a hysterectomy specimen above the dotted line. The cancer below the *dotted line* in proximity to myometrium (*asterix*) is well fixed. (**b**, **c**) Well fixed cancer and improper fixed cancer; the latter one represents with fragmented glands. Table 18.1 Major points within the dialog between the gynaecologic surgeon and the gynaecologic surgical pathologist (for details see text)

Needs from the clinician	Why needed by the pathologist
1. **Anamnestic/clinical data**	
Anamnestic data about malignancies	Proper interpretation of the findings,
	Proper selection of immunohistochemical stains
If available, tumor markers should be given on the requisition sheet	Proper interpretation of the findings,
	Proper selection of immunohistochemical stains
Technique used in surgical approach	Proper interpretation and description of the specimen, quality control of surgical management and pathological workup
Special intraoperative findings should be communicated on the requisition sheet	Proper orientation and handling of the specimen
Relevant structures/landmarks/resection margins should be marked by sutures	Proper orientation and handling of the specimen
Contact your pathologist as early as possible in case of questions or re-orders	In-time re-examination and re-cutting, before the tissue is discarded
2. **Frozen section (FS) examination**	
Prevent "unnecessary" frozen sections	Prevention of tissue destruction
	Prevent loss of diagnostic relevant tissue
Guide FS analyses by marking the relevant resection margins by sutures and ask clear questions on requisition sheet	Reducing the stress level of the pathologist
	Reducing the time necessary for FS
	Reducing the number of FS-blocks
3. **Pre-analytic variables**	
Use of 10 % buffered formalin for fixation	Improved quality of (immuno-) stains and moleculas analyser
Adequate relation between tissue and formaline 1:10	Improved quality of (immuno-) stains and moleculas analyser
Give adequate time-line for the fixation, processing and histopathologic interpretation of complex surgical specimens	Proper quality of staining and interpretation

Table 18.2 Issues for frozen section examination in endometrial cancer and its relative risk for lymph node involvement [5, 147, 183]

Feature	Relative increase for lymph node involvement
Invasion of the outer half of the myometrium	5×
Involvement of the cervical stroma	4×
Ovarian/adnexal involvement	4×
Grade 3 endometrioid carcinoma	3×
Serous/clear cell histology	3×

General Aspects of Cutup for Pathologists

The techniques of the cutup of resection specimens, i.e. its gross description and cutting and processing, should be guided by the needs of the clinician for patients management and recommendation of national guidelines and recommendations of several societies ([7, 17, 38, 88, 96, 107]; see Table 18.2).

A good gross description enables the examining/re-examining pathologist but also the gynaecologic surgeon to reconstruct an image which corresponds to the treated lesion. Several general key points can be determined for good medical practice in surgical pathology [17, 63, 143]:

- appropriate gross description and selection of paraffin blocks for histopathology requires a full understanding of what should be in the final report for each specimen type and why,
- opening sentence of gross description should indicate how the tissue is received (fresh or inadequate/adequate fixed),
- it should be mentioned if the specimen received intact or if there are some incisions made by the gynaecologic surgeon,
- sutures for marking the specimens should be mentioned,
- the weight and three dimensional measurement should be given,
- gross description should be given in an orderly fashion, focussing on the primary lesion,
- descriptions should be full but economical in words and space,
- elaborate descriptions of normal anatomy of adjacent, uninvolved anatomy should be avoided,
- obvious lesions should be described using diagnostic terms, not by prosaic texts,
- gross description should focus on the site and the extent of the lesion,
- the main lesion should be described in detail by giving its three-dimensional size, the presence of its borders to adjacent tissue (its contour) and organs, its consistency and colour, the presence/absence of necroses and haemorrhage, its presence of the cutting surface,
- application of ink is useful for the identification of margins that lack natural margins (i.e. surgical resection margins),
- inking should be sparingly and blot-dry to prevent spill-over or running,
- the reporting of the status of the resection margins is mandatory,
- the reporting of the metric distance between the infiltrating edge of the tumor and adjacent resection margin is mandatory,
- in complex cases or specimens with inadequate orientation drawings or photographs may be helpful for adequate interpretation,
- photographic documentation of complex specimens or those with rare disease is helpful and mandatory in our digital world,
- the number of blocks embedded should be given to document how many tissue has been processed
- the use of adequate section codes is mandatory.

Resection Margins and Inking

The determination of resection margins is mandatory for the management of the patients, for prognostic evaluation and for quality control of gynaecologic surgical treatment.

The status of all resection margins of a lesion should be given in the gross description with the metric distance between the lesion and the margin. All close margins (e.g., margins <1 cm) should be examined histologically.

Application of ink is necessary to identify surgical resection margins on histological slides (Fig. 18.3). The use of multiple colours may be helpful, but it is also adequate to use only one colour. At the authors department we have good experiences to use writing correction fluid if only one colour is needed for inking. In our opinion it represents a good practicable, cheap and easiely handling tool. The correction fluid appears white on macroscopy but black on histology Fig. 18.3a–g). Sometime it is helpful to dry up the specimen before inking using a tissue towel. The application of the ink should avoid a spill-over of the ink and an inadvertently covering of the lesion. The use of perpendicular sections is favoured by the authors rather than the use of

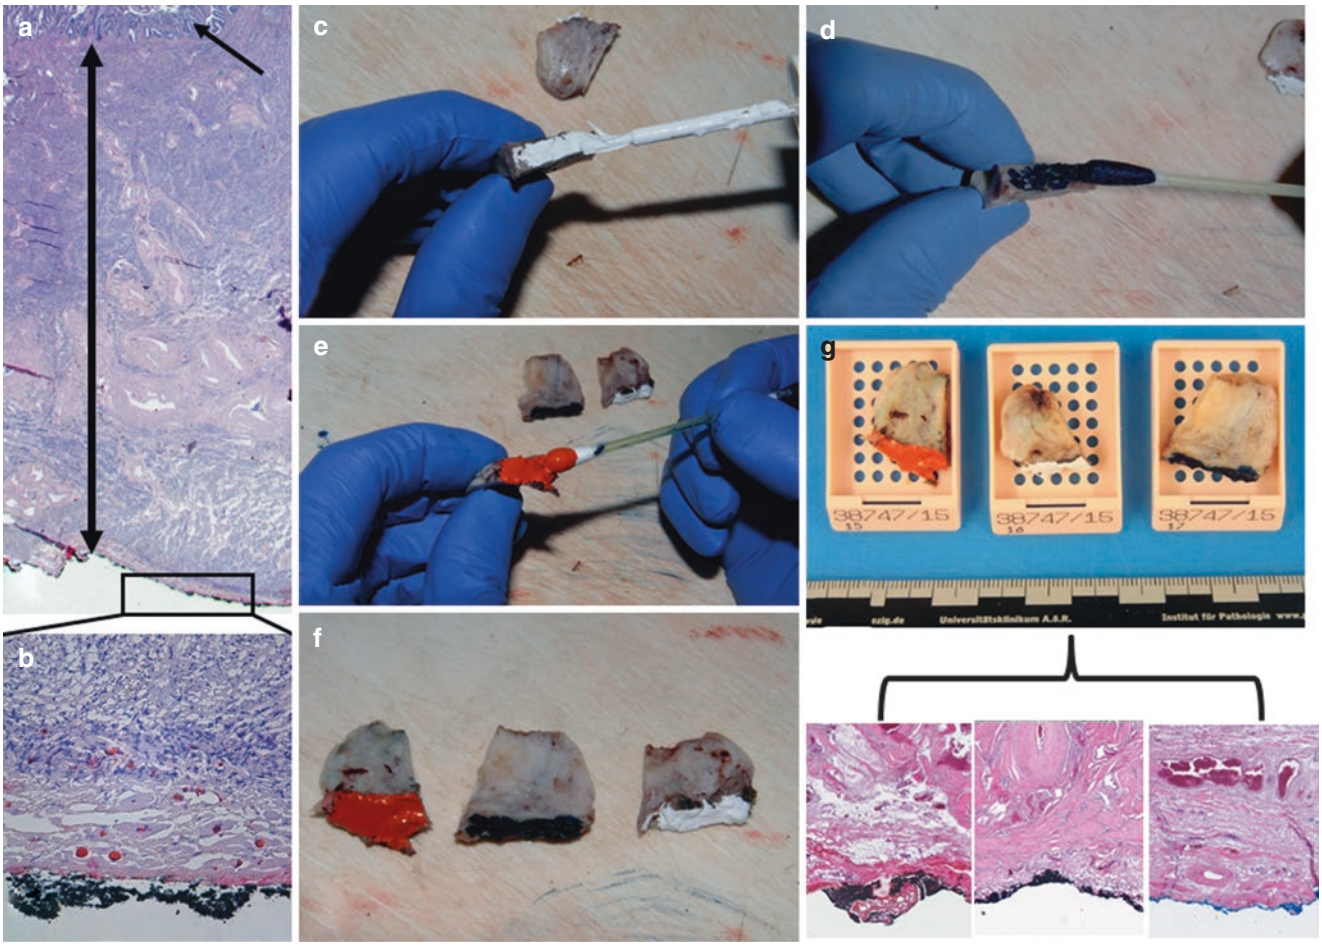

Fig. 18.3 Inking of hysterectomy specimens. (**a**, **b**) Inking of the serosal surface with correction fluid of a hysterectomy specimen with endometrioid endometrial cancer (*arrow*) indicating the distance from the serosal surface (*double headed arrow*). The serosal surface appears black inkend on the microscope. (**b**–**g**) Inking of the anterior resection margin of radical hysterectomy specimens by different colours (for details please see text)

sections parallel to the margins. But in special cases transverse sections fits. Although the number of blocks might be higher, the use of perpendicular sections allows the exact measurement of the distance to the margin.

During frozen section examination but also on permanent sections, the interpretation of the resection margins may be difficult because of cautering artifacts.

Frozen Section Analyses

Frozen section examination of a specimen may be necessary to evaluate the dignity of a uterine lesion (rarely), the extent of a lesion, its relation to the resection margins or to guide the extension of the surgical approach intraoperatively.

For adequate evaluation of the specimens the requirements and questions of the gynaecologic surgeon directly guide the pathologist how to handle the specimen [37, 47]. It is very helpful to contact the surgeon by phone call if there are missing/unclear marking sutures within the specimen or if it is unclear why the specimen was sent for frozen section analyses *before* any cutting of the tissue. To avoid misinterpretation of histological findings the pathologist should get in dialogue with the surgeon, rather than with the anaesthesiologist and/or the operation room nurses or technicians.

For special issues regarding the handling and reporting of hysterectomy specimens sent for frozen section, see Chap. starting at line 312.

Fixation of the Specimen

Well fixed specimens allow an easier handling and cutting of the tissue and produce better results in H&E-staining and immunohistochemical examination (Fig. 18.1).

Especially in exenteration specimens a complete or partial opening of resected bladder or bowel followed by tamponation using tissue towels (preferred by the authors, because of easier handling) or cellulose may be helpful. At the authors experiences a minimum fixation time of (radical) hysterectomies is about 24 h and of exenteration specimens 48 h. Large specimens might be cross-sectioned at intervals of about 1–2 cm. If there is a need to speed up the examination, the specimen may be fixed in an adequate amount of formalin and heating it up (at ~40 °C) in an incubator. The time depends of the size from the specimen. In the author opinion, (radical) hysterectomy specimen may heated up for about 6–8 h without any damage of the tissue.

Number of Sections Required

Judging what number of blocks required to optimally examine a specimen is one of the more controversial subjects in gynaecological pathology [143].

In the authors opinion, each resection margin and each resected structure should be documented by histologic slides. In case of smaller anatomic structures resected two identical ones (i.e. anterior and posterior vaginal margin) can be blocked into one cassette and one of the tissue slices (e.g. the anterior one) can be marked by ink. The relationship of a lesion to its adjacent structures as well as its resection margins should be documented. During the cutting of the specimen it should be determined which cut brings the most information on the histologic slide within one block. In lesions with known difficulties in histologic diagnosis and/or high intratumoral heterogeneity (e.g. MMMTs, leiomyosarcomas, endometrial stromal sarcomas, carcinomas after previous radio-(chemo-)therapy), a more extensive embedding is recommended.

Definition Relevant Parameters for Tumor Staging

The diagnosis of *lymphovascular space involvement (LVSI)* requires the demonstration of tumor cells (single cells or groups) within channels that are unequivocal lined with endothelium (Fig. 18.4a, e; [182]). It has been stated within the TNM-supplement of the UICC that if spaces around tumor cell nests caused by shrinkage during tissue processing and spaces which cannot clearly defined as lymphatic vessels should be classified as no LVSI (i.e. L0; [182]). The use of immunohistochemical stains (e.g. D2-40) to indentify LVSI is not being recommended for routine use.

The most recent TNM-supplement has defined (venous) *vessel invasion* if there is a tumor invasion within the vessels wall. It is not necessarily require demonstration of tumor cells in the lumen of the vessels (Fig. 18.3b; [182]).

Perineural involvement (PNI) has been defined as the detection of malignant cells in the perineural space of nerves, regardless if the nerve itself is infiltrated by the tumor and regardless of the extension of the involvement of the perineural tissue (Fig. 18.4c, d; [68, 72, 101, 116]).

Isolated tumor cells (ITC) are single tumor cells or small clusters of cells not more than 0.2 mm in greatest extent that can be detected by routine H&E-staining or immunohistochemically (Fig. 18.4f; [182]). ITC do not typically show evidence of metastatic activity (e.g. proliferation or stromal reaction) or penetration of lymphatic sinus walls [182]. The use of immunistochemistry to detect ITC cannot be recommended in routine workup. The presence of ITC within lymph nodes should not categorised as pN1 but as pN0(i+) if the ITC were morphologically identified (H&E or by immunohistochemistry) and as pN0(mol+) if they were diagnoses by non-morphologic techniques (e.g. DNA-cytometry or molecular techniques; [182]).

Micrometastases within lymph nodes are defined as tumor cell deposits larger than or equal 0.2 mm but not larger than 0.2 cm (Fig. 18.4g; [182]). The TNM/UICC suggest the use of pN1(mi) within the tumor classification [159, 182]. For easier communication, the authors prefer the use of pN1mic for the designation of micrometastases within lymph nodes according to the earlier TNM-classification in breast cancer.

Frozen Section Analyses of Hysterectomy Specimens

Frozen section diagnosis (FS) will guide the gynaecologic surgeon to perform lymph node dissection, the removal of additional tissue to complete the resection of possibly tumor burden tissue or to perform other surgical staging procedures (e.g. peritoneal biopsies, omentectomy etc.).

There are different approaches and indications for intraoperative frozen section analyses for hysterectomy specimens [26]. Some of them are dependent from the surgical philosophy and individual experience of the surgeon [190]. Within the authors institution there is a wide range of intraoperative treatment of the patient by the pathologist. The distribution of FS-examination during a 5-year period is illustrated in Fig. 18.5.

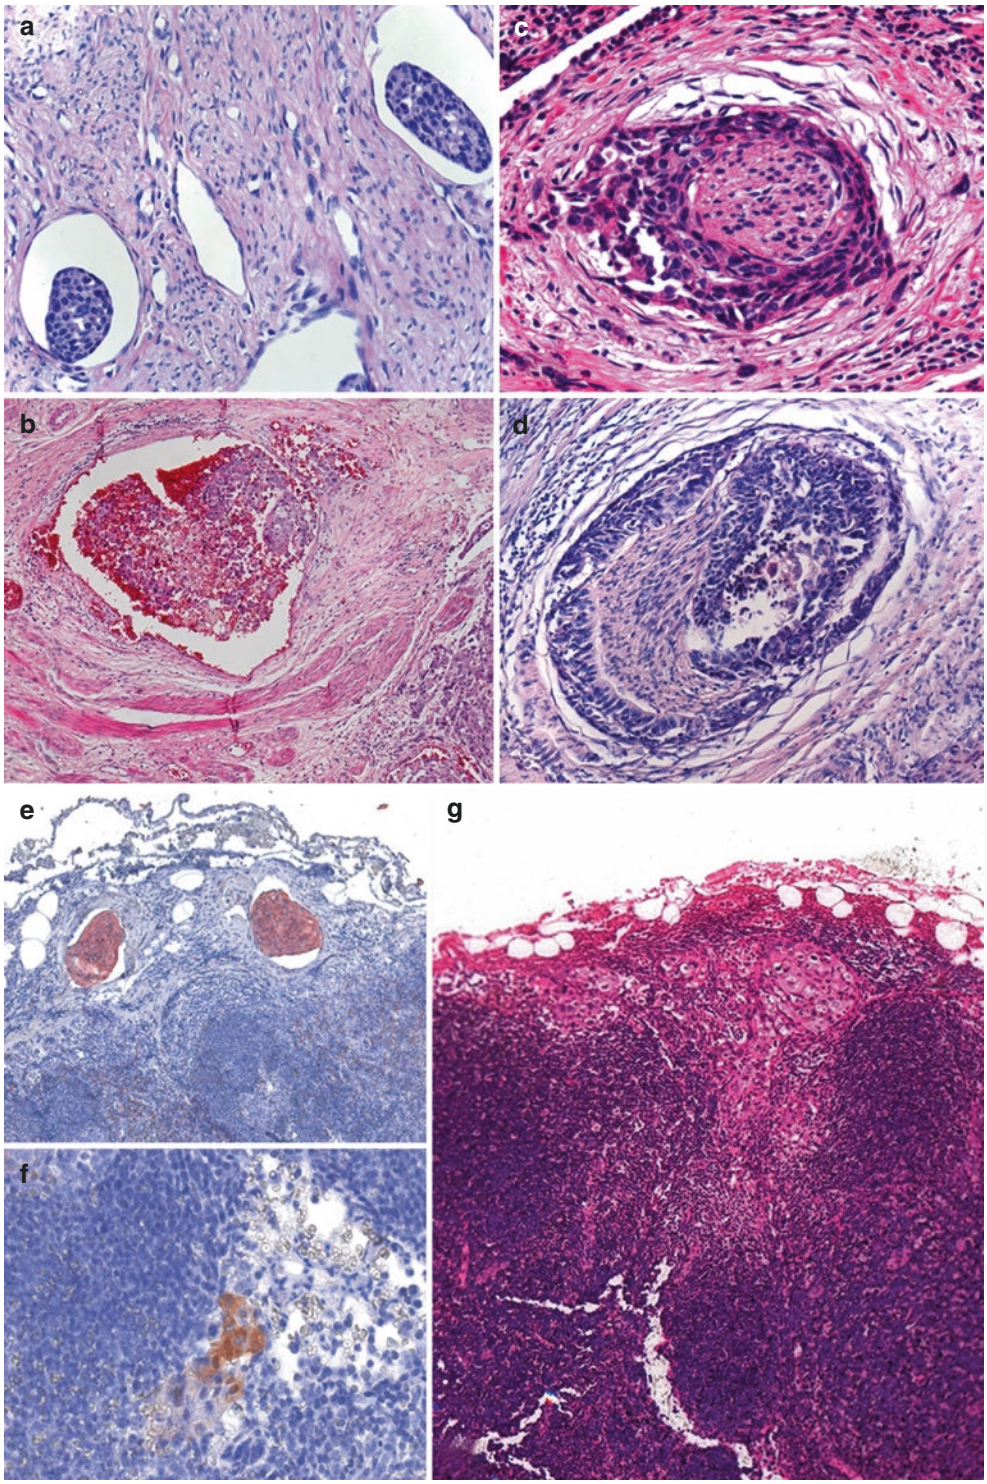

Fig. 18.4 Histopathologic parameters for staging of uterine cancers. (**a**) Lymphovascular space involvement by a squamous cell carcinoma within lymphatic vessels, lined by a single layer of endothelial cells (H&E staining). (**b**) Venous infiltration by a squamous cell carcinoma, note the erythrocytes admixed with tumor cells (H&E staining). (**c**, **d**) Perineural involvement by a squamous cell (**c**) and poorly differentiated adenocarcinoma of the uterine cervix (**d**). (**e**) lymphovascular space involvement within the capsule of a pelvic lymph node by squamous cell carcinoma which will categorised as L1 and not as lymph node metastasis (immunostain for cytokeratines; AE 1/3). (**f**) Isolated tumor cells of a squamous cell carcinoma within a pelvic lymph node (immunostain for p16). (**g**) Micrometastasis of a squamous cell carcinoma within a pelvic lymph node (H&E staining)

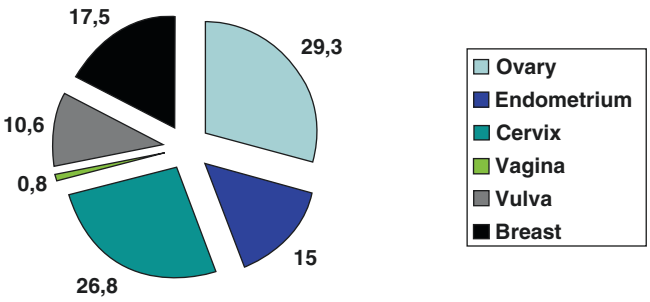

Fig. 18.5 Percentage of requested frozen section analysis from gynaecologic oncology during a 5-year period [74]. Within 7,921 frozen sections, 17.5 % (N = 1.368) were requested by gynecologic oncologic surgeons

Frozen Section in Endometrial Cancer, Malignant Mixed Müllerian Tumors (MMMT) and Atypical Endometrial Hyperplasia

FS-examination in hysterectomies is done to document the extent of the tumor which will directly impact patient's surgical management. The issues for FS-examination in endometrial cancer and its relative risk for lymph node involvement is summarised in Table 18.2.

Within the majority of cases the assessment of the depth of invasion represents the leading question [5, 42, 83, 146, 162] in endometrial cancer surgery. If the involvement of endocervical stroma represents a prognostic factor is still under discussion [132, 187], but its recognition mandatory for staging.

To determine the extent of the endometrial cancer the serosal surface and adnexal tissue should inspected. The ovaries should be incised along its long axis and all suspicious findings should be examined by histology. The uterus should be opened (by scissor at 12-o'clock position or bivalved at 3-o'clock and 9-o'clock position). Then the tumor and its adjacent myometrium should be sliced and the deepest point of infiltration should be frozen, ideally as full thickness or in a manner to preserve the overall depth and total thickness measurements [143, 183]. The macroscopic only evaluation of the depth of invasion may be problematic [33, 50, 97, 138]. Within the authors opinion macroscopic only evaluation may result in an underestimation of the depth of invasion especially in cases of endometrioid cancer representing microcystic, elongated, fragmented glands (MELF) pattern of invasion [40, 125], in case of endometrioid carcinoma with minimal deviation growth pattern [2, 76, 79, 92, 104, 126] as well as in cases of serous endometrial cancer with glandular pattern [11, 76] where the diagnosis was not made on the curetting. So, the depth of invasion should be proofed by histologic examination of FS in all cases [138]. One example of minimal deviation carcinoma is illustrated in Fig. 18.6.

The gross assessment of myometrial invasion is no better than 70 % [44, 50] and increases up to 90 % by histologic examination [86, 134, 146, 162, 173].

The differentiation between myometrial invasion and involvement of an endometriosis by endometrial adenocarcinoma may be challenging [5, 55, 83]. Helpful features distinguishing involvement of an endometriosis versus true myometrial invasion are discussed in the paragraps of cut-up of hysterectomies with uterine cancer and MMMT at page 1021.

Areas for suspicion of endocervical involvement should also be frozen to determine endocervical stromal invasion. The involvement of endocervical glands has no longer impact for staging. Although, there is still a debate about the necessity of radical hysterectomy in endometrial cancer with endocervical stromal invasion (stage pT2; [132, 167]), this feature should be examined and reported during frozen section examination also [112, 187].

The evaluation of the tumor grade by intraoperative biopsy has a reported sensitivity and a specificity of 40 % and 98 %, respectively [86, 134, 146]. A recommendation may be to report the grade at frozen section if there is an upgrade of the tumor [162].

The determination of the histologic subtype, mainly the distinction between type 1 and type 2 endometrial cancers should base on the histology of the curetting specimen, if there is a previously undiagnosed serous/clear cell cancer on frozen section the diagnosis should be given to the clinician [162].

Malignant mixed Müllerian tumors (MMMT) represent high grade carcinomas of the uterus [61] and will be treated by hysterectomy with bilateral salpingo-oophorectomy and pelvic and para-aortic lymphonodectomy [157]. So, intraoperative evaluation is of no impact.

A significant number of women diagnosed with atypical endometrial hyperplasia on endometrial curetting will be diagnosed with endometrial cancer on the hysterectomy specimen [71]. So, in individual cases there may be an indication for frozen section on hysterectomies with previously diagnosed endometrial hyperplasia [169, 171]. There may be some challenges within the diagnosis of low grade endometrioid endometrial cancers [141], high risk cancers are efficiently identified in frozen section [123, 141].

Frozen section analysis of lymph nodes in endometrial cancer may result in a discrepancy betwenn frozen and permanent section in 7–13 % [87, 175].

Frozen Section Radical Hysterectomies for Cervical Cancer

Frozen section analyses may be indicated in radical trachelectomy to determine the status of endocervical margins [20, 49, 122].

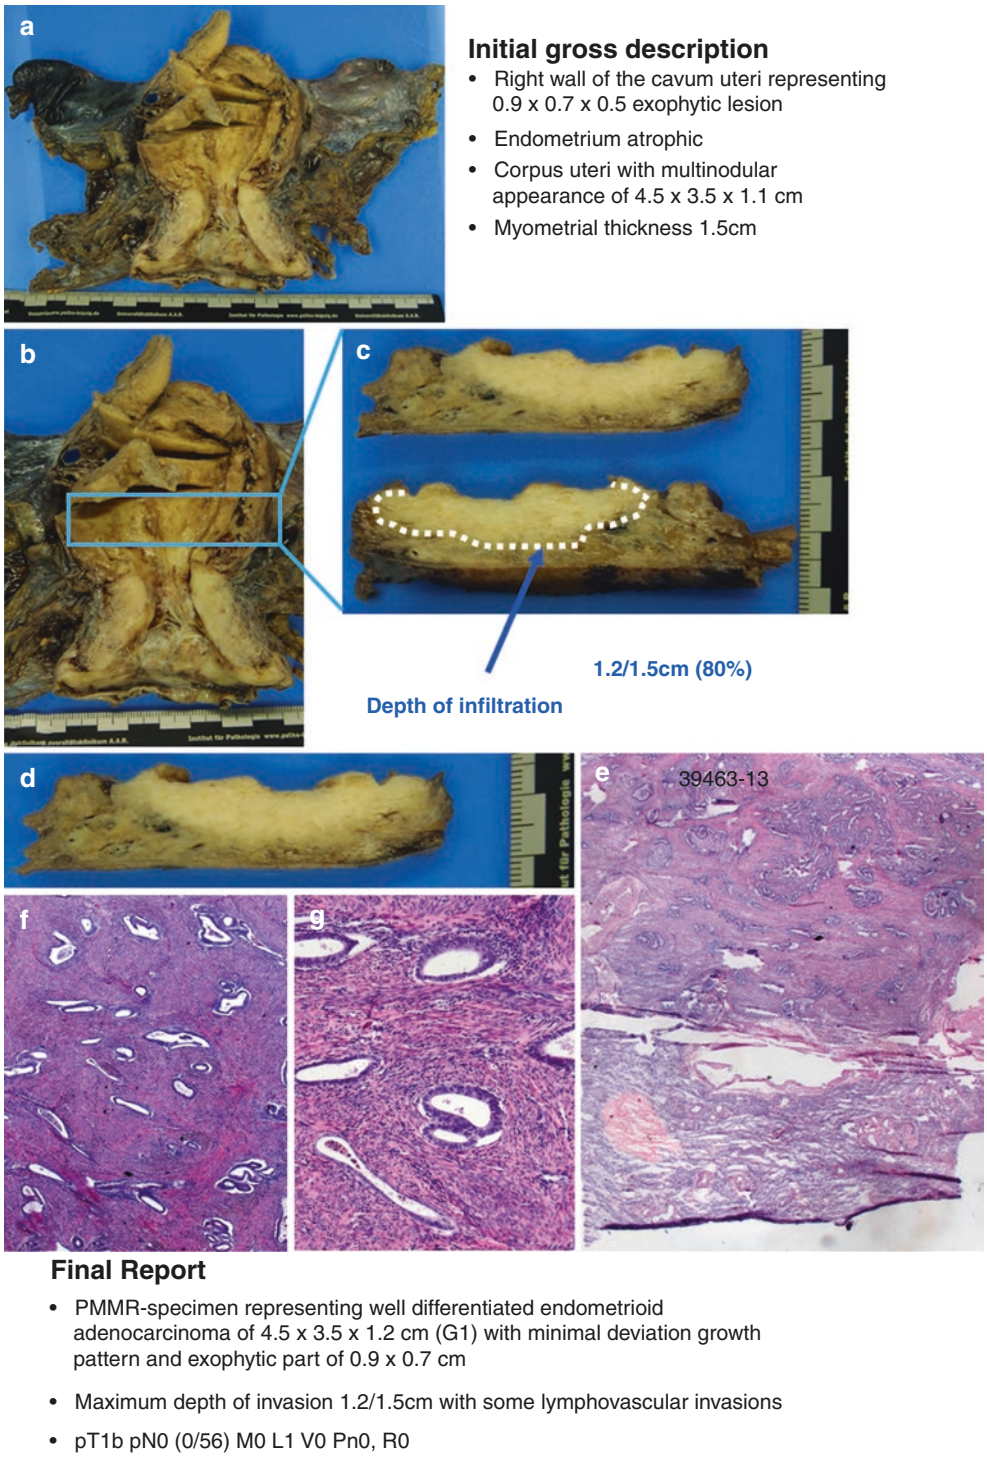

Fig. 18.6 PMMR specimen of endometrial cancer with well differentiated endometrioid adenocarcinoma with minimal deviation growth pattern. The initial gross description indicated a 0.9 cm exophytic tumor in maximal dimension. But frozen section analysis revealed a deeply invasive tumor with maximal depth of invasion of 1.2 into the myometrium which represented a maximal thickness of 1.5 cm. Final tumor size of 4.5 × 3.5 × 1.2 cm

But intraoperative examination of radical hysterectomy for cervical cancer is rarely requested within most institutions [9]. At the authors institution, that procedure was requested in all cases representing 26.8 % of all frozen section analyses for gynaecologic malignancies [73]. Routinely, the vaginal resection margin was examined by tangential sections. In cases with close posterior or anterior resection margins (i.e. in direction to the mesorectum and urinary bladder) and in cases with close margins at mesometrial (parametrial) infiltration the margins are examined using perpendicular sectioning. Recognising the concept of ontogenetic anatomy of the female genital tract [58] and the concept of therapeutic lymphonodectomy [56], routinely we examine the hysterectomy specimen for corpus involvement

by the cervical tumor macroscopically. In suspicious cases the leading edge of the cervical tumor in direction to the uterine corpus will be examined by frozen section histologically. In case of corpus involvement the lymph node dissection will be expanded to the para-aortic nodes, even in cases in which the first-line pelvic nodes were without metastatic deposits on previous frozen section examination.

The examination of lymph nodes in cervical cancer may be challenging and an inaccuracy up to 33 % has been reported [12, 41, 48]. These numbers are very high in the authors opinion. But these high rates are caused by the examination of sentinel nodes and under recognition of micrometastases. In case of macrometastases the accuracy rates will be higher.

Frozen Section Hysterectomies for Mesenchymal Tumors of the Uterus

Frozen section for mesenchymal tumors of the uterus is rarely requested [5, 9, 49, 97, 122, 183]. So, here is limited information in the literature addressing the practical issues commonly encountered regarding intraoperative frozen section of uterine mesenchymal lesions [10].

The depth of myometrial involvement of endometrial stromal sarcoma may be determined by frozen section analysis but has no direct impact of surgical procedure. Some leiomyosarcoma may be diagnosed by frozen section but it is impossible to separate between low grade spindle cell leimoysarcomas from smooth muscle tumors of uncertain malignant potential (STUMP) or highly cellular leiomyomas with mitotic activity [77] as well as between myxoid leiomyomas and myxoid leiomyosarcomas. The same diagnostic dilemma exists within the differential diagnosis of endometrial stromal nodules and low-grade endometrial stromal sarcomas (LG-ESS) as well as for the differential between high-grade endometrial stromal sarcomas (HG-ESS) and undifferentiated uterine sarcomas (UUS). Because of the limitations of the diagnostic safety and its impact on surgery frozen section examination of uterine sarcomas is not indicated within the majority of cases [46, 135].

There are case reports about frozen section examination of biopsies obtained from mesenchymal uterine lesions before laparoscopic morcellation procedure [172].

Handling of Hysterectomy Specimens for Final Cutup

Hysterectomy in Benign Diseases (Figs. 18.7 and 18.8)

There are several causes for hysterectomy in benign diseases. Cutting and examination of uteri removed for functional diseases is one of the most performed procedures in gynaecologic surgery [160]. This includes hysterectomy for decensus uteri, leiomyomas, pelvic discomfort in case of endometriosis/adenomyosis, persistent dysfunctional and/or postmenopausal bleeding and endometrial hyperplasia. A special indication is the risk-reducing (elective or prophylactic) hysterectomy in women at risk of hereditary endometrial cancer [89]. For a detailed description, see page 612.

Hysterectomy in Uterine Prolapse, Persistent Dysfunctional Bleeding and Pelvic Dyscomfort

There are some general aspects of the gross description of any hysterectomy specimen, regardless of the background disease for surgery which are summarised in Tables 18.3 and 18.4.

For normal appearing cervix one section of the anterior and one of the posterior lips fits. The sections are adequate if the squamo-columnar junction (transition zone) is included, because it represents the preferred location of CIN or ACIS [54, 119]. If the uterus is small, both sections can be embedded in one block and one lip (e.g., the anterior one) may be inked.

For examination of the endometrium in premenopausal women two sections, one of the anterior and one of the posterior parts of the fundus uteri is adequate. If the endometrium is atrophic and the woman is postmenopausal, one section is adequate. The section of the endometrium should represent a full thickness section, including the endometrium, adjacent myometrium and the uterine serosa, if not too thick.

The number of sections should be increased if there is a dysfunctional bleeding up to four. Alternatively, wedge sections can be performed by cutting small peaces of the endometrium and the immediately adjoining myometrium putting them in one cassette [143].

From any suspicious lesion within the uterine serosa and the myometrium, one block should be embedded.

The details of histopathology report are listed in Table 18.4.

Hysterectomy in Endometrial Hyperplasia

General aspects of gross description and parameters of the histopathology report are summarised in Table 18.3.

Uteri removed with the previous histopathology of endometrial hyperplasia require more extensive sampling of the myometrium to state residual disease and to exclude / diagnose endometrial carcinoma.

About six sections, three of the anterior and three of the posterior parts of the fundus uteri is have been recommended [143] to detect small well differentiated endometrial cancer [154]. The section of the endometrium should represent a full thickness section. Alternatively, wedge sections can be performed by cutting small peaces of the endometrium and the immediately adjoining myometrium putting them in one cassette [143]. The preferred site of embedding is the macroscopically thickened endometrium.

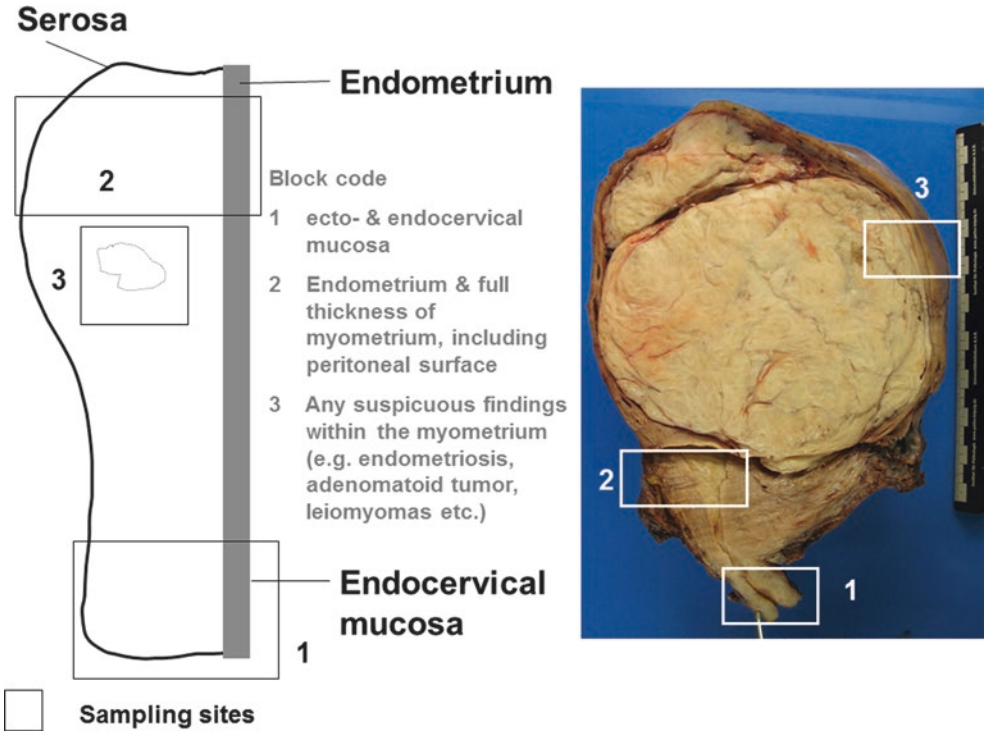

Fig. 18.7 Handling of a hysterectomy specimen for benign disease (see text)

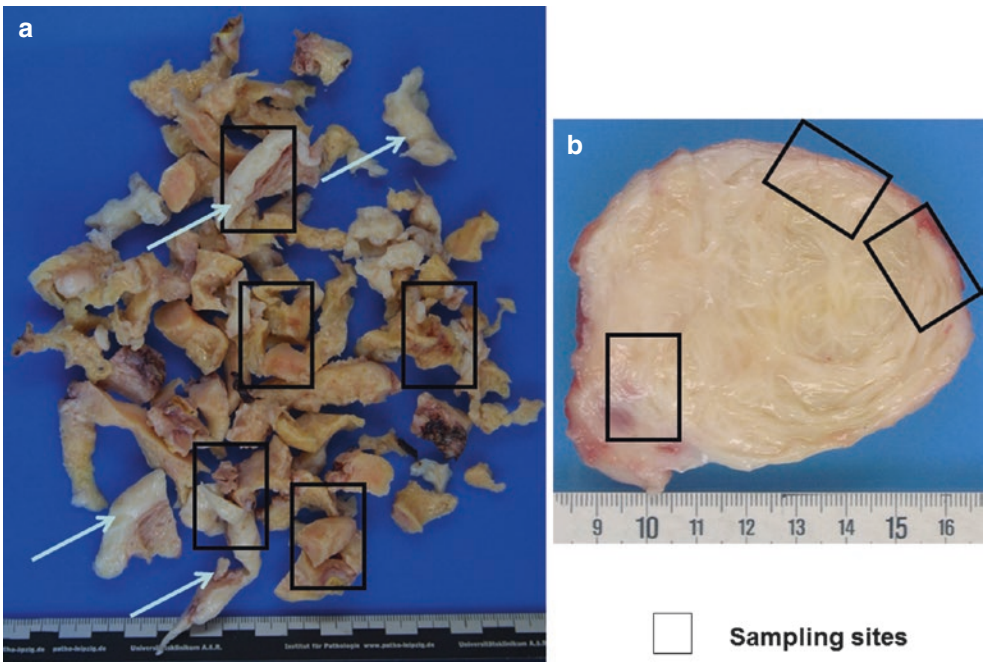

Fig. 18.8 Morcellated uterus and myomectomy. (**a**) Fragments resulted from morcellation during LASH-procedure with fragments of a leimoyma (*arrow*). (**b**) Myomectomy specimen with smooth outline of the leiomyoma with fasciculas (whirled) cutting surface, no necroses, no hemorrhage. Quadrats indicate embedding sites

Table 18.3 General aspects for the cutup of hysterectomy specimens [17, 62, 69, 88, 95, 143, 145]

List which specimens received (uterus alone, with one/two adnexae, tubes only etc.)
Indicate, how the tissue is received (fresh or inadequate/adequate fixed)
Note if the specimen is received intact or in parts or if it is morcellated
Note any defects on the uterine surface
Note if there are sutures made by the clinician to reconstruct the specimen
Make a proper orientation of the uterus
If the adnexae are present: the ovaries lay posteriorily to the Fallopian tubes
The posterior surface of the uterus is covered by a larger area of the peritoneum and extends farther down (in direction of cul-de-sac)
Give the appearance of the uterine surface (serosa)
The posterior part is of special interest
state if the surface is smooth or if there are peritoneal adhesions
State if there is rough surface or some discolorations
Look for small cysts (peritoneal cysts or endosalpingiosis) or probably implants of ovarian borderline tumor
State if there is a vaginal cuff present or not
State if mesometrial/parametrial tissue is present
State if ovarian ligament and/or infundibulum pelvicum is present
Weight the specimen
Give the size of each resected structure in three dimensions
State the performance of the ectocervical surface
Measure the thickness of the normal appearing myometrium
State if the cutting surface of the myometrium is abnormal
Irregular thickening, whirled appearance, cysts, haemorrhages
State the appearance of the endometrium and measure it
State if the endometrium is atrophic, polypoid, irregularly shaped or haemorrhagic
Record the location, shape (sessile or polypoid) and size of any polyps
State if there are abnormal findings within the myometrium (leiomyomata, endometriosis etc.)

Table 18.4 Details of the histopathology report within a hysterectomyspecimen without previously determined malignant disease [62, 69, 95, 143]

List the findings of ecto- and endocervix
List the findings of the endometrium
Atrophic/cyst-atrophic endometrium
Different phases of proliferation and secretion of the endometrium
Changes caused by hormones (oral contraceptives, HRT, selective progesterone receptor modulators, IUD etc.)
Any inflammatory changes
Presence of disordered proliferation/endometrial hyperplasia
List the findings of the myometrium
Leiomyomas, endometriosis/adenomyosis etc.

In case of atypical endometrial hyperplasia a careful examination is required to exclude well differentiated endometrioid adenocarcinoma.

The histopathologic report should give the kind of endometrial hyperplasia according to the most recent WHO-classification [186].

Hysterectomy in Precancerous Lesions or Microinvasive Carcinoma of the Cervix

Precancerous lesion of the cervix includes those deriving from the squamous epithelium (CIN-lesions, [165]) and from the endocervical columnar epithelium (adenocarcinoma in situ; AIS; [179]), some proceed to microinvasive carcinomas.

In the majority of cases there is a history of previous conisation. In hysterectomy specimens with the previous diagnosis of precancerous lesion of the cervix the transformation zone should be embedded completely.

The cervix should be amputated about 1.5 cm above the external os and should be processed similarly to a cone. Radial sectioning in a clockwise manner is the preferred method [17, 61, 62, 69, 88, 143]. Serially blocks should be submitted. Some authors prefer the submission of one sliced specimen within one cassette (e.g. cassette with number 1

indicates 1:00 o'clock). But, in the authors opinion and of others [143] it is also possible to put three sliced specimen in one cassette (e.g. cassette with number 1 indicates 1:00 to 3:00 o'clock and so on). Especially in case of previously diagnosed AIS one additional block of the endocervical mucosa immediate to the complete embedded transition zone is required.

The complete embedding of the transition zone is recommended if previous conisation was performed within the last six months. If it was up to 12 months previously, the embedding of the transition zone performing one block from the 12:00; 3:00; 6:00 and 9:00 o'clock position may be adequate. Perhaps the slices from 12:00 and 6:00 as well as from 3:00 and 6:00 may be processed together and one slice (e.g. 12:00) may be inked. Is there a history of previous CIN/AIS or conisation of >12 months, the cervix should be handled as described in the chapter Hysterectomy in Benign disease at page 435.

The performance of step sectioning (three sections with an interval of 200 µm; [7]) will be required in cases in which the diagnosis was made only be colposcopic guided biopsy or endocervical curetting without previous conisation to exclude microinvasive carcinoma and to document the extension of the lesion. (Secondary) step sectioning is also required when a precancerous lesion is microscopically suspicious for microinvasion. In all other cases up-front step sectioning is not indicated.

General aspects of gross description and parameters of the histopathology report are summarised in Tables 18.3 and 18.4.

The histopathologic report should state the precancerous/micro-invasive lesion according to the most recent WHO-classification [165, 179] and the status (perhaps distance) to the distal (ectocervical/vaginal/ circumferential) resection margin should be given.

Risk-Reducing Hysterectomy in Hereditary Cancer Syndromes

A special condition is the risk-reducing (elective or prophylactic) hysterectomy in women with hereditary cancer syndromes or familial history of endometrial cancer [15, 89, 90, 102, 148].

In those cases the endometrium should carefully examined [27, 80]. As in endometrial hyperplasia, embedding of about six sections, three of the anterior and three of the posterior parts of the fundus uteri is recommended. In some cases complete examination of the endometrium, especially of the lower uterine segment may be required [34]. The section of the endometrium in any grossly visible tumor should represent a full thickness section. Without grossly evident tumor, wedge sections can be performed by cutting small peaces of the endometrium and the immediately adjoining myometrium putting them in one cassette [143].

Some endometrial malignancy in women with HNPCC-(Lynch-) syndrome, occur within the isthmus uteri (lower uterine segment; [11, 27, 139]), so about three additional blocks are recommended to cover the isthmic endometrium. Some authors recommend complete embedding [34].

Colonic adenocarcinoma is the most common malignancy in hereditary nonpolyposis colon cancer (HNPCC; Lynch syndrome). However, endometrial carcinoma may develop before colon carcinoma in ~50 % of women with HNPCC [18, 177, 178]. There may be some features associated with HNPCC-related endometrial carcinoma i.e. age 50 year or younger, personal/family cancer pedigree that meets Bethesda guideline criteria, presence of MMR-associated tumor morphology (poorly differentiated endometrioid carcinoma, presence of high peri-/intratumoral lymphocytes; i.e. ≥40/10 HPF; [27, 152]), or location in the lower uterine segment [11]. In these cases, testing for defective DNA mismatch repair genes (MSH1, MLH2, MLH6, and PMS2) may be performed by immunohistochemistry [27]. Loss of MSH2 expression indicates Lynch syndrome and MSH6 is related to MSH2. HNPCC-related endometrial carcinoma is predominantly associated with MSH2 mutations, and MLH6 mutations in particular [18, 177, 178]. PMS2 loss is often associated with loss of MLH1 and is only independently meaningful if MLH1 is intact. More recently, a first-line testing for defective MMR-genes, followed by methylation testing was suggested for all endometrial cancer patients younger than 60-years of age [14, 43, 139] and by some authors for all newly diagnosed endometrial cancers [118].

The histopathologic report should give the endometrial pathology according to the most recent WHO-classification [186].

Hysterectomy for Leiomyomas and Endometriosis/Adenomyosis (Figs. 18.7 and 18.9)

In *uteri removed for leiomyomas*, the number and its location of the leiomyomas should be recorded. Their minimal and maximal size should be given. It should be stated if the myoma distorts the endometrium or protrudes into the isthmus uteri. These conditions may represent the cause for dysfunctional bleeding or may mimic endometrial polyp clinically and on ultrasound.

Each leiomyoma should be sectioned and examined grossly. If the cutting surface obtaining represents a white, fasciculas, well circumscribed appearance, obtaining one block with the surrounding myometrium will be adequate. If the lesion is >5 cm in largest dimension or represents some necroses or haemorrhagic foci or a softening of its consistence, one block per 1–2 cm largest diameter should be taken in context with the surrounding myometrium.

General aspects of gross description and parameters of the histopathology report are summarised in Tables 18.3 and 18.4.

Two conditions may clinically simulate uterine leiomyomas. For endometriosis/adenomyosis see the paragraph below. Another smooth muscle proliferation with unusual growth pattern represents the (diffuse) myometrial hypertrophia. *Myometrial hypertrophy* is a condition in which the myometrium is thickened and the uterus is (in the majority of cases) symmetrically enlarged without any microscopically abnormalities and without present and most recent pregnancy. This condition is not well defined. The weight of an uterus decreases after menopause and is influenced by the number of previous pregnancies. A weight of >130 g for nulliparous women, >210 g for parity 1–3 and >250 g for parity for and above 4 has been defined as myometrial hypertrophia [93]. Another, less plausible, definition indicates a weight of >200 g with a myometrial thickness of >2 cm [170].

Sometimes the clinicians perform a *myomectomy*. The tissue received should be weighted and measured in three dimensions. Each tissue should be transacted and examined grossly. The embedding of multiple slices in one cassette, altogether of two cassettes fits. Sometimes tiny surrounding tissue is grossly visible and the cuts should cover the transition of the lesion to its surrounding tissue (Fig. 18.8b). If the lesion is >5 cm or present with suspicious findings (see above), additional embedding is required.

The histopathologic report should recognise the criteria for the diagnostic of mesenchymal lesions of the uterus and their terminology of most recent WHO-classification [129].

Within the English literature the *endometriosis uteri* is termed adenomyosis. It is defined as the ectopic presence of endometrial glands surrounded by stroma within the myometrium beyond the histological interface with the endometrium (Fig. 18.9a). No commonly accepted diagnostic criteria of uterine endometriosis exist. On practical purpose the endometriosis should represent more than the field width of an intermediate magnification (i.e. deeper than the microscopic field seen using 10× objective and 10× ocular lenses, within a conventionally configured microscope, or 0.2–0.3 cm below the endometrial (myometrial interface) [128]. Consequently the diagnosis of uterine endometriosis is made on a hysterectomy specimen and not on currettings. Endometriosis uteri may provoke some diagnostic challenges within the clinicians because it may be associated with non-specific signs, may be asymptomatic or may mimic uterine tumors. On histology the endometriotic glands and its surrounding stroma may display the same range of changes seen within the endometrium. Especially on postmenopausal women the glands may disappear (so called gland poor or stromal endometriosis; Fig. 18.9b). Larger foci of stromal endometriosis must be separated from uterine stromal nodule and low-grade endometrial stromal sarcomas [21].

Within a serious number of cases the diagnosin of endometriosis uteri is incidental on microscopy. By careful examination a circumscribed whirling of the myometrium may occur (Fig. 18.9c). Some uterine endometrioses may be tumorlike and may clinically as well as macroscopically mimic leiomyomas (e.g. provoking pelvic discomfort, tumorlike appearance, bleeding disorders). On histology the endometriotic foci are surrounded by a reactive proliferation of the myometrium (Fig. 18.9d, e; representing a "real" adenomyosis of the uterus). Tumorlike uterine endometriosis may mimic low-grade endometrial stromal sarcomas with glandular features [111].

Hysterectomy with Morcellated Uterus

There may be an increased frequency of operation procedures resulting in the fragmentation and morcellation of the uterus (as laparoscopic assisted supracervical hysterectomy; LASH) especially in heavily adipose women [13, 52].

In a serious number of cases it is difficult to get an orientation within the fragmented tissue to identify the endometrium. The preoperative use of methylene blue [136] may simplify macroscopic identification of the endometrium.

The risk of incident malignancies after morcellated hysterectomy ranges between 0.2 and 1 % [36, 51, 53, 149] but may increase with increasing age of the women treated [184].

The tissue received should be weighted and measured in three dimensions as well as examined carefully. From any suspicious findings/discolorations tissue should be processed. Four cassettes, containing two to three tissue slices may be submitted for histopathologic examination. Other authors prefer the embedding of one block per cm largest dimension of the fragmented tissue (D. Mayr, personal communication 2015). From all tissue with any discoloration or different consistency additional embedding is required. The endometrium should be identified. In case of lesions suspicious for leiomyoma, the lesion and the adjacent myometrium should be embedded (Fig. 18.8a). In case of incident malignancies, unclear smooth muscle proliferations or missing endometrium, additional embedding is required.

Hysterectomy with Macroinvasive Cervical Cancer

Trachelectomy (Fig. 18.10)

The specimen should be weighted and measured in three dimensions. The presence and its size of adjacent mesome-

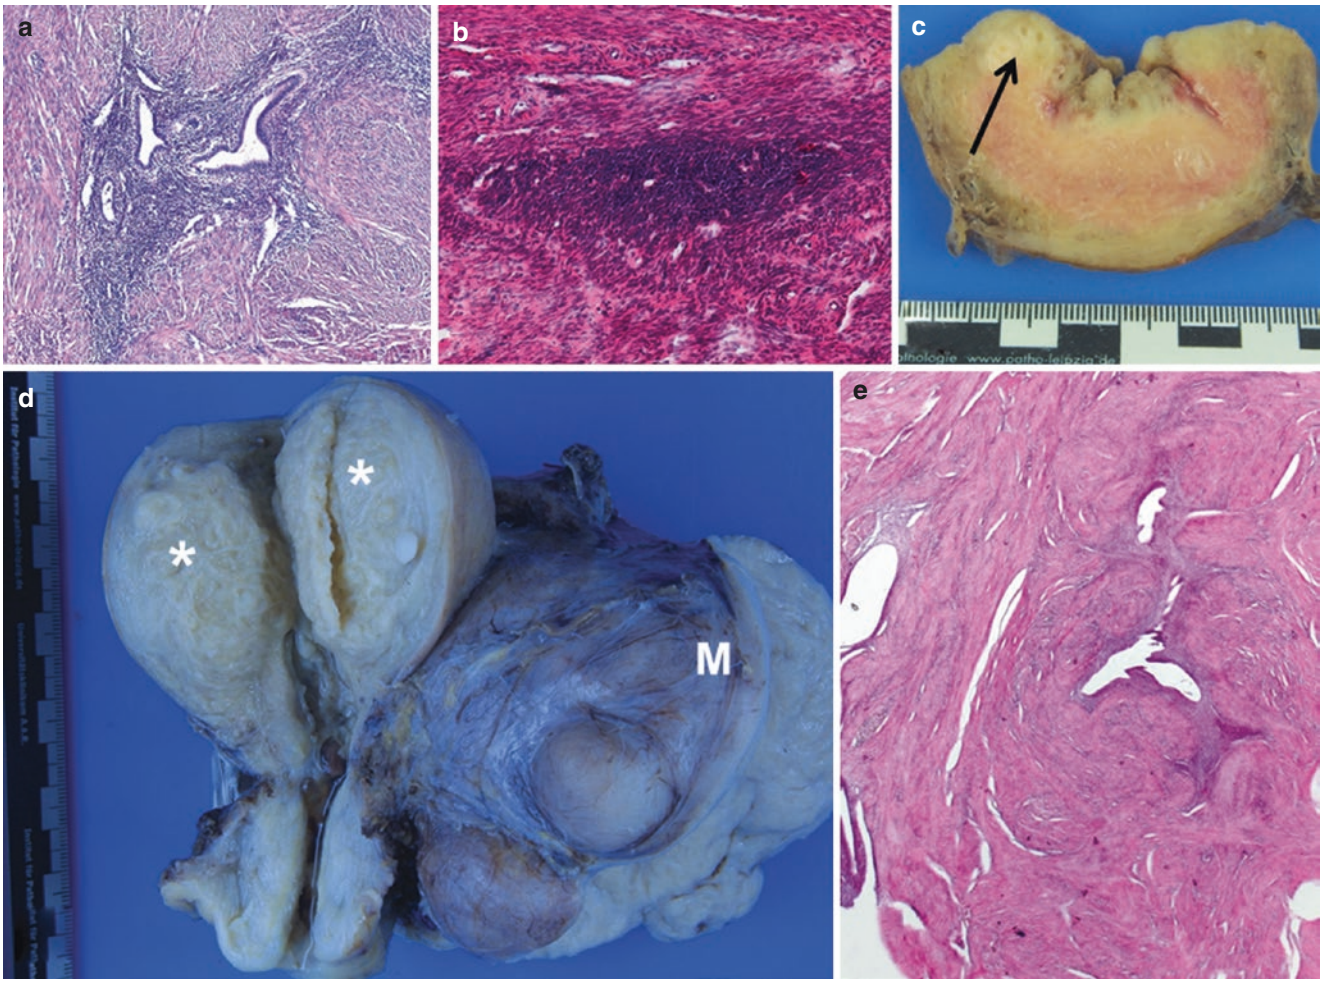

Fig. 18.9 Endometriosis affecting hysterectomy specimen. (**a**) Typical histologic appearance of uterine endometriosis representing endometrial glands and surrounding stroma within the myometrium. (**b**) So called gland poor (or stromal) endometriosis representing solely endometrial stroma without glands within uterine myometrium. (**c**) Macroscopic appearance of small endometriosis (*arrow*). (**d**, **e**) Tumorlike endometriosis within uterine corpus (*stars*), the endometrial glands are surrounded by circular reactive proliferation of smooth muscle fibers of the myometrium, representing an adenomyosis uteri. *M* uterine leiomyoma

trial/parametrial tissue should be given. The length of the vaginal cuff, if present, should be given, separately for its anterior and posterior part. The appearance of the ectocervix and external os should be stated (smooth, erosions, ulcerated, funnel-shaped etc.). The presence of lymph nodes within mesometrial/parametrial tissue should be stated and its size given.

The distal vaginal resection margin should be embedded separately or inked. The proximal endocervical resection margin should be examined separately as well. If present and not removed by previous conisation, the size of the cervical tumor should be given in three dimensions. Its distance to the resection margins (distal/ectocervical, proximal/endocervical, anterior and posterior) should be stated as the involvement of mesometrial/parametrial tissue.

The transformation zone should be embedded completely. Radial sectioning in a clockwise manner is the preferred method. Serially blocks should be submitted preferring the submission of one sliced specimen within one cassette (e.g. cassette with number 1 indicates 1:00 o'clock). The adjacent endocervical tissue should be processed completely as is for the mesometrial/parametrial tissue. The resection margin of the mesometrial/parametrial tissue may be inked.

A synopsis of histopathologic oncology report is summarised in Table 18.5.

The tumor typing and staging should be performed according to the most recent WHO- and TNM-classification [159, 165, 179].

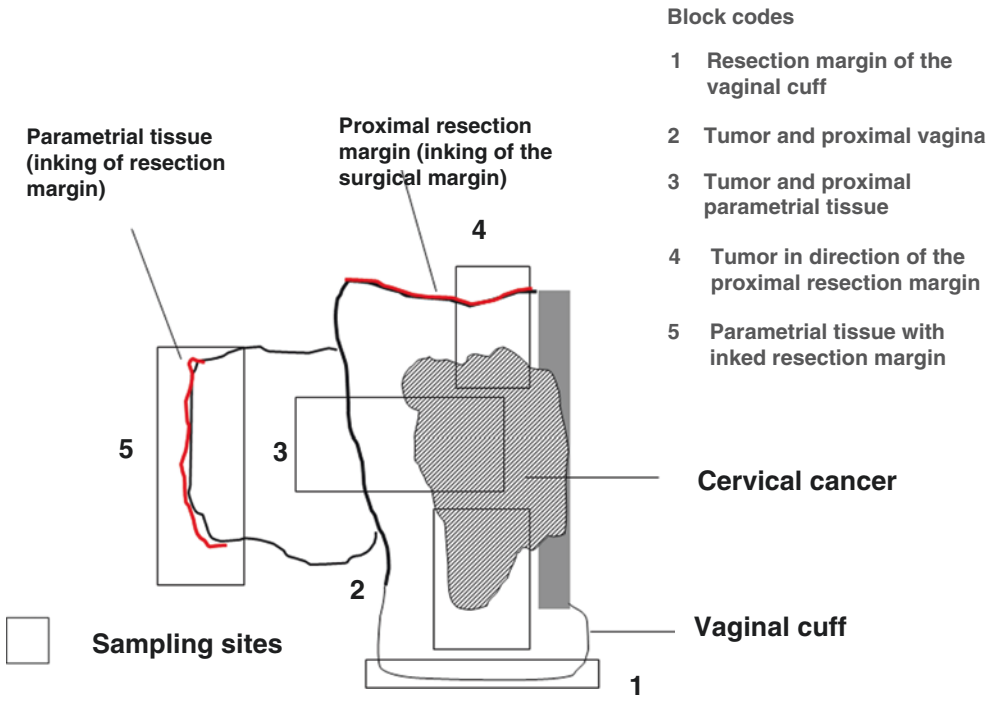

Fig. 18.10 Schematic sectioning of a radical trachelectomy specimen with cervical carcinoma and block codes (for details see text; adopted from Horn et al. 60)

Radical Hysterectomy (Figs. 18.11, 18.12, and 18.13)

Radical hysterectomy will be performed for macroinvasive cervical carcinoma [142, 176] or in some cases with endometrial carcinoma/MMMT with cervical stromal involvement.

General aspects of gross description and parameters of the histopathology report are summarised in Table 18.3.

The final oncology pathology report should recognise the most recent WHO-classification [165, 179] for tumor typing the TNM-classification [159] for staging.

The gross description in radical hysterectomy needs the documentation of the location of the tumor, its three dimensional measurement and its relation to the vaginal cuff (if present) and the resected mesometrial/parametrial tissue as well as the involvement of the corpus uteri. The exact anatomic location of the cervical tumor should be stated (e.g. anterior or posterior lip, ecto- or endocervix; the authors prefer to give an "o'clock location" on localised tumors or to state circular involvement of the transition zone).

The three dimensional size of the resected mesometrial/parametrial tissue should be given. Within specimens resulted from the surgical TMMR-technique the macroscopic description should be separate between the ligamental and vascular part of the mesometrial tissue (Figs. 18.11 and 18.13). By the way, almost all lymph nodes within the mesometrial tissue are located within its vascular part (Fig. 18.11).

The circumferential distal vaginal margin should be embedded separately, one block covering the margin between 9:00 and 3:00 (anterior margin) and one covering the margin between 3:00 and 9:00 (posterior margin) in a tangential manner. Sections of the tumor need to demonstrate the depth of invasion into the cervical stroma, its relationship to the vaginal cuff, the mesometrial/parametrial tissue and the distance to the resection margins. Each section should be perpendicular (if possible) and full thickness and should include the maximum amount of tissue that will fit into the cassette. One block should document the distance to the anterior and posterior resection margin of the cervix uteri.

Since there is a low intratumoral heterogeneity in cervical carcinomas [8, 109], two blocks each from the anterior and posterior part of the cervical stroma is adequate. Especially in larger tumors and/or deep cervical stromal invasion, careful embedding of the transition zone between the cervical stroma and the adjacent mesometrial/parametrial tissue is mandatory. After transecting the resected mesometrial/parametrial tissue, the transition zone to the endocervical stroma should be embedded using perpendicular sections. In the authors institution, in small tumors where there is macroscopically no evidence for mesometrial/parametrial invasion one block from the right and left side will be embedded. In larger tumors or grossly suspicion of mesometrial/parametrial involvement two blocks from each side will be processed.

The transected mesometrial/parametrial tissue will be processed completely to evaluate lymphovascular space or perineural involvement, discontinuity of tumor spread and the detection of small lymph nodes. The mesometrial/para-

Table 18.5 Synopsis of the features within the final oncologic histopathology report of cancer of the cervix uteri [7, 17, 62, 69, 88, 95, 143, 145]

Histopathologic tumor type (WHO)[a]
Grading (WHO)
Tumor regression after previous radio (chemo-) therapy
Absence/presence of lymphovascular and blood vessel (venous) involvement (L- and V-status)
Absence/presence of perineural invasion (Pn-status)
Tumor stage (TNM)
Tumor size and depth of invasion in microinvasive disease (pT1a1 and pT1a2)
Tumor size in three dimensions in macroinvasive disease (≥pT1b1)
Relative depth of invasion within (endo-) cervical stroma (pT1b and pT2a)
Presence/localisation and extension of vaginal invasion
Presence/localisation and extension of mesometrial/parametrial invasion
Minimal distance to the resection margins
R-classification (UICC)
Status of the adnexae

[a]it is important to note that (small cell) neuroendocrine carcinomas of the uterine cervix represent a poor prognosis [6, 185] and that up to 33% of these tumors represent a non-neuroendocrine component [64]. Because mixed neuroendocrine/non-neuroendocrine carcinomas represent decreased survival [64], the percentage of the neuroendocrine component of the whole tumor should be stated within the report [7]

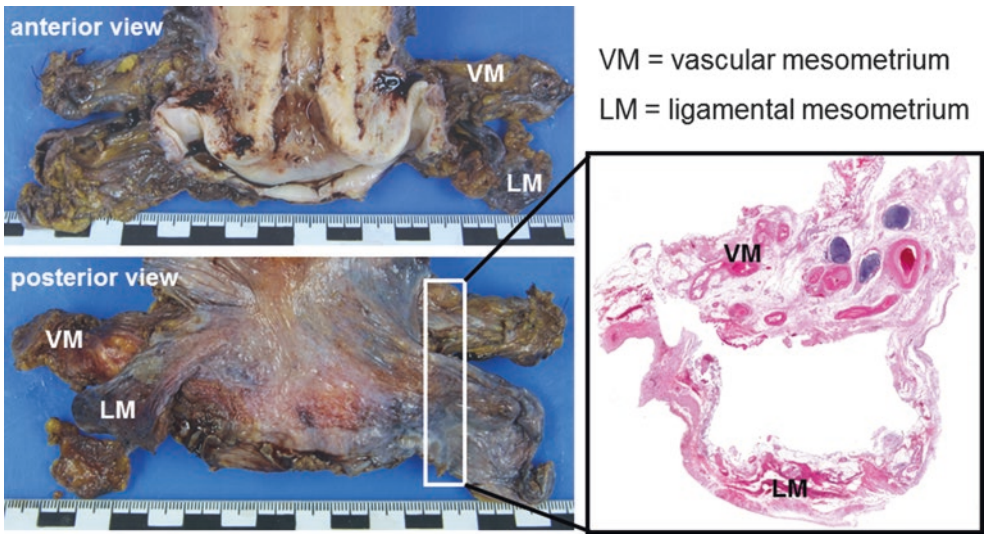

Fig. 18.11 TMMR-specimen (previously opened by scissor at 12 o'clock) representing vascular and ligamental mesometrium using perpendicular section for embedding (see text). Within the vascular mesometrium small lymph nodes are present

metrial tissue will be virtually separated in its proximal (near the uterus), medial and distal third and processed each within one (ore more) cassette. If small lymph nodes are grossly visible, step sections (three sections with an interval of 200 µm) are performed.

Because there may be an increased risk of (para-aortic) lymph node spread [117] and higher frequency of ovarian metastases [81] in cases representing invasion of the uterine corpus this feature should be documented. In each case of macroscopically suspected corpus infiltration (especially in larger tumors), one or two blocks from the cranial end of the tumor into the direction to the corpus uteri should be embedded. Although, involvement of the corpus uteri has no impact on staging at time, that feature should be given within the pathology report, perhaps stating if the infiltration occurs at endometrial or myometrial level or both.

In cases with previous conisation and grossly no visible tumor within the radical hysterectomy specimen, the distal part of the cervix should be embedded completely as described in the chapter about Hysterectomy in Precancerous Lesions or Microinvasive Carcinoma of the Cervix at page 560. The transition zone between the endocervical stroma and the mesometrial/parametrial tissue should be handled as described above.

Based on ontogenetic rather than functional anatomy, new surgical approaches of radical hysterectomy in uterine cervical cancer, known as TMMR-technique [56, 57], has been described. A more radical approach represents the extended mesometrial resection (EMMR; [56]). In EMMR additional

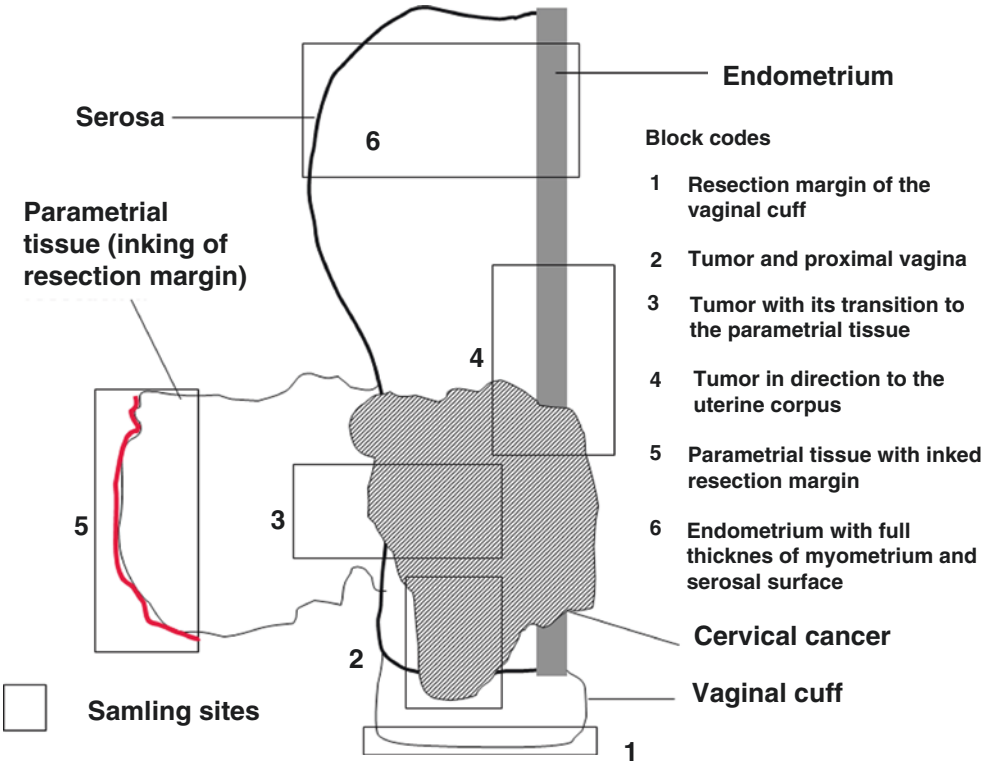

Fig. 18.12 Schematic sectioning of a radical hysterectomy specimen with cervical carcinoma and block codes (for details see text and Table 18.5)

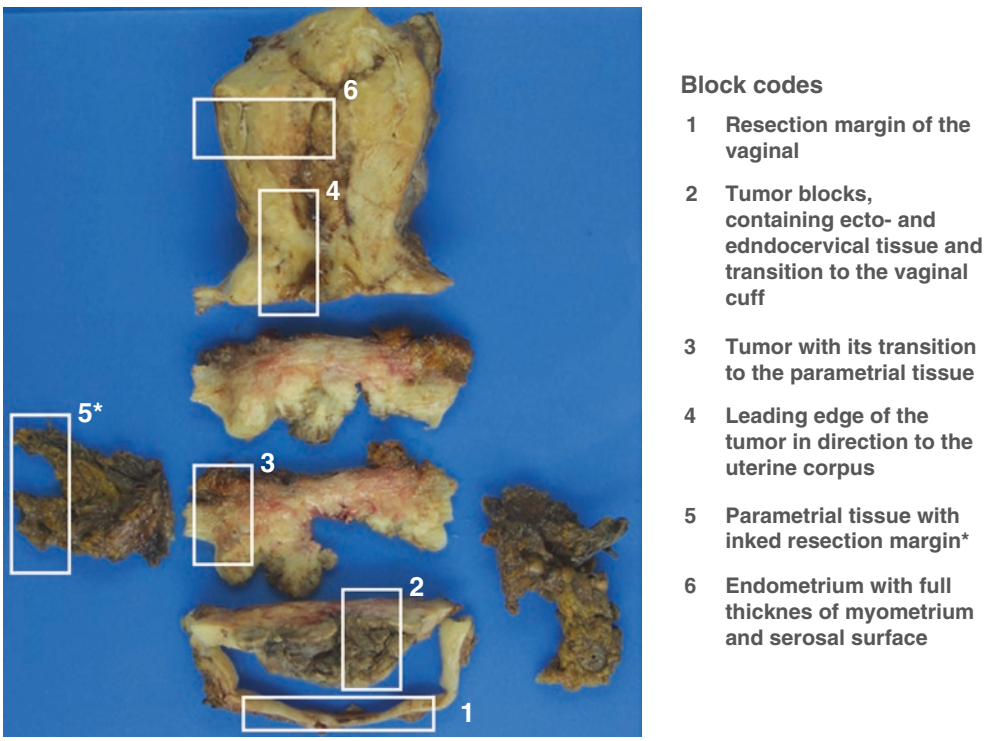

Fig. 18.13 Sectioning of a TMMR-specimen with cervical cancer. For more information please see text (*For detailed handling of the mesometrial tissue please see Fig. 18.11)

pelvic tissue, suspected to be involved by the tumor clinically or on radiologic findings will be removed (Fig. 18.14). This includes for example lipo-fibrous tissue surrounding the ureter (mesoureter) or the resection of the ureter itself and/or the dorso-lateral parts of the urinary bladder (meso of the urinary bladder). This tissue is sometimes incorporated within the mesometrial tissue and may be hard to be identified on macroscopic description and dissection. So, detailed information from the gynaecologic surgeon is mandatory which tissue was removed during EMMR-operation

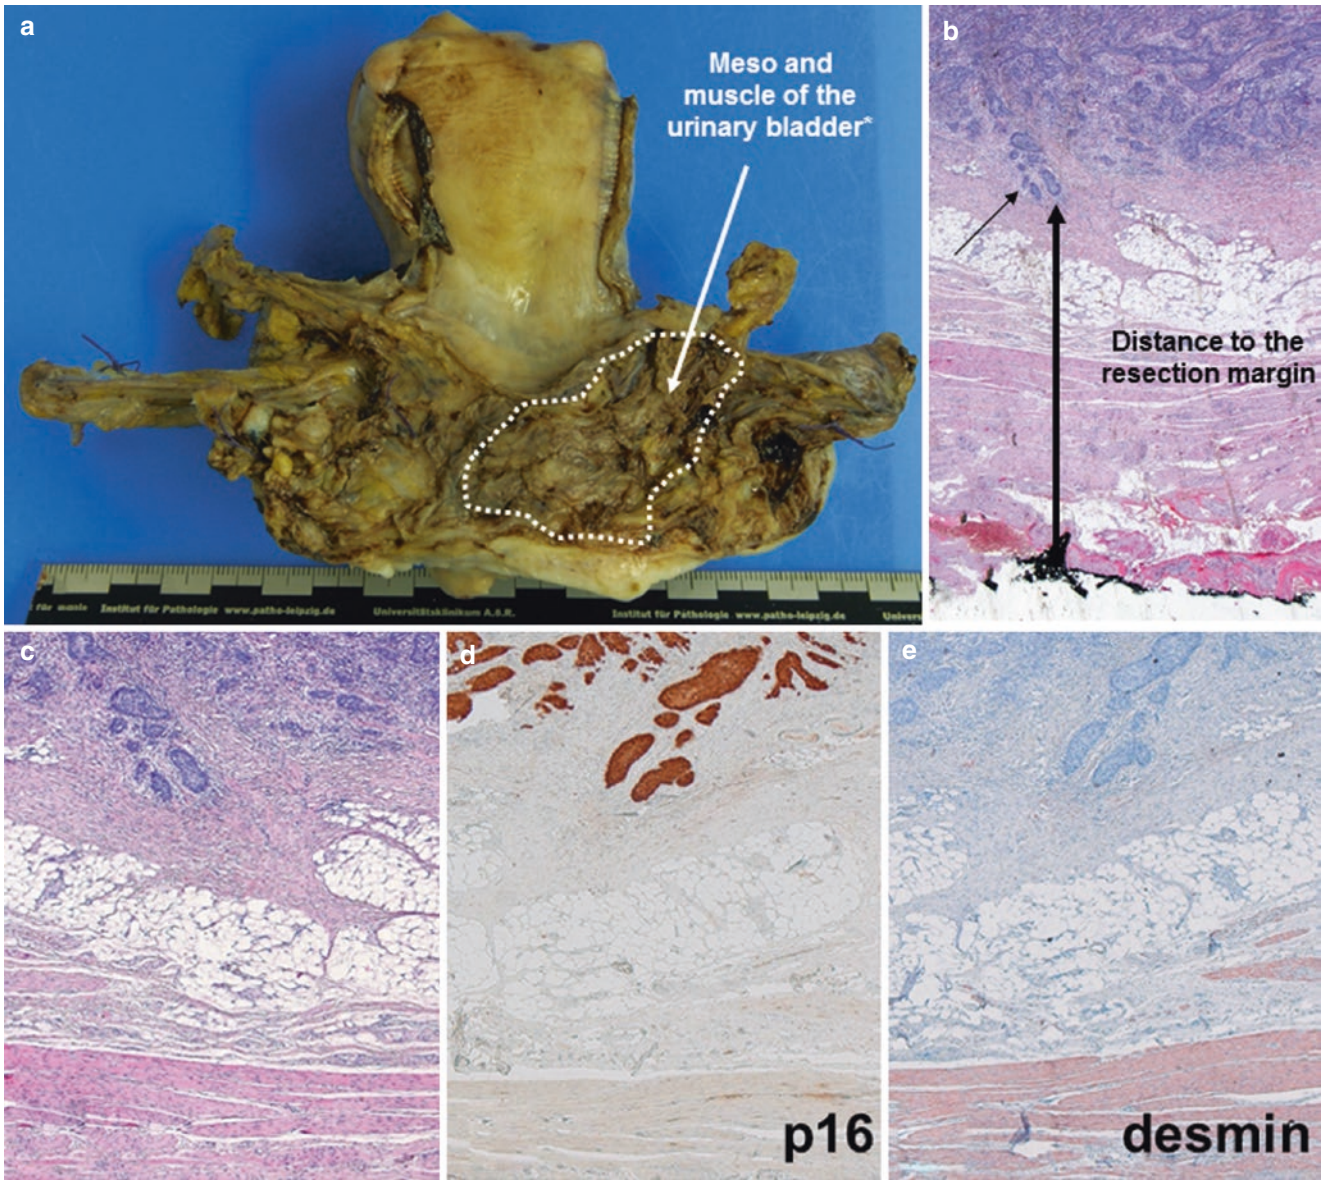

Fig. 18.14 Extended mesometrial resection (EMMR). (**a**) Anterior view of EMMR specimen, encircled the additional removed tissue containing the fatty tissue surrounding the dorsal part of the urinary bladder (bladder's meso) and some outer lines of smooth muscle of the bladders wall, (**b**) microscopic view representing squamous cell carcinoma infiltrating the bladder's meso (*small arrow*), note the peritumoral desmoplastic stromal response surrounding the leading edge of the tumor. *The thick double headed arrow* indicates the distance to the inked resection margin, (**c**–**e**) higher magnification from (**b**) featuring the infiltration of the bladder's meso by the tumor which stained positive for p16, no infiltration of the bladder's muscle which is stained positive for desmin in (**e**)

procedure. The size of that additionally resected tissue should be incorporated in the measurement at gross description and its resection margins should carefully be examined. Sometimes individual components are only detected by histologic examination (Fig. 18.14c–e). The presence or absence of tumor infiltration and its distances should be given in the oncologic pathology report to exactly document the tumor spread within the pelvis and to correlate the pathologic findings with the clinical and radiologic ones.

In cases with radical hysterectomy after neoadjuvant radio- (chemo-) therapy, and grossly no visible tumor within the radical hysterectomy specimen, the distal part of the cervix should be embedded completely as described in the chapter about Hysterectomy in Precancerous Lesions or Microinvasive Carcinoma of the Cervix at page 560. The transition zone between the endocervical stroma and the mesometrial/parametrial tissue should be handled as described above.

The tumor typing and staging should be performed according to the most resent WHO- and TNM-classification [159, 165, 179].

A synopsis of histopathologic oncology report is summarised in Table 18.5.

There may be a prognostic effect of the distance to the anterior and posterior resection margins in patients with were treated by radical hysterectomy using the Wertheim-Meigs-technique [39, 106], but not in patients who were treated by TMMR-technique [59]. Regardless of the used surgical approach, the (metric) distance to the margins should be given in the pathology report. In small tumors the distance can be determined macroscopically, but in large tumors or close resection margins it should be determined histologically using a liner after marking on the slide or in even much more closer margins using an ocular micrometre (Fig. 18.15).

Despite there is no established regression grading system in cervical carcinomas [189] after neoadjuvant radio-(chemo-) therapy, the histopathological report should state if there are any therapeutic effects or not.

Regardless if there is a mesometrial/parametrial involvement, infiltration of the vaginal cuff should be given in the final report with its extension, localisation and distance to the resection margin.

Microscopically, there is no clear transition between the endocervical stroma and the mesometrial/parametrial tissue [94, 131]. But, if tumor is seen outside the endocervical stroma with infiltrative growth within the fibrous paracervical tissue, mesometrial/parametrial involvement should be diagnosed (Fig. 18.16). There is no doubt that the presence of tumor between large vessels and/or fatty tissue it represents stage pT2b. Some authors suggest that the infiltration of paracervical (fibrous) tissue and that of mesometrial tissue with invasion of fatty tissue represents two different ontogenetic tumor stages (oT-stage; [56]).

Metastatic involvement of mesometrial/parametrial lymph nodes represent lymph node involvement and should be staged as pN1 and not as stage pT2b.

There is no doubt that deep cervical stromal invasion represents a prognostic factor but, different studies have used different cut-off points for defining deep infiltrative growth, ranging from >25 to >75 % [28, 84, 91, 191]. Within the German guidelines for the diagnosis and treatment of carcinoma of the uterine cervix, deep stromal invasion was defined very recently as infiltration of >66 % [7]. Depth of invasion is measured from the level of the cervical mucosa up to the deepest point of invasion. The relative depth on invasion is calculated by the relationship between the deepest point of invasion and the full thickness of the cervical wall (see Fig. 18.17). The presence of lymphovascular space involvement outside the deepest point of tumor stromal infiltration will not alter the depth of invasion and should be diagnosed as L1.

There may be a prognostic impact of different patterns of invasion in squamous cell carcinoma of the uterine cervix ([64, 67]; Fig. 18.18). For adenocarcinomas a prognostic relevant 3-tired pattern of invasion has been described [31]. Pattern A represents an infiltrative growth of well-demarced well or moderate differentiated glands with rounded contours, frequently forming groups of glands or cribriform pattern, without lymphovascular space involvement, desmoplastic stromal reaction and without single cell invasion. Pattern B is characterised by early destructive stromal invasion arising from glands with pattern A-like features, with or without lymphovascular space involvement, whereas pattern C shows destructive invasion. It may be recommended to add the pattern of invasion within the histology report.

In case of radical hysterectomy after previous conisation and availability of the histopathology report of the conisation a final (maximal) tumor size should be calculated by summarising both sizes [7].

Histologic pictures of the different types of infiltrative growth: (**a**) closed pattern of invasion with cohesive tumor growth with well-delineated infiltrating borders and "pushing" margins, (**b**) finger-like pattern of invasion with trabecular tumor growth in solid cords and tumor cell nests, (**c**) spray-like pattern of invasion with tumor growth in small groups of infiltrating cells and high tumor cell dissociation

There is one major unclear topic within the staging of uterine cervical cancer [55]. The involvement of the Fallopian tube, ovary or adjacent mesoadnexal tissue ("adnexal involvement") is not recognised within the TNM-/FIGO-system [70, 159]. There are only limited studies dealing with the prognostic impact of that topic [78, 81, 153]. So, the impact of "adnexal involvement" is quite unclear at time. In the authors opinion, adnexal involvement represents a feature of local advanced disease and poor prognostic outcome [81] within uterine cervical carcinoma and should be stated as distant metastatic disease, categorised as pM1 OTH.

Hysterectomy with Endometrial Carcinoma and Malignant Mixed Müllerian Tumors (MMMT) (Figs. 18.19, 18.20, 18.21, 18.22, 18.23, and 18.24)

The term *endometrial* designs a lesion which is located within the endometrium. It says nothing about a special histopathological type and its clinical behaviour. Whereas the term *endometrioid* defines a lesion which is histopathologically similar to the morphology of endometrial glands (of the proliferative endometrium). So, an endometrioid endometrial adenocarcinoma means an adenocarcinoma within the endometrium representing a glandular morphology which is similar to the non-neoplastic glands of the endometrium (the adenocarcinoma looks alike normal glands of the endometrium).

According to recent research results MMMTs represent a special morphologic type of endometrial cancer [103, 114]. Consequently, the staging should be performed according to endometrial cancer [159].

The gross description of the endometrial tumor must include the exact anatomic location of the tumor (isthmus uteri (lower uterine segment), or where it is located within the corpus (anterior, posterior wall, dome), its three dimensional measurement and its relation to the cervix uteri as well as its shape (polypoid, sessile, diffuse). Sometimes the length of the vaginal cuff will be important. So, the length (or its absence) of the vaginal cuff should be given, separately for its anterior and posterior part. Some authors state the distance of the tumor to the internal/external cervical os.

For prognostic purposes, staging and adjuvant treatment, the size of the lesion, its depth of invasion within the myometrium and cervical involvement is very important [15, 16].

The cervix uteri should be sampled by one block from anterior and one from the posterior lip [127]. Regardless of macroscopic involvement of the cervix uteri or not, the endocervix should be sampled by (one) perpendicular section (Fig. 18.19). For adequate sampling some authors recommend embedding of several blocks [166]. In some cases,

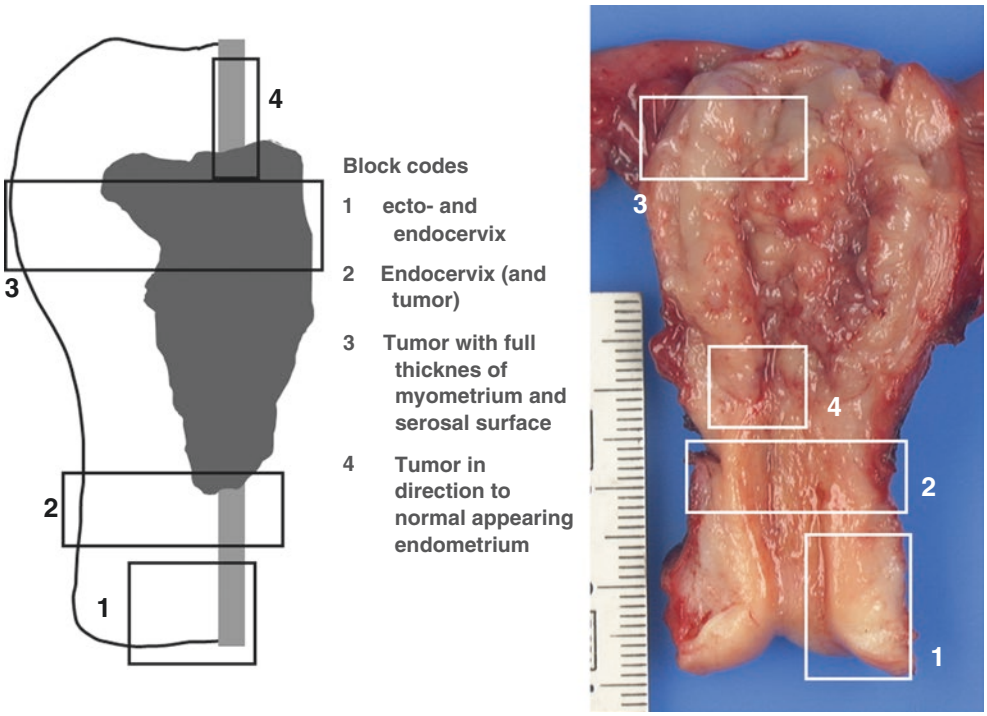

Fig. 18.19 Schematic sectioning of a hysterectomy specimen with endometrial carcinoma and block codes (for details see text and Tables 18.6 and 18.7)

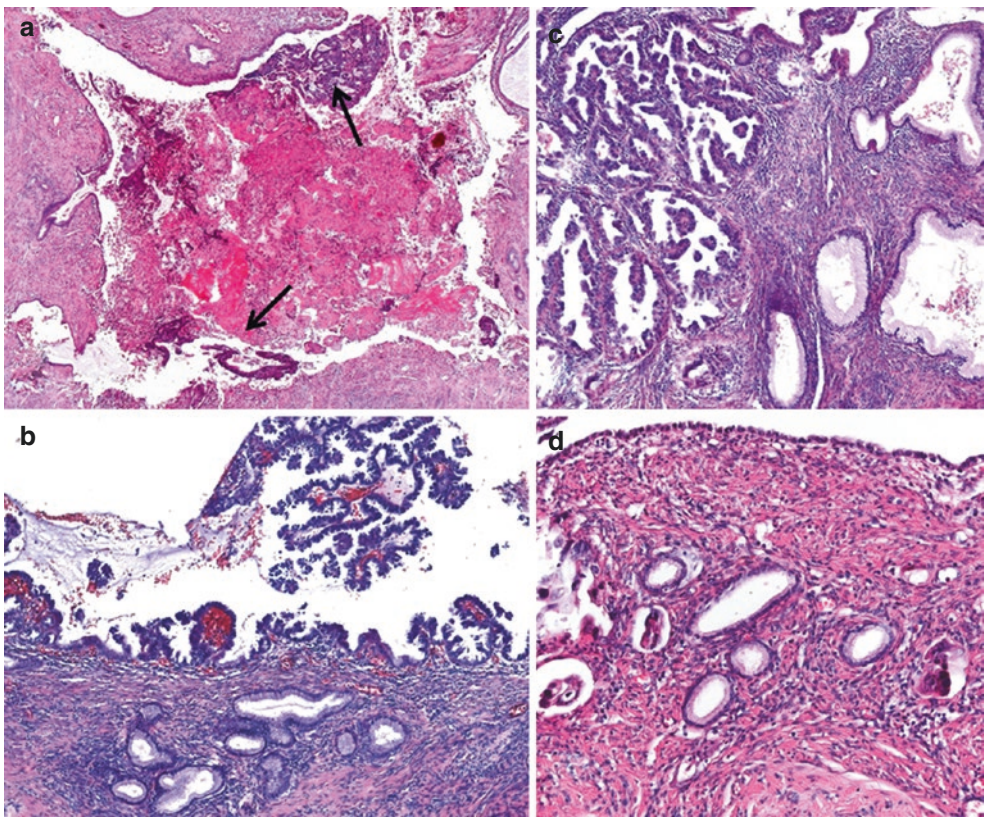

Fig. 18.20 Different patterns of cervical involvement by an endometrial carcinoma (**a**–**c** adopted from: Horn et al. 2011 [70]): (**a**) dislocated tissue of a well differentiated endometrioid ECX (*arrows*) within the cervical channel during irregular bleeding. (**b**) Involvement of endocervical glands by a serous endometrial carcinoma. Note the dislocated glands within the cervical channel (*arrows*) (**c**) infiltration of the cervical stroma by a serous endometrial carcinoma. (**d**) Lymphovascular space involvement of the endocervical stroma by a serous endometrial carcinoma

especially in those with serous endometrial carcinoma, lymphovascular space involvement (LVSI) or occult (microscopic) involvement of the endocervical stroma may occur (Fig. 18.20d). The presence of LVSI represents no "invasion" of the endocervical stroma and should not stated as pT2-tumor, but should be separately mentioned within the report and categorised as L1 [159]. Involvement of the endocervical glands (Fig. 18.20b) by the endometrial carcinoma has no longer impact on staging, whereas the invasion of the endocervical stroma has [132, 159]. The assessment of cervical involvement in endometrial carcinoma may cause some diagnostic problems but there is at most a fair-to-good agreement among specialist gynaecologic pathologists [112]. The determination and reporting of the depth of cervical stromal involvement is facultative at time (but may be asked by the clinicians), because it has no impact on treatment decisions and prognosis.

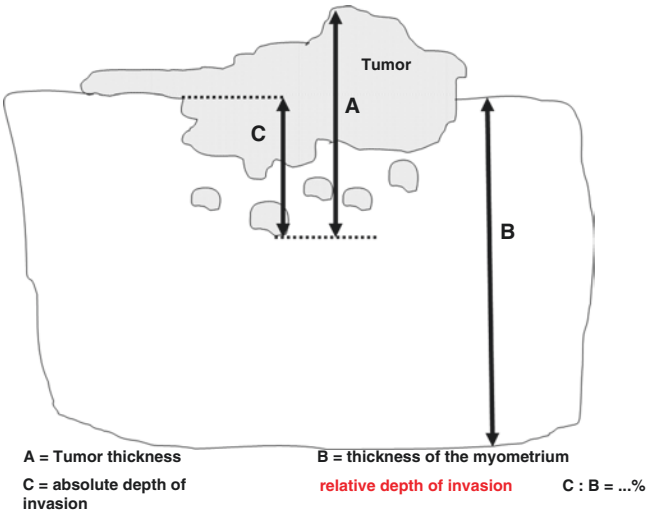

Fig. 18.21 Scheme for the measurement of the depth of invasion for endometrial cancer (Adopted from Robboy et al. [143]).

Within previously diagnosed pure endometrioid or serous endometrial cancer on fractional curetting one block per 2 cm largest tumor dimension is adequate. In mixed endometrioid/serous cancer (or other mixed histologic types, e.g. neuroendocrine carcinoma) and in MMMTs one block per 1 cm largest tumor dimension is recommended.

If there is no grossly visible tumor at the hysterectomy specimen extensive embedding as described for endometrial hyperplasia with embedding of about six sections, three of the anterior and three of the posterior parts of the fundus uteri [143] is recommended. Alternatively, wedge sections

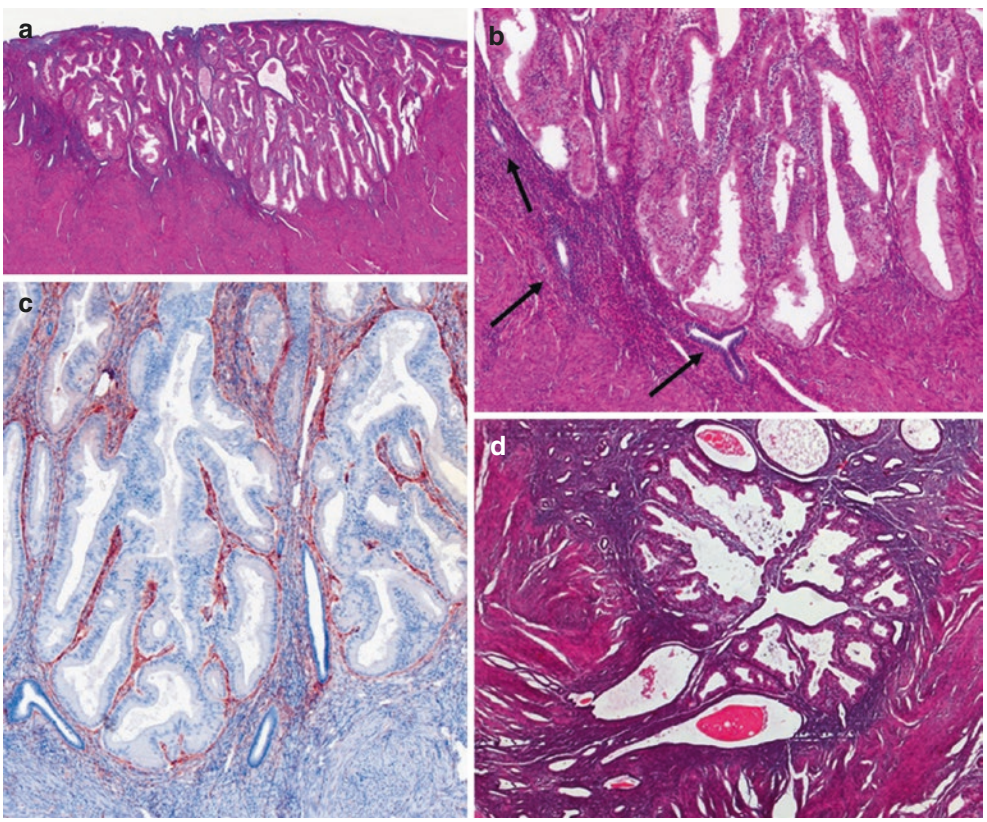

Fig. 18.22 Endometrioid endometrial adenocarcinoma. (**a**) Small well differentiated carcinoma within hysterectomy specimen. (**b**) Tumor glands protruding in direction to the myometrium. Note benign glands at the base of the tumor (*arrows*) as an morphologic feature that the carcinoma is confined to the endometrium. (**c**) Tumor glands are surrounded by a small rim of endometrial stroma cells, highlighted by CD 10 immunostaining (*brown colour*). **(d)** Endometrioid adenocarcinoma involving an endometriosis (see text)

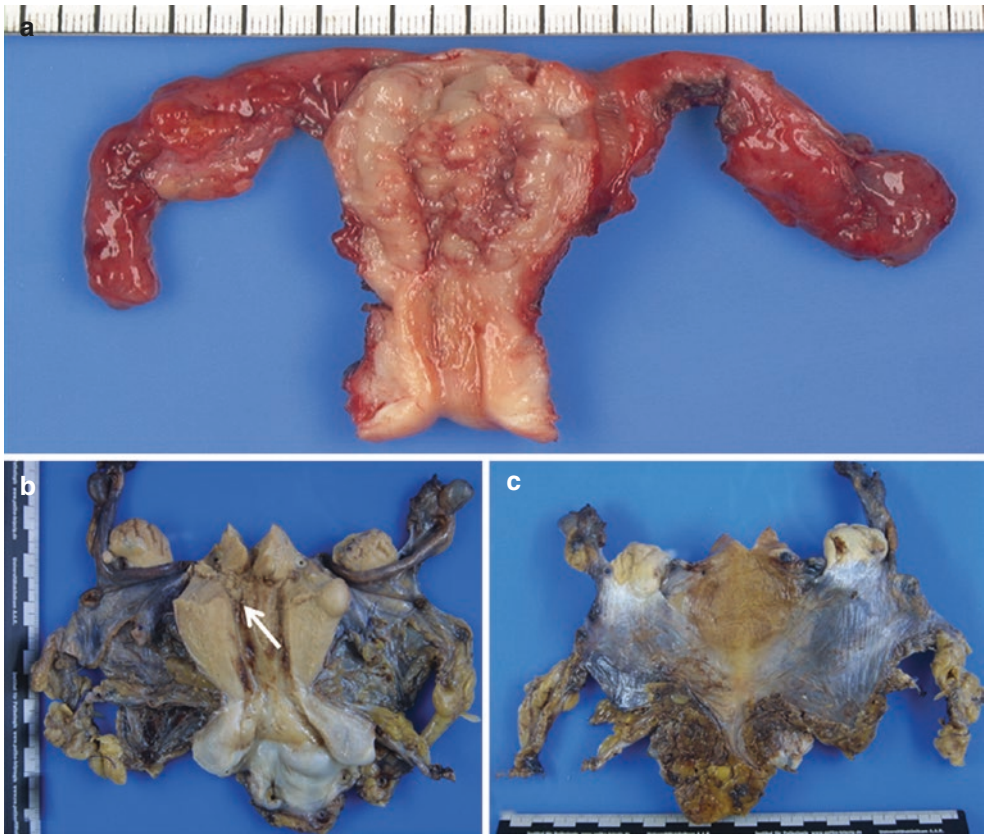

Fig. 18.23 Hysterectomy specimens with endometrial carcinoma. (**b**, **c**) Anterior and posterior view of a endometrial carcinoma at the right tubal insertion within the uterine corpus (*arrow*) in a PMMR-Specimen (please see text)

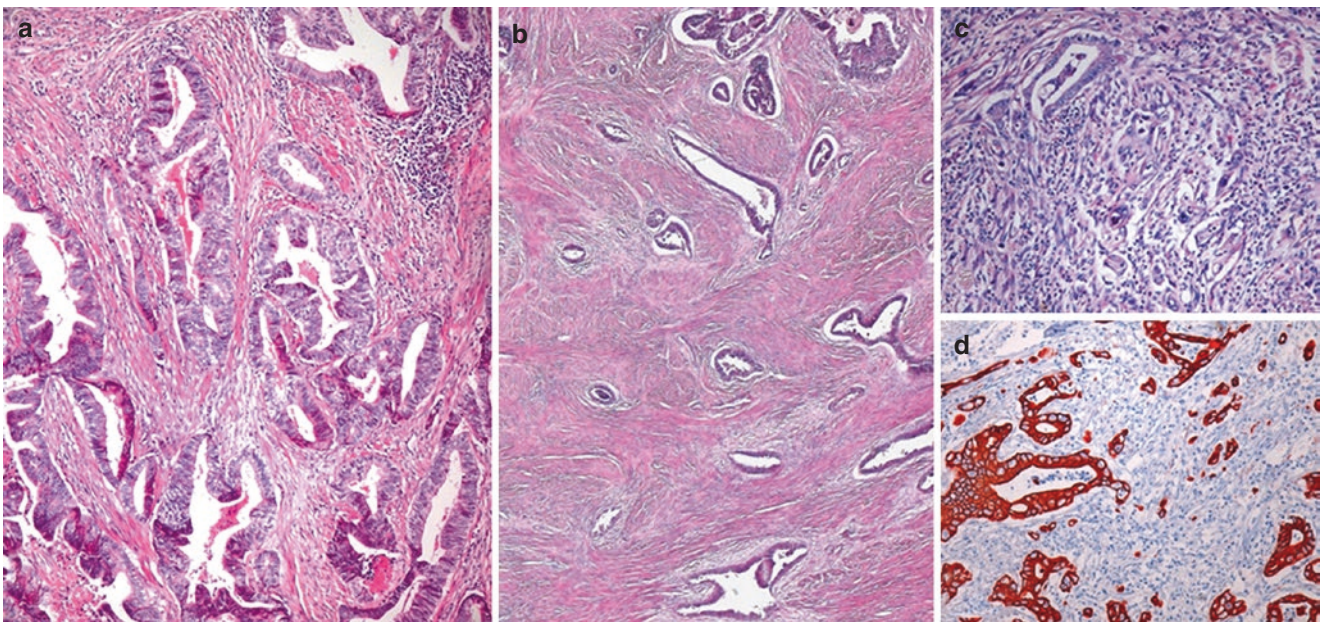

Fig. 18.24 Different patterns of invasion of endometrial adenocarcinoma. (**a**) Conventional pattern of myometrial invasion by a well differentiated endometrioid adenocarcinoma. (**b**) Minimal deviation pattern of myometrial invasion [62, 69]. (**c**, **d**) MELF-pattern of invasion, representing infiltrative growth of microcystic, elongated, fragmented glands (MELF), fragmented glands; highlighted in (**d**) by CK 18 immunostaining

can be performed by cutting small peaces of the endometrium and the immediately adjoining myometrium putting them in one cassette [143]. If there is no residual tumor seen (i.e. *vanishing endometrial cancer*; [3, 35]), complete embedding of the endometrium is recommended using wedge sections.

According to the WHO-classification [186], the term mixed carcinoma should only be used when two or more distinctive subtypes of endometrial carcinoma are identified, each representing more than 5 % of the tumor. When a carcinoma is classified as "mixed," the major and minor types and their relative proportions should be specified and the different percentages should be given in the pathology report.

It should be noted that for mixed endometrioid and serous carcinomas, studies have found variable results regarding tumor behaviour based on percentage of the serous component. Some studies have found that tumors with >25 % serous component behave like pure serous carcinomas [181], whereas other studies have shown that tumors with <10 % serous component also behave like pure serous carcinomas [100].

The depth of invasion should be noted grossly and the embedded tissue should document the area with maximal tumor invasion. The final depth on invasion should be calculated using the histological slides. The depth of invasion should be measured from the level of the adjacent endometrium up to the deepest point of tumor infiltration. If there is an exophytic growth of the tumor, the adjacent endometrium should be identified and an imaginary line should be drawn from that level through the tumor [143]. The distance below that line up to the deepest point of direct tumor infiltration represents the depth on invasion. This distance plus the distance above that line up to the surface of the tumor represent its thickness (Fig. 18.21). Any lymphovascular invasion below the infiltrating tumor front does not alter the depth of invasion and should be categorised as L1. The fact of LVSI below the infiltrating tumor edge should be transferred to the clinician.

Very rarely, *endometrial carcinoma* arises *within an uterine endometriosis* [85]. There, the depth of invasion should be calculated from the most superficial endometrial gland of that endometriosis up to the most distant tumor edge.

Determination of depth of invasion may be challenging [4]. There is no sharp border between the normal endometrium and myometrium, rather than a serrating/interdigitating appearance [55]. Infiltrating glands of endometrial cancer represent in a direct contact to the myometrium, sometimes surrounded by a tiny desmoplastic change (sometimes highlighted by van Gieson stain), but are not surrounded by normal endometrial ands and/or endometrial stroma. The latter one may be highlighted by CD 10-immunohistochemistry (Fig. 18.22a–c).

Involvement of endometriosis by endometrioid adenocarcinoma (Fig. 18.22d) is a known mimicker of myometrial infiltration and may occur in ~25 % of the cases. There is no adverse prognostic impact of that feature. The following features may be useful distinguishing involvement of an endometriosis versus true myometrial invasion [5, 55]:

- presence of benign and endometrial glands adjacent to the carcinoma,
- benign endometrial glands admixed within the carcinoma
- lack of desmoplastic stromal response,
- lack of inflammatory response,
- rounded appearance of the lesion with smooth border on low power.

It has been reported that there is the same thickness of the anterior and posterior wall of the uterus [180] so, the uninvolved myometrium from the opposite wall can be used as reference value determining myometrial thickness.

In contrast to simple hysterectomy for endometrial cancer (or radical hysterectomy in FIGO-stage II disease), women may be treated by peritoneal mesometrial resection (PMMR; Fig. 18.23b, c; [82]; in the chapter about Hysterectomy in Precancerous Lesions or Microinvasive Carcinoma of the Cervix at page 560).

There are some different patterns of invasion within endometrial carcinomas (Fig. 18.24). Beside the classic pattern of growth, an adenoma malignum-like pattern has been described [79].

The so called MELF-pattern of invasion, representing infiltrative growth of microcystic, elongated, fragmented glands (MELF), surrounded by peritumoral desmoplastic stromal response [125] may represent an indicator for high epithelial-mesenchymal transition [164] and has recently been discussed as prognostic factor [40]. So, the different types of invasive growth should be stated within the histopathological report.

There is one major unclear topic within the staging of endometrial cancer and MMMTs, which has been discussed previously [55, 68, 72, 137, 188].

Within the current issue of FIGO/TNM-classification, stage pT3a disease is defined as "tumor invades uterine serous and/or adnexa (direct extension or metastasis) and/or cancer cells in ascites or peritoneal washings" [70, 159]. There is no clear statement how the term adnexal involvement is defined. Tumor deposits within the Fallopian tube and the ovary with histologically proven stromal invasion represents adnexal involvement as is in case of adnexal meso-infiltration (see Fig. 18.25).

The recently recognised intramucosal spread of endometrial and non-gynaecologic cancers to the Fallopians tubal

mucosa [163] also represents adnexal involvement (Fig. 18.25e). But, what is about the presence of LVSI within the meso-salpinx, mes-ovarium, the Fallopian tube and the ovarian stroma?

In our opinion LVSI at that location represents biologically stage pT3a-disease [68, 72]. But under staging purposes, LVSI within the adnexal structures must be categorised as L1 rather than as stage pT3a-disease [159, 182]. The histopathologic report should give the clinician detailed information about the localisation of LVSI and the patterns in case of adnexal involvement.

Because the adnexal involvement may be grossly not evident in a serious number of cases [68, 72], careful examination of adnexal tissue is recommended. The majority of patients with ECX are postmenopausal and the ovaries are usually small and atrophic, so extensive/complete embedding may not be time and/or cost consuming. As suggested by others [156], and under recognition of our above mentioned results, we would recommend complete processing of macroscopic inconspicuous adnexae, regardless of the histologic type of ECX. Within the cutting of the ovary we prefer sectioning along the short axis of the ovary with embedding of the adjacent mesovarian tissue [62, 69] and for handling of the Fallopian tube we adopted the protocol which is currently used for the handling of the tubes in prophylactic adnexectomies from women with BRCA mutations (so called SEE-FIM-protocol; [115, 151]).

A direct invasion or metastatic spread into the parametrial tissue and/or vagina will be staged as pT3b [159]. The presence of LVSI represents no "metastatic spread" and should

Table 18.6 Synopsis of the features within the final oncologic histopathology report of endometrial cancer and malignant Müllerian mixed tumors (MMMT) of the uterus [17, 62, 69, 110, 124, 145, 155]

Histopathologic tumor type (WHO)[a]
Grading (WHO/FIGO)
Absence/presence of lymphovascular and blood vessel (venous) involvement (L- and V-status)
Absence/presence of perineural invasion (Pn-status)
Tumor stage (TNM)
Tumor size and depth of invasion into the myometrium
Tumor size in three dimensions in macroinvasive disease
Presence of (endo-) cervical stromal invasion
Presence/localisation and extension of mesometrial/parametrial invasion
Minimal distance to the resection margins
R-classification (UICC)
Status of the adnexae

[a]the WHO-classification [186] defines mixed carcinomas as tumors where two or more distinctive subtypes are identified, each representing more than 5 % of the tumor. Some studies have found that mixed serous cancer with even >10 % or >25 % of serous component represent adverse outcome [100, 181]. So, each percentage of serous component should be given within the pathology report

not be stated as pT3b-tumor, but should be separately mentioned within the pathology report and categorised as L1 [159].

An unclear issue by definition is the categorisation of the presence of lymph node metastases within the parametrial tissue in endometrial cancer. Lymph node metastases at that location represent metastatic involvement and according to the TNM-classification it represents a pT3b tumor. But, parametrial lymph nodes are defined as regional lymph nodes in endometrial cancer. So, the question appears, if the parametrial nodes are involved should they counted as pN1 as well? Uninvolved parametrial nodes should be counted within the overall number of resected regional nodes.

General aspects of gross description and parameters of the histopathology report are summarised in Tables 18.3 and 18.6.

The final oncology pathology report should recognise the most recent WHO-classification [186] for tumor typing the TNM-classification for staging [159].

Hysterectomy with Uterine Sarcomas

The majority of uterine sarcomas occur within the corpus uteri.

So, the cervix uteri should be sampled by one block from anterior and one from the posterior lip. In case of gross involvement of the endocervix, it should be sampled by perpendicular section(s). To ensure correct diagnosis, extensive sampling i.e. one paraffine block per 1 cm largest tumor dimension should be performed [110, 133, 168]. To cover different morphologic features within the tumor it is helpful to obtain different blocks from different locations with embedding the edges of hemorrhagic and necrotic foci or those with different colours and edges of the lesion protruding in the adjacent myometrium [110, 130, 133].

At time, there is no grading for leimoysarcomas in the WHO classification [129]. Some clinical oncologists urge their pathologist to give a grading for these tumors. In those cases the grading system of the Fédération Nationale des Centres de Lutte Contre le Cancer [23, 24, 30] i.e. FNCLCC-grading system should be adopted.

General aspects of gross description and parameters of the histopathology report are summarised in Tables 18.3 and 18.7.

The final oncology pathology report should recognise the most recent WHO-classification [129] for tumor typing the TNM-classification for staging [159].

Handling of Lymphonodectomy Specimens in Uterine Malignancies (Figs. 18.3 and 18.26)

In uterine cancer and MMMT regional lymph node involvement represents the locoregional spread.

It should be documented (three dimensional measuring) how many tissue was sent for each defined location of lymph node resection. Careful dissection of the specimen is necessary with submission of all visible and palpable lymph nodes. The embedding of the whole lymph node up a maxi-

Table 18.7 Synopsis of the features within the final oncologic histopathology report of uterine sarcomas [22, 26, 77, 110, 133, 168]

Histopathologic tumor type (WHO)
Grading (WHO) of endometrial stromal sarcomas[a]
Tumor regression after previous treatment (including hormonal treatment)
Absence/presence of lymphovascular and blood vessel (venous) involvement (L- and V-status)
Absence/presence of perineural invasion (Pn-status)
Tumor stage (TNM)
Tumor size in three dimensions
Depth of invasion within the myometrium
Presence/localisation and extension of extrauterine infiltration
Minimal distance to the resection margins
R-classification (UICC)

[a]The WHO-classification separate endometrial stromal tumor in low-grade and high-grade enodmetrial stromal tumors and separate them from undifferentiated uterine sarcomas (UUS)

mum dimension of 0.3 cm without slicing has been recommended [63]. Larger nodes should be bivalved along its longest axis and processed completely as well [63, 75, 96, 145].

If the gross lymph node number is small and the remaining soft tissue is small, it may be worthwhile to entirely submit the tissue from that special location for histopathologic analysis [143]. Extensive or complete embedding of the soft tissue resulting from lymph node resection may reassure the clinician that a thorough examination of the tissue has been performed. The use of so called clearing techniques may increase the number of detected nodes [1]. But in case of careful handling of the removed tissue during lymph node resection, clearing techniques cannot being recommended by the authors and others [145] for gynaecologic malignancies.

The performance of step sections (e.g. three step sections with an interval of 200 μm) may increase the detection of small metastases [75, 96].

Isolated tumor cells (ITC) within a lymph node are single tumor cells or small tumor cell clusters not more than 0.2 mm in greatest dimension that can be detected on routine H&E-staining or using immunohistochemistry [182]. To the best of our knowledge, there are no studies regarding prognostic impact of ITC for cervical and endometrial cancer at time. Two reports are dealing with "low volume lymphe node involvement" in patients with cervical carcinoma [19, 161]. In these studies there are no definitions of ITC and micrometastases according to the UICC and AJCC definitions and cases with ITC and micrometastases were not seprated within statistical evaluation. So the question of the prognostic impact of ITC in cervical carcinoma is still unanswered. In the author opinion, the presence of ITC should be reported to the clinician, because that feature indicates the capability for lymphovascuar spread of the given tumor.

The same issues must be stated for the presence of lymphovascular involvement within the fatty tissue surrounding the lymph nodes and within the Vasa afferentia of the lymph nodes in the lymph nodes capsule (Fig. 18.26a, e). Both features are categorised within the L-category of the TNM-system but not as lymph node involvement (N-category).

Micrometastases within lymph nodes are defined by the UICC as the presence of tumor cell deposits larger than 0.2 mm, but not exceeding 0.2 cm ([182]; Figs. 18.4g and 18.26b). This definition was adopted for cervical carcinoma by the last version of the German National guidelines for the diagnosis and treatment of cervical cancer [7] and will be adopted within the next issue of the guidelines for endometrial cancer.

There are some studies which reported the prognostic impact of micrometastases (pN1mic) for cervical carcinomas [45, 65, 66, 99, 105]. Within one study patients with pN1mic have had a poor prognostic outcome than node negative patients but an improved one when it was compared to those with macrometastatic disease [65, 66].

Extracapsular extension of the metastatic deposits into the perinodal fatty tissue (i.e. extracapsular extension; ECS; Fig. 18.26f, g) is an established prognostic factor for vulvar cancer and that feature is included in the N-categorisation within the TNM-system. For carcinoma of the uterine cervix it has been reported that ECS may be of prognostic impact as well [62, 69, 108]. So, that feature may be included within the pathology report of removed lymph nodes representing with metastases of any gynecologic malignancy.

A synopsis of histopathologic report of lymphonodectomy specimens is summarised in Table 18.8.

Block codes

1 Ectocervix

2 Endocervix (and placenta)

3 Myometrium and chorionis membrane

4 Umbilical cord#

5 Amnion membrane

6 Placenta and implatation site within the myometrium

7 Placenta and implantation site with thinned myometrium

8 Placenta and thinned uterine wall within the lower uterine segment

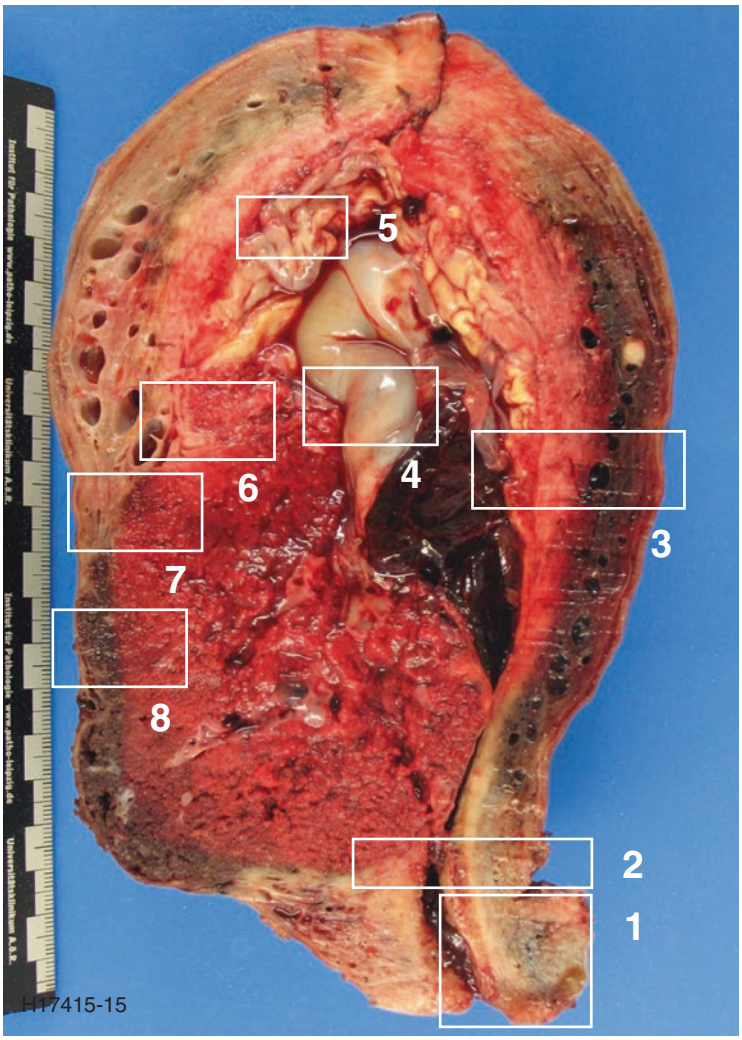

Fig. 18.26 Frontal cut of an hysterectomy with placenta praevia with block code for tissue embedding

Table 18.8 Synopsis of the features within the final histopathology report for removed lymph nodes [63, 96, 143, 145]

Give the location and the dimension of the removed tissue for lymphonodectomy
Give the number of removed/examined nodes per location
Give the number of positive nodes in relation to the number of removed/examined nodes (e.g. 4/13 right pelvic nodes or 0/15 para-aortic nodes)
Largest dimension of nodal metastatic deposit per location
Absence of presence of extracapsular spread of the metastatic deposits per location
Presence or absence of lymphovascular space involvement within the fatty tissue surrounding the lymph node
After pre-operative chemotherapy and/or radiotherapy, regressive changes should be roprted

Handling Omentectomy Specimens

Omentectomy represents a routine part of staging surgery in type 2 endometrial carcinomas (serous and clear-cell carcinomas) and in some cases of malignant mixed Müllerian tumors as well as in selected cases of endometrioid adenocarcinoma.

Macroscopically three dimensions of the omentum should be provided in the pathology report to document the size. This may be useful in certain scenarios to direct the need for further surgery. Additionally, the size may be also helpful to determine the extent of sampling for histologic examination. Any unusual gross findings should be noted and proofed by tissue embedding.

At time, there are no standardized guidelines for sampling omental specimens in gynecologic malignancies. Interestingly, omental sampling is not mentioned within the recommendations of the College of American Pathologists (CAP) and the International Collaboration on Cancer Reporting (ICCR) within their protocols for endometrial malignancies.

The following suggestions are based mainly on studies of ovarian malignancies.

In a *grossly involved omentum*, submitting 1 block for histologic examination is probably sufficient [32, 174].

For *grossly negative omental specimens* the sampling methods vary within different studies.

For ovarian borderline tumors, a meticulously gross examination with an embedding of at least 1 section per 2 cm of maximum dimension was suggested [150]. Usubütün et al. [174] recommended one section per 2–3 cm of maximum omental diameter in cases with ovarian or endometrial cancer. Another studie suggest 1 block for every 67 mm of maximal dimension of omentum in ovarian neoplasms [32]. A recent study reported an estimated sensitivity of 82 % by an examination of 5 blocks and of 95 % by 10 blocks performing a theoretical model ("*in silico*")for optimal sampling of grossly normal omentum in various gynecologic malignancies [158]. In real life studies, the examination of 3–5 blocks was suggested as representative in cases with gynecologic malignancies [158, 174]. The CAP-protocol for ovarian neoplasms generally recommend to take 5–10 sections (a section means a tissue sample transferred to the embedding cassette) from the omentum [25] which may blocked in about 5 paraffine blocks.

For practical purposes in the author opinion, the recommendation for omental sampling of the ICCR for primary ovarian, Fallopian tube and peritoneal cancer [113] should be adopted for endometrial cancer. There, the embedding of 4–6 blocks in cases where the omentum is grossly negative is recommended.

Within pathology report, the size of the largest tumour deposit should be recorded. It should also be reported the presence of omental lymph nodes with or without metastatic deposits. Omental lymph nodes represent not regional lymph nodes in endometrial cancer by the definition of the TNM. So, omental lymph node involvement represents stage T3/FIGO III disease. Any additional findings (e.g. inflammatory change, mesothelial hyperplasia, scaring) should be noted as well.

Part VII

Specific Hematological and Anesthesiological Aspects

19 Perioperative Management of Antithrombotic Therapy in the Periprocedural Period of Patients Undergoing Hysterectomy

Verena Limperger, Florian Langer, Rolf Mesters, Ralf Ulrich Trappe, and Ulrike Nowak-Göttl

Introduction

The use of oral anticoagulants (OAC) especially Vitamin-K-antagonists (VKA) and antiplatelet agents (AA) (ASA, Clopidogrel, Prasugrel, Ticagrelor) alone or combined is necessary to prevent or treat thromboembolic diseases. Patients with the indication for a long-term therapy with OAC, for example with chronic atrial fibrillation, artificial cardiac valve or after thromboembolic events, or patients with the indication for treatment with AA for example after a stroke, TIA, myocardial infarct, implantation of a bare-metal-stent (BMS) or drug-eluting-stent (DES), need in case of surgical interventions a bridging with medication with a short half-time [1, 3, 5–9, 14, 21, 23, 25].

This review covers the recent published recommendations and guidelines related to elective hysterectomies in patients taking an OAC or AA. These recommendations are based on a few randomized trials with limited data only [8, 9, 34, 35]; therefore is the evidence level of these recommendations grade "2C" [1, 3, 5–9, 12, 14, 18, 21, 23, 25, 38]: In contrast with recommendation grade "1″ are these [7]; it is comparable with "we suggest, that". The impact of study quality is divided into A, B and C, where as "C" is weaker than "A" or "B".

Preoperative Evaluation

In every patient taking an oral anticoagulant (Table 19.1) or antiplatelet agent (Table 19.2) the risk of the bleeding versus the risk for thromboembolic events must be evaluated at least two to three weeks prior to an elective surgical intervention: The risk of bleeding in terms of hysterectomy is fairly low but stays in contrast to the medium risk for thromboembolic events [7, 21]. Table 19.3 shows the yearly risk for thromboembolic recurrence after withdrawal of the oral anticoagulant or antiplatelet agent therapy.

The risk of bleeding is a summary of the patients inherited and acquired risk factors. A standardized bleeding questionnaire is the best way to identify the individual bleeding risk [16, 18, 26, 27]. This includes the record of the oral anticoagulant or antiplatelet agent taken as well as the documentation of potentially taken co-medication and of acquired diseases which can affect the hemostasis [13]: This includes the liver as the most important organ for the synthesis of coagulation factors, the kidneys as organs for the elimination of heparin and the direct oral anticoagulants [DOACs] und possibly hemostatic changes due to hemato-oncological diseases. In addition to that is it possible that for example cardiac diseases can lead to an acquired von Willebrand's disease [42].

Drugs, that for example can increase the effect of OACs, are androgen steroids, anabolic drugs, antacids, antibiotics, antidepressants, ß-inhibitors, gout medication, insulin, cholesterol lowering medication and thyroid hormones.

Conclusion: in every patient using an anticoagulant the risk of bleeding versus the risk for thromboembolism has to be evaluated.

The risk for thromboembolism in patients with inherited thrombophilia depends on the risk factor (Tables 19.4 and 19.5).

Table 19.1 Oral or parenteral anticoagulant agents

Agent	Half-time	Target enzyme	Antidote
VKA: Phenprocoumon Warfarin Acenocoumarol	6 days 35–45 h 6,6 h	VK-depending y-carboxylation	Vitamin K1 oral/iv PPSB
Heparins: UFH LMWH Fondaparinux	30–60 min 3–7 h 17–21 h	AT-depending serine proteinase	Protamine –[a]
Dabigatran	11–14 h	Thrombin	Idarucizumab –[a]
Rivaroxaban	7–13 h	Factor Xa	Andexanet alfa & Ciraparantag –[a]
Apixaban	8–18 h	Factor Xa	Andexanet alfa & Ciraparantag –[a]
Edoxaban	10–14 h	Factor Xa	Andexanet alfa & Ciraparantag –[a]

Abbreviations: *AT* Antithrombin, *LMWH* low molecular weight Heparin, *UFH* unfractionated Heparin, *VK* Vitamin K, *VKA* Vitamin-K-Antagonist, *PPSB* Prothrombin complex concentrate

[a]General procedures for hemostasis: mechanical compression/ sealing the source of bleeding, volume replacement, if necessary infusion of erythrocyte concentrates, platelet concentrate, plasma, PPSB, rFVIIa, tranexamic acid [20 mg/kg body weight: 31,39]. The use of dialysis (Dabigatran) or the administration of active coal may be useful in case of overdose of DOACs

Table 19.2 Antiplatelet agents

Agent	Half-time	Target enzyme	Antidote
Acetylsalicylic acid [ASA]	15–30 min	COX-1; COX-2	–[a]
Clopidogrel	8 h [with loading-dose shorter]	$P2Y_{12}$ ADP receptor-irreversible	–[a]
Ticlopidin [is rarely used]	24–36 h	$P2Y_{12}$ ADP receptor-irreversible	–[a]
Prasugrel	7 h	$P2Y_{12}$ ADP receptor -irreversible	–[a]
Ticagrelor	7 h	$P2Y_{12}$ ADP receptor-reversible	–[a]
Cangrelor	2–5 min	$P2Y_{12}$ ADP receptor-reversible	
GPIIb-IIIa antagonists: Abciximab[b] Eptifibatide Tirofiban	10–30 min 150 min 1,8 h	Fibrinogen- receptor (GPIIb-IIIa)	platelet concentrate[a] Hemodialysis

[a]General procedures for hemostasis: mechanical compression/sealing the source of bleeding, volume replacement, if necessary infusion of erythrocyte concentrates, platelet concentrate, plasma, PPSB, rFVIIa, tranexamic acid [16–18, 20–22, 31, 39]. In case of platelet disorders due to ASA platelet concentrates can be combined with DDAVP i.v. [20, 22, 32, 38]

[b]Caution: not eligible for "bridging", because the effect on the receptor is too long

Table 19.3 Risk of arterial / venous thromboembolism in case of interruption of the OAC/AA therapy

High risk of thrombosis [circa 10 % per year]	Medium risk of thrombosis [4–10 % per year]	Low risk of thrombosis [<4 % per year]
Artificial heart valves	Biological heart valves [first 3 months]	Biological heart valves [>3 months]
Atrial fibrillation with fresh stroke/TIA or CHADS2 score[a]> 5	Atrial fibrillation & CHADS2 score[a] 3–4 without stroke / TIA	Atrial Fibrillation & CHADS2 score [a] 0–2 without stroke/TIA
BMS [<4 weeks]	BMS [4 weeks; – 12 months][b]	BMS [>12 months][b]
DES [<6 months]	DES [6–24 months][b]	DES [>24 months][b]
MI [<6 weeks] rheumatic valvular disease	MI [6 weeks – 12 months]	MI [>12 months]
Venous thromboembolism [<3 months]	Venous thromboembolism [3–12 months]	Venous thromboembolism [>12 months]
Severe thrombophilia[antiphospholipid syndrome, antithrombin, protein C- / S- deficiency]	Recurrent venous thromboembolism	
	Active malignancy	

Abbreviations: *BMS* Bare-metal-Stent, *DES* Drug-eluting-Stent; *MI* heart attack, *TIA* transient ischemic attack

[a]$CHADS_2$: heart failure, hypertension, age > 75 years, diabetes mellitus, stroke or TIA

[b]Recent studies come to the conclusion that the antiplatelet therapy can be discontinued in case of BMS the dual after 3 months and in case of new DES often already after 6 weeks [11, 16]

Table 19.4 Risk of thromboembolism in various interventions

High risk of thrombosis	Medium risk of thrombosis	Low risk of thrombosis
Arthroplasty	Upper limb & other interventions lower extremity	Visceral surgery, **gynecology**, urology [<30 min]
Hip fractures	visceral surgery, **gynecology**, urology [>30 min]	Metal removal
Large abdominal surgery	surgery of lung, chest wall, mediastinum	juxtaarticular surgeries without immobilization
Tumor surgery	Varicosis surgery	
	Vascular surgery	

Table 19.5 Relative risk [RR] of inherited thrombophilia on venous thromboembolism in family studies [43]

Risk factor	Prevalence [%]	RR of first venous thrombosis
Antithrombin deficiency	0.02	5–10
Protein C deficiency	0.2	4–6.5
Protein S deficiency	0.03–0.13	1–10
Faktor V Leiden/APC-Resistance	3.0–7.0	3–5
Prothrombin G20210A	0.7–4.0	2–3
High factor VIII	10	5

Venous thromboembolism is a multifactorial disorder. Antithrombin-, protein C- protein S- deficiency are high risk factors for the onset of venous thromboembolism. In contrast, factor V Leiden, the prothrombin mutation G20210A and elevated factor VIII levels are discussed as common but mild risk factors of thromboembolism. Combinations between established prothrombotic risk factors increase the risk of thrombosis [19, 43].

In patients with or without a history a venous thromboembolism and inherited thrombophilia the updated Chest guidelines and the German AWMF Guidelines suggest a prophylaxis in risk situations for thrombosis. The dosage has to be determined on an individual basis, inter alia depending on the body weight [7, 33].

Perioperative Management: Vitamin K-Antagonists

The median risk for thromboembolism is the most common situation in the daily praxis, so is the risk of hysterectomy for thromboembolism: the current guidelines for the perioperative management focus the expecting bleeding tendency in this case. In case of intervention with a high risk for bleeding an interruption of the OAC can be taken place without a bridging, in case of a low bleeding tendency a bridging with UFH or LMWH can be taken place depending the half-time of the OAC [1, 3, 5–7, 9, 14, 21, 23, 25, 40].

(i). low bleeding risk & median thromboembolic risk: is there a minor bleeding risk due to the scheduled intervention, in most cases the oral anticoagulation can be taken unmodified or can be reduced in its intensity.

(ii). medium to high bleeding risk & medium thromboembolic risk: when the intervention causes a medium to high bleeding risk the anticoagulant therapy can be paused for a short period.

(iii). high bleeding risk & high thromboembolic risk: when the intervention causes a high bleeding und thromboembolic risk the change of a vitamin K antagonist to UFH [limited renal function] or LMWH is necessary. In this cases the VKA is paused approximately 7 days [Phenprocoumon] respectively 5 days [Warfarin] prior to the scheduled intervention or if the INR is below its therapeutic level [INR < 2] and UFH or LMWH is used for bridging. If there will be high thromboembolic risk a therapeutic heparin use should be aimed: For UFH an aPTT prolongation of 1.5–2 times the standard is intended, for LMWH the dose which is recommended by their manufacturers for the acute treatment of deep vein thrombosis or pulmonary embolism should be selected.

There are only a few comparative studies for UHF and LMWH for bridging therapy [9, 9]. These show no difference in bleeding and the occurrence of thromboembolic complications, however, the length of hospital stay was significantly shorter with LMWH and hence more cost-effective.

For (iii) applies, in cases of severe renal insufficiency [creatinine clearance <30 ml/min] the heparin therapy should be carried out with UFH [7, 21], in other cases, LMWH can be used. In the current 9th guideline of the "American College of Chest Physicians" it is recommended, that stop UFH 6–8 h and LMWH 24 h before the procedure and to start the therapy again after 24–48 h depending on postoperative bleeding tendency [7]. In early resuming heparin therapy a reduced dose of LMWH or a heparin is discussed without a bolus of UFH.

The reuptake of OAC depends on the risk of bleeding of the performed surgery and should be done at the earliest from 1 to 2 days post-surgery, the parallel heparinization should be continued up to a reproducible INR > 2 [7, 21, 25].

Unlike in elective surgeries the management in emergency cases cannot be planned: The effect of the OAC must be lifted as soon as possible. To do this the administration of vitamin K1 10 mg iv [effectiveness within 24 h] or the substitution of vitamin K-dependent coagulation factors [PPSB: 4-factor concentrate] which work within minutes can be performed. If there is a life-threatening bleeding under OAC vitamin K1 and PPSB ca be administered simultaneously.

When bridging with a parenteral anticoagulant the INR, aPTT and anti-Factor Xa activity should be measured in addition to the clinical evaluation of the bleeding preoperatively. During the postoperative period the blood count, prothrombin time according to thromboplastin time and aPTT should be determined to evaluate the bleeding tendency before reuptake.

To summarize: the current recommendations for the perioperative management are based on the expected risk of bleeding. For planned interventions with high risk of bleeding the interruption of OAC without bridging may be considered. At a low risk of bleeding a bridging therapy with UFH or LMWH can be applied after discontinuation of OAC.

Perioperative Management: Platelet Inhibition Therapy

The use of medication with reversible and irreversible inhibition of platelets (Table 19.2) is indicated for primary and secondary prevention of atherothrombosis-related cerebrovascular and cardiovascular diseases. This includes for example stroke, TIA, myocardial infarction, interventional radiological procedures such as PTCA with or without implantation of bare-metal stents [BMS] or drug-eluting stents [DES], radiofrequency ablation, and peripheral arterial thromboembolic diseases. Platelet-inhibitory substances are used either as monotherapy [primary prophylaxis or long-term therapy] or as a temporary combination therapy for example in high risk patients after stenting. In this group of patients is the annual recurrence risk of atherothrombotic occlusion or stent thrombosis after discontinuation of a AA therapy within 6 months after a implantation of a BMS and up to 12 months after using a DES is high to very high. According to the current guidelines elective procedures should not carried out or planned in this period, vice versa, a stent implantation should be performed only after an urgent surgical intervention has taken place [7, 16–18, 20–22, 32]. Recent publications show a broad consensus that the dual platelet inhibition may be often finished after 3 months when using a BMS and when using a novel DES already after 6 weeks [12, 17].

The assessment of periprocedural bleeding risk (Table 19.3) is similar to the assessment taking an OAC [35]. At medium to high risk of bleeding the cardiovascular risk determines the procedures for non cardiosurgical necessary interventions [5, 7, 21].

(i). *Low risk of bleeding and high cardiovascular risk: Is the risk of bleeding through the planned intervention low, the AA therapy can be continued unchanged in most cases.*
(ii). *Medium to high risk of bleeding and high cardiovascular risk: aspirin in these patients should not be paused but continued [if the intervention cannot be moved].*
(iii). High risk of bleeding and high cardiovascular risk: if a surgery is urgent and not unmovable, the short-term interruption of the AA therapy by administration of platelet concentrates and the use of a short-acting GPIIb-IIIa antagonists iv can be performed.
(iv). *Medium to high risk of bleeding and low cardiovascular risk: an interruption of the AA medication is justifiable.*

ASA, [common dose 100 mg per day] can be discontinued 5 days before the planned intervention, clopidogrel or ticagrelor should be paused 5 days and prasugrel 7 days in advance [16–18].

In aspirin-induced bleeding, DDAVP can be administered i.v. [0.3–0.4 mg/kg] in consideration of the contraindications for DDAVP in combination of platelet concentrates administration [18, 20, 22, 32, 38]: in 2014 the EMA approval has been extended in this indication for DDAVP administration.

After interruption of an AA therapy to the procedure can be applied in analogy for OAC, approximately 24 h following surgery the reuptake of the AA therapy can be scheduled. ASA is effective within minutes; Clopidogrel reaches its full effect without saturation after about 7 days.

For high-risk patients who have to undergo a necessary intervention, a bridging with a short-acting GPIIb-IIIa antagonists iv [Eptifibatide, Tirofiban: 29] is possible in addition to the short-term interruption of AA therapy with platelet concentrates.

In patients with renal impairment Eptifibatide is the GPIIb-IIIa inhibitor of choice. First experiences on the short-term bridging therapy with reversible direct P2Y12 inhibitor Cangrelor are available [1], but this substance is not yet approved in Germany.

When bridging an AA therapy in addition to the clinical evaluation of the bleeding measurements of blood count, thromboplastin time and aPTT should be performed preoperatively and postoperative. In addition, preoperative and possibly in the inpatient period of time the measurement of the residual platelet function by appropriate test methods might be helpful.

To summarize: the risk of recurrence of stent thrombosis after (too) early discontinuation of AA therapy after implantation of a BMS or DES is high [−please consider

manufacturer's instructions and current guidelines-]. Generally, elective surgery should not be performed during this period. ASA may be discontinued 5 days before the planned intervention, Clopidogrel or Ticagrelor should be discontinued 5 days and Prasugrel should be paused 7 days in advance.

Perioperative Management: Direct Oral Anticoagulants

Among the class of DOACs the class of thrombin inhibitors and factor Xa inhibitors are combined [2, 15, 31]. Dabigatran is a thrombin inhibitor, Rivaroxaban, Apixaban and Edoxaban are factor Xa inhibitors. Both classes are used in fixed dosage without laboratory control both for primary prevention as well as in therapeutic indications.

The audited dosage for the treatment of deep vein thrombosis will be for Dabigatran 2 × 150 mg daily after the initial use of UFH, LMWH or Fondaparinux for at least 5 days, for Rivaroxaban in the first three weeks 2 × 15 mg followed by 1 × 20 mg daily, for Apixaban initial 2 × 10 mg daily for 7 days and then 2 × 5 mg and 60 mg once daily for Edoxaban after initial administration of UFH, LMWH or Fondaparinux for at least 5 days. In atrial fibrillation, the standard dose of Dabigatran is 150 mg 2 × daily, 1 × 20 mg daily of Rivaroxaban, 2 × 5 mg per day for Apixaban and 60 mg once daily for Edoxaban (regarding dosage recommendations, for example in renal impairment, we refer to the prescribing information respectively) [4, 31].

For DOACs no bridging therapy in the perioperative period is usually required due to the short half-lives because the necessary treatment interruption can be achieved by simply omitting before surgery [23, 24]. Peak levels are reached after oral administration of Dabigatran after 1.5–2 h, for Rivaroxaban 2–4 h, for Apixaban after 3–4 h and for Edoxaban after 1–2 h [2, 4, 25].

For Dabigatran discontinuation is recommended 2 days before a standard intervention in normal renal function, mild and moderate renal impairment a break of 3–4 days should be discussed [21]. For Rivaroxaban a break usually ranges from of at least 24 h before planned surgery, Apixaban and Edoxaban should be discontinued 24–48 h before the planned surgery [4, 21].

If the time of last intake is unclear and urgently required intervention with high bleeding tendency is a determination by modified thrombin time possible for Dabigatran and an anti-factor Xa determination for Rivaroxaban, Apixaban and Edoxaban possible [11, 15, 28, 41]: It this context it should be noted that the respective anti-factor Xa test for the DOAC-substance must be calibrated. In addition, it should be mentioned that a Rivaroxaban-sensitive thromboplastin time (for example Neoplastin reagent) for detecting the effect of Rivaroxaban is also suitable [15].

In contrast to therapy with OAC the DOACs achieve at point of restart with DOACs in the original dose an immediate anticoagulant effect, it is recommended to start these drug classes again only after a secure clinical exclusion of postoperative bleeding tendency or to reduce the starting dose of both agents [21]. If necessary, the administration of UFH or LMWH should post-operatively initially carried out (in the first 48–72 h), as there is no experience for the post-operative administration of DOACs outside of VTE prophylaxis in hip and knee replacement surgery. If oral drug absorption should not be possible for a long time postoperatively a thromboembolic prophylaxis is to be ensured with for example UFH or LMWH.

Finally, we have to point out that DOACs do not represent a medication to bridge a therapy with OAC or AA.

To summarize: Dabigatran is discontinued in normal renal function 2 days before a standard procedure, Rivaroxaban should be discontinued at least 24 h in advance and Apixaban and Edoxaban 24–48 h before. DOACs are no medication for a bridging therapy with OAC or AA.

Future Prospects

Further prospective and randomized trials and meta-analyzes of randomized studies are needed to be able to pronounce recommendations on a higher evidence level in the future. These studies should be based on a harmonized definition and evaluation criteria for study endpoints and bridging therapies [10, 29, 30, 36, 37].

Conclusions for Clinical Practice

Current recommendations for bridging a chronic OAK or AA-therapy are still based on not sufficient data and therefore are subject to uncertainty, so that in each patient the bleeding and thromboembolic risk must be weighed against each other.

With a medium risk of thromboembolism, such as during the hysterectomy**,** the individual bleeding risk of the planned intervention determines the bridging therapy:

Is the risk of bleeding due to the planned intervention low, the OAK / AA therapy can be continued unchanged or be slightly reduced in intensity in most cases.

Is risk of thrombosis low in case of a medium to high risk of bleeding, antiplatelet therapy can be paused temporarily.

At high risk of bleeding and thromboembolism, a change of OAC to UFH [impaired renal function] or LMWH is required.

The AA-therapy can be bridged with cases of a high risk of bleeding and thromboembolism with platelet concentrates and short-acting GPIIb-IIIa antagonists [Eptifibatide, Tirofiban].

Patients using a direct oral anticoagulant [Dabigatran, Rivaroxaban, Apixaban, Edoxaban] need an intermission

of therapy prior to the planned intervention depending the individual half-time of the specific medication and the individually renal function. These patients do not need a bridging with heparins.

Gynaecologists and anaesthesiologists are both at the patient's service when performing gynaecological procedures.

In order to achieve the best possible outcome concerning patient safety and comfort and to establish a smooth course in the operating theatre and a good environment for performing surgery it is necessary to maintain an on-going communication and teamwork between gynaecologists and anaesthesiologists. Both sides have to be aware of each other's specific needs and problems.

Therefore this book, which is addressed to operating gynaecologists includes a chapter emphasizing on anaesthesiological difficulties of vaginal procedures, laparotomy, laparoscopy and robotic assisted gynaecological surgery.

General Considerations of Gynaecological Anaesthesia

Gynaecological procedures are often perceived as mutilating by patients. Therefore a high level of fear has to be expected and considered by all involved disciplines. The first contact between anaesthesiologist and patient usually takes place at the pre-operative assessment. The main objective here is the evaluation of cardiopulmonary risk factors and the completion of additionally necessary diagnostic investigations. Especially when dealing with multimorbid patients or invasive surgery an interdisciplinary perioperative risk evaluation is important. By taking account of the patient's wishes the anaesthesiologist chooses a certain technique. The pre--operative assessment needs to be discussed with the patient. All information as well as the patient's consent are documented. The patient is informed about fasting times and administration of her own medication. Furthermore the anaesthesiologist should try to reduce the patient's fears during the conversation. The pre-operative administration of anxiolytic medication is an integral component for achieving this goal.

An outpatient surgical procedure is only permitted if the procedural and patient-related requirements are fulfilled. The patient's status should be passed on to the anaesthesiological

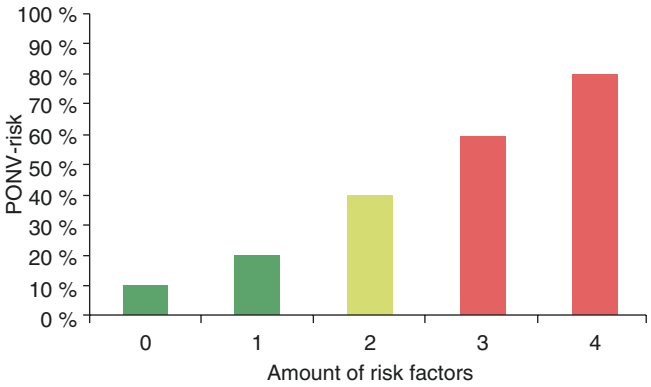
department prior to their assessment. Thereby possible contraindications can be detected and an inpatient treatment can be planned if necessary.

Postoperative Nausea and Vomiting



One of the most common complications after anaesthesia is the occurrence of PONV. The general incidence is about 30 % [1–3]. In gynaecological surgery the incidence is even two to three times higher and lies at ca. 80 % [4]. Even though the exact pathogenesis of PONV remains unknown it was possible to identify numerous significant independent risk factors by analysis of large cohort studies. In addition to patient-specific risk factors anaesthesia- and surgery-related risk factors should be determined (Table 20.1). Surgical risk factors include "gynaecological surgery "as well as" laparoscopy" [3, 5] underlining the gynaecology-specific relevance of PONV for the anaesthesiological care. The patient's discomfort due to PONV is one of the most common reasons for poor patient satisfaction rating in the postoperative period [6]. Given the possibility to allocate a certain amount of money to prevent all postoperative complications, patients would spend one third and also the largest amount to avoid PONV [7]. Persistent PONV can lead to a prolonged stay in the postoperative care unit [3] and unanticipated hospital admission which results in a significant increase of overall health care costs [8, 9]. To address these findings risk scores are used to objectify the patient's individual baseline risk for PONV. Simplified PONV risk scores with a sensitivity and specificity of about 70 % [1, 2, 10] are equally precise in predicting PONV as compared to more complex approaches and may significantly reduce the rate of PONV (Fig. 20.1); Nowadays they are part of everyday practice at most institutions. Prevention and treatment of PONV may be achieved by altering the anaesthesiological approach and by applicating antiemetic drugs (Table 20.1).

Positioning

Lithotomy position is commonly used during gynaecological interventions. It allows the best access to the perineum. An additional advantage is the extra space between the patient's legs for an assistant surgeon during abdominal procedures without restricting the operator's mobility.

When placing patients in lithotomy position awareness for nerve injuries caused by intraoperative positioning is crucial.

Femoral neuropathy may occur due to distinctive angulation of the femoral nerve beneath the unyielding inguinal ligament. Sciatic nerve function may be compromised since

it is fixed at the sciatic notch and extreme positioning, especially external rotation may lead to stretch injury. The common peroneal nerve is susceptible to compression injury due to its superficial course near the lateral fibular head.

Excessive hip flexion (>90°), abduction (>45°) and external hip rotation should be avoided. Maximum abduction is reached when the contralateral shoulder is in line with thigh, knee and heel of the patient.

Special care must be taken if the patient's mobility in the knee and hip joint is limited (e.g. condition after hip replacement). In these cases it is advisable to perform positioning while the patient is still awake.

Nerve injury of the brachial plexus may occur when shoulder padding is used during Trendelenburg position to prevent sliding of the patient. The neural structures of the brachial plexus pass the cervical intervertebral foramina, the interscalene triangle and run between the clavicle and the first rib to the axilla. Potential compression along the way can be caused by soft tissue as well as bony structures when pressure is applied. The contact point of shoulder padding should be at the acromioclavicular joint. Abduction of the arm increases the risk of nerve injury and should never exceed 90° [11].

Less common is the development of a compartment syndrome (CS) during lithotomy position. The incidence of CS lies around 1:3500 during gynaecological procedures. Since delayed diagnosis and treatment may result in catastrophic consequences for the patient this rather rare complication will be further discussed in this chapter. The occurrence of CS in a previously healthy leg is also described as "well-leg-compartment-syndrome".

The arterio-venous pressure gradient theory is the most accepted theory today for description of the pathophysiology of CS [12]. This hypothesis states that capillary perfusion is only assured when the arterial pressure transcends the venous pressure.

During lithotomy position increased external pressure on the calf, the weight of the calf itself in the positioning devise and venous obstruction due to kinking of the veins will increase venous pressure.

Arterial pressure may be decreased by elevation of the lower extremity, anaesthesia-related hypotension or hypovolemia due to haemorrhage [13]. This constellation especially during long-lasting lithotomy position can result in a reduction of capillary perfusion beyond tissue viability. Ischemia itself and post ischemia reperfusion injury can cause increased endothelial permeability due to liberation of inflammatory mediators with a leakage of fluid into the interstitial space. The resulting edema within the non-expandable compartment causes further reduction of arterial and increase of venous pressure and is ultimately the start of a vicious circle (Fig. 20.2).

If necrosis occurs the function of the extremity can be compromised and amputation may be the only option. In the case of cell death rhabdomyolisis, kidney failure, hyperkalaemia and acidosis can lead to multiple organ failure and death.

So far it was not possible to identify any independent risk factors for CS. However, increased body mass index (BMI) and peripheral arterial disease have been considered to predispose an individual to be affected by CS. From what is known duration and extent of lithotomy position seems to be

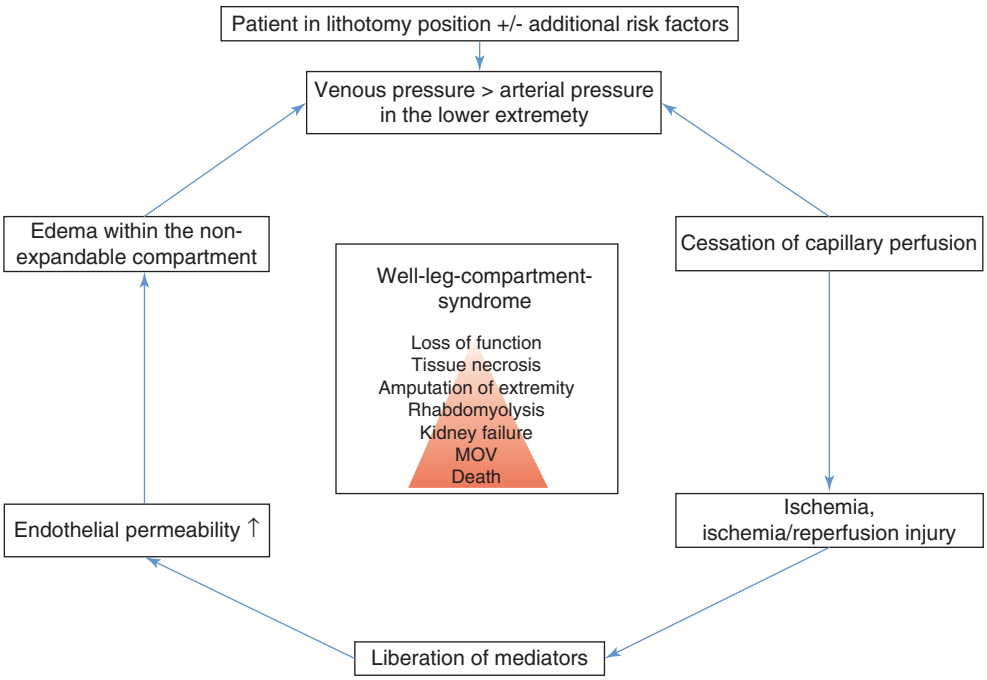

Fig. 20.2 Vicious cycle of the development of well-leg-compartment-syndrome. *MOV* Multiple organ failure

the major cornerstone in the development of CS [14]. Seventy percent of CS occur after more than 5 h [15] spent in lithotomy position (which also means that 30 % occur before that). So far evidence-based recommendations for preventing CS have not been established [15].

At some institutions preventive measures have been implemented. It remains unclear whether one of these measures or their combination can achieve the desired impact (Table 20.2).

Treatment of CS is achieved by pressure release through fasciotomy of the affected compartment [16]. To reduce edema and ischemia/reperfusion injury intravenous mannitol can be considered as a treatment option [17].

CS is primarily a clinical diagnosis. Leg pain, that is not otherwise explainable and is intensified by passive stretch and paraesthesia have to be interpreted as alarming symptoms and should be recognized.

Although large reviews could find no correlation it has been controversially discussed if diagnosis of CS may be delayed due to the use of epidural anaesthesia [18, 19]. Strong breakthrough pain has to be expected even if sufficient epidural anaesthesia is in place [20–22].

Vaginal (Access-) Surgery

The majority of vaginal procedures are less invasive. Due to short duration and limited tissue trauma many of these interventions are performed as outpatient surgery. For the anaesthesiological management the use of short-acting substances is preferred to ensure a prompt dismissal while the patient is objectively and subjectively at comfort. Postoperative nausea and vomiting can lead to prolonged observation time in the post anaesthesia care unit and unexpected admissions. Therefore adequate prophylaxis and treatment of PONV is advised.

If lack of contraindications is assured (e.g. gastro--oesophageal reflux) the airway can be secured with supraglottic devices. Thereby the use of muscle relaxants can be avoided and the risk of prolonged respiratory assistance due to overdosing or overhang can be minimized.

During short procedures an on-going communication between gynaecologist and anaesthesiologist is necessary to assure a well scheduled and adequate depth of anaesthesia. Hereby a smooth process in the operating theatre with little delay can be achieved.

Possible complications during vaginal procedures can develop when surgical manipulation leads to vagal reaction. In most cases interruption of that manipulation is sufficient as a causal treatment although cardiac arrest may occur [23].

For surgical procedures with a duration of 1–2 h or patient-specific factors (e.g. COPD) spinal anaesthesia may be an alternative technique if steep Trendelenburg position is not required. Respectful and considerate interaction with the conscious patient and an appropriate conversation and noise level need to be regarded. Spinal anaesthesia per se is not a contraindication for outpatient surgery.

Fluid Overload Syndrome

Diagnosis and treatment of intra-uterine pathologies requires distension of the uterus. Today fluid distending media are predominantly used. Distension of the endometrial cavity is only feasible if the distending media is applied with a certain pressure. Systemic absorption may cause “fluid overload syndrome”. Heart failure and lung edema can develop due to sudden exposure to additional preload. Pathogenesis and clinical appearance are similar to TUR-syndrome known from urological surgery.

In diagnostic hysteroscopy the anticipated risk for systemic absorption is low due to the lack of vessel transection since media has no opportunity to enter systemic circulation. Consequently the risk increases if resection (e.g. of a myoma) is performed and tissue is traumatised.

While mechanical instruments may be an alternative for resection in some cases, most hysteroscopic resectoscopies are performed using monopolar or bipolar electrosurgical instru-

Table 20.2 Potential risk factors of CS and potential strategies for preventing CS during lithotomy position

Potential risk factors of CS during lithotomy position	Potential strategies for preventing CS during lithotomy position
Extreme lithotomy position	Avoidance of lithotomy position whenever there is no need for perineal and vaginal access
Trendelenburg position	Intraoperative modification of position of lower extremity
Long duration of lithotomy position and head down tilt	Intraoperative warming of lower extremity
Intraoperative hypotension/hypovolemia	Avoidance of hypotension
Hypothermia	Minimization of time in lithotomy−/Trendelenburg position
High extent of flexion in knee- and hip joints	Avoidance of high degree of lithotomy−/Trendelenburg position
External pressure due to positioning support material	Adequate substitution of fluid loss
Patient-specific risk factors	Intermittent compression of lower extremity
Misinterpretation of clinical symptoms	Awareness of clinical symptoms

CS compartment syndrome

ments. Monopolar cauterisation requires completion of an electrical circuit between the surgical instrument and the remotely located dispersive electrode to achieve a thermal effect. If such instruments are used in the presence of conductive particles (e.g. ions in saline) dispersion prevents the completion of the electrical circuit and therefore the surgical effect.

This explains the requirement of electrolyte-free and hypotonic distension media if monopolar electrocauterisation is used. If these hypotonic fluids find their way into the systemic circulation of the patient not only fluid overload may occur, but also hypotonic haemodilution. Resulting hyponatremia and osmotic imbalances can lead to cerebral edema with symptoms as seizures, coma or death [24, 25].

Premenopausal women are at increased risk of neurological complications due to sodium-potassium adenosine triphosphatase (NA^+/K^+- ATPase) "pump"-inhibition by female sex steroids, most likely oestrogens [26]. Preoperative GnRH-agonist administration may therefore be considered [27].

The risk of neurological complication using electrolyte--free distending media has led to the development of bipolar electrosurgical instruments that can be used even in complex hysteroscopic surgery [28, 29]. The electrical circuit is completed at the tip of the instrument. The presence of charged particles is therefore required and electrolyte-containing media (e.g. normal saline) is used.

To prevent neurological complications during hysteroscopy it is recommended to avoid hypotonic distending media whenever possible. The uterine cavity distension pressure should be the lowest pressure necessary to distend the uterine cavity and ideally should be maintained below the mean arterial pressure (MAP) especially with regard to long--lasting procedures.

Input and output of distending solution should be accurately monitored, since differences may indicate increased absorption or fluid loss due to accidental uterus perforation.

When using hypotonic distending media not more than 1000 mL should be absorbed. For elderly patients and others with comorbid conditions including compromised cardiovascular systems, a maximum fluid deficit of 750 mL is recommended.

In case of use of high-viscosity distending media, the maximum infused volume should be maintained below 500 mL in healthy patients, and below 300 mL if risk factors are present.

The maximum limit for isotonic media remains unclear, but absorption volumes of more than 2500 mL even in healthy patients should be prevented.

Preoperatively gynaecologist and anaesthesiologist should agree upon a maximum deficit volume with respect to the distending media used, the planned procedure and patient-specific risk factors. If that limit is exceeded during surgery termination has to be considered. If absorption of hypotonic solution is suspected, immediate measurement of plasma electrolytes and osmolality is indicated [30].

Some authors propagate intra-cervical injection of a dilute vasopressin solution to reduce distending media absorption during resectoscopy [31, 32]. This approach should be communicated with the anaesthesiologist, since absorption of large systemic doses have resulted in cardiovascular collapse, myocardial infarction and death [33].

Treatment options for manifest fluid overload syndrome include supportive intensive care, use of diuretics and substitution with sodium-containing solution. Special care must be taken when correcting severe hyponatremia, since pontine myelinolysis can occur (Fig. 20.3).

Laparoscopy

In recent centuries laparoscopy has become the standard technique for numerous gynaecological procedures. Advantageous for the anaesthesiologist are less haemorrhage, less postoperative pain and an improved lung function that results in a shorter hospital stay [34]. Especially overweight patients and patients with significant cardiopulmonary comorbidities benefit from laparoscopy.

However insufflation of carbon dioxide (CO_2) in order to establish and maintain pneumoperitoneum causes relevant changes in haemodynamics, lung function and the acid-base balance. Other organ systems like liver and kidney function may be altered as well.

Pulmonary Difficulties During Laparoscopy

CO_2 best satisfies the characteristics demanded from a gas used for pneumoperitoneum insufflation. It is non-flammable, inexpensive and easily expelled from the body, the latter because CO_2 is readily soluble. Therefore the risk for embolism is low but insufflation of CO_2 into the peritoneal cavity causes increased blood levels. To prevent development of hypercarbia and following acidosis the anaesthesiologist needs to alter ventilator settings. An increased respiratory rate (RR) and inspiratory pressures (P_{insp}) generate the necessary elevation of respiratory minute volume (MV).

$$\text{Pneumoperitoneum} \rightarrow CO_2 \uparrow \rightarrow MV \uparrow \left(RR \uparrow \text{ and } P_{insp} \uparrow\right)$$

Increased inspiratory pressures are also required due to the pneumoperitoneum itself. Increased intra-abdominal pressure will shift the diaphragm cranial. Therefore higher pressure settings are required to maintain a certain tidal volume. Thus pulmonary compliance decreases. Also functional residual capacity and vital capacity decline following pneumoperitoneum. The use of Trendelenburg

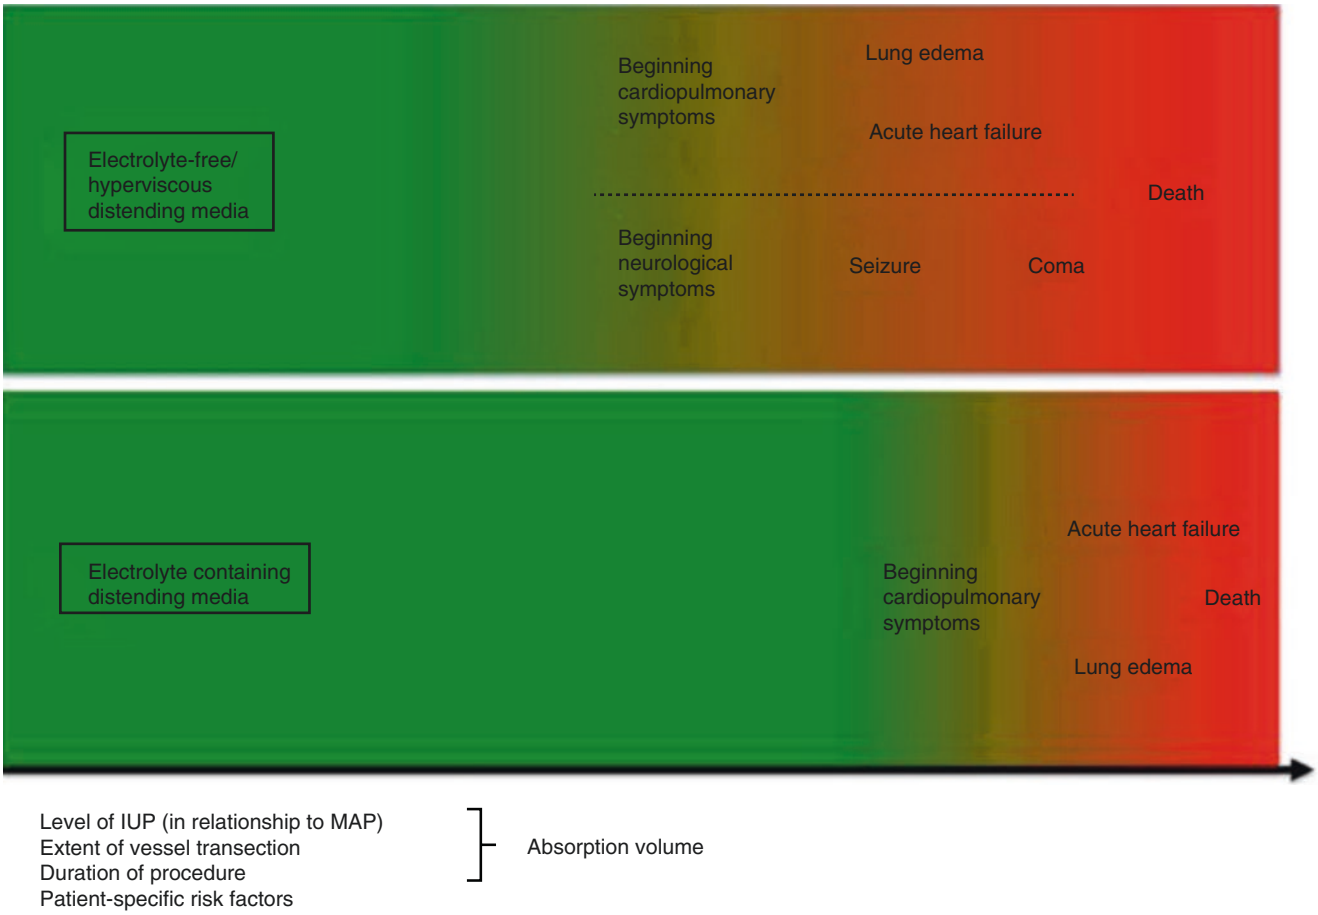

Fig. 20.3 Risk for complications using electrolyte-containing and electrolyte-free/hyperviscous distending media in hysteroscopic procedures. *IUP* intra-uterine pressure, *MAP* mean arterial pressure

position intensifies diaphragm transfer with its pulmonary consequences.

$$\text{Pneumoperitoneum} \rightarrow \text{cranial shift of the diaphragm} \rightarrow \text{compliance} \downarrow \rightarrow P_{insp} \uparrow$$

Increased inspiratory pressure leads to increased intra-thoracic pressure that directly affect the vessels of the pulmonary circuit resulting in decreased lung perfusion. Additionally the development of atelectasis leads to a reduction of lung tissue taking part in gas exchange. Consequently ventilation/perfusion ratio will be decreased inducing a deterioration of CO_2 elimination and an oxygenation deficiency.

$$P_{insp} \uparrow \rightarrow \text{intra-thoracic pressure} \uparrow \rightarrow \text{ventilation / perfusion mismatch} \uparrow \leftarrow \text{atelectasis} \uparrow$$

Summarizing, pneumoperitoneum results in increased levels of CO_2 in the blood. At the same time decreasing pulmonary compliance and an increasing ventilation/perfusion mismatch lead to reduced performance of the pulmonary system, which is supposed to eliminate CO_2. It needs to be kept in mind that the anaesthesiologist can hardly improve the pulmonary system itself during laparoscopy/Trendelenburg position. To avoid acidosis the invasiveness of ventilator settings needs to be increased which may eventually harm the patient.

For the patient's safety the gynaecologist therefore needs to be informed by the anaesthesiologist if excessive acidosis and/or oxygenation deficiency develop. Since pneumoperitoneum is the main cornerstone for pulmonary exacerbation during laparoscopic surgery reduction of intra-abdominal pressure and Trendelenburg position is the adequate de-escalation strategy. If the pulmonary status remains critical the termination of the procedure has to be taken into account.

Subcutaneous Emphysema During Laparoscopy

In rare cases the insufflation gas extends beyond the peritoneum causing subcutaneous emphysema. Extension of insufflated gas may directly harm the patient if extravasation occurs within the mediastinum. Swelling of the larynx region may result in dyspnoea and stridor after extubation.

Pneumothorax caused by extension of insufflated gas through diaphragmatic congenital channels into the pleural cavities has been reported [35–37].

While minor extravasations of gas can only be detected by radiological imaging distinctive manifestations may be palpated as crepitations.

CO_2 extension beyond peritoneal cavity
→ direct harm due to gas expansion

Extension of CO_2 beyond the peritoneal cavity impairs integrity of pneumoperitoneum required by the operator. To maintain the predetermined pressure set point the insufflator increases the gas flow rate resulting in an increased overall exposure with CO_2. CO_2 is therefore not only absorbed from the peritoneal cavity but also the surrounding tissue. Severe, long-lasting acidosis may develop.

Excessive hypercarbia requires invasive respirator settings with high tidal volumes and inspiratory pressures that may also harm the patient.

Hypercarbia beyond extubation requires increased work of breathing. Exhaustion may result in CO_2 narcosis and possible reintubation.

It is therefore recommended to not only monitor pressure and flow rate but also the total CO_2 volume during laparoscopy in order to detect loss of gas [38].

CO_2 extension beyond peritoneal cavity → pressure of pneumoperitoneum ↓→ flow rate of insufflator ↑→ total exposition to CO_2 ↑→ absorption ↑→ acidosis ↑→ escalation of ventilatory support

The incidence of subcutaneous emphysema varies with regard to the extent of extravasation. Grossly detectable subcutaneous emphysema can be found in 0.43–2.3% [38]. Postoperative computed tomography scans showed subcutaneous emphysema in 56 % 24 h after laparoscopy [39]. Mediastinal emphysema was detectable in 20 % after laparoscopy using x-ray imaging [40–43].

High intra-abdominal pressure leads to increased incidence of subcutaneous emphysema, especially during long-lasting procedures. Each increase in pressure is transmitted against the inner abdominal wall and transmitted to tissues, resulting in decreased perfusion, hypoxia, increased gas absorption, and increased likelihood of tissue dissection and subcutaneous emphysema. Even though intra-abdominal pressures between 0 and 20 mmHg are considered as safe, the use of pressures between 12 and 14 mmHg is recommended.

Locations of increased vulnerability of CO_2 escape are the insertion sites of the trocars. Gas extension beyond the peritoneal cavity increases with the amount and size of the trocars used. Due to their length surgical instruments act as lever arms and the force applied is multiplied at the fulcrum, which in case of laparoscopy is the boundary between the trocars and the tissue surrounding it. Shear forces may cause trauma and eventually lead to dissection of tissue and loss of CO_2. Knowledge of this fact is particularly crucial when performing robotic assisted surgery since the surgeon lacks haptic feedback from the tissue [38].

Cardiocirculatory Difficulties During Laparoscopy

Prediction of cardiocirculatory reactions during laparoscopy is difficult due to complex processes, since both, pneumoperitoneum and Trendelenburg position cause a cardiocirculatory response.

Pneumoperitoneum affects circulation through increased intra-abdominal pressure and acidosis resulting from CO_2 absorption.

IAP < 15 mmHg causes mobilization of pooled venous blood and increases cardiac preload and cardiac output. If IAP exceeds 15 mmHg the contrary has to be expected. Increased pressure is directly transmitted to the vessel walls and causes compression resulting in reduced venous return. At the same time the arterial system is affected and systemic vascular resistance increases. Decreased CO and elevated MAP may be witnessed [44].

Mesenterial and renal perfusion decreases during pneumoperitoneum, causing activation of renin-angiotensin-aldosterone system (RAAS) and thus liberation of catecholamines.

Acidosis resulting from hypercarbia causes sympathetic activation while severe acidosis decreases left ventricular function [45].

As mentioned above pneumoperitoneum is associated with increased inspiratory pressures that compromise venous return. Trendelenburg position may partly revoke these effects due to orthostatic effects. Possible tachycardia and hypertension due to a lack of analgesia as well as cardiocirculatory effective medication taken by the patient may alter cardiocirculatory response as well.

Therefore implementation of pneumoperitoneum and changes in patient position should occur gently, especially in patients with cardiopulmonary comorbidities, to allow circulation to adapt.

Introduction of the veress-needle, trocars and establishing pneumoperitoneum may cause vagal reactions that can lead to bradycardia and asystole even in healthy individuals [44].

Similar symptoms can occur through manipulation on uterus and adnexa [23].

Additional Considerations During Laparoscopic Surgery

CO_2 absorption and Trendelenburg position may cause an increase in cerebral blood flow, which can result in cerebral edema and increased intracranial pressure especially during long-lasting procedures. If cerebral edema is suspected prolonged ventilatory support in anti-Trendelenburg position and treatment with mannitol should be considered. Pre-existing increased intracranial pressure is a contraindication for laparoscopy [46].

Intra-ocular pressure may also increase during pneumoperitoneum. Vision loss after long-lasting laparoscopy in steep Trendelenburg position is a rare but catastrophic complication [47, 48]. In patients with glaucoma ophthalmologic assessment is advised.

Elevated intra-abdominal pressure during laparoscopy increases the risk for aspiration. The airway is therefore secured via endotracheal tube. Intra-gastric pressure is resolved using a gastric tube.

The anaesthesiologist must be aware that inadvertent one-sided intubation and consequent hypoxemia is a distinct possibility during laparoscopic surgery because of the Trendelenburg position, which with the raised IAP, lifts the diaphragm and carina, while the endotracheal tube remains fixed at its proximal end. This complication can easily be detected by auscultating the patient and then resolved.

Restricted Access in emergency situations to the patient's airway, intravenous lines and thorax for possible resuscitation during laparoscopy has to be considered.

Gas Embolism

With implementation of pneumoperitoneum, immediate gas embolism may occur, and in very rare cases it may lead to severe cardiovascular failure, decreased pulmonary blood flow, and death. Since CO_2 is readily soluble this complication is extremely rare during laparoscopy. Contamination of the abdominal cavity with room air needs to be prevented because the contained oxygen can maintain combustion and nitrogen could cause embolism due to its poor solubility. If embolism occurs pulmonary circulation is generally affected causing an increased vascular resistance. Sudden elevation of right hearted afterload may cause right heart failure. Transfer to arterial circulation (patent foramen ovale) can result in end organ failure, especially stroke. The clinical manifestations of embolism generally include a sudden increase followed by a rapid reduction in end-tidal CO_2, tachycardia and hypotension. If suspected the patient should be brought in head down/left-side tilt (durant maneuver) to prevent further embolism of the pulmonary circulation. Gas embolism can be detected sonographically and a central venous line can be used to evacuate emboli via aspiration (Fig. 20.4).

Robotic Surgery

Improved precision and three-dimensional display allows execution of even complex gynaecological procedures in minimal invasive technique. Further dissemination of robotic assisted surgery in the years to come can be expected.

For anaesthesiologists the evolution of laparoscopy to robotic assisted surgery can be a challenge.

The considerations for laparoscopy are even more valid for the robotic approach. Essential problems include patient positioning, duration of the procedures and limited access to the patient.

Patient positioning is crucial in robotic assisted surgery since after docking of the robot no further movement of the patient is permitted. Patient movement while the robot is docked can cause serious injury at the insertion site of the trocars, which is why adequate muscle relaxation is critical for success. To achieve optimal circumstances to perform surgery the patient is positioned in steep (up to 45°) Trendelenburg position. Especially in overweight patients undesired sliding and intraoperative neuropathic injury can only be prevented if positioning is performed meticulously prior to robot docking using shoulder braces, antiskid foam material and vacuum mattresses etc.

The creation of pneumoperitoneum is associated with the earlier mentioned problems as hypercarbia, decreased pulmonary compliance, ventilation/perfusion mismatch and interference with venous return and systemic vascular resistance.

Intravenous lines should be introduced on both sides of the upper extremity to compensate for loss since access (for further puncturing) after robot docking may be restricted. Preoperative communication between gynaecologist and anaesthesiologist is essential to plan anaesthesiological management with regard to extent and duration of the procedure [49, 50]. Moreover the anaesthesiologist evaluates the indication for arterial line and central venous catheter considering the patient's comorbidities.

If the bulky robot is draped and docked access to the patient's thorax is limited. In emergency situation chest compressions or cardiac defibrillation can only be executed once the robotic arms have been removed. That way the resuscitation can be initiated immediately. Removal of the trocars and the robot itself has to be done subsequently to allow access to the entire patient. Reaction time in emergency situations during robotic assisted surgery can be improved with simulator training [51].

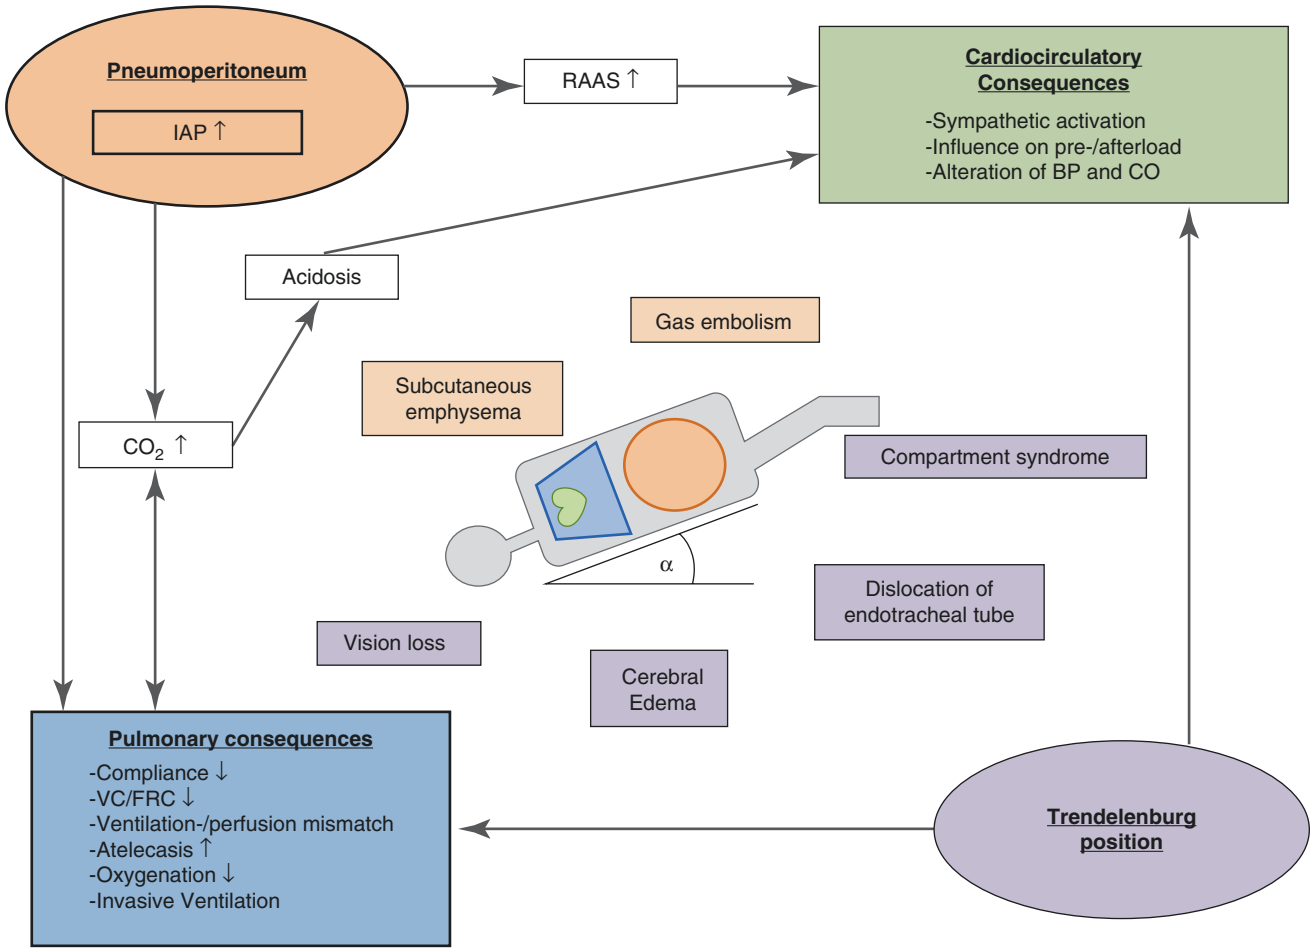

Fig. 20.4 (Patho-) Physiological alterations and complications during laparoscopy/robotic assisted surgery. The complications are coloured corresponding to the leading risk factor. CO_2 Carbon dioxide, *CO* Cardiac output, *IAP* intra-abdominal pressure, *FRC* Functional residual capacity, *RAAS* Renin-angiotensin-aldosterone system, *BP* Blood pressure, *VC* Vital capacity, *α* angle (extent) of Trendelenburg position

Resuscitation

Remove the arms of the robot → start chest compressions / defibrillation → remove all trocars from the robot → remove the robot

The long duration of most robotic assisted procedures intensifies the effects of pneumoperitoneum and patient position (also see Fig. 20.4). Therefore all issues discussed above concerning laparoscopy need to be considered during robotic assisted surgery in particular. That includes:

- Pulmonary difficulties (including risk of subcutaneous emphysema)
- Cardiocirculatory difficulties
- Risk of cerebral edema and increased intra-ocular pressure
- Risk of nerve injuries and compartment syndrome
- Risk of aspiration due to increased intra-abdominal pressure
- Risk of one-sided intubation
- Restricted access

Also general factors of long-lasting surgery as fluid loss, hypothermia and haemorrhage need to be anticipated by the anaesthesiologist.

Laparotomy

Despite the advances in laparoscopic techniques oncologic surgery in gynaecology is today mostly performed via laparotomy.

Oncologic patients more often present in poor general condition and are older than the usual gynaecologic cohort. Preoperative tumor-associated anaemia is common. Large intra-abdominal masses and the presence of ascites may increase intra-abdominal pressure and risk for aspiration.

Compared to laparoscopy tissue trauma during laparotomy is more severe. Therefore vast, long-lasting procedures may promote the development of systemic inflammatory response syndrome (SIRS). The liberation of mediators causes increased capillary permeability, endothelial dysfunction and impaired cardiac function.

The anaestheseological management relies on the knowledge of anticipated blood loss, duration and patient-specific risk factors. Particularly for the operative setting it has to be considered if vasopressors or postoperative parenteral nutrition are required. Extravasation of vasopressors (e.g. norepinephrine and epinephrine) can propagate cell damage by inducing venous and arterial vasospasms and causing disruption to vein wall integrity. Parenteral nutrition is a hypertonic agent that can cause tissue damage by shifting the equilibrium between intracellular and extracellular fluid. Intracellular fluid is forced out of cells and into the interstitial space, causing direct cell damage. Extravasation of these substances may lead to significant tissue damage, skin sloughing, and dermal necrosis with following infection and even amputation [52–54]. Therefore central venous line placement is advisable whenever there is a high probability that these substances need to be administered perioperatively. When evaluating the indication for central venous line placement possible adverse effects like pneumothorax, central-line associated bloodstream infections, thrombosis, misplacement and arrhythmias need to be considered.

While measurement of central venous pressure is no longer recommended for controlling volume management, central venous oxygenation may pose essential information regarding the patient's circulation [55].

Introduction of an arterial line should be performed for vast, long-lasting surgery or in patients with cardiopulmonary comorbidities. It allows the continuous and exact monitoring of blood pressure and the analysis of the arterial blood gases may give additional information on the patient's volume and respiratory status.

To decrease the risk of hypothermia the patient's temperature is monitored and convective warming systems and preheated infusion solution are used. In the case of severe hypothermia adapting the room temperature in the operating theatre can be considered.

Adequate muscle relaxation during abdominal surgery improves conditions to perform surgery by decreasing tone of skeletal muscle of the abdominal wall and the diaphragm. Muscle relaxants decrease transmission of nerve impulses at the site of neuromuscular junction. Therefore the muscle itself will be susceptible to direct electrical stimulation even after a muscle relaxant has been administered. The clinical effect of muscle relaxants is commonly monitored by acceleromyography (quality of muscle response after repeated nerve stimulation). Smooth muscle cell function and therefore intestinal motility is not affected by muscle relaxants.

The introduction of an epidural catheter is an important tool to shorten the time of recovery, manage pain and improve postoperative lung function. Nevertheless epidural haematoma with the risk of persisting paraplegia has an incidence between 1:3000 and 1:6000 [56–58] and therefore is far more common than previously suspected. The placement is performed prior to the operation while the patient is still awake in order to detect paraesthesia during catheter introduction and possible misplacement of the catheter into the subarachnoid space. The patient's wish, pre-existing anti--coagulant medication and possible patient-specific risk factors need to be evaluated in a risk benefit assessment prior to operation. The recent implementation of newer anticoagulants has to be considered with regard to timing of puncture and removal of epidural catheters (Table 20.3). A monotherapy with acetylsalicylic acid is not a contraindication for epidural puncture. While the epidural catheter is in place an anaesthesiologist and/or pain nurse will consult the patient at least once daily to asses adequate pain relieve and to detect signs for infection or neurological abnormalities. Usually the catheter is removed once sufficient analgesia without epidural infusion has been assured. When removing an epidural catheter intake of anticoagulant medication needs to be considered (Table 20.3).

For abdominal surgery intravenous lidocaine infusion poses a possible option to reduce perioperative pain and to improve recovery of postoperative bowel function [59]. Analgesic [60], anti-hyperalgesic [61] and anti-inflammatory effects [60, 62] characterize intravenous lidocaine. Increased postoperative sedation and the occurrence of cardiac arrhythmias may be possible side effects [63].

Vast oncologic surgery is associated with a high risk for haemorrhage and distinctive fluid shifts. Thus compatible erythrocyte concentrate needs to be provided. It has to be considered that transfusion of erythrocyte concentrate poses an independent risk factor for infection and sepsis [64], multiple organ failure [65] and death [66]. This reflects in more restrictive transfusion recommendations. Due to early presentation prior to surgery existing anaemia can be detected and possibly treated. Hereby the patient's red blood cell count and haemoglobin concentration can be optimized and mortality may be decreased [67–69].

If acute profuse bleeding (e.g. due to vessel transection) occurs during surgery basic physiology (Ohm's law) teaches that during hypertension will cause an increased blood loss due to an increased pressure gradient (pressure within the vessel vs. surrounding (atmospheric) pressure). Not only because the bleeding itself is stronger but also because haemostasis may be impeded due to clot disruption [70].

Therefore lower blood pressure via intraoperative controlled hypotension may be advantageous during acute bleeding and possibly reduce transfusion rate and blood loss. However intraoperative hypotension (IOH) is one of the

Table 20.3 Recommended time intervals prior to and after epidural catheter placement and removal [78]

Substance	Half-life period	Interval prior to placement/removal	Interval after placement/removal
Heparin, unfractionated (prophylaxis)	1, 5–2 h	4 h	1 h
Heparin, unfractionated (therapeutic)	2–3 h	i.v. 4–6 h s.c. 8–12 h	1 h
Low molecular weight heparin (prophylaxis)	4–6 h[a]	12 h	4 h
Low molecular weight heparin (therapeutic)		24 h	4 h
Fondaparinux (1 × 2.5 mg/day)	15–20 h[a]	36–42 h	6–12 h
Danaparaoid (2 × 750 I.E./day)	22–24 h[a]	48 h	3–4 h
Hirudinea Desirudin Bivalirudin	120 min[a] 25 min[a]	8–10 h 4 h	6 h 8 h
Argatroban (prophylaxis)[b]	35–45 min	4 h	5–7 h
Dabigatran (max. 1 × 150–220 mg/day)	14–17 h[a]	28–34 h	6 h
Dabigatran (max. 2 × 150 mg/day)	14–17 h[a]	56–85 h	6 h
Rivaroxaban (1 × 10 mg/day)	11–13 h[a]	22–26 h	4–5.5 h
Rivaroxaban (2 × 15 mg/day, 1 × 20 mg/day)	11–13 h[a]	44–65 h	4–5.5 h
Apixaban (2 × 2.5 mg/day)	10–15 h[a]	26–30 h	5–7 h
Apixaban (2 × 5 mg/day)	10–15 h[a]	40–75 h	5–7 h
Vitamin k antagonists	Days	INR < 1.4	After removal
Acetylsalicylic acid (100 mg/day)[c]	Life span of thrombocytes	None	None
Clopidogrel Ticlopidin	Life span of thrombocytes	7–10 days	After removal
Prasugrel	Life span of thrombocytes	7–10 days	6 h
Ticagrelor	7–8.5 h	5 days	6 h
Abciximab	12–24 h	Contraindication for puncture/48 h prior to removal	8 h

[a]Half-life period depends on renal function
[b]Half-life period depends on liver function
[c]Treatment with acetylsalicylic acid requires disruption of other anticoagulants for 4–5 half-life periods, while acetylsalicylic acid may be continued

most important concerns associated with the occurrence of postoperative myocardial ischemia and infarction, acute kidney failure and stroke (watershed infarcts) [71, 72].

IOH still lacks exact definition and needs to be considered a dynamic phenomenon depending on patient specific risk factors such as comorbidity, age and surgical factors. Therefore intraoperative controlled hypotension should not be based on fixed, arbitrarily chosen thresholds but needs to be adapted (extent and duration of IOH) according to the clinical setting [71–73].

Perioperative coagulopathy may occur during gynaecologic surgery and necessitate substitution of coagulant factors. Coagulopathy in the operative setting often is initiated due to blood loss and dilution but remains a multifactorial disorder involving:

- Abnormalities of basic physiological conditions (e.g. temperature, pH, ionized calcium),
- Disorders of primary haemostasis (pre-existing or acquired),
- Abnormalities of blood plasma (clotting-factor deficits) or
- Complex coagulopathies (hyperfibrinolysis, disseminated intravascular coagulation).

Detection of perioperative coagulopathies and the monitoring of their treatment are difficult tasks and an on-going field of research [74–77].

While "classical" routine testing of blood coagulation (INR, aPTT) is limited in terms reflecting the complexity of bleeding disorders, point-of-care (POC) testing (e.g. aggregometric or viscoelastic testing) may potentially reveal additional information on the underlying coagulopathy and help guide the use of allogeneic blood products, clotting-factor concentrates and other hemotherapeutic agents.

Part VIII

Laparoscopic Hysterectomy and Extended Procedures for Benign and Malignant Indications

Indications and Contraindications for Laparoscopic Hysterectomy

21

Helder Ferreira and António Braga

Introduction

Hysterectomy is one of the most common surgical procedures performed worldwide. Laparoscopic hysterectomy (LH) ultimate aim is to reduce morbidity and mortality of abdominal hysterectomy (AH) to the levels seen with vaginal hysterectomy (VH) and minimise the rate of AH. Many advantages are referred to laparoscopy like the image magnification offering better visualization of anatomical structures and disease identification. It allows improved access to retroperitoneal spaces due to CO_2 pneumo-dissection. The vessels, ureter, and nerves can be better recognized. When LH is compared with AH, the laparoscopic approach is associated with less blood loss, fewer transfusions, less post-operative pain, shorter hospital stay, decrease risk of wound infection, better quality of life and lower levels of disability [1–12] (Table 21.1).

In 2015, Cochrane published a meta-analysis of 47 randomizes controlled trials with the aim to determine the most appropriate type of hysterectomy for gynaecologic nonmalignant conditions [13]. This study concluded that there are no differences between laparoscopic and vaginal hysterectomies in time to return to normal activities, duration of hospital stay and the rate of conversion to laparotomy. This study also concluded that the incidence of pelvic hematoma, vaginal cuff infection, urinary tract or respiratory infections, and venous thromboembolism were similar for these two types of hysterectomies [13]. There was a higher rate of bladder and ureteral injuries in total laparoscopic hysterectomy (TLH) in comparison with total abdominal hysterectomy (TAH), but similar to total vaginal hysterectomy (TVH) [13].

Classically, the operative time is higher with TLH when compared with TAH or TVH. However, with an increment of surgical experience and expertise, the operative time, as well as the conversion rate to laparotomy or the incidence of major complications is significantly reduced [14, 15].

In spite of these, according to the American College of Obstetricians and Gynaecologists 2009 Committee Opinion[16] and American Association of Gynecologic Laparoscopists [17] TVH is the overall preferred approach when feasible. Factors that influence the surgical approach in hysterectomy include vagina and uterus size and shape, the mobility and accessibility of uterus, the extension of extra uterine disease when present, the need for concurrent procedures and the surgical team experience.

Table 21.1 Advantages of laparoscopic hysterectomy *versus* abdominal hysterectomy

Less blood loss
Fewer transfusions
Less post-operative pain
Shorter hospital stay
Decreased risk of wound infection
Better quality of life
Lower levels of disability

Indications

TLH indications are similar to those for TAH. Usual indications include leiomyomata (Figs. 21.1 and 21.2), pelvic organ prolapse, abnormal uterine bleeding, adnexal pathology (Fig. 21.3), chronic pelvic pain and endometriosis (Fig. 21.4) [18]. TLH may also be indicated for resection and debulking of both malignant and premalignant disease, especially endometrial and cervical cancer, as noted by extensive case series in the gynaecologic oncologic literature (Table 21.2).

Laparoscopic approach to hysterectomy may be indicated when vaginal access is complicated by a narrow subpubic arch, a nulliparous pelvis, a large uterus (16-week size is usually the upper limit for a TVH) [19] when uterine mobilization is compromised by adhesions or by multiple or large leiomyomas [18].

In case of a very large uterus, it is more feasible to perform transitory uterine arteries clamping using a laparoscopic approach than a vaginal or abdominal access. The need of concomitant procedures and the necessity to explore the pelvis is also an indication for the laparoscopic approach (e.g. endometriosis, pelvic inflammatory disease).

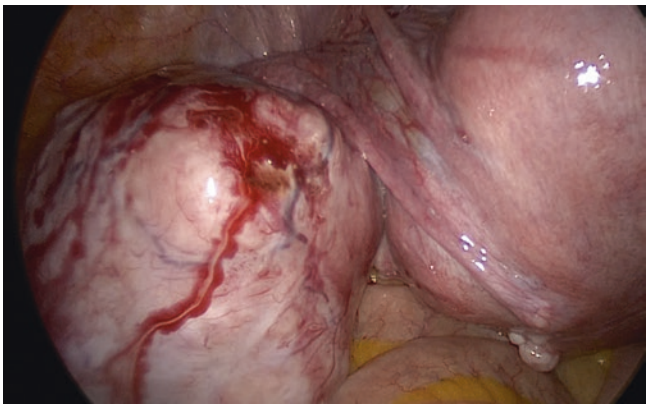

Fig. 21.1 Uterine leiomyomas

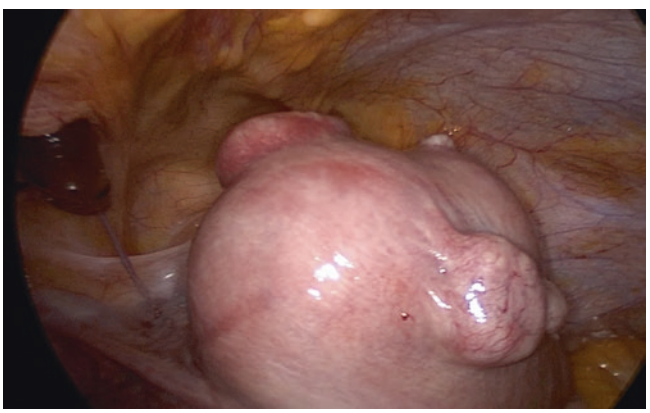

Fig. 21.2 Uterine leiomyomas

An old argument against the use of TLH was the procedure cost. A meta-analysis of 12 randomized controlled studies compared the cost of TLH against the TAH. The total direct costs for the laparoscopic approach were slightly higher, whereas the total indirect cost for TLH was half of TAH. This study concluded that the shorter hospital stay and decreased morbidity in the laparoscopic group compensates for the increased operating cost compared to the laparotomic route [20] (Fig. 21.5).

Table 21.2 Indications for total laparoscopic hysterectomy

Benign indications	Adenomyosis
	Chronic pelvic pain
	Dysfunctional uterine bleeding
	Endometriosis
	Leiomyoma
	Pelvic organ prolapse
Premalignant indications	Adnexial mass
	Cervical intraepithelial neoplasia
	Endometrial hyperplasia
Malignant indications	Cervical cancer
	Endometrial Cancer

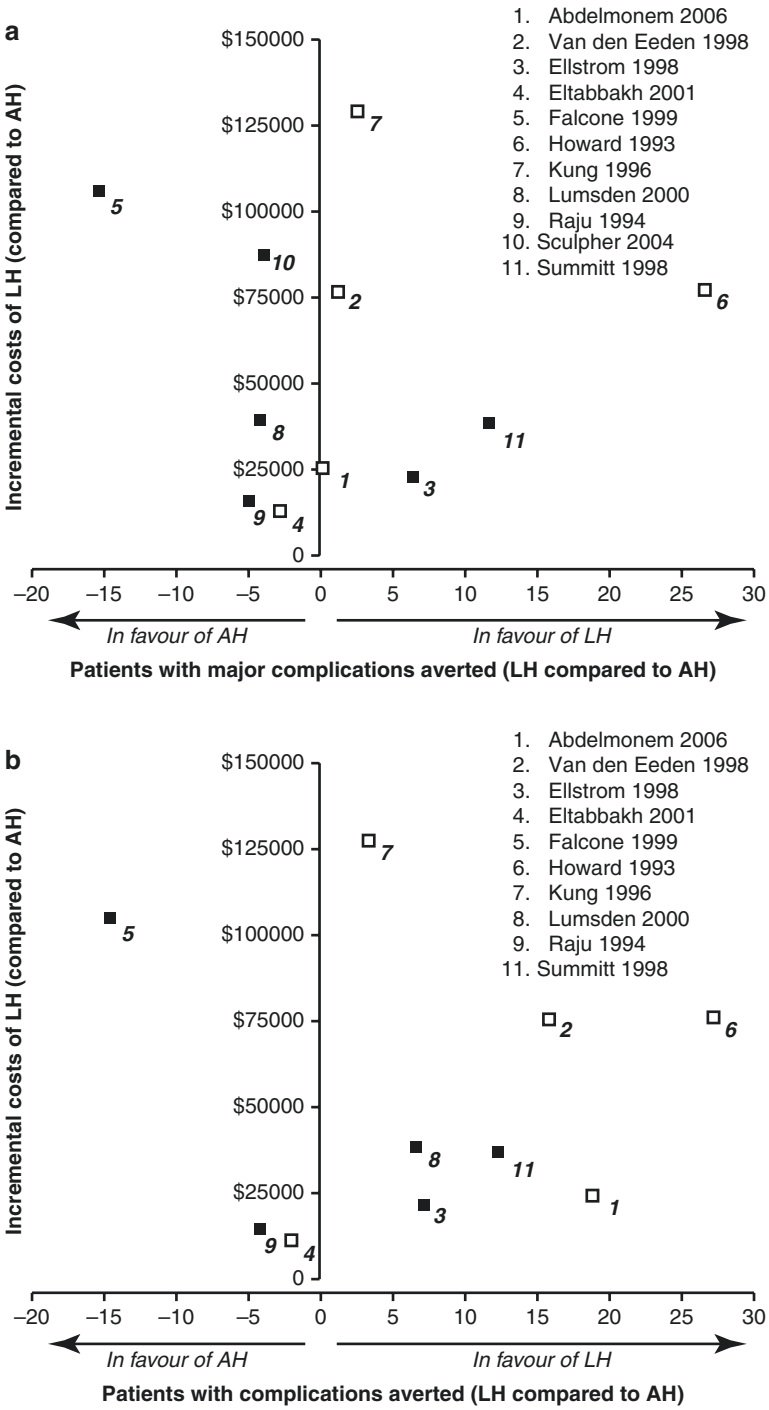

Fig. 21.5 Incremental costs and effects for patients with major complications (**a**) and all complications (**b**) per 100 patients. ■ RC T, □ CCT (From Bijen et al. [20])

Contraindications

There are no absolute contraindications for laparoscopic hysterectomy with the exception to the anaesthetic contraindication to perform the pneumoperitoneum. The experience of the surgical team and the patient's pelvic anatomy are the most important factors. The presence of severe adhesive disease, obstructive uterus or leiomyoma or any other anatomic limitation that prevent a safe entry or adequate working space remain the leading contraindication for the laparoscopic route. LH is also not advised for the diagnosis and treatment of a suspicious pelvic mass that cannot be removed intact through, for example, a culdotomy incision or into an impermeable sack. This is important because, in the presence of a malignant lesion, spillage may change the surgical stage of an ovarian cancer or an uterine sarcoma [21].

Risk factors for conversion to laparotomy include an elevated body mass index, increased uterine width greater than 10 cm, lateral or lower uterine segment fibroids over 5 cm, and previous adhesion-forming abdominopelvic surgery [14]. Previous abdominal scars, especially midline incisions, increase the risk of abdominal adhesions. This can make abdominal entry and surgery more difficult, leading to a major incidence of bowel lesions and conversion to a laparotomic approach [14] (Table 21.3).

Considerations

Remarkably, the most relevant contraindication for laparoscopic hysterectomy is the lack of expertise of the surgical team. In some countries, the rate of TLH increased very quickly at the beginning but, because many surgeons have not received a proper education, many complications happened and the number of minimally invasive procedures decreased. Fortunately, in the recent years, more and better educational programs have allowed a significant increase in TLH offering much superior outcomes in comparison to classic laparotomic approach.

If the surgeon respects the rules, the risk of complications is really low. The placement of the patient in a correct position (Fig. 21.6), the use of correct instrumentation (Figs. 21.7 and 21.8) and trocars positioning (Fig. 21.9) are factors of paramount importance. The key of the success to perform a laparoscopic hysterectomy is to follow the standard steps (Figs. 21.10, 21.11, 21.12, 21.13, 21.14, 21.15, 21.16, 21.17, 21.18, 21.19, 21.20, 21.21, 21.22, 21.23, 21.24, 21.25, and 21.26).

Conclusion

Surely, the old paradigm "big surgeon means big incisions" has absolutely changed. Laparoscopic hysterectomy is noticeably favorable for patients in whom vaginal surgery is contraindicated or cannot be done. We go towards a concept that the best surgeon performs the smallest incisions.

Preparation (Medical History, Surgical Set-Up, Antibiotics, Anticoagulants)

22

Magdalena Zalewski and Mohamed Elessawy

Introduction

Hysterectomy is the most frequently performed major gynaecologic surgical procedure [1, 2]. The overall rate of hysterectomy in Germany in the period 2005–2006 was 362.9 (295.0 for benign diseases of the genital tract and 44.0 for primary malignant tumors of the genital tract) per 100,000 person-years. Hysterectomy rates varied considerably across federal states: the rate for benign disease was lowest in Hamburg (213.8 per 100,000 women per year) and highest in Mecklenburg–West Pomerania (361.9 per 100,000 women per year) [3]. The CDC (Centers for Disease Control and Prevention) reported that in the USA the hysterectomy rate in 2000–2004 was 5.4/1000 per year [4].

Hysterectomies are preformed abdominally, vaginally, or with laparoscopic or robotic assistance. When choosing the route of hysterectomy, the physician should take into consideration the safest and most cost-effective route to fulfil all needs of the patient. The surgeon's decision is based on the patient's wishes and the route preferred by the surgeon. The art of surgery has developed and changed with the advancement of technology so that nowadays hysterectomy nowadays is mostly performed as a minimal invasive operation, accounting for nearly 60 % of all hysterectomy operations [5].

The preparation of the patient is a crucial factor towards obtaining the best surgical results. It should include the preparation of the tissues to encourage healing and bowel preparation to optimize the endoscopic space. In this chapter we will discuss our experience in preparing patients for laparoscopic hysterectomy.

Medical History

Taking a detailed medical history is the first step towards planning and successfully achieving a safe surgery.

Our patients complete a standardized questionnaire sheet covering their personal data and medical history. A Pap smear test is important before deciding to perform a supracervical hysterectomy.

Special consideration is given to patients with an oncological history in their families. Ongoing treatment for a breast cancer patient or a high-risk tumour patient might influence our decision to perform prophylactic adnectomy during the hysterectomy procedure.

Additional consideration must be given to prolapse and incontinence, which account for up to 14 % of indications for hysterectomy, in order to plan the best operative route for hysterectomy with corrective fixation surgery [5].

A detailed surgical history revealing the number of vaginal deliveries, laparotomies and cesarean section is important for deciding the route and the preparation for the hysterectomy operation.

Cesarean section is the most commonly performed surgery in obstetrics, and its incidence is increasing with rates as high as 17–31 % in some countries [6]. Estimates of the prevalence of cesarean delivery on maternal request range from 1–18 % of all caesarean deliveries worldwide, and <−1 to 3 % of all cesarean deliveries in the United States [7]. In certain cases, resulting scar formation may lead to adhesions and pain in many patients and possible difficulties at a later hysterectomy operation. In addition, cesarean scar dehiscence can be a risk for perforation during insertion of the uterine manipulator at total laparoscopic hysterectomy (Fig. 22.1).

© Springer International Publishing Switzerland 2018

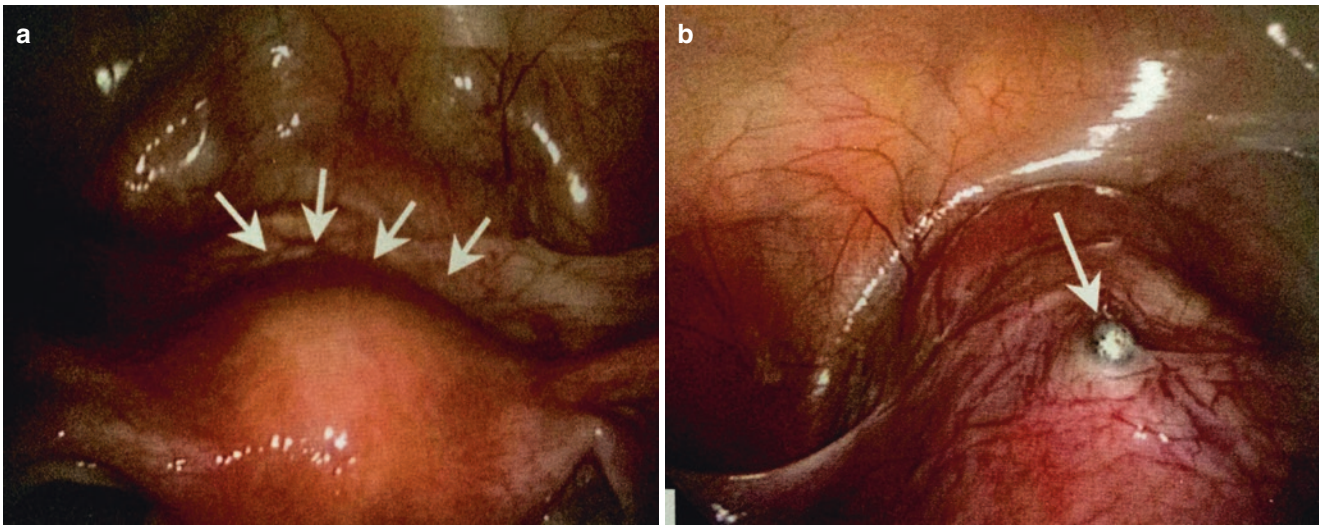

Fig. 22.1 Shows that cesarean scar dehiscence can be a risk for perforation during insertion of the uterine manipulator at total laparoscopic hysterectomy (**a**). Shows that the inseration of utrine manipulator should be carefully inserted to avoid perforation of the thin uterine wall by cesarean scar dehiscence (**b**)

In the literature, there is little information on the ability of MRI findings to detect cesarean scar dehiscence. Ultrasonographic evaluation of the anterior uterine wall is mandatory to evaluate the thickness of the lower uterine segment in the case of previous cesarean section.

It is well known that previous operations can result in the development of postoperative adhesions, which are a natural consequence of tissue trauma. This leads to an inclusion entity of adhesiolysis which is usually associated with a higher risk of complications. A review of the PubMed library shows that the correlation between a preoperative risk score and the complication incidence at the time of hysterectomy has not been sufficiently examined. At the Kiel University Department of Obstetrics and Gynecology, Germany, the estimated risk has been examined in comparison with the incidence of the intraoperative and post-operative complications. The data were statistically evaluated to investigate the relationship between the occurrence of the complication and the preoperative score at the time of the hysterectomy. For the preoperative score, patients who had undergone a previous laparoscopy were assigned 1 point; those who had undergone a previous Pfannenstiel laparotomy were assigned 2 points; those who had undergone 1 cesarean delivery were assigned 3 points; those who had undergone 2 cesarean deliveries were assigned 4 points; those who had undergone 3 cesarean deliveries were assigned 5 points; and those with no previous operations were assigned 0 points.

Of the intraoperative complications recorded 28.6 % of patients had a preoperative score more than 1, of the major postoperative complications recorded 33.3 % had a preoperative score more than 1 and of the minor postoperative complications recorded 25 % of patients had a preoperative score more than 1 [8]. Patients with a history of previous operations have to be informed of the risk of adhesions which can lead to a prolongation of the operative procedure to achieve a sufficient adhesiolysis and a longer hospital stay.

Gilmour et al. found from studies without routine cystoscopy that combined ureter and bladder injury rates varied according to the complexity of the surgery, ranging from less than 1 injury per 1000 for subtotal hysterectomy with or without bilateral salpingo-oophorectomy to as many as 13 injuries per 1000 surgeries for laparoscopic hysterectomy with or without bilateral salpingo-oophorectomy and for other gynecologic and urogynecologic surgeries [9].

Preoperative Evaluation and Treatment

Preoperative detection and evaluation differs according to the symptoms, needs of the patient and the indication for hysterectomy. The six most common reasons for performing a hysterectomy in the period 2002–2010 at the Kiel university hospital were uterine myoma (65.19 %), adenomyosis (11.21 %), dysfunctional uterine bleeding (12.99 %), endometriosis (5.03 %), hyperplasia of the endometrium of the cervix (1.99 %) and total uterine prolapse (14.79 %) [5].

This data is comparable to national data. In Germany the main reasons for performing a hysterectomy were uterine myoma (60.7 %), uterine prolapse (27.9 %), bleeding disorders (25.2 %), hyperplasia (2.9 %) and endometriosis (15.1 %).

The preoperative work-up should include: the measurement of preoperative haemoglobin levels and an abdominal and transvaginal ultrasonography. A blood count and serum ferritin test provide information on the necessity of administering oral iron, particularly in patients with menometrorrhagia. The correction of sideropenic anemia by giving oral iron is essential to reduce the risk of a blood transfusion.

Ultrasonography should include the measurement of the entire uterus (length, depth and width) and the number, size and location of myomas. Such information may play an important role in the determination of the operative strategy.

Magnetic resonance imaging is mandatory when the ultrasound examination is difficult to analyse and in cases of associated adnexal pathology. We follow the concept of obtaining the required information with minimum exploration for both psychological and economic reasons.

Ulipristal acetate (UPA) significantly reduces uterine fibroid volume, reduces menstrual blood loss and improves quality of life without serious adverse events. UPA is a selective progesterone receptor modulator (SPRM) blocking most progestational effects with a reduced antiglucocorticoid activity [10]. Gonadotropin-releasing hormone agonists (GnRH) cause myoma shrinkage by reducing the circulating oestrogen levels [11].

A vaginal preparation with 0.05 mg oestrogen is the standard dose recommended for regeneration of the vagina; however, preparations with 0.03 mg are currently in use and are usually administered for one to three weeks. With the absence of sufficient feedback a vaginal oestrogen preparation is sometimes prescribed for at least one month prior to surgery to improve the vaginal cell regeneration and proliferation of tissues. This enables a better healing in the case of additional vaginal corrective surgery for prolapse patients. Recent studies suggest that hormone replacement therapy decreases the risk of recurrence of breast cancer [12].

Informed Consent

No intervention can be undertaken without the patient's voluntary consent. For consent to be valid, the patient must be considered competent. In the setting of informed consent, competence or capacity means that the patient has the mental ability to understand problems and make decisions about accepting or rejecting medical treatments that are offered (Table 22.1).

Table 22.1 Informed consent – important topics

Personal discussion about the recommended therapy and the alternatives
Making clear the necessity and the urgency
Possible risks
Making sure the patient understands everything (especially foreign patients)
Provision of sufficient time for an informed decision (day before surgery)
Consent must be voluntary

Bowel Preparation

We aim to empty the bowel to facilitate pushing the loops of the bowel out of the way and flattening them so as to enlarge the operating space. Preparation starts with a standard low residue diet which the patient is required to follow for 5 days prior to the operation. Two days before the operation, the bowel is emptied by administering a laxative solution such as Xprep. Finally, the day before the operation, the lower bowel should be cleaned with an enema. It is important to follow this chronological order to avoid any loss from the anus onto the table, which would give rise to a high risk infection.

Antibiotics

The United States Centers for Disease Control and Prevention (CDC) has published an internationally accepted definition of surgical site infection (SSI). The term SSI is defined as an infection of the skin or the subcutaneous tissue of the incision within 30 days of an operative procedure. Antimicrobial prophylaxis can help to avoid SSI.

The decision for an antimicrobial prophylaxis in a surgical procedure is based on risk stratification for the onset of SSI. The stratification of wounds (clean, clean-contaminated, contaminated, dirty wounds) is the most important factor in this decision. The hysterectomy is defined as a surgery with a clean-contaminated wound and therefore there is a risk of infection during the performed surgery.

However, several additional risk-factors are known to increase the risk of SSI (AWMF-Leitlinie: Perioperative Antibiotikaprophylaxe; Recommendations of the "Paul-Ehrlich-Gesellschaft für Chemotherapie e.V."):

- patient age,
- comorbidities (especially diabetes and immunosuppression),
- obesity,
- nicotine or drug abuse,

Table 22.2 The effect of perioperative antibiotic prophylaxis in different kinds of hysterectomy

Kind of hysterectomy and antibiotic prophylaxis	Number of patients [n]	Number of infections [n (%)]
Abdominal hysterectomy		
Combination	532	31 (5.8)
Cefuroxime	405	28 (6.9)
Metronidazole	178	27 (15.2)
Laparoscopic hysterectomy		
Combination	806	50 (6.2)
Cefuroxime	645	37 (5.7)
Metronidazole	90	13 (14.4)
Vaginal hysterectomy		
Combination	914	35 (3.8)
Cefuroxime	969	38 (3.9)
Metronidazole	250	31 (12.4)

- preoperative infections,
- length of surgery (more than 2 h),
- blood transfusion,
- hypothermia,
- previous radiotherapy,
- previous surgery.

In general SSI occurs less often in laparoscopic surgery than in abdominal surgery [13]. We expect any SSI in abdominal hysterectomy in 10.5 %, and in laparoscopic hysterectomy in 9.0 % of patients.

Nevertheless, a hysterectomy is an indication for an antibiotic prophylaxis, independent of the surgical approach used (abdominal, vaginal, laparoscopic or robotic). The preferred regimen is a single intravenous dose of a second-generation cephalosporin, possibly combined with metronidazole.

In 2013 a prospective study from Finland with 5279 patients compared the effect of perioperative antibiotic prophylaxis in different kinds of hysterectomy. Data on 1115 abdominal hysterectomies (AH), 1541 laparoscopic hysterectomies (LH), and 2133 vaginal hysterectomies (VH) were analysed. The patients received cefuroxime alone, metronidazole alone or a combination of both (Table 22.2).

The results revealed that adding metronidazole to a prophylaxis with cefuroxime did not show any statistically significant additional advantage. A prophylaxis with metronidazole alone led to more infections after surgery [14].

The correct timing of antimicrobial prophylaxis plays a crucial role for an effective prophylaxis. The ideal moment for the first application is 30–60 min before incision. An application more than 60 min before incision significantly increases the risk of SSI. For surgical procedures shorter than 2 h a single shot therapy is sufficient. Longer procedures require a repetition of the prophylaxis. Timing of repeated administration depends on the half-life of the chosen antimicrobial agent. A repetition is needed after 2 half-life periods (half-life of cefuroxime: 70 min; half-life of metronidazole: 7 h). In general, there is no need for continuing the prophylaxis after the end of the procedure.

Anticoagulants

In case of a permanent therapy with anticoagulants some considerations should be made before planning a hysterectomy. Coumarin derivatives should be paused for an operation. A bridging with low molecular weight heparin is recommended. A normalisation of the INR is expected four to seven days later. Rivaroxaban should be paused 24 h before starting the operation. A monitoring is possible by measuring anti-Factor Xa activity. The taking of acetylsalicylic acid should be continued if it is taken for secondary prevention and can be paused if taken for primary prevention. In these cases an interval of seven days is necessary until the platelet aggregation is no longer affected.

Installation and Disinfection

After the induction of anaesthesia, the patient is placed on her back with legs apart and half bent. The buttocks must protrude a few centimetres from the edge of the table to allow uterine manipulation. This position creates three operating spaces: one occupied by the surgeon, another one on the right occupied by the first assistant and a third one between the legs for the second assistant (Fig. 22.2).

The patient's arm is placed alongside her body to avoid any brachial injury.

A warming system can be used to avoid any chilling of the patient. The abdomen, perineum and vagina are prepared with a suitable bactericidal solution and a Foley catheter is inserted.

Conclusion

A laparoscopic hysterectomy can be a long and difficult operation; therefore, the optimal preparation of the patient is of prime ergonomic and economic importance (Table 22.3).

Instrumentation Systems, Apparatus and Materials in Hysterectomy

23

Liselotte Mettler, Ibrahim Alkatout, and Artin Ternamian

Introduction

Instruments and apparatus for laparoscopic hysterectomy have been developed over the last 30 years for interventions with multiple ports as well as for single port surgery. Different set of instruments are necessary for subtotal and total laparoscopic hysterectomy and radical hysterectomies. This chapter is divided into.

1. History.
2. General systems for adhesion prevention, mesh, sutures, stables, glue, drains, rinsing solutions and suction.
3. Instrument systems and apparatus for laparoscopic hysterectomies.

All equipment as used in gynecological and general laparoscopic surgery is assembled on instrument trolleys, so called smart carts, which are available as rolling carts or on special platforms hanging down from the ceiling. Panoramic operating room endoscopic settings such as OR1 TM Neo (Karl Storz GmbH, Tuttlingen) or the Endoalpha by Olympus (Olympus Europa SE & CO.KG, Hamburg) or the Stryker unit with SDC Ultra as digital documentation system form the basis to position the necessary equipment for easy use of the surgeon.

The idea of warming and humidifying the CO_2 gas to avoid damage to the peritoneum has been propagated by Douglas Ott and Philippe Koninckx. The HumiGard TM of Fisher & Paykel Healthcare (Auckland, New Zealand) provides heated, humidified and filtered gas to a patient at a predetermined temperature.

Today, every CO_2 pneu automatic provides up to 37 °C heated CO_2, gas which is controlled by a pressure regulator and within the machine by applying the Quadro-test. In the Quadro-test, the volume of gas flowing through the Veress needle during insufflation, intra-abdominal pressure, total volume and preset filling pressure are measured. Cold light is provided by xenon lamps. The video camera systems are equipped with three-chip camera or HD-cameras and can be used for laparoscopy as well as hysteroscopy. High-resolution video monitors guarantee optimal picture quality. The technological development allows the use of larger monitors in HD quality that facilitate a relaxed working atmosphere for the surgeon.

A realistic, true to life 3D picture is possible due to various technological elements such as digital simulation, a second camera system or the use of shutter lens. Digital devices for the video camera control the picture quality and facilitate automatic white balancing. The Karl Storz company already offers the TRICAM 3D imaging system that allows the surgeon to view crisp, dear image through a pair of lightweight polarizing glasses. Their ENDOCAMELEON laparoscope provides a viewing angle that can be adjusted continuously between 0 and 120° (Fig. 23.1a).

The Olympus 3D system allows a direct vision through the ENDOEYE FLEX 3D, a deflectable tip 3D laparoscope. This tool allows for 100° angulation in 4 directions while the image on the screen is maintaining a fixed horizon. The dual-lens design of the ENOEYE FLEX 3D and the high-density image sensors for high-definition 3D images give a focus-free view (Fig. 23.1b).

History

Although the origin of endoscopy can be found already in a reference of the Babylonian Talmud. Endoscopic surgery has mainly be developed by the use of Bozzini's light guide and the rigid optic system developed by Max Nizze as cystoscope. We consider Georg Kelling, (1866–1945) of Dresden, who added his experience in oral air insufflation as the father of endoscopic surgery. The knowledge of gastric and esophageal endoscopy of air insufflation where the foundation of future trials for the diagnostic and therapeutic examination of enclosed body cavities.

Subtotal hysterectomy by laparotomy, total hysterectomy by laparotomy and vaginal hysterectomy dominated till 1980 the field for this gynecologic surgical procedure. In relation to the development of save instruments and apparatus to be used in endoscopic surgical procedures the desire to perform laparoscopic hysterectomy was noticed worldwide in the groups of many gynecologic endoscopic surgeons. In Kiel we applied laparoscopic assistance to vaginal hysterectomy, first published by Kurt Semm in 1984, routinely in difficult vaginal hysterectomies [1]. In those days the aggression towards laparoscopy as surgical procedure was still very pronounced. We did not dare in Kiel to even talk about laparoscopic hysterectomy in our own department although we freed the uterus from the pelvic side wall in many occasions and then extracted the uterus through the vagina, because everybody already blamed us as irresponsible surgeons. This procedure was later described as laparoscopic vaginal hysterectomy (LAVH). We did not dissect the uterine vessels laparoscopically in those early years.

As worldwide accepted, however, the first laparoscopic hysterectomy was performed by Harry Reich in the 1989 in the William Nesbitt Memorial Hospital in Kingston, Pennsylvania, U.S.A. [2]. Simultaneously Kurt Semm developed the laparoscopic subtotal hysterectomy and performed on Sept.07, 1989 on a Saturday afternoon in Kiel the first then called "Classic Intrafascial Subtotal Hysterectomy" (CISH), which was first published in 1993 [3]. In the same years Jaques Donnez, 1993 and Thomas Lyons, 1993 published their approaches of laparoscopic subtotal hysterectomy. Over the consecutive years till today various modifications and classifications of laparoscopic hysterectomies for benign indications have been described. Radical hysterectomies using laparoscopy date back to the early experience of Daniel Dargent 1986 [4] and have only been performed worldwide on a larger scale in the twenty first century.

General Systems, Adhesion Prevention, Mesh, Sutures, Staples, Glue, Drains, Rising Solutions and Suction)

Generators and Set-Ups

All essential equipment for laparoscopic hysterectomy is assembled on equipment trolleys which are integrated into the panoramic operating rooms. Panoramic viewing possibilities and integrating commanding functions for all operating procedures and documentation are given today by many companies set-ups. An equipment trolley always contains the following apparatus: CO_2 insufflation unit with the possibility of producing heated and humidified gas, endoscopic camera, light sources (cold light is provided by Xenon lamps), suction and irrigation pumps, electrical energy systems, documentation systems. These systems are compatible with third party devices such as operating room lights, energy units, lasers and thermofusion systems. Higher solution video monitors guarantee optimal picture quality. The technical development allows the use of larger monitors in HD quality on flexible arms that fascilitate to position them into a relaxed working atmosphere for the surgeon. A realistic, nearly true to live 3D picuture, various technical elements such as digital simulation, a second camera system or the use of shutter lenses, are engaged. Digital devices for the video camera control the picture quality and facilitate automatic white balancing.

Adhesion Prevention

Adhesions during surgery are primarily defined as a condition in which bodily tissues that are normally separate grow together.

A fibrous band of scar tissue that binds together normally separates anatomical structures (Fig. 23.2). In this chapter, we want to stress the impact of adhesions as defined above as the most common post-surgical complication.

Adhesion formation is influenced by various factors. It starts with a trauma to the peritoneum or any other body site when rapidly fibrin de-position occurs. In peritoneal healing for example there is a balance between fibrin deposition and fibrinolysis. Any impairment of this process leads to increased fibrin deposition, the formation of fibrin strands and stable adhesions may be formed. The incidence of intraperitoneal adhesions in patients following general abdominal or gynecological surgery ranges from 63 to 97 % [5, 6]. The overall risk of hospital readmission related to adhesions following either laparoscopic or open surgery is similar [7]. Although the majority of patients remain asymptomatic, a considerable number experience serious complications, including bowel obstruction [8], female secondary infertility [9] and re-operative complications [10]. The presence of adhesions from previous surgery significantly increases the length of time required in subsequent surgical procedures, adversely affecting the workloads of surgical teams [11]. Certain surgical procedures carry a greater risk of adhesion-related complications. Surgical procedures on the ovary and fallopian tube were shown to have the highest risk of adhesion-related readmission (48.1 % and 41.2 % of women readmitted, respectively) [12]. For laparoscopic myomectomy this increases to 41 in every 100 procedures [13]. In one study, the number of adhesion-related readmissions increased steadily over a ten-year period, with 16 % occurring within the first year after the initial surgical procedure [12]. Some studies have also shown that adhesion-related complications can occur ten years after the initial surgical procedure [6].

Let us introduce into this discussion first an overview on the most common anti adhesion agents, which can be divided into two groups: "Site specific Agents" and compare them with the "broad coverage fluid agents".

Site-Specific Agents: Membranes

Mechanical barriers Interceed® (Gynecare, Ethicon, a Johnson & Johnson Company, Sommerville, NJ, USA): Interceed® is an oxidized regenerated cellulose membrane placed over a suture or a deperitonealised area. No sutures are required to keep Interceed® in place; slight moistening after positioning a single layer will make it adhere to the injured site, where it is absorbed within 4 weeks. Interceed® has been shown to be effective in various studies, and significantly reduces adhesion formation even in severe endometriosis [14].

Seprafilm® (Genzyme, Cambridge, MA, USA) Seprafilm®: is a hyaluronate-carboxymethyl cellulose membrane, which is placed over a suture or an injured area without stitches and remains in place for 7 days. In contrast to Interceed® no loss of efficacy in the presence of blood has

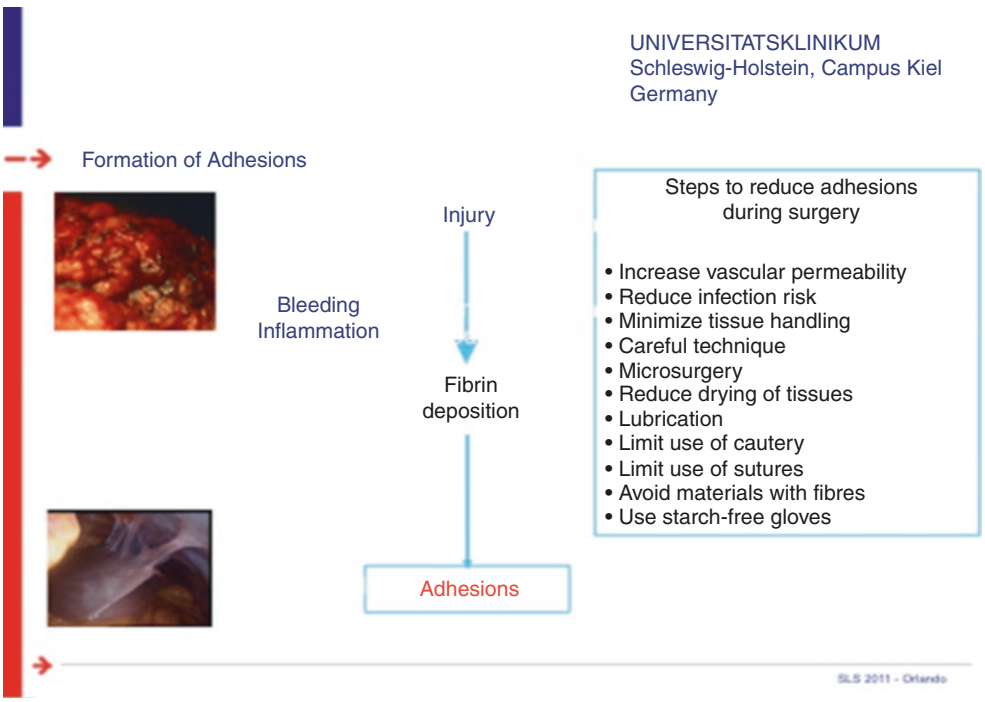

Fig. 23.2 Formation of adhesions from injury to adhesions

been reported. Several studies have demonstrated the efficacy of Seprafilm® mainly in general surgery, especially bowel surgery [15].

Gel barriers:SprayShield/Spray Gel® (Covidien Bio-Surgery, Waltham, MA, USA): SprayShield® is a synthetic polyethylene glycol solution which is sprayed over the affected area where it remains for approximately 5–7 days. After that period, it is degraded and absorbed. It consists of two components that react immediately on contact with the tissue to form an adherent layer. One of the components contains a blue food colourant, so there is an intraoperative visualization of where SprayShield® was used [16, 17]. In the case of myomectomy a reduction of adhesion formation was demonstrated for SprayGel® in a multi-center randomized controlled trial.

Intercoat®/Oxiplex/AP (FzioMed, Inc., San Luis Ob-ispo, CA, USA): Intercoat® is an absorbable gel composed of polyethylene oxide and sodium carboxymethyl cellulose. Functioning as a mechanical barrier during the healing process, Intercoat® is applied as a single layer at the end of the procedures.

HYA CORP ENDOGEL (BIO SCIENCE, GERMANY) is an absorbable sterile, transparent, high viscous gel produced by condensation of hyaluronic acid, which is one of the main components of human connective tissue. It adheres to tissue surfaces and to the abdominal wall and is effective as an anti-adhesion barrier substance on the local level. The development of Hyacorp Endogel is based on a composition of a substance that already exists for treating and filling tissue defects (Hyacorp Body Con-touring MLF 1).

Hyalobarrier Gel® (Fidia Advanced Biopolymers, Abano Terme, Italy): Hyalobarrier gel is a highly viscous autocrosslinked hyaluronate used to separate organs and tissues after surgery. The use of hyaluronic acid agents may decrease adhesion formation and prevent the deterioration of preexisting adhesions [18]. CoSeal® (Baxter Healthcare Corporation, Deerfield, IL, USA).

CoSeal® is a resorbable hydrogel consisting of two polyethylene glycol polymer solutions which are mixed together when applied during surgery. The technology is similar to that seen with SprayShield® but in CoSeal® the polyethylene glycol esters have a different isomer structure. CoSeal® is long available for preventing adhesions in cardiac surgery where its efficacy has already been proved. First researches in women undergoing myomectomy demonstrated safety and efficacy of CoSeal® in abdominopelvic surgery [19].

Broad-Coverage Fluid Agents

Adept® (Icodextrin 4 % solution; Baxter Healthcare, Deerfield, II, USA): Adept® is a clear solution containing icodextrin at a concentration of 4 %. Icodextrin is an a 1–4-linked glucose polymer and is responsible for the longer absorption time of Adept® compared to the previously used crystalloid instillates like saline solution or lactated Ringer's solution, which is rapidly resorbed by the peritoneum and therefore not suitable for adhesion prevention. At the end of a procedure, 1.000 ml of Adept® is instilled into the abdominal cavity. Instillates separate the injured tissue by hydroflotation and should stay in the abdominal cavity during the first days after surgery.

In laparoscopic hysterectomies out of the available pellet of adhesion prevention strategies we advise at present time the application of a site specific barrier either on hyaluronic acid basis (HyaCorp Endo Gel – Bioscience or Hyalobarrier – Nordic Pharma) and in case a large peritoneal defect results as broad liquid barrier Icodextrine – 4 % – adept – Baxter.

Meshes

There are many new kits on the market that involve the placement of the same nylon-like mesh in the TVT but instead used in large sheets between the bladder and the vagina and the rectum and the vagina to reinforce prolapse repair. There is no long term information on these techniques. Therefore we will hold off promoting or criticizing these techniques until there is adequate information available. As these materials are permanent, there is always a benefit in waiting to see the long term complications before jumping on the bandwagon of laparoscopic mesh application in sacro colpopexy or the new technique of prolapse surgery pectopexy after laparoscopic hysterectomy, as the long term complications may include mesh erosion into the vagina, bladder or rectum, painful intercourse, infection or bleeding etc.

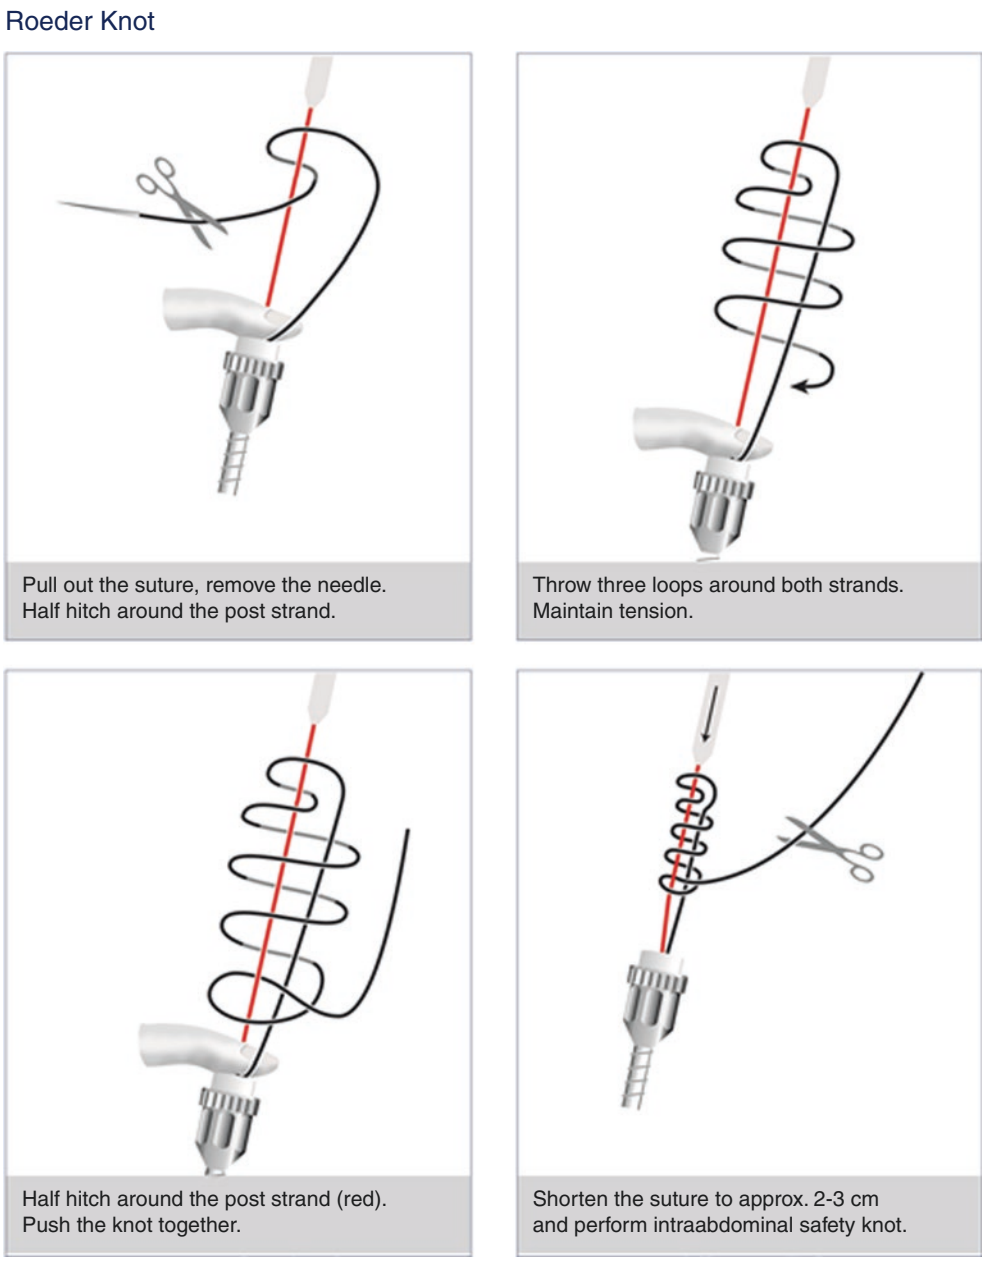
Sutures

Ligatures and suturing techniques are besides all the modern coagulation advances many times still necessary for safe surgery in hysterectomy. Therefore we would like to give some basic ideas on hemostasis by loop ligatures, endosutures with extra corporeal knotting technique and endosutures with intra corporeal knotting technique.

Haemostasis by Endosuture with Extra Corporal Knot Tying

In many cases, it is convenient to ligate vascular bundles, adhesion bundles and similar structures with sling ligatures. Timewise it is worthwhile to tie the vascular omental and intestinal adhesions before cutting because searching for

bleeders later can be time consuming and associated with much blood loss. Primarily, an 80 cm long Ethi-Endoligature ® with a plastic knot pusher by Ethicon is used as a ligature. As an endosuture, it has a 3 cm long and 0,8 mm thick needle. The endosuture with extracorporeal knotting has a 2.5 and 3.5 cm long sharp needle as well as a 2.5 cm round needle. It is supplied with a suture applicator and a 3 mm trocar by Autosuture. After taking a purse string suture, the needle is cut; extracorporeal knots are formed and pushed down in the usual way with the plastic pusher (Figs. 23.3, 23.4, 23.5, 23.6 and 23.7). To push the knot, the applicator is pulled up. When it is pushed again into the 5 mm trocar, the plastic tube pushes the knot into the abdominal cavity. The loop is tightened under vision and the wound edges are adapted, e.g. the wound edges of the vaginal cuff. Cutting scissors are inserted in place of the 5 mm needle holder to cut the thread. The thread must be long enough to be able to form extracorporeal knots outside.



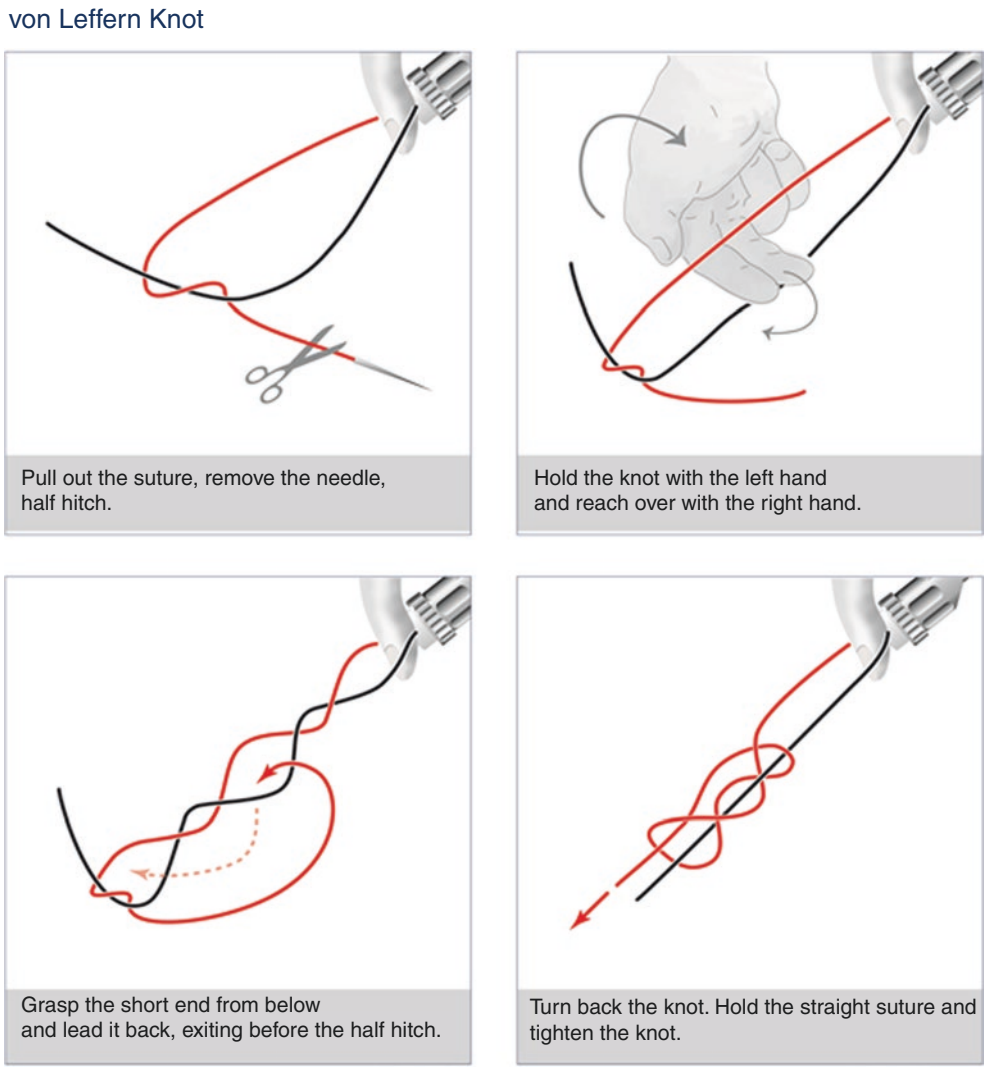


Fig. 23.3 Roeder Knot

Fig. 23.4 von Leffern Knot

Hemostasis by Endosuture with Intracorporeal Knotting

For intracorporeal knotting, a straight or curved needle with different suture calibers is used. For microsurgical interventions, such as end-to-end anastomosis of the tube, 4–0 to 6–0 sutures are used otherwise 1–0 is adequate for vaginal cuff suture. The long-end of a thread, originally knotted extracorporeally, is wrapped around the needle holder twice while the needle holder is aiming for the short-end of the tread to perform an additional, intracorporeal safety knot (Fig. 23.8). Among many other intracorporeal suturings, the baseball suture is specially suitable to compress wounds, e.g. after enucleation of myomas.

Due to this technique of suturing, the size of the wound is minimized and along with it the risk of immediate and later bleeding. In addition, the occurrence of adhesions is reduced since the wound is closed toward the surrounding tissue. Stitching and tying of the whole uterine vessel bundle requires good knowledge of anatomy.

Hemostasis by Suture and Tying Knot with Half Hitch

The Clark knot pusher is used for this procedure. With the extracorporeal thread, a half-hitch is formed and the knot is then pushed down with the knot pusher.

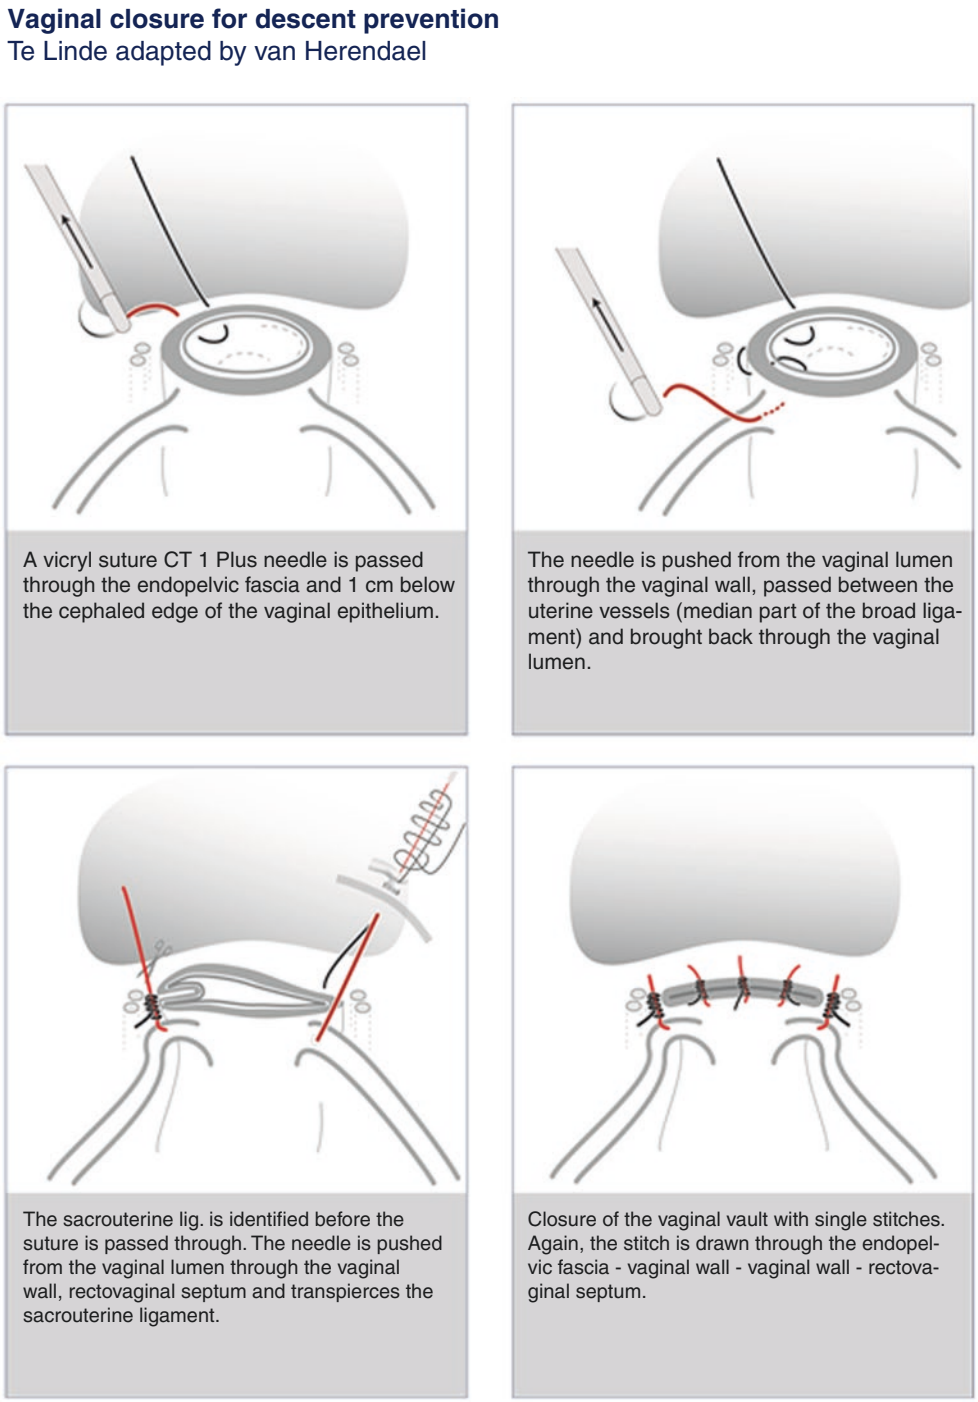

Fig. 23.5 Vaginal closure for descent prevention

Staples and Stapling Instruments

A safe way for vessel occlusion at laparoscopic hysterectomies is provided by "ENDO GIA" These ENDO GIA's are available with straight and curved tips. The unique Endo GIA™ Curved Tip Reload with Tri-Staple™ Technology of COVIDIEN is a stapler designed with a curved tip at the distal end of the anvil to provide enhanced visibility and maneuverability around target tissues and vessels.

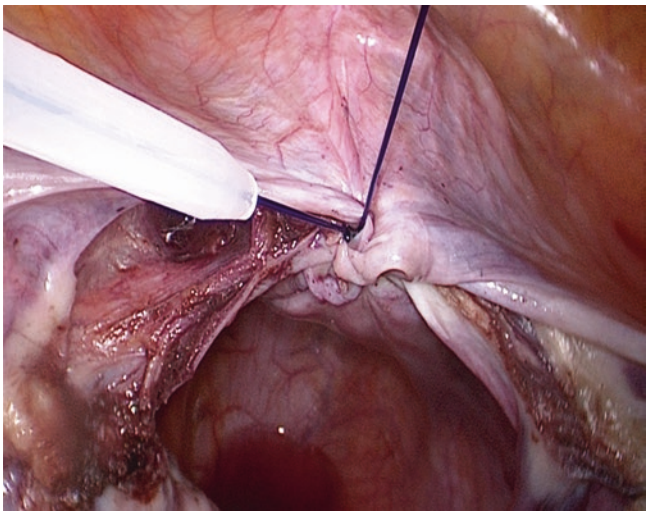

Fig. 23.6 After having formed the knot extracorporally, it is pushed down with the plastic knot pusher

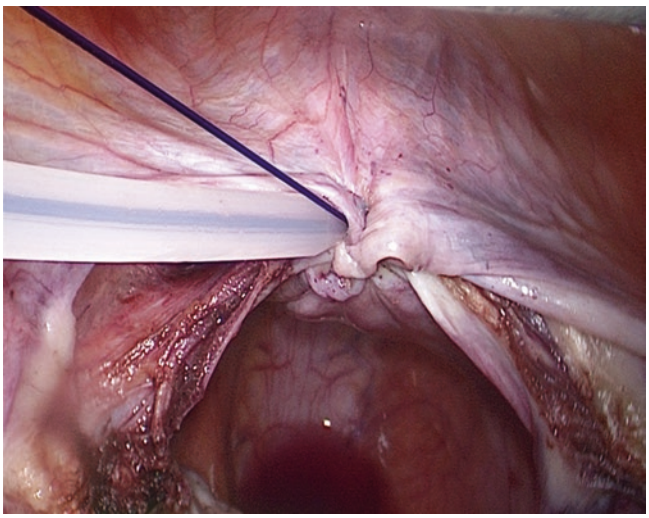

Fig. 23.7 To tighten the knot, the other end of the thread is held with some tension while the knot pusher is pressed onto the knot firmly

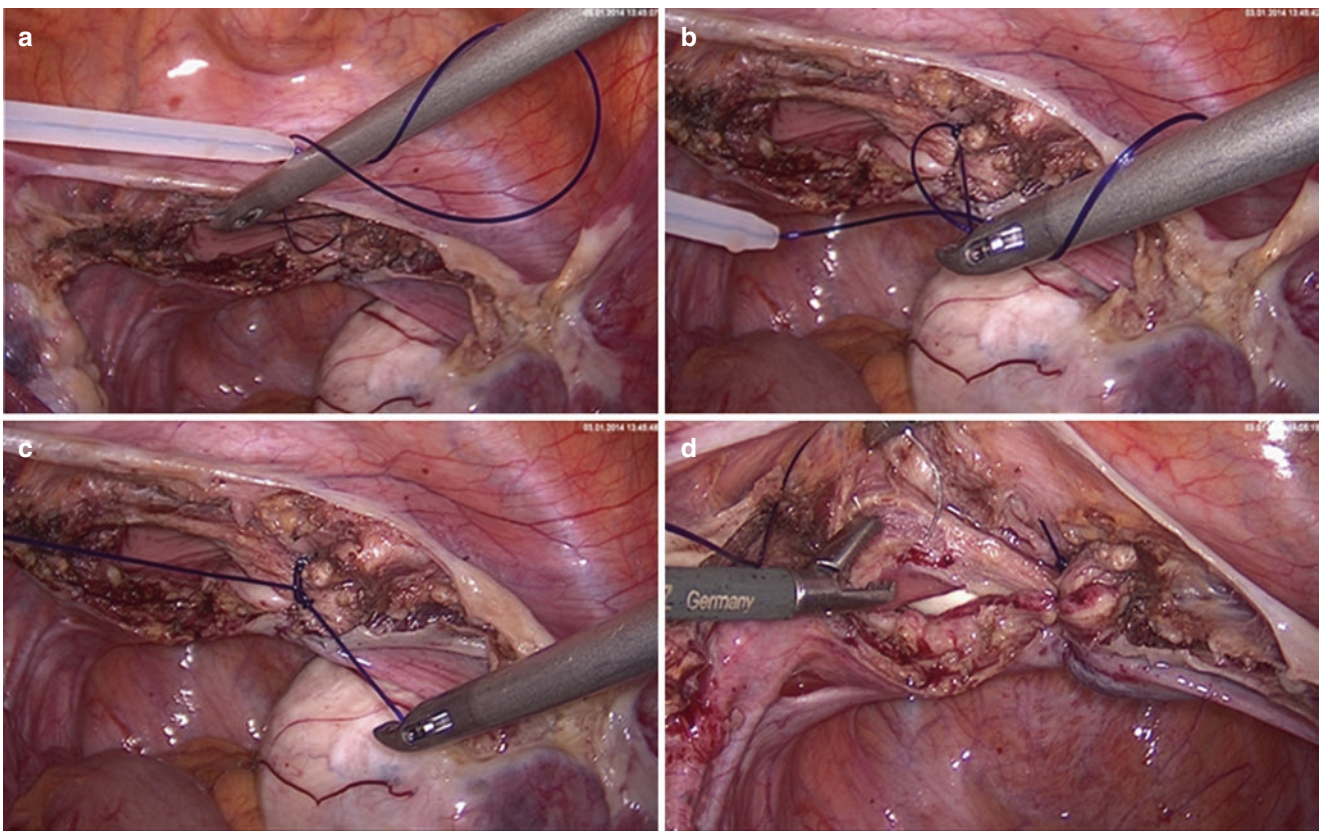

Fig. 23.8 Intracorporal knot to give final tension

Tissue Glues

A variety of adhesive substances can be applied locally during laparoscopic hysterectomy for hemostasis or wound closure. The main classes of tissue adhesives are cyanoacrylate glues, fibrin glue, and thrombin. Cyanoacrylate glues are widely used in GI endoscopy for control of bleeding from gastric varices and, to a much lesser degree, for hemostasis of bleeding peptic ulceration and for closure of fistulas and anastomotic leaks. Fibrin glue (fibrinogen and thrombin) and thrombin have been used extensively in all surgical

disciplines for tissue adhesion; suture support; hemostasis; wound care; and the sealing of body cavities, including the subarachnoid space;

Biosurgical agents designed to promote tissue adhesion and hemostasis are being increasingly employed also in hysterectomies. Fibrin sealant is the most widely utilized biosurgical product. Gelatin matrix thrombin has proven to be an efficacious hemostatic agent. Bovine serum albumin-glutaraldehyde is a new promising tissue glue.

TachoSil of Takeda represents a new fibrine sealant with excellent thermostatic possibilities. It contains fibrinogen and thrombin as a dried coating on the surface of a collagen matrix. In contactwith physiological fluids, e.g. blood, lymph or physiological saline solution the components of the coating dissolve and partly diffuse into the wound surface. This is followed by the fibrinogen-thrombin reaction.

which initiates the last phase of physiological blood coagulation.

Instrument Systems and Apparatus for Laparoscopic Hysterectomies

Conventional Laparoscopy

Of the multitude of laparoscopic instruments known today for hysterectomies, we describe here only a selected few which are absolutely necessary and which should be available in duplicate or triplicate on the instrument trolley. Multiple use instruments for cutting, grasping, dissection, pushing, traction, coagulation, irrigation and suction are very helpful.

Instruments for Perforation

- The **Veress needle** is blindly introduced into the abdomen after lifting the anterior abdomen wall [20]. Trocars of 3 mm, 7 mm, 10 mm, 12 mm, 15 mm, 20 mm, 24 mm diameter are used for guiding the endoscopes and operative instruments, irrigation, coagulation and during employment of needle holders and morcellators.
- The simple **automatic flap valves** can leak because of soiling with blood or tissue particles. Therefore they are to be used for single use only. **Trumpet valves** are stable, but must be always opened and closed. They hinder the introduction of needles and thread.
- **Endoscopic lenses** must be frequently washed and removed because of soiling during the operation. Therefore, for such trocars we reluctantly use automatic valve, but prefer trumpet valve.
- **Primary trocars** can be inserted by the Z-puncture technique to prevent dehiscence of aponeurosis and late prolapse of the omentum. The decision, however, depends on the surgeon. We recommend conical and pyramidal trocars. Pyramidal trocars carry the advantage of a sharp cutting edge Optiview^{R} by Ethicon (Ethicon Endo-Surgery, Cincinnati, USA) , Visiport^{R} by Covidien (Mansfield, MA, USA) and XCel by Ethicon (Fig. 23.9) offer **insertion under vision**. At present, only 10–11 mm trocars are available through which the 10 mm laparoscope can be passed under direct vision.
- **Optical Veress needles** can be inserted under vision but one looks still through a plastic layer. The insertion under vision can be done below left costal margin also; a suitable trocar can inserted through the umbilicus under vision.
- The linear **expansion trocars** help controlled widening of a narrow canal by serial dilatation
- The **Endo-Tip** is the only trocar to be inserted under direct vision (Fig. 23.10)

Fig. 23.9 XCeltrocar by Ethicon for entry under vision

Dilatation Instruments

It is possible to dilate up to 10 mm, 12 mm, 15 mm and 20 mm through an introduced rod and a suitable 5 mm threaded trocar.

Holding, Grasping Instruments and Screws

Various types of traumatic and atraumatic forceps are used as endoscopic grasping tools for laparoscopic hysterectomies. They are in 5–20 mm sizes. In 10 mm size we recommend the big toothed forceps and lymph node holding forceps to hold the tissues firmly. The 10 mm swab holding forceps are suitable for holding tissues lightly and for pushing. The 5 and 10 mm swab holders are used in tissue dissection. The 5 and 10 mm myoma screw may be used for traction of the uterus. The handles of the Robi instruments of the Karl Storz company are easier and more ergonomic to use than older roundgrip handle versions. Olympus offers with its HICURA line (Fig. 23.11) a new generation of laparoscopic hand instruments consisting of a wide range of product offerings of different lengths, shafts, handles, and jaws to accommodate surgeon's needs. The adapted handle design for grasping and dissection forceps has new ergonomic handles availbale in two sizes, developed with the goal to improve handling and safety of the instruments).

Cutting Instruments

Five millimeter curved scissors and the 5 mm and the 11 mm saw-toothed scissors as well as different micro knives with changeable disposable blades are available. Mostly, curved scissors are used, but round scissors with electric connection are frequently employed because of their extreme safety. The latter one is often used as a disposable instrument.

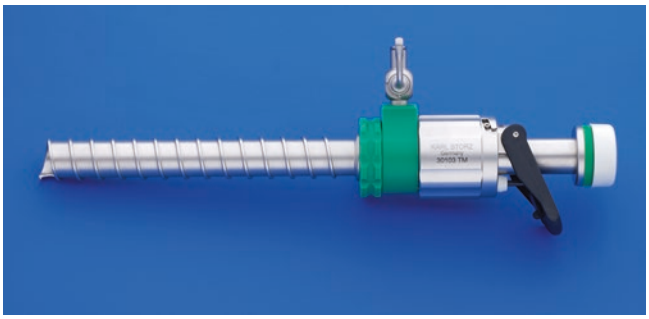

Fig. 23.10 Endo-tip by Ternamian (Karl Storz) for smooth laparoscopic entry under direct vision

Fig. 23.11 HICURA line laparoscopic instruments

Suction and Irrigation Instruments

The suction irrigation devices of Karl Storz, Olympus, Wolf etc. are well known.

The suction cannula is used either with an open tip or with a perforated tip. Large volumes of fluids are aspirated with these suction irrigation cannulas (Fig. 23.12). They are set at an irrigation pressure of up to 300 mmHg and an aspiration force of up to 1 bar. The normal suction force is maximum 800 mbar; irrigation pressure is 300 mmHg. With extra-long (50 cm) suction irrigation tubes, it is possible to suck even under the dome of diaphragm from the pelvic region. Many disposable systems are also available.

Morcellation Instruments

The development of morcellation instruments was slow. In ovarian resection and enucleation of myoma, the tissue was cut with scissors and knives, depending on the size. The specimen can be removed either with big toothed forceps or a big sponge holding forceps directly through the 11 or 15 mm trocar with conical end. However, the so-called motor drive morcellators in 10 mm, 15 mm and 20 mm diameters are electrically powered and function well. The tissue is slowly cut electrically, nearly shaved from the surface, and pulled into the trocar sleeve. It is particularly suitable for horizontal operations as in vertical use a laceration of bowel or vessels can easily occur. Karl Storz produces the Steiner morcellator®, the Rotocut and a new development, the Sawalhe II Supercut morcellator, all with a tissue protection shield (Figs. 23.13 and 23.14). Single-use devices are available from various companies such as the PKS PlasmaSORD by Olympus. In bag morcellation is more and more being developed to prevent tissue particles being left in the abdominal cavity. Sarcomas should, of course, not be morcelllated and be recognized prior to hysterectomy and morcellation.

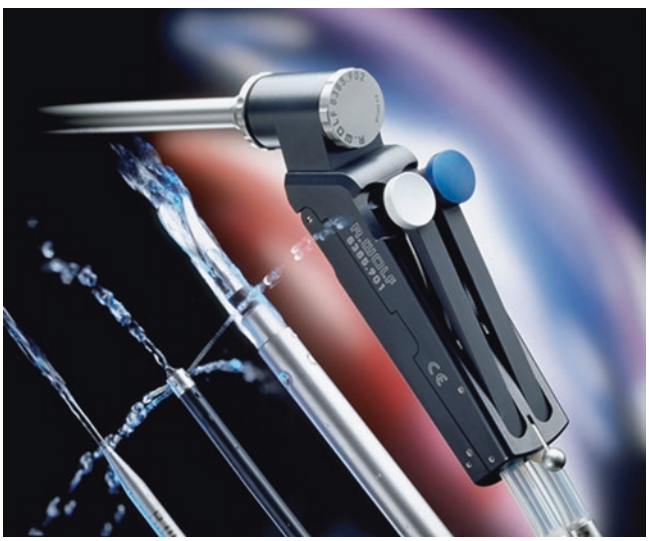

Fig. 23.12 Suction irrigation system (R. Wolf, Knittlingen, Germany)

Many companies have disposable morcellators. The WISAP electric morcellator was the first on the international market. Alternatively, the surgical specimen from the abdominal cavity is put in an endobag (small plastic bags) with forceps. Morcellation is only advised at present for benign specimens. However, I foresee the transformation of fibroid-like material into powder, which can then be aspirated and examined by the molecular geneticist- pathologist for malignancy. In case of uterine tissue this would mean to detect mutations in these carcinosarcomas that are found in about 1–4 per thousand in myomas. Of course any hysterectomy is preceded by careful imaging with ultrasound and often MRI, where bulky polyploid masses with heterogeneous appearance and increased vascularity, lacking calcifications would lead the surgeon to avoid morcellation.

However, after the Boston case of a non-recognition of a sarcoma at morcellation, was published over all public media everyone became more careful not to spread tissue at morcellation. Morcellation in bags became available and some companies have retracted their morcellation devices.

Fig. 23.13 ROTOCUT GI (Karl Storz), morcellation tool with protectivshield, available in 2 sizes (12 and 15 mm)

Fig. 23.14 SAWALHE II SUPERCUT Morcellator (Karl Storz)

Instruments for Hemostasis

Instruments for tying the blood vessels such as the Roeder loop, the endoligature or the endosutures with extra or intracorporeal knotting are widely known. Needle holders for straight, curved or Ski needles must be available in different variations.

For hemostasis, endocoagulation, heat denaturation at 100–120 °C, bipolar coagulation in various forms (see section on energy sources in this chapter) and monopolar needle, melting hook, high frequency scissors or other instruments are suitable [21]. For localized ischemia a vasopressin derivative in a dilution of 1–100 is injected subcapsular with an applicator.

Gynaecologists prefer suturing and coagulation devices. However, clips and stapling devices, which are more frequently used by general surgeons, are also used for fixing meshes, for pelvic floor surgery, lymphadenectomy and hysterectomy in our field. Both Ethicon, a Johnson & Johnson company (New Bunswick, NJ, USA), and Covidien have fascinating devices on the market. Let me just mention here Covidien's new Endo Clip Applicator III (5 mm) with easy to be situated clips and a digital clip counter as well as the Ultra Handle Group (Fig. 23.15a, b) and the Endo GIA™ Stapler (Fig. 23.16).

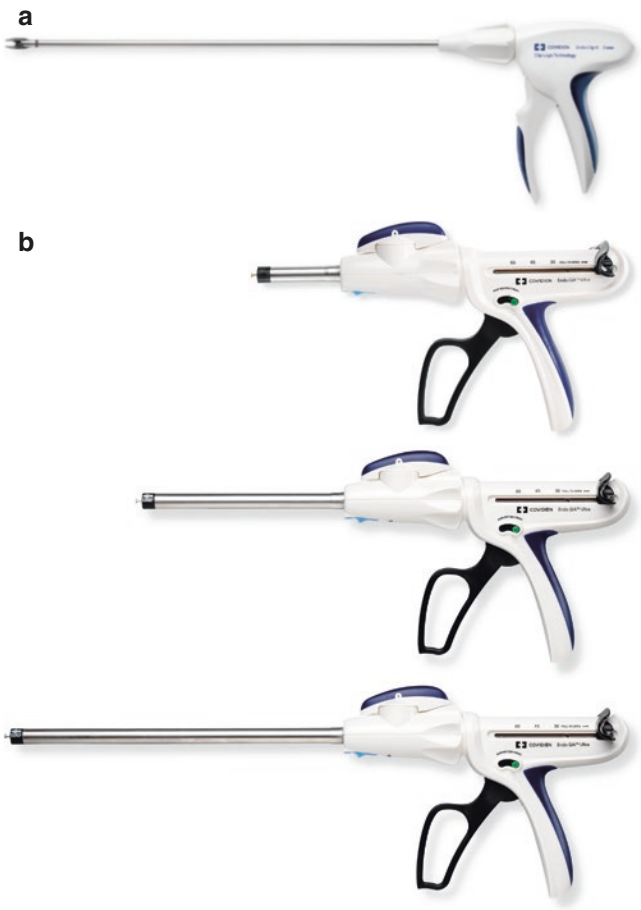

Fig. 23.15 (**a**) Endo-Clip (Covidien) (**b**) Handle Group (Covidien)

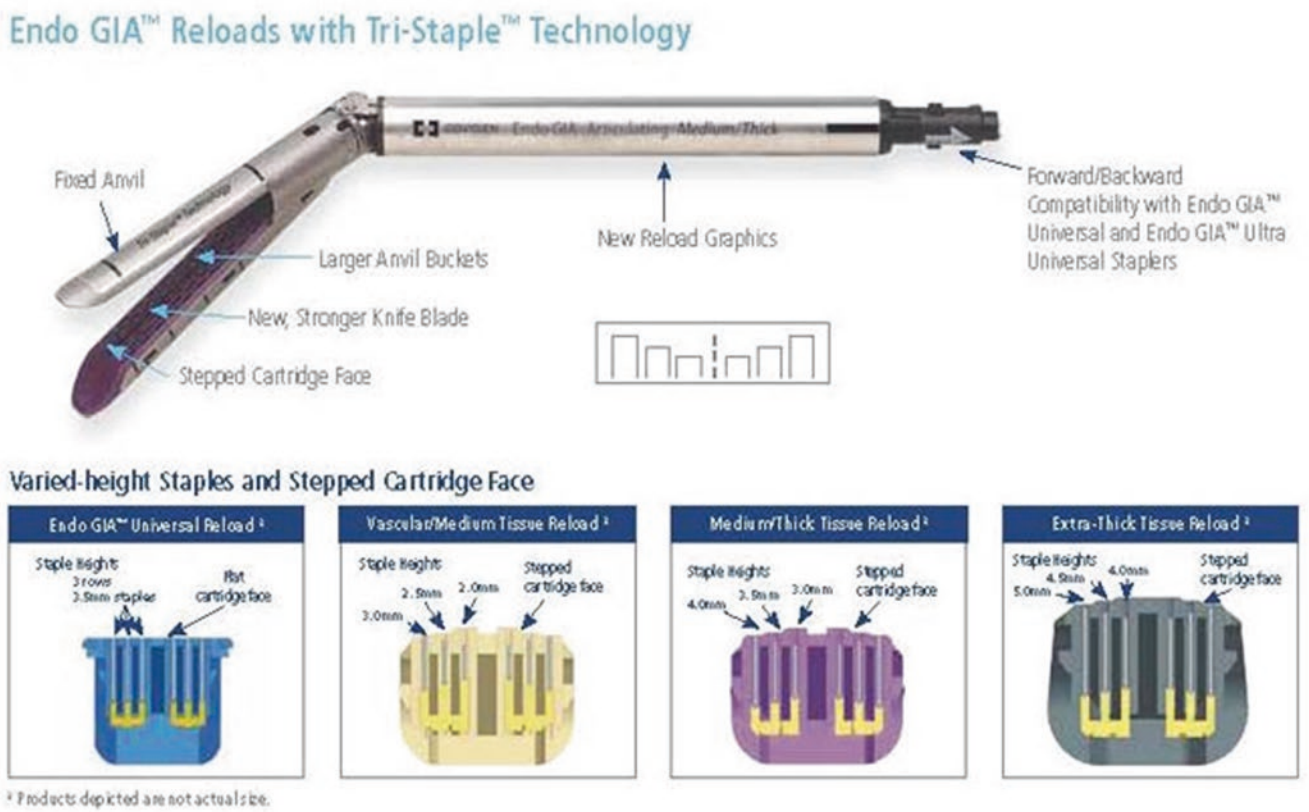

Fig. 23.16 Endo GIA™ Reloads with Tri-Staple™ Technology (Covidien)

Instruments for Clamping Large Vessels, Emergency Needle

Emergency instruments and usual clamps used in routine gynecological operations should not be used for clamping the vessels. Vascular clamps must be readily available. Large vessel injury must be immediately explored by laparotomy and the bleeding vessel clamped. If a vessel in the anterior abdominal wall is injured (epigastric artery), it is advisable to ligate it at an appropriate place with a large emergency needle.

Instruments for Drainage

The Robinson drainage is suitable for abdominal drainage. It works on a gravity basis and as a rule can be left in situ over 24 h.

Instruments for Uterine Manipulation

Vacuum intracervical probes in the standard three sizes allow only partial movement of the uterus and facilitate tubal chrompertubation.

Various instruments for intra uterine manipulation make it possible to move the uterus in side-to-side, ante and retroflexion as well as rotation movements and sometimes allow the possibility of chromopertubation. Uterine manipulation is required in endometriosis of the pouch of Douglas, for hysterectomies, in bladder dome endometriosis and for enucleation of myoma. The ACE (Abdominal Cavity Expander) serves to elevate the anterior abdominal wall in cases with adhesions. Further versions of this principle are used in the gasless laparoscopy, e.g. as Laparolift®.

The Hohl, the Mangeshikar and the Donnez intra–uterine manipulators or mobilizers as well as the Koninckx uterine twister are all produced by Karl Storz and have a cup with a well palpable and visible border to visualize the resection level between vagina and cervix for all cases of TLH (Total Laparoscopic Hysterectomy) (Fig. 23.17). This facilitates the intracervical approach of TLH; however, they are not to be used for the extracervical approach and in oncologic cases of hysterectomy. Many companies have disposable manipulators.

Lenses and Endoscopes

Scopes are available in rigid and flexible systems (Figs. 23.18 and 23.19). The rigid system is based on Hopkins's experience with a rod lens system, which results in good resolution and depth of focus ratio [22]. Flexible endoscopes are based on the use of optical fibre bundles. The rigid laparoscopes are in 3–11 mm sizes, e.g. the arthroscope with a 14° angle. Most of the rigid endoscopes are directly connected to the telescope through the camera coupling system. The picture is enlarged so that it looks even bigger on the monitor. In flexible endoscopes, the bundle of fibres is also enlarged. The standard laparoscopes are rigid instruments

Fig. 23.17 Intrauterine manipulators produced by Karl Storz according to Koninckx, Clermont-Ferrand, Mangeshikar, Hohl, Donnez and Tintara

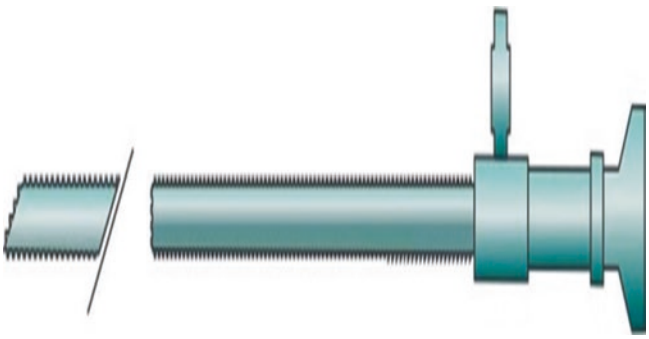

Fig. 23.18 Rigid standard laparoscope (10 mm) with 0° and 30° optic

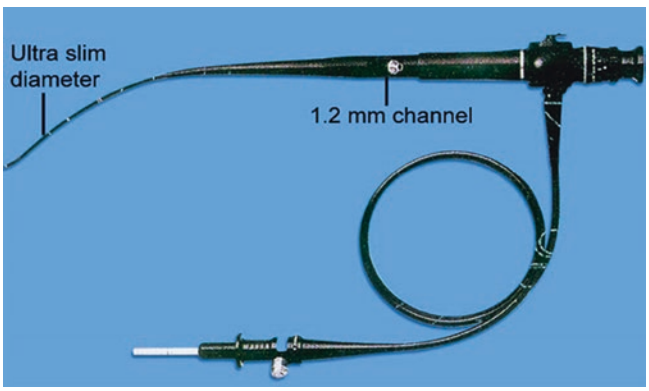

Fig. 23.19 Flexible endoscope

with a 0° lens. The 30° lens has the advantage of a wide panoramic view. With the Endo-Cameleon (Karl Storz) a 120° panoramic view is possible (Fig. 23.1).

Each camera has two components: head and control. A 35 mm coupling system yields a much more enlarged picture than a 28 mm coupler. A direct coupling transmits the picture directly to the camera.

Olympus offers different endoscopes with the chip on the tip of the optic the observation light passes through fewer lenses than on a rigid scope. This allows brighter and sharper images than when the camera is attached to the head of the optic. The ENDOEYE concept includes a range of 5 mm and 10 mmm scopes with advanced optical design that expands the clinical possibilities laparoscopic surgery. The images are smooth and clear, with reproduction so accurate that details and colours remain sharp and true to life. The ENDOEYE FLEX has a flexible tip which can be bend up to 100° in four directions. This means the relevant organs and tissues can be thoroughly examined head-on, from above and from behind (Fig. 23.20).

Energy Systems for Laparoscopic Subtotal, Total and Radical hysterectomies (Electrosurgery and Thermofusion)

Electro section, i.e. cutting of tissue between the active electrode and the tissue where an electrical arc is generated, takes place above 200 °C. During coagulation and desiccation the tissue is heated slowly. It results in denaturation, evaporation of water and secondary hemostasis. The argon beam coagulator is a monopolar electrosurgical instrument. In principle, non-combustible argon gas (4 L/min) across an electrode cannula acts as a bridge for electrical current to burn the tissue superficially (up to 5 mm depth) [23]. As the gas is easier to ionize than air, electrical arcs develop up to 1 cm above the tissue surface. In monopolar electrosurgery, high-density current is used at the active electrode that is conducted to the patient on touching. In bipolar electro surgery, two small electrodes of same size are used which lie close to each other and function as active passive electrodes.

While the use of thermal hemostasis goes back to the glowing iron, according to Paquelin, the development of safe high frequency current techniques took 40 years. The application of the laser technique, ultrasonic cutting and coagulation techniques and the local thermal effects, such as thermocoagulation, take place in the range of 80–120 °C. Suturing and clip techniques are handled in next chapter.

We differentiate between fulguration and coagulation in high frequency hemostasis. In fulguration, electromagnetic oscillations across an air bridge produce radio frequency between the tip of the electrode and the surface of the organ, i.e. they come in direct contact. The generated heat is limited to tissue surface, i.e. the area visible through the scope. By coagulation we mean the heating of the tissues until intracellular water boils under the influence of high frequency current.

Fig. 23.20 (**a**) EndoEYE video laparoscopes (Olympus) as Endoeyerigid (**b**) EndoEye video laparoscopes (Olympus) as Endoeyeflex

In addition to the technique used for fulguration and for coagulation, the most important technique in medicine and endoscopic surgery is the **electrotomy,** the cutting of tissue with the so-called electrical knife or the electrical loop.

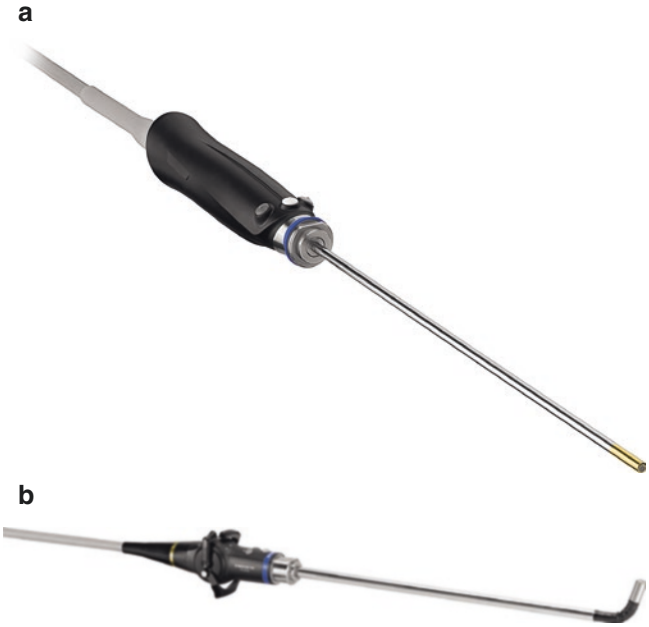

Fig. 23.21 (**a**) BiCision coagulation and cutting forceps (Erbe) (**b**) Erbe Gynaecological Workstation VIO 300 D

At present even with high frequency instruments there is no blind and uncontrolled burning because of the electrical system control. Therefore, we use monopolar current for cutting and bipolar instruments when coagulation is required before cutting big vessels in endoscopic surgery. Most of the systems have an autostop, so that only the required tissue is denatured. It is not set for a very big coagulation zone. Bi-Clamp for vaginal and open surgery and BiCision (Fig. 23.21a) for laparoscopic surgery are the thermofusion devices of Erbe Elektromedizin GmbH (Tübingen, Germany). Their effect is electronically controlled thermofusion and the mechanical separation of tissue.

The electrocoagulation system of Erbe (Fig. 23.21) uses an additional argon beamer, controlled by a foot switch, which facilitates linear coagulation by switching on the argon gas. This gynecological workstation with the high frequency module VIO 300 D can be connected to any monopolar or bipolar coagulation device. It contains several modules, such as the argon plasma coagulation (APC 2) and the smoke plume evacuator (IES 2). The Erbe electro surgical unit (ESU) has a color monitor display that provides the user with an on-screen tutorial as well as settings and operational information. The unit has various cutting and coagulation modes with defined effect levels to provide the physician flexibility in interventional applications (i.e. its ability to generate HF current). The system has automatic start and stop features. The equipment is programmable and various accessories (e.g. footswitches, hand instruments, etc.) as well as modes may be assigned to perform specific functions. Upon activation, the energy

Fig. 23.22 LigaSure (Covidien), bipolar vessel sealing system, 10 mm (Atlas) and 5 mm

Fig. 23.23 LigaSure (Covidien) jaw providing a combination of pressure and energy to create vessel fusion

delivered (in watts) from the ESU to the tissue is displayed on the display screen.

Bipolar vessel sealing, also described as thermofusion, combined with pressure between the branches of the instruments, is a new, easy to use technique that has been picked up by many companies in the production of disposable instruments with integrated cutting devices such as LigaSure (Covidien) (Figs. 23.22 and 23.23).

The BOWA ARC 400 electrosurgical unit is a multifunctional generator for all surgical specialities. Two monopolar and three bipolar instruments can be used with the generator, and, ARC 400 offers specific setting for gynaecology as for every other supported speciality. Monopolar and bipolar resections for hysteroscopic treatments:

- Laparoscopic interventions

LIGATION and Coagulation: Permanent sealing of vessels and tissue bundles with BOWA LIGATION instruments for laparoscopic procedures with BOWA ERGO 310D and NightKNIFE instruments and open surgical applications with BOWA TissueSeal PLUS.

The Nightknife (BOWA-electronic GmbH, Gomaringen, Germany) (Fig. 23.24) is a bipolar vessel sealing device. The instrument incorporates atraumatic tips for secure dissecting and sealing. The integrated cutting system saves changing instruments for tissue separation. The Ergo 310 D knife 5 mm in diameter integrates the sealing and cutting function likewise

- A special mode for BOWA MetraLOOP, a special laparoscopic instrument for the fast and secure removal of the uterus (LSH surgeries). SimCoag mode offers the possibility for two surgeons to activate monopolar or bipolar instruments simultaneously.
- In combination with the ARC PLUS argon unit, electrosurgical system offers Argon plasma coagulation and argon enhanced cutting. The ionized Argon beam offers homogeneous superficial coagulations which is perfectly suitable for e.g. endometriosis treatments.

To support the surgeon's work, the ARC 400 has a very user-friendly design concept.

- COMFORT instruments are automatically detected during insertion by the Plug'n Cut COMFORT function of the generator. The specific settings of the instrument are preselected and the operation can be carried out immediately.
- The intuitive touch display makes settings easy and the layout of the interface allows the user to always know which socket is being set at the moment.
- The EASY neutral electrode monitoring system increases patient safety in monopolar applications by deactivation and alarm in case of insufficient contact between the neutral electrode and the patient.

Additionally, the system can be equipped with the SHE SHA smoke evacuation system, which helps to protect health of the OR-team by evacuating surgical smoke.

The PKS HALO Cutting Forceps by Olympus are ergonomically designed forceps that allow easy operator use, serrated jaws enable strong grasping, better dissecting, reliable coagulation and cutting. PK Technology is an impedance feedback controlled, advanced bipolar vessel

Fig. 23.24 Nightknife (BOWA-electronic) in 5 and 10 mm versions (**a**)Ergo 310 D knife, (**b**) Ergo 310 D, (**c**) open jaws, (**d**) ARC 400 Gynecology/ligation monitor, (**e**) ARC 400 Gynecology plugncut.

sealing system that allows tissue and device tip to cool during the 'energy off' phase, minimizing sticking and charring (Fig. 23.25).

By means of the smart electrode technology, the ENSEAL sealing instrument (Ethicon Endo-Surgery,) permits simultaneous sealing and the possibility of tissue separation, including vessels up to 7 mm (Fig. 23.26). The tip of the instrument has either a 5 mm round tip or a 3 mm slightly curved tip enabling tissue preparation and sealing.

Laser

Laser beam is often described as "light that heals." Laser is acronym for **L**ight **A**mplification by **S**timulated **E**mission of **R**adiation. Fox established the first surgical laser in 1960. Bruhat and his colleagues in 1979 and Tadir and colleagues in 1996 introduced CO_2 laser in laparoscopy. Today, there are enthusiasts of laser surgery and enthusiasts of electro surgery. Light energy is amplified to generate increased coherent electromagnetic radiation. Here we mention the three forms of laser used in endoscopic surgery:

- CO_2-laser
- Nd: YAG-laser
- KTP-lasers

The Neodymium: Yttrium-Aluminium-Garnet (Nd: YAG-) laser, the Argon laser and KTP- (Potassium-Titanium-phosphate-) laser are used for cutting and coagulation. All the tissue effects are produced because of the continuous or pulsing thermodynamic conversion of light in thermal energy. Because of the 15° refraction of the laser beam after arising from the fiber bundle, the effect can be achieved only up to 2 cm from the tip of the fibers. In 1996 Wallwiener et al. introduced laser treatment in the reproductive surgery [24].

Harmonic Scalpel – Ultrasonic Energy

The harmonic scalpel is an ultrasonically activated laparoscopic instrument that uses mechanical energy to cut and coagulate tissues. Today, the harmonic scalpel can be used as 5–10 mm cutting blades and scissors. Activation of the titanium blade takes place by a piezoelectric crystal with a frequency of 55,500/s in the hand set. The cutting and coagulation effects are comparable to that of the CO_2-laser [25]. The lateral thermal damage is less than by high frequency coagulation. Burning and carbonization of tissues are not observed.

The advantages of ultrasound energy in surgical endoscopic instruments produced by Ethicon Endo-Surgery

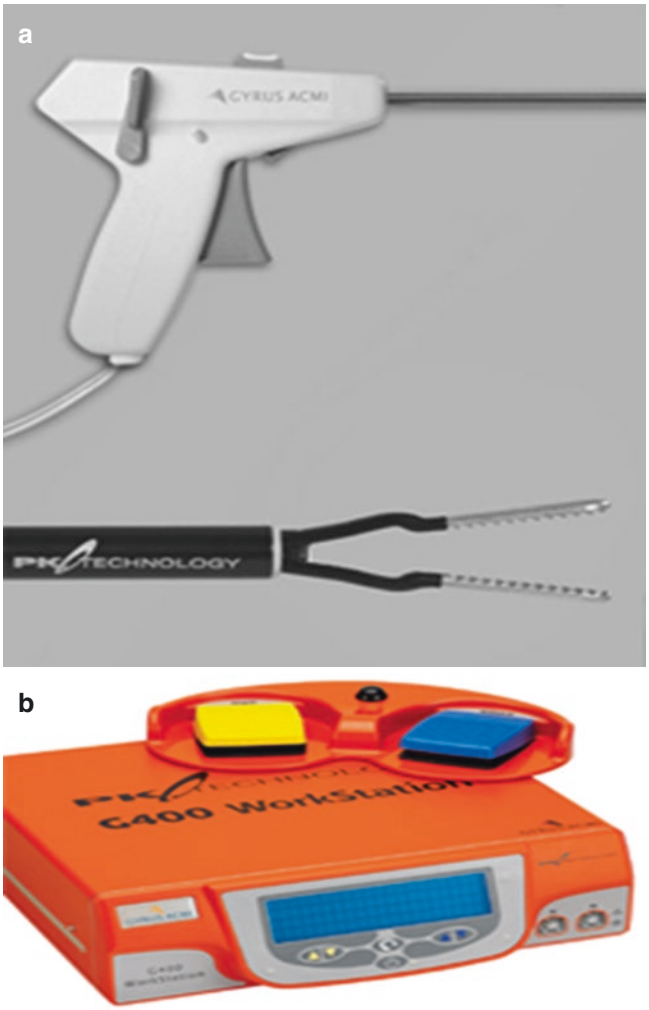

Fig. 23.25 (**a**) Gyrus PK integrated vessel sealing and cutting system (Olympus) (**b**) Gyrus PK control unit (Olympus)

Fig. 23.26 ENSEAL sealing instrument (Ethicon Endo-Surgery)

and Olympus are well known today and highly appreciated. As an example let us focus on the harmonic ace of Ethicon (Fig. 23.27) which with its specific control unit (Fig. 23.28) allows a shorter and a longer effect of sealing and cutting. The mechanical energy works with low temperatures, small lateral damage and minimal desiccation of the tissue.

Fig. 23.27 Harmonic Ace forceps (Ethicon)

The THUNDERBEAT by Olympus is the world's first integrated hand instrument that delivers the benefits of both advanced bipolar and ultrasonic energy in a single device. This unique integration of energy modalities combines proven safety of secure haemostasis from advanced bipolar energy with the speed and precision of ultrasonic dissection (Fig. 23.29).

The different harmonic instruments on the market today, such as harmonic shears, forceps and cutting rings, are applied for adhesiolysis as well as any type of adenexectomy, ovarectomy and hysterectomy. It remains up to the surgeon whether he uses them in combination with other sealing instruments or bipolar coagulation.

Summary of Specific Instruments to Be Used in Total Laparoscopic Hysterectomies (TLH)

All the above mentioned instruments are excellent tools to be used for TLH. There are 2 ways of applying traction and contra-traction for the operative field either by using an intrauterine manipulator in uteri up to a certain size or using traction with a myoma screw, introduced from the lateral ports, a principle widely applied in "Radical hysterectomies" in cases of malignancies. The absolutely necessary instruments for TLH, with or without adnexectomies are detailed in Fig. 23.30.

Summary of Specific Instruments to Be Used in Subtotal Hysterectomies (SLH)

Subtotal hysterectomy, as CISH (Classic Intrafascial Supracervical Hysterectomy) or LSH (Laparoscopic Assisted Supracervical Hysterectomy), is facilitated by the use of an electric loop produced by LiNA Medical ApS, Glostrup,

Fig. 23.28 Harmonic Ace control unit (Ethicon)

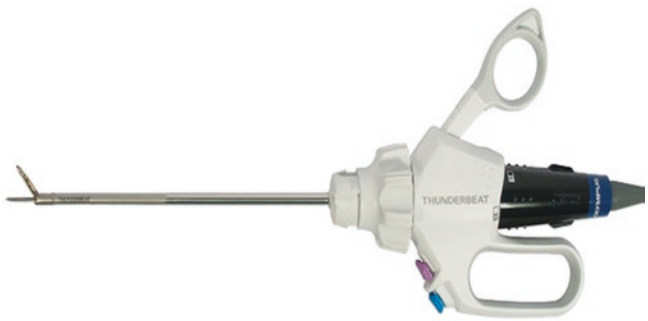

Fig. 23.29 Thunderbeat (Olmypus)

Denmark (Fig. 23.31) as the LiNA Loop and the Storz Loop. With this electric cutting look the cervix is separated from the uterine body. It is of utmost importance not to touch any bowel loops during the activation of the cutting part of the loop.

The PKS BiLL by Olympus is currently the only available bipolar loop for more safety for your patients and fast cutting of the uterus during LSH procedures. With immediate ignition and dry and fast cutting, the PKS BiLL allows for shorter procedure times. The big diamond-shaped loop opens up automatically in the abdomen and is easy and convenient for the surgeon to place even in enlarged uteri (Fig. 23.32). Figure 23.33 details the most necessary instruments for SLH today.

Micro Endoscopy

By rigorously following the concept of minimally invasive access for hysteroscopy and laparoscopy through advances in instrument designing, today optic systems measuring only about 1.8–2 mm including the trocar surrounding

Fig. 23.30 Instrument set for Total Laparoscopic Hysterectomy (TLH)

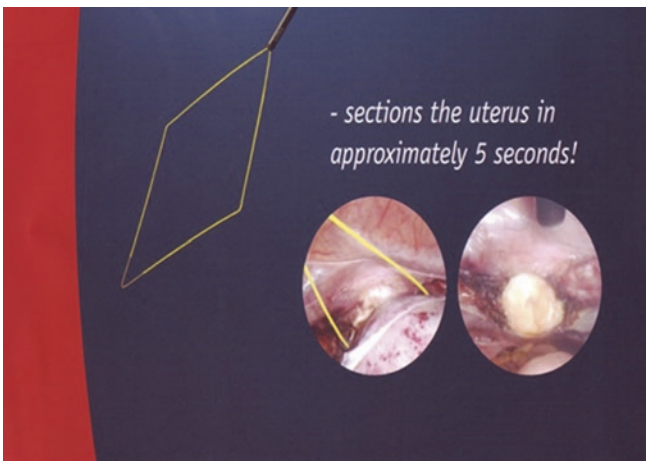

Fig. 23.31 LiNA Loop at Subtotal Hysterectomy (SLH)

Fig. 23.32 Bipolar cutting loop for SLH (Billbipolar)

them are available. Phase optic and lens optic system with diameter between 1.2 and 2 mm are offered by instrument manufacturers. Common to both of them is that the laparoscope can be passed through the Veress needle or the sleeve. Additional trocar insertion after gas insufflation is therefore superfluous. However, compared to the standard 5 and 10 mm optics, even the most satisfactory of the mini-systems shows deficient lighting efficiency. The instrument trocars are also available in correspondingly small diameters.

The merits of minimal operative trauma and the avoidance of umbilical trocar insertion done by inserting the laparoscope through the Veress cannula in minilaparoscopies used to have disadvantages, such as the mechanical fragility of the minilaparoscopes and difficult operative sites with a restricted view. Today new optics and stabile instruments have virtually eliminated these disadvantages. Therefore, a set of minilaparoscopic instruments must always be available for use in certain surgical interventions. The small diameter of the mini-instruments contributes towards reducing trauma and pain in children and in smaller surgical procedures.

For TLH and SLH in small uteri microendoscopic instruments can be used. However, there should be no limitation to combine the procedure by using conventional laparoscopic instruments, as well.

Single Port or Single Entry Laparoscopy (SEL)

Laparoscopy in the 1940s started with the angled laparoscope (optic and one working channel) of Raoul Palmer in France as SEL. Laparoscopy at that time was mainly used for diagnostic purposes and for sterilizations. Kurt Semm in Germany further developed the procedure into operative laparoscopy by using multiple entries and instruments.

Fig. 23.33 Instrument set for Subtotal Laparoscopic Hysterectomy (SLH)

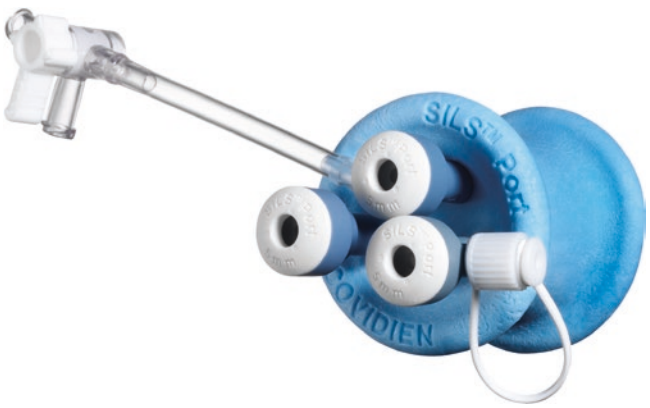

Fig. 23.34 SILS (Covidien) Port New

Fig. 23.35 LESS - Laparo-Endoscopic Single-Site Tri-Port Surgery (Olympus)

With the improved technology of today, SEL takes the idea of the early laparoscopy to new horizons. Of the multitude of SEL ports available, let us mention two disposable and one reusable:

1. The SILS port (Covidien) (Fig. 23.34) is a disposable port. Here a silicone port is introduced into the abdominal cavity using a classical curved grasper with a beak of 5–6 cm. The surgeon has the choice of two ports of five mm and one allowing for a large barrel instrument of 10–12 mm or one with four 5 mm ports. The SILS, with the possibility to introduce larger instruments, is suitable for hysterectomies.
2. Another disposable port is the LESS QuadPort + (Fig. 23.35) of Olympus which contains duckbill valves and requires no gel for insertion. Instruments of 5, 10, 12 and 15 mm can be introduced easily for ergonomic surgery. The 5 mm LESS EndoEYE video-laparoscopes provide excellent visualization and help to avoid instrument clashing. Specialized curved HiQ+ LESS instruments allow internal triangulation and mimic traditional laparoscopy

Fig. 23.36 LESS System with EndoEYE and curved instruments (Olympus)

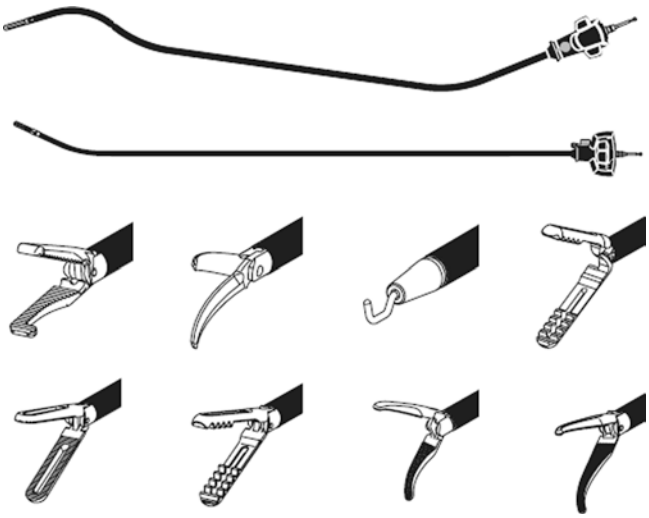

Fig. 23.37 Seven variations of LESS curved instruments (Olympus)

(Figs. 23.36 and 23.37). As a reusable port we use the XCONE (Fig. 23.38) of Karl Storz. This system is operational in the abdomen with 3–5 entry channels, one allowing large barrel instruments. Usually the 3 or 5 mm optic is placed into the middle entry and at least one curved instrument on the left or right side. The ENDOCONE® (Fig. 23.39) is a special access system developed by the general surgeon Cuschieri in which seven instruments can be introduced simultaneously.

Fig. 23.38 XCONE (Karl Storz)

Developments are ongoing as can be seen by the ETHOS Surgical Platform™ (Ethos Surgical, Beaverton, USA), on which the surgeon is postured over the midline of the patient with optimal port triangulation options. New instruments and apparatus are continuously being appraised. They assist the surgeon but do not replace his knowledge and have always to be critically evaluated and studied before they are applied.

For TLH and SLH at Single Port Laparoscopy an intrauterine manipulator is essential to be used in combination with the following necessary instruments: Graspers, coagulation devices, scissors, electro loop and morcellator.

In summary conventional laparoscopic hysterectomies with single and multiple port entries are easy to be performed with modern gyne-endoscopic instrument and apparatus.

Fig. 23.39 ENDOCONE® (Karl Storz) according to CUSCHIERI

Uterine Manipulators for Total Laparoscopic Hysterectomy

24

Prashant Mangeshikar and Abhishek P. Mangeshikar

Introduction

With the advent of development of laparoscopic hysterectomy, improving the ease by which the surgery is done, the need to develop the ideal uterine manipulator became necessary. Each new uterine manipulator improved the shortcomings of its predecessor. This chapter will address the significant benefits and shortcomings of the manipulators invented thus far.

Laparoscopic Hysterectomy is in present time, the standard practice of hysterectomy in experienced hands for diseased uteri where vaginal hysterectomy is not possible. Described by Harry Reich, initially as a LAVH procedure (Laparoscopic Assisted Vaginal Hysterectomy) and later as a Total Laparoscopic Hysterectomy (TLH) operation, the operation like all laparoscopic surgeries requires good and optimal surgical exposure. Optimal exposure of the operative field is of prime importance during Laparoscopic Hysterectomy. Despite the advent of high definition cameras, superior optics and newer light sources, complications can occur if optimal exposure is not available at laparoscopy.

Manipulation of the uterus during LH is essential to provide maximal exposure with minimal access. Though manipulation of the uterus is possible by using a laparoscopic myoma screw, it is not as effective in comparison to the multiple functions provided by the uterine manipulator. In addition, the use of the myoma screw blocks an accessory portal, immobilizing one instrument and one hand which is no longer available for help. The use of the myoma screw may not be able to provide uterine access in all the possible views. This would require shifting the fixation of the myoma screw in the uterus in multiple positions. Bleeding can ensue as a result of screwing and unscrewing the myoma screw from the uterus necessitating arrest of bleeding from the fixation sites in the body of the uterus.

The role of uterine manipulators at Laparoscopic Hysterectomy has been well described and established by numerous studies as a safe and effective way to handle the uterus during laparoscopic hysterectomy. This enables the surgeon to develop spaces along the lines of cleavage, facilitating safe dissection and avoiding unnecessary complications.

The ideal uterine manipulator should have the following characteristics:

1. Inexpensive
2. Safe and nonconductive of electricity
3. Quick assembly and disassembly
4. Reusable
5. Have a wide range of movement and mobilize the uterus in different axis.
6. Easy placement and removal within the uterus
7. No complications arising from its use.
8. Maintain the pneumoperitoneum following the circumcision of the vagina.
9. Should not break down into pieces or fragment during surgery
10. Special functions

According to Gamal Eltabbakh [1], a uterine manipulator should perform the following functions:

1. Raise the uterus cephalad bringing it closer to the laparoscopic instruments.
2. Manipulating the uterus, thereby keep the side to be operated upon, on a stretch.
3. Increase the distance between the uterus and the ureters, bladder and rectum preventing any injury or damage to these vital organs

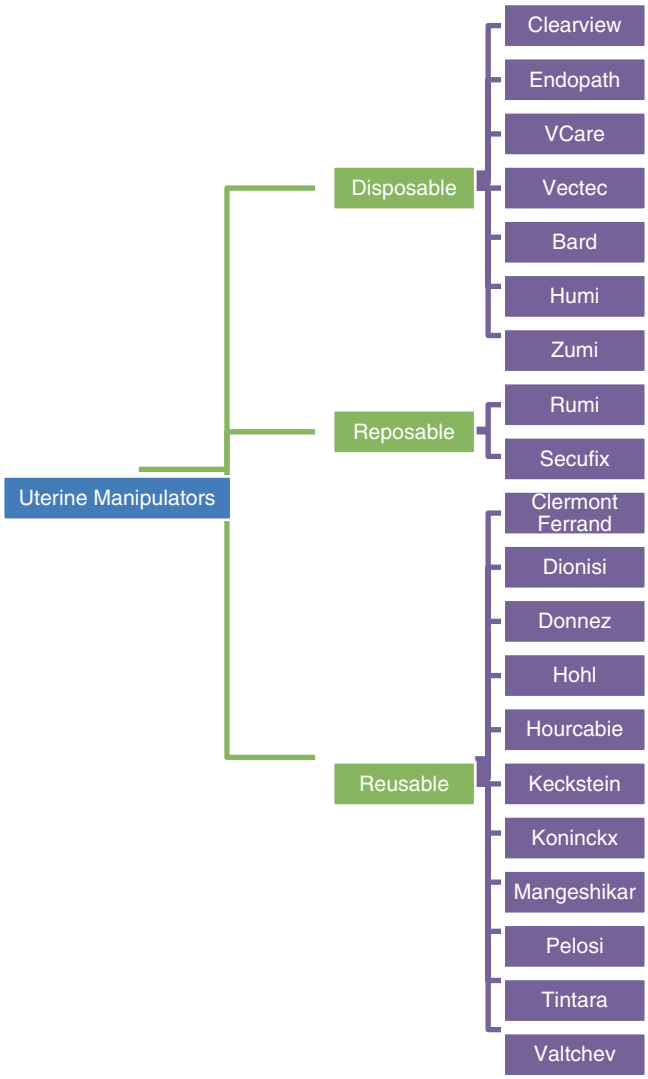

Fig. 24.1 List of Uterine manipulators for Total Laparoscopic Hysterectomy

4. Facilitate identification of the utero-vesical fold of peritoneum, cul-de-sac, and the vaginal cuff at the cervico-vaginal junction.
5. Enable the delivery of the uterus via the vagina once it is free.
6. Maintain the pneumoperitoneum following the circumcision of the vagina.

The uterine manipulator is termed as "The FIFTH Hand in the Pelvis" where in the vaginal assistant is manipulating the uterus via the indwelling instrument: the uterine manipulator. Numerous uterine manipulators have been designed by different authors across the world with the aim to facilitate maximal access during LH as shown in Fig. 24.1.

Clearview Manipulator

The Clearview Manipulator previously known as the Endopath uterine manipulator is a disposable device with ease of handling and assembly with the following characteristics:

1. Allows the uterine manipulation with an inbuilt inflatable balloon in the AP and lateral axis and elevation without the need of a vaginal assistant.
2. In view of the fact that even though it allows 210° of movement in the AP axis, it is not suitable for the TLH operation since it does not allow dextro- and laevo-rotation of the uterus, does not delineate the vagina and also does not maintain the pneumoperitoneum.
3. Two cases of uterine perforation during dilation of cervix due to cervical stenosis reported. Two cases of the Clearview manipulator breaking down into small pieces retained within the patient were reported.

VCare Uterine Manipulator

The VCare Uterine Manipulator is a disposable lightweight device with the following characteristics:

1. It has a wide range of motion (AP, lateral and elevation).
2. It allows easy handling and assembly with an inflatable intrauterine balloon device.
3. Though it offers good vaginal delineation and well maintains the pneumoperitoneum, it is not suitable for TLH in large uteri.
4. Disintegration of the VCare and laceration of the vaginal have been reported as also one case of melting of the cervical cup.

Vectec Manipulator

The Vectec manipulator is an ultra light, inexpensive disposable instrument available either with suction or a screw device to hold the uterus during manipulation.

Rumi Manipulator

The RUMI system consist of the Rumi Manipulator, the Koh cervical cup, and the Koh Colpo-pneumo–occluder, that facilitates 140° degree movement in the AP axis, lateral movements and elevation in the cephaled direction. The indwelling balloon facilitates the manipulation. The injury

rate for 0.2 % for ureter and 0.4 % for bladder, and 1 % for the vagina. Two patients had uterine rupture due to hyperinflation of the intra uterine balloon of the Rumi. In another series the Koh cup was found 14 months after the operative procedure. Following other reports of the disintegration of the instruments, parts being left behind, and vaginal wall laceration, the RUMI has been updated to the RUMI II system.

Clermont Ferrand Manipulator

The Clermont Ferrand Manipulator is a reusable device offering movements in the AP axis, lateral movements and elevation in the cephalad direction (Fig. 24.2). Though it is versatile, it is considered difficult to assemble.

However it does not allow levo –and dextro rotation unlike the Mangeshikar uterine manipulator.

Donnez Uterine Manipulator

The Donnez Uterine Manipulator is a reusable device, lightweight in design. It is not a self retaining instrument (Fig. 24.3). The working insert at the distal end of the manipulator facilitate the positioning of the cervix and is available in three sizes as also the caps which delineate the vagina and seal the gas during opening of the vagina. However, though the inherent design is good for small to moderately enlarged uteri, it has limitations in the range of movement as also with variations in the length of the cervix and associated vaginal prolapse.

Fig. 24.2 Clermont Ferrand Manipulator

Dionisi Uterine Manipulator

The Dionisi uterine manipulator is a reusable device, which is inserted into the uterine cavity: the distal insert being in a closed position (Fig. 24.4). The rotatory wheel at the proximal end is rotated to open up the distal working insert once in proper position. The distal working inserts are available in three different sizes depending upon the size of the uterus for the hysterectomy. The inherent design does not allow the various ranges of movement unlike the Mangeshikar Uterine manipulator. Further there are no vaginal delineating caps available with this instrument.

Hohl Uterine Manipulator

The Hohl uterine manipulator is a reusable device, which is tightly screwed into the cervical canal using spiral inserts (Fig. 24.5). The working inserts, available in different lengths (60 mm, 80 mm, 100 mm) allows this device to be used for uteri of varying sizes. The ceramic caps in varying sizes are available to match the size of the portio. The caps provide optimal presentation over the fornix during circumcision of

Fig. 24.3 Donnez Uterine Manipulator

Fig. 24.4 Dionisi Uterine Manipulator

the vagina. Whilst the manipulator provides a wide range of movement of the uterus rotation of the uterus around its axis is not possible.

Keckstein Uterine Manipulator

The Keckstein uterine manipulator is a reusable lightweight device that enables the uterus to be manipulated with maximum mobility: 95° anteflexion and 30° retroflexion (Fig. 24.6). The movable spiral insert facilitates the movement of the uterus whilst the screw mechanism into the cervix fixes the manipulator. Whilst the Keckstein manipulator allows dorsal, ventral and lateral movements, it cannot rotate the uterus around its axis. This versatile device is provided with caps to present the vagina during the hysterectomy procedure and also to prevent loss of pneumoperitoneum. The shallow fixed height of the cap could be a limiting factor for the identification of the cervico-vaginal junction unlike the Mangeshikar Uterine mobilisar, considering the length of the cervix and associated vaginal descent.

Mangeshikar Uterine Mobilizar

The Mangeshikar Uterine Mobilizar was developed by the primary author with the idea of maximizing uterine manipulation in multiple axis or directions to facilitate excellent exposure for surgical dissection during the total lapaoscopic hysterectomy and colpotomy (Fig. 24.7).

Fig. 24.5 Hohl Uterine Manipulator

Fig. 24.6 Keckstein Uterine Manipulator

The Mangeshikar Uterine Mobilizar consists of two main components (Fig. 24.8):

1. The central assembly
2. Vaginal Fornix Presenter

The central assembly comprises of:

1. A reusable insert, which is housed in an outer stainless steel tube, has at its distal central end a fixation device for the intrauterine steel element (IUE) (Fig. 24.9) and two built in single toothed tenaculum (Fig. 24.10). At its

Fig. 24.7 Mangeshikar Uterine Mobilizar

Fig. 24.8 Different parts of Mangeshikar Uterine Mobilizar

Fig. 24.9 Distal end of MUM with Intrauterine element (IUE)

proximal end, the insert fits snugly into the handle of the manipulator that has a locking device to fix the tenacula into the cervix.

2. The Vaginal Delineating Cup / Vaginal Fornix Presenter (VDC) is made of reusable medical grade PVC (Fig. 24.11). The VDC has a cup at its distal end and houses a tricuspid valve apparatus at the proximal end. It has a locking device within its handle. Once positioned inside the vagina to expose the cervicovaginal junction, it can be locked in place with the inbuilt handle so that the assistant does not have to be concerned with the persistent pushing and handing of the VFP. The cup has a ceramic lip and is flat and not beveled. The standard supplied cup is available in three fixed sizes 30, 35 and 40 mms. Outer diameter.

The Mangeshikar Uterine Mobilizar has no disposable elements and is made up of stainless steel and medical grade PVC that is steam autoclavable.

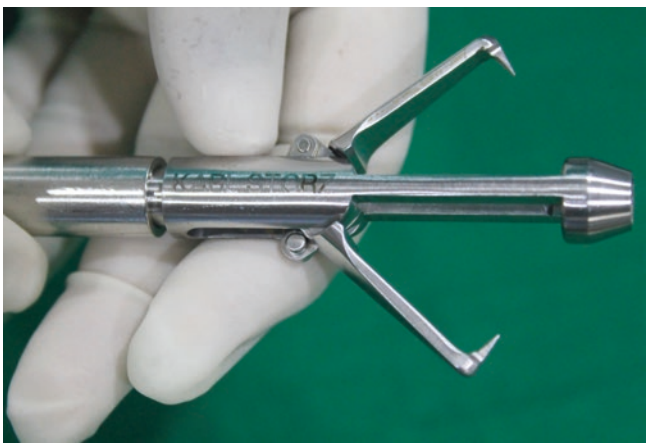

Fig. 24.10 Distal end of MUM showing inbuilt tenaculum

Fig. 24.11 Vaginal Delineating cups with Handle

Operative Steps:

1. With the patient positioned in a modified lithotomy position under general anesthesia, with an indwelling catheter in the Bladder after draping under aseptic precautions, an Assessment is made under anesthesia to determine the uterine size, mobility and the Utero-cervical Length.
2. The cervix is held with a vulsellum at the anterior lip and dilated to 10 Hegar.
3. The uterocervical length (UCL) is determined in cms. With the hysterometer / uterine sound and the appropriate intrauterine element is selected. The length of the element in cms. Is etched at its base as a Number e.g. 8, 9 etc. The correct IUE chosen reduces the risk of uterine perforation and trauma.
4. The MUM is assembled with the appropriate IUE and the vaginal tube Fig. 24.12). The VDC is selected depending upon the width of the vagina and the diameter of the cervix.

After removing the Mangeshikar Uterine Mobilisar from its sterilizing box, the instrument is assembled choosing the appropriate:

A. Intra Uterine Element according to the Utero-cervical length in cms. The appropriate IUE is identified by a Numeral etched at its base e.g. 8, 9, 10 etc.
B. Vaginal Delineating Cup, which is selected depending upon the width of the vagina and the diameter of the cervix (Fig. 24.13).

Fig. 24.12 MUM is assembled with the appropriate IUE

Fig. 24.13 Fixing the Vaginal Delineating Cup to the Handle

Fig. 24.14 Close-up view of the final assembly of MUM at the distal end

5. Holding the anterior lip of the cervix with vulsellum, the MUM is introduced safely into the uterus with the appropriate IUE and VDC and the two in-built tenacula grasp the cervix securely at 3 and 9 o'clock position (Fig. 24.14). Rotating the proximal knob on the handle in an anti-clockwise manner opens the tenacula.

Precautions are taken to ensure that the vagina is not included in the grip. The steel rotating knob on the handle is rotated in a clockwise direction to secure the grip of the tenacula of the MUM on the cervix avoiding any injury to the vagina or the bladder. The vulsellum on the ant lip of the cervix is now removed.

6. The MUM is now ready for use. Traditionally, the vaginal tube is not inserted into the vagina at the beginning of the TLH. In cases of previous C-section, one may insert the tube at the very beginning of the operation to facilitate bladder dissection as the tube acts as a platform on which safe dissection of the bladder fascia and the adhesions can be performed.

Note:

1. The MUM Mobilizes the Uterus in FOUR directions:
   a. Cephalad
   b. Lateral
   c. Anterior and posterior
   d. Levo-rotation and Dextro-rotation on the shaft of MUM
2. By pushing the uterus cephalad, the MUM lifts the uterus out of the pelvis into the abdomen and increases the space between the uterus and the lateral wall of the pelvis.
3. The lateral movements of the uterus by the MUM provide maximal exposure and access to the round ligament, the tube and ovary as well as the broad ligament with all its structures. Further, with the lateral push provided by the MUM, maximal access is available for dealing with the uterine vessels and the ureter (Fig. 24.15). The lateral mobilization by the Mum increases the distance between the uterine vessels and the ureter providing safety to the ureter from injury.
4. The MUM can antevert and retrovert the uterus to gain access to the lower part of the uterus in cases of fibroids blocking straight vision. In addition, the cul-de-sac can be well identified with the MUM and the vaginal tube being pushed deep into the depth of the vagina.
5. The secure grip by the tenacula on the cervix enables the MUM to rotate the uterus around its axis thus bringing the uterine vessels anteriorly at 1 and 11 o'clock position while the ureters remain at their normal 3 and 9 o'clock positions. This provides a safe and clear view of the uterine vessels and the ureter Fig. 24.16). The tenacula grip the cervix and this in addition ensures that uterine perforation due to the instrument will not occur during introduction and surgery.

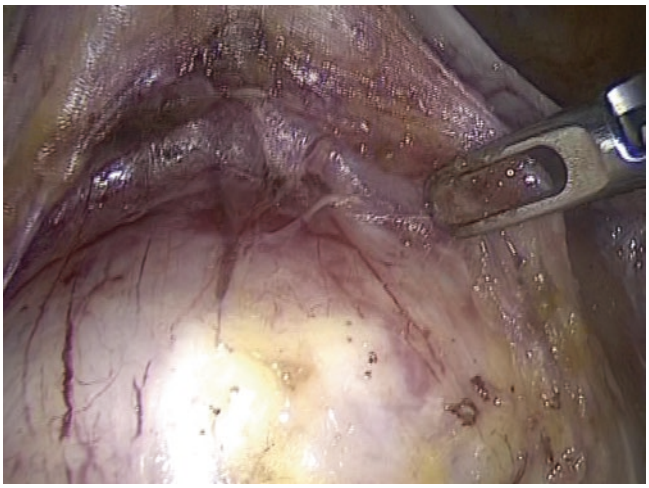

Fig. 24.15 Exposure of Vagina and Bladder dissection

The Mangeshikar Uterine Manipulator aims to be the IDEAL Uterine Manipulator due to its characteristics (Figs. 24.17, 24.18, 24.19, 24.20, 24.21 and 24.22):

1. Lightweight
2. Reusable

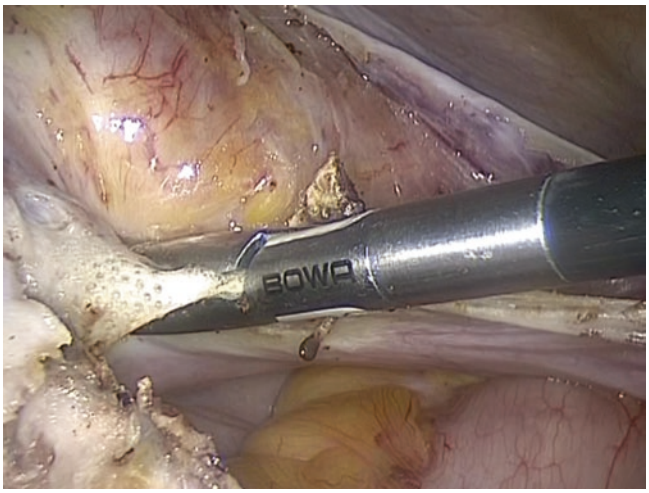

Fig. 24.16 Exposure of Uterine vessels using MUM

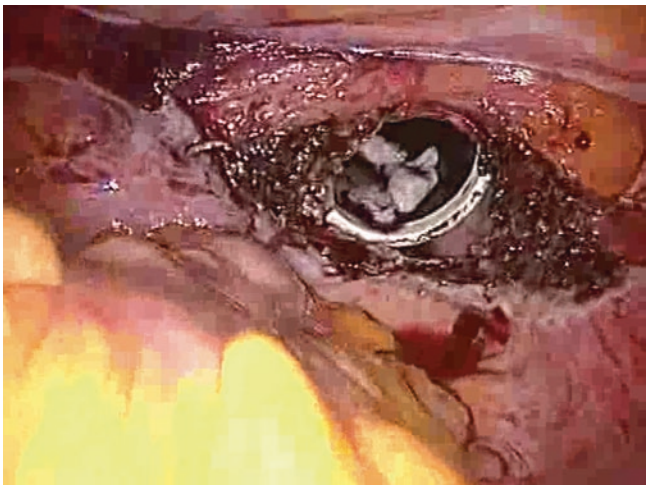

Fig. 24.17 Easy Retrieval of Morcellated tissue via Vaginal Cup

3. Multifunctional
4. Robust
5. For varying uterine sizes
6. Safe
7. Easy to Assemble and Disassemble
8. Easy to Clean and Sterilize
9. Vehicle for Sutures and Needles and Passover Clip
10. Displaces Cervix away from ureters
11. Displaces Bladder Anteriorly and Rectum posteriorly
12. Defines Dissecting plane for Colpotomy
13. Receptacle for sterile gauze pieces
14. Exposes the vaginal edges during laparoscopic closure of the vagina
15. Receptacle for the morcellated tissue remnants, uterine tissue, tubes and ovaries.

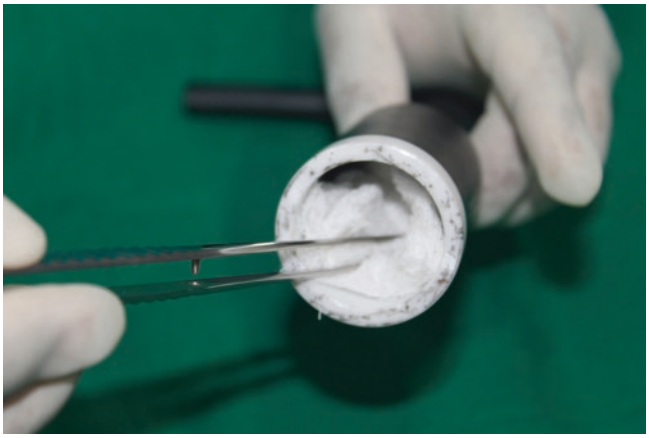

Fig. 24.18 Vaginal Delineating Cup: Storage of gauze piece for mopping the surgical area

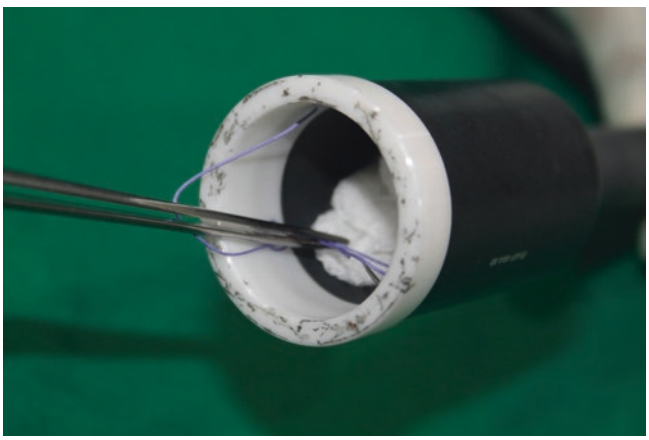

Fig. 24.19 Vaginal Delineating Cup: Storage of Needle with Suture

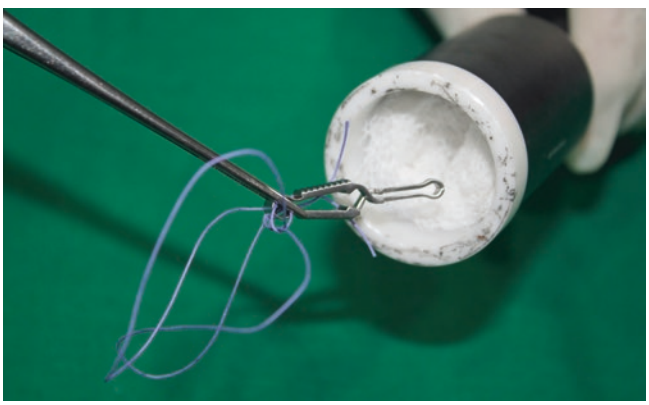

Fig. 24.20 Vaginal Delineating Cup: Storage of Possover Clip

16. Prevents loss and Maintains pneumoperitoneum during circumcision of the vagina as well as during laparoscopic closure of the vagina.

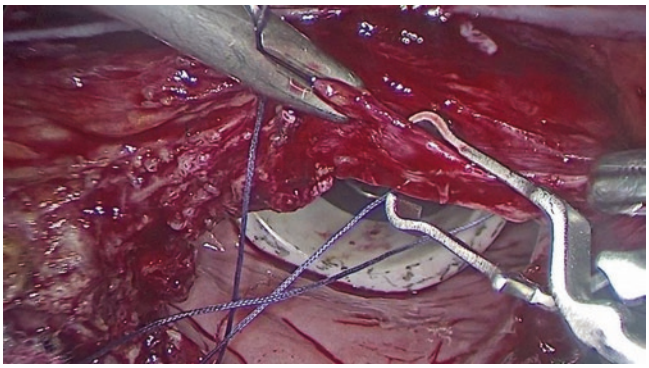

Fig. 24.21 Possover Clip being applied laparoscopically on anterior vaginal wall

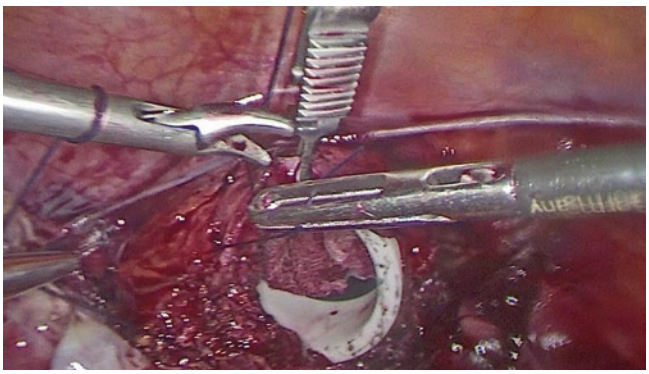

Fig. 24.22 Possover Clip holding anterior vaginal wall providing optimal exposure for easy closure of vagina

Tintara Uterine Manipulator

The Tintara Uterine Manipulator is a lightweight reusable device (Fig. 24.23). It is held in position with the vulsellum on the cervix and allows elevation of the uterus in a cephalad direction and anteflexion upto 90°. It is suitable for LASH (Laparoscopic Supracervical Hysterectomy) and not for Total Laparoscopic Hysterectomy.

Complications

Complications with the use of Uterine Manipulators at Laparoscopic Hysterectomy include:

1. Cervical Tears and Lacerations
2. Vaginal Lacerations
3. Perforation of the uterus during introduction and usage
4. Laceration of Uterine vessels and colporrhexis
5. Bleeding: Intraperitoneal or retroperitoneal.
6. Perforation of Bladder/Bowel/Rectum
7. Breakdown of the Uterine manipulator within the uterus

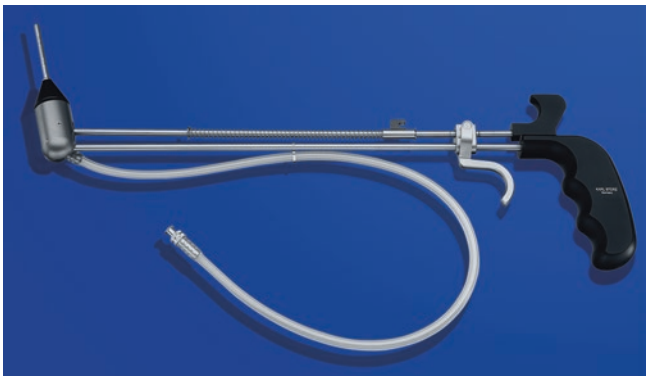

Fig. 24.23 Tintara Uterine Manipulator

Complications are more likely to occur in postmenopausal women or nulliparous women or women who have had no vaginal delivery. The stenotic cervix and the retroverted uterus predispose to complications. Complications can be avoided by proper insertion of the manipulator under laparoscopic visualization.

Ali Akdemir and Teksin Cirpan [2] reported a case of iatrogenic uterine perforation and sigmoid colon penetration caused by the Hohl uterine manipulator during TLH, which required conversion to laparotomy. A prospective study involving 1432 patients undergoing TLH using the Hohl manipulator reported 1 ureter and 8 bladder injuries [3].

The use of uterine manipulators during laparoscopic hysterectomy for endometrial cancer has been a cause of concern that the instrument may push the malignant cells intraperitoneally upstaging the cancer as a retrospective study by Sonoda etal [4] (2001) suggested a higher incidence of 1988 FIGO Stage IIIa (positive peritoneal cytology) among women treated by LAVH. However a prospective study by Eltabbakh and Mount [5] found no such difference in a prospective study in 42 women with endometrial carcinoma who underwent Laparoscopic Hysterectomy using uterine manipulators.

A relatively higher positive peritoneal cytology was found in women who had laparotomy compared to laparoscopy in a study by Walker et al. involving 2616 women with endometrial cancer [6]. These patients were randomly selected for surgery either by laparotomy or by laparoscopy involving different uterine manipulators.

Diagnostic Laparoscopy and Final Site Recognition

25

Julia Serno

With diagnostic or exploratory laparoscopy a direct inspection of intraabdominal organs is possible. Primary access to the intraperitoneal cavity is usually accomplished through the umbilicus, either by direct trocar insertion (open laparoscopy) or by Veress needle placement. This is the most worrisome step in laparoscopic surgery as the surgeon has at this point no knowledge of intraperitoneal adhesions. There is no clear consensus as to the optimal method of entry into the peritoneal cavity [1]. In the open technique, a small subumbilical laparotomy is performed. Skin, rectus sheath, and peritoneum are then incised under direct vision followed by the insertion of a blunt trocar. After that a pneumoperitoneum is created [2]. The closed laparoscopic entry with the use of a Veress needle for insufflation followed by the blind insertion of a trocar is the most common approach used by gynecologists worldwide [3]. A nasogastric or orogastric tube should be placed in order to decompress the stomach prior to insertion of the Veress needle [4]. During the insertion of the needle two "clicks" can be felt, the first corresponds to the piercing of the anterior rectus sheath, the second to the piercing of the posterior rectus sheath and the peritoneum. An intraabdominal pressure of 20–25 mmHg should be administered to elevate the anterior abdominal wall for safety before inserting the first trocar. After the insertion of the first trocar, a scope is introduced to confirm the correct entry into the abdomen without CO_2 insufflation. Once safe entry into the peritoneal cavity is obtained, the pressure can be reduced to the working pressure (10–12 mmHg). All secondary ports should be introduced under vision. Transillumination of the abdominal wall with the endoscope can help identify superficial abdominal wall vessels. Moreover, the anterior surface of the peritoneal cavity should be inspected to locate and avoid injury to the epigastric vessels.

Patients who have had abdominal incisions which extended to or through the umbilicus have a higher risk for bowel adhesions to the anterior abdominal wall area. In this case it is recommended to place the Veress needle in the left upper quadrant (Palmer's Point). Raoul Palmer described this point as being "3 cm below the middle of the left costal margin" [5]. Thus, the risk of bowl injuries can be reduced [6].

The trocar placement depends on surgical indications, organ pathology, adhesions and adipose tissue distribution. A traditional trocar placement for many benign gynecologic surgeries is demonstrated in Fig. 25.1. Two 5 mm ports are inserted on the right and left side of the lower abdomen. In non-obese women with a normal sized uterus, hysterectomy can be performed using this trocar placement.

In more difficult cases additional trocars can be added for example on the right and left side of the umbilicus. With

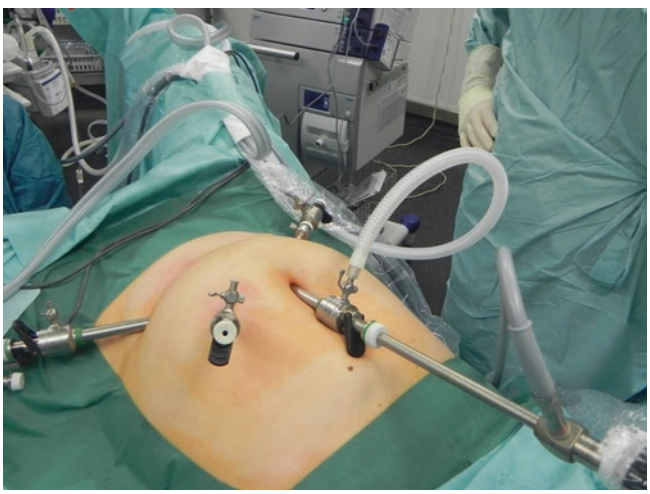

Fig. 25.1 The traditional trocar placement with two trocars on the right and left side of the lower abdomen is complemented by a trocar in the paraumbilical region

Fig. 25.2 Trocar placement for laparoscopic radical hysterectomy

large uteri or in oncological hysterectomies trocars are generally placed more superior (see Fig. 25.2).

During the course of diagnostic laparoscopy all visible peritoneal surfaces are inspected. The first step is to rule out any injuries that might have been caused by the Veress needle or by the blind insertion of the first trocar. After that the laparoscope can be turned and the upper abdominal organs are displayed (liver, stomach, spleen). After moving the patient in Trendelenburg position two graspers can be used to move the small bowel in the upper abdomen. Thus, a good vision of the pelvic organs is obtained. In case of suspected malignancy any free fluid should be aspirated or normal saline is instilled and then aspirated for cytologic examination [7]. In case of lower abdominal pain it is essential to check the appendix and sigma for signs of inflammation. To rule out unknown endometriosis the most common sites of involvement should be inspected, including the ovaries, the posterior cul-de-sac, the broad ligaments, the uterosacral ligaments, the recto sigmoid colon, the bladder and the distal ureters.

Final Site Recognition

At the end of every laparoscopic surgery the most common complications of laparoscopic surgery should be checked and ruled out (see Table 25.1). Gastrointestinal trauma may occur during the creation of the pneumoperitoneum or during the operative portion of laparoscopy [8]. Both types of injuries are more frequent in cases of previous surgery with present adhesions of the bowel [9]. One simple step to prevent delay in diagnosis is to view the initial trocar site through an alternative port if there is concern about anterior wall adhesions. The bowel close to the operating site should be checked for thermal injuries. Superficial thermal injuries to the bowel can often be repaired by a laparoscopic guided purse-string suture placed beyond the thermally affected

Table 25.1 Checklist final site recognition

Check for thermal injuries (bowel, bladder, ureter)
Check for pneumaturia or hematuria
Consider bladder installation of indigo carmine or methylene blue dye
Remove trocars under vision
Reduce the intra-abdominal pressure and check for (venous) bleeding

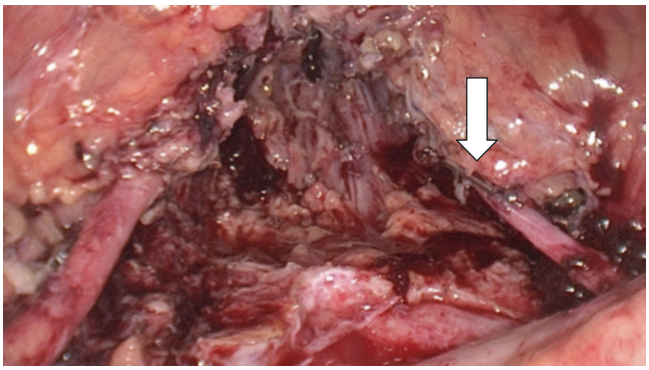

Fig. 25.3 Final site after radical hysterectomy. The veins in the uretric tunnel have been clipped (*arrow*) to avoid thermal damage

tissues. Thus, late onset perforation of the bowel with the risk of sepsis, multi-organ failure and even death can be prevented.

Significant bladder injuries usually result from the placement of a lower midline trocar. The surgeon should check the urine catheter for pneumaturia or hematuria which is a sign for potential bladder injury If a bladder injury is suspected, installation of indigo carmine or methylene blue dye into the bladder may help identify the site of injury. When an injury is noted, laparoscopic suture repair can be used to close the defect ([8], [10]).

Ureteral injury is a serious complication of laparoscopy and unfortunately, in most patients may not be diagnosed at the time of surgery. If injury is identified or suspected intraoperative ureteral stenting may be considered. For intraoperative prevention of ureteral injuries a thorough knowledge of the anatomy is mandatory. Using cautery or any kind of energy source close to the ureter should be avoided. Control of hemorrhage in the area of the ureters should be performed with surgical clips whenever possible (see Fig. 25.3).

All trocars should be removed under vision and it is good practice to inspect all secondary trocar sites for active bleeding before the laparoscope is finally withdrawn. The inspection should be carried out when the intra-abdominal pressure has been lowered, because the pneumoperitoneum can tamponade venous bleeding and by lowering the pressure, these vessels can be identified. In case of injuries to the epigastric vessels blood can be seen dripping down the trocar into the abdomen or haematoma formation can be detected around the trocar site. Minimal bleeding can often be controlled by coagulation of the parietal peritoneum above and below the

trocar. A Foley catheter can be passed through the trocar site and used as a tamponade. For moderate to severe bleeding, full thickness abdominal wall sutures can be placed under laparoscopic control both above and below the trocar site using a long and straight needle.

In case of minimal bleeding close to the rectum or the ureter the use of topical haemostatic agents can be considered. Several topical haemostatic agents are currently available in a range of configurations. They improve primary haemostasis, stimulate fibrin formation or inhibit fibrinolysis. Sometimes the procoagulant substance is combined with a vehicle such as collagen matrix.

General Aspects and Their Handling: Adhesions

26

Andreas Hackethal, Jörg Engel, Hans-Rudolf Tinneberg, and Sebastian F.M. Häusler

Introduction

Intraabdominal adhesions severely increase the risk of injuries to bladder, omentum, ureter or vessels followed by major blood loss. An enterotomie occurs in 20 % of cases followed by an impaired patient outcome [1]. Elis found, that one third of patients with intraperitoneal operations are readmitted an average of 2.1 times for a disorder directly or possibly related to adhesions, or for repeat surgery that could potentially be complicated by adhesions [2]. Additionally, adhesions are responsible for 65–75 % of small bowel obstructions which could be life threatening and evoke further need of subsequent surgical intervention [2–7]. Therefore, intraabdominal adhesions have a severe impact on the quality of life of many patients. Nevertheless, social and healthcare system associated impacts as well as the increasing burden of medicolegal claims linked to intraperitoneal adhesions and their consequences are often underestimated.

Adhesions result from wound healing processes after peritoneal injury (Fig. 26.1). Since early publications over 100 years ago, a variety of factors influencing mesothelial healing and adhesion formation as well as factors preventing adhesion formation have been discussed and identified [8–13].

Anticipation, Diagnosis and Considerations of Preoperative Intraabdominal Adhesions

To minimize the risk of adhesion related complications during abdominal entry, one of the key steps is awareness of adhesions and identification of patients with potential intraabdominal adhesions preoperatively. Hence, patients with previous abdominal trauma, histories of pelvic inflammatory or other chronic diseases warrant special attention.

Epidemiologic studies describe postoperative adhesion formation in 50–100 % of surgical patients [4, 15]. The adhesion prevention in gynecological surgery guideline by the Society of Obstetricians and Gynecologists of Canada (SOGC) summarizes in a statement that the risk of adhesion increases with the total number of abdominal and pelvic surgeries performed on one patient [16]. It is well known, that operative laparotomies result in more adhesions than operative laparoscopic approaches [17]. Additionally, adhesions were found more frequently after vertical midline incisions than after transverse suprapubic incisions (59 % vs. 29 %) [17]. Sepilian et al. identified umbilical adhesions after previous laparoscopy in 21 % [18].

The incidence of intraabdominal adhesions after gynecological surgeries is difficult to estimate. Apart from surgeons' experiences, studies with evaluation of adhesion-related complications might help to delineate the incidence.

Within three surveys amongst German, British and European gynecologists regarding their awareness and perceptions of adhesions and adhesion-related consequences, the respondents thought surgeries for endometriosis, adhesiolysis and myomectomy to highest likely be associated with adhesion formation [19–21]. However, the highest rate of readmission to hospital after open gynecological surgery was found after prior adnexal surgery [22]. Additionally, adhesion-related small bowel obstruction after hysterectomy was found to be a significant cause of re-admission to hospital within a Canadian retrospective study [23]. Muffly et al. found 17 small bowel obstructions (SBO) in 3229 hysterectomies within a retrospective analysis. SBOs were identified after abdominal hysterectomy in 9 of 17 (53 %), vaginal hysterectomies in 5/17 (29.4 %) and laparoscopic hysterectomies in 3/17 (17.6 %). The authors claim, that despite the clinical tendency there were no statistical significant differences within the surgical approaches [24].

It is a well-established fact that intra-abdominal adhesions and intra-operative complications increase with successive number of cesarean sections [25, 26]. In regards to adhesion prevention, a recent Cochrane analysis reviewed closure of the peritoneum versus non-closure of the peritoneum [27]. Data of 17,276 women does not support the additional operative time and suture material to close the peritoneum, since the evidence on adhesion formation was limited and inconsistent [27].

Furthermore, intraabdominal adhesions are often found in women with previous pelvic inflammatory disease and suspected or diagnosed endometriosis. Intraabdominal adhesions cause 15–20 % of female infertility and the most common morphologic changes seen in women with chronic abdominal pain are pelvic adhesions [28–30].

Additional to patient history and symptoms, the per vaginal examination might raise the suspicion for pelvic adhesions. Palpation of a fixed pelvic organs or a frozen pelvis, in absence

of other causes, may reflect pelvic adhesions. Demco analyzed pain scores of nature and location of adhesion during awake laparoscopy in 30 women. On a visual analogue scale, the highest pain was associated with filmy adhesions that allowed movement between two structures. Fixed adhesions that did not allow movement had the lowest pain scores [31].

To date, only sparse data exist on non-invasive imaging techniques to identify intraabdominal adhesions. However, certain real-time or functional imaging modalities can delineate intraabdominal adhesions. A literature review published in 2010 found 16 studies on transabdominal ultrasonography and cine-MRI which identified adhesions using visceral slide with accuracy of 76 % and 92 %, respectively [32]. The authors conclude that all but one study were biased by not being blinded and they suggest further double-blinded comparative studies to validate the results [32]. Seow and colleagues found a sensitivity of 90 and specificity of 100 % using three-dimensional transvaginal ultrasonography and level of CA12–5 to detect pelvic adhesions preoperatively [33]. More recently, Reid et al. reported on the transvaginal sonographic sliding sign and Kikuchi et al. evaluated the usefulness of the MRI jelly method to predict obliteration of the pouch of Douglas [34, 35]. A positive sign, signalizing no pouch of Douglas obliteration, is shown by gentle pressure with the transvaginal ultrasonography probe. In this case, the anterior rectum glides over the posterior vaginal wall and part of the cervix and the rectosigmoid glides over the posterior uterine wall [34]. Kikuchi et al. used ultrasonography jelly within vagina and rectum during MRI and found an increased sensitivity and specificity in identifying an obliterated pouch of Douglas [35]. However, both imaging modalities could not visualize filmy adhesions and adnexal adhesions.

As stated above, intraabdominal adhesions are a common finding during surgery and lead to a significant higher complications rate. In light of this, an adequate preoperative consent about possible adhesions and their consequences should be mandatory. Rajab et al. evaluated 200 surgical consent forms from 6 hospitals for the documented risk of adhesions related complications, which was only stated in 8.5 % of consent forms [36]. Similar results were found in two nationwide Dutch surveys. Only 5.2 % of Gynecologists and 9.8 % of General Surgeons reported to routinely include adhesion-related morbidity in the informed consent [37, 38]. In spite of the implications of adhesion-related complications, a standardized consent form was developed to educate patients adequately and document this process [39].

Apart from adequate preoperative patient consent, different presurgical measures have been examined to reduce potential adhesion related complications. Seow et al. suggested mechanical bowel preparation to decrease intraabdominal bowel volume and surgical complications [33]. More important are surgical steps during abdominal entry. Here, the site of entry should be adopted if previous laparotomies or laparoscopies have been performed or large pelvic masses are present. The Palmers point entry, 2 cm below the costal margin at midclavicular line left upper quadrant, can be considered as a safe entry approach, if no left upper quadrant abdominal surgery was performed previously [40, 41]. Additionally, a direct optical entry (DOE) was less time consuming and associated with less blood loss compared to an open entry [42]. Though the authors claim no statistical significance, the number of bowel and vascular injuries was 1/86 (1,2 %) in the DOE group compared to 10/82 (12,2 %) in the open entry group [42].

Surgical Management of Intraabdominal Adhesions

As intraabdominal adhesions result from wound healing, every attempt to lyse or dissect adhesions will likely re-form new adhesions. Data suggests the de novo-formation or reformation in 55–100 % of patients [43, 44]. Consequently, it is a valid question whether performing a full adhesiolysis during surgery should be mandatory, or whether exclusively the lysis of symptomatic or potentially symptomatic adhesions should be recommended. Studies from surveys underline, that Gynecologists agree, adhesiolysis should be performed in symptomatic patients [19, 21].

If patients lack symptoms and have no impairment of their quality of life, adhesions should not be treated [5]. However, in symptomatic patients, it is debatable whether to perform an adhesiolysis during diagnostic laparoscopy or not, as the impact of adhesiolysis cannot be predicted confidently. A well-recognized randomized controlled multicenter trial of laparoscopic adhesiolysis in chronic abdominal pain patients showed no significant differences in follow-up pain scores for patients with only diagnostic laparoscopy and those with performed adhesiolysis [45]. It is noteworthy, that patients with bowel obstructing adhesions were excluded in this study. In contrast, other studies have shown chronic abdominopelvic pain improvement rates after laparoscopic adhesiolysis of up to 84 % [46, 47].

Additionally, infertile patients with adnexal adhesions benefit from adhesiolysis. The pregnancy rate were 32 % after 12 month and 45 % after 24 month in the treated group compared with 15 % after 12 month and 16 % after 24 month in women left untreated [48].

It remains common sense that not the question of how many adhesions have been lysed, but rather, which adhesions have been lysed impacts on patients well-being.

Surgical adhesiolysis can be performed in various ways: sharp dissection with scissors with or without bipolar diathermy, with monopolar diathermy, with laser dissection or

blunt by traction and counter traction. In general, the latter is the most important step in adhesiolysis. Especially in laparoscopic surgery it is of outmost importance to define the adhesions and involved structures to minimize the risk of organ injury before dissection. We usually use traction and counter traction with a 3D movement of the adhesion to better define the involved structures and define the starting point of adhesiolysis. Studies evaluating the impact on the tissue and reformation of adhesions using these different approaches are lacking.

Strategies to Reduce Adhesions Reformation

The medical professional's awareness of intraabdominal adhesion formation is the key for adhesion reduction or prophylaxis. Therefore, numerous articles and statements concerning the burden of adhesions and strategies for prevention have been published especially within the last few years. The Practice Committee of the American Society for Reproductive Medicine (ASRM) with the Society of Reproductive Surgeons (SRS) published a committee statement concerning pathogenesis, consequences and control of peritoneal adhesions in gynecologic surgery [49]. The Society of Obstetricians and Gynecologists Canada (SOGC) summarized recommendations of adhesion prevention in Gynecology in a guideline published in 2010 [16]. On behalf of the European Society for Gynecological Endoscopy (ESGE), a consensus paper has been published to guide gynecologists in "state of the art" handling of adhesions and to fulfill their duty of patient care [50, 51].

Additionally, a recent Cochrane review analyzed Cochrane data on adhesion prevention agents for gynecological surgery [13].

Apart from individual patient characteristics and the impact of surgical procedures on adhesion formation, the main focus of adhesion prophylaxis comprises surgical technique and barrier methods.

Recognizing that no prevention of adhesions is possible, most authors agree that their formation can be reduced with good surgical practice to minimize tissue trauma and diminished placement of foreign materials in the peritoneal cavity [14, 15, 49, 50, 52, 53]. It is understood, that good surgical technique comprises gentle tissue handling, meticulous hemostasis, excision of necrotic tissue, minimizing ischemia and desiccation, the use of fine, nonreactive suture materials and prevention of foreign body reaction and infection (Table 26.1) [14, 16, 49].

Table 26.1 Good surgical practice [14]

Gentle tissue handling
Meticulous hemostasis
Excision of necrotic tissue
Minimizing ischemia and desiccation
Use of fine, non-reactive sutures
Prevention of foreign body reaction
Prevention of infection

An experimental study by Kraemer et al. analyzed different surgical trauma and their impact on inducing peritoneal adhesions in rats [54]. Brushing of the parietal peritoneum and bipolar coagulation of the peritoneum were the least adhesiogenic trauma. Highest rates of adhesions were found after traumatizing with electrocoagulation of the peritoneum and defect closure with Vicryl sutures [54].

Surgical separation of wound sites, i.e., transient ovariopexy in surgical excision of severe endometriosis, is helpful in reducing adhesion formation and improving fertility outcomes [55, 56]. Interestingly, a recent systematic review and meta-analysis concludes however, that the two main adhesion-related outcomes, small bowel obstruction and infertility, are not reduced by less-invasive techniques or introducing less foreign bodies [57].

Reducing peritoneal adhesions is attempted by various strategies. Pharmacological, mechanical and other adhesion prevention strategies are summarized in Table 26.2.

In recent decades, the armamentarium of commercially available anti-adhesion products has increased. Generally, anti-adhesion agents aim to either reduce the inflammatory response after surgery or act as direct or indirect physical barrier on surgical sites. Reduction of inflammatory response, as example, might be achieved by Non-steroidal antirheumatics or steroids, physical barrier by modified hyaluronic acid or modified cellulose.

Surveys examining the awareness for intraabdominal adhesions in health care practitioners underline that there is uncertainty in the treatment and prophylactic strategies in dealing with adhesions [10, 19, 55].

The American Society for Reproductive Medicine concludes that FDA-approved surgical barriers have been demonstrated effective for reducing postoperative adhesions, but not having an impact on clinical symptoms [49]. The European field guideline for gynecological surgery states, that the implementation of good surgical practice, together with the adoption of adhesion-reduction agents, is paramount to reduce adhesion formation [12]. The Society of Gynecologists and Obstetricians Canada recommends that surgeons could consider using an adhesion barrier for patients who are at high risk of forming clinically significant adhesions [16].

A recent Cochrane review analyzed previous Cochrane reviews on adhesion prevention agents for gynaecological surgery and concludes that there is insufficient evidence to draw any conclusions about the effectiveness and safety of anti-adhesion agents in gynaecological surgery, due to the lack of data on pelvic pain, fertility outcomes, quality of life or safety [13].

Table 26.2 Different pharmacological, mechanical, and other adhesion prevention strategies [10, 56, 57]

Pharmacologic	Ileus prophylactics	*Exogenic tissue*
Anticoagulation	Plication of the intestines (Noble)	Amnotic membrane
Dicumarol	Plication of the mesentery	Fish bladder
Heparin	Intestinal catheter	Gel Photopolymerization
Hirudin	**Suface isolation**	Gore Tex
Oxalate	*Insufflation*	Rubber- and Plastic film
Citrate	Pneumoperitoneum	Bowine peritoneum
Fibrinolysis	*Instillation*	Polytetrafluoroethylene membrane
Actase	Agar	Silk
Chymotrysin	Albumin	Silver- and Gold films
Hyaluronidase	Amnotic fluid	Cellulose and Gelatine films
Calcium antagonists	Chymus	Oxygenized cellulose
Papain	Dextran	*Others*
Pepsin	Ironhyaluronidase gel Intergel	Allopurinol
Plasminogen activator	Electrolyt fluids	Aprotinin
Protoporphyrin	Gelatine	Chinese herbs
Streptokinase	Vitreous body fluid	Fibrin glue
Typsin	Gycot	Infrasound
Urokinase	Honey	Moor mud wrap
Reduction of fibrosis	Sodium Hyaluronate/ Carboxymethylcellulose	Peristaltics
Anti histaminics	Hydroxyethylstark	Progesterone
Cochicin	Lanoline	Prostacycline
Non steroidal antirheumatics	Olive oile	Superoxiddismutase
Steroids	Paraffine	Tetrachlorodecaoxide
Vitamin E	Phosphatdicholine	**Others**
Cytostatics	Polysiloxan	Ultrasound to stimulate motility
Antibiotics	Polyvinylpyrrolidon	Iron turnings to stimulate bowel motility by external magnets
Antiseptics	Silicone	
Procinetics	Vaseline	
Cisapride	*Autolouge tissue*	
Neostigmine	Bladder	
	Omentum	
	Peritoneum	
	Mesenchymal stem cells	

Conclusion

Intraabdominal adhesions are the most common complication of abdominopelvic surgery. Surgeons' awareness is crucial and should include an adequate preoperative patient counsel. Apart from good surgical practice and continuous education on new surgical strategies to reduce adhesions, results of anti-adhesion products in randomized trials are difficult to obtain and interpretation may be influenced by various factors. It is understood, that not the number of adhesions within the abdomen but rather the clinical impact of adhesions on the patients well-being plays the important role. Though the scientific results of adhesion reduction are promising, the regular use of these agents in clinical practice is mostly uncommon and health care providers mostly do not refund the cost of anti-adhesion products adequately.

Strategies to identify adhesions with clinical impact and classifications of adhesions at the beginning and the end of surgery could eventually help to generate more robust data to define useful adhesion reduction strategies with and without agents.

Comorbidities

27

Ralf Rothmund

Clinical Comorbidity

It can generally be said that a laparoscopic or vaginal approach should be chosen where possible in the presence of serious concomitant disorders, since the intraoperative and postoperative stresses especially are relatively minor compared to those of open surgery. Convalescence usually proves to be correspondingly quick and straightforward.

The duration of surgery, as well as the intra- and postoperative complication rates, increase in obese patients compared to groups of patients of normal weight [1, 2]. The duration of surgery increases further in cases of extreme obesity, as does the risk of severe complications. It is these patients who particularly benefit from a laparoscopic approach [3] when a vaginal hysterectomy is not technically feasible [4, 5].

The technique of the surgical intervention itself remains unchanged in patients with severe obesity; however, the placement of the first trocar is extremely important in these patients. The risk of preperitoneal insufflation is higher in obese patients especially if a Veress-needle is used for insufflation. Therefore, the use of a trocar that enables the insertion of the optic device before CO_2 insufflation is recommended (see Table 27.1). While the surgical technique of hysterectomy in patients with obesity unchanged remains compared to normal weight patients, the surgeon is often constrained to operate with a reduced insufflational pressure and consequently a limited view of the neighbouring structures. In patients with severe obesity the combination of Trendelenburg-positioning and high intraabdominal pressure leads to a higher ventilation pressure. The surgeon is thus forced to work with lower intrabdominal pressure (10–12 mmHg) in order to enable a sufficient ventilation pressure (see Table 27.1). If the respiratory capacity of the patient is further limited by additional factors (e.g. COPD) a laparoscopic approach becomes impossible in some cases [6]. Hence, a COPD might become a limiting factor for the laparoscopic hysterectomy if sufficient intraoperative ventilation is not possible. In contrast, the presence of hypertension, a diagnose that often confounds with obesity, is managed perioperatively by the anaesthesiologist and has no direct implications for laparoscopic hysterectomy (see Table 27.1).

Obesity and diabetes are important risk factors for the development of postoperative infections and sepsis after abdominal hysterectomy. However, the risk of developing postoperative infection or sepsis after a laparoscopic hysterectomy is not increased for obese patients compared to patients of normal weight [7–10].

Table 27.1 Appropriate risk and management

Risk Factor	Intraoperative management	Postoperative management
Obesity	Adaption of the entrance technique (e.g. go without Veress-needle) Lower insufflational pressure	Venous thromboembolism prophylaxis
Chronic obstructive pulmonary disease	Lower insufflational pressure	Monitoring of the lung function
Hypertension	Regulation of blood pressure	Regulation of blood pressure
Diabetes	Monitoring of blood sugar	Monitoring of blood sugar Possible antibiotic prophylaxis in case of coexisting obesity
Deep infiltrating endometriosis	Adaption of preparation technique (e.g. retroperitoneal entrance in analogy to radical hysterectomy; nerve sparing technique) Surgery in dedicated centres	Monitoring of bladder and bowel function

In several studies, obesity was associated with a longer duration of surgery; however the intra- and postoperative complication rates were not increased [11–15].

Thromboembolism occurs less commonly after laparoscopic hysterectomy than after abdominal hysterectomy. It can therefore be concluded that a laparoscopic approach should be chosen where possible if there are risk factors for the development of thromboembolism, naturally in accordance with thromboprophylaxis guidelines [16].

Comorbidities such as obesity, smoking and diabetes do not increase the risk of vaginal cuff dehiscence [17].

Coexistence of Deep Infiltrating Endometriosis or Frozen Pelvis
(See Figs. 27.1, 27.2 and 27.3)

Vaginal cuff dehiscence occurs more commonly where there is coexisting deep infiltrating endometriosis [18]. The presence of deep infiltrating endometriosis, especially in the retrovaginal fascia or the parametrial area, makes laparoscopic hysterectomy considerably more difficult. It is then necessary to adapt surgical dissection along the lines of a radical hysterectomy (see Table 27.1). Careful dissection of the ureters and distancing of the rectum from the posterior vaginal wall to avoid injury to the ureters or minimise the risk of fistula development between the rectum and vagina are particularly important in these cases. These procedures, with their significantly increased level of complexity, should only be performed in suitably qualified centres wherever possible.

General Surgery Conditions and Techniques for Gyne-Endoscopic Surgeons

28

John E. Morrison

Abdominal and Pelvic Wall: Hernias

The abdominal wall from the umbilicus superiorly to the symphysis pubis inferiorly and laterally to the iliac crests is an area that can be the site of abnormalities that are encountered either upon entering the abdominal cavity or be identified during the performance of laparoscopic procedures. The different techniques used to enter the abdomen are not within the scope of this chapter, but some of these abnormalities when encountered in the abdominal wall may make safe access a challenge.

The most commonly performed surgical procedure by general surgeons is hernia repair. Approximately 800,000 inguinal hernia repairs and over 200,000 incisional hernia repairs are performed yearly in the US. Primary hernias occur most commonly in the anterior abdominal wall either at the umbilicus or in the inguinal canal. They also may be present lateral to the rectus sheath at the linea semicircularis, the Spigelian Hernia however this is an uncommon type of defect.

The diagnosis of small incisional or inguinal hernias may be difficult preoperatively particularly if the patient is obese or the defect is small, and their presence may not be certain until insufflation is achieved.

Large hernias on the other hand are usually diagnosed preoperatively through a thorough physical exam, or by preoperative imaging, however in the morbidly obese patients this can be a difficult task. When an incisional hernia is suspected, CT scan of the abdomen and pelvis without contrast is the most sensitive imaging exam for hernia defects and is routinely performed to assess the size and number of defects in order to better plan operative repair and safe access into the abdomen.

The treatment of hernias differs depending on the symptoms, location, size and etiology so their diagnosis, location and size are crucial to planning appropriate care.

Umbilical Hernias

Primary umbilical hernias are usually diagnosed preoperatively and may be symptomatic particularly when small. If abdominal entry is planned through the umbilicus, an open (Hasson) technique is preferred because the fascial defect is already present and can be easily closed when exiting the abdominal cavity. Direct entry through the umbilicus when a hernia defect is present can be a very dangerous task, as omentum or bowel can easily be included in the hernia defect and as such can be injured with the Veress needle or visual port entry device. It is not uncommon for adhesions to form at the hernia site even without prior surgery so caution is advised. See Fig. 28.1.

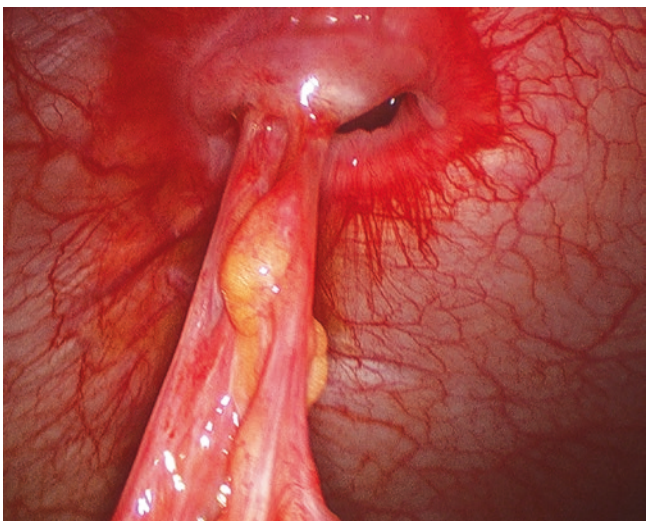

Fig. 28.1 Primary umbilical hernia with adhesions in a patient that has not had previous surgery

Defects 2 cm or less in diameter are closed primarily with permanent suture and do not require mesh reinforcement. The suture chosen is usually a permanent material, polypropylene, or polyester, size 0, and the fascial edges approximated using simple or mattress suture techniques.

If the patient has had an umbilical hernia repaired previously and it is recurrent, then the defect is usually closed utilizing a reinforcing synthetic mesh material. There are several devices available which are designed specifically for these repairs. One such design is C-QUR V-Patch manufactured by Atrium corp. (Fig. 28.2) which is a circular polypropylene mesh coated with omega 3 fatty acid and is placed in the defect then sutured lateral to the fascial edges making certain that the mesh extends at least 3 cm from the fascial edge in all directions. The defect is then closed primarily over the reinforcing mesh.

Any mesh placed intrabdominally should have a barrier substance on the surface of the mesh coming in contact with the underlying bowel in order to reduce adhesions to these structures. Several products exist that have absorbable material incorporated onto the mesh to provide this barrier. If the reinforcing mesh is placed extraperitoneally then barrier material is not necessary.

Tips

Primary umbilical hernias 2 cm or less, close primarily with permanent suture.

Fig. 28.2 Circular polypropylene mesh with barrier coating manufactured by Atrium Corp

Recurrent umbilical hernias or larger than 2 cm: repair with mesh reinforcement.

Mesh should extend at least 3–5 cm from the fascial edge.

Entry into abdomen through umbilical hernia: open technique is safest.

Incisional Hernias

Patients that have had any prior abdominal surgery are potential candidates for incisional hernias. There are approximately 250,000 incisional hernia repairs performed in the US yearly [1]. If the patient is found to have an incisional hernia, then the surgeon can usually anticipate more than one defect being present in the incision. The majority of incisional hernia defects are asymptomatic when they are small <1 cm Defects between 2 cm and 6 cm usually are symptomatic, and are repaired using a reinforcing synthetic material when they are encountered. There is no difference in treatment of incisional hernias with regards to their location in the abdominal wall whether above or below the umbilicus.

Large defects in the fascia are most often identified on physical exam but the most sensitive method again for diagnosis and measurement of the defect is a CT scan of the abdomen and pelvis.

Primary repair of incisional hernias without reinforcement of mesh has an unacceptably high recurrence rate [2]. The choices for reinforcement material are either synthetic or biologic. There are certain conditions where the biologic grafts have distinct advantages over synthetic materials but discussion of this topic is out of the scope of this chapter.

Most 2–8 cm incisional hernia defects currently are repaired using the laparoscopic approach. The repair most commonly utilized is referred to as a "bridge" repair where the defect is covered by mesh and the fascial edges are not reapproximated. The fascial defect may be primarily approximated and then covered with mesh but this technique is used less commonly. In both instances a reinforcing material is used.

When an incisional hernia defect is encountered during an "open" procedure, the fascia is closed primarily with suture, either permanent or long lasting absorbable suture, with synthetic mesh reinforcement. The synthetic mesh can be placed either (1) under the abdominal wall on the peritoneal surface in which instance the material should have an adhesive barrier, or (2) Between the posterior rectus fascia and anterior rectus muscle and fascia (retro rectus) or (3) as an onlay where the mesh is simply anchored to the abdominal wall covering the reapproximated midline incision and extending laterally at least 5–8 cm from the midline. The onlay method is the easiest and safest approach. See Fig. 28.3.

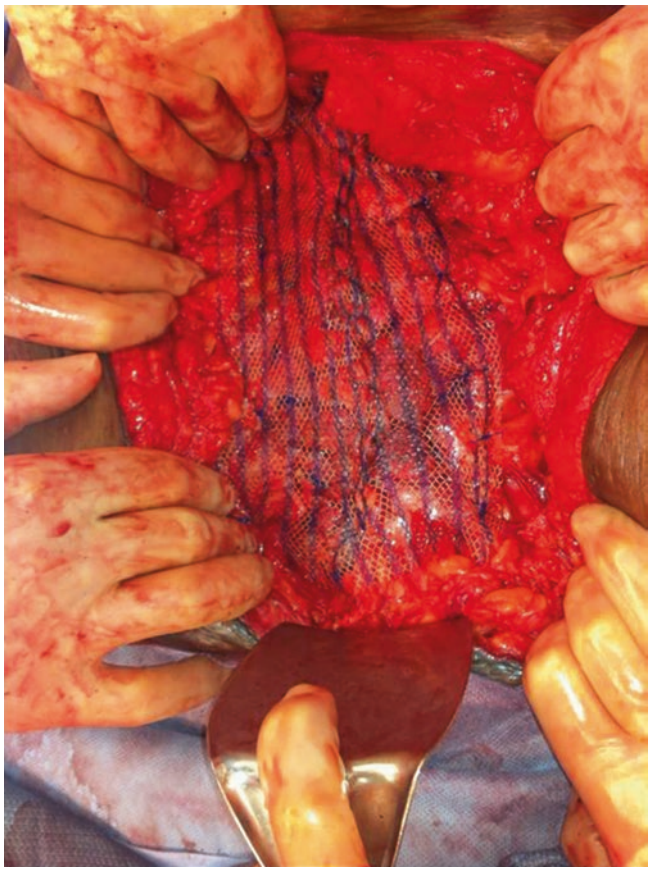

Fig. 28.3 Light weight polypropylene mesh lying over fascial closure

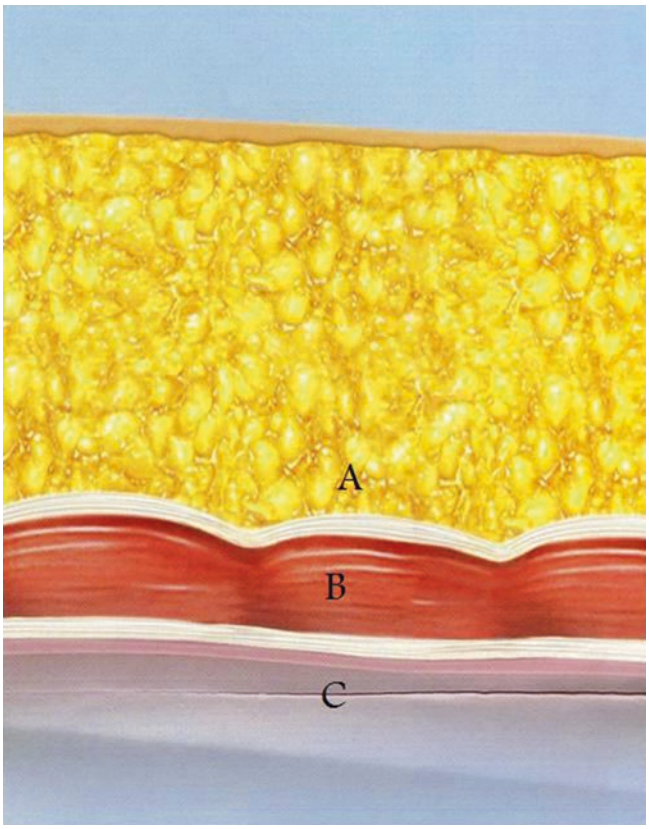

Fig. 28.4 Diagram of abdominal wall: (**A**) area where onlay graft is placed (**B**) area where retrorectus mesh placement occurs (**C**) area where underlay mesh placed and laparoscopic mesh placed

Figure 28.4 demonstrates commonly used sites for mesh placement. A: is where an onlay graft is placed. B: is where an inlay graft is placed. It usually lies between the fascia and muscle layers of the abdominal wall. C: is an underlay. Site C is the site where placement of laparoscopic mesh is usually performed.

Synthetic Materials Used for Repair

The materials used in these repairs must have certain properties:

First: the material must have the strength to tolerate pressures that are generated in the abdominal and pelvic cavity.

There are several studies currently ongoing that are addressing the most accurate way of determining the actual pressures generated in the abdominal and pelvic cavities and thus what strength characteristics the synthetic material must have in order to maintain an adequate repair. Over the past several years the density and structure of the synthetic mesh material used has undergone significant change. The main change is one of thinner, lighter weight materials with large pore structure for flexibility and easy incorporation into the abdominal wall tissues.

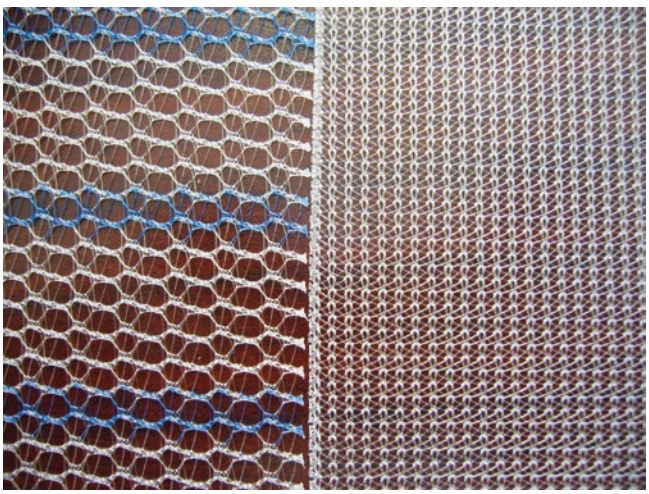

Fig. 28.5 Lightweight polypropylene mesh on left. Medium weight polypropylene mesh on right

Figure 28.5 demonstrates the two most commonly used polypropylene mesh types. The mesh on the left is a light weight mesh and the material on the right of the figure is a medium weight material. The differences are a combination of pore size and weight of the material used. The trend now

is to utilize lighter weight materials however in large incisional hernia repairs tearing of this lightweight mesh is being seen with more frequency and there may be a return to using medium or heavier weight materials.

Second characteristic is that the material must adhere securely to the abdominal wall. The material is anchored either with suture or tacking devices or a combination of the two. The anchoring devices assist in preventing slippage of the material while it is being incorporated onto the abdominal wall. Depending on the physical properties of the material used, the mesh elicits a reaction that results in scar formation around the material that also assists in incorporation of the material into the abdominal wall and adding to the strength of the repair.

Third characteristic and one of the most important characteristics is that the material must possess a property that reduces adherence to the bowel and any underlying structures. The mesh must have secured onto it a barrier device that helps reduce adherence to the underlying bowel if it is placed intraperitoneally. Synthetic mesh placed into the abdominal cavity without any barrier carries a risk of erosion into the bowel or any other structure it comes in contact with and thus fistula formation. If this does occur then the synthetic mesh must be removed and the fistula closed. Replacement of the mesh by synthetic materials in this situation is not recommended and a biologic material is usually needed.

Fourth characterisitc is that the material should elicit a minimal inflammatory or immunologic response. Research is ongoing in this area and materials are constantly being tested and refined to reduce this reaction.

Fig. 28.6 Polypropylene mesh with barrier incorporated onto mesh for intraabdominal placement

Fig. 28.7 Microporous PTFE mesh for intraabdominal repair

Materials for Repair

The most frequently utilized synthetic material in hernia repairs is polypropylene mesh. Figure 28.6 is an example of a coated polypropylene mesh used for hernia repair when the mesh is placed intraabdominally.

Polypropylene has been used for decades and because surgeons have a long experience and great familiarity with it, it is the preferred mesh material. Because of the hydrophilic nature of the material it does result in the formation of a fibrous capsule which can become firm over time and a source for pain but with reduction of polypropylene mesh weight, this phenomenon is becoming less of a problem.

PTFE (polytetrafluorethylene) is another material utilized in hernia repair in the abdomen. It has properties of minimal adherence to surrounding tissues, and flexibility, but because of its propensity for nonadherance, other materials must be incorporated into the mesh in order to make it adhere to the anterior abdominal wall. Otherwise the material is not incorporated and the repair not secured. Figure 28.7 is an example of a PTFE mesh used for hernia repair.

The PTFE mesh is a micro porous material, so seroma formation above the mesh and below the overlying skin and subcutaneous tissue after bridge repair is not uncommon. These seromas usually are asymptomatic and over time resolve, however if they become infected or symptomatic they can be drained percutaneousely or if mature excised after adequate incorporation of the underlying mesh has occurred. Seroma formation is not uncommon after any bridge type repair regardless of the material used. See Fig. 28.8.

When PTFE material is used for repair if an overlying seroma or the material itself becomes infected, it must be removed. The pore size is such that bacteria are able to enter the mesh but neutrophils cannot so the resulting infection cannot be cleared without mesh removal.

All grafts contract over time, but PTFE grafts do contract the most when compared to other synthetic materials, so this characteristic must be taken into consideration when placing the material and ensuring adequate overlapping of the defect [3].

Polyester mesh is also utilized for hernia repair but less frequently. The material is a woven braided polyester fiber that incorporates into the surrounding tissues well. This material has been used for decades in the manufacture of vascular grafts, so its use has a long history in surgery and thus experience with this material is large. It is a hydrophilic material so

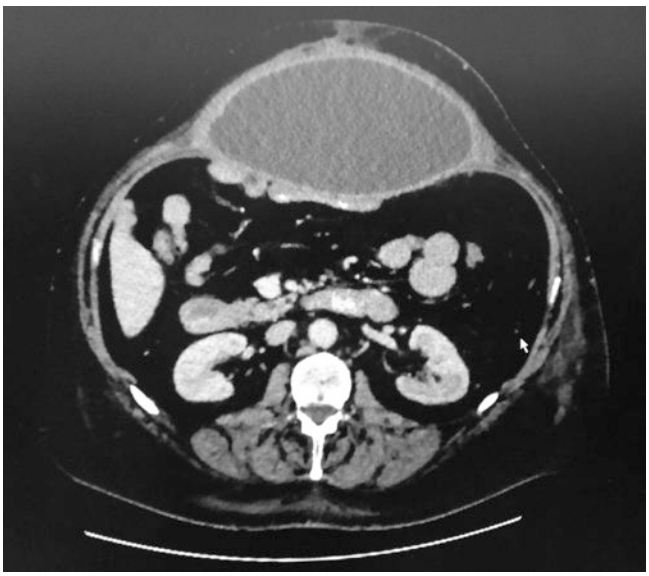

Fig. 28.8 Seroma over mesh under skin of abdominal wall

it does not elicit the intense fibrotic reaction that polypropylene does, but as with any braided material if it does become contaminated with bacteria or infected, it is difficult to clear of bacteria so it may require excision if this does occur.

When and How for Incisional Hernia Repairs?

Defects 2 cm or less may be repaired primarily with permanent suture material as in umbilical hernia repair.

Hernia defects >8 cm may require mobilization of anterior abdominal wall fascial layers with reinforcement by synthetic or biologic material in order to reapproximate the midline fascial edges and restore a dynamic abdominal wall.

To accomplish this there are a number of options which include relaxing incisions in the external oblique muscle bilaterally or in the posterior rectus fascia and transverse abdominal muscle layers in order to mobilize the fascia to get the midline fascial edges together. Discussion of this type of repair is out of the scope of this chapter and these large defects should be **referred** for definitive repair either before gynecologic procedures are performed or preferably repaired at the time of gynecologic surgery by a General Surgeon or Plastic Surgeon familiar with these type of repairs.

The treatment of choice for repair of incisional hernia defects from 2 cm to 6 cm currently is via laparoscopy and is usually performed at the end of other surgical procedures. The mesh should overlap the defect by at least 3 cm preferably up to 5 cm or more on all edges and be anchored to the abdominal wall. If during the primary operative procedure the bowel is entered, gross contamination with infected material is encountered or the vagina or bladder are entered, and an incisional hernia repair is considered, then the use of synthetic mesh is discouraged and biologic graft used in its place. Biologic grafts may be used in a bridge repair or as a reinforcing material to primary closure but there are no good studies to gauge its long-term success and these materials are very expensive.

Procedure for Repair of Incisional Hernia

All contents in the hernia defect must be reduced into the abdominal cavity and the surrounding fascial edges cleared of overlying tissue, bowel and fat in order to ensure adequate incorporation of mesh into the abdominal wall fascia. Figure 28.9 demonstrates a defect prepared for repair.

The material chosen for repair must have an adequate size in order to overlap all aspects of the defect by 5 cm or more and have a barrier for reduction of adhesions.

If the defect is large and a large piece of mesh is needed for coverage, sutures are placed at the four quadrants of the mesh; the sutures are retrieved through the abdominal wall to align the mesh adequately over the defect for final anchoring of the mesh. These sutures can be used to primarily anchor the mesh to the abdominal wall. Figures 28.10 and 28.11 demonstrate the mesh with anchoring sutures and retrieval of the sutures through the abdominal wall.

The mesh is then anchored to the abdominal wall with either suture, or tacking devices or a combination of the two. Particular attention is addressed to the edges of the mesh in order to ensure that adequate anchoring of the mesh has taken place and the possibility of bowel herniation between the mesh and abdominal wall tacks does not take place. Figure 28.12 demonstrates anchoring of the mesh with a permanent tacking device.

Abdominal binders are usually placed on the patient immediately postoperatively to give support to the abdominal wall and reduce pain. It is recommended that the patients wear such devices for 6 weeks or more after surgery.

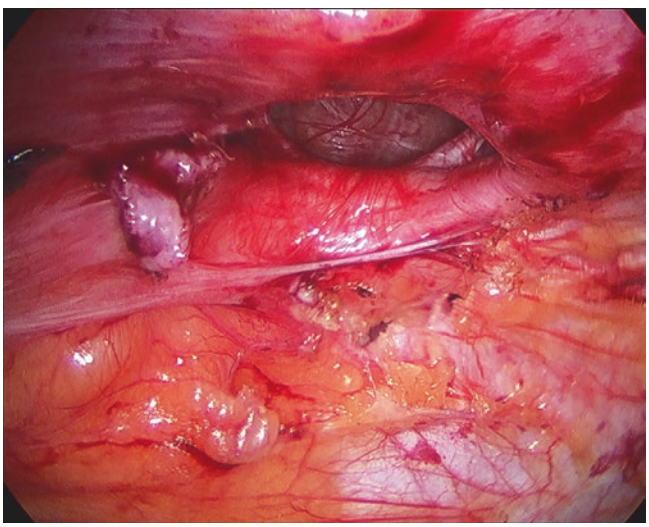

Fig. 28.9 Incisional hernia with adhesions, bowel and fat cleared for placement of mesh on fascia and peritoneum

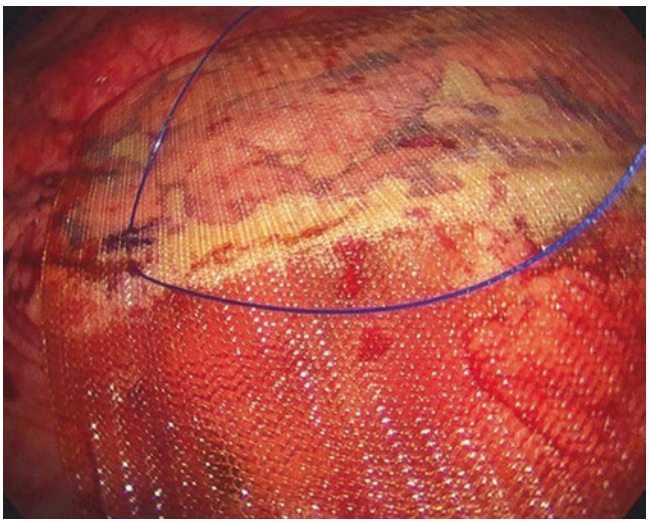

Fig. 28.10 Mesh intraabdominally with suture loop for placement

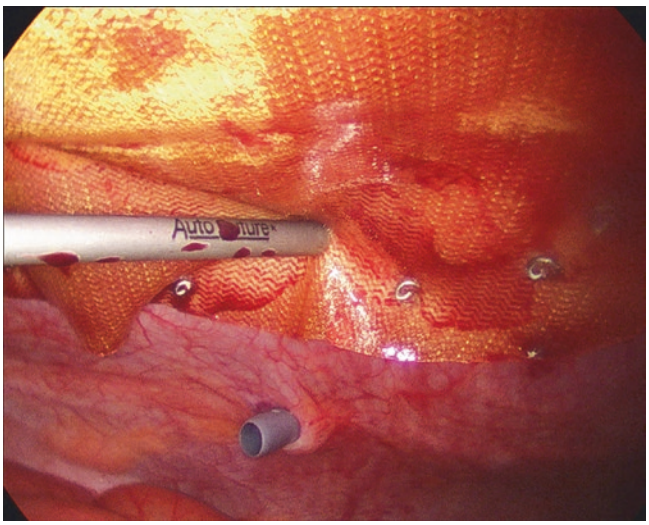

Fig. 28.12 Permanent tacking device securing mesh to fascia

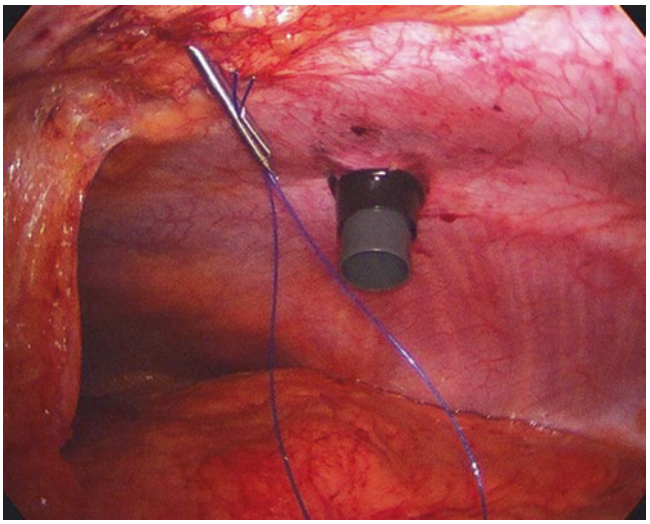

Fig. 28.11 Grasping suture loop to bring mesh under hernia defect for anchoring

Results with laparoscopic bridge repair of incisional hernias have been very good with comparable low recurrence rates when compared to open repair, but with higher major intraoperative complication rates when compared to open repair. Patients do return to normal activities sooner, have less pain and hospital stay is shorter [4].

Special Considerations After Hernia Repair

If a patient has had prior hernia repair utilizing mesh, then special consideration must be given for safe entry into the abdomen. Despite the application and incorporation of adhesive barriers into the mesh, or even if the mesh is completely covered by peritoneum, the presence of adherent bowel or omentum to the mesh and particularly to the edge of the mesh should be expected.

Entry into the abdominal cavity can be accomplished in these instances either by remote entry i.e. Palmer's Point in the left upper quadrant or other sites outside of the prior surgical field. Entry can also be accomplished through the mesh itself. If a laparoscopic procedure is planned, then open (Hasson) technique is recommended either directly through the mesh utilizing careful blunt dissection of adherent bowel and omentum away from the mesh as the abdominal cavity is entered or at a remote site lateral to the prior incision. Extreme care must be taken around the edges of the mesh as this is the area most involved with adhesion formation. Figure 28.13 demonstrates adhesions at the edge of a previously placed mesh.

Once the procedure is completed, upon closure of the incision if it was made through the mesh, the closure should be accomplished with permanent suture.

Repair of complex incisional wall hernia defects may involve the use of biologic grafts intraabdominally or with an onlay over the anterior fascia. The biologic materials used currently consist of an acellular matrix of collagen and come in a variety of substances. The matrix is infiltrated with fibroblasts over time and the hosts' native collagen incorporated into the matrix resulting in a thick scar. In complex hernia repairs, if a biologic graft is used internally, opening directly through the material is recommended with the same considerations and precautions being taken as recommended with opening through synthetic material for abdominal entry.

As discussed above, complex hernia repairs are being performed with primary closure and with combinations of onlay mesh, inlay (between the layers of the abdominal wall) and underlay mesh. It is strongly recommended that the surgeon obtain prior operative notes in order to be familiar with the repair performed so entry into the abdomen can be accomplished safely. A prior knowledge of where the mesh was placed helps makes this possible.

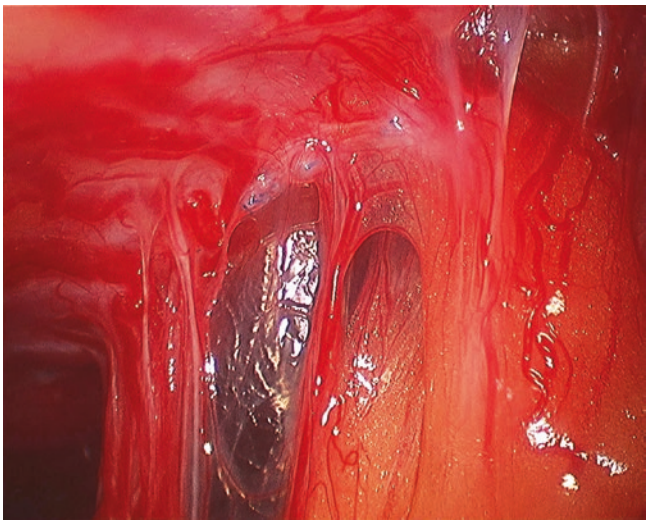

Fig. 28.13 Dense vascular adhesions seen at the lateral border of previously placed mesh

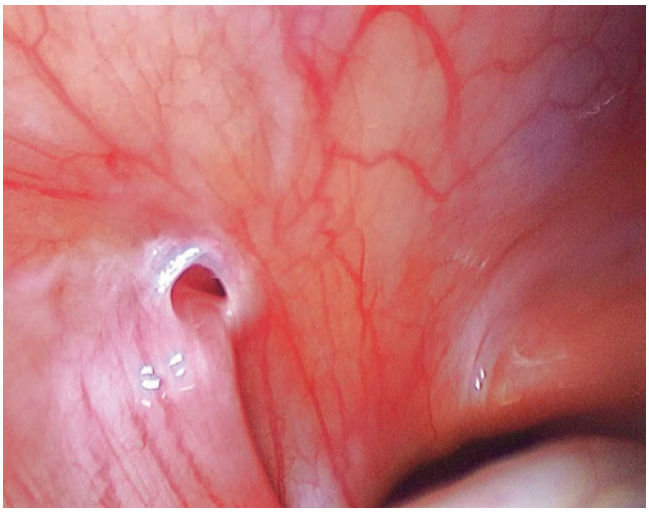

Fig. 28.14 Small indirect hernia on the left inguinal area with round ligament in defect

Tips

2 cm or less defects: close primarily with nonabsorbable suture.

2–8 cm defects: Laparoscopic bridge repair with synthetic material with adhesive barrier. Anchor to the abdominal wall with tacking device and overlap fascial edges 5 cm.

2–8 cm defects: Open repair, reapproximate the fascial edges and incorporate synthetic mesh reinforcement either intrabdominally, subfascial or overlay the midline closure.

Defects larger than 8 cm usually require a more complex repair for closure of the midline fascia and should be performed in conjunction with surgeons familiar with these repair techniques.

When entering the abdomen after prior incisional hernia repair with mesh, enter either through the center of the mesh with caution or at distant point and avoid the edges.

Know beforehand what type of repair was performed on the patient prior to entry to help anticipate when the mesh will be encountered in opening.

Inguinal Hernias

Inguinal hernia defects, when seen during laparoscopy are located in the pelvic side walls lateral to the obliterated umbilical veins. The two most common types of inguinal defects are direct and indirect hernias. Direct defects are medial to the inferior epigastric vessels and indirect defects are lateral to these vessels. The indirect defects can also be identified by the presence of the round ligament in or medial to the defect. Figure 28.14 is an example of a small asymptomatic indirect inguinal hernia and does not require repair.

Symptoms of inguinal hernia include: swelling or bulge in the inguinal floor usually superior to the inguinal ligament. It may or may not be associated with pain. Pain in the area of the inguinal ligament may be the only symptom or sign of a hernia. Inguinal hernias are more difficult to diagnose in females as compared to males. The dilemma is when the hernia is identified at the time of surgery what needs to be done?

Tip

If an inguinal defect is identified and the patient is asymptomatic i.e. the patient does not have inguinal pain, then the defect is noted, the patient is informed but repair is not necessary.

When a single symptomatic inguinal hernia defect is discovered, the choice of repair technique is controversial among surgeons. Patients with a single inguinal hernia are still most commonly repaired using standard open technique. In single surgeon series, the recurrence rate with laparoscopic repair is comparable to open repair and pain scores much better [5]. In large studies, results with laparoscopic repair show slightly higher recurrence rate, but pain scores and return to normal activity was better in the laparoscopic group versus open [6, 7].

Cost must be taken into consideration when choosing a repair, but when evaluated, there is little difference in operating room costs but there can be large differences in facility reimbursement [8].

The laparoscopic repair of inguinal hernias can be either performed entirely preperitoneal or transperitoneal. The principles of the repair and results are similar for both techniques. The anatomy of the inguinal canal and pelvic floor is constant, predictable and familiar to the gynecologic surgeon that performs anterior vaginal wall repairs or vesico-urethral neck suspensions such as Burch procedure. This is the same space routinely dissected and entered in a laparoscopic inguinal hernia repair (Video 28.1).

In either repair, the peritoneum is dissected from the lower pelvic and inguinal floor exposing the inguinal canal, iliac vessels, pubic tubercle, femoral canal and lateral inguinal side wall. It is important to completely reduce the hernia

contents into the preperitoneal space. Simply closing the peritoneal defect is inadequate for repair; the inguinal floor must be reinforced with synthetic materials.

The mesh dimensions should be 10 cm by 15 cm in order to adequately cover, the inguinal floor and all potential defects. If polypropylene mesh is used, then this material should be anchored to the inguinal floor. Care must be taken when anchoring the mesh to avoid the major vascular and neural structures that are in the dissection site as injury to these structures is possible.

Anchoring of mesh should only be performed medial to the inferior epigastric vessels on the anterior lower abdominal wall and into the symphysis pubis and Cooper's ligament. Tacking devices should not be utilized in the lateral pelvic side wall as the genitofemoral and ilioinguinal nerves are present and can be easily trapped causing significant postoperative pain.

If polyester mesh is used for repair, because of the hydrophilic nature of the material, the mesh adheres to the underlying tissues well and does not need to be tacked if the repair is performed in a preperitoneal fashion. Results with this type of repair are very good and as such problems with tacking are avoided. Figure 28.15 demonstrates coverage of the inguinal floor with mesh at the end of a repair.

Femoral hernias are more common in females than males and may be a source of chronic pelvic or lower abdominal pain.

Femoral hernia is difficult to diagnose preoperatively. Symptoms usually include pain radiating down the inner aspect of the thigh and or under the inguinal ligament with no palpable mass or bulge. Frequently the first sign that a femoral hernia is present is acute incarceration. The repair of femoral hernia defects can be accomplished either by open or laparoscopic techniques, but the laparoscopic approach affords excellent exposure and allows accurate placement of a single layer of mesh that adequately covers the femoral and inguinal canals creating a very good repair.

The contents of a femoral hernia must be carefully reduced into the preperitoneal space in order to adequately identify the femoral canal structures and complete the repair. Again, if polypropylene mesh is utilized it should be anchored to the pelvis taking precautions as noted previously to avoid major vascular or neural injuries (Video 28.2).

Special Considerations in Inguinal Hernias

Techniques for laparoscopic inguinal hernia repair have evolved over the past 15 years. In the 1990's plug type repair was common, where a mesh plug usually consisting of polypropylene material was simply placed into the defect. This type of repair resulted in significant pain at the repair site because of scarring and contraction of the material, and as a result, this procedure currently is rarely used. Patients that have had this type of repair may present with significant pain with no external palpable "mass" and removal of the mesh plug is usually required for relief. Figure 28.16 is an example of a plug type repair in a patient that presented with pain several years later.

Fig. 28.15 Mesh placed over inguinal floor encircling the round ligament and covering the hernia defect

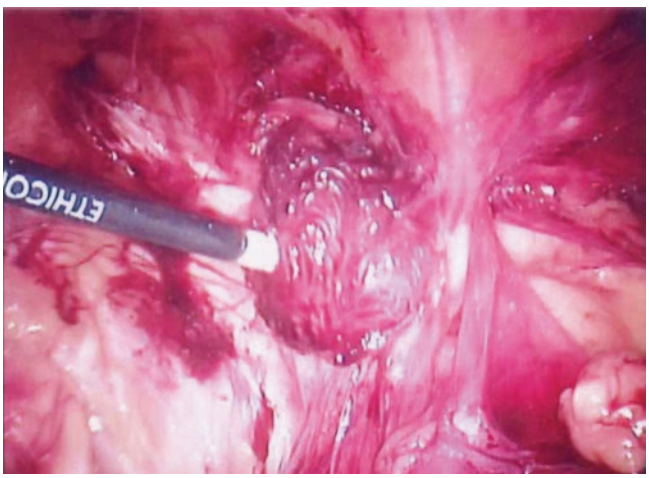

Fig. 28.16 Previously placed mesh plug in inguinal hernia defect

The plug repairs when performed currently utilize an absorbable material primarily or are in combination with open repair systems that utilize lower weight permanent synthetic materials. Figure 28.17 is an example of an absorbable material currently used in plug repairs. The material is Bio-A; manufactured by Gore corporation. This material provides a substrate for collagen deposition by the host resulting in an adequate support for the repair.

Tips

Asymptomatic inguinal hernias found at the time of surgery: Note and inform the patient of their presence but they do not require repair.

Femoral hernias may be a source of pelvic pain: symptoms are: radiating pain to the inner thigh and pain

Fig. 28.17 Bio-A absorbable hernia plug manufactured by Gore Corp. used in plug hernia repair

in the groin below the inguinal ligament. If a femoral hernia is found it should be repaired as incarceration is common.

Previous repairs with plug type materials may be a source of chronic pain: diagnosis can be made by prior history of surgery and imaging of the inguinal floor. Resolution of pain usually requires removal of the material.

Single symptomatic inguinal hernias are usually repaired with open technique.

Bilateral or recurrent inguinal hernias usually are repaired with laparoscopic technique.

In patients who have had a prior laparoscopic inguinal hernia repair, the retropubic space will be very difficult to enter due to adherence of the mesh material to the underlying structures.

Internal Hernias

An internal hernia is an opening between any two adjacent structures in the abdominal cavity that has the potential for abdominal contents to protrude through creating a site for obstruction. These hernias are very difficult to diagnose preoperatively and can also be a source of chronic lower abdominal or pelvic pain. They most commonly present with incarceration and bowel obstruction as the first presenting symptom.

Internal hernias are usually the result of prior surgery and adhesive disease. When bowel resection with anastomosis or gastric bypass is performed and the mesenteric defect is not sufficiently closed then this site may be the location of an internal hernia.

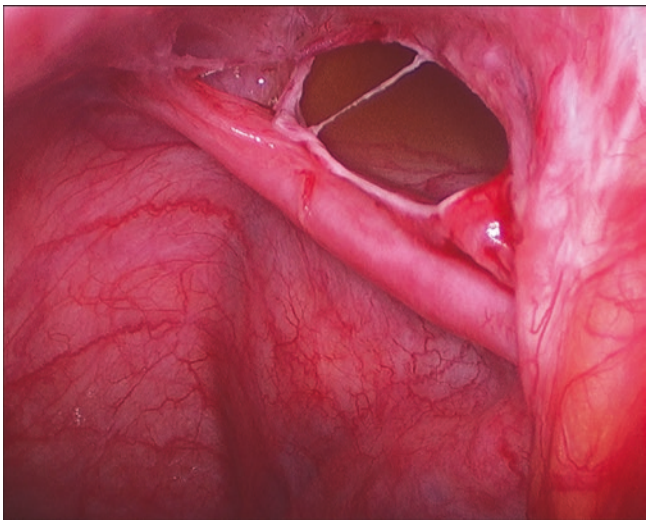

Fig. 28.18 Reduced internal hernia defect in left pelvic side wall

Figure 28.18 demonstrates such an internal hernia where adhesions created a small defect and bowel became entrapped and obstructed. The prior operation that resulted in this defect was a caesarian section with scarring between the uterus, anterior abdominal wall and lateral pelvic side wall.

When an internal hernia is diagnosed it needs to be either fixed by primary closure of the defect or the defect opened widely so the bowel cannot become incarcerated because the potential for complications is high.

Tips

When an internal hernia defect is encountered, it should be either closed completely or opened completely to prevent incarceration of bowel.

Visceral Pathologies

In the true pelvis, the rectosigmoid and the appendix are common sources of pathology. It is important to be able to recognize common conditions affecting these structures that may mimic gynecologic conditions, and be aware of the treatment for these processes. The small bowel also visits the pelvis and conditions that involve this organ may also mimic gynecologic pathologies.

Colon

The most common condition involving the colon in the West that may mimic gynecologic pathology is diverticular disease. Patients with acute hemorrhage or perforation as a result of their diverticular disease usually are referred directly to General Surgery for care; however chronic pain from diverticulosis or low grade diverticulitis may be difficult to distinguish from a gynecologic etiology.

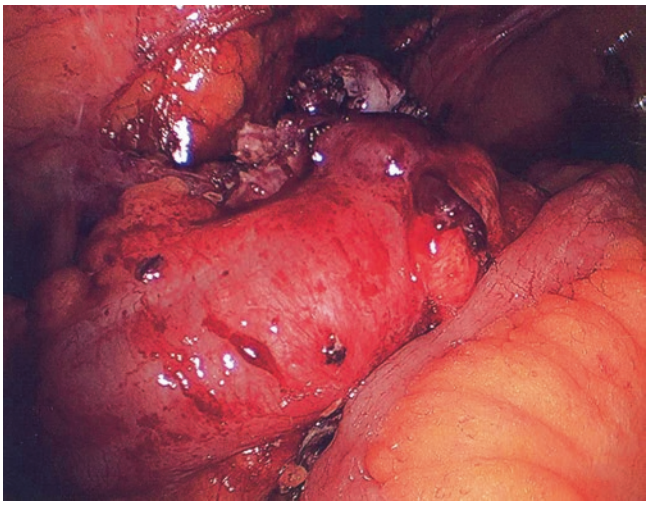

Fig. 28.19 Acute sigmoid diverticulitis with normal appearing bowel in the right lower aspect of the picture

The sigmoid colon is the region of the colon that is most commonly involved with symptomatic diverticuli and the pain is usually present in the left lower quadrant, but may be suprapubic or even in the right lower quadrant.

On inspection and manipulation of the involved colon during laparoscopy, the bowel wall is usually thickened and has lost its normal pliability. In patients that have chronic diverticular disease there are usually adhesions adjacent to the involved segment as a result of repeated bouts of inflammation. See Fig. 28.19.

Diverticuli may actually be seen protruding through the muscular wall of the colon aiding in diagnosis.

Once the GYN surgeon has ruled out any gynecologic pathology and the findings suggest diverticular disease whether it be chronic or acute, no further surgical intervention is necessary. Treatment consists of dietary fiber increase with or without intravenous or oral antibiotics depending on whether an acute process is present or not.

When a patient is explored for pelvic inflammatory disease or presumed tuboovarian abscess, one of the differentials is a contained diverticular perforation with abscess formation. When this is encountered, the segment of involved colon **does not require resection** (except in free perforation and peritonitis where a resection and diverting colostomy may be necessary). The abscess can be drained laparoscopically and a drain left in the abscess cavity.

Malignancies may also perforate however this is less common than in diverticular disease and these patients commonly manifest symptoms of bowel obstruction and as such are usually seen by General Surgeons prior to this happening.

Frequently when operating in the pelvis, congenital "adhesions" are encountered between the sigmoid colon, cecum and the abdominal wall or pelvic side wall. When these structures are noted, if they do not interfere with the planned procedure they are usually left in place and not taken down. The potential problem with mobilizing these structures (sigmoid and cecum) too vigorously is the possibility of volvulus, or twisting of the bowel. So as a rule of thumb, if it is not interfering with the planned procedure leave these support bands in place.

Tips

Diverticular disease of the sigmoid whether it is chronic or acute without perforation; does not require resection. Note and inform the patient.

Perforation with abscess formation: drain the abscess; leave a drain in the cavity, no resection is required.

Appendix

The use of pelvic ultrasound and or CT scan to accurately diagnose appendicitis has been on the rise recently but these have sometimes been unreliable tools to include or exclude the diagnosis, so the use of laparoscopy particularly in the female patient is becoming more frequent when the diagnosis is uncertain. The benefits of laparoscopic appendectomy when compared to open appendectomy are still being hotly debated in the General surgery literature [9]. The majority of appendectomies performed in the US are currently being done laparoscopically. The main advantage being reduction in wound infection rate when compared to open techniques.

The surgical technique used by GI Surgeons for appendectomy most commonly involves utilizing a linear stapling device. These instruments provide a quick simple technique for removal of the appendix; however they are expensive, and may not be readily available so other methods for dissection and removal should be in the surgeons' armamentarium. The technique for appendectomy will be described in stepwise detail.

Procedure Appendectomy

First the appendix must be mobilized from any retroperitoneal or lateral pelvic attachments. This step is important in order to have adequate access to the mesentery of the appendix and avoid injury to retroperitoneal structures, cecum or the ileocecal valve during removal.

Next, a small window is created in the mesoappendix at the base of the appendix. This can be done bluntly using dissectors or energy sources.

Once this is accomplished, the third step is either ligation of the mesoappendix or appendix base. The choice of which one of these structures is to be ligated first is dependent on the anatomy and ease of visualization. Control can also be accomplished using a linear stapling device. The appendix base is usually transected using the 3.5 or 2.8 mm staple depth. The choice depends on whether the base of the appen-

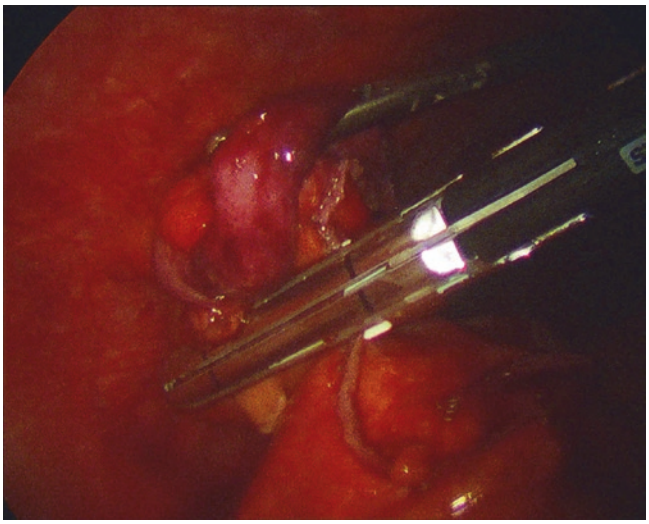

Fig. 28.20 Stapler being applied to the base of the appendix

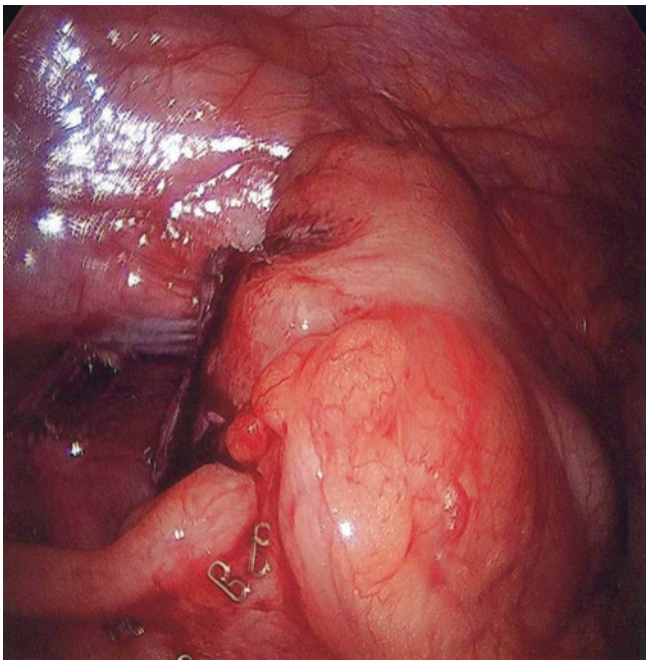

Fig. 28.21 Stapled appendix base to the left and normal cecum to the right of the picture

dix is inflamed or normal. The vascular pedicle is divided using the 2.8 mm staple load. Figure 28.20 shows placement of the stapling device and Fig. 28.21 shows the appendix base after stapling.

Simple ligation of the appendix base or its vascular pedicle using 0-silk or other suture offers good control prior to transection of these structures. This method is much more cost effective when compared to stapling devices. Video 28.3 demonstrates ligation of the appendix base with suture.

After the base of the appendix or mesoappendix is ligated and transected, an Endoloop may be applied for extra security. Video 28.4 shows the transaction of the appendix base after ligation.

In instances where the appendix is necrotic at its base, the stapler has its best utility. The proximal staple line should cross normal cecal wall in order to insure viable tissue is left in the staple line. Stapling across a necrotic appendix can result in delayed perforation and peritonitis since there is no viable tissue left in the staple line.

When the primary ligation method is utilized, and the base of the appendix is necrotic, the appendix base should be inverted into the cecum utilizing either a Z stitch or purse string seromuscular stitch of 2-0 or 3-0 suture. Historically silk suture has been used however an absorbable suture may be utilized but the crucial point is that the tissue in question be closed and inverted with normal viable tissue overlying it.

Special Considerations

In instances where the appendix has perforated and an abscess is encountered which may be the case in exploration for suspected tuboovarian abscess, then just as for diverticular abscess, the surgeon should drain the abscess, leave a drain in the abscess cavity and end the procedure. The appendix does not need to be removed at that time but this can be done at a later date usually several months later if indicated.

In patients with chronic lower abdominal or pelvic pain who are undergoing laparoscopy and the appendix is still present, it is recommended that the appendix be removed. In several studies, relief of pain after appendectomy even without obvious gross pathology shows benefit [10, 11].

Tips

Appendectomy should be performed in patients with pelvic pain when the organ is still present and appears grossly normal.

Appendectomy can easily be accomplished utilizing a stapling device, 3.5 or 2.8 mm load for the appendix base and 2.8 mm size for the mesentery.

Suture ligation using 0-silk or other suture material is as effective as stapling and more cost effective. Pretied loops can also be used to control the appendix base and mesentery base.

In perforation and abscess formation, drain the abscess, do not remove the appendix and leave a drain in the cavity.

Small Bowel

Small bowel pathology is much less common than either colon or appendix pathology, however conditions do exist that may be found during exploration that mimic pelvic pathology.

Fig. 28.22 Meckel's diverticulum

Meckel's diverticulum is a true diverticulum that classically is located 2 ft from the ileocecal valve and can be a source of chronic pain. The appearance is typically that of an antimesenteric diverticulum with its own blood supply originating from the mesentery.

Figure 28.22 shows a typical Meckel's diverticulum.

The diverticulum can harbor gastric mucosa that can lead to GI bleeding and also perforation. Bowel obstruction from intussusception also has been described. So when these structures are encountered they are usually removed.

Resection with a linear stapling device 3.5 mm size staple load, placed at the base of the Meckel's diverticulum so as not to compromise the remaining bowel lumen is recommended. Resection utilizing simple excision with two layer suture closure may be used if the surgeon is adept with laparoscopic resection and suturing techniques.

Tips

When Meckel's Diverticulum is found it should be removed.

GIST or gastrointestinal stromal tumors can be found in the small bowel and have the same gross appearance as leiomyomas. Figure 28.23 is that of a small bowel GIST preoperatively mimicking a leiomyoma.

GIST tumors are most commonly found in the stomach 60% with 30% incidence in the large and small bowel. They can be intraluminal or extraluminal with a pedunculated base which can lead to misdiagnosis via imaging as originating from the uterus or ovary. Figure 28.24 shows the appearance on CT of the lesion in Fig. 28.23.

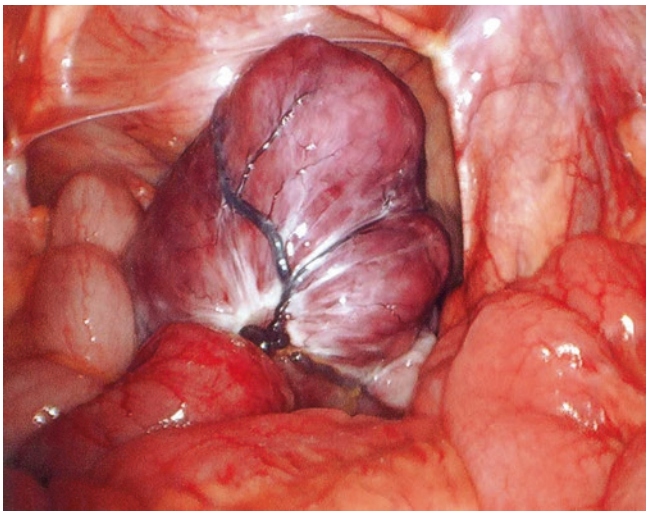

Fig. 28.23 Pedunculated GIST tumor of the small bowel resembling leiomyoma

Fig. 28.24 CT scan of the pelvis demonstrating the GIST tumor in Fig. 28.23

These tumors do have a malignant potential and so when encountered they should be removed. Despite their malignant potential, removal of GIST lesions requires only clear resection margins and a formal nodal dissection is not necessary. Lesions greater than 5 cm or with >5 mitoses per high power field should be referred for consideration for adjuvant chemotherapy.

Because these tumors resemble leiomyomas the urge to morcellate should be avoided when they are removed. They should be removed from the abdomen intact by extending the incision or utilizing a specimen retrieval bag device.

Tips

GIST tumors grossly resemble leiomyomas and as such may be mistaken for gynecologic pathology. When found, they should

be removed intact, not morcellated, and no formal cancer nodal dissection is necessary. The bowel margins should be clear.

Regional enteritis or Crohn's Disease can also cause pelvic or lower abdominal pain. The gross appearance is similar to that seen with chronic diverticular disease with marked thickening of the bowel wall, loss of pliability and the characteristic mesenteric creeping fat may be present.

Without any acute problems or complications of the patient's disease (perforation, obstruction), the involved segment does not need to be removed and in fact it is recommended that the involved bowel be left in place. Medical therapy is the mainstay of treatment with surgery being left only for complications such as perforation, stricture, obstruction or fistula formation.

Tips

Crohn's disease when encountered should be noted with no resection recommended except only for complications such as perforation, obstruction, stricture or fistula formation.

Special Considerations in Encountering Bowel, Injuries

In the course of dissection particularly when adhesive disease is encountered, occasionally injury to the bowel wall is noted. Avoidance of injury is the key. The use of any energy source to release bowel from the abdominal wall is to be discouraged and when used, should be performed only with extreme caution.

Use of scissors without cautery is the preferred method. When very loose adhesions are encountered, the bowel may be gently pushed from the abdominal wall with the convex side of the instrument. Figure 28.25 demonstrates the recommended position of the scissors.

This helps reduce chance of an unseen injury by the tip of the scissors on the bowel.

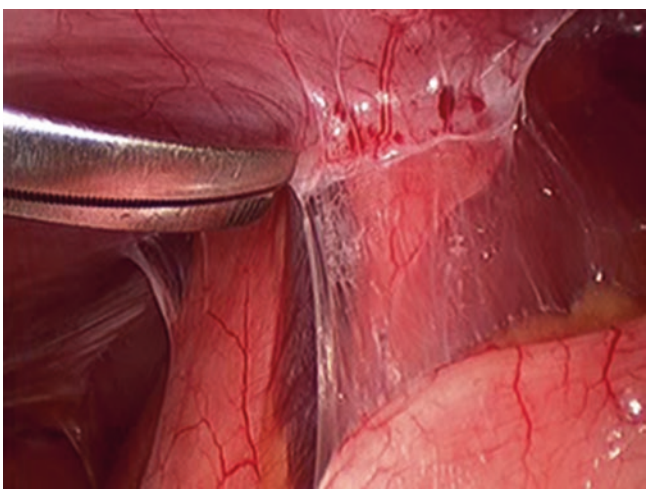

Fig. 28.25 Fibrinous adhesions between the bowel and anterior abdominal wall

Small bowel and colon are encountered frequently in the pelvis during surgery, despite placing the patient in Trendelenberg position. These structures must be mobilized from the pelvis in order to achieve adequate visualization. When grasping the bowel, a method recommended to help reduce the possibility of injury, is that the bowel be grasped gently with an instrument with a large surface area and at an angle parallel to the mesentery (Fig. 28.26) or grasp the mesentery directly (Fig. 28.27).

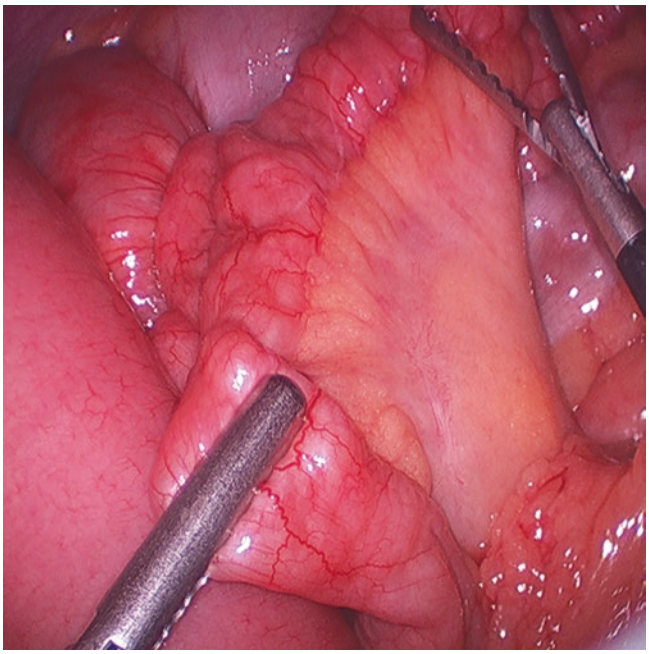

Fig. 28.26 Grasping the bowel with broad based instrument at a 0 degree angle

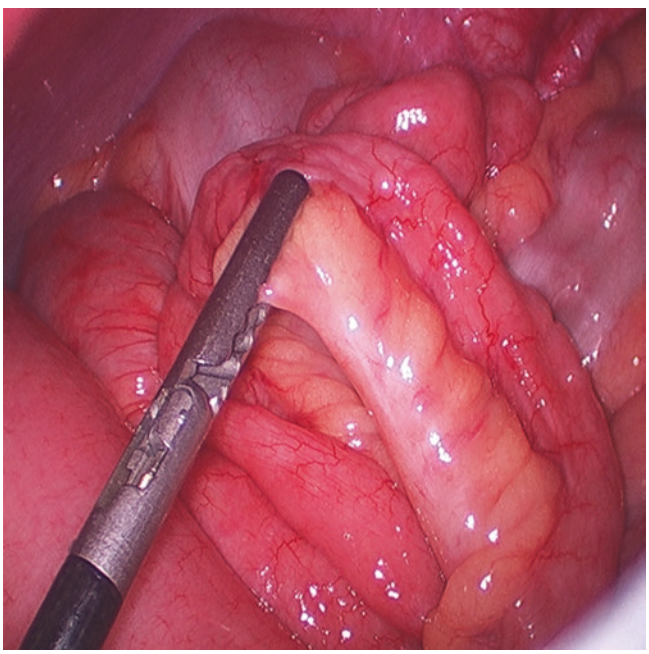

Fig. 28.27 Grasping the mesentery of the bowel avoiding the bowel wall completely

The larger surfaced area grasper disperses the force generated by the grasper and by grasping the mesentery the bowel itself is avoided thus reducing the risk of injury. The amount of force generated at the tip of laparoscopic instruments has been measured at up to 1500 kPa which is equal to a human bite so excessive force on the instrument can be transferred to the bowel and must be avoided [12].

Extra care must be taken when the bowel is inflamed or diseased as this makes the possibility of injury more likely.

When to Repair Bowel Wall Injuries?

1. If the mucosa is entered or visible, then primary repair is mandatory. Repair is accomplished either in one or two layers. Suture size used may be 4–0 or 3–0 and may be permanent or absorbable suture. The critical aspect of the repair is that the mucosa be completely inverted.
2. When the muscular wall is damaged and mucosa is visible but not injured, see Fig. 28.28, it is still recommended that the bowel wall be repaired. Again either a two or one layer closure is used.
3. When muscular wall is damaged and no mucosa is visible, depending on the length of injury, the bowel wall may not need to be repaired. The decision is surgeon dependant but any injury over 1 cm in size should be reinforced.
4. Serosal injuries do not need to be repaired. See Fig. 28.29

Tips

Full thickness bowel wall injuries need to be repaired either with two layer or one layer technique making certain that mucosa is adequately inverted and or covered with viable tissue.

Muscular wall injury should be repaired depending on degree and size. When in doubt: repair.

Serosal injuries do not require repair.

Grasp bowel carefully with large surface area instruments.

Other Topics

Endometriosis may involve organs other than the uterus or ovaries and this can include bowel particularly the rectosigmoid. Figure 28.30 demonstrates an endometriotic plaque in the Pouch of Douglas.

In order to adequately treat and relieve the patient from their symptoms, complete resection of the involved area is usually required.

When endometriosis involves the colon or rectum, the endometriotic nodule can usually be completely resected without having to perform a formal segmental resection [13]. Anticipation of the need to resect part of the large bowel is usually noted preoperatively and if necessary a general surgeon can be called to assist, however a well trained laparoscopic surgeon competent in suturing can also treat the involved bowel.

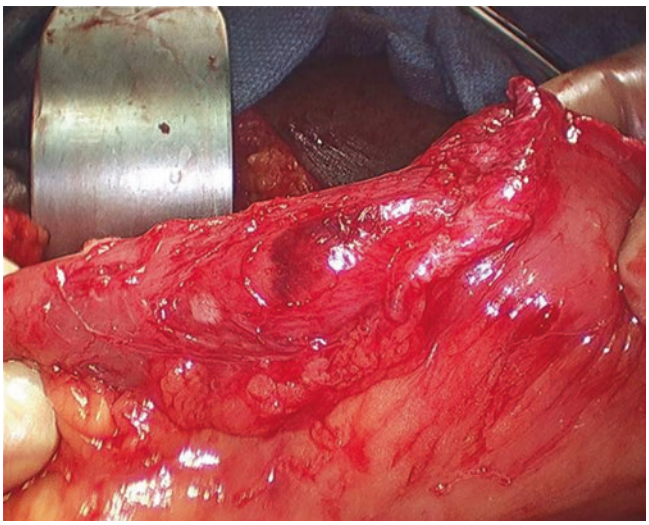

Fig. 28.28 Bowel wall injury with intact mucosa, disrupted serosa and both muscular walls requiring repair

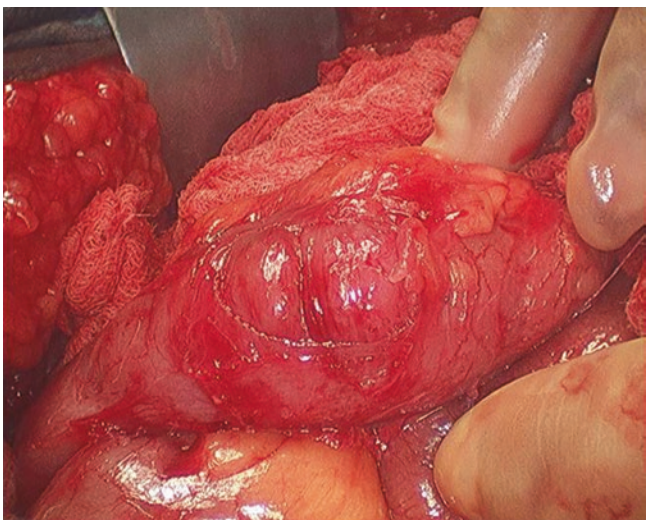

Fig. 28.29 Serosal injury with intact muscular layers not requiring repair

Fig. 28.30 Endometriosis involving the anterior wall of the rectum and posterior wall of the vagina

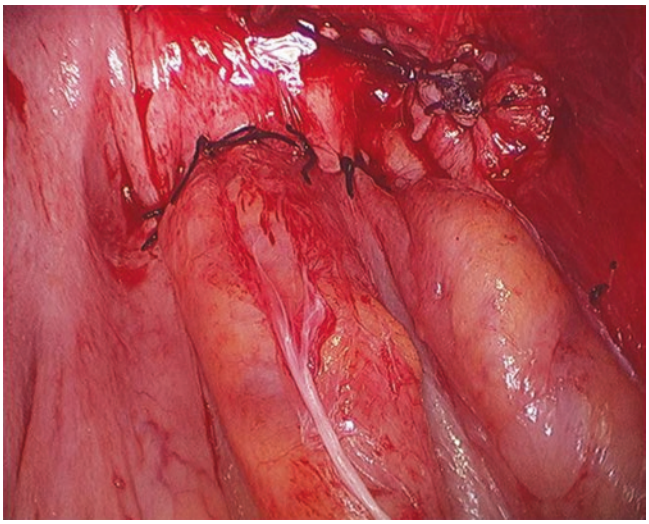

Fig. 28.31 Repair of the rectal wall closed in transverse fashion

If the nodule requires full thickness resection of the bowel wall and closure would not result in compromise of bowel lumen, (usually 50% or less of the bowel wall circumference) then primary repair in a two layer manner is appropriate. The first inverting layer is usually an absorbable suture (chromic or polyglactin) 4-0 or 3-0 size. The injury should be closed so as not to compromise the lumen of the bowel so closure in a transverse fashion rather than longitudinal with interrupted suture is best. See Fig. 28.31.

The second layer may be either absorbable or permanent and is usually either 4-0 or 3-0 size.

The ultimate success of closure depends on standard well recognized principals of general surgery. The first being a tension-free repair and the second being adequate blood supply.

If the rectum and not the sigmoid colon is involved, because of the lack of serosa, the anastomosis is at higher risk of leak since there is no serosa to aid in sealing of the anastomosis, so it is recommended that in these instances, the use of anti-adhesive agents be avoided. The successful sealing of an anastomosis in this circumstance is very dependent on adherence from surrounding tissues, so adhesions in this instance are crucial to good outcome.

Tips

When endometriosis is encountered involving the bowel, it usually can be removed by local excision and primary closure.

Two layer closure without tension and adequate blood supply to the remaining tissues is standard.

When rectum is involved, antiadhesive barrier products should be avoided.

The same management principles apply in a situation where the distal colon or rectum is injured during surgery or entry. The injury is usually repaired in a two layer fashion. If the defect is small, then a one layer closure is adequate as long as the bowel mucosa is inverted. The need for creation of a colostomy is extremely rare when the injury is recognized early and closed primarily.

When bowel resection is anticipated preoperatively, usually the patients are placed on mechanical bowel prep. There is good evidence that when patients have not had bowel prep and subsequently underwent resection when compared to patients that did have a bowel prep and underwent resection with anastomosis, there was no difference in leak rate, abscess formation or complication such as wound infection [14]. The long held notion that all patients that are to undergo bowel surgery need to be on a mechanical prep is now questioned.

In special cases where an entire segment of bowel needs to be removed, the availability of circular staplers has made creation of a low colonic anastomosis simpler. There are certain principles that need to be understood when using these devices. First is that there should be no tension on the anastomosis and staple line. The proximal bowel should easily reach into the pelvis without tension. The descending colon or splenic flexure may need to be mobilized in order to reach the distal sigmoid or rectal stump; if this is needed then care must be taken that the blood supply is not compromised in the process as this is the second important factor in a successful anastomosis.

Choosing staple size is very important. Lower colon anastamosis using a circular stapler should be performed with a 28 mm diameter stapler or larger. Figure 28.32 shows a stapling device manufactured by Covidien Corporation. The anvil and stapler are demonstrated.

Using a stapler smaller than 28 mm usually will lead to stricture. If the proximal bowel lumen is small the staple anvil may be placed in a side fashion forming an end-to-side anastamosis and thus creating an adequately large lumen.

In placing the anvil in the proximal bowel, the bowel should be closed firmly around the anvil post so that when the stapler is closed and fired no bowel wall is extruded from the side of the stapler resulting in a compromised anastomosis.

Fig. 28.32 EEA stapler manufactured by Covidien Corp. showing the anvil and stapler

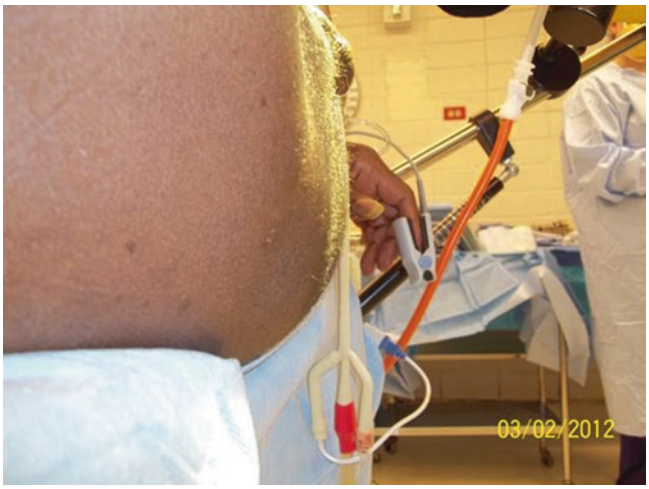

Fig. 28.33 The patient's buttocks extending past the end of the operating table

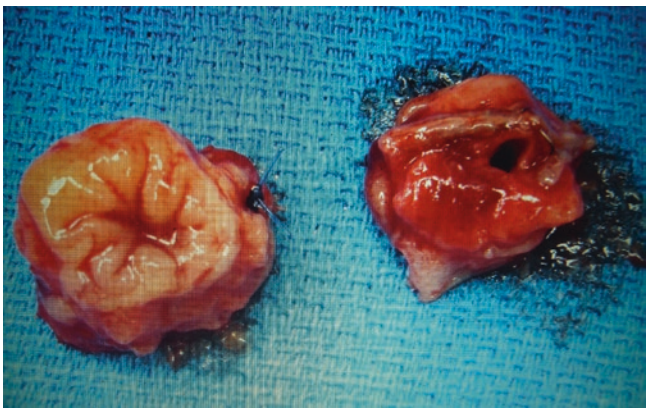

Fig. 28.34 Circular staple tissue donuts from the proximal and distal bowel

In placing the stapling device transanaly, it is very important that the patient's lower buttocks and perineum extend past the edge of the operating table. This allows adequate angling of the stapler into the rectum and first part of the sigmoid. This is absolutely crucial to successful docking and firing of the stapler. See Fig. 28.33.

Once the stapler and anvil are docked, the stapler fired, and removed, the confirmation of two intact tissue "doughnuts" (see Fig. 28.34) and a secure anastomosis via colonoscopy or insufflation using proctoscopy or other device with submersion leak testing should be performed. In the instance of a questionable staple line, the anastomosis site can be reinforced with an inverting stitch or redone. Drains are not usually placed.

Tips

Mechanical bowel prep is not mandatory in colon surgery.

Closure of colon after partial resection or injury should be in two layer fashion.

Circular stapling devices should be 28 mm or greater in diameter when used for anastomosis after segmental resection.

In closure of rectal injury or resection, avoid anti-adhesive materials.

Colostomies are rarely needed when the bowel is injured during surgery; primary repair is preferred.

General surgical conditions can mimic gynecologic disease and may be encountered in the course of surgery for GYN conditions. It is important to be able to recognize, diagnose and have knowledge of treatment for these conditions in order to have good surgical outcomes.

Uterine fibroids are the most common gynecologic benign tumors. Depending on different symptoms, options for management of uterine fibroids include follow-up observation, medication, surgery or embolization.

Laparoscopic hysterectomy is the most frequently performed minimally invasive procedure for treatment of fibroids. It is applied to patients with indications of surgery but with no desire for fertility or reservation of uterus. It is divided into complete laparoscopic hysterectomy and laparoscopic-assisted vaginal hysterectomy. According to resection range, hysterectomy can be total or supracervical.

With the development of laparoscopic technology and accumulation of surgical experiences, almost all the laparoscopic hysterectomy due to fibroids can be performed successfully, including conditions of large uterus, severe adhesion or specially located fibroids [1–5]. But supracervical hysterectomy or hysterectomy of a large uterus requires power morcellation to facilitate removal, which links to an increased risk of disseminating occult malignancy into the abdominal and peritoneal cavities, and it has become a main concern and reason for restriction of laparoscopic hysterectomy [6–10].

Most of hysterectomies for fibroids can be completed safely by laparoscopy. The crucial part of laparoscopic hysterectomy is safely processing the uterine vessels [11]. The vessels supplied the uterus mainly come from two sources, one is the uterine artery and vein, the other is the anastomoses branch of utero-ovary vessels. The uterus becomes ischemic after devascularization of the two sites and then resection won't be difficult. Core of the whole procedure is to reveal the two groups of vessels precisely and bloodlessly, followed by transfixion or electro-coagulation. Large uteri, cervical fibroids or fibroids located in the lower segment of the uterus may greatly increase the difficulty of devascularization [12]. We will analyze the procedure of laparoscopic hysterectomy step by step.

Appropriate exposure and operating space are the precondition for laparoscopic hysterectomy. To achieve better exposure and operating space, the use of a uterine manipulator and placement of trocars are important. A uterine manipulator should push up the uterus to expose cervico-vesical fold, and provide a good motion range. The placement of trocars is one of the most critical factors for a successful operation. On the basis of anatomical characteristics, the cervix is a relatively fixed point, while the uterus is a partially

free organ with relatively bilateral mobility, so three trocars are generally most favorable for hysterectomy. More trocars make no contribution to exposure of anatomic and operative view. The first port-site is for laparoscopic lens. For uteri smaller than the size of 18 weeks gestation, the first port-site is usually at umbilicus point. For bigger uteri, upper umbilicus point is chosen, but often lower than the umbilico-xiphoid midpoint. The left and right port-sites are operating sites, commonly near the anterior axillary line, 2 cm higher than the utero-ovarian ligaments. One side of port-site is for operating and the other side is to help exposure during the procedure. Proper rotation of the uterus helps exposure. Rotate the uterus clockwise when deal with the left side. Rotate anti-clockwise when go to the right.

We first deal with the anastomoses branch of utero-ovarian vessels, which are surrounded by the round ligament, utero-ovarian ligament and fallopian tube (see Fig. 29.1). For uteri that are not too large, a uterine manipulator can help exposure. For large uteri, the effect of uterine manipulator is limited, and grasping forceps are needed to grasp the point where the round ligament connects the uterus, pull and rotate the uterus to one side so that the operative side can be exposed. For patients whose ligaments are thick, transection of fallopian tube, round ligament and utero-ovarian ligament is done before devascularization. For patients with thin ligaments, do the devascularization directly. Transection of these structures should be done 1 cm away from the uterus to avoid injury of vessels on the lateral uterine wall. Then open the broad ligament, dissect the anterior and posterior leaf (see Fig. 29.2). Usually there are only small vessels and loose connective tissue within the broad ligament. Be careful not to injury the uterine vessels which are closed to the lateral uterine wall. Now a uterine manipulator is necessary to push the uterus up to help expose, meanwhile the contra-lateral grasping forceps continue pulling and assist rotation. Open the anterior leaf of the broad ligament up to the cervix, continue to open the utero-vesical fold. Open the posterior leaf of the broad ligament to where the utero-sacral ligament attaches to the cervix. Avoid tear and bleeding of the small veins, electro-coagulate timely to keep the wound bloodless and the operative view clear.

The contra-lateral side is done with the same rule.

With the broad ligaments done, we need to push up the uterus as far as possible, and pin the anterior uterine wall by forceps, thus reveal the cervico-vesical gap, and open the utero-vesical fold and bilateral vesico-cervical ligaments (see Fig. 29.3). Find the correct cervico-vesical gap, reflect the bladder downwards carefully not to cause any bleeding. For supracervical hysterectomy, reflect the ladder just enough to do the devascularization. For total hysterectomy, the bladder has to be reflected down to 1 cm below the upper end of the vagina. It is crucial to reflect the bladder downwards before devascularization, so that the vessels can be processed successfully without injury of the bladder and ureters.

Continue to dissect the peripheral structure of cervical vessels after the bladder is reflected down (see Fig. 29.4). There is often one uterine artery surrounded by several uterine veins. Uterine veins are wide and thin-walled, easy to be damaged, and not easy to electro-coagulate. Once big uterine vein bleeding occurs, clamp the bleeding point and push away the bladder with caution to make space for transfixion. When cervical vessels are dissected, suture the uterine vessels below the isthmus, or electro-coagulate and transect. Desiccation of a vessel should be of a certain width in order to avoid bleeding after transection and blurring of the operative view.

After devascularization, go further to next steps according to total or supracervical hysterectomy.

For supracervical hysterectomy, withdraw the uterine manipulator and remove the uterus by morcellation (see Fig. 29.5). The cervix stump is scissored into a wedge shape, coagulated by electrotome and interruptedly sutured, usually by three stitches. The middle stitch must be deep to the base of the wedge, upper end of the cervical canal, in case of possible postoperative bleeding.

For total hysterectomy, after devascularization, transect the cardinal ligament to the cervico-vaginal fornix junction through the space between uterine vessels and the cervix, then resect the uterus circumferentially off the vaginal fornix, aided by the cup of uterine manipulator , extract the uterine corpus through vagina(see Fig. 29.6). To find the space between uterine vessels and the cervix correctly is vital to prevent bleeding.

Close the vaginal cuff after hysterectomy by interrupted or running suture. Pay special attention to the suture of bilateral utero-sacral ends.

At last, irrigate the pelvic cavity, stanch thoroughly, and examine the ureters, bladder, rectum and other pelvic organs, finish the operation.

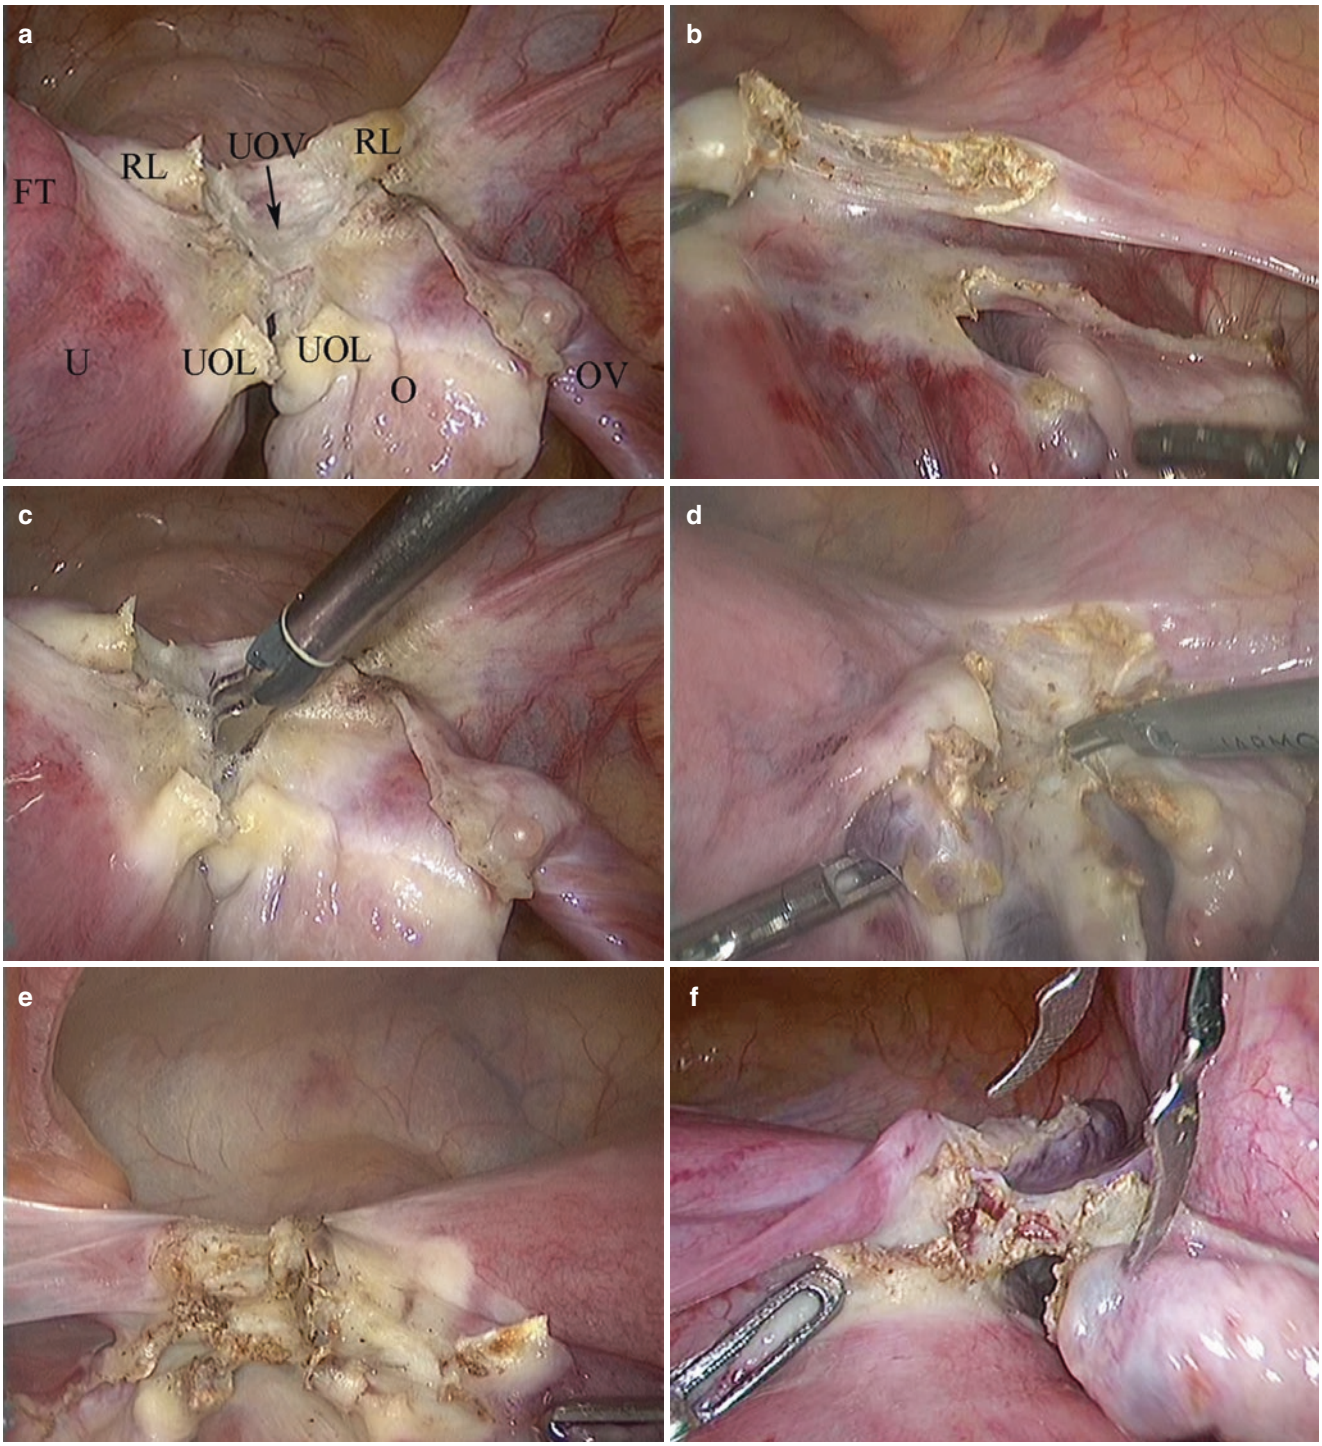

Fig. 29.1 Utero-ovarian vessels and surrounded structures. The anastomoses branch of utero-ovarian vessels, which are surrounded by the round ligament, utero-ovarian ligament and fallopian tube. Round ligament, utero-ovarian ligament and fallopian tube are usually done before devascularization. For patients with thin ligaments, do the devascularization directly. Transection of these structures should be done 1 cm away from the uterus to avoid injury of vessels on the lateral uterine wall. (**a**) Divide the surrounding structure and expose the anastomoses branch of utero-ovarian vessels. (**b**) The round ligament is transected 1 cm away from the uterus. Symptomatic Fibroids as Main Indication for Laparoscopic Hysterectomy and Their Handling

30

Liselotte Mettler and Ibrahim Alkatout

Introduction

One of the multiple treatment possibilities for myomas considering all laparoscopic surgical, medical or interventional techniques is total laparoscopic hysterectomy (TLH) or subtotal laparoscopic hysterectomy (SLH). As SLH is a much less invasive procedure, a good number of patients with myomas can consider a subtotal approach. However, only a total laparoscopic hysterectomy (TLH) can offer 100 % protection from new fibroid formation, later sarcoma formation, uncontrolled bleedings, cervical and endometrial cancer or any other problems arising from the uterus.

In spite of numerous theories, the etiology of fibroid formation remains unclear. While a genetic disposition must be given, as Africans have a much higher frequency of multiple myomas than Caucasians certain up- and down-regulations in the genes of patients with and without myomas have been described. However, as yet no clear guidelines for the prevention of fibroids are available. Hereditary leioyomatosis and renal cell carcinoma syndrome is a rare syndrome involving fibroids. Individuals with the gene that leads to both fibroids and skin leiomyomas have an increased risk of developing a rare case of kidney cell cancer (papillary renal cell carcinoma).

Understanding which genes are involved in fibroids does not automatically tell us why fibroids develop or how to control them. From our understanding of fibroid behavior, we would guess that genes involved in estrogen or progesterone production, metabolism or action are involved. Unfortunately, science is seldom that straightforward. Most guesses regarding these "candidate genes" turn out to be wrong and much research is still required to find out how these genes lead to disease. There are also small variations, called polymorphisms, in genes that may play a role in influencing the risk of fibroids. Both polymorphisms and mutations are changes in the sequence of genes, but the difference is in the degree of change. A mutation makes a major change in the gene that leads to a change in the protein the gene is coding for. For example, it can change the amino acid from alanine to glycine or cause the protein to be prematurely cut off.

The Genetics of Fibroids, Genotype, Phenotype

The discovery of the structure of DNA (desoxyribonucleic acid) by Watson and Crick revolutionized biology and medicine. They discovered that DNA carries the code for life in a ladder-like structure. Today, it is known that the genes from a single person take up the space of 400,000 times the distance from the earth to the moon or 1000 times the distance from the earth to the sun = 150 billion kilometers [1–3].

Before going further, it is important to define the terms genotype and phenotype. The genotype is the pattern of genes that you inherit. For example, with eye color, brown is a dominant color and is represented by a "B". Blue is a recessive trait and represented by a "b". Therefore, a person can have "BB", "bb", or "Bb" as genotypes for eye color. Each person gets two copies of the gene, one originally from his or her mother and the other from his or her father. The dominant gene will always dominate; it has the power to trump a recessive trait. Phenotype is the physical manifestation, or end result, of the genotype. Although there are three different genotypes (BB, bb, or Bb), there are only two phenotypes: brown eyes and blue eyes. People with the "BB" or the "Bb" genotype have brown eyes because brown is the dominant trait; only the people with the "bb" genotype have blue eyes.

We believe that fibroids are a common phenotype that represents many different underlying genotypes. In other words, in our view, fibroids can arise through multiple

different pathways. In this case, "Bb" might represent two different genes that code for the estrogen receptor beta which influences the action of estrogen on fibroid tissue. A "B" gene may make the fibroid more sensitive to this hormone and therefore more likely to grow. In addition, probably multiple genes influence fibroids so that in addition to "Bb" we may also have "Pp" for progesterone receptors, "Ff" for fibrotic factors, and so on. This information would be most helpful in advancing treatment as women who carry a high risk of recurrent fibroids and have completed their family planning might choose to have a hysterectomy because of the higher chance of their having an additional surgery. We currently have some clinical information (based on physicians' clinical experience with many patients) to predict prognosis for recurrence after myomectomy, but our clinical information for alternative forms of treatment options is limited.

Evidence for the Role of Genes in Fibroid Development and Growth

Studies of women with fibroids suggest several reasons to suspect that genes play a role in fibroid formation. The first is that both women in a pair of identical twins are twice as likely to have had a fibroid-related hysterectomy as both women in a pair of fraternal (non identical) twins. Identical twins share 100 % of their genes, while fraternal twins share only 50 % of their genes. This suggests that the genes that identical twins share make them more likely to form fibroids, since both are identical and non identical twins have equal exposure to environmental factors. This difference between identical and fraternal twins has been observed in a general population of women undergoing hysterectomy and a population of women with fibroids leading to hysterectomy [4, 5].

There is also evidence that women who have close relatives, such as a mother or sister, with fibroids are much more likely to have fibroids themselves [6, 7]. This propensity is called familial aggregation. Just as with breast cancer, if you have many relatives affected by fibroids, your risk of disease is likely to be increased.

Molecular Genetics and Genome-Wide Scan for Fibroid Genes

Finally, in the age of molecular genetics, we can scan markers across the complete sets of DNA, or genomes, of many people to find genetic variations associated with a particular disease. This process is called a genome-wide scan. This is a common approach to finding genes in complex diseases, such as diabetes, asthma and heart disease. With a genome-wide scan, women who are sisters and both have fibroids (an affected sibling pair) are recruited to participate in the study. Their DNA is studied for common genes. If hundreds of women are studied, each region of every chromosome can be examined, and it can be determined which genes are shared by the sisters who share the fibroid phenotype but are different in many other respects. This approach often produces novel genes that were not previously thought to be involved in the disease process [8–11].

Microscopic Facts and Fibroid Viability

Fibroids are composed primarily of smooth muscle cells. The uterus, stomach and bladder are all organs made of smooth muscle. Smooth muscles cells are arranged so that the organ can stretch, instead of being arranged in rigid units like the cells in skeletal muscle in arms and legs that are designed to "pull" in a particular direction. In women with fibroids, tissue from the endometrium typically looks normal under the microscope. Sometimes, however, in submucosal fibroids there is an unusual type of uterine lining that does not have the normal glandular structure. The presence of this abnormality, called aglandular functionalis (functional endometrium with no glands), in women having bleeding disorders is sometimes a clinical clue for their doctors to look more closely for a submucosal fibroid [12]. A second pattern of endometrium, termed chronic endometritis, can also suggest that there may be a submucosal fibroid, although this pattern can also be associated with other problems, such as retained products of conception and various infections of the uterus. Hysterectomy is not the only solution for treating fibroids; distinctions in size, position, and appearance have to be taken into account when deciding upon the best treatment option. If we understand these issues, we may be able to tell why some women have severe bleeding and other women with a similarly sized fibroid have no problem.

Costs of Fibroids

In fact, accurately capturing all the costs attributable to uterine fibroids will help us move toward more, and more effective, innovative therapies. When deciding whether or not to launch a new concept, companies typically look at the amount currently spent for other treatments. The economics of fibroids has chiefly been discussed in terms of the health care costs of hysterectomy. This in itself is a huge amount of money. According to a recent estimate, in the United States, more than $2 billion dollars are spent every year on hospitalization costs due to uterine fibroids alone [13]. Additionally, one study estimates that the health care costs due to uterine fibroids are more than $ 4600 per woman per year [14].

When you incorporate all the costs of fibroids, however, the way of treatment becomes even more significant. Let us consider what costs arise

- The costs of myomectomy, uterine artery embolization (UAE), and other minimally invasive therapies
- The costs of birth control pills and other hormonal treatments to control bleeding
- The costs of tampons, pads, and the adult diapers many women require to contain the bleeding
- The costs of alternative and complementary therapies
- The cost of doing nothing (for many women this means missing work or working less productively during their period).

Reasons for Hysterectomies in Fibroid Patients

Why should a patient have a hysterectomy today when so many alterative treatment possibilities are available? Firstly, up to a certain size of the enlarged uterus, laparoscopic subtotal hysterectomy completely solves the problem and if women want to eliminate every risk of recurrent fibroids, hysterectomy is their only choice. Hysterectomy also solves coexisting problems, such as adenomyosis, endometriosis and endometrial polyps or cervical dysplasia, and there is no danger of ever leaving a sarcoma or carcinoma behind.

Review of All Uterine-Preserving Treatment Possibilities for Fibroids

The surgical treatment of fibroids can be differentiated between less invasive and more invasive surgical techniques. Time and type of treatment have to be chosen individually and are dependent on the patient and the treating gynecologist (Tables 30.1 and 30.2).

Table 30.1 Uterine fibroids or myomatous uterus

Asymptomatic	Symptomatic
Conservative treatment	Operative treatment
No acute need for action	Acute need for action
Medical therapy	Primary operative treatment
Expectant management	Delayed operative treatment with medical pre-treatment

Expectant Management

Wait-and-see is a possibility if patients are asymptomatic, decline medical or surgical treatment or have contraindications to any kind of treatment. However, existing data describe the possibility that fibroids can shrink substantially either by optimizing endocrinological disorders, such as hypothyroidism, or during the postpartum period [15, 16].

To pursue the idea of expectant management, the pelvic mass must definitely be classified as a fibroid and differentiated from an ovarian mass. The complete blood count (CBC) should be normal, especially in patients with severe symptoms, such as menorrhagia or hypermenorrhea. The women must also be informed that the risk of miscarriage, premature labor and delivery, abnormal fetal position and placental abruption is increased during pregnancies with uterine fibroids [17].

Medical Therapy

The benefit of medical treatment in the management of women with symptomatic fibroids is still difficult to prove. Medical therapy can provide adequate symptom relief, especially in cases where hypermenorrhea is the leading problem. The benefit of symptom improvement decreases in long-term treatment periods so that more than 50 % undergo surgery within two years [18].

Nevertheless, there has been a shift in traditional thinking that medical treatment of fibroids is solely based on the manipulation of steroid hormones. A deeper analysis and understanding of specific genes or pathways associated with leiomyomatosis may open new possibilities for prevention and medical treatment [19].

Primarily as a preoperative treatment to decrease heavy bleedings in patients with fibroids, hormonal treatment with selective progesterone modulators, such as ulipristal acetate 5–10 mg daily, have become widely used over the last 2 years [20–22].

Alternative Treatment Methods

If the patient does not want to undergo surgery or there are contraindications to surgery, there are alternative procedures:

Table 30.2 Treatment options for uterine fibroids

Alternative	Surgical						
Uterine artery Embolization	Myomectomy				Hysterectomy		
High intensity focused ultrasound	Hysteroscopic	Laparoscopic	Abdomical	Robotic assisted	Vaginal	Laparoscopic	Abdominal
Miscellaneous methods (myoma coagulation, myolysis)						Supracervical	
						Total	

Uterine Artery Embolization (UAE): This minimally invasive therapeutical option allows an occlusion of the specific arteries supplying blood to the fibroids. A catheter is introduced via the femoral artery under local anesthesia and particles are injected to block the blood flow to the fibroid. This can be an effective treatment option if the uterus should not be removed, surgery is contraindicated and family planning is completed. It results in myoma shrinkage of up to 46 %. Nevertheless, there is still a significant rate of postinterventional complications [23, 24].

Magnetic Resonance-guided focused UltraSound (MgRf-US): This is a more recent treatment method for uterine fibroids in premenopausal women. Again, the patients should have completed their family planning. In this noninvasive thermo ablative technique multiple waves of ultrasound energy are converged on a small volume of tissue, resulting in maximal thermal destruction. The limiting factors are size, vascularity and access [25, 26].

Uterine-Preserving Surgical Treatment of Fibroids

The surgical removal of fibroids is still the main pillar in the treatment of leiomyomas. Hysterectomy is the only definitive solution and can be performed as supracervical or total hysterectomy. Myomectomy performed by hysteroscopy, conventional laparoscopy or laparoscopy with robotic assistance and by the open or vaginal approach are alternative surgical methods.

Indications for surgical therapy of uterine fibroids are:

1. Abnormal uterine bleeding disorders (hypermenorrhea, dysmenorrhea, menorrhagia- and metrorrhagia)
2. Bulk-related symptoms
3. Primary or secondary infertility and recurrent pregnancy loss.

Counseling and Informed Consent

Patients undergoing an operative procedure have to be informed of the risks and potential complications as well as alternative operating methods. Counseling before surgery should include discussion of the entry technique and the associated risks: injury of the bowel, urinary tract, blood vessels, omentum and other surrounding organs and, at a later date, wound infection, adhesion-associated pain and hernia formation.

Counseling needs to integrate the individual risk dependent on the BMI of the patient. Depending on the medical history, it is important to consider anatomical malformations, number of vaginal births, midline abdominal incisions, a history of peritonitis or inflammatory bowel disease [27].

Myomectomy

Myomectomy is a surgical treatment option for women who have not completed their family planning or who wish to retain their uterus for any other reasons. The enucleation of fibroids by any method is an effective therapy for bleeding disorders or displacement pressure in the pelvis. Nevertheless, the risk of recurrence remains after myomectomy. Furthermore, if any other pathologies might be causative or only co-causative for the symptoms (such as adenomyosis uteri), these problems will persist [28]. Complications arising at myoma enucleations and pregnancy-related complications have been investigated extensively. All operating possibilities, especially laparoscopic versus laparotomic, but recently also laparoscopic versus robotic-assisted myomectomy have been evaluated. Uterine rupture or uterine dehiscence is rare and occurs in less than 1 % of laparoscopic cases and even less seldom in robotic-assisted and laparotomic cases. Careful patient selection and preparation, as well as suture techniques, appear to be the most important variables for myomectomy in women of reproductive age [29, 30]. Uteri with multiple fibroids have an increased number of uterine arterioles and venules. Therefore, myomectomy can lead to a significant blood loss and corresponding arrangements should be made [31].

Hysteroscopic Myomectomy

Submucosal fibroids have their origin in myometrial cells underneath the endometrium and represent about 15–20 % of all fibroids. Before the establishment of hysteroscopy as a minimally invasive and effective treatment method, these myomas were removed by hysterotomy or even hysterectomy. Increased surgical training, improvement of technology and the widespread use of hysteroscopic myomectomy have made it a safe, fast, effective and cheap method of fibroid resection while preserving the uterus [32].

Patient selection concentrates on intracavitary submucous and some intramural fibroids. More than 50 % of the fibroid circumference needs to be protruding into the uterine cavity. Deep myometrial leiomyomas require advanced operative skills and have an increased risk for perioperative complications and incomplete resection. The depth of myometrial penetration correlates with the volume of distension fluid absorbed [33, 34]. Few data are available on the size of myoma that prevents the use of the hysteroscopic approach. The European Society of Hysteroscopy suggests to limit the myoma size to 4 cm but the few existing data report a significant increase of complications in fibroids that are >3 cm. Surgical skills determine the size and number of myomas that can be resected [35].

Prior to hysteroscopy, knowledge of the patient's medical history is important e.g. history of caesarean section or any other reason to expect an anatomical disorder. A vaginal ultrasound scan must be performed to precisely determine the uterus location, size and all cervical and uterine pathologies [36]. If available and feasible, fluid hystero-sonography should be performed to better differentiate the relationship of leiomyoma to the endometrial cavity and the myometrium. No prophylactic antibiotic is required to prevent surgical site infection.

The first step is the dilation of the cervical channel with Hegar dilators up to Hegar 9. The most commonly used instrument for fibroid resection is the monopolar or bipolar wire loop. Using a monopolar device the fluid medium must be non-electrolytic, using a bipolar device the fluid medium is isotonic [37]. A continuous flow allows the clearance of blood out of the uterine cavity to improve visualization. Furthermore, the resected pieces can be retracted. Nevertheless, the surface of the myoma and the time needed for resection increase the risk of excessive fluid absorption [38].

The resectoscope is inserted through the cervix into the uterine cavity and after distension with fluid the uterine cavity is carefully inspected. The monopolar resectoscope requires a cutting current of 60–120 W. Bipolar resectoscopes offer the possibility of simultaneous cut and coagulation. The wire loop passes easily through the tissue. The incision starts at the highest point of the myoma. Only in pedunculated fibroids might the incision cut the peduncle first. The loop is then moved towards the surgeon using the spring mechanism and simultaneously the entire resectoscope is gently pulled backwards. The wire loop must be in view of the surgeon during the whole procedure. This motion is repeated until the whole myoma has been resected and the surrounding myometrium (depth) and endometrium (side) can be differentiated. All resected specimen is sent to the pathologist. In cases of heavy bleeding and reduced vision the endometrium and the cutting surface have to be reinspected. These areas can be desiccated with the coagulating current.

The resected area will be recovered by the surrounding endometrium during the following weeks. The complication rate is low (0.8–2.6 %) [38, 39]. Complications that can occur, especially after extensive resection, are uterine perforation or excessive fluid absorption. Absorption of distension fluid might result in hyponatremia or volume overload [40]. The recurrence rate is about 20 % in a follow-up period of more than 3 years [35] .

Laparoscopic Myomectomy

With the improvement of laparoscopic techniques and skills myomectomy can be performed laparoscopically in most women. The laparoscopic approach is usually used for intramural or subserosal fibroids. The main advantage compared to abdominal myomectomy is decreased morbidity and a shorter recovery period. Nevertheless, laparoscopic myomectomy is limited by surgical expertise and especially laparoscopic suturing skills [41, 42]. Selection criteria for laparoscopic myomectomy are location, size and number of fibroids. Nevertheless, these characteristics are variable in relation to the surgical expertise. Preoperative imaging is performed by vaginal ultrasound to assess the precise features of the leiomyomas [31, 36, 43, 44].

Laparoscopic myomectomy starts with the usual placement of ports and trocars. After placement of the initial port in the umbilicus or higher up in the midline, depending on the size of the fibroids, 2–3 ancillary trocars are placed in the lower abdomen about 2 cm medial of each iliac crest and possibly in the midline [31, 45, 46]. Myomectomy can lead to severe bleeding that will complicate the procedure due to reduced vision. Vessel bleeding is controlled by bipolar electrosurgical power tools. Intraoperative bleeding can be reduced using vasopressin or other vasoconstrictors. Vasopressin is diluted (e.g. 20 units in 100 ml of saline) and injected into the planned uterine incision site. Vasopressin constricts the smooth muscle in the walls of capillaries, small arterioles and venules. Nevertheless, due to side effects the surgeon should pull back the plunger of the syringe before insertion to check that the needle is not inserted intravascularly [47–49]. Alternatively, misoprostol can be administered vaginally about one hour before surgery to reduce blood loss [50].

The uterine incision is preferably made vertically as this allows a more ergonomic suturing of the defect. The incision is performed with a monopolar hook directly over the fibroid and carried through deeply until the entire myoma tissue has been reached (Figs. 30.1, 30.2, 30.3, 30.4, 30.5 and 30.6).

After exposure of the myoma, it is grasped with a tenaculum or sharp forceps and traction and countertraction are applied. The removal of the myoma can easily be performed with blunt and sharp dissecting devices. Capsular vessels should be coagulated before complete removal of the myoma as coagulation becomes more difficult if traction is unsuccessful and bipolar coagulation occurs in the remaining myometrium wall. Subsequent to removal, the myoma is morcellated with an electromechanical device under direct vision and at a safe distance to all structures, such as the small bowel, to avoid inadvertent injury. The myoma tissue is removed and sent for pathologic evaluation. The uterine defect is closed with delayed absorbable sutures in one or two layers, depending upon the depth of the myometrial defect. It is important that the suture starts at the deepest point to avoid any cavity that might lead to a weak uterine wall. Furthermore, we tie the knot extracorporally so that the knot can be pushed into the deep layers with full strength (Fig. 30.7).

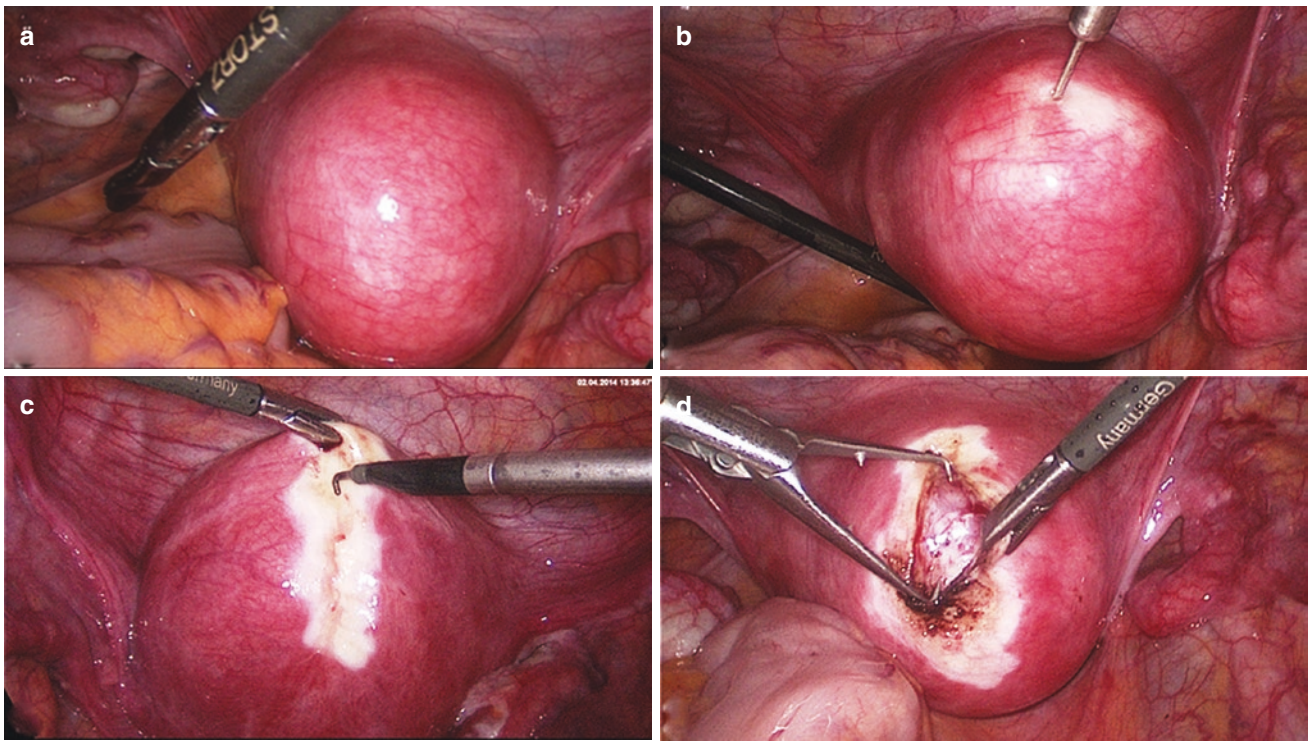

Fig. 30.1 Laparoscopic myoma enucleation. (**a**) Situs of a fundal/anterior wall fibroid. (**b**) Prophylactic hemostasis with 1:100 diluted vasopressin solution (Gylcilpressin) in separate wells. The injection intends to separate the pseudocapsule from the fibroid and reduces bleedings. (**c**) Bipolar superficial coagulation of the longitudinal incision strip and opening of the uterine wall with the monopolar hook or needle up to the fibroid surface. (**d**) Grasping of the fibroid and beginning of the enucleation. The pseudocapsule remains within the uterine wall and is pushed off bluntly

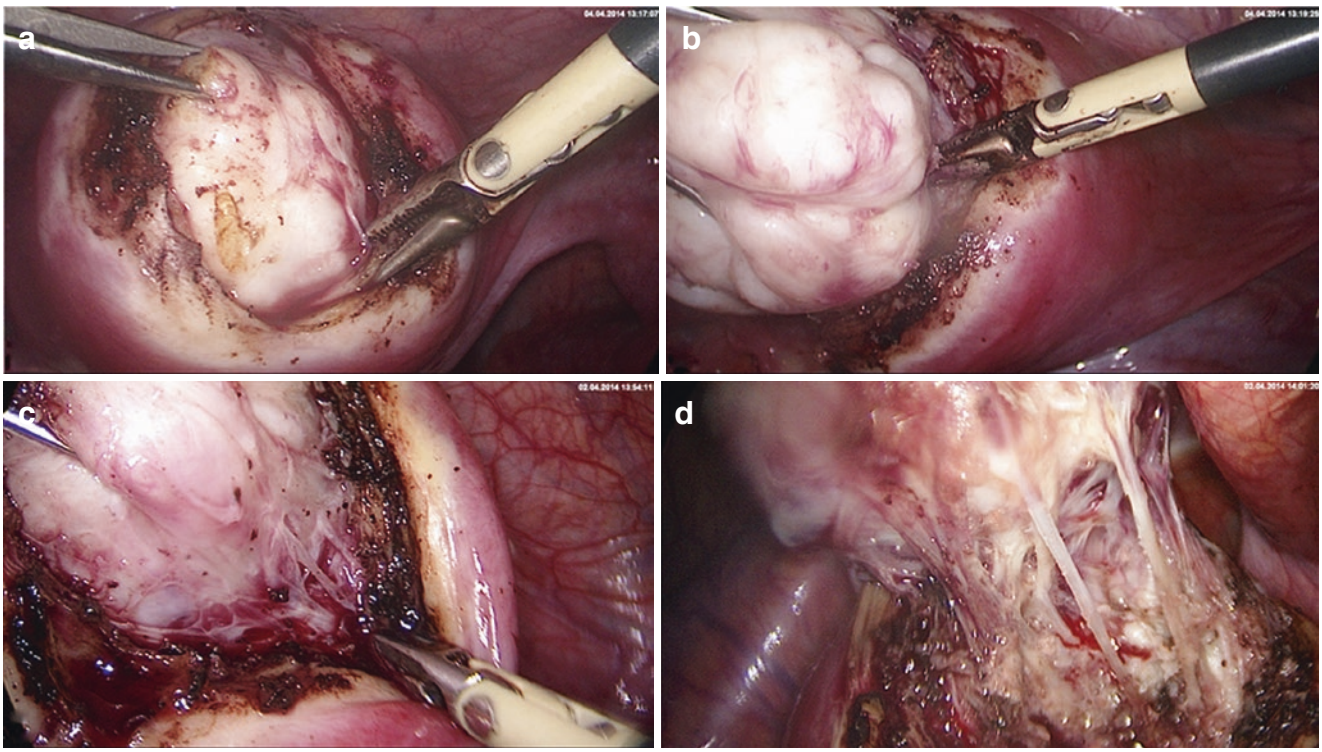

Fig. 30.2 Laparoscopic myoma enucleation. (**a**) Traction of the fibroid with a tenaculum and blunt delineation from the capsule. (**b**) Focal bipolar coagulation of basic vessels. (**c**) Continuous enucleation of the fibroid under traction and specific coagulation of capsule vessels containing fibers. (**d**) Magnification of remaining capsule fibers to be coagulated and cut

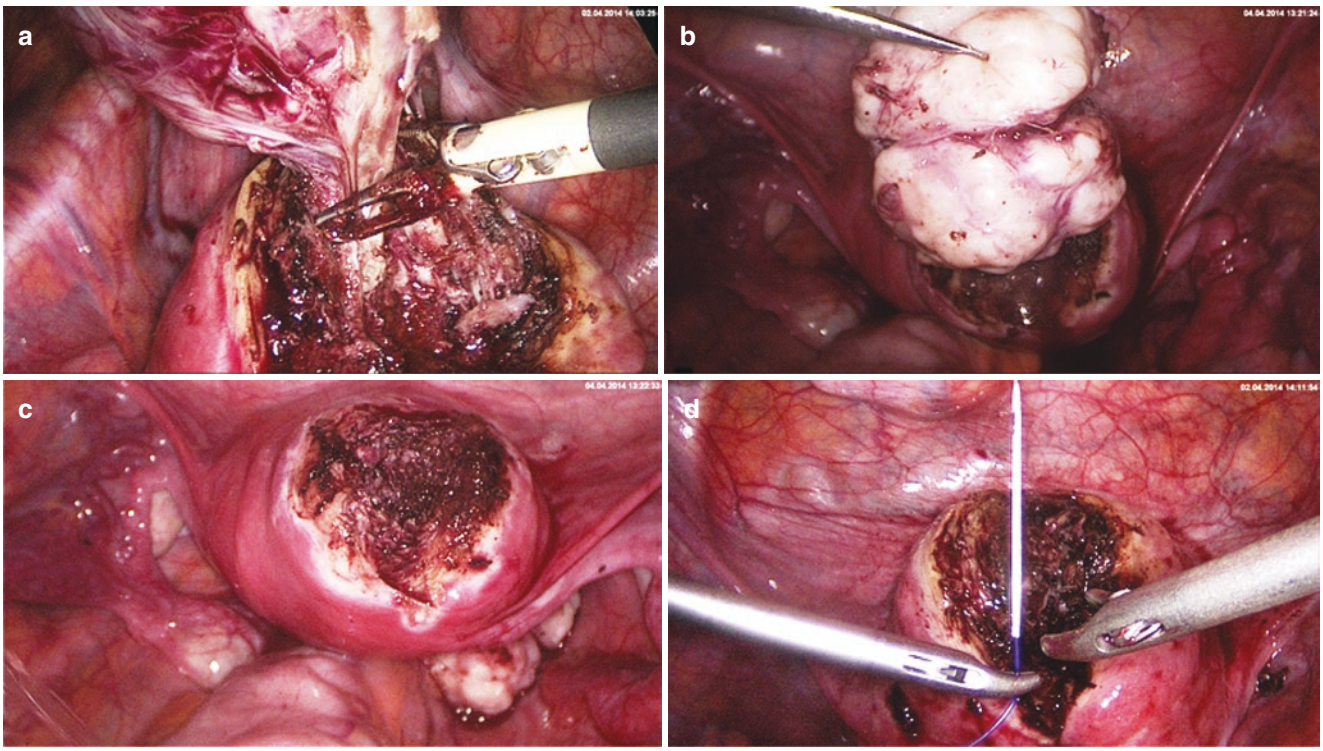

Fig. 30.3 Laparoscopic myoma enucleation. (**a**) Final coagulation of the capsule vessels. (**b**) Double belly fibroid after complete enucleation. (**c**) Minimal coagulation of bleeding vessels under suction and irrigation. (**d**) Approximation of wound edges with either straight or round, sharp needle and a monofilar late-absorbable suture

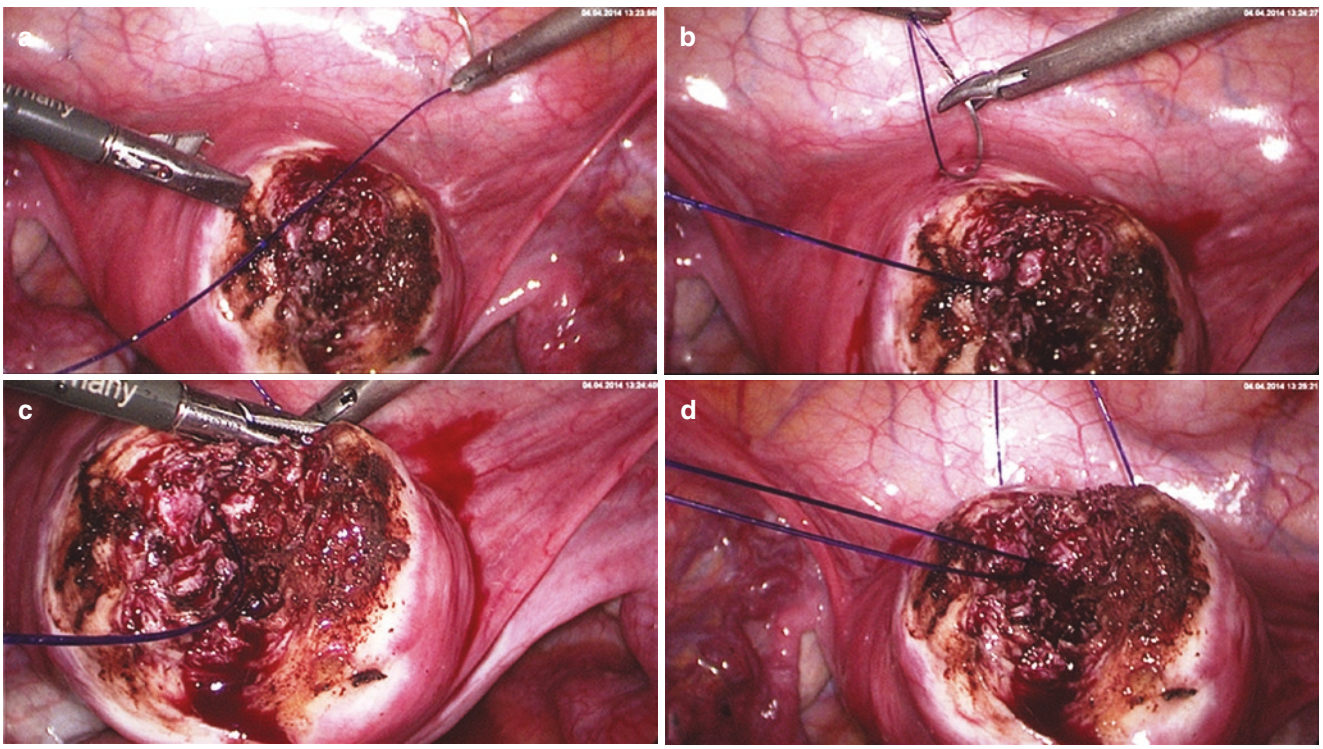

Fig. 30.4 Laparoscopic myoma enucleation. (**a**) Advantage of round needle stitch. The wound angle is elevated safely and completely by elevation with a Manhes forceps. Deeper layers of the myometrium can be grasped more easily using a round needle. (**b**) Needle exit and simplified regrasping with the right needle holder. (**c**) Final stitch to invert the knot. (**d**) Extirpation of the needle and completion of the extracorporeal knot and preparation to push down the extracorporeal knot

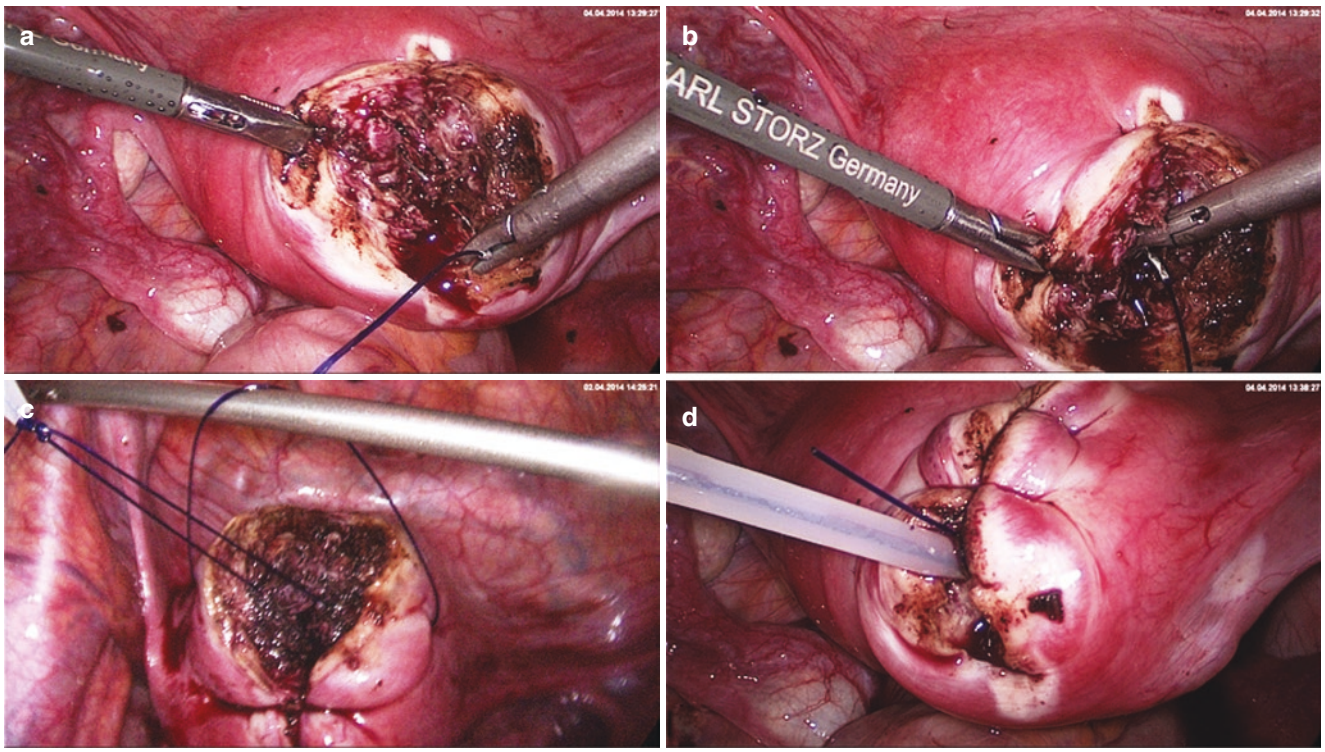

Fig. 30.5 Performance of the extracorporeal "von Leffern" knot. (**a**) Pulling out the suture, removing the needle, half hitch. (**b**) Holding the knot with the left hand and reaching over with the right hand. (**c**) Grasping the short end from below and leading it back, exiting before the half hitch. (**d**) Turning back the knot. Holding the straight suture and tightening the knot

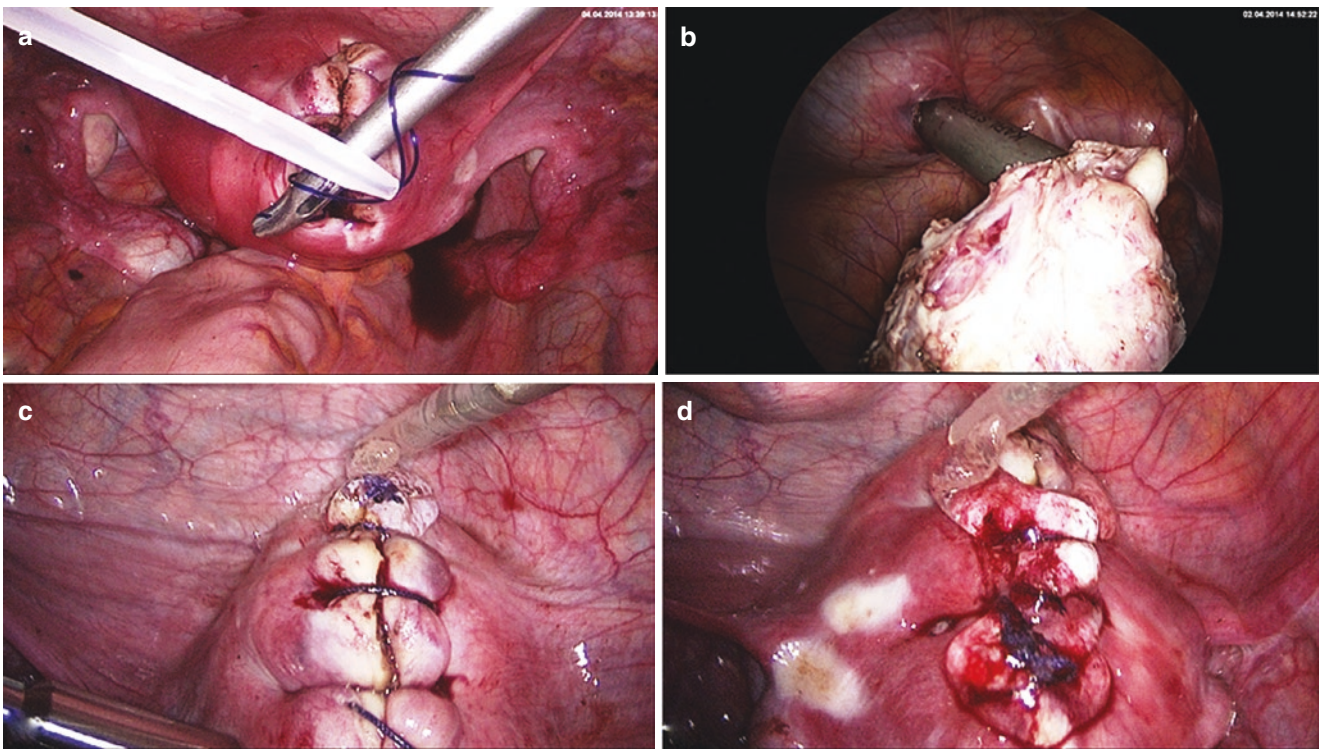

Fig. 30.6 Laparoscopic myoma enucleation. (**a**) Second single stitch starting as deep as possible in the uterine wound. (**b**) Exit of the needle on the left wound margin (just next to the Manhes forceps). (**c**) Completion of the stitch and preparation of the extracorporeal von Leffern knot. The needle holder elevates the thread to avoid tearing of the uterine wall while pulling through the monofilar thread (PDS). (**d**) The extracorporeal knot is pushed down with a plastic push-rod and deposited deep in the wound minimizing the external suture part

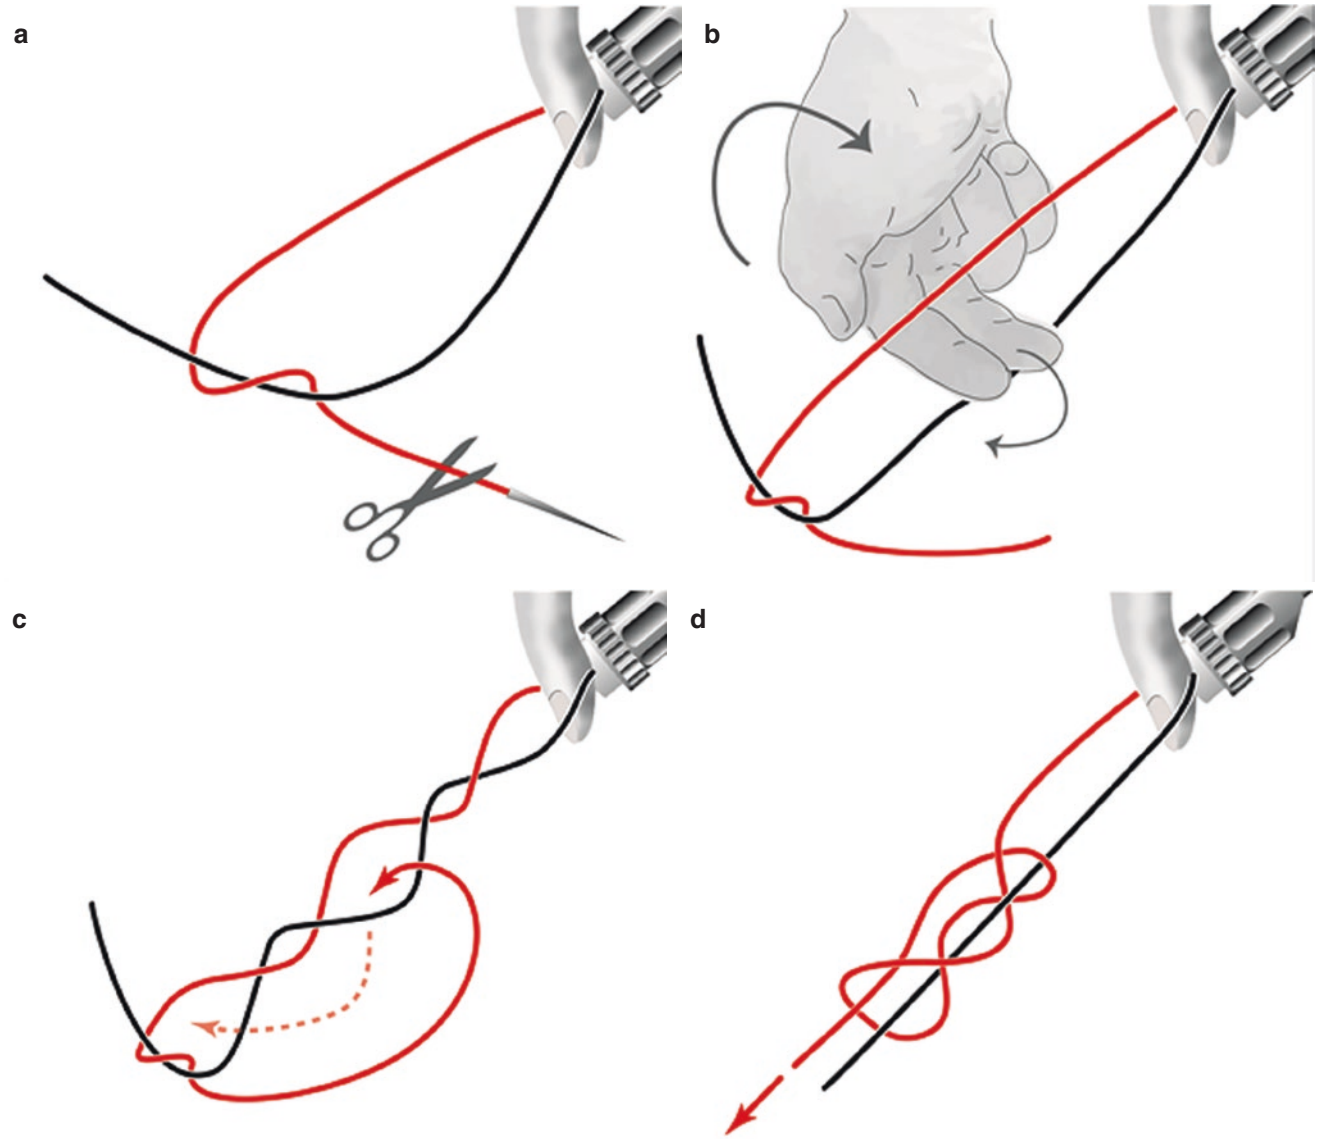

Fig. 30.7 Laparoscopic myoma enucleation. (**a**) Intracorporeal safety knot of the knot performed extracorporeally. (**b**) Morcellation of the fibroid with the Rotocut morcellator (Storz) in an apple-peeling manner. (**c**) Final situs showing the extracorporeal sutures to adapt the uterine wound edges. (**d**) Application of Hyalo Barrier (Nordic Pharma) for adhesion prevention

Alternatively, barbed sutures, such as V-lock, can be used to tighten the tissue or a third ancillary trocar can be inserted to hold the suture tight. The security of the uterine closure has bearing on the risk of uterine rupture in subsequent pregnancy. Different kinds of adhesion prevention barriers can be applied (Fig. 30.8) [51–53]. Women should wait at least 4–6 months before attempting to conceive [54].

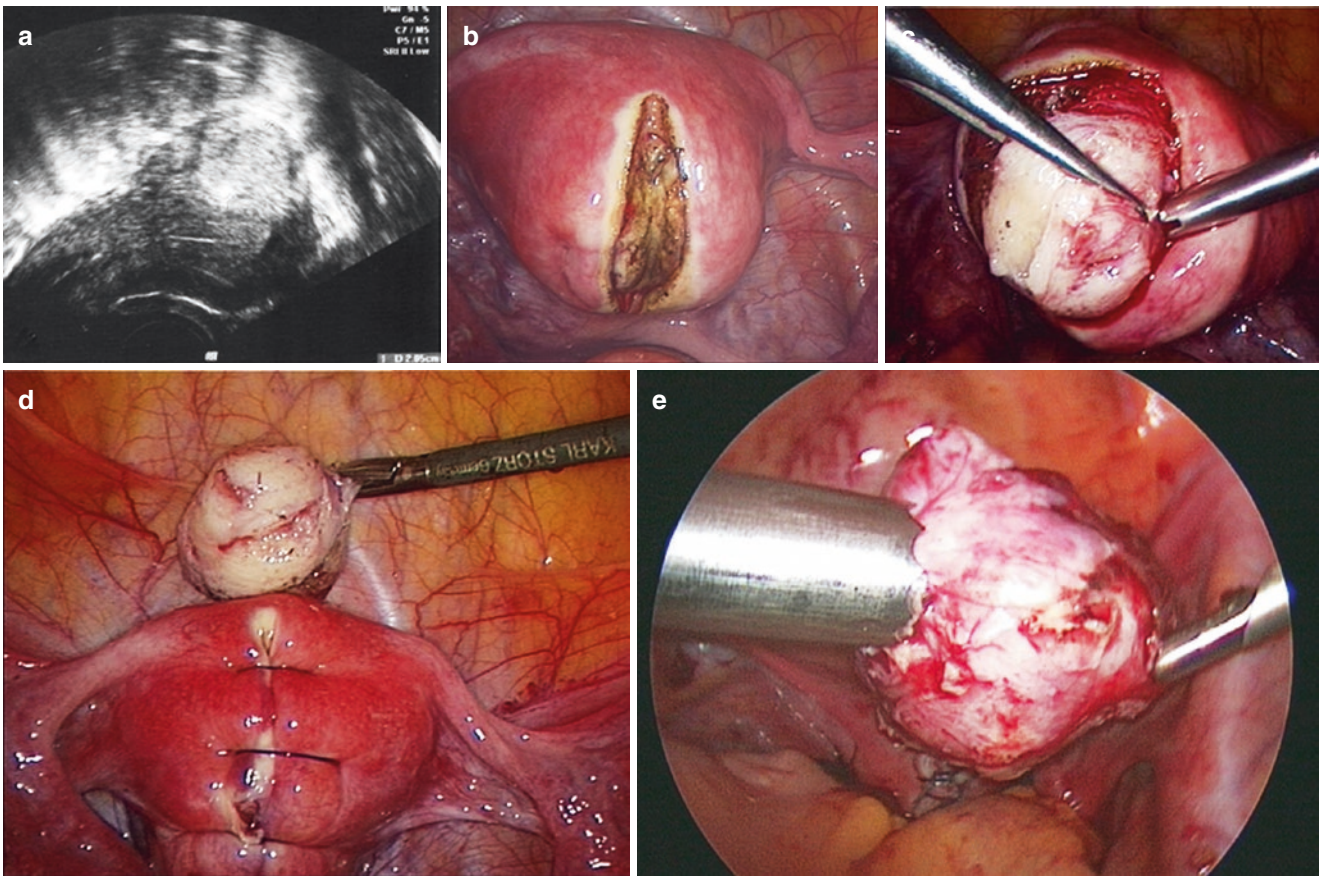

Fig. 30.8 (**a**) Transvaginal ultrasound shows a 3.5 cm intramural myoma in the back wall of the uterus. (**b**) Intraoperative uterotomy just above the myoma after injection of vasopressin. The uterotomy includes the myometrium and the myoma capsule and is done with a monopolar needle. All different tissue layers can be differentiated (**c**) Intraoperative sight of the myoma and its surrounding vascularized capsule. (**d**) Reconstruction of the uterine wall after excision of the tumor. (**e**) Removal of the myoma by morcellation

Abdominal Myomectomy

Abdominal or open myomectomy has its origin in the early 1900s as a uterus-preserving procedure. Today, it is mostly performed for women with intramural or subserosal myomas and less frequently for submucosal localization. Since the introduction of endoscopic procedures, the indication for abdominal myomectomy has become rare. It becomes an option if hysteroscopic or laparoscopic myomectomy is not feasible or if a laparotomy is required for any other reason. The indication to exclude uterine sarcomas has to be taken very strictly; however, uterine sarcoma is a very rare malignancy and the rate of sarcoma after clinical diagnosis of myoma is very low. The risk of severe complications in association with open surgery is higher than with hysteroscopic or laparoscopic moymectomy. Prophylactic antibiotics should be given for any abdominal fibroid operation [55, 56]. After the Pfannenstil incision either a vertical or transverse uterine incision is performed [57]. The myoma enucleation is performed by traction on the myometrial edges, e.g. with Allis clamps. After exposure of the fibroid it can be extirpated. The pseudocapsule is typically dissected bluntly. The uterine defects are closed with sutures in in several layers to reapproximate the tissue and achieve haemostasis without excessive bipolar coagulation.

Robotic Myomectomy

Robot-assisted laparoscopic myomectomy is a relatively new approach. The advantages of robotic surgery are three-dimensional imaging, mechanical improvement, including 7 ° of freedom for each instrument, stabilization of the instruments within the surgical field and improved ergonomics for the surgeon. Technical difficulties are decreased as suturing is easier than during conventional laparoscopy; however, there are few data comparing robot-assisted with conventional laparoscopic myomectomy [58–60]. The advantages compared to abdominal myomectomy are decreased blood loss and shorter recovery time. Nevertheless,

operation duration and operating costs are much higher than for conventional procedures. Furthermore, robotic devices are large and bulky. Robotic surgery is limited by the lack of tactile feedback and additional team training is necessary to minimize the risk of mechanical failure [61]. To date, no advantage compared to conventional laparoscopy could be demonstrated regarding blood loss or operative duration. A more secure myometrial closure has not yet been proven [59]. In obese patients robot-assisted surgery might be beneficial [62].

Hysterectomy as Treatment for Myomas

As fibroids are also the most common indication for hysterectomy (30 % of hysterectomies in white and 50 % of hysterectomies in black women), specific focus is given to hysterectomies within this chapter. The decision for a hysterectomy in a multifibroid uterus depends on the wish of the patient, her health status, whether childbearing has been completed and on the combined decision with the doctor. Only if the patient suffers from metrorrhagia does the disorder need to be examined pre-operatively in more detail as this may be a sign of endometrial cancer or sarcoma. Nevertheless, the combined evaluation of MRI and tumor makers pre-operatively leads to a more specific diagnosis of rapidly growing uterine masses or adnexas in the case of a leiomyomatous uterus or adnexal tumors. Only in cases where malignancy is not suspected is a simple TLH or SLH recommended, otherwise an oncological approach has to be selected. Hysterectomy as TLH or SLH is recommended for the following indications:

- Acute hemorrhage with non-response to other therapies
- Completion of family planning and current or increased future risk of other diseases, such as cervical intraepithelial neoplasia, endometrial hyperplasia or an increased risk of uterine or ovarian cancer. Precondition for the indication for hysterectomy is that these risks can be eliminated or decreased by hysterectomy.
- Failure of previous treatment.
- Completion of family planning and significant symptoms (e.g. multiple fibroids or adenomyosis) and the desire for a definitive solution.

The main advantage of hysterectomy over all other therapeutical possibilities is the definitive solution in eliminating all existing symptoms and the risk of recurrence. Nevertheless, the advantage of a definitive solution that allows freedom from future problems can be an obstacle if family planning has not been completed or the patient has a personal inhibition against the removal of the central genital female organ [63]. These issues must be discussed in advance with the patient before the decision for a hysterectomy is taken. Furthermore, for a solitary submucous, subserous, pedunculated or intramural myoma, the complication rate of a hysterectomy has to be compared with the complication rate of a myomectomy. The operational risks have to be compared to the operational risks of hysteroscopy, laparoscopic fibroid enucleation or conservative management. With the advances in cervical cancer screening the prevention of future cervical or uterine pathologies is no longer a relevant indication for hysterectomy. The decision must be tailored to meet the needs of each individual patient.

Laparoscopic hysterectomy was first introduced in 1989 with the aim of reducing the morbidity and mortality of abdominal hysterectomy to the level reached with vaginal hysterectomy. Laparoscopic assistance for vaginal hysterectomy can be of advantage if there is a need for adhesiolysis, a need to treat endometriosis simultaneously, a need to treat large leiomyomas and to ensure an easier and safer adnexectomy. If feasible, vaginal hysterectomy allows a more rapid and less painful recovery than open or laparoscopic surgery and is much cheaper [64].

Should Ovaries and/or Fallopian Tubes Be Removed or Left in Place at Hysterectomy?

Ovaries

Generally, the ovaries are not removed when a hysterectomy is performed for uterine fibroids. Removing the uterus alone will cure the bleeding and the size-related symptoms caused by the fibroids. When treating fibroids it is not necessary to remove the ovaries or fallopian tubes as is sometimes the case when treating other diseases, such as endometriosis or gynecologic cancers.

Many physicians were taught that at a set age (which varies between 35 and 50) women should be told that removal of the ovaries is recommended as part of the surgery, with the speculation of “while we are there, we may as well.” The general teaching has been that ovaries do not have any function after menopause and the risk of ovarian cancer increases with increasing age, so removing the ovaries near the time of menopause was a no-lose proposition. This was especially true if hormone replacement therapy could be used to help younger women transition to the time when they would naturally go through menopause.

However, more recent research suggests that although after menopause the ovaries produce little estradiol (the major estrogen in premenopausal women), they produce a tremendous amount of androgens (usually thought of as male hormones) [65]. It is thought that these androgens may be important in maintaining mood and sex drive [66–68]. In

addition, the risks of hormone replacement have become clearer, and many women choose to use hormones following menopause [69, 70]. Most women are aware of the research from the Women's Health Initiative demonstrating significant complications with postmenopausal hormone replacement therapy. However, it is not widely known that the risks are lower for women without a uterus, who are able to take estrogen alone [70]. Recently the association of premature loss of ovarian function and the increasing risk of heart disease has also been investigated [71].

Considering all these factors, there are good reasons to retain the ovaries if possible. The major reason to remove them at the time of fibroid surgery is if the woman has a high risk of ovarian cancer.

Fallopian Tubes

According to new research presented at the Annual Clinical Meeting of The American College of Obstetricians and Gynecologists in 2013, bilateral salpingectomy at hysterectomy, with preservation of the ovaries, is considered a safe way of potentially reducing the development of ovarian serous carcinoma, the most common type of ovarian cancer. Increasing evidence points toward the fallopian tubes as the origin of this type of cancer. Removing the fallopian tubes does not cause the onset of menopause, as does the removal of the ovaries.

Prophylactic removal of the fallopian tubes during hysterectomy or sterilization would rule out any subsequent tubal pathology, such as hydrosalpinx, which is observed in up to 30 % of women after hysterectomy. Moreover, this intervention is likely to offer considerable protection against later tumor development, even if the ovaries are retained. Thus, we recommend that any hysterectomy should be combined with salpingectomy. Women undergoing hysterectomy with retained fallopian tubes or sterilization have at least a doubled risk of subsequent salpingectomy. Removal of the fallopian tubes at hysterectomy should therefore be recommended [72, 73].

For this reason, once the reproductive function is completed the tubes of a female of reproductive age should be removed while the ovaries should remain to support the female wellbeing. Beyond the reproductive age, tubes should always be removed with the uterus while ovaries, as previously discussed, are routinely removed only above the age of 65 years.

Abdominal Hysterectomy

As the indication for abdominal hysterectomy in benign diseases has become very rare, it is not discussed in this article [74].

Vaginal Hysterectomy

Before beginning a vaginal hysterectomy, a bimanual pelvic examination is performed to assess uterine mobility and descent and to exclude unsuspected pathology of the adnexa. Only then can a final decision be made whether to proceed with a vaginal or abdominal approach. The operation starts with entry into the cul-de-sac or the vesico vaginal fold. Here we describe the posterior peritoneal opening. The uterosacral ligaments are identified and clamped, including the lower portion of the cardinal ligaments. In the next step the vesicovaginal space is opened and after identification of the peritoneal fold it is cut and the cardinal ligaments are ligated, including the uterine vessels. Most adnexa can be removed by grasping the ovary and clamping the infundibulopelvic ligament. The uterus can then be enucleated stepwise from the remaining peritoneal fold at a safe distance from the bladder. The peritoneum can either be closed or left open and the vaginal epithelium is reapproximated in either a vertical or a horizontal manner. A myomatous uterus has to be morcellated in a circular manner. Sometimes it is necessary to enucleate large solitary myomas or perform intramyometrial coring, especially in cases of diffusely enlarged uteri [75, 76].

Subtotal Laparoscopic Hysterectomy (SLH)

The supracervical (subtotal) hysterectomy was first described by Semm in 1990 and in another technique by Lyons. The operative technique is similar to the total laparoscopic hysterectomy. Only after occluding the ascending branch of the uterine artery is the uterine corpus resected as a reverse conus down to the endocervical canal [77]. For SLH and TLH the trocar placements are the same as for laparoscopic myomectomy and depend on the size of the uterus (see above). There is no need to perform ureterolysis at the beginning of the operation as the ureter is at a safe distance if the suturing line is kept strictly at the uterine wall. The infundibulopelvic ligament and the round ligament are divided from the pelvic side wall and, if the adnexa are to remain in situ, division of the adnexa from the uterus is performed. The broad ligament is then opened, dissected and each leaf separately coagulated. The bladder is separated from the uterus by opening the vesicouterine ligament and pushing the bladder downwards for about 1–2 cm. This is followed by presentation of the ramus ascendens of the uterine artery and division of the uterine pedicles with the same stepwise dissection of the left adnexa. A thorough inspection of the cervix then takes place. The cervix is separated from the uterus with the help of the electric cutting loop or any other cutting instrument. This is followed by coagulation of the cervical canal and closure of the peritoneum over the remaining cer-

vical stump for infection and adhesion prevention. However, the peritoneum can also be left open, according to surgeon preference. Afterwards, morcellation of the uterine body is performed and, if the adnexa are also resected, they should be put into an endo bag for extraction.

As morcellation techniques are described in detail in other chapters of the book, the importance of this technique is not dealt with here.

Total Laparoscopic Hysterectomy (TLH)

LSH should be avoided if adenomyosis uteri is suspected because part of the endometrial glands remain in the cervical and paracervical channel. These can cause an early recurrence or persistence of the symptoms although the few existing data offer no direct confirmation of this view [78, 79].

The surgical steps are identical to the LSH, the only difference being that a uterine manipulator is placed in the vagina before the operation. After separation of the bladder from the uterus, the bladder is pushed and dissected down 2–3 cm to clearly visualize the rim of the cervical cup. In cases of post-caesarean section, a gentle, blunt and intermediate sharp dissection has to be carried out. After the uterus has been lateralized by pushing up the manipulator, the uterine artery and vein with collateral vessels are completely coagulated near the cervix and dissected. The vagina is resected from the cervix with the monopolar hook by firmly stretching the manipulator cranially and carefully performing an intrafascial dissection leaving the sacrouterine ligaments almost completely in place. This is in accordance with the CISH technique introduced by Kurt Semm [80]. The uterus is then retracted through the vagina while still fixed to the manipulator. If the uterus is too large, it has to be morcellated either intraabdominally or transvaginally. The vagina is closed with 2 corner sutures and 1 or 2 sutures in between the corner sutures. The sacrouterine ligaments and the middle portion of the vagina are stitched and elevated by the corner sutures to prevent vaginal prolapse or enterocele formation at a later time. Peritonealization and drainage are not required.

With the improvement of endoscopic surgery and above all the improvement in endoscopic suturing laparoscopic-assisted vaginal hysterectomy has become obsolete, especially as this technique does not include a suspension of the cardinal and sacrouterine ligaments.

Conclusions

Treatment options for uterine leiomyomas vary. The choice of treatment should be made on an individual basis taking into account the following factors: the patient's level of suffering due to bleeding disorders or displacement-caused pain, the status of family planning and the patient's preferences regarding the different treatment options.

In *asymptomatic women* expectant management is suggested except for hydronephrosis caused by displacement or hysteroscopically resectable submucous fibroids in women who pursue pregnancy.

In *postmenopausal women* without hormonal therapy fibroids usually shrink and become asymptomatic. Therefore, expectant management is the method of choice. However, sarcoma should be excluded if a new or an enlarging pelvic mass occurs in a postmenopausal woman. Surgical treatment is the option of choice if the leiomyomas are symptomatic. If there are contraindications to operative procedures or hysterectomy is declined by the patient for personal reasons, any of the alternative treatment options can be considered (medical, embolization or guided ultrasound).

In *premenopausal women* appropriate submucosal leiomyomas should be resected hysteroscopically if the women wish to preserve their childbearing potential and/or they are symptomatic (e.g. bleeding, miscarriage). Intramural and subserosal leiomyomas in women who wish to preserve their fertility can be removed laparoscopically. Nevertheless, an appropriate surgical technique and advanced laparoscopic skills are necessary. If this cannot be guaranteed, abdominal myomectomy has to be recommended or referral to a laparoscopic center to maximize the possibility and safety of pregnancy after uterine reconstruction. The risk of uterine rupture in pregnancy following myomectomy needs to be discussed with the patient.

Robotic assistance makes laparoscopic suturing easier and offers surgery with 3 dimensional vision; however, costs are still high. Further developments in robotic assistance, including force feedback, will catch more of our attention in the future.

For *women who have completed their family planning,* hysterectomy is the definitive procedure for relief of symptoms and prevention of recurrence of fibroid-related problems. With increasing experience in laparoscopic hysterectomies, the risk of side effects has become manageable. In relation to the compliance and individuality of the patient, a suitable solution can be either laparoscopic supracervical or total laparoscopic hysterectomy.

Introduction

Uterine fibroids (also known as leiomyomas or myomas) (Fig. 31.1) are the most common benign tumors of the genital organs in women of childbearing age. They could have negative impact on reproductive system and can be single, but are more often multiple, causing significant morbidity, and impairment of the quality of life [1, 2]. According to the literature, 40–60 % of all hysterectomies are performed for the presence of myomas. Myomas are the most common indication for hysterectomy in the USA and Australia [3, 4]. The first who described myomas was Matthew Baille in 1793 [5]. Myomas consist mainly of smooth muscle cells containing different amounts of fibrous tissue [5].

During its growth, myoma determines compression on the surrounding structures (myometrium and endometrium),

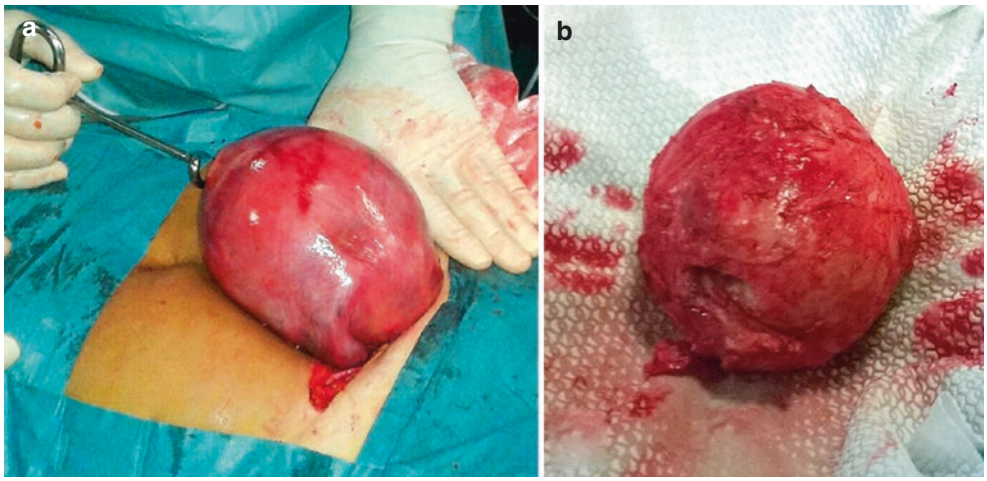

Fig. 31.1 To the left, a uterus removed from the abdomen by suprapubic transverse laparotomy; the uterus is deformed by large intramural myoma of the fundal-body of about 12 cm of diameter (*H*). On the right shows the enucleated myoma myomectomy by laparotomy (**b**)

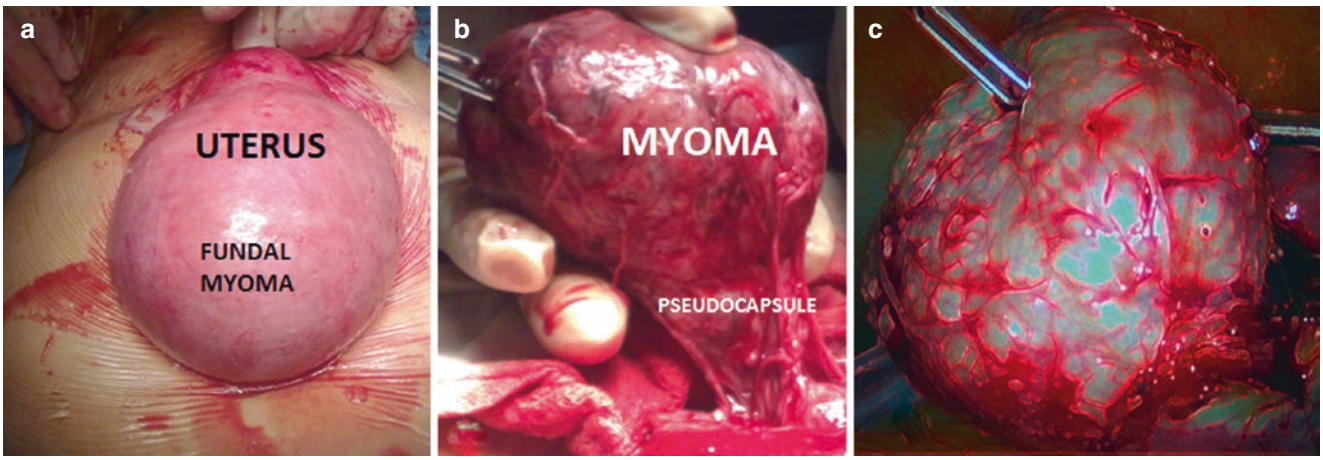

Fig. 31.2 On the left, the picture shows a uterus removed by laparotomy, deformed by a fundal fibroid 7 cm in diameter (**a**); at the center, the image shows a laparotomic myomectomy, with fibroid extraction and highlighting myoma pseudocapsule (**b**); to the right, a myoma with overhanging trace of the myoma pseudocapsule on the fibroid surface (**c**)

causing the progressive formation of a sort of pseudocapsule, rich of collagen fibers, neurofibers and blood vessels (Fig. 31.2).

Occasionally, the pseudocapsule surface is interrupted by bridges of collagen fibers and vessels that anchor the myoma to the myometrium. This causes the formation of a clear cleavage plane between myoma and pseudocapsule, and between pseudocapsule and the surrounding myometrium. This pseudocapsule causes a displacement and not destructive action on the myometrium, maintaining the integrity and contractility of uterine structure [6, 7].

Literature data has show that between 5.4 and 77 % of women have myomas; this wide range depends on the study population or on the diagnostic techniques applied to myoma detection [8].

Ultrasound studies documented that myoma prevalence is lower in Europe than in the United States, probably because of racial differences [9, 10]. In 65–70 % of cases, fibroids are multiple and can be found in various uterine locations. Most frequently they are within the wall of the uterus (Fig. 31.3) where they can expand in the myometrium (intramural leiomyoma), beneath the endometrium, simulating a polyp (submucosal leiomyoma), beneath the serosal surface (subserosal leiomyoma), within the broad ligament, simulating an adnexal neoplasia (intraligamentous leiomyoma) or under the uterine isthmus, called cervical leiomyoma (Fig. 31.4) [8].

The compression of the endometrium causes atrophy and erosion with bleeding. Subserosal leiomyomata (Fig. 31.5) can be pedunculated (Fig. 31.5) and in some cases can separate from the uterus and create a new vascular peduncle with another nearby organ (parasitic leiomyoma) [6–8].

They are well circumscribed, firm, and grey-white and with a whorled cut surface (Fig. 31.6). They may degenerate, especially in pregnancy, and become soft with a yellowish hue in necrosis or a reddish color due to hemorrhaging [8].

Myomas have been in 70 % of cases after hysterectomy, and multiple myomas have been present in more than 80 % of cases [11].

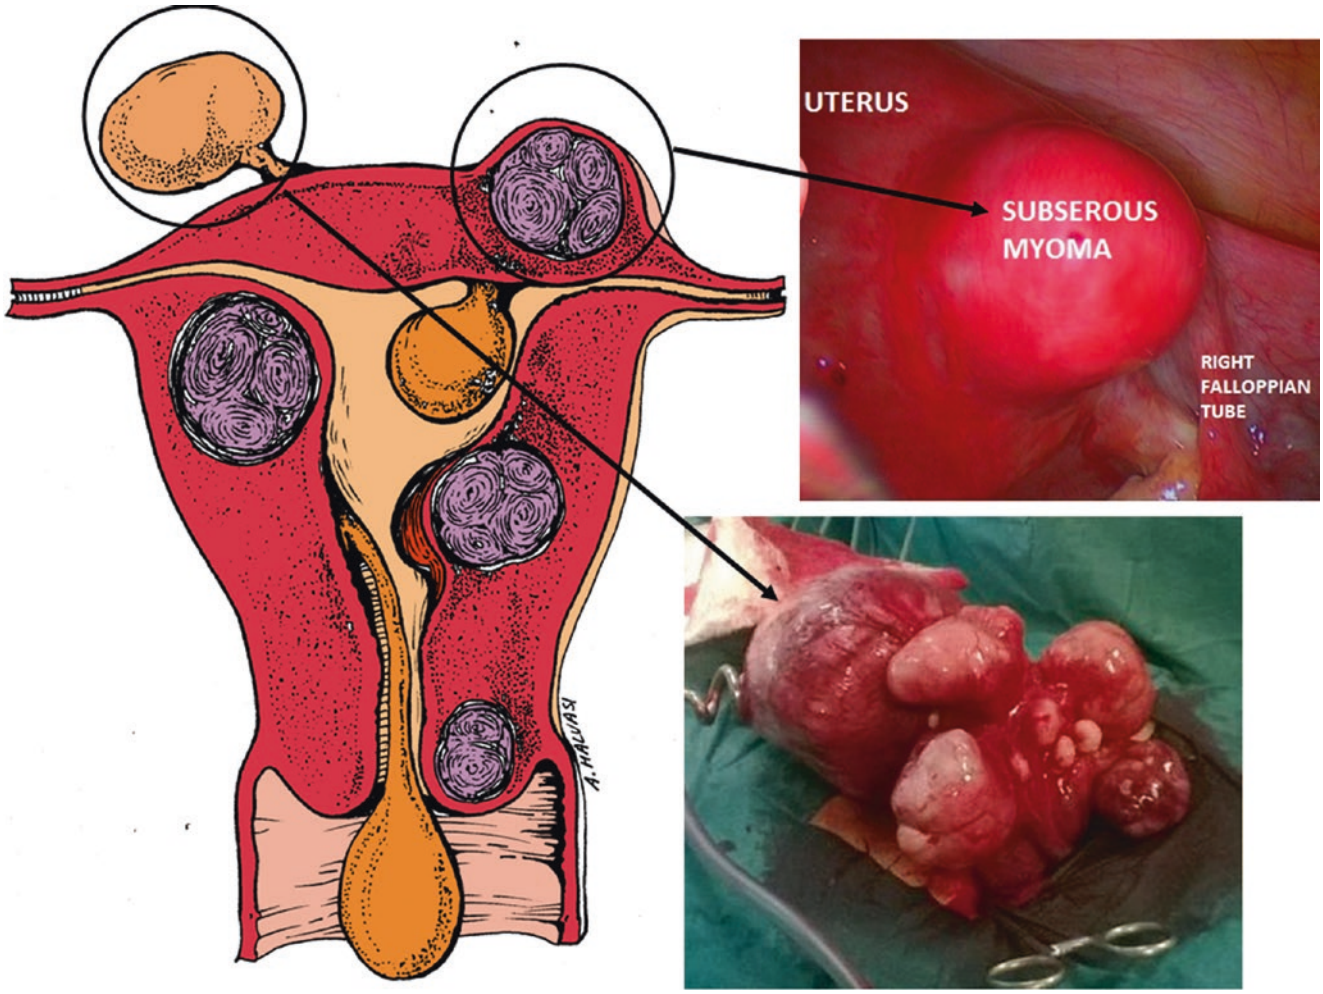

Fig. 31.5 On the left, a representation of fibroids location; on the right, at the top, a laparoscopic image showing a subserosal myoma on uterine body, near right fallopian tube. On the right, below, a laparotomic image showing a myomatosic uterus with several pedunculated fibroids

Fig. 31.6 The picture shows a uterus with a large number of myomas, anteriorly dissected from the bottom up to the cervix: fibroids appear well circumscribed, firm, *grey-white* and with a whorled cut surface

Previous epidemiological studies, focusing mostly on symptomatic women, have largely underestimated myoma prevalence [5, 10–12].

Over the past two decades, epidemiological studies have become more accurate, since they investigate a wide range of general population and use advanced non invasive imaging techniques, such as accurate 3D–4D ultrasound screening [1, 10].

Thus, Laughlin et al. [12], demonstrated the prevalence of myomas in 10.7 % of women in the first trimester of pregnancy (Fig. 31.7), which is lower than previously reported.

Some of the data on epidemiologic factors associated with myoma risk are well defined, while the others are not yet fully understood [10].

Documented predispositions in myoma formation and development include: age, race, body mass index (BMI), as well as heritage, reproductive factors, sex hormones, obesity, lifestyle (including diet, caffeine and alcohol consumption, smoking, physical activity and stress), environmental and other pathologies (as hypertension and infection) [1, 10–14].

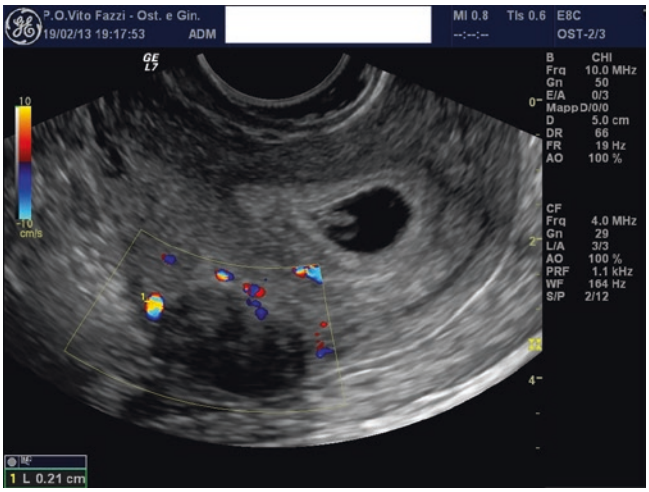

Fig. 31.7 A traditional transvaginal ultrasonographic image by 2D and Doppler ultrasound probe, showing a posterior subserous myoma and a gestational sac with within the embryo of 6 weeks

Clinical Presentation of the Fibroids

Uterine myomas may be present for years in some women without any symptoms and diagnosed incidentally, during routine gynecological examination or investigation for other illness [15, 16]. In other cases, they are an important cause of morbidity and may result in the need for multiple surgical procedures [16–18].

It is believed that the only 20–50 % of women with uterine fibroids have symptoms. The reasons why some myomas are symptomatic and some not, have not been yet full understood [19], although size, localization and number of fibroids are factors affecting the symptoms [19, 20]. Sometimes women with the fundus uteri reaching the umbilicus do not report any problems, except for the enlargement of the abdomen and the increase in body weight (Fig. 31.8) [19]. It is also unproven that women with multiple fibroids (Fig. 31.9) tend to have more symptoms, compared with those who have only one fibroid [19].

Fig. 31.8 The picture shows, on the right, a 46 years' women on the surgical table with a significant abdomen enlargement; the patients referred just an increase in body weight and poor clinical symptoms; On the right, the laparotomic hysterectomy with a uterus deformed by a huge myoma of 3.5 kg in weight

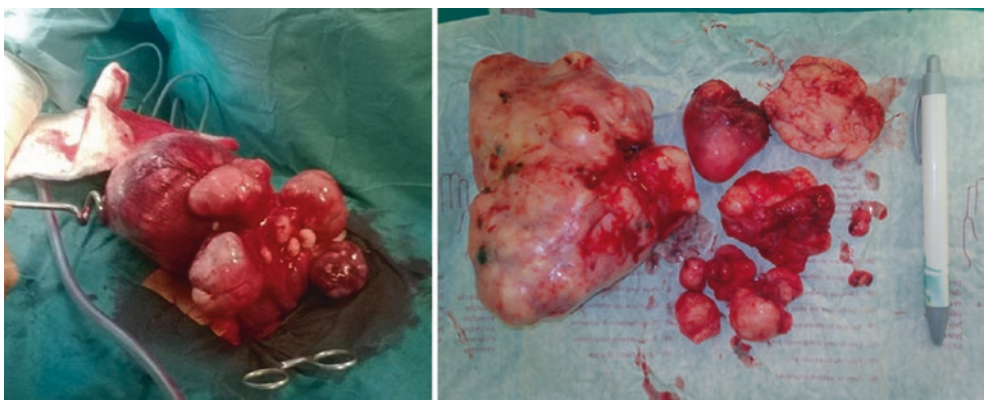

Fig. 31.9 On the left, the picture shows a uterus, deformed by many fibroids, located over the abdomen during a laparotomic myomectomy; on the right, the 11 enucleated myomas

Symptomatic fibroids usually occur in women in their thirties and forties, although they can occur, as well, in other age groups [21, 22]. In 62 % of women affected by uterine fibroids are symptomatic [20].

The most common presenting symptoms of uterine fibroids are: bleeding (menometrorrhagia, metrorrhagia or intermenstrual bleeding), pain, symptoms of compression of adjacent organs, change of the abdomen wall outline and infertility [16, 21, 23].

The Problem of Suspected Fibroid Malignant Alterations

Malignant alteration of uterine fibroids occurs mainly in postmenopausal women and is rarely asymptomatic. The main presenting symptoms of uterine leiomyosarcomas are abnormal vaginal bleeding, pain in the lower abdomen and a pelvic or abdominal mass [40]. In the past, if sudden growth of uterine fibroids is observed, especially after menopause, malignancy should be suspected and these tumors should be surgically removed. Recent evidences indicate that in premenopausal women, "rapid uterine growth" almost never indicates presence of uterine sarcoma [24].

Parker and colleagues examined 1332 women who had undergone a hysterectomy for uterine fibroids as the sole indication for surgery. Only 1 patient out of 371 women operated on for a "'myoma fast-growing" had proved to be a leiomyosarcoma. When the surgeons had judged that the myoma was at "rapid growth", defined as an increase of uterine volume as a womb of 6 weeks of pregnancy in 1 year of observation, none of the 198 patients who had this diagnosis was later shown to a uterine sarcoma at histological examination. Two of these women had instead endometrial stromal sarcoma. A patient of 30 years in the group of patients candidates for hysterectomy showed a normal uterus 22 months before; to gynecological presurgical, had a very large size of the uterus, such as a uterus of 16 weeks. After surgery, histological examination was shown a leiomyosarcoma. None of the 198 patients who had the criteria of "rapidly growing myoma" had a leiomyosarcoma, a mixed mesodermal tumor, or endometrial stromal sarcoma. None of the 17 postmenopausal women admitted for rapid uterine growth proved to be a sarcoma [25].

The uterine leiomyosarcoma (Fig. 31.10) is a very rare condition, has an incidence ranging from 0.5 to 3.3 per 100,000 women per year, with a further incidence of sarcomas in women with myomas at rapid growth of 0.27 % [26].

The transformation of leiomyomas in leiomyosarcoma is very rare [27].

Indisputable scientific data strongly suggest that uterine leiomyosarcomas are solitary lesions and are not commonly found in association with uterine myomas. If there is malignant transformation of uterine leiomyomas, is a rare event. The hypothesis that a uterine leiomyosarcoma derived from a myoma or are the result of malignant transformation of benign leiomyomas is never demonstrated [28].

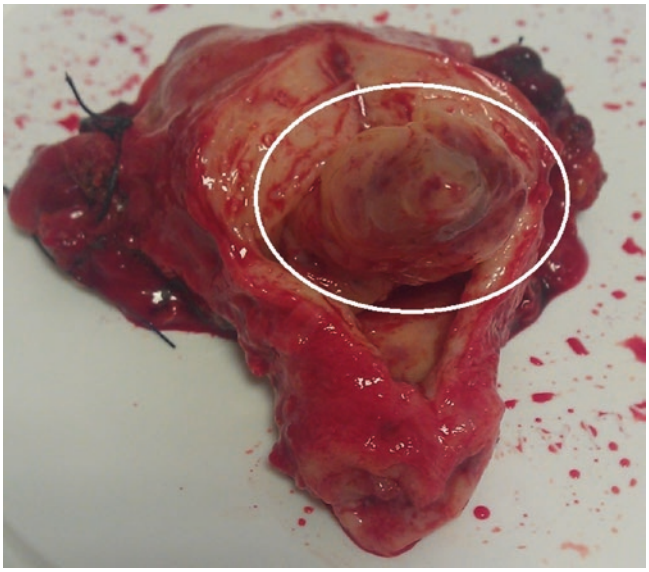

Fig. 31.10 A section uterus by pathologist with, in the white ring, a protruding single leiomyosarcoma of 4 cm, occupying almost the uterine cavity

There is no scientifically validated screening instrument that allow to diagnoses a sarcoma, since the diagnosis of sarcoma is purely histological and sometimes mixed with areas of benign myoma. In fact, to perform a diagnosis of leiomyosarcoma is not easy, even on extemporaneous histological examination. In most medical centers, the frozen section is not the histological technique for the final diagnosis. From one to three slides of a so-called "fibroid" can be routinely assessed when examining the frozen sections. It is more common than you think wrong or missing the diagnosis of uterine leiomyosarcoma in the frozen section [29, 30].

The Histopathology of Myomas

Histologically, the tumor is made up of cells similar to that of the contiguous endometrium (elongated, eosinophilic cytoplasm with central, blunt-ended, pale elongated nucleus, sometimes with clumped chromatin. The cells form whirling fascicles interlaced at right angles. This arrangement clearly distinguishes the leiomyoma (Fig. 31.11) from the surrounding myometrium, which shows a more regular pattern of the muscle fibers (Fig. 31.12). Furthermore, a large number of tumors show a clear border with the myometrium, even forming a valley, exaggerated by fixation artifact, with the

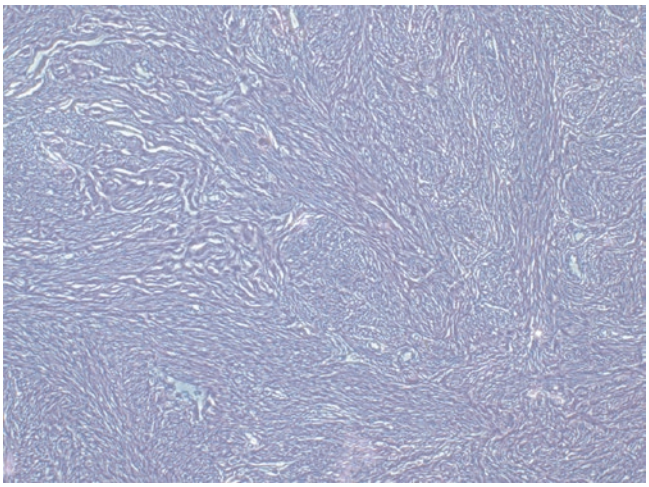

Fig. 31.11 A uterine leiomyoma composed by bundles of spindle cells, similar to those present in the myometrial wall: only the whirling and irregular arrangement of the cellular bundles distinguish the neoplastic proliferation

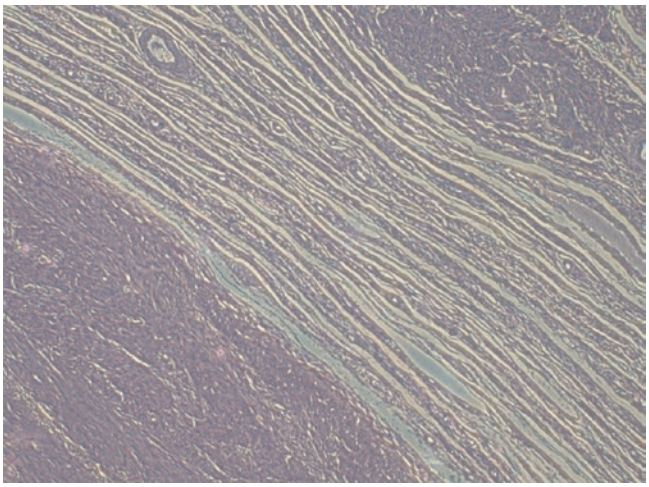

Fig. 31.13 At the center of the image shows a bundle of muscle fibers, collagen tissue and blood vessels are surrounded by extracellular matrix; this is what is known as a myoma pseudocapsule

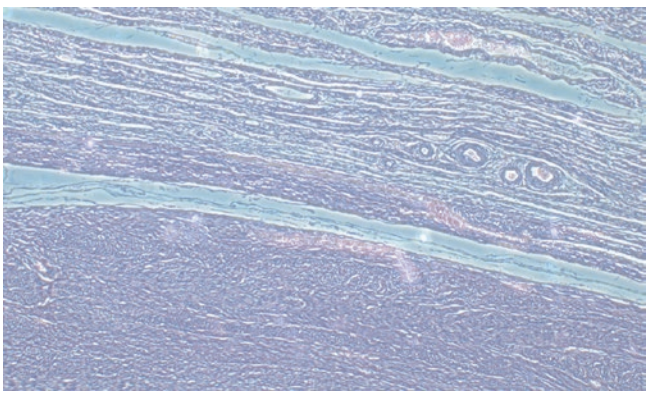

Fig. 31.12 The myometrium (in the *lower part*) surrounding myoma (in the *upper part*) shows a more regular pattern of the muscle fibers

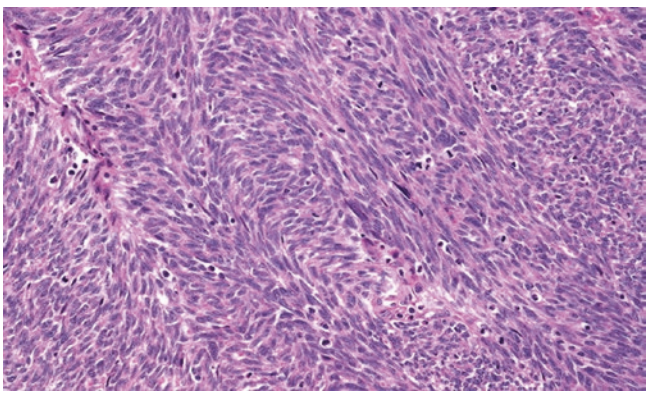

Fig. 31.14 A leiomyosarcoma: other than "tumor cell necrosis", it is detecting the presence of moderate-severe atypia and a mitotic index over 10/10HPF

formation of a ring of compressed myometrial cells, the pseudocapsule. In conservative myomectomy the surgeon exploits this valley to allow an easy excision of the tumor from the uterine wall. This interstitial space is formed from a variable amount of connective tissue (increasing with age and the menopausal state), possible edema and many blood vessels of different caliber, and it is called myoma pseudocapsule (Fig. 31.13).

Leiomyomata variants have differences that can be macroscopic or histological and thereby pose a serious problem of differential diagnosis with leiomyosarcoma.

First of all, there can be "infarct-type" necrosis or hyaline necrosis according to Bell et al. [31], characterized by areas of seemingly coagulative necrosis separated from the rest of the tumor by rings of fibrous or granulation tissue. This type of necrosis must not be confused with "tumor cell necrosis" observed in leiomyosarcoma where the cells are frequently necrotic, there is no separation from the surrounding tumor and often there are clumps of the residue of neoplastic cells surrounding residual vascular structures, commonly known as ghost outlines.

The differential diagnosis with leiomyosarcoma supposes, other than "tumor cell necrosis", the presence of moderate-severe atypia and a mitotic index over 10/10HPF: according to the Bell criteria of Bell [31] the presence of two out of three of these parameters is enough to diagnose leiomyosarcoma (Fig. 31.14). Immunohistochemistry does not bring any further advantages to the differential diagnosis. The borders of the tumor often infiltrate the near myometrium without the presence of the pseudocapsule observed in benign leiomyomata. Clearly malignant tumors express more p16, p21 and p53 immunoreactivity, but this is not helpful in single cases [32].

The expression of Ki 67 is also higher in leiomyosarcomas: in our experience Ki 67 is constantly higher than 40 %,

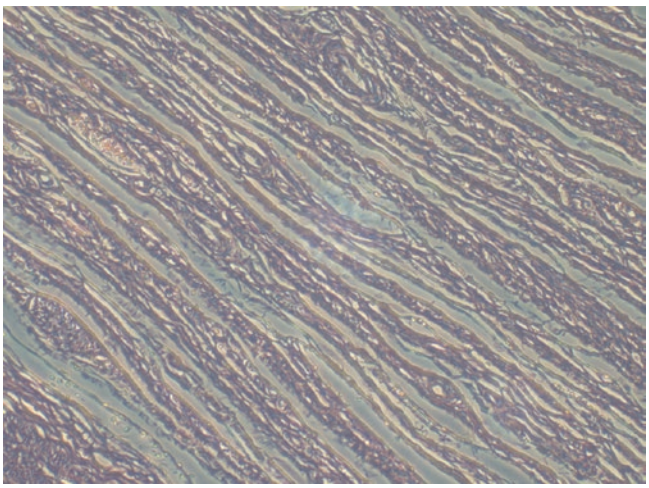

Fig. 31.15 The myometrium surrounding fibroid produce a sort of pseudocapsule, for ischemic phenomena, constituted by a network of: collagen fibers, extracellular matrix, neurofibers and blood vessels, as a separate fibroneurovascular tissue

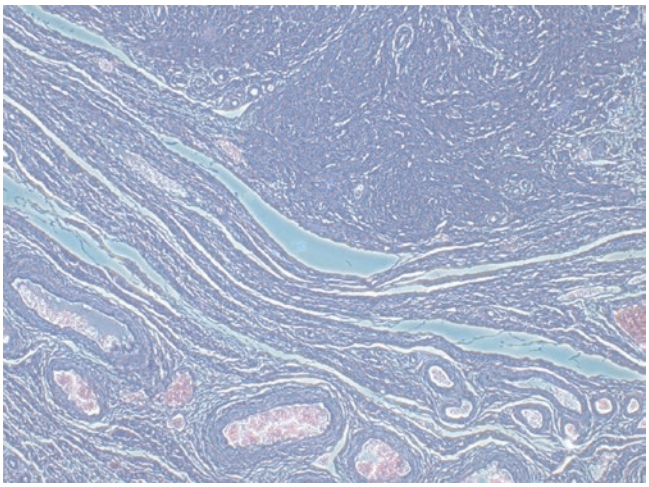

Fig. 31.16 A microscopic section showing the myoma pseudocapsule surface occasionally interrupted by collagen fibers and vessels that anchors the fibroid to myometrium

while in leiomyomata it is always less than 10 %. Necrosis can also be observed beneath the endometrium in tumors that grow into the uterine cavity which ulcerate and bleed, and therefore the necrotic cells are found together with inflammatory infiltrates. Other degenerative changes, more of less common, are: *hyaline transformation* of the stroma, leading to the wide substitution of the tumor, *dystrophic calcification* for a calcium salt deposition in the interstitial stroma (more common in menopausal women), a *hydropic degeneration* that can lead even to the formation of pseudocysts full of clear liquid.

A rarer but important type of change is myxoid degeneration of the fibroid when a gelatinous material is formed and the leiomuscolar cells can appear star-shaped and immersed in a slightly basophile stroma. Here the margins of the tumor must be closely examined as well circumscribed and the mitotic index is an essential point. A myxoid leiomyosarcoma, besides invading the surrounding myometrium, displays evident mitotic figures with only 2 per 10 HPF necessary to presume a malignant behavior. During pregnancy, leiomyomata can undergo necrosis and suffer bleeding (red degeneration), depending on the hormonal situation. Similar degeneration has been seen in hormonal therapy with estroprogestins. GnRH – analogue therapy causes a high degree of cellularity of the tumor which can confuse the pathologist when analyzing the mitotic figures. The increase in cellularity is apparently an effect linked to cell atrophy which reduces the cytoplasm thickness with closer nuclei, often with densely packed chromatin. As we discussed in a previous paper, the arteries we have described alterations of the inner wall agree with the proliferation of muscle cells and distortion or restriction of the lumen [33].

Analyzing leiomyomas composition, they are stiff tumors characterized by an excessive deposition of disordered extracellular matrix (ECM) components, particularly collagen I, III, and IV, proteoglycans, and fibronectin [34]. Matrix metalloproteinases (MMPs) are implicated in leiomyoma remodeling with a higher activity of MMP-2 in leiomyomas than in surrounding myometrium [35], separating by the myoma pseudocapsule.

During its growth, fibroid causes compressive phenomena on the surrounding myometrium, which for ischemic phenomena, seems to produce a sort of pseudocapsule, constituted by a surrounding network of collagen fibers, neurofibers and blood vessels, as a separate fibroneurovascular tissue (Fig. 31.15) [6].

Occasionally the pseudocapsule surface is interrupted by collagen fibers and vessels that anchor the fibroid to myometrium, well represented in microscopic sections (Fig. 31.16). It allows a constitution of a macroscopically clear cleavage plane between fibroid and the pseudocapsule, and between the pseudocapsule and the surrounding myometrium (Fig. 31.17) [36]. The pseudocapsule allows to fibroid only a displacement action (but not destructive) on myometrium, retaining the integrity and contractility of uterine structure [37]. We will discuss the importance of this small structure in the context of the myometrium, for the purpose anatomical, pathophysiological and reproductive systems.

Anatomy of Fibroid Pseudocapsule

Microscopically, the pseudocapsule seems to be as a continuous layer between the fibroid and surrounding myometrium and is made of a thickening of collagen fibers and blood

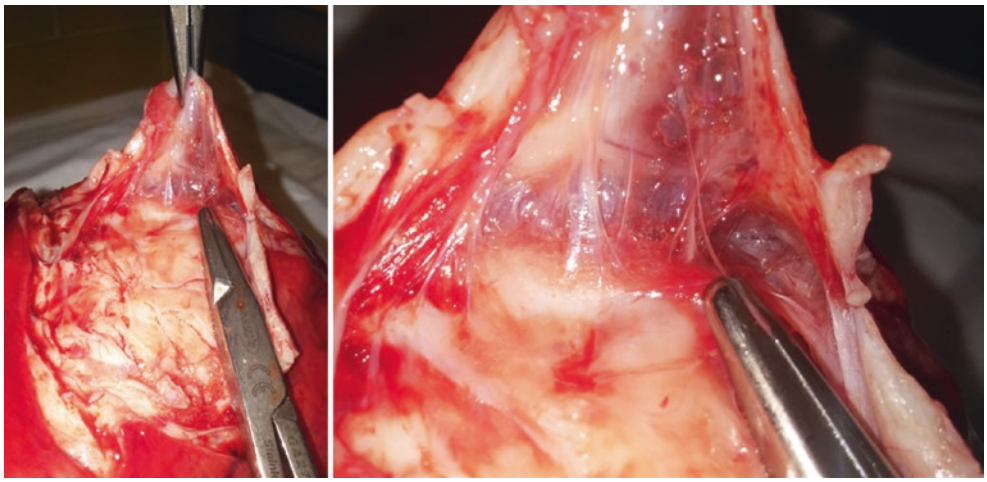

Fig. 31.17 Anatomical section of uterus with intramural myoma detecting myoma pseudocapsule: on the left the clamp shows a clear cleavage plane between fibroid and the pseudocapsule; on the right a surgical image magnification showing the small fibrovascular bridges connecting the pseudocapsule to the fibroid

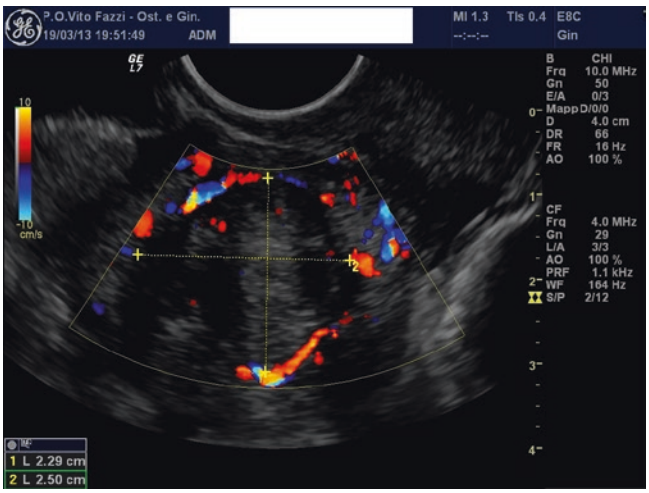

Fig. 31.18 A uterine section by transvaginal ultrasound scan: the pseudocapsule forms a vascular ring around fibroid, sonographically called "ring of fire" by echo-color Doppler, separating myoma from the surrounding myometrium

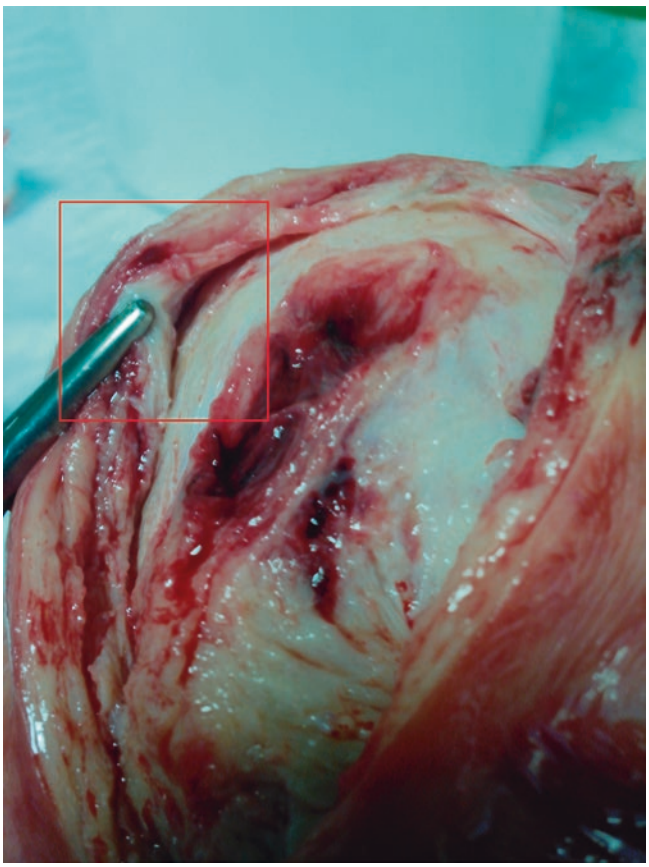

Fig. 31.19 Anatomic section of uterus with intramural myoma showing, in the *red box*, the cleavage plane to identify and to respect during a myomectomy, between fibroid and pseudocapsule

vessels that form a vascular ring, sonographically called "ring of fire" by echo-color Doppler: the pseudocapsule is separated from the surrounding myometrium, sonographically forming a hyperechogenic ring that surrounds and defines myoma (Fig. 31.18) [18]. To help with understanding of the micro-neuroanatomy of the fibroid peripheral area, we should get close with the story of pseudocapsule entity. An anatomical textbook, published at the end of last century, asserted: "*myoma shows a nodular aspect, a round image, well circumscribed, to enucleate even if they miss a pseudocapsule*" [6]. These authors confirmed the existence of the fibroid pseudocapsule and cleavage plane to identify and to respect during a myomectomy (Fig. 31.19) [6]. The first paper that described a fibrovascular system over a fibroid as "a mass of proliferating arteries" was in 1944 [38] and then, Farrer-Brown in 1970 [39] and Awataguchi in 1982 [40] found a fibrovascular plexus around the periphery of the fibroid. Lately, Casey et al. reported significantly higher microvasculature density in the surrounding myometrium in large fibroids; the author discovered that the vascular capsule

was a substantial feature of all fibroids, excluding those smaller, and that it reaches the highest density of blood vessels in large tumors [41].

Pathologists examined the relationship between ultrasound and histological findings of the fibroids vascular capsule in the last century, in a series of women using Gn-RH analogues in preoperative treatment before myomectomy [42–44].

Walocha et al. [45] performed a microstructural evaluation of the fibroid pseudocapsule and found that the density of blood vessels increases around myoma. As the fibroid grows, new blood vessels penetrate the tumor from its periphery where "the vascular capsule" network is formed. Some of the vessels in the pseudocapsule connect at the base of the myoma and form a little foot which often bleeds during an extra-capsular myomectomy. These authors analyzed the fibroid vascular system using corrosion casting combined with scanning electron microscopy and affirmed that the pre-existing blood vessels undergo in regression and new vessels invade the tumor from the periphery during the development of myomas. Myoma pseudocapsule originates from small vessels entering the tumor from the periphery, forming a "vascular network" around the myoma, with flattened veins compressed by the tumor [45]. Forssman et al. reported the vascular capsule surrounding myoma of 2 cm of diameter and found that the inner aspect of the capsule contained large vessels that invade the capsule from the periphery [46]. Wei et al. already demonstrated that in large uterine fibroids, the most biologically active zone is the region next to the periphery with a higher level of gene expression, a higher density of blood vessels, a higher proliferative rate, and a lower level of hyaline degeneration [47]. Finally, a preliminary study showed neurotransmitters into the myoma pseudocapsule [48], outline some neuro-biological properties of this structure [49], since the vascular structure has a proper characteristic, similar to cancers [50].

The Ratio of Uterine-Preserving Operative Therapy of Uterus Myomatosus

Uterine fibroid is a multifactorial and still enigmatic pathology. Traditional studies were associated to molecular and genetic investigations, detecting an important role in fibroids' growth and development, with cytogenetic anomalies observed in about 40 % of patients [34, 35]. Starting from the data on myoma and its pseudocapsule mentioned below, we focused our investigations on the morphological and biomolecular properties of myoma pseudocapsule, explaining the ration of uterine-preserving operative therapy.

Uterine Myoma Pseudocapsule Analisysed by Trasmission Electron Microscopy

In such study, we investigated the ultra-structure of myoma pseudocapsule by transmission electron microscopy analysis, to best detail the pseudocapsule structure and its involvement in fibroid growth and removal [51]. In two Universities affiliated Hospitals, ten women with a mean age of 36.7, underwent single laparoscopic intracapsular myomectomy (removing fibroid form its pseudocapsule). The selected patients requested myomectomy for the following associated symptoms: pelvic pain, menorrhagia, and growth of myomatic nodules, verified by ultrasound, with increasing symptoms. Exclusion enrolling criteria for the investigation were: previous uterine surgery (excluding caesarean section), pre-surgical treatment with GnRH-analogues, history of gynecological malignancy and primary sub fertility. Exclusion criteria for preoperative GnRH-analogue treatment was due to reported increased risk of recurrence, a possible delay in the diagnosis of leiomyosarcoma, a risk of massive hemorrhage from degeneration, a greater difficulty in finding the cleavage plane, and a greater extent of hyalinization phenomena [52, 53]. In the study setting, all fibroids were selected through standardized transvaginal ultrasound: all patients had subserous and/or intramural fibroids and transvaginal ultrasound clearly evidenced the fibroid pseudocapsule. The myomas' sizes were between 5 and 8 cm; the 4–9 cm limit was selected by surgeons to avoid longer operation time and pointless uterine trauma for smaller fibroids. To give homogeneity to the intracapsular laparoscopical myomectomy, the authors excluded pedunculated, cervical and intra-ligamentary myomas – because they are extra-myometrium., and suboptimal for authors' purpose. Patients underwent a standardized technique [7, 54] (Fig. 31.20): hysterotomy, pseudocapsule incision, extracting the myoma by stretching and uterine suturing. Samples were taken by scissors from the surface of the pseudocapsule as soon as good hemostasis was reached. Ten myoma pseudocapsule biopsy specimens of approximately 5 mm in depth, which included full thickness of the surrounding myometrium, were collected and processed for transmission electron microscopy (TEM). In semi thin sections the cells are fusiform with a centrally located nucleus. Inflammatory infiltration has not been detected in any section. At the electron microscopy level the cells have the features of the smooth muscle cells. They show nucleus with rounded end, often folded (concertina fashion), notched or with many invaginations. The cytoplasm is packed with thin (about 6 nm thick) filaments; between filaments fusiform dense bodies are interspersed. There are few organelles like mitochondria, glycogen particles and sparse elements of endoplasmic reticulum. Abundant micropinocytotic vesicles

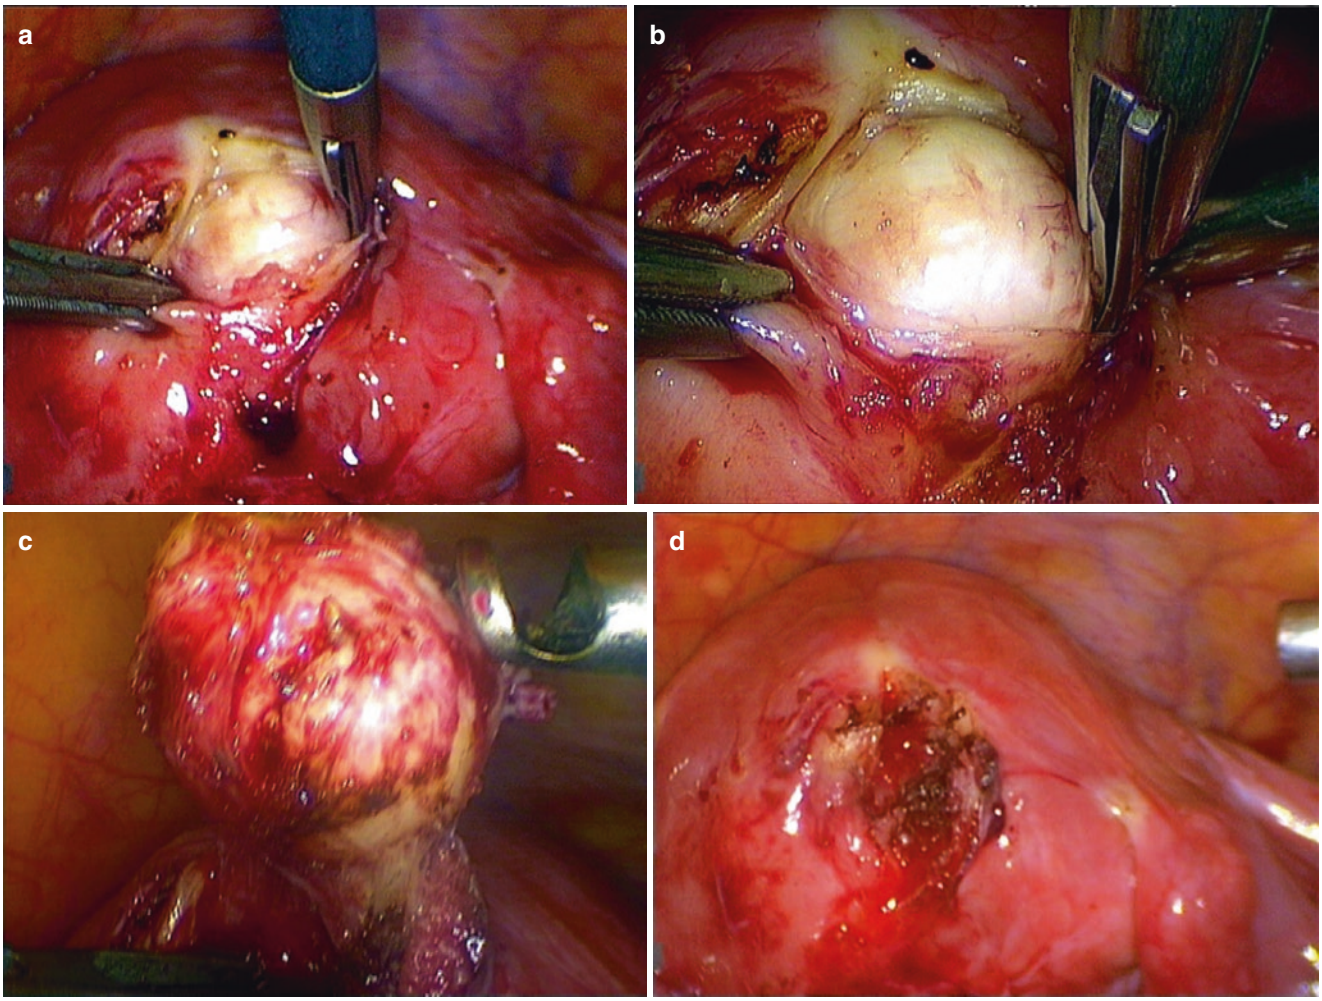

Fig. 31.20 The image shows a laparoscopic intracapsular myomectomy: (**a**) a womb incision over myoma; (**b**) the myoma enucleation by intracapsular technique; (**c**) myoma removal from uterus; (**d**) the minimal uterine bleeding after pseudocapsule sparing

are also present. The cells are surrounded by a thin but distinct basal lamina. The results of this study showed that at the electron microscopy level, the pseudocapsule cells had the features of the smooth muscle cells, as in myometrium. Basing on these findings, myoma pseudocapsule should be a part of myometrium who compresses leiomyoma, being a structure different from leiomyoma. Anatomically, fibroids arise from the uterine myometrium and typically are comprised of fascicles of smooth muscle cells with abundant pink cytoplasm and uniform spindle-shaped nuclei. Fibroids show a monoclonal proliferation of smooth muscle cells with isolated mitoses, minimal atypical nuclei, and an absence of coagulative necrosis and pseudocyst formation. In this investigation, authors investigated the ultra-structure of myoma pseudocapsule by transmission electron microscopy analysis, to best detail the pseudocapsule structure and its involvement in fibroid growth and removal.

Neurotransmitters in Myoma Pseudocapsule

Other investigations [55, 56] showed the presence of neurotrasmitters in myoma pseudocapsule. These studies confirmed the preliminary evidence that pseudocapsules contain neuropeptides together with their related fibers, as a neurovascular bundle, containing a vascular network rich in neurotransmitters like a neurovascular bundle [48, 49].

In the first paper [55], we evaluated the presence of neuropeptide tyrosine (NPY) in pseudocapsule of intramural, corporal, and fundal UMs, as well as in the normal myometrium. In addition, the presence of neurotensin (NT) associated with uterine contraction, and protein gene product 9.5 (PGP 9.5) as marker for uterine innervation, were both evaluated in the same tissues of NPY, in 75 women scheduled for single or multiple myomectomies. The indications for myomectomy were: severe pelvic pain, heavy menorrhagia not

responding to conservative treatment, or uncontrolled growth of UMs, as verified by repeated ultrasound. Among the patients, 67 women agreed to sign an informed consent for surgery; pregnancy was ruled out by a β-human chorionic gonadotropin test. All women were Caucasians. The exclusion criteria were: no previous myomectomy or cesarean sections, treatment with gonadotropin-releasing hormone (GnRH) analogs, to avoid eventual influence on results [52, 53] and a history of gynecological tumors. All fibroids were diagnosed using standardized transabdominal and transvaginal ultrasound myoma mapping by expert clinicians. The UMs' location were classified depending on their positions and the ultrasound data were recorded for postsurgical evaluations. Investigated UMs were single or multiple, and were located in the fundus uteri and in the corpus. Pedunculated, subserous, cervico-isthmic, and intraligamentary UMs were excluded. All myomectomies were performed by laparotomy or laparoscopy, depending on their dimensions and the surgeon's preference. The diameters of the UMs were between 4 and −9 cm of diameter. All women were administered a standard prophylactic antibiotic dose of 2 g Cefazolin intravenously. All operations were performed under general anesthesia with endotracheal intubation. All surgical procedures were performed by experienced gynecologists or senior residents who had paramount experience in removing UMs from within the pseudocapsule, as evidence-based data have shown [7, 54]. Once the UM removing and the UM pseudocapsule (PUM) spared on normal myometrium (NM), the surgeons sampled full thickness specimens that included the PUM as well as the surrounding NM from the fundus of the uterus (FU) and the uterine body (UB). These samples were approximately 20 mm in depth, obtained using scissors and were collected in peers, but separately. All samples were sent to the laboratory in a dry-ice container for histological and immunofluorescent analyses. A quantitative analysis of images (QAI) was performed on slides and on microphotographs using a the Quantimet Analyzer (Quantimet 500 Leica Microsystems Imaging Solutions Ltd., Cambridge, UK), equipped with specific software for a detailed evaluation. The densities of NT, NPY, and PGP 9.5 fibers were calculated using a Quantimet Leitz image analyzer that measures the following parameters: (1) detection of NT, NPY, and PGP 9.5 nerve containing fibers counted in 10 fields randomly chosen; (2) the percentage of total area occupied by those fields; (3) the number of observed varicosities; (4) the number of intersections of the nerve fibers; and (5) the total perimeter of NT, NPY, and PGP 9.5 structures in proportion to an average value (100 for each field). Morphometric quantification of the density of each type of nerve fiber was performed on photographs of stained samples using the Quantimet Leica 2000 image analyzer by a single pathologist. The software provided with the analyzer counts and expresses these fluorescent areas in "Conventional Units" or C.U. [48], i.e., as percentages of area occupied by a single type of nerve fiber related to the total observed area. By adding these values (single type of nerve fiber), it is possible to evaluate the sum of the areas occupied by the different types of nerve fibers. The software also calculates the average values and translates them to a single value with a standard deviation, which is reported on the instrument display as the "standard error of the mean (SEM)." Other details about the experimental procedures used for morphometric quantification by the Quantimet Leica are reported in the Anon manual of methods [36]. Statistical analysis of the data was based on the results obtained by the image analyzer software; and the data were averaged to obtain a median value per case. The means ± SEMs were then calculated and reported for each nerve fiber group. Repeated immunofluorescent controls were prepared and the differences were calculated by using Student's *t*-test. A P-value <0.05 was considered statistically significant.

Morphometric quantification of the neurotransmitters was performed on photographs using quantitative image analysis of 67 specimens. Fibers containing neuropeptides were not significantly higher in PUMs than in NM of FUs: 4 ± 0.2 C.U. for NT, 1 ± 0.5 C.U. for NPY, 4 ± 0.3 C.U. for PGP 9.5 in PUMs vs. 3 ± 0.9 C.U. for NT, 2 ± 0.1 C.U. for NPY, 3 ± 0.4 C.U. for PGP 9.5 in NM. Statistical evaluation did not report any significant difference (Table 31.1).

Nerve fibers containing the neurotransmitters increased slightly but not significantly in UBs with respect to FUs, with, 5 ± 0.3 C.U. for NT, 7 ± 0.2 C.U. for NPY, 6 ± 0.5 C.U. for PGP 9.5 in UBs vs. 4 ± 0.9 C.U. for NT, 6 ± 0.8 C.U. for NPY, 5 ± 0.7 C.U. for PGP 9.5 in FUs ($p > 0.05$). Also in such case, statistical evaluation did not report any significant difference among FU and UB neuropeptide concentration (Table 31.2).

Our results showed that NT, NPY, and PGP 9.5 neurofibers are almost equally present in PUF as in NM of a nonpregnant uterus. As all of these neuropeptides are present in the uterine muscle and can affect muscle contractility, uterine peristalsis and muscular healing. A myomectomy respecting the pseudocapsule neurofibers should facilitate smooth muscle scarring and promote restoration of normal uterine peristalsis with a possible positive influence on fertility.

In the second investigation, we compared the quantitative distributions of OXY and ENK in nerve fibers of fibroid pseudocapsules, sampled from uterine fundal, corporal and isthmo-cervical regions. We included 64 women in the study protocol: a well-designed non-randomization controlled trial (Level of evidence: II-1). The following were the inclusion criteria: a large uterus with symptomatic myomas, a myomatous uterus with severe pelvic pain, and menorrhagia, that was not controlled by conservative treatment, or uncontrolled growth of myomas revealed by dynamic ultrasound examinations. The main exclusion criterion was pregnancy,

Table 31.1 Distribution of the neurotensin (NT), the neuropeptide tyrosine (NPY) and the protein gene product 9.5 (PGP 9.5) nerve fibers in uterine fibroid pseudocapsule and in normal myometrium

	Fibroid pseudocapsule	**Normal myometrium**	***P* value**
Neurotensin (NT)	4 ± 0.2 C.U.	3 ± 0.9 C.U.	P > 0.05
	Fibroid pseudocapsule	**Normal myometrium**	**P value**
Neuropeptide Tyrosine (NPY)	1 ± 0.5 C.U.	2 ± 0.1 C.U.	P > 0.05
	Fibroid pseudocapsule	**Normal myometrium**	**P value**
Protein Gene Product 9.5 (PGP 9.5)	4 ± 0.3 C.U.	3 ± 0.4 C.U.	P > 0.05

Table 31.2 Distribution of the neurotensin (NT), the neuropeptide tyrosine (NPY) and the protein gene product 9.5 (PGP 9.5) nerve fibers in uterine fibroid pseudocapsule of uterine body and fundus uteri

	Fibroid pseudocapsule of uterine body	**Fibroid pseudocapsule of fundus uteri**	**P value**
Neurotensin (NT)	5 ± 0.3 C.U.	4 ± 0.9 C.U.	P > 0.05
	Fibroid pseudocapsule of uterine body	**Fibroid pseudocapsule of fundus uteri**	**P value**
Neuropeptide Tyrosine (NPY)	7 ± 0.2 C.U.	6 ± 0.8 C.U.	P > 0.05
	Fibroid pseudocapsule of uterine body	**Fibroid pseudocapsule of fundus uteri**	**P value**
Protein Gene Product 9.5 (PGP 9.5)	6 ± 0.5 C.U.	5 ± 0.7 C.U.	P > 0.05

as confirmed by the betaHCG test, performed prior to surgery and women not belonging to the Caucasian group were excluded. Other exclusion criteria included: (1) uterine scarring from previous surgeries (including cesarean section), (2) a treatment history of gonadotropin-releasing hormone (GnRH) analogues, and (3) a history of gynecological tumors. Treatment with GnRH analogues was seen as an exclusion criterion due to their reported association with an increased risk of recurrent myomas, delays in leiomyosarcoma diagnosis, and massive hemorrhages due to difficulties in entering the cleavage plane at a greater extent of hyalinization [52, 53]. Patients with pedunculated, submucous, and intraligamentary fibroids were excluded because of the risk of a distinctly uncommon pseudocapsule that engages the surrounding myometrium following presurgical ultrasound [18] performed by expert clinicians to determine the presence of the ultrasound screen, a white ring surrounding the fibroids, indicated by Doppler sonography as a "ring of fire". The study was designed to include patients of both the single and the multiple fibroid with more than two myomas. Total laparotomic hysterectomies were performed under general anesthesia with endotracheal intubation by experienced gynecologists or senior residents. During surgery, cefazolin (2.0 g) was intravenously administrated as a preventive antibiotic therapy. Following hysterectomy, 3 full-thickness specimens (2 cm wide × 2 cm deep) were acquired from the fundus uteri, corpus, and cervix using a sterile scalpel, referred to Gray's Anatomy Book for the classification of the uterine segments [57].

Separate samples from an identical uterine specimen were collected in peers. The full-thickness specimens contained part of the myoma with its fibroid pseudocapsule and the surrounding myometrium. In patients with multiple myomas, tissues were resected from each site. All tissues were histological examined, prior to analyze them by polyclonal antibodies for the ENK and OXT immunohistochemical assays. Further evaluation of specimens was performed blindly processing samples by their numbers and pathologist was not informed about origin of evaluated samples. The distribution (density) of each type of nerve fiber was performed on digital images of stained samples using a Quantimet Leica 2000 image analyzer (Leica Microsystems Cambridge Ltd., Cambridge, UK) by a single pathologist. The software with the Quantimet Leica 2000 image analyzer enables the counting and expression of fluorescent areas in conventional units (CU) [48], which is the percentage of the area occupied by a single type of nerve fiber relative to the observed area. By adding these values (single nerve fiber types) it is possible to evaluate the sum of the areas occupied by different types of nerve fibers. The software also calculates the average values and translates them into a single value with the standard deviation displayed on the instrument. The density of ENK and OXT fibers was calculated by quantitative analysis using the Quantimet Leica 2000 image analyzer. Results were averaged to obtain a median value per sample and analyzed using one-way analysis of variance (ANOVA) with Bonferroni correction for multiple comparisons of normally distributed data set of 3 groups. Statistical calculations were performed with MedCalc software (version 11.4.1.0). Data are displayed as the mean (m) and standard deviation (SD) overall. Values of $P < 0.01$ were considered statistically significant.

We tested null (Ho) and alternative (Ha) hypotheses for both ENK and OXT positive nerve fibers to distinguish distribution differences of neuropeptides in pseudocapsules depending on localization of fibroids in different uterine regions, i.e., μHo: fundal=corporal=isthmian-cervical region; μHa: fundal≠corporal≠isthmian-cervical region.

Table 31.3 The distribution of neuropeptides enkephalin (ENK) – and oxytocin (OXT) -positive nerve fibers in uterine fibroids pseudocapsules of the uterine fundal, corporal, and isthmian–cervical regions

Parameters	Uterine regions			*Total P*-value
	Fundal	Corporal	Isthmian–cervical	
Number of patients	19 (33.3 %)	18 (31.5 %)	20 (35.2 %)	57 (100.0 %)-
Number of fibroids	22 (33.8 %)	23 (35.4 %)	20 (30.8 %)	65 (100.0 %)
ENK-positive nerve fibers (CU)	0	0	94 ± 0.7	0.01
OXT-positive nerve fibers (CU)	6.3 ± 0.8	15.0 ± 1.4	72.1 ± 5.1	0.01

Sixty-four women were consecutively assessed for eligibility, seven women were excluded and, finally, the study included 57 patients with myomas and hysterectomy. The patients were 36.4 ± 3.6 years old with the body mass index – 23.8 ± 2.5, and the parity index – 1.4 ± 0.3. Analysis of localization of myomas during surgery demonstrated, that in 18 patients myomas were located in restricted uterine regions such as in 5 patients (8.7 %) – in the fundus, in 7 patients (12.2 %) – in the corpus and in 6 patients (10.5 %) – in the isthmian–cervical region, whereas in 39 patients distribution of myomas was expanded with combination of two or all three regions (Table 31.3).

So, in 10 patients (17.5 %) fibroids were found in both fundus and corpus of uteri, in 12 patients (21 %) – in the fundus and isthmian–cervical region, in 13 patients (22.8 %) – in the corpus and isthmian–cervical region and in 4 patients (7 %) – in all 3 regions. Subsequently we obtained samples for ENK and OXT assays in total from 65 fibroid pseudocapsules obtained from 57 removed uteri. Among these, 22 (33.8 %) samples of fibroid pseudocapsules were obtained from fundus, 23 (35.4 %) – from corpus and 20 (30.8 %) – from isthmian-cervix region. Distribution of fibroid pseudocapsule nerve fibers containing ENK and OXT was identified by immunohistochemistry and quantified by morphometric evaluation in relevant number of samples for valid statistical analysis. An absence of ENK-positive nerve fibers was seen in the uterine fundus and corpus fibroid pseudocapsules, whereas ENK values of up to 94 ± 0.7 CU were observed in the nerve fibers in fibroid pseudocapsules obtained from the isthmian–cervical region. OXT-positive fibers were present in fibroid pseudocapsules of all uterine regions. However, density of OXT-positive fibers was comparatively lower in the fundus (6.3 ± 0.8 CU) and at a slightly increased number in the corpus (15.0 ± 1.4 CU), whereas the distribution of OXT-positive fibers was significantly higher in the isthmian–cervical region (72.1 ± 5.1 CU) ($p < 0.01$).

Thus, the uterine cervix, contains a wide amount of immunoreactive nerve fibers filled with a great number of neuropeptides, neurotransmitters play a crucial role in the regulation of woman's sexual and reproductive functions as the central neuronal structure orchestrating the functions of the female tract organs by accepting/activating and passing signals between the central nervous system and all genital tract structures. A high density of ENK and OXT in nerve fibers in the isthmian–cervical region fibroid pseudocapsules highlights the importance of this region for female reproductive and sexual functions, and pregnancy-related complications. The present findings are important to discern the pathophysiology of the female reproductive system and sexual disorders manifesting after surgical procedures in the cervix, including complications during pregnancy and delivery (i.e., miscarriage and cervical dystocia during labor). the uterine cervix, containing a wide amount of immunoreactive nerve fibers filled with a great number of neuropeptides, neurotransmitters play a crucial role in the regulation of woman's sexual and reproductive functions as the central neuronal structure orchestrating the functions of the female tract organs by accepting/activating and passing signals between the central nervous system and all genital tract structures. The present findings are important to discern the pathophysiology of the female reproductive system and sexual disorders manifesting after surgical procedures in the cervix, including complications during pregnancy and delivery (i.e., miscarriage and cervical dystocia during labor).

Our and literature data confirmed that pseudocapsules contain many neuropeptides and neurotransmitters [48, 49, 55, 56, 58], physiologically active. Moreover, these substances may play a significant role in wound healing and innervation repair [18, 59, 60], and may be essential for reproductive [61–63] and sexual function [64, 65]. Indeed, the lower urinary tract neuropeptide–receptor systems may represent a potential target for therapeutic interventions [66, 67].

The Gentical Analysis of Pseudocapsule

Another of my investigations stated that biochemical growth factors evaluated in the pseudocapsule vessels cause intense angiogenesis in pseudocapsule, probably promoted by the fibroids [68]. The angiogenesis of the myoma pseudocapsule likely leads to the formation of a "protective" vascular

capsule responsible for the supply of blood to the growing tumor [69]. However, studies demonstrated a dysregulation of various growth factors and their receptors in uterine myomas [40, 69]. In fact, a research on gene expression analysis in uterine leiomyoma pseudocapsule revealed an angiogenic profile in pseudocapsule [68]. In this investigation we performed, by quantitative real-time RT-PCR method (qRT-PCR), a gene expression analysis of pseudocapsule (PC), matching it with the same analysis in uterine leiomyoma (UL) and uterine myometrium (UM), evaluating the expression levels of IGF-2, used as tumoral marker, and COL4A2, CYR61/CCN1, CTGF/CCN2, VEGF-A and vWF, known to be involved in angiogenic processes. A group of 18 patients underwent laparoscopic myomectomy pseudocapsule sparing. Patients were selected on the basis of their symptoms as pain or pressure, menstrual disorders, large and growing myomas, infertility or reproductive dysfunction. The number, size and location of ULs were assessed for all patients: 11 women had subserous UL (61.1 %) whereas 7 women had intramural UL (38.9 %); ULs were single in 10 patients (55.5 %) and multiple in 8 patients (44.4 %) with the dominant fibroid measured between 3 and 12 cm in diameter. Patients with suspected adenomyosis or adenomyoma were excluded. Pedunculated, small and submucous ULs were also excluded. Preoperative treatment with gonadotropin releasing hormone analogues (GnRHa), known to induce distortion of the UL pseudocapsule [50, 53], has also been considered as an exclusion indication for the purposes of this study. As all women were to be subjected to intracapsular myomectomy, the protocol was primarily explained to the patients and full written consent to operation and protocol was obtained prior surgery. Pre-surgical trans-vaginal (TV) ultrasound (US) was performed to determine the presence of the UL-PC as a white ring surrounding the UL. Laparoscopic myomectomy by intracapsular technique (LIM) was performed as mentioned above [7, 54]. Tissues sampling from the fibroids were taken approximately 20 mm in depth, including full thickness of the UL, UL-PC and the surrounding UM; samples of UL-PC were taken by scissors from its surface, as soon as good hemostasis was reached, while UM tissues were biopsied at 2 cm distance from UL. All samples were orientated as surgeons proceed in case of cervical conization. All samples were collected and stored in saline solution, then sent to the genetic laboratory for successive analysis. To examine the molecular characteristics of PC, the expression levels of CYR61/CCN1, CTGF/CCN2, COL4A2, VEGF-A, vWF, endoglin/CD105 and IGF-2 genes were analyzed in eighteen matched PC, UM and UL specimens. The last gene was chosen because known to be a tumor proliferation marker in UL pathology, the others were selected for their involvement in angiogenesis. mRNA levels were measured by quantitative RT-PCR and corrected against the housekeeping GADPH gene. Normalized data were reported by the medians and interquartile ranges and the degree of variability among the three tissues was statistically determined. The IGF-2 expression varied significantly among the three tissues ($p = 0.0011$ by Kruskal-Wallis test). In particular, it was significantly higher in UL (0.0165 relative units mean) compared to UM (0.0028 relative units mean; $p = 0.033$ by Mann-Whitney test) and PC (0.0026 relative units mean; $p = 0.032$ by Mann-Whitney test). The difference between UM and PC was not significant ($p = 0.916$ by Mann-Whitney test). Expression levels analysis of endoglin/CD105 revealed a significant difference among the three tissues ($p = 0.016$ by Kruskal-Wallis test). In particular there was a significant over-expression in PC (0.031 relative units mean) with respect to both UL (0.013 relative units mean, $p = 0.020$ by Mann-Whitney test) and UM (0.008 relative units mean; $p = 0.021$ by Mann-Whitney test). The difference between UL and UM was not significant ($p = 0.23$ by Mann-Whitney test). Both CYR61 and CTGF showed a significant degree of variability among the three tissues in our samples ($p = 0.044$ and $p = 0.021$ respectively by Kruskal-Wallis test). The down-regulation of CYR61 gene in UL (0.0278 relative units mean) with respect to UM (0.0588 relative units mean) was statistically significant ($p = 0.032$ by Mann-Whitney test), while difference with respect to PC (0.0479 relative units mean) doesn't reach significance ($p = 0.067$ by Mann-Whitney test). The difference between UM and PC was no significant as well ($p = 0.92$ by Mann-Whitney test). The down-regulation of CTGF in UL (0.0049 relative units mean) with respect to UM (0.0121 relative units mean) was significant ($p = 0.006$ by Mann-Whitney test), while no significant differences were found in the CTGF mRNA level between UL and PC (0.0111 relative units mean; $p = 0.090$ by Mann-Whitney test) and between PC and UM ($p = 0.15$ by Mann-Whitney test). Similarly, COL4A2 expression is significantly different across the three tissues ($p = 0.018$ by Kruskal-Wallis test). Moreover in this case, COL4A2 was expressed at significant higher in UL (2313 relative units mean) than in UM (1157 relative units mean, with $p = 0.007$ by Mann-Whitney test) while difference with PC (1658 relative units mean) was not significant ($p = 0.137$ by Mann-Whitney test).

The difference between UM and PC was not significant too ($p = 0.154$ by Mann-Whitney test).

VEGF-A and vWF mRNA levels showed no significant differences across the three tissues ($p = 0.73$ and $p = 0.24$ respectively by Kruskal-Wallis test).

The study' results clearly indicated that the pseudocapsule is a structure anatomically distinguishable from the myometrium and the surrounding fibroid, displaying a significant and specific gene expression profile. The pseudocapsule, as the fibroid, exhibited a significantly reduced expression of the IGF-2 gene, known to be a tumor growth marker, if compared to the fibroid, suggesting that it has a

non-fibroid origin and that it has a structural continuity with myometrium. The pseudocapsule also showed a statistical relevant over-expression of the endoglin/CD105 gene, when compared to the myometrium and to the fibroid. Based on these evidences, the over-expression of the endoglin gene, rather than of other angiogenic genes, seemed to indicate the presence of an active angiogenesis correlated with reparative process in the pseudocapsule. All together these data clearly depicted the pseudocapsule as a site of intense angiogenesis linked to the endoglin activation rather than other angiogenic factors such as VEGF-A or vWF. The presence of an active angiogenesis is concordant with the histological studies that describe a parallel array of extremely dense capillaries in the pseudocapsule and in the adjacent myometrium, that are absent in fibroid. This can define the structural and functional features of pseudocapsule that could explain its possible roles in the uterine regenerative process [68].

Although the reported investigations conformed the myometrial origin of pseudocapsule, it has never been established its biological genesis. Thus authors analyzed the nature of this uterine structure by defining the mutational state of Mediator Complex Subunit 12 (MED12) gene, known to be mutated in more that 70 % of fibroids [70], in leiomyoma pseudocapsule by a genetic investigation [71].

MED12 gene encode for a component of the Mediator Complex, which act as a transcription factor involved in general and specific gene regulation. Mutations in MED12 gene could [70] be involved in the overall gene de-regulation commonly observed in fibroids and, as a consequence, in its genesis and evolution [72].

In our prospective, non-randomized, observational study (level of evidence II-2), samples of uterine leiomyomas (ULs) and corresponding uterine myometrium (UM) and PC were collected from 36 females who underwent at laparoscopic myomectomy by the intracapsular technique mentioned above [7, 54]. Patient selection was based upon the following criteria: pain or pressure symptoms, ULs causing infertility or reproductive dysfunction, large and growing UFs, or menstrual disorders. Women taking oral contraceptives, GnRH analogues or other hormonal therapies were not included in this study. Additional exclusion criteria as abnormal uterine bleeding, endometrial hyperplasia, uterine polyps, cervical intraepithelial neoplasia, uterine or cervical cancer, and confirmed or suspected primary adnexal pathology were additionally applied according to the presurgical US examinations, by bidimensional (2D) power Doppler ultrasound (PDU) studies, performed in the first 10 days of menstrual cycle, either with a Logic 7 Pro US system (GE-Kretz, Zipf, Austria), an IU 22 xMATRIX US system (Philips Healthcare, Eindhoven, the Netherlands), or a Voluson 730 US system (GE-Kretz, Zipf, Austria) equipped with a 3.8–5.2 MHz transvaginal transducer. All machines had a standard US setting of Doppler and gray scale, provided by companies. Presurgical vaginal US was performed by 2 well-trained physicians with similar expertise to determine the number, size, and location of any fibroid together with the pseudocapsule, which presents as a white ring surrounding the fibroid and is often colored as a "ring of fire" by Doppler scans. LIM was performed using a standardized method previously described. During the operation, the surgeons sampled specimens for analysis. Tissues sampled from the fibroids were taken to approximately 20 mm in depth, including the full thickness of the UL, the UL-PC interface and the surrounding UM; samples of the PC were obtained using scissors as soon as good hemostasis was achieved, while the UM tissues were biopsied at a distance of 2 cm from the UL. The samples were transported to the laboratory for subsequent analysis.

The patients' ages ranged from 32 to 45 years, with an average of 38.5 years. Twenty females had subserous ULs (55.6 %), 16 females had intramural ULs (44.4 %), 15 had single ULs (41.7 %), and 21 had multiple ULs (58.3 %). Authors investigated MED12 gene mutational state by PCR on genomic DNA followed by direct sequencing from each of the 36 ULs collected and their corresponding PCs. Since up to now most mutations in ULs have been found in intervening sequence (IVS) I and in exon 2 of MED12 gene, we focused our analysis on this portion of the gene. We identified specific already known missense mutation in 12 ULs and different deletions never described before in other 6 ULs (data not shown). We extended the analysis to the corresponding pseudocapsules and we find that none of the pseudocapsules associated to a mutated UL show the corresponding mutation. The same wild type profile was obtained by sequencing of the genomic DNA extracted from randomly selected UMs. To the best of our knowledge, we showed, for the first time, the non tumor origin of the PC, by analyzing the mutational state of the MED12 gene. Mutations in MED12 gene could be involved in the overall gene de-regulation commonly observed in fibroids and, as a consequence, in its genesis and evolution. We confirm the high frequency (18 out of 36) of mutations in MED12 gene among our set of fibroids; then we extend the analysis to the corresponding PCs and we find that each PC show a wild type sequence profile, even when associated to a MED12-mutated UL.

This data clearly indicate the non-tumor origin of the PC and a genomic profile comparable to that of the adjacent healthy myometrium, whose MED12 sequence always results as wild type too. The gene expression profile of PC is well distinguishable from that of the fibroid, as well: in particular it exhibits lower IGF-2 and higher endoglin/CD105 transcript levels when compared to the UL [68]. Since IGF-2 overexpression is known to be a specific leiomyoma marker, this data seem to support the non-tumor origin of PC; by the

other side, the high expression level of endoglin gene, involved in neo-angiogenic processes and wound healing [73, 74], could explain the regenerative processes observed at the scar site, after a myomectomy performed by pseudocapsule sparing.

Another genetic investigation [75] involved the analysis of insulin-like growth factor II (IGF-2) and collagen type IV alpha 2 (COL4A2) expression levels in the same set of ULs. To assess whether the MED12 mutational state affects the gene expression profile in UL, we analyzed, using quantitative real-time PCR, the expression of IGF-2 and COL4A2 in our set of ULs. These genes were selected for this investigation because they are known to be up-regulated in UL when compared to matching myometrium. On the basis of the different mutational status, the UL samples were divided into three groups: group A consisted of samples without MED12 mutations, group B consisted of samples exhibiting deletions in the MED12 gene, and group C consisted of samples harboring missense mutations. Firstly, we defined IGF-2 and COL4A2 expression level in UM: we observed that the health tissues always express low level of both genes without any statistical variation depending on the corresponding UL's state ($p = 0.84$ by Kruskal–Wallis test). As a consequence, having ascertained that expression levels in ULs are not influenced by basal levels of expression in the corresponding UMs, we were able to compare the three groups of ULs, directly considering the mRNA relative units of expression of IGF-2 and COL4A2. The analysis of the IGF-2 expression level revealed a significant difference among the groups ($p = 0.0004$ by Kruskal–Wallis test). In particular, the mean relative expression units were significantly higher as assessed by the Mann-Whitney tests in group C (0.017 units mean) compared with group A (0.004 units mean, $p = 0.0004$) and group B (0.003 units mean, $p = 0.002$). The difference between groups A and B was not statistically significant ($p = 0.76$ by the Mann-Whitney test). These data demonstrated a specific correlation between missense mutations in exon 2 of the MED12 gene and IGF-2 overexpression. Conversely, the COL4A2 mRNA levels, although resulted higher in ULs when compared to those expressed by the corresponding UMs, showed no significant differences among the three groups of samples ($p = 0.132$ by Kruskal–Wallis test).

Concluding, the study interestingly revealed that only those with MED12-missense mutations expressed significantly higher levels of the IGF-2 gene. Otherwise, the MED12 gene status does not appear to affect the expression levels of the COL4A2 gene. On the basis of this finding, we suggest that the MED12 status stratified the ULs into two mutually exclusive pathways of leiomyoma genesis with IGF-2 overexpression and the absence of IGF-2 activation. The occurrence of IGF-2 overexpression could be therapeutically targeted in uterine myomas for the non-surgical myoma treatment.

Finally, since pseudocapsule is also genetically different from myoma, all pharmacological and hormonal commonly proposed treatments to prevent the growth of myomas, such as aromatase inhibitor, progestins and anti-progestins, estrogens, Selective Progestin Receptor Modulators (SPRMs), Selective Estrogen Receptor Modulators (SERMs) and GnRH, i.e., should not act on the pseudocapsule as acting on the myoma.

Uterine Myoma Pseudocapsule Analysed by Ultrasound and Histology

Fibroid pseudocapsule sizes, although its biological importance, is often underestimated by surgeons because of difficulties in visualizing the pseudocapsule during laparotomy or laparoscopy so as the pseudocapsule thickness was never morphologically measured in a study. The aim of our study was to measure the myoma pseudocapsule by a feasible and reproducible method, the gynecological ultrasound (US), comparing the thickness with histology according to fibroid location within the uterine wall.

We also hypothesized that pseudocapsule thickness depended on fibroid location within the uterine wall, whether near the endometrial cavity (FEC), intramural (IMF), or subserosal (SSF), and that the pseudocapsule thickness will be equivalent by US and histological measurement. Therefore, we planned to measure in a study [76] the presurgical fibroid pseudocapsule thickness by US and the histological features following hysterectomy in patients undergoing hysterectomy for symptomatic uterine fibroids. Thus, we organized a prospective cohort trial investigating pseudocapsule thickness using US and histology on a total, 90 women with large (from 6 cm in diameter), growing, symptomatic (pain, pressure, or menstrual) fibroids scheduled for hysterectomy. All procedures were conducted in accordance with the guidelines of the Helsinki Declaration on human experimentation. All patients had a heavy menstrual cycle and provided written, informed, and signed consent for the hysterectomy and anonymous use of information concerning fibroid pseudocapsules for research purposes. The following exclusion criteria were applied: abnormal uterine bleeding, endometrial hyperplasia, uterine polyps, cervical intraepithelial neoplasia, uterine or cervical cancer, and confirmed or suspected primary adnexal pathology. The following exclusion criteria were additionally applied according to the presurgical US examinations in order to maintain the homogeneity of fibroid pseudocapsule thickness: adenomyosis or adenomyoma and isthmic-cervical, intraligamentary, or pedunculated fibroids to give analytic homogeneity. Following presurgical US screening, 15 women were excluded and 75 patients were enrolled for further investigation. Bi-dimensional (2D) power Doppler

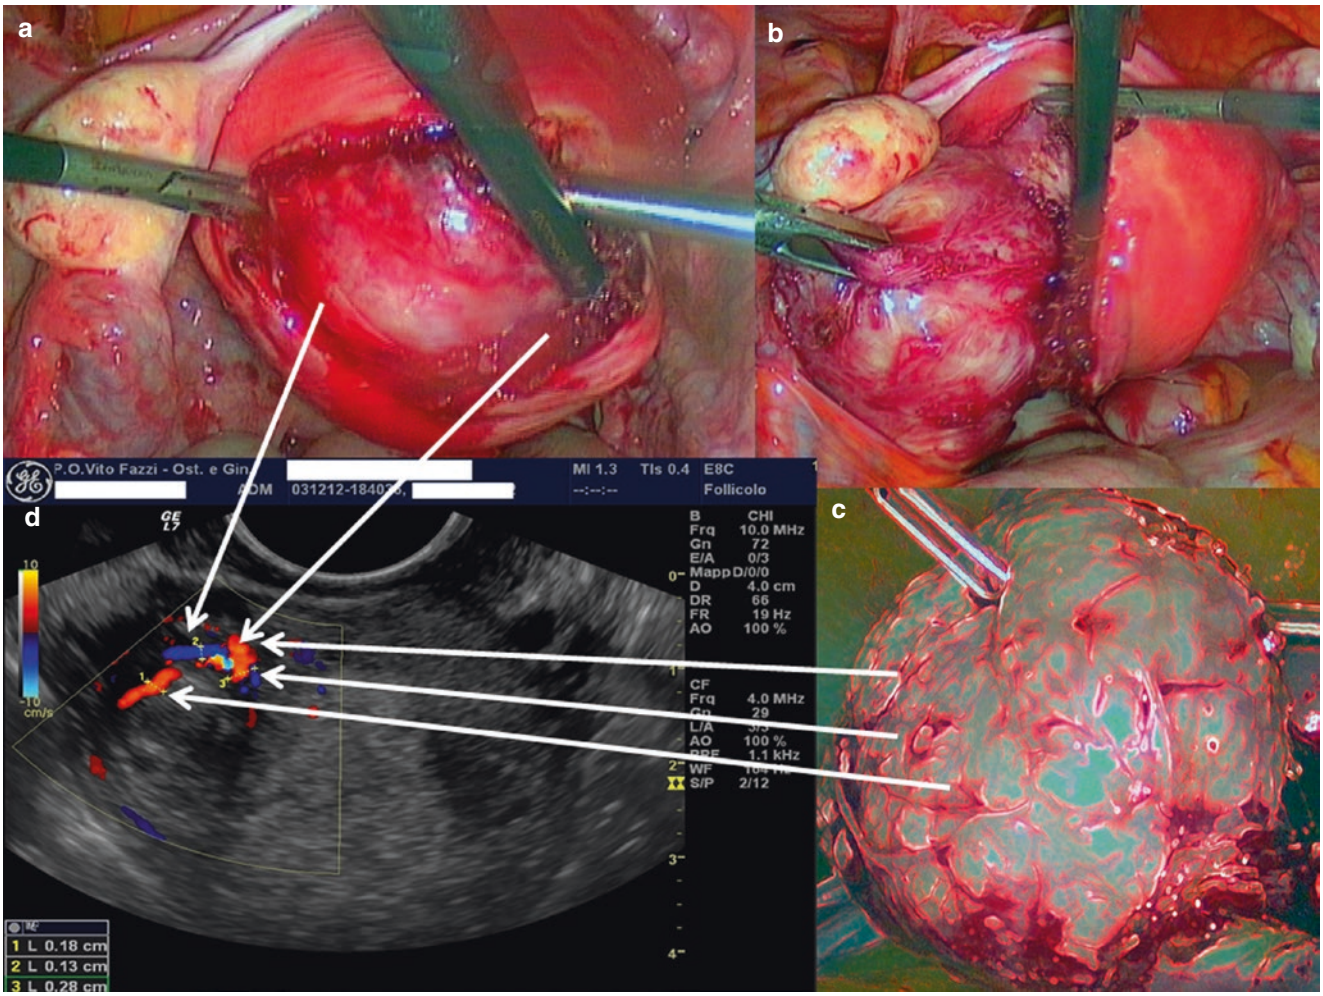

Fig. 31.21 Clockwise, starting from top left: the technique of fibroid enucleation with pseudocapsule sparing (**a**–**c**). White arrows indicate the pseudocapsule saved during fibroid enucleation, which appears finely covered by a thin fibrovascular matrix (neurovascular bundle). This is joined in the ultrasound image (**d**) to highlight the ring of fire during presurgical evaluation

ultrasound (PDU) studies were conducted in the first ten days of menstrual cycle, either with a Logic 7 Pro US system (GE-Kretz, Zipf, Austria), an IU 22 xMATRIX US system (Philips Healthcare, Eindhoven, The Netherlands), or a Voluson 730 US system (GE-Kretz, Zipf, Austria) equipped with a 3.8–5.2 MHz transvaginal transducer. All machines had a standard US setting of Doppler and gray scale, provided by Companies. Presurgical vaginal US was performed by two well trained physicians with similar expertise to determine the number, size, and location of any fibroid [27], together with the pseudocapsule, which presents as a white ring surrounding the fibroid and is often colored as a "ring of fire" by Doppler scans (Fig. 31.21). The fibroid pseudocapsule thickness was measured by transvaginal 2D-PDU in a clockwise manner in the longitudinal and transversal planes (Fig. 31.22), with 4 measurements: superior–inferior and lateral–lateral; measuring the thickness of two measurements, clinicians added the measurements and split for two, getting the average thickness of the myoma pseudocapsule. The US scanner cursor was placed at the thickest point between the 2 layers on the anterior and posterior pseudocapsule walls, both as regards to the white ring of fire on 2D-PDU. To analyze the fibroid location and pseudocapsule thickness, the uterus was artificially divided in a transverse plane to record each fibroid's location compared to pseudocapsule thickness. In order to strictly standardize the fibroid location in the uterus, we used the leiomyoma subclassification system of Wamsteker et al. (currently used by International Federation of Gynecology and Obstetrics), identifying subserosal fibroids (n° 6 and 5 by Wamsteker classification), intramural fibroids (n° 4), and fibroids near endometrial cavity (n° 3) [18]. All the collected thickness parameters were mapped and recorded. Total hysterectomies were performed either via laparotomy or laparoscopy in the first ten days of menstrual cycle, and the excised uterus was immediately sent to the pathology department

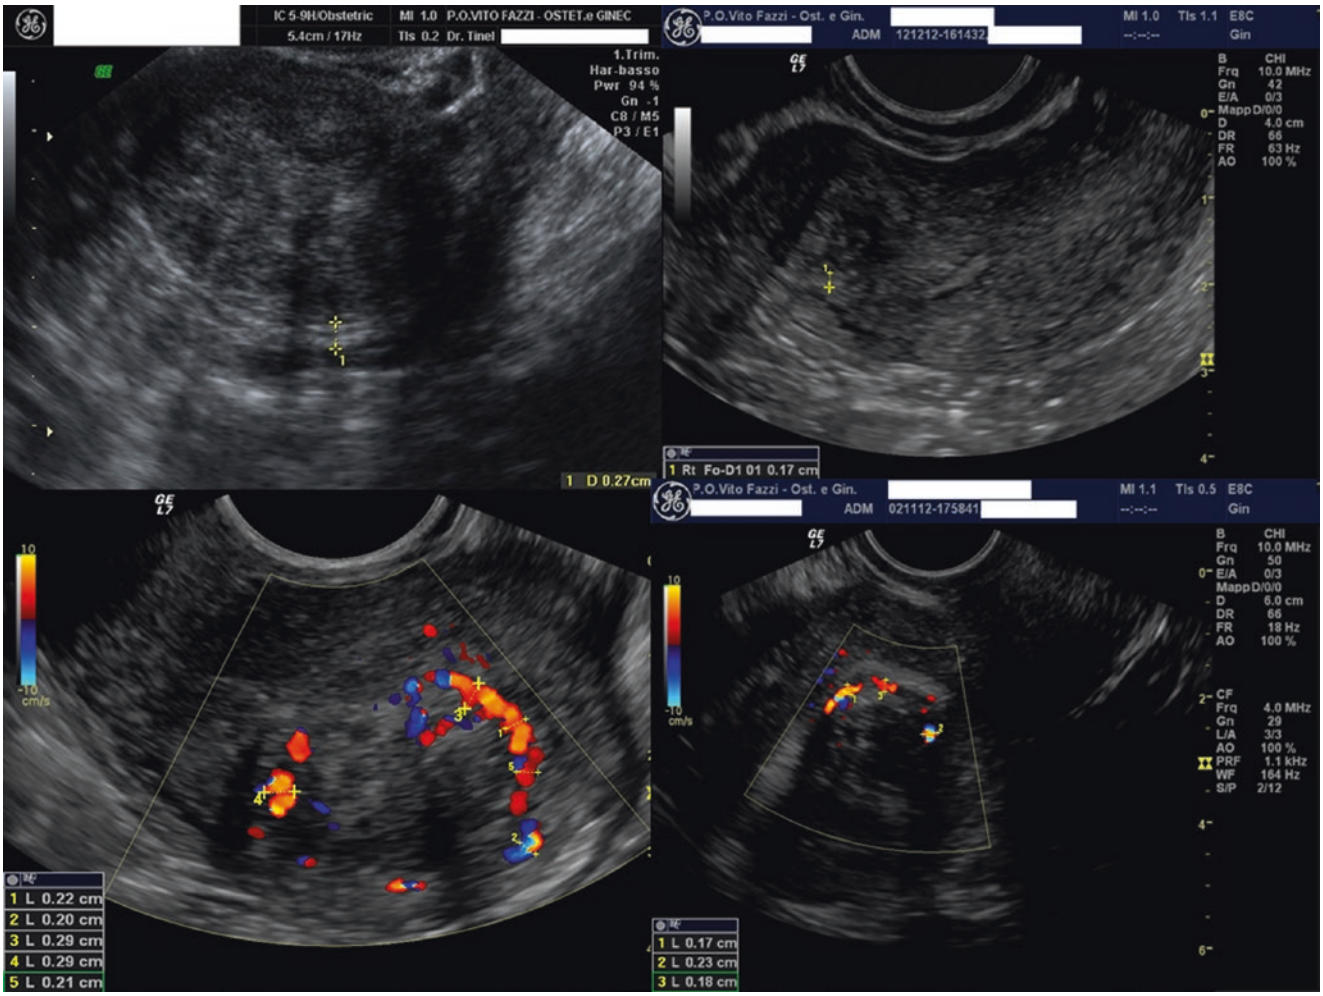

Fig. 31.22 Clockwise, starting from top left: 4 presurgical vaginal ultrasound images demonstrating the presence of the pseudocapsule as a white ring surrounding the fibroid (2 images in the *box above*) or colored as a "ring of fire" by a Doppler scan (in the *box below*)

for macroscopic and histological examination by expert pathologists, already involved in other studies on myoma pseudocapsules. Four fibroid-pseudocapsule–myometrium specimens measuring 2 × 2 cm (superior–inferior and lateral–lateral) were obtained. All specimens were numbered and fixed, before being embedded in paraffin wax for cross-sectional sagittal slices. The sections were obtained at 7-μm intervals and placed on a glass slide for Hematoxylin and Eosin staining. The fibroid-pseudocapsule–myometrium specimen borders were analyzed on each side using conventional light microscopy (10× to 40× magnification) to detail the pseudocapsule thickness.

Pathologists measured the thickness of two measurements, and then they added the measurements and split for two, getting the average thickness of the myoma pseudocapsule for histological evaluation. Artifacts were considered with the correct plane of cleavage of the fibroid from the myometrium. Finally, all US and histological data were matched by an independent researcher for comparison.

All measures are calculated as means ± Standard Deviation (Ultrasound and Histology or U&H). Both variables are normally distributed, because Q-Q plots approximate a diagonal straight line, not showed into the paper. A small difference in the skewness and in the Kurtosis between the two samples (U&H measurements) was observed. Pseudocapsule thicknesses were analyzed by one-way analysis of variance (ANOVA) with Tukey's multiple comparisons and post hoc paired t-test on US and histological measurements. Cut-off levels were defined with receiver operating characteristic (ROC) curves was used to predict sensitivity and specificity. Differences between ultrasonographic and histological pseudocapsule measurements were assessed by Bland Altman method. The nonparametric Kruskal–Wallis test was used to compare US and histological measurements (3 groups of matched measurements). A p value of $P < 0.05$ was considered statistically significant. Analyses were conducted with the statistical package for the Social Sciences Version 12.0 (SPSS, Inc., Chicago, IL, USA)

and JMP 8 for ANOVA and Kruskal-Wallis. The following hypotheses were tested: H1- Pseudocapsule thickness differs according to fibroid location within the uterine wall sites, i.e., FEC, IMF, and SSF; H2 – Pseudocapsule thickness differs according to the examination technique employed; in this case, either US or histology. All P values are 2 – tailed.

The mean age of the 75 patients was 47 years (range 43–51). Past obstetric history was as follows: 24 %, 41 %, and 35 % had a parity of 1, 2, and ≥3, respectively. Previous delivery was vaginal in 69 % and by cesarean section in 31 %. Past surgical histories included cholecystectomy (12 %), appendectomy (25 %), ovarian cysts (27 %), and surgery for pelvic pain and adhesions (21 %). Multiple past surgeries were recorded for 22 % of the cases. None of the patients reported prior surgical complications. In total, 108 fibroids were sampled, of which 53 were from the uterine body and 55 were from the fundus. The fibroids were subdivided according to their location within the uterine wall into subserosal (n = 57), intramural (n = 33), and near the endometrial cavity (n = 18). There was no significant difference in the mean or median diameter of the fibroid in each location. The first hypothesis (H1) was analyzed by one-way ANOVA, and it was determined that significant differences in pseudocapsule thickness depended on fibroid location within the uterine wall (FEC, IMF, or SSF), independent of measurement technique ($P < 0.001$). The FEC pseudocapsule walls measured by US were considerably thicker than the IMF ($P < 0.001$) and SSF ($P < 0.001$) pseudocapsule walls: 2.64 ± 0.28, 1.70 ± 0.14, and 0.95 ± 0.33 mm, respectively. The thickness measured by histological examination was 2.79 ± 0.25, 1.72 ± 0.21, and 1.03 ± 0.4 mm, respectively. In turn, the IMF pseudocapsule walls were thicker than the SSF pseudocapsule walls ($P < 0.001$). The results were further analyzed for the second hypothesis (H2), to determine whether US pseudocapsule measurements are comparable with histological measurements. Our measurements revealed a high correlation (correlation coefficient: 0.963) and significance level ($P = 0.001$) using paired sample t-tests. Only IMF pseudocapsule measurements showed similarity between the histological and US methods ($P = 0.625$). Conversely, a significant difference was observed between measurements in FEC ($P = 0.001$) and SSF ($P = 0.014$) locations. Overall, a difference was observed between US and histological measurements ($P = 0.0001$) (paired sample t-test). A clear cut-off was observed between FEC pseudocapsule and all other pseudocapsule measurements, i.e., at 2 mm, the difference was significant ($P = 0.001$). The area under the curve (AUC) was 1 for US measurement and 0.999 for histological measurement. ROC analysis revealed that a cut off value of 2 mm provided almost 100 % sensitivity and specificity for diagnosing a FEC, in this limited sample. Overall Bland Altman limit of agreement analysis revealed that histological measurements tended to be slightly higher than ultrasonographic measurements. However, for 95 % of all cases this difference represented a small range. From a clinical standpoint this difference is unlikely to be significant. The pseudocapsule of fibroids is considerably thicker near the endometrial cavity when compared those of both intramural and subserosal fibroids. Since fibroids closest to the endometrial cavity are the most involved in fertility and infertility and fibroid pseudocapsule is considerably thicker near the endometrial cavity, it is possible to hypothesize an involvement of FP of fibroid near on endometrium, since FP contains many neuropeptides and neurotransmitters that are physiologically active, even if this data may take on a broader meaning in a study on a larger number of patients.

Another investigation [18] evaluated the uterine scar healing after laparoscopic myomectomy, monitored by traditional 2D ultrasound (US) and Doppler velocimetry, in 149 women underwent laparoscopic intracapsular myomectomy (LIM). The indications and surgical techniques were evaluated to consider the benefits and limitations of LIM. The procedures used in the present study were in accordance with guidelines of the Helsinki Declaration on human experimentation. The study protocol was carefully explained to the patients before they entered the study and written consent for operation was obtained. Patient selection was based upon the following criteria: pain or pressure symptoms, UFs causing infertility or reproductive dysfunction, large and growing UFs, or menstrual disorders. Regarding menstrual disorders, the authors used similar criteria established by an international consensus that determined normal limits for menstrual parameters in the mid-reproductive years: excessively frequent menses (each < 25 days), irregular menses (cycle-to-cycle variation greater than 20 days), excessive duration of flow (prolonged 6–8 days) and high volume of monthly blood loss [77]. Presurgical vaginal ultrasound (US) was performed by expert clinician to determine the presence of the pseudocapsule as a white ring surrounding the UF, colored by Doppler as a "ring of fire". The number, size and location of UFs were assessed and patients with suspected adenomyosis or adenomyoma were excluded. All 2D-PDU studies were performed either with a Logic 7 Pro US system (GE-Kretz, Zipf, Austria) or IU 22 xMATRIX US system (Philips Healthcare, Eindhoven, The Netherlands) or with a Voluson 730 US system (GE-Kretz, Zipf, Austria), each equipped with a 3.8–5.2 MHz transvaginal transducer. The uterus and the UF were measured in two planes, sagittal and coronal and all the data were recorded. The Resistance Index (RI) was calculated from the flow velocity waveform of the uterine arteries, at their ascending branch. Magnetic resonance imaging was not used to diagnose fibroids due to expense and time. All UFs were subserous or intramural, single or multiple, and the dominant fibroid measured between 5 and 9 cm in diameter. The study excluded women with UFs that were pedun-

culated, small (<3 cm in diameter) or submucous. Preoperative evaluation included office hysteroscopy to exclude submucus UFs and other uterine abnormalities. We used the UF classification system of Wamsteker to describe fibroid location, as usually done. Preoperative treatment with GnRH analogues was performed in rare cases, to avoid distortion of the UF pseudocapsule [52, 53, 78]. All patients received prophylactic Cefazolin 2 g I.V prior to laparoscopy and an intrauterine manipulator was used. Laparoscopic myomectomy was performed under general anesthesia by endotracheal intubation with a standardized four port approach: one port for the laparoscope and three lower quadrant ancillary ports (one suprapubic central 10 mm port and two lateral 5 mm ports). The 10 mm central suprapubic port was often changed to 15–20 mm for the introduction of the morcellator at the end of the procedure. Laparoscopic myomectomy by the intracapsular technique was performed without injection of an ischemic solution, as vasopressin, into the myometrium [7]. Its use could mask the musculature vascularization by collapsing vessels, making difficult the selective and gentle pseudocapsule vessel hemostasis during LIM and favouring subsequent intra-myometrial hematomas. Authors used the US to monitor the scar size and the muscular healing following LIM, detailed as following for consistency in the study. The visceral peritoneum was incised in the midline longitudinal plane with monopolar scissors or a crochet needle electrode, quickly proceeding into the myometrium to reach the right plane to detect the fibroid below. Once the pseudocapsule was identified, it was exposed by a Johannes or Manhes clamp or by an irrigator cannula to provide a panoramic laparoscopic view of the pseudocapsule. The pseudocapsule was opened with a longitudinal cut using monopolar scissors or a crochet needle to expose the UF surface. Then the fibroid was secured by a myoma screw or Collins laparoscopic forceps to provide the traction necessary for gentle enucleation, and inserting the irrigator cannula into the space between the UF pseudocapsule and fibroid for assistance. Hemostasis of the small vessels was selectively achieved using a low energy bipolar clamp or by monopolar crochet, to free the base of the UF and the connective bridges from the pseudocapsule, with minimal trauma, minimal blood loss, and pseudocapsule sparing. In cases of deep intramural UFs, chromopertubation was applied via a cervical cannula not only to check tubal patency but also to facilitate the direct recognition of an inadvertently opened uterine cavity. The myometrium was closed in a single (for subserous) or double layer (for intramural) with 1/0 Vicryl (polyglactine; Ethicon, USA), including overlying serosa, with a round CT-1 curved needle, using intra or extracorporeal knots. In sub-serosal myomectomies (types 5 and 6), the edges of the uterine defect were approximated with introflexing U-inverted stitches (myometrium/serosa-serosa/myometrium direction) at 1 cm increments (a baseball-type suture). Interrupted closure or a traditional unidirectional running suture was chosen by the surgeon. Deep intramural UFs (types 2–5 and 3) were closed in two-layers using introflexing baseball-type sutures. If the uterine cavities were accidentally opened during UF enucleation, 2–3 single or continuous sutures were used to close the edge of the uterine cavity. UFs were morcellated with a reusable Rotocut G1 morcellator (Karl Storz GmbH & Co. KG, Germany) or by a Gynecare Morcellex tissue morcellator (Ethicon, Inc., Somerville, NJ, USA). Patients were re-evaluated by transvaginal US on days 1, 7, 30 and 45 after surgery. The myometrial scar pattern was compared to the previous myometrial area occupied by the UF. The scar diameter was measured by placing callipers on the outer edge of the echogenic, heterogeneous, and ill-defined area to determine the healing pattern of the uterine scar after LIM [79–82]. Moreover, authors measured the RI of the uterine arteries at their ascending branch during each US examination. The myometrial area of the scar was calculated as the percentage of the preoperative UF diameter. The parameters were analyzed by an independent statistician using the Student's t-test for paired samples. A significant p-value was considered as $p < 0.05$.

One hundred and thirty-six operated patients completed the study and the follow up. The mean age of our population was 37.2 ± 3.6 years (range 33–40 years), mean BMI was 22.9 ± 2.5 and mean parity was 1.3 ± 0.7. The primary preoperative indications included pelvic pain in 24 %, menorrhagia or metrorrhagia in 23 %, a large growing UF in 13 %, and infertility in 40 %. The size of UFs was 5–6 cm diameter in 35 women (25.7 %), 6–7 cm in 37 (27.2 %), 7–8 cm in 34 (25 %), and 8–9 cm in 30 women (22.1 %). UF were subserosal in 48 women (35.2 %) and intramural in 88 (64.8 %). Of the 136 women, 82 had a single fibroid (60.2 %): 29 subserous (35.3 %) and 53 intramural (64.7 %). Fifty-four had multiple UFs (39.7 %): 19 subserous (35.2 %) and 35 intramural (64.8 %). Of the 48 subserosal fibroids, 29 were type 5 (60.4 %) and 19 were type 6 (39.6 %), with no type 7. Of the 88 intramural UF, 21 were transmural types 2-5 (23.8 %), 38 were type 3 (43.1 %) and 29 were type 4 (33.1 %). Single intracapsular myomectomy was performed for intramural fibroids in 7 women with UF types 2–5 (33.3 %), 16 with type 3 (42.1 %) and 17 with type 4 (58.6 %), and for subserous fibroids in 16 patients with type 5 (55.1 %) and 11 with type 6 (57.8 %). Multiple intracapsular myomectomy was performed for intramural fibroids in 14 women with UF type 2–5 (66.7 %), 22 with type 3 (57.9 %) and 12 with type 4 (41.4 %), and for subserous fibroids in 13 patients with UF type 5 (44.9 %) and 8 with type 6 (42.2 %). Two women (1.4 %) were pre-treated with 3.75 mg leuprolide acetate for 3 months before surgery to shrink the UFs. During surgery, a monopolar crochet needle was used to cut the connective bridges of the pseudocapsule from the surrounding myome-

trium in 59 women (43.4 %), and bipolar clamp scissors (30 W energy) were used in the remaining 77 (56.6 %). The uterine cavity was entered during myomectomy in 2 women with a single UF (2.4 %) and in 5 with multiple UFs (9.2 %). All laparoscopies were successful without conversion to laparotomy.

On the first and 7th post-operative days, the US pattern of uterine scar area was represented by a highly echogenic area having an-ill defined heterogeneous myometrial texture; from day 30–45 the image shifted to a normal echogenic myometrial texture. There was a progressive reduction of uterine scar. The scar after LIM was 78 % of the previous UF diameter on the first day, 61 % on 7th day, and 19 % on the 30th day, and disappeared (<4 %) on the 45th day. The progressive reduction in size of US pattern of uterine scar area was significant ($p < 0.05$). There was no correlation with the size of the fibroid and the relative reduction in the scar diameter, either on days 1 or 45. There was an increase of the RI value of the ipsilateral uterine arteries from 0.57 of the preoperative day (range 0.45–0.69) to 0.65 on the first postoperative day (range 0.59–0.73). This difference was statistically significant ($p < 0.05$). After 1 week the RI was always elevated to 0.83 (range 0.74–0.92), then the RI decreased to 0.71 (range 0.59–0.83) at the 30th post operative day and to 0.61 (range 0.50–0.72) at the 45th post operative day. All of these comparisons were statistically significant ($p < 0.05$). During the postoperative US evaluations, the authors noted the persistence of small linear hyperechoic points, the stitches of polyglactine that have an absorption time of 50–60 days. No important fluid-filled areas were seen. The authors found a few small anechoic areas < 5 mm at the site of LIM on the first day, and two patients had an anechoic area of 1–2 cm at the myomectomy site (1.5 %), possibly indicating the presence of a hematoma.

Basing on these results, the myometrial area of the scar after LIM can be followed by 2D US and Doppler velocimetry, a non-invasive, safe method to check uterine perfusion, postoperative hematoma and disechogenic, heterogeneous, or an ill-defined scar area, all unfavourable signs for myometrial scarring. Moreover, Doppler transvaginal monitoring, evaluating PI and RI of the uterine arteries at their ascending branch, could identify patients with altered PI and RI parameters, possible markers of impaired wound healing.

The Potential Impact of Pseudocapsule Sparing on Muscular Healing

Uterine muscle is an amazing tissue, specialized to generate force but for that function to be well-served, muscle must be a precisely organized and excitable tissue, in function to pregnancy, labor and delivery. It also shows an impressive ability to adapt to changing functional demands during fetal growth, and provides a major site for energy storage for labor.

Uterine myometrial repair and regeneration that follow surgical injury, as myomectomy, requires that muscle first re-establish homeostasis following the damaging perturbation and then restore the normal structural and functional capacities of the fully differentiated tissue. Restoration of muscle structure and function is a key, early feature in successful repair and regeneration of muscle. However, muscle membrane damage itself can initiate signalling processes that activate muscle regeneration. The synthesis and release of signalling molecules that are activated by muscle fibers subjected to membrane damage can induce the activation and attraction of a diverse population of cells that promote muscle regeneration and growth [83]. Following acute muscle injury, the sequence of muscle injury-repair-regeneration leads to full functional recovery with days to weeks of the initial damage [84].

A vital process in the regeneration of an injured muscle is the vascularization of the injured area. The restoration of vascular supply to the injured area is the first sign of regeneration and a prerequisite for the subsequent morphological and functional recovery of the injured muscle. The new capillaries sprout from the surviving trunks of the blood vessels toward the centre of the injured area to provide the area with an adequate supply of oxygen, subsequently enabling aerobic energy metabolism for the regenerating myofibers [85].

In such regenerative process, there is also the involvement of neuropeptides and neurotransmitters, extremely important in wound healing. In fact, there is evidence that the nervous system and its neurotransmitters, such as Substance P (SP), Vasoactive Intestinal Peptide (VIP), neuropeptide Y (NPY), Oxytocin, Vasopressin (VP), PGP9.5, calcitonin gene-related peptide (CGRP), growth hormone-releasing hormone (GHRH), play a role in mediating inflammation and healing [83, 85–87].

Referring to uterine musculature scar physiology, these peptides sparing enhances a correct healing of a hysterotomy. Most of these neuropeptides have been highlighted in the pseudocapsule, as evidenced [48, 49, 55, 56].

As the neuropeptides are transported to the tissues by the neurovascular network, the myoma pseudocapsule, as neurovascular bundle [49], is therefore a structure rich of neuropeptides. Pseudocapsule vessels were also studied by a preliminary three-dimensional mathematical model [50], who showed an increase vascular tortuosity, disarray, an abnormal branching and the presence of "cul-de-sac" pseudocapsule vessels. All of these features are similar to malignant neoplastic tissue vessels features, present in malignant tumors. It was not possible to clarify if the pseudocapsule vasculature network could be sustained by mechanical and inflammatory effects of myoma on myometrium, or pro-

duced by a sort of neoangiogenesis "neoplastic-type", due to the fibroid growth or even to a muscle and tissue healing process, such as a neurovascular preparative reaction of female body to a fibroid expulsion (pedunculated fibroids), necrosis or degeneration, allowing a normal uterine restoration [88].

In human body, difficulties in obtaining serial samples of the hysterotomic scar during myomectomy or cesarean section, are a major barrier to our understanding of the events involved in the post-myomectomy and post-cesarean section remodelling processes of the uterine wound. They can be only monitored by ultrasound or MRI [18].

However, irrespective of the ultimate result, wound healing is a dynamic, interactive process involving neuromediators, angiogenetic factors, neuropeptides, blood cells, extracellular matrix, and parenchymal cells that follows three complex and overlapping phases: inflammation, tissue formation, and tissue remodelling [89].

And the biochemical growth factors evaluated in the pseudocapsule vessels cause intense angiogenesis in pseudocapsule, probably promoted by the fibroids [68].

Anyway, the biological genesis of myoma pseudocapsule sustains the necessity either to better analyze hormonal and pharmacological impacts of drugs on pseudocapsule (based on reducing fibroid growth without compromise pseudocapsule properties), or to remodelling the presurgical uterine fibroid therapy and the post-surgical follow up, in order to preserve uterine functionality, as much as possible.

Translation of Scientific Research on Myoma Pseudocapsule on Medical and Surgical Practice

Since the ultimate goal of scientific research is the application in clinical practice, I tried to translate the studies on the myoma pseudocapsule in surgical practice of reproductive surgery. Fibroids can cause clinical symptoms and myomectomy can significantly improve symptoms and quality of life and, in some clinical situations, improve reproductive outcomes in aged women, who delay childbirth into their 30s and 40s, when the incidence of fibroids is significantly increased. So far, reproductive surgery was supported by a large number of publications that have discussed the benefits of myomectomy. However, very few articles have evaluated, per se, the rationale of the surgical technique, explaining all the steps of the scientific techniques. And this is what I tried to do I explain the rationale for the removal of myomas starting with the preservation of its pseudocapsule, rich of neurotrasmitters and vessels, a neurovascular bundle containing neuropeptides and related fibers surrounding prostate [88].

The idea of a neurovascular bundle surrounding a myoma, inside pseudocapsule, derives from a multidisciplinary discussion among gynecologists and urologists, on analogies of myoma pseudocapsule with the prostate capsule. Based on the purpose of reducing the probability of impotence associated prostate cancer treatment, urologist generally must preserve neurovascular bundles surrounds prostate. Anatomically, the neurovascular bundles are situated on the peripheral to the prostate.

The prostatic neurovascular bundle provide both somatic and autonomic innervations to the continence mechanism. The excision of neurovascular bundle causes more incontinence and impotency than when the neurovascular bundles are preserved [49, 88]. In order to spare the prostatic neurovascular bundles, laparoscopic or robotic assisted prostatectomy are both useful [90], since the magnification facilitates a more gentle dissection with less traction and careful dissection [91].

Although these nerves are microscopic [92], their anatomic location can be evaluated intraoperatively through the use of the capsular vessels as a landmark. An opening in the levator fascia is performed by sharp incision along the anterolateral surface of the prostate starting at the base of the prostate and proceeding toward the apex. This manoeuvre releases the bundle laterally, thus making it easier to make the next step, where the bundle is released posteriorly at the apex. Once the superficial fascia has been released, the site of the neurovascular bundles can be identified by the presence of a thin "groove" on the posterolateral edge of the prostate. The interfascial plane (i.e., between the levator and prostatic fascia) is developed gently using blunt dissection with a fine curved dissector and a gentle diathermocoagulation. Dissection continues in close approximation to the surface of the prostatic fascia in efforts to optimize quantitative cavernous nerve preservation. If bleeding occurs from periprostatic vessels, insufflation pressure can be in the meanwhile increased and pressure applied to the source of bleeding with hemostatic gauze. Hemostasis with high wattage diathermocoagulation or ultrasonic heat energy should be always avoided during dissection near the neurovascular bundles, as these energy sources have been shown to be injurious to cavernous nerve function in the canine model [93].

On the bases of these findings about the importance of the prostatic capsule and the important and physiologic role of nerve-sparing techniques for prostatectomy, and comparing this structure to the fibroid pseudocapsule, the knowledge of peripheral neurovascular bundle of the uterine leiomyoma was challenged and revisited by me and my colleagues (Fig. 31.23).

In fact, literature showed the possibility to perform myomectomy by removing the fibroid from its surrounding structure, the fibroid pseudocapsule [94, 95], I called "intracapsular myomectomy" [7, 79]. It performs by stretching and extracting fibroid directly from the surrounding fibromuscular skeleton, breaking up the fibrous bridges.

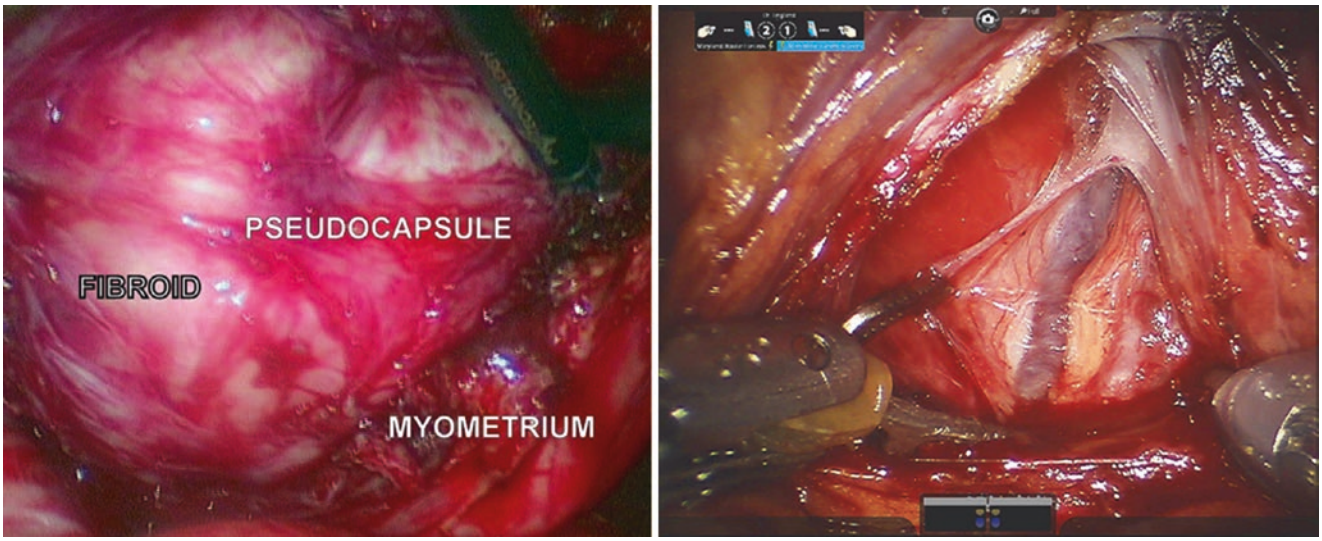

Fig. 31.23 A parallelism between laparoscopic myomectomy sparing pseudocapsule (*on the left*) and radical robotic prostatectomy sparing prostatic vein and neurovascular bundle (*on the right*)

The general myomectomy dogma is that "each surgical fibroid enucleating needs to be gently performed to enhance a correct healing process of the uterine musculature and to facilitate successively the correct uterine musculature anatomical-functional restoring".

So, the main principle of myomectomy is to perform all manipulations as precisely and bloodlessly as possible, and the new surgical technique of intracapsular myomectomy meets this requirement. Nevertheless, the impact of surgical myomectomy differs depending on the technique used [96]. The laparotomic myomectomy is different from the laparoscopic technique, also with same intracapsular method: the laparoscopic access route proved to be the most beneficial. The advantages of the laparoscopic approach are the significantly reduced parameters of both intra- and post-surgical blood loss, decreased bladder pain after Foley removal, the lower number of patients requiring pain relief medication and the shorter hospital stay. In addition, laparoscopic intracapsular myomectomy resulted in slightly improved short-term outcomes in relation to postoperative fever, myometrium scar hematomas, ileus and antibiotic treatment compared to open surgery. Finally, the laparoscopic myomectomy has a favourable impact on blood loss by intracapsular method, aiming to preserve musculature under hysterotomy. The CO2 insufflation can influence blood loss during intracapsular myomectomy, as the increased intraperitoneal pressure can lead to the occlusion of the small blood vessels and capillaries of the pseudocapsule. This effect, combined with less traumatic endoscopic micro-manipulations, could result in beneficial outcomes of surgery. To better clarify these results, I remember that my intracapsular myomectomy was standardized and published [7, 79].

Laparoscopic myomectomies are performed under general anesthesia by endotracheal intubation with a standardized four port approach: one port for the laparoscope and three lower quadrant ancillary ports (one suprapubic central 10 mm port and two lateral 5 mm ports). The 10 mm central suprapubic port is often changed to 15–20 mm for the introduction of the morcellator at the end of the procedure. All patients receive an intrauterine manipulator prior to laparoscopy, to better mobilize uterus. Intracapsular laparoscopic myomectomy of sub mucous and intramural fibroids is generally performed without injection of ischemic solution into the myometrium. The visceral peritoneum is incised in the midline longitudinal plane, by monopolar scissors or crochet needle electrode, proceeding in depth into myometrium to reach the right plane under myometrium, to detect myoma pseudocapsule with the fibroid below.

Once identified the myoma pseudocapsule, it is well exposed by atraumatic clamp or by irrigator cannula, to provide a panoramic laparoscopic view of pseudocapsule of all subserous-intramural leiomyomas. Then surgeon affects the pseudocapsule by a longitudinal cut, performed by monopolar scissors or Hook electrode at low wattage (30 W), to expose the myoma surface. Then fibroid is hooked by a myoma screw or Collins laparoscopic forceps to perform the traction necessary for its gentle enucleating, helping by irrigator cannula to be inserted in the space under myoma pseudocapsule and fibroid. Hemostasis of the small vessels bleeding is selectively achieved by a low wattage bipolar clamp or by Hook electrode or monopolar scissors, always at 30 W, to free the base of the myoma and the connective bridges from the pseudocapsule. In such way, complete minimal traumatic fibroid removal from its pseudocapsule was accomplished with a minimal blood loss and pseudocapsule sparing. In case of pseudo-pedunculated myomas, the pedicle is coagulated by bipolar

forceps and cut by laparoscopic scissors or cut after placement of loops or staples, without suturing. In cases of deep intramural myomas, chromopertubation is always applied via a cervical cannula not only to check tubal patency but also to facilitate the direct recognition of an inadvertently opened uterine cavity.

The myometrium closuring is performed by a single (for subserous fibroids) or double layer (for intramurals), including overlying serosa, with a round CT-1 curved needle, using intra or extracorporeal knots. In sub-serosal myomectomies, the edges of the uterine defect were approximated with introflexing U-inverted stitches (myometrium/serosa-serosa/myometrium direction) with intra myometrial knot, at 1 cm increments from the edge of the incision (as a "baseball-type" suture). The closure was by surgeon choice: interrupted closure or traditional unidirectional running suture, stared at the end of one of hysterotomic sides.

Deep intramural fibroids required a two-layer myometrial closure with introflexing sutures, ever by a "baseball-type" suture. If the uterine cavity was accidentally opened during fibroid enucleating, 2–3 deep myometrial single or continuous sutures were applied on the uterine cavity edges. After hysterorrhaphy, fibroids are usually morcellated.

Thus, during myomectomy, as reported by literature [88], the fibroid pseudocapsule neurovascular bundle needs to be always protected, avoiding destructive surgical proceedings such as extensive and high wattage diathermocoagulation (> 30 W) or excessive tissue manipulating or trauma. This method of myomectomy maximally respects the fibroid pseudocapsule neurovascular bundle, rich of neurofibers involved in the correct successive scar healing. The iatrogenic myoma pseudocapsule damage should therefore alter the successive neurotransmitters' function in myometrial repair, with negative effect on uterine healing. Thus, the surgical sequels of an uncorrected myomectomy with pseudocapsule damaging should be: a reduction in neurofibers' presence at hysterotomic site, a deterioration of uterine musculature healing, and a deficit either of myometrial neurotransmission or of muscular impulse and contractility, with final reduced uterine musculature functionality.

The Intracapsular Cesarean Myomectomy

This type of technique to perform a myomectomy sparing pseudocapsule can also be reproduced in another very complex and risky operation: the cesarean myomectomy.

Uterine myomas are observed these days more frequently in pregnancy with an estimated incidence of 2–4 %, because many women are delaying childbearing until their late thirties or the beginning of their forties, the time of greatest risk for myoma growth [97, 98]. Uterine myomas are commonly encountered in women older than 30 years [99] and their growth is directly related to exposure to the circulating estrogens levels. The prevalence of leiomyomas among pregnant women ranges from 0.1 to 3.9 % [99–104]. The effective rate of uterine myomas in pregnancy is unknown; however, they are associated with numerous pregnancy-related maternal and fetal complications like spontaneous abortion, preterm labor, placental abruption, post partum hemorrhage and high rate of cesarean deliveries [99, 105].

Complications in pregnancy, labor and delivery occur almost twice as frequently among women diagnosed with uterine myomas than in those without [99–103]. The literature suggests a high rate of cesarean deliveries in women with myomas up to 39.95 % [106].

Thus, any surgical procedure performed on or around the uterus has the potential of causing severe hemorrhage and, for this reason, uterine myomectomy during cesarean section has consistently been discouraged, in the past years, as a high-risk procedure.

On the contrary, resection of an intramural myoma is inadvisable and contraindicated during cesarean section by some obstetric textbooks [107, 108], due to the risk of profuse uncontrolled bleeding that could lead to hysterectomy.

So, after the development of my well detailed and published technique [7, 18, 79], the intracapsular myomectomy, successfully performed during laparoscopy in non pregnant women with single or multiple fibroids, the authors decided to study their methods of myomas removal during CS, exploring its outcomes (Fig. 31.24).

Thus I prospectively evaluated the surgical outcome of intracapsular myomectomy during CS by a case-control study on 68 patients who underwent intracapsular cesarean myomectomy, compared with a control group of 72 patients with myomatosic pregnant uterus who underwent cesarean section without myomectomy [109].

All operations were ever performed by CS by Stark's method, under regional anesthesia. A routine intracapsular cesarean myomectomy was then done for all anterior fibroids: cervical, body, or fundal, using the same cesarean incision where possible, or utilizing other incisions, when necessary. Each intracapsular cesarean myomectomy was performed after LUS closure. A linear incision was made over the uterine serosa direct to myoma by a scalpel or a monopolar electro-scalpel at low voltage (≤ 30 W), gradually until opening the pseudocapsule, enabling to enter the relatively bloodless plan between the pseudocapsule and its myoma. Once the surface of the myoma was reached and its fibre bridges separated, the myoma was hooked and extracted from its capsule, also by traction and pushing down the capsule using a sharp Metzenbaum scissors. The hemostasis during intracapsular cesarean myomectomy was always reached by gentle low voltage coagulation (≤ 30 W) of pseudocapsule vessels, with minimal blood loss. Generally, 10 I.U. of intravenous oxytocin drip was given as a standard to

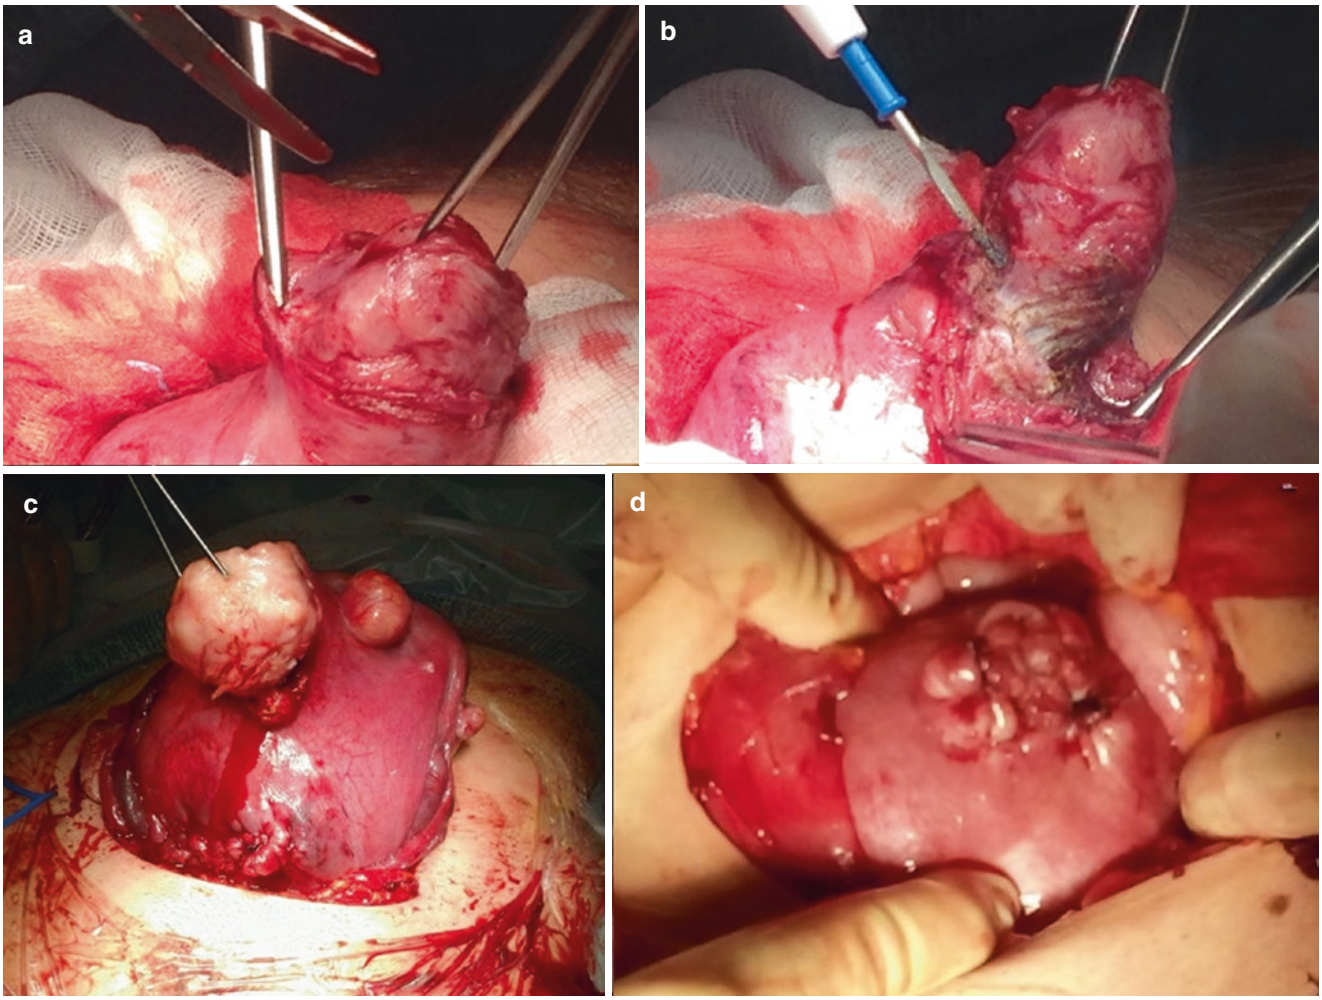

Fig. 31.24 Intracapsular cesarean myomectomy: (**a**) pregnant uterine incision after hysterorrhaphy and myoma pseudocapsule exposure by scissors; (**b**) gentle myoma dissection from myometrium; (**c**) myoma enucleating; (**d**) suture of uterine wall after myoma enucleation

all patients to control bleeding, after enucleating of the fibroid. For myomas located near LUS, we temporarily changed operation' steps: after completion of the CS, an interlocked suture is temporarily placed on the edge of the cesarean uterine incision without closure. Then we performed intracapsular cesarean myomectomies from the edge of the cesarean incision. This also facilitates working from within the uterine cavity or from the outer part of the uterus without significant bleeding from the CS incision. After that, in case of other myomas far from LUS, surgeons made a new incision above the myoma in instances where they were located in a site remote from the CS incision. Suturing of the fibroid base was routinely performed by using two layers of interrupted absorbable sutures (1–0 calibre vicryl) and a baseball-type suture was used for the serosa, using a continuous absorbable suture (2– 0 or 3–0 calibres vicryl), as a third layer. Pelvic irrigation was done with saline solution. Postoperatively, the oxytocin infusion was continued for 12–24 h in parallel with normal saline infusion. Seventy-two control subjects were randomly selected among pregnant women with myomas undergoing CS without myomectomy, at the same Institutions and during the same period, and CS' indications were: breech presentation, more than one previous CS, CS on demand. These women did not receive cesarean myomectomy since they refuse this operations and both myomectomy and control groups were similar in terms of characteristics without any statistical differences.

Most of the removed myomas were subserous or intramural: 48 subserous, 14 intramural and 6 pedunculated. Of these, 12 had multiple sites myomas (17,6 %), but we try to use always the same hysterotomy for neighbours fibroids.

Sites of myomas' removal were: fundal in 37 women (54.4 %), corporal in 22 (32.3 %) and around the lower uterine segment in 9 women (18.7 %), where we temporarily changed operation' steps just in 5 women. The average myoma' size was 8 cm (1.5–20), in 40 women, with 8 myomas measuring 4–6 cm, 14 myomas between 10 and 12 cm and > 13 cm in 6 patients. Differences in blood chemistry

and surgical outcome in intracapsular cesarean myomectomy were not statistically significant ($p > 0.05$). Concerning the post-operative course, 5 patients had postpartum fever of 38.8 °C, on average, for two consecutive days after surgery (7.3 %); the blood culture didn't show any bacteria and patients were treated by large spectrum antibiotics. The average duration of hospitalization of intracapsular cesarean myomectomies was 5 days, with six patients requiring more than 5 days of hospital stay (8,8 %); these five patients felt too weak to be discharged, so they preferred to stay in the hospital an extra day.

There was no correlation between complications or duration of hospital stay and patient age, gravidity, parity or indication for CS. None of the patients underwent repeated surgery after intracapsular cesarean myomectomy and no hysterectomy was required after intracapsular cesarean myomectomy. My data show no difference between intracapsular cesarean myomectomy group and control group, in term of pre and post-operative hemoglobin values, mean change in hemoglobin values, incidence of intraoperative hemorrhage, frequency of blood transfusion and of post-operative fever. The only two parameters that affect negatively the group submitted to intracapsular cesarean myomectomy are the duration of operation and the length of hospital stay.

Since obstetricians often confronted with fibroids while performing CS and face the dilemma of how they should be managed, considering the cost-benefit of our study, authors affirmed that intracapsular cesarean myomectomy procedure can be performed with some confidence, without affecting adversely the postoperative course and clinical outcomes.

Hysteroscopic Intracapsular Myomectomy: The Cold Loop Technique

The advent of surgical endoscopy in clinical practice has led to a conservative approach to uterine fibroids, especially for women who want to have children. To date, surgical hysteroscopy is considered an effective and safe treatment for submucous myomas [110]. Hysteroscopic myomectomy is currently the most widely used minimally invasive surgical procedure for the treatment of submucous myomas [111]. Despite its widespread use and ease of implementation, several complications have been reported, some of which are particularly serious [112–115].

Different techniques have been described in the hysteroscopic treatment of submucous myomas, but cold loop myomectomy, ideally performed in a single surgical procedure, seems to be the most effective and safe treatment for G1–G2 myomas [111]. It is an effective method providing greater safety for patients and reducing surgical risks [116].

The technique, conceived by Mazzon and firstly described in 1995 [117], was developed in order to preserve the muscular fibres in the myometrium and ensures the complete removal of the myoma. Indeed, the cold loop technique allows to apply the surgical principles utilized in laparotomic and laparoscopic myomectomy [7, 88, 118] to the hysteroscopic setting.

The importance of pseudocapsule in treating myomas was stressed and a hysteroscopic procedure taking advantage from such anatomic structure was specifically designed. The enucleation of myoma within its pseudocapsule not only ensured a reduced blood loss but it also allowed a complete treatment of the intramural part of myoma. Indeed, since the beginning of hysteroscopy, the intramural extension of myomas represented a challenge for the surgeons, as it influences the possibility to complete the myomectomy in a single-step procedure [111, 119], while increasing the risk for intraoperative complications and repeated surgeries [111, 115, 120]. In case of distention media warning level reached, it is recommended to interrupt the procedure in order to avoid clinical intravasation syndrome, and a second surgery should be scheduled [121].

To ensure a blunt dissection of the fibro-connetival bridges, which anchor the myoma to the pseudocapsule, mechanical loops have been designed (Mazzon's cold loops®, Karl Storz Tuttlingen, Germany). These new instruments allows to avoid the recourse to coagulation or cutting combined with coagulation. In this way the thermal damage of surrounding myometrium and dramatic intraoperative complications, as uterine electrical loop perforation, are theoretically eliminated.

Furthermore, using the cold loop technique, the infiltration of the myoma into the myometrium, which has always been considered a major difficulty in hysteroscopic myomectomy, especially when associated with multiple myomas [111, 120], does not play an important role. Indeed, it makes the intramural extension of the fibroids an intracavitary lesion that is easy to treat.

Before the surgical act, an accurate preoperative diagnostic investigation should be done. A good surgery starts with a good diagnosis. Firstly, to assess the number and size of myomas and the extent of their intramural development, an ultrasonographic evaluation should be carried out in all the patients.

Particular attention must be paid to the measurement of the free myometrial margin (FMM), the thickness of the myometrium between the myoma and the perimetrium, because a reduced FMM is a major risk factor for uterine perforation. In order to avoid such complication, the FMM should be at least 1 cm, nevertheless, even few millimetres of FMM may be considered safe by an expert hysteroscopist. Indeed, it has been shown that this is a dynamic parameter during surgery and tends to progressively grow during the removal of the myoma [122].

However, even in case of uterine perforation, the cold loop allows to avoid the dramatic consequence due to the thermal loop [123–125].

Secondly, a diagnostic hysteroscopy is mandatory for the preoperative evaluation. The knowledge of the number, the position of myomas relatively to the uterine wall, the endometrium thickness, the presence of other intracavitary pathologies and the size of the uterine cavity, may influence the favourable outcome of the hysteroscopic myomectomy. Moreover only with the diagnostic hysteroscopy is possible to really categorize the grading of myoma, according to the classification proposed by Wamsteker [119]. Such classification, officially adopted by the European Society of Gynaecological Endoscopy organizes the myomas based on the intramural development:

- **G0**: completely endocavitary, pedunculated myoma, with no intramural extension;
- **G1**: submucous myoma with less than 50 % intramural extension;
- **G2**: submucous myoma with more than 50 % intramural extension.

Recently, multiple variables and not only the degree of myometrial penetration were considered in the "STEPW classification" proposed by Lasmar et al. [121], to more accurately predict a complete or an incomplete removal of the myoma in one-step procedure before treatment [126].

In addition to the intramural extension, the STEPW classification considered the size, topography, and extension of the base myomas in relation to the uterine wall. The five parameters of STEPW are as follows [121]:

1. Size: the largest diameter found by any of the imaging methods. When the nodule measures ≥2 cm, it is given a score of 0; if it is 2.1–5 cm, it gets a score of 1; and if it measures >5 cm, it gets a score of 2.
2. Topography: defined by the third of the uterine cavity where the fibroid is situated. If it is in the lower third, the score is 0; if in the middle third, the score is 1; and if in the upper third, the score is 2.
3. Extension of the base of the myoma: when the fibroid covers one third or less of the wall, it is given a score of 0; when the base of the nodule occupies between one and two thirds of the wall, the score is 1; and when it affects more than two thirds of the wall, the score is 2.
4. Penetration of the nodule into the myometrium: when the fibroid is completely within the uterine cavity it is given a score of 0; if it has its larger part in the uterine cavity it is given a score of 1; and when it has its larger part in the myometrium it is given a score of 2.
5. Wall: when the fibroid is on the lateral wall, 1 extra point is added regardless of the third that is affected.

In case of a score from 5 to 6, the GnRH analogue (GnRHa) preoperative treatment was suggested by the Authors.

The role of GnRHa before hysteroscopic myomectomy is still controversial in the scientific literature. Concerning the hysteroscopic myomectomy, although some papers reported longer surgical times with GnRHa [127], Muzii in a RCT [128] showed a shorter duration of the procedure. On the contrary, Mavrelos advised against the use of GnRHa before myomectomy as any benefit in such treatment was not identified [53]. A recent meta-analysis [129], including the only 2 available RCT [53, 128], concluded that GnRHa "may improve some outcomes but there is insufficient evidence to support their routine use prior to hysteroscopic resection of submucous fibroids". In order to clarify this issue, randomized controlled trials investigating the efficacy of GnRHa pre-treatment in hysteroscopic myomectomy, especially with cold loop technique, are needed.

Considering the scientific evidence available on the usefulness of the GnRHa therapy before laparoscopic or hysteroscopic myomectomy [129, 130] and based on our experience, we are able to affirm that, waiting for more consistent data, the GnRHa pre-treatment in cold loop myomectomy should be reserved only to the patients with severe anaemia.

At the end of the diagnostic (ultrasonographic and hysteroscopic) evaluation, the surgeon should gain sufficient information about the possibility to perform the procedure in one or two-step.

At the beginning of the cold loop hysteroscopic myomectomy, a dilation of the cervix is carried out.

In the event that dilation proves difficult with this technique, the resectoscope is inserted into the cervical canal to visualize the direction and to complete the dilation.

No drugs should be used for cervical dilation.

Slicing of the Intracavitary Component of the Myoma

The intracavitary component of the myoma is progressively removed up to the surface of the endometrium using the conventional slicing technique (Fig. 31.25). During this phase, an electric loop powered by a 100 W monopolar current in pure cutting mode should be used. When the cleavage plane between the myoma and myometrium is identified, the slicing is stopped.

Enucleation of the Intramural Component of the Myoma

The electric cutting loop is subsequently replaced with a cold loop, which is inserted into the cleavage plane and repeatedly applied along the surface of the myoma (Fig. 31.26). In this way the connective fibers anchoring the myoma to the myometrium are disconnected by blunt dissection (Fig. 31.26). Using the cold loop, the damage of myometrial fibers around the myoma is minimal. The muscle bundles are spared any surgical trauma owing to the thermal damage of electrical cutting.

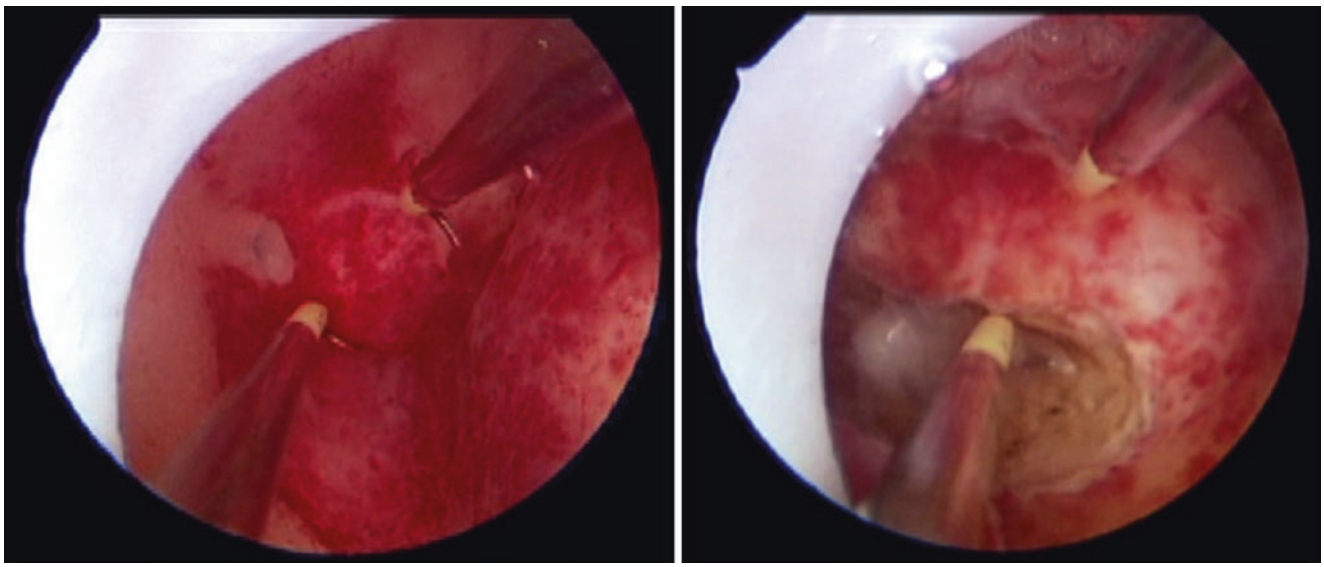

Fig. 31.25 The intracavitary component of the myoma is progressively removed up to the surface of the endometrium using the conventional slicing technique

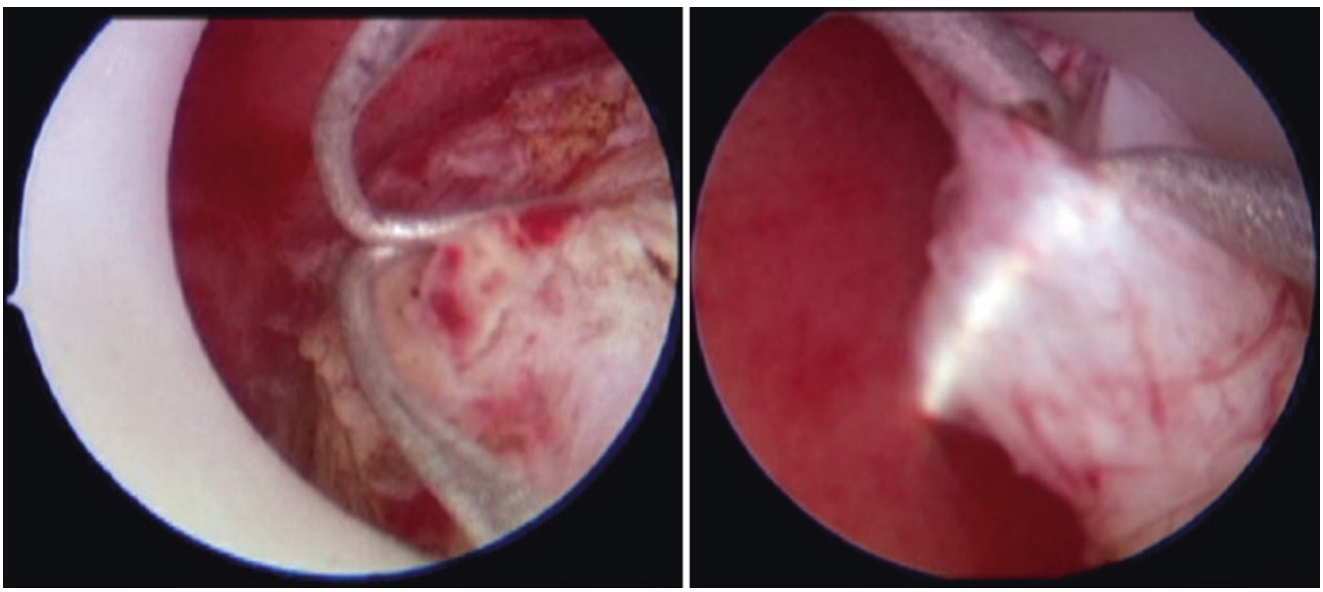

Fig. 31.26 The cold loop is inserted into the cleavage plane and repeatedly applied along the surface of the myoma

Slicing of the Intramural Component of the Myoma

After detachment, the intramural part of the myoma becomes an endocavitary neoformation and is safely removed by slicing as previously described, without damaging the surrounding myometrium (Fig. 31.27). During the slicing phase, the cutting action is always directed from the notch of the myoma towards the uterine cavity and never in the opposite direction: this is done to avoid thermal damage and the risk of accidentally cutting the myometrium around the notch (where the uterine wall is thinnest), or uterine perforation caused by the thermal loop. The electric loop is never used under the endometrial lining.

Control of Uterine Cavity Integrity

The integrity of the cavity and the absence of residual fragments are verified at the end of the procedure, to avoid the risk of inflammation and intracavitary synechiae (Fig. 31.28).

If the surgical procedure is interrupted due to excessive absorption of the distension liquid or other complications, thus the myomas are not totally removed, an additional resectoscopic procedure is scheduled.

The cold loop hysteroscopic myomectomy is usually performed using a 9 mm resectoscope with 0° optical system (HOPKINSII® Karl Storz Tuttlingen, Germany) and glycine 1.5 % for distension of the uterine cavity. For safety reasons,

coagulation or blended waveforms are never used: this is also to avoid significant thermal damage deriving from coagulation.

To prevent the risk of clinical intravasation syndrome, the surgeon is constantly informed of the volumetric difference between the inflow and outflow fluid: the surgical procedure must be interrupted when absorption reached 1000 cm^3. The absorption of distending media should be continuously monitored along with the serum sodium level (arterial blood gas analysis). In accordance with the scientific literature [131–133], the critical value limit that we suggest to observe is 125 mEq/l.

Antibiotic prophylaxis should be only administered to patients with specific indications (e.g. cardiac valvulopathies).

According to Hamou who firstly suggested the importance and the usefulness of diagnostic hysteroscopic follow up because of the possibility to directly treat any postoperative adherence [134], 2 months after surgery a diagnostic hysteroscopy should be carried out. Intrauterine adhesions may impair many important reproductive aspects such as menstruation, normal fertility and pregnancy, being able to cause recurrent pregnancy loss, placenta accreta and intrauterine growth restriction. For these reasons, such synechiae have to be considered as a new pathology and not only as a complication or collateral effect correlated to the surgical treatment. According to the American Fertility Society criteria [135], the light synechiae can be easily treated during the endoscopic follow-up using the tip of the hysteroscope.

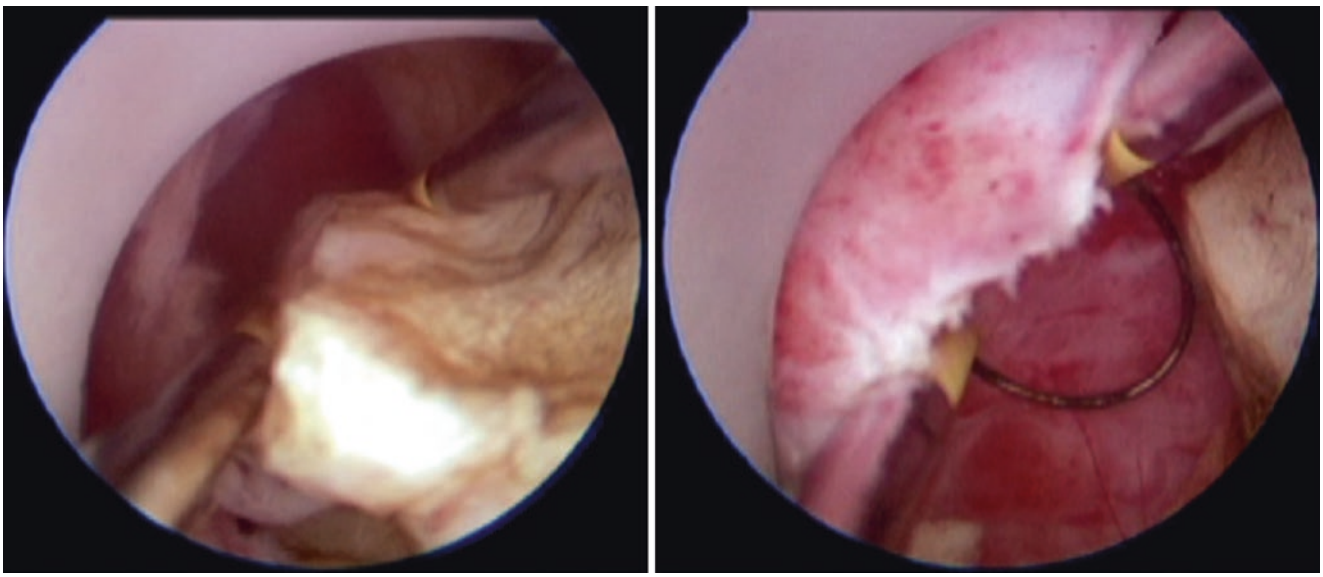

Fig. 31.27 The intramural part of the myoma is now an endocavitary neoformation and is safely removed by slicing, without damaging the surrounding myometrium

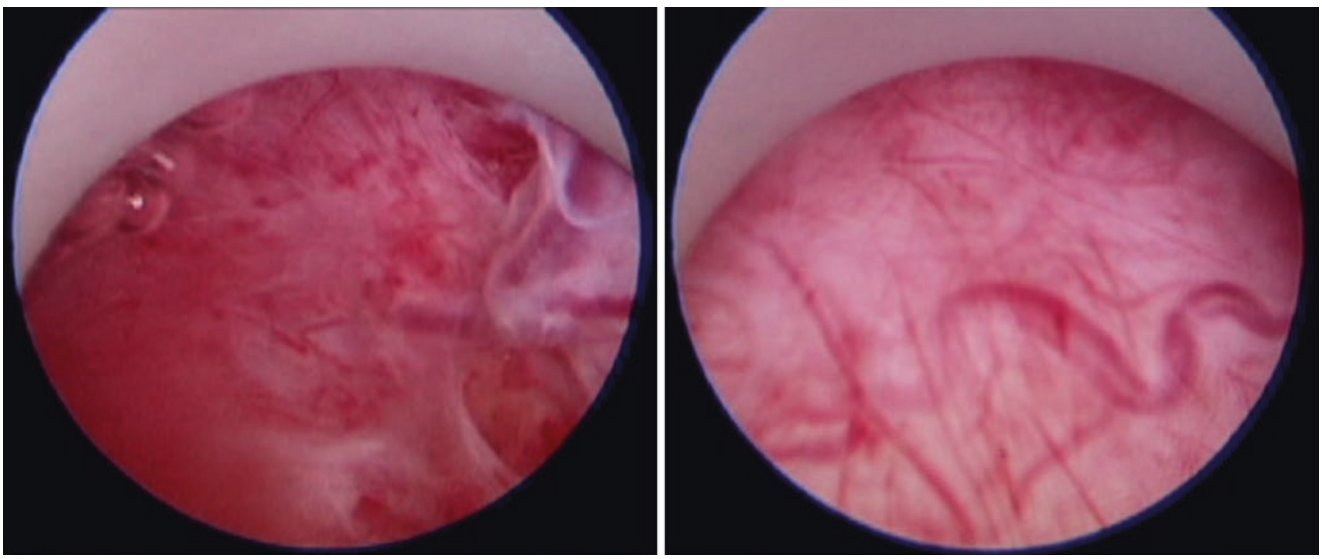

Fig. 31.28 The integrity of the fovea and the absence of sectioned residual fragments are verified at the end of the procedure

Synechiae of the uterine cavity represent the most common post-operative complication following resectoscopic myomectomy [136], and are related to the healing following the removal of myomas or to a possible perforation of the uterine wall [134]. Despite the frequency of this episode, there are few examples available in literature that describe its prevalence [137–140]. Some authors have suggested the use of anti-adherence liquid mixtures, or intrauterine devices aimed at preventing synechiae after resectoscopy [139, 141]. However, other authors have studied the influence of different types of electric energy used during myomectomy and their effect on the formation of adherences [138].

Taskin et al., in a prospective randomised study, reported a rate of synechiae of 31.3 % following resectoscopic myomectomy of a single myoma, reaching a rate of 45.5 % in case of multiple myomas [136]. In 2008 Yang et al. published a study where was reported a rate of 1.5 % in case of the resection of single myoma and a rate of 78 % in case of myomas located one in front of the other. In both groups of patients an IUD after the surgery was placed. The authors remarked the importance of diagnostic hysteroscopy within 2 weeks after the resectoscopic surgical treatment, with the aim to easily treat light intrauterine adherences [140].

In 2014, the results of a retrospective study conducted on a group of 688 patients with one or more G1–G2 myomas showed that the cold loop hysteroscopic myomectomy is a safe and effective procedure capable of ensuring a low prevalence of intrauterine synechiae [116].

The rate of adhesions reported 2 months after resectoscopic myomectomy was approximately 4 %, of which only 0.29 % were represented by fibrous synechiae, even in case of multiple myomas enucleated. The occurrence of synechiae in patients in whom 2 myomas were removed was almost the same as in those with a single myoma treated (4.48 % and 3.22 %, respectively). However, differently from expected, post-surgical synechiae were not found in the group of patients in which more than 2 myomas were removed.

The low rate of adherences can be ascribed to the non-use of electricity in coagulation mode (characterised by a higher thermic damage) and conversely to the use of the cold loop, preventing electric energy, whichever the type (monopolar or bipolar), from getting in contact with the myometrium of the uterine wall and inducing thermic damage which may increase the appearance of synechiae. Moreover, 8 cases of intraoperative complications were reported in in the same series (1.16 %). Furthermore the low rate of complications, such as perforations and the complete absence of damage to the entire layer of the uterine wall caused by thermal loop, might have a positive influence in the low rate of the post-surgical synechiae registered [116]. Moreover, no cases of uterine rupture in subsequent pregnancies were recorded. Several cases have been reported in the literature, some of which with dramatic consequence [142–144]. The possible negative effects on fertility and on pregnancies outcome due to the use of intraoperative monopolar or bipolar coagulation has been already described. The damage of surrounding healthy myometrium is considered as the major risk factor for uterine rupture in pregnancy after laparoscopic myomectomy [143].

In conclusion, it is therefore possible to affirm that the cold loop hysteroscopic myomectomy is a safe and feasible procedure, ensuring the respect of pseudocapsule and of surrounding healthy myometrium. Such technique allows to limit the blood loss during surgery, the damage to healthy myometrium fibers and is associated with a low rate of intraoperative complications. Moreover the rate of adhesions seems to be lower in comparison with the reported literature [18, 116]. These issues are of great importance for fertility patients and the surgeons should pay more attention in pseudocapsule preserving.

Translational Research and Virtual Biomodeling for Personalized Management of Patients with Uterine Myoma: Future Perspectives

Computational simulations of pelvic organs' topographic anatomy is a perspective direction of the translational biomodeling research aimed to design personalized approaches of minimally invasive restorations of women's reproductive health.

Uterine myoma is a common disease with serious consequences for women's well-being by causing such problems as infertility, recurrent miscarriages, dyspareunia, pelvic pain, bowel and bladder dysfunctions, dysmenorrhea, as well as irregular and excessive bleedings are associated with anemia. It is well known that uterine myoma is the most common indication for surgical procedures such as myomectomy and hysterectomy making this condition as an enormous healthcare concern with considerable healthcare expenditures.

From this view it is logical to design a special mathematical tool for preliminary patient-specific structural virtual analysis. It may help to come up with decision on the type of optimal treatment strategy. A mathematical biomodeling would become essential part of patient management. This approach will help to choose conservative or surgical intervention options which will be planned together with patients by demonstrating them virtual events are related with disease and its different treatment options as well as possible risks and beneficial outcomes.

We developed semi-automatic algorithm for constructing personalized virtual 3D anatomical model of uterine myoma which was based on MRI data set of a particular subject as well as on the medical applications of our previous mathematical model-system entitled "Personalized anatomical meshing of human body with applications" [145]. In order to design our semi-automatic technology we have used following algorithms and methods. The medical image segmentation is performed using user-guided active contour segmentation

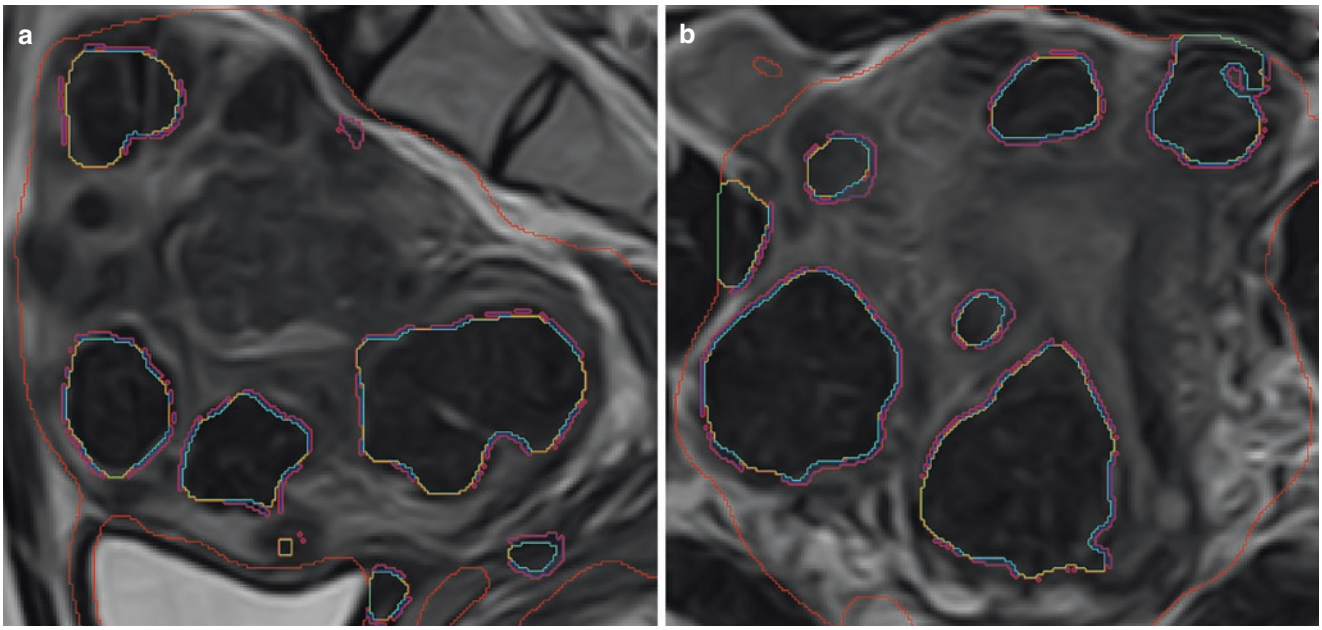

Fig. 31.29 MRI based 2D analysis of myoma pseudocapsule inner and outer boundaries: (**a**) sagittal plane; (**b**) transverse plane

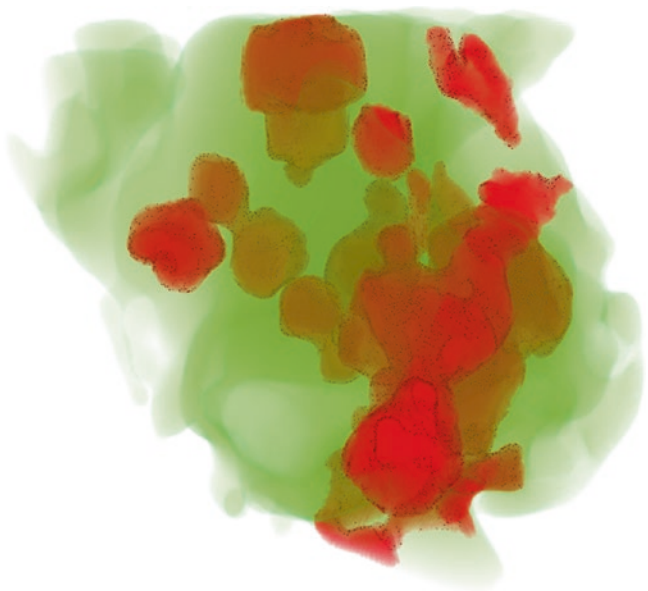

Fig. 31.30 3D reconstruction of multiple large uterine myoma case

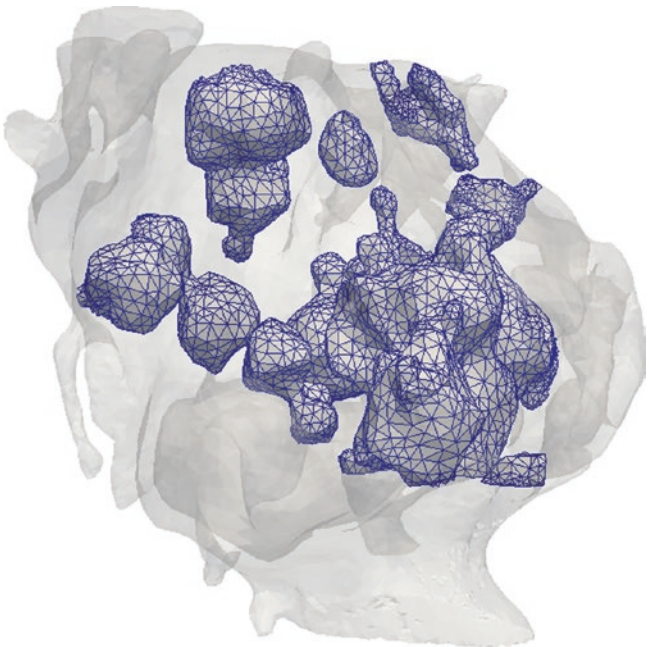

Fig. 31.31 3D computation mesh generated for segmentation results

[146] with supervised random forest classification from ITK-SNAP segmentation software [147]. The inner and outer boundaries of fibroid pseudocapsule can be determined at this stage (Fig. 31.29). Several post-processing algorithms were applied for filling remaining gaps between tissues and final segmented data smoothing. These algorithms are based on Gaussian smoothing, connected-component labelling and mathematical morphology operations: erosion, dilation, opening and closing [148]. As a result, a 3D model of multiple uterine fibroids is produced (Fig. 31.30). This post-processing step is essential for generation of valid mesh, which is suitable for future finite element modelling.

The following algorithms were used for mesh generation: a marching cubes algorithm for surface reconstruction [149]; surface triangulation, smoothing and coarsening techniques [150, 151]; 3D Delaunay triangulation algorithm from the CGAL-Mesh library [152], allowing specific mesh size for each model material; advancing front technique for volume mesh generation [153, 154].

Fig. 31.32 The image shows a 32 years' old patients with multiple fibroids searching pregnancy; the operation was by laparotomic intracapsular multiple myomectomy and uterus reconstruction sparing myoma pseudocapsule

The essential post-processing mesh cosmetics step is applied using Ani3D library [155] in order to increase mesh quality. Preliminary results of our biomodeling cooperation are presented as computational mesh suitable for further computational simulations (A virtual model of multiple fibroids in patient with large uterine myoma) (Fig. 31.31).

In future 3D model will allow us to conduct non invasive virtual topographic anatomical analysis of the individual features of uterine fibroids including number and size of fibroids and their location in the uterine wall (subserosal, intramural, submucosal and pedunculated myomas) as well as in different uterine regions (fundal, corporal and isthmian–cervical) in order to design a personalized management strategy and optimized treatment choice.

Our biomodeling researches will cover wide range of topics are related with uterine topographic anatomy and uterine myoma, such as a mathematical model of fibroid pseudocapsule [156], virtual mechanical soft tissue computational simulations of uterine scar after myomectomy [157] and a virtual 3D model of uterine scar after caesarean section [158], as well as an original concept of angiogenesis initiation and vascular network development during uterine fibroid formation and growth [159].

Conclusions

The morphological and molecular research we conducted on the myoma pseudocapsule produced many interesting scientific results. The fibroid deforms the surrounding myometrium as it grows, giving rise to a dense fibroneurovascular pseudocapsule, rich of neurotrasmitters and growth factors, with a proper angiogenic profile. The discovery of the richness of the fibroneurovascular structure in neurotransmitters and morphological analysis of the pseudocapsule made it possible to translate the results in reproductive surgery and the whole topic of fertility and clinical practice, even for giant fibroids (Fig. 31.32) and during pregnancy (Fig. 31.33). My evidences on the presence of dedicate angiogenesis, neurofibers and neuropeptides in few millimetre structure, the pseudocapsule, suggested to preserve as much as possible such

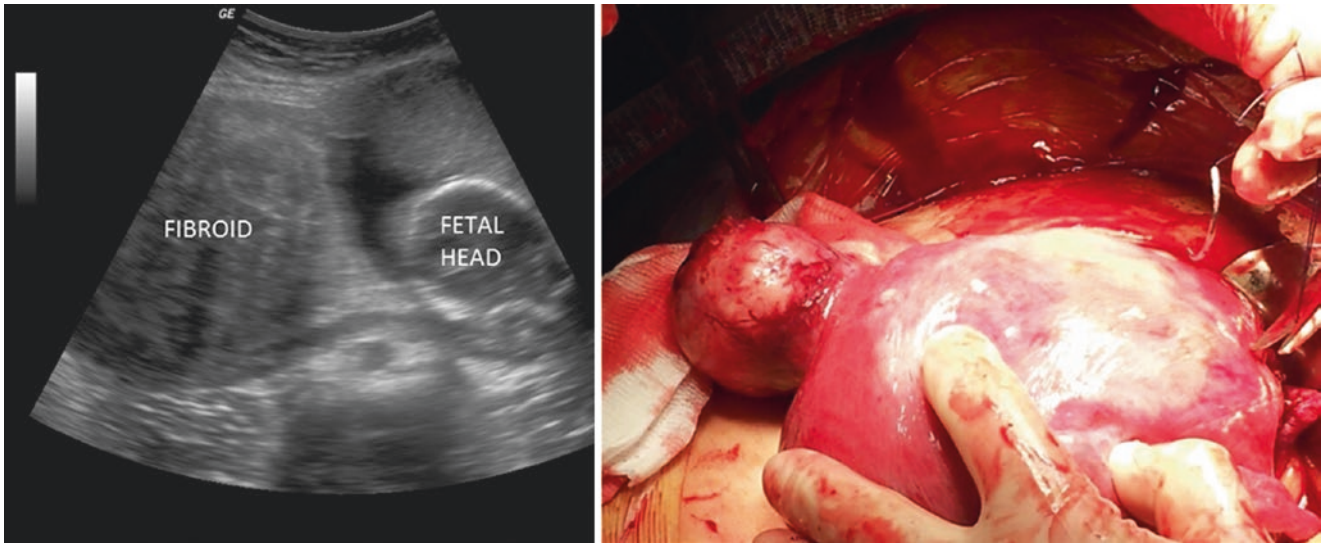

Fig. 31.33 A patient with a subserous fibroid of 4 cm of diameter located near lower uterine segment: on the left, the ultrasonographic image, on the right the image before a cesarean intracapsular myomectomy, after hysterorraphy

structure, during myomectomy. Pseudocapsule sparing during myomectomy should preserve myometrium integrity peripheral to fibroid site, enhancing myometrial healing after myomectomy. Moreover, intracapsular myomectomy, via traditional laparotomy, laparoscopy or hysteroscopy, should favour reproductive outcomes [160] and normal labor and delivery, for less bleeding [13], better neurovascular bundle sparing [88], and postoperative adhesions reduction [37, 116]. So the mix of intracapsular myomectomy and pseudocapsule-sparing by endoscopic "microsurgical" magnification, can be reproduced in all myomectomies, as a safe and feasible minimally invasive technique [7, 18, 54, 116, 161, 162].

Laparoscopic Subtotal Hysterectomy (LSH)

32

Bernd Bojahr and Garri Tchartchian

Introduction

Various benign gynecological conditions including dysfunctional uterine bleeding, meno-metrorrhagia due to endometrial hyperplasia, fibroids, diffuse myomatosis, adenomyosis, endometriosis, pressure symptoms related to bowel or bladder function, large uterine fibroids, and treatment of excessive menstrual loss not responding to medical therapy [1–3] are indicative for a laparoscopic hysterectomy. For nonmalignant conditions LSH represents an alternative to total hysterectomy, with a low level of intraoperative and postoperative morbidity [4].

The difference between a subtotal, or supracervical hysterectomy and a total hysterectomy is as follows:

The total hysterectomy removes the entire uterus, including the cervix, whereas in the subtotal or supracervical hysterectomy the excision of the body of the uterus is performed, at or below the level of the isthmus, and conserves the cervix.

Leaving the cervix intact laparoscopically is easier to perform on a technical level, making the Laparoscopic subtotal hysterectomy (LSH) favorable over a total laparoscopic hysterectomy (TLH). With the LSH technique the two pitfalls of TLH, uterine vessel haemorrhage and ureteric injury, can be avoided. The risk of cervical cancer can also be reduced by coring out the entire transformation zone and endocervical canal.

Other advantages can be seen in reports that LSH results in lower levels of sexual, bladder and bowel dysfunction and offers superior protection of the integrity of the pelvic floor compared to total hysterectomy [5–7]. In developed industrial countries there is an increasing uptake rate of LSH [8, 9].

Although laparoscopic surgery is well accepted by gynaecologists worldwide, laparoscopic hysterectomy in Germany is still only performed by a few specialists as it is a highly skilled technique. At the "Klinik für MIC" (a hospital specialized in minimally invasive surgery) in Berlin, Germany, the surgeons are leading experts in laparoscopic subtotal hysterectomy. Between 1998 to December 2014 11,598 LSH procedures were performed there 909 of these extirpated uteri had a weight of more than 500 g and the largest removed uterus had a weight of 4065 g.

This article will describe and illustrate in detail the surgical technique of LSH and will comment on complications, as well as providing some tips and suggestions for implementation.

Surgical Procedure

After bladder catheterism and vaginal disinfection, the patient is placed in a horizontal position, with stretched legs (Fig. 32.1). Positioned on the left side of the patient are the surgeon, the assistant and the surgical nurse, along with instrument tables, facing the monitors and endoscopic tower on the right side of the patient the electronic equipment is set up (Fig. 32.2). No uterus manipulators are needed. A CO_2 pneumoperitoneum to an intra-abdominal pressure of 15 mmHg is established utilizing a Veress needle, placed through an incision in the inferior umbilical fossa. A 5-mm trocar is used for the laparoscopy with 30 ° optics.

Tip When the situs is obscure, and especially in the case of large multimodal myomatous uteri, the excellent image quality provided by the new digital 3-ship camera (STORZ), and the benefits of the 30° telescope can be much appreciated.

The patient is then placed in Trendelenberg position, a maximum (steep) position. Two more 5 mm puncture sites in the lower abdomen are required (Fig. 32.3), the location of which depends on the size of the uterus.

Two additional trocars are introduced left and right lateral to the epigastric vessels in the region of the pubic hair line in cases of a normal sized uterus. The larger the uterus, the further

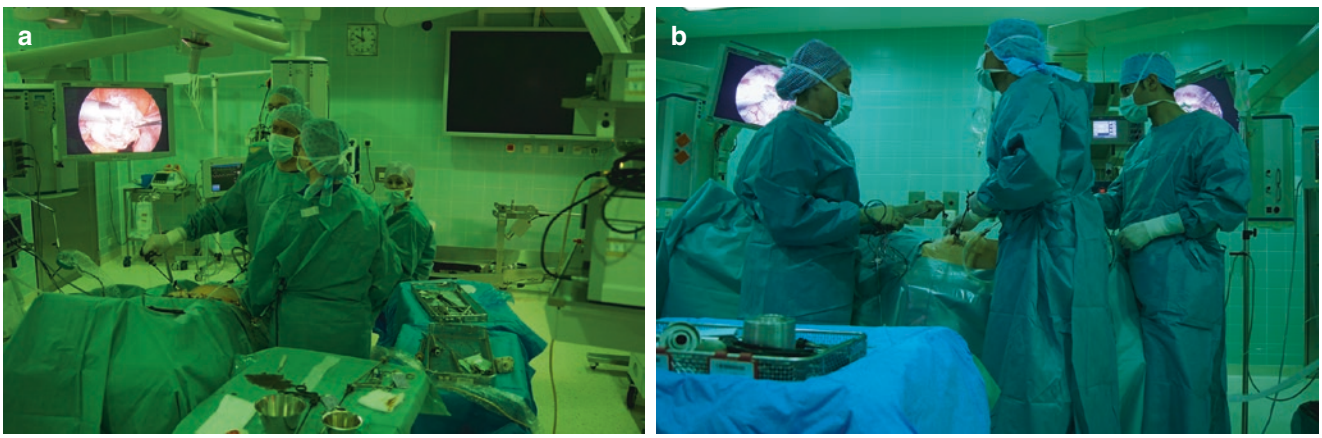

Fig. 32.2 The surgeon, the assistant, the scrub nurse and the instrument table are positioned on the left side of the patient (**a**, **b**)

Fig. 32.3 Trocar placement for a LASH (normal sized uterus)

above the symphysis pubis the lateral trocars need to be positioned. In the case of uterus extension as far as the umbilicus, insufflation is performed on the left, below the costal arch with trocar introduction there or in the umbilicus. Correspondingly higher, additional trocars are positioned according to the size of the uterus, to enable the adnexa to be dissected (Fig. 32.4).

Tip With a large myomatous uterus (Fig. 32.5), localization of the two trocars in the lower abdomen depends on the size of the uterus. They are then usually placed two to three centimeters above the pubic hair border. A fourth trocar should be introduced on the left below the costal arch or above the umbilicus to obtain a better overview of the uterus. From

there, visualization can be performed with the telescope (Fig. 32.6). The uterus can then be pressed to the right or left using a palpation probe, so as to remove the adnexa laterally. With such large findings, good visualization of the anatomic structures with the 30 ° telescope is essential to avoid unnecessary bleeding.

The only additional re-usable instruments needed for LSH include a bipolar coagulation clamp, Metzenbaum scissors, three various grasping forceps, a needle holder, a unipolar hook, and a suction-irrigation system.

The round ligaments, the fallopian tubes and the ovarian ligaments are coagulated using bipolar forceps for mobilization of the uterus (Fig. 32.7) and subsequently dissected using endoscopic Metzenbaum scissors (Fig. 32.8).

Tip Mobilization of the uterus can also be performed with the ultracision harmonic scalpel. Less frequent instrument changing is required. But also the use of ultracision instruments, monopolar scissors and unipolar loops for the dissection of the corpus uteri has been described [10–12]. Safety,

precision of the cut, and shortage of operating time are definite advantages of the unipolar loop are [10].

Tip In the case of intraligamentous myomas the essential requirements are, on the one hand, sufficient hemostasis and, on the other hand, that dissection is always close up against the myoma. The majority of myomas can be mobilized with a blunt instrument. It is necessary for the ureter to be visualized during and after the removal if the myomas extend as far as the pelvic wall. To ensure that the symptoms complained of before the operation do not persist afterwards if endometriosis foci are present, irrespective of whether they are located in the Douglas, in the area of the round ligaments or in the area of the bladder peritoneum, it is important to also resect these foci completely.

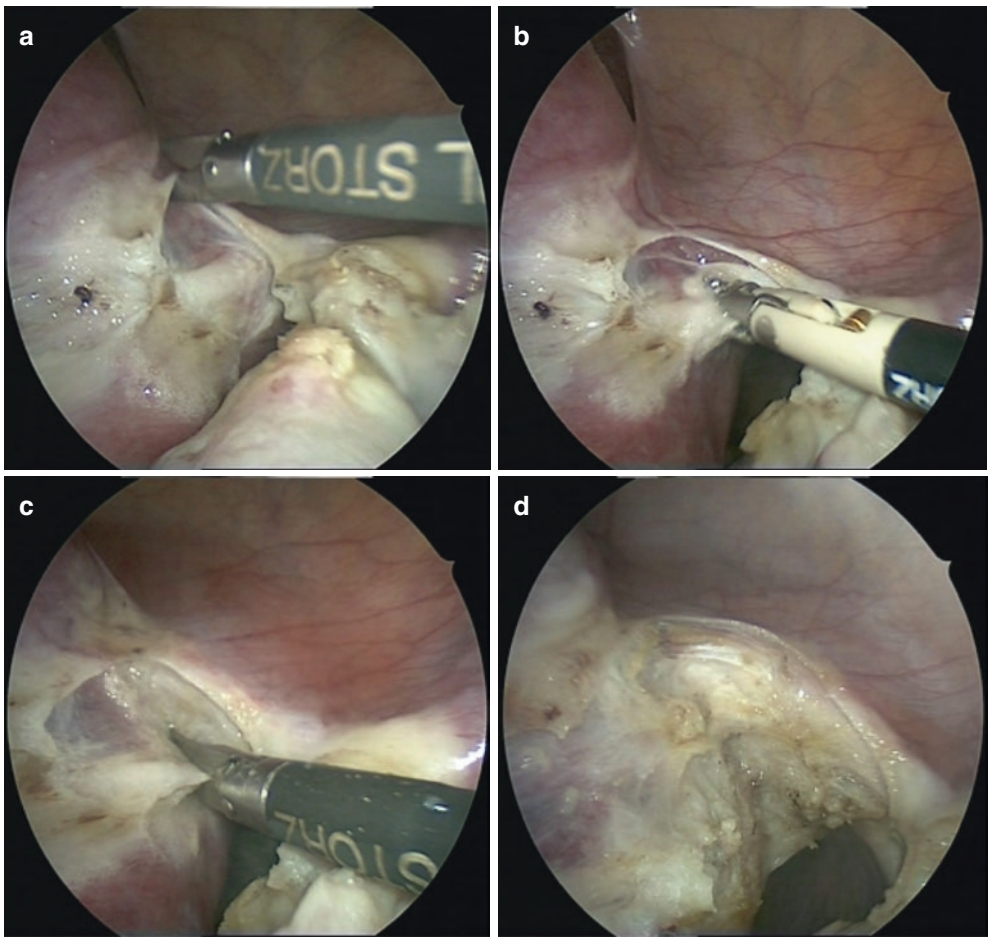

Fig. 32.9 Identification and skeletonization, bipolar coagulation and dissection of uterine vessels on the right side (**a**–**d**)

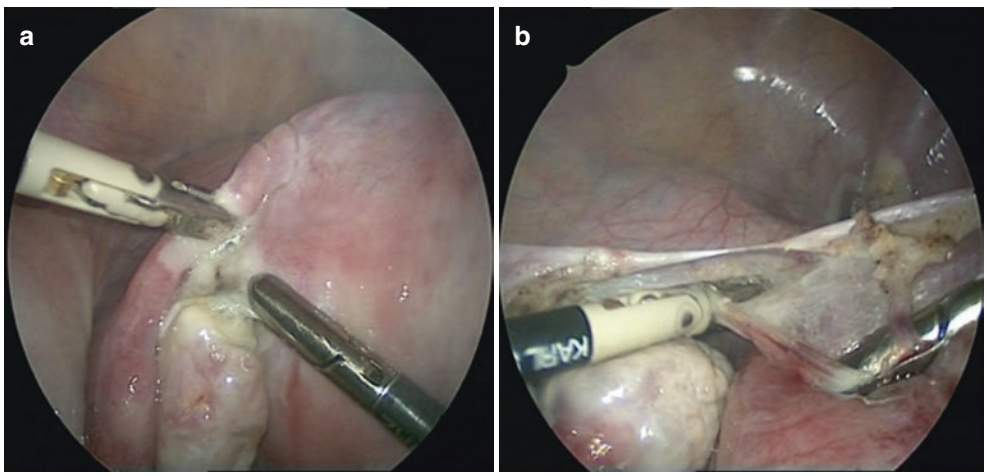

Fig. 32.10 Bipolar coagulation and dissection of round ligament, fallopian tube and ovarian ligament from left side (**a**, **b**)

After identification and skeletonization of the uterine vessels, bleeding is controlled by bipolar coagulation and the vessels dissected using Metzenbaum scissors on the right side (Fig. 32.9).

Grasping forceps are used to pull the uterus to the contralateral side. After separation of the uterus from the ovaries and fallopian tubes and dissection through the round ligaments on the left side (Fig. 32.10) the uterine vessels will be also coagulated and dissected (Fig. 32.11) and a bipolar coagulation zone is placed on the bladder peritoneum for the delineation of the planned direction of incision to open the bladder peritoneum (Fig. 32.12). Once the bladder peritoneum has been separated from the dissected round ligaments using scissors, it can be opened and the bladder pushed slightly caudally. It is not necessary to push away the bladder as it is in total hysterectomy. This is because dissection of the

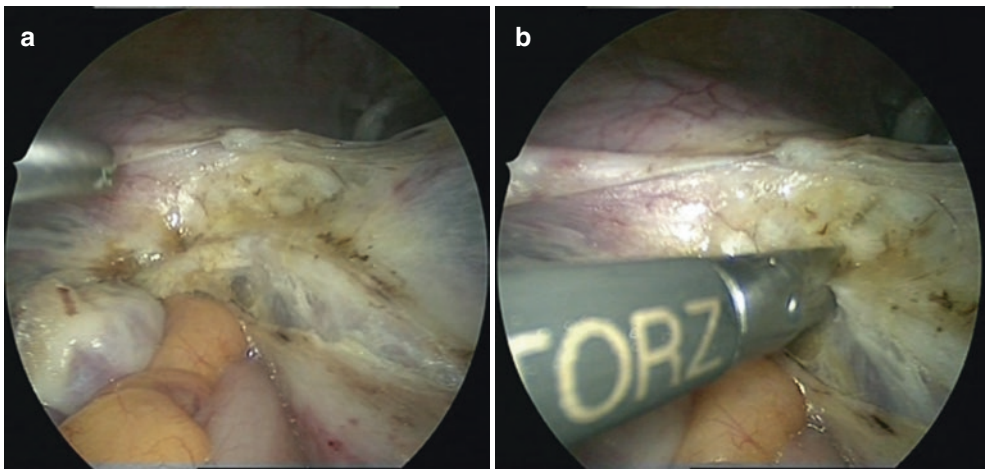

Fig. 32.11 Identification and skeletonization, bipolar coagulation and dissection of uterine vessels on the left side (**a**, **b**)

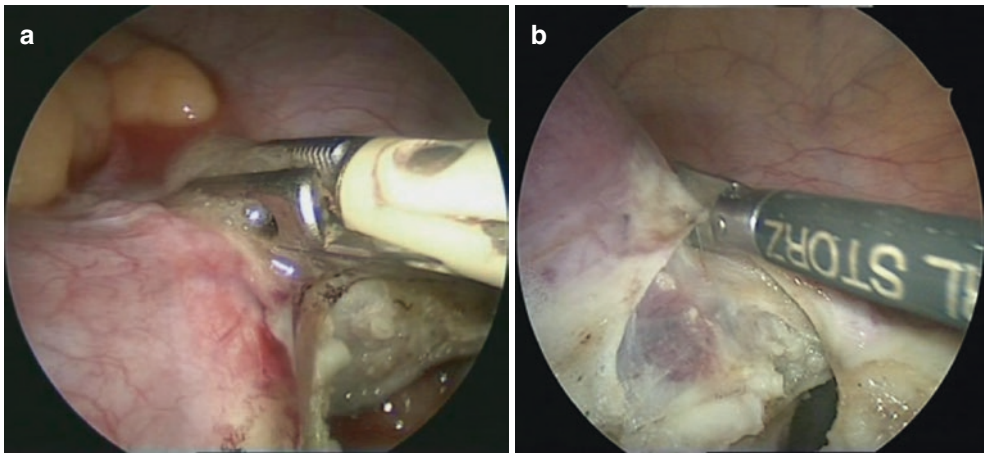

Fig. 32.12 A Coagulation zone is made on the bladder peritoneum (**a**) – Undermining and opening of the bladder peritoneum (**b**)

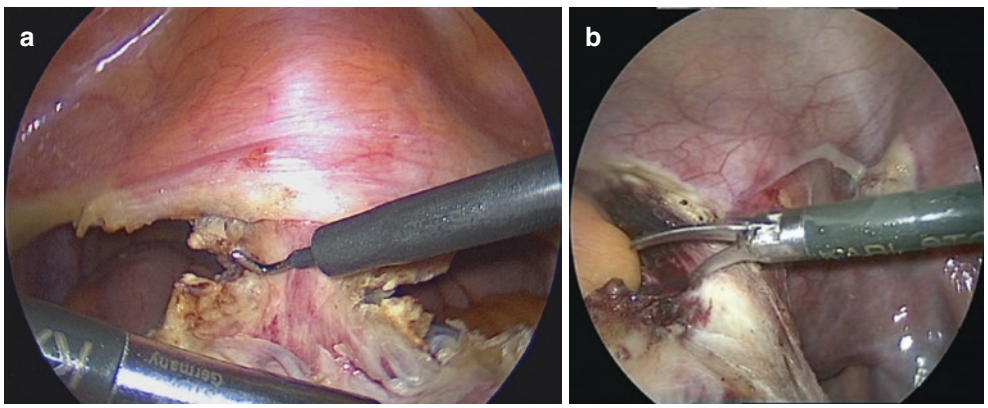

Fig. 32.13 Transection of corpus uteri with unipolar hook (**a**) or with a pair of scissors (**b**)

uterine body with a unipolar hook or with a pair of scissors (Fig. 32.13) is done in the upper third, cranial to where the uterosacral ligaments leave the cervix. If dissection starts from the left side, the uterus is held against the anterior wall using grasping forceps and pulled in cranial direction.

Due to the traction of the uterus to the opposite side (where the dissection is to be performed) space can be created to identify the uterine vessels in the cervical area and the ureter. If coagulation and dissection of the uterine vessels is performed close to the cervix, we do not visualize the ureter. In cases of cervical myomas, even traction of the uterus to the contralateral side is very helpful for visualizing the ureter.

The dissection is done step by step starting from the right using the unipolar hook. In this phase of surgery the surgeon needs clear vision to prevent injuries of adjacent organs; the development of excessive smoke can be prevented by actuating

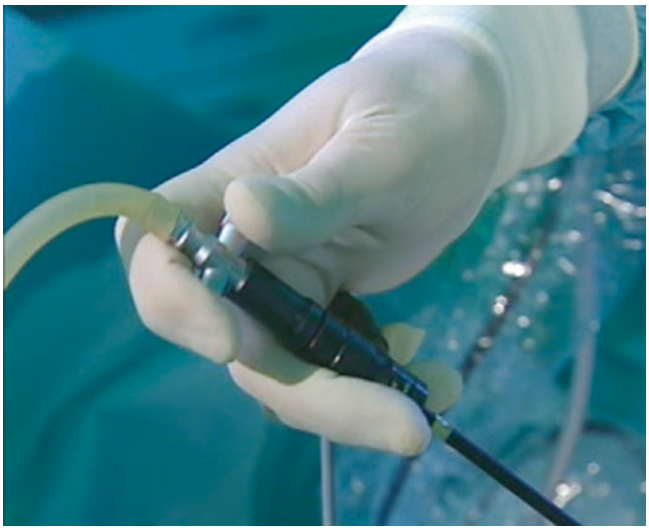

Fig. 32.14 Suction device connected to the unipolar hook

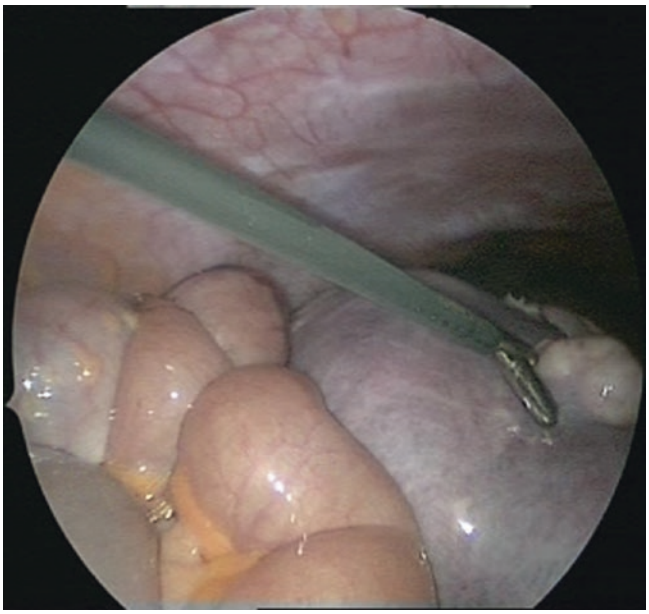

Fig. 32.15 Positionning of the transected corpus in the right-hand mesogastrium

the suction on the hook (Fig. 32.14). The dissected body of the uterus is positioned in the right-hand mesogastrium to enable haemostasis in the wound area (Fig. 32.15), followed by bipolar coagulation of the cervical canal (Fig. 32.16) after efficient haemostasis (Fig. 32.17) in the area of the cervix stump.

Tip The cervix can be held from the left using grasping forceps while searching for the entrance into the cervical canal with the palpation probe or bipolar forceps if identification of the cervical canal is difficult. Coagulation is performed by opening and simultaneously rotating the damp in the cervical canal.

Fig. 32.16 Bipolar coagulation of the cervical canal

A vicryl thread shortened to approximately instrument length is used for peritonealisation of the cervical stump. Under vision, the round needle is introduced through the 5 mm incision (Fig. 32.18). The cervix stump is then covered with peritoneum using a continuous purse-string suture, including both uterosacral ligaments (Fig. 32.19). Following the preparation of a triple knot, the peritoneum is pulled together, with a fourth knot to secure the suture (Fig. 32.20).

The incision is widened to 10–20 mm in the left-hand lower abdomen to remove the uterus. Following injection of a local anaesthetic beneath the wound area of the left-hand incision, an electric morcellator (STORZ® or WISAP®) (Fig. 32.21) is introduced under direct vision. The uterus is then gripped from the left and pulled into the morcellator, which is activated by hand or via foot pedal. It is of utmost importance to keep the sharp rotating blade continuously in vision at the centre of the laparoscopic image to avoid injuries (Fig. 32.22). To remove a large section of tissue in a single piece, it is helpful to assist the process of morcellation with the right-handed grasping forceps so that the blade is always visible on the surface of the uterus (Fig. 32.23). Morcellation is therefore performed around the exterior of the uterus. The uterus is effectively peeled like a potato.

Tip It is particularly important to ensure a good overview during morcellation, and in the case of large uteri a 20 mm morcellator can also be used. This leads to a considerably shorter operation, as the sections of uterus removed in this way are far larger.

Remaining smaller pieces of the uterus or the myoma are retrieved using 10 mm spoon grasping forceps after removal of the uterus (Figs. 32.24 and 32.25).

The operation is completed with lavage and a final checking of the cervical stump (Fig. 32.26). The peritoneum in the area of 15 or 20 mm incisions is closed from the inside using bipolar coagulation. To avoid incision hernias Closure of the fasciae is also necessary. The skin is then closed using single-button sutures. The final position for a normal sized uterus shows 5 mm incisions in the umbilicus and on the right side of the lower abdomen, and a 15 mm incision on the left (Fig. 32.27). If the uterus is noticeably enlarged, an additional 5 mm and a 20 mm incision for the morcellation may become necessary.

Laparoscopic combined hysterectomy (LACH) with "change over technique" – this is a special surgical tech-

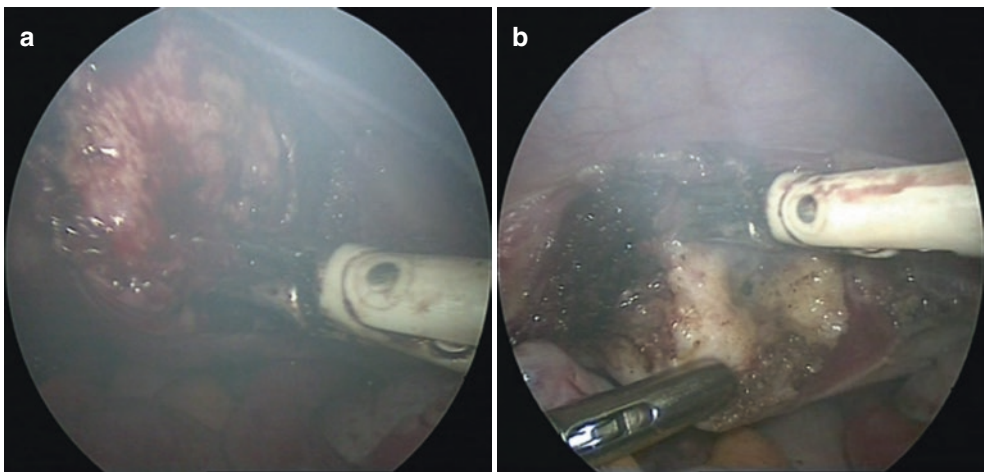

Fig. 32.17 Hemostasis in the area of the cervical stump (**a**, **b**)

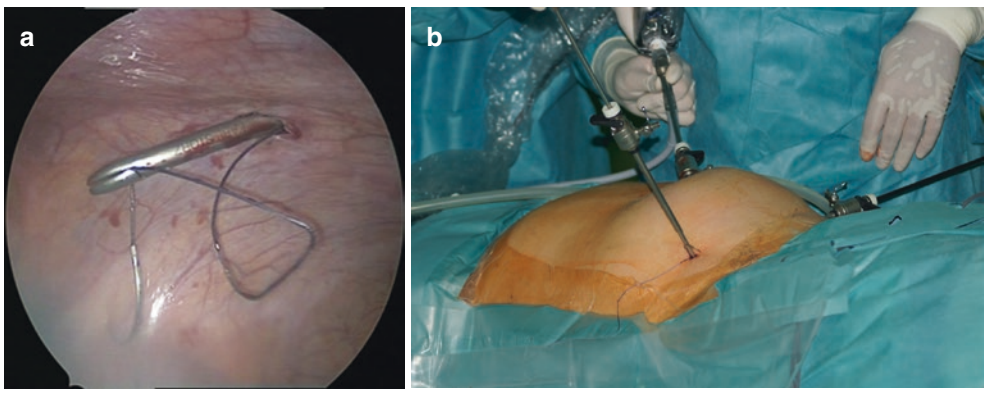

Fig. 32.18 Introduction of a round needle (endoscopic view and view from outside **a**, **b**)

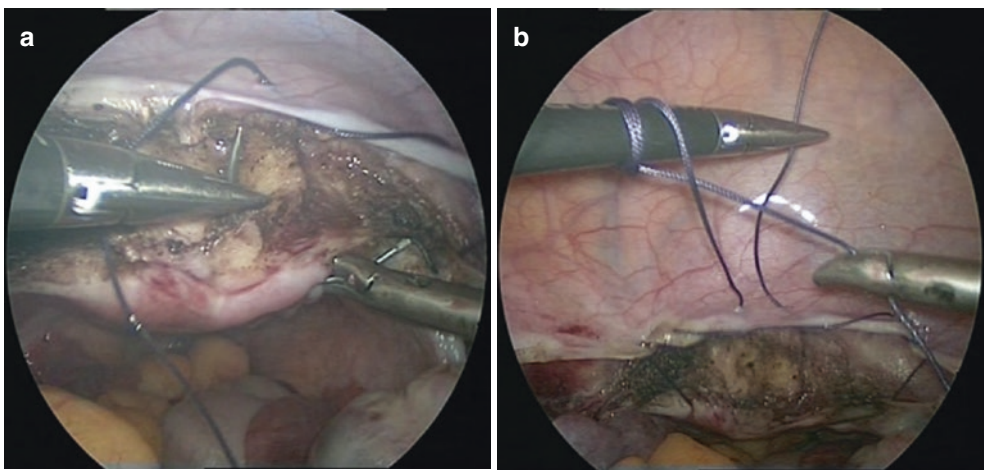

Fig. 32.19 Continuous purse-string suture (**a**, **b**)

nique for the removal of a very large uterus [13, 14]. Here, the uterine corpus is abscised and morcellated laparoscopically. For this, the above mentioned "change over technique" is applied, where the operation-team changes from one side of the patient to the other (Figs. 32.28 and 32.29). The "change over technique" can also be used in LSH given a difficult-case-uterus. The specialty of the "change over technique" lies in the fact that for successful abscission of the uterine corpus in case of very large uterine myomata, the surgeon begins operating on the left side of the uterus, respectively on the left side of the parametrium. After sealing and cutting off the left parametrium and the vascular bundle, the surgeon and the assistant move to the right side of the patient and now operate on the right side of the uterus.

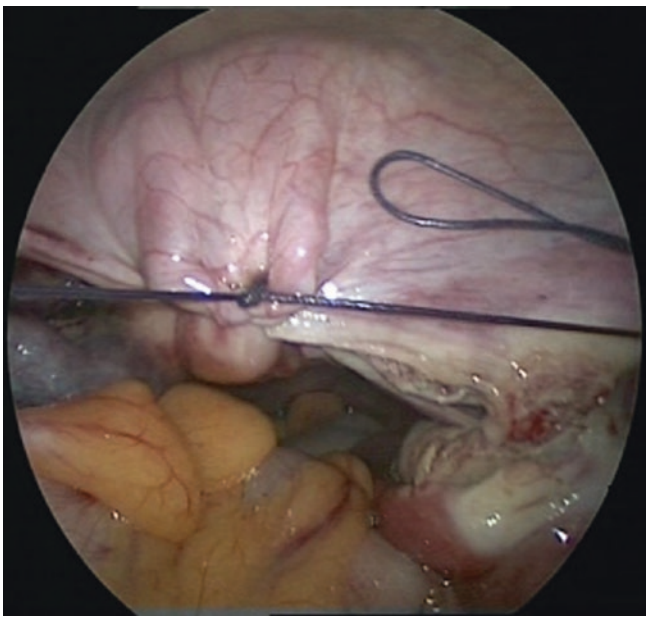

Fig. 32.20 Peritonealization of the cervical stump

Tip Doubtlessly, an umbilical entry of the optical trocar into the epigastrium is possible. However, we always recommend using Palmer's point for the camera trocar on the left side. For the right optical trocar, we use the exact symmetrical counterpoint on the right side. Surgery is always carried out using 5 mm 30 ° optics made by the Karl Storz company. Next, the patient is placed in maximum Trendelenburg position. For the first phase the surgery on the left side we place two more working trocars on the left axillary line of the abdomen, leaving a space of about 8–10 cm between them [14].

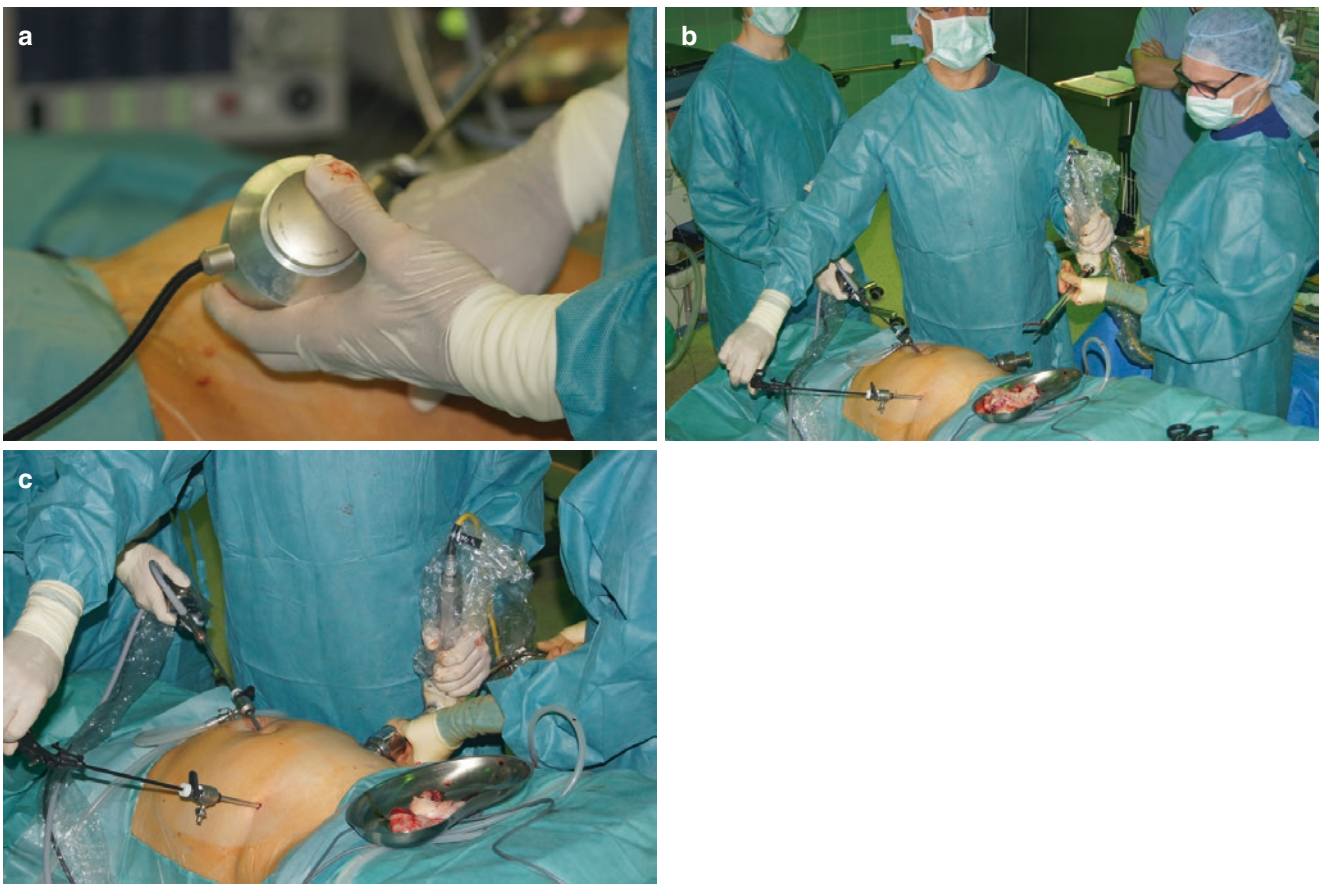

Fig. 32.21 Introduction of a 15 mm Rotocut electric morcellator (Storz) (**a**) or a 20 mm WISAP morcellator (**b**, **c**)

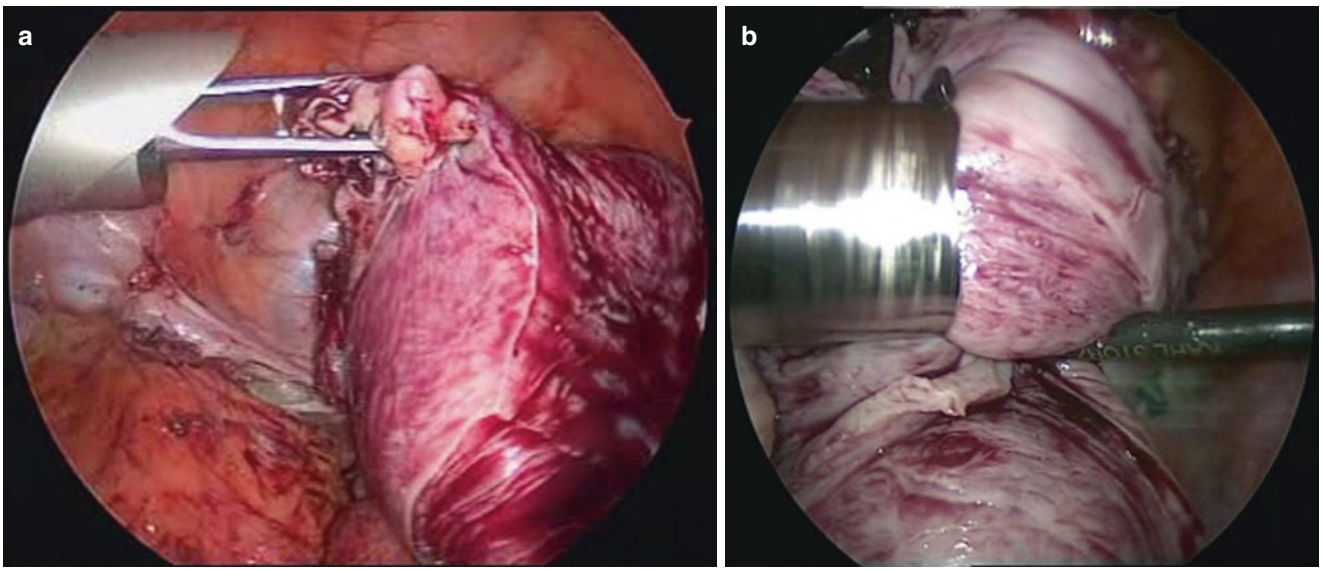

Fig. 32.22 The sharp rotating blade of the morcellator is visible during morcellation (**a** – Rotocut electric morcellator (Storz), **b** – WISAP electric morcellator)

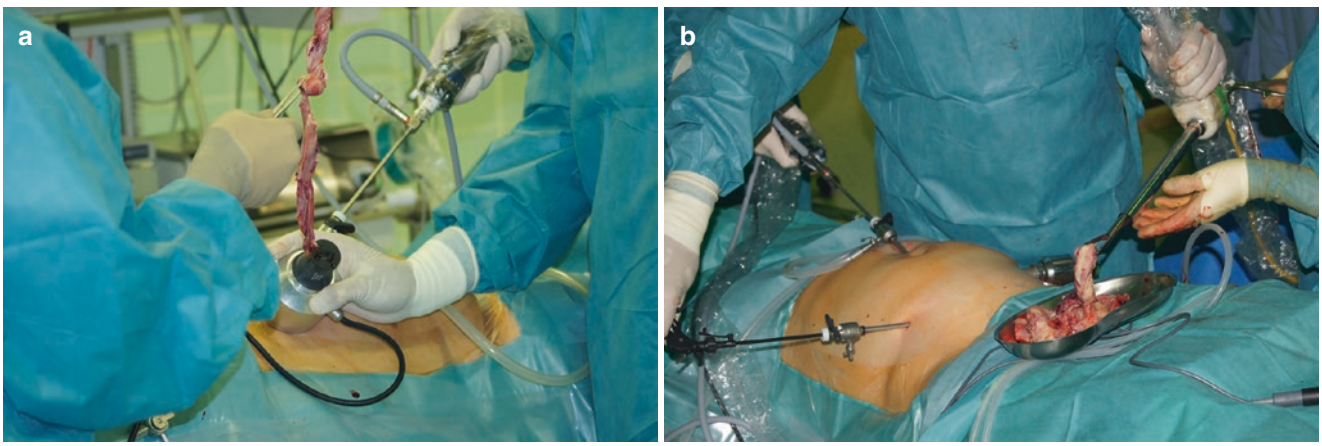

Fig. 32.23 Morcellation - View from outside (**a** – with the Rotocut electric morcellator (Storz), **b** – with the WISAP electric morcellator)

Tip The lower working trocar should be placed at about the height of the uterotubal junction.

After parameterization on the left side is conducted, the second optical trocar is placed in a position symmetrical to the Palmer's point area on the right costal arch under laparoscopic observation for the second phase of the "change over technique". The surgeon and his assistant change their position to the right side of the patient and the operation is resumed from the right. Leaving space of 8–10 cm between them, two further working trocars are placed along the right axillary line.

Complications

Reported complication rates in literature for all different hysterectomy procedures vary tremendously. It appears that complication rates in general are reduced using endoscopic techniques. Complication rates for abdominal hysterectomies are between 13.1 and 48 % [15–17] and for vaginal hysterectomies between 2 and 27.7 % [15, 17–19]. Complication rates for LSH are lower (0–4.35 %) than for TLH (0–18%) [4, 9, 19–23 34].

Compared to vaginal and abdominal hysterectomies, major complications (e.g. haemorrhage, vesicoperitoneal fistula, ureteral injury, rectal perforation or fistula) are more common after laparoscopic hysterectomies, as shown in multicenter studies [24], however the comparison to total laparoscopic hysterectomy shows that LSH has a lower major complication rate [25].

We reported intraoperative and postoperative complication rates of LSH of 0.2 % and 1.2 %, respectively, and a conversion rate of 0.82 % [4], which are similar to the low rates of conversion (0.7 %) and of intraoperative complication (0.1 %) in a second study [26]. Lyons [27] reports low rates

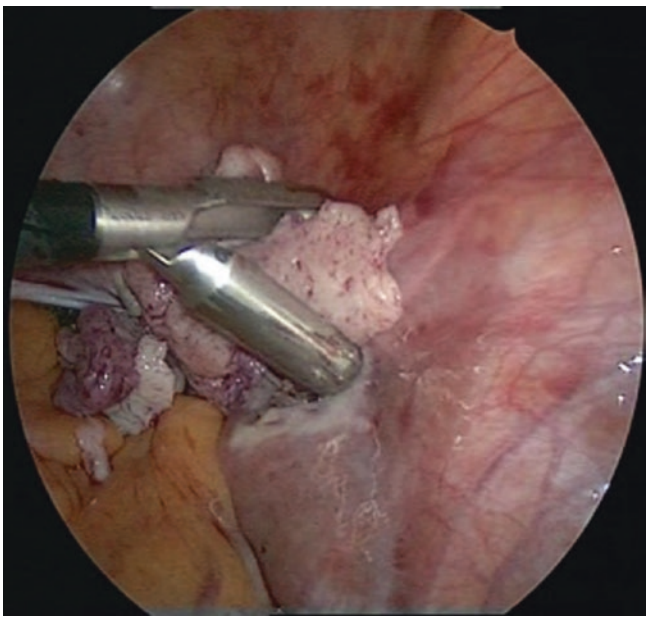

Fig. 32.24 Removal of smaller pieces using a 10 mm spoon grasping forceps

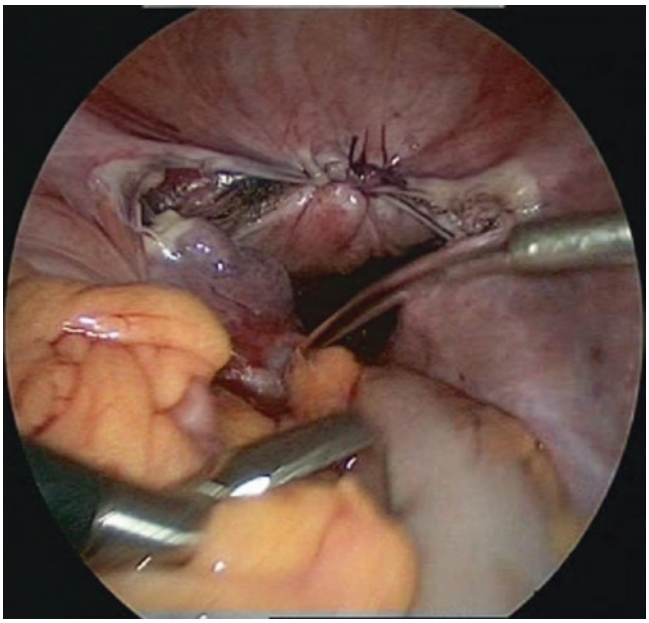

Fig. 32.26 Rinsing of the abdomen

Fig. 32.25 Morcellated pieces of a 1107 g uterus

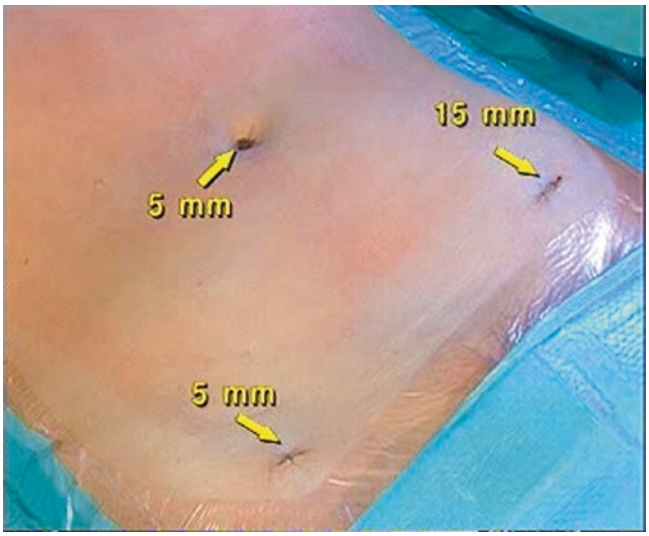

Fig. 32.27 Final abdominal situs

of blood transfusion (0 %), and reoperation (0.001 %), out of 1500 procedures, including patients with severe adhesive disease and severe endometriosis.

The majority of complications associated with a hysterectomy involve injuries to the urinary tract. One multicenter study showed highest complication rates of injury to the urinary tract for TLH (2.26 %) compared to abdominal (0.17 %) and vaginal hysterectomy (0.04 %) [28]. The risk of injury to the ureter or bladder during TLH increases as the bladder is dissected off the vaginal tissue [29]. Because the dissection ends superior to the bladder and ureter during LSH, the risk of direct damage to the ureter and bladder is presumably decreased [28, 30, 31]. Four retrospective studies have reported urinary tract (ureteral) injury rates of less than 1 % out of a total of more than 30,000 laparoscopic hysterectomies [4, 32, 33, 35].

Minor complication rates occurring after LSH are lower (0.25–1.35 %), including bladder incision (0.1–0.25 %), iatrogenic adenomyosis (0–0.56 %) and ileus (0.5 %) [11, 24, 25, 31, 33].

There are several reasons for the conversion of laparoscopic hysterectomies. Uterine size, weight and lack of mobility are clearly limiting factors for laparoscopic surgery, resulting in limited vision available during laparoscopy and higher rates of conversion [26]. Other risk factors are previous gynecological operations [4]. the close proximity of myomas to the cervix or the lateral wall of the pelvis has also made conversion necessary [26], technical difficulties caused

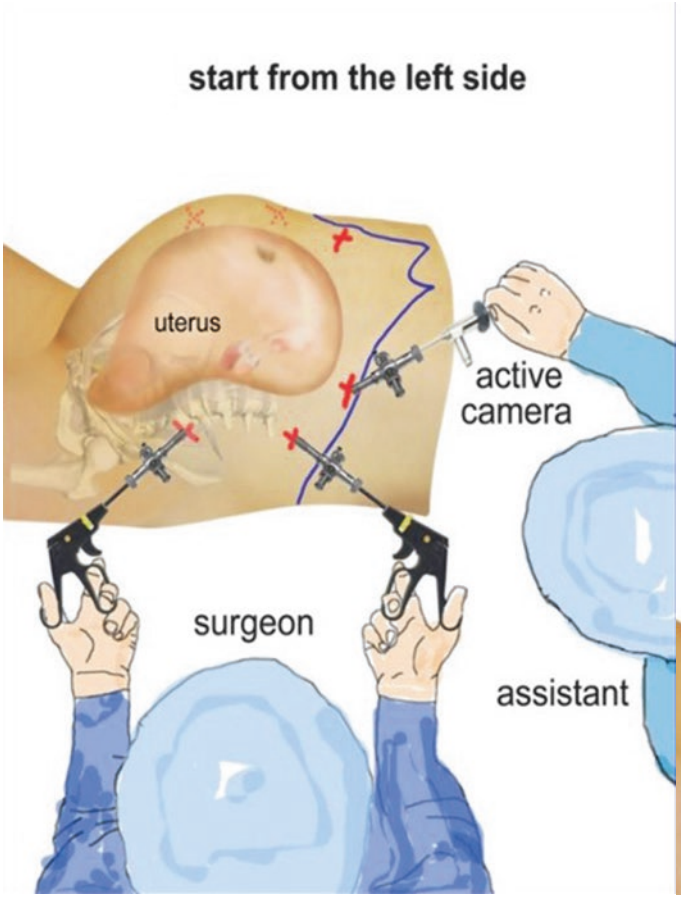

Fig. 32.28 Change Over Technique – Start of parameterization on the left side

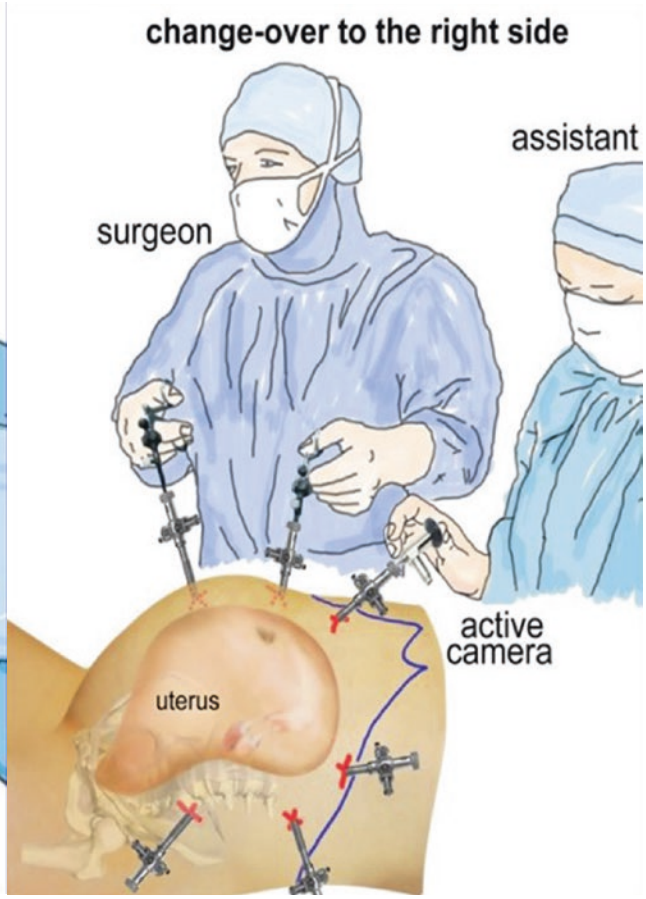

Fig. 32.29 Change Over Technique – Operation team changes side. Continuation of parameterization on the right side

by adhesions, difficulty in controlling intraoperative bleeding, or the repair of a complication [33]. Endometriosis is a major challenge to the surgeon [36], and should be completely resected, as further surgery might otherwise become necessary [37].

Further interventions needed due to postoperative complications include postoperative abdominal pain due to adhesions [4]. Other causes of postoperative complications are infections of the cervical stump and of the incision sites [4]. Conservative treatment with antibiotics is indicated.

Remnants of uterine myoma left in the abdominal cavity after morcellation [38] can be rare postoperative complications leading to unclear persisting abdominal pain.

Performed by skilled, experienced surgeons, laparoscopic hysterectomy is a safe procedure resulting in very low rates of complication [35]. Various studies have shown that low complication rates correspond to the level of experience of the surgeons involved, whereas high complication rates observed in other studies are not the result of the technique itself but rather lack of experience. The laparoscopic technique requires a high level of expertise with a learning curve of 30 operations to significantly decrease operating time and complication rates [39].

Conclusion

Minimal morbidity and an equally low complication rate are typically associated with LSH. The majority of complications associated with a hysterectomy are bladder and ureteral lesions and vaginal stump infections. These risks can be reduced significantly as the cervix is conserved, which is reflected in lower surgical morbidity and fewer postoperative complications.

The rate of postoperative complications is lower, hospital stays are shorter, patients recover more quickly and return to normal activity and work after a shorter convalescence compared to abdominal or vaginal hysterectomy. The procedure therefore appears to be beneficial to

patients [37, 40–43]. In addition, a comparison to total laparoscopic hysterectomy shows that LSH has a remarkably lower major complication rate [25]. Furthermore, the use of reusable laparoscopic instruments reduces the total cost of the procedure [44].

Laparoscopic Supracervical Hysterectomy for Large Uteri

33

Funlayo Odejinmi and Reeba Oliver

Introduction

Routes of Hysterectomy

The routes of hysterectomy have evolved since ancient times. The first vaginal hysterectomy was performed by Soranus of Ephesus around AD 120 and employment of the vaginal route to remove the uterus continued through the medieval times. The next advance in an alternative route occurred in 1843 when Charles Clay performed the first abdominal hysterectomy in Manchester, England [1]. It was only in 1988 after the advent of modern endoscopic techniques, did the route of hysterectomies evolve again. Harry Reich performed the first laparoscopic hysterectomy in Pennsylvania [1]. Since then, the challenge has always been to push the boundaries of endoscopic surgery to achieve removal of the uterus for all women within the remits of surgical safety.

Once the decision is undertaken that a woman needs a hysterectomy, the route of the hysterectomy is the next debatable issue that is taken into consideration. The decision about the route depends on the patient characteristics, indication for hysterectomy, extrauterine pathology and size of the uterus. Recent reviews comparing routes of hysterectomy suggest that vaginal hysterectomy is the preferred route for hysterectomy for benign conditions and where vaginal hysterectomy is not possible, laparoscopic hysterectomy may avoid the need for an abdominal procedure necessitating a laparotomy [2].

Many perceived barriers to laparoscopic hysterectomy have been identified. The size of the uterus is considered to be a limiting factor to performing most hysterectomies endoscopically. Traditionally the large uterus was exclusively extirpated by the abdominal route, often by a midline incision [3] with the associated risk of infective complications [4].

For the vaginal route, randomised trials have shown that large uteri can be removed vaginallywith no added complications and reduced length of hospital stay [5]. This however requires a higher level of expertise, and even then uterine size has often been cited as a limiting factor and increases the rate of conversion to laparotomy particularly when the vagina is narrow. The use of GnRH analogues to reduce the size of the uterus to allow for vaginal hysterectomy has been advocated [6]. However, the use of GnRH analogues can be associated with unwanted side effects. Thus where vaginal hysterectomy is not possible, and if possible, the laparoscopic approach should be used in order tos avoid abdominal hysterectomy. Randomized trials have shown the benefits of laparoscopic hysterectomy over open abdominal hysterectomy [7].

With the advent of new modern alternatives to the management of menorrhagia such as endometrial ablations and Mirena IUS, most hysterectomies are no longer on “normal sized” uteri. However for the large uterus whatever route is used, uterine size remains a bastion to conquer for the generalist gynaecologist and is often a reason for conversion to abdominal hysterectomy.

Supracervical Hysterectomy

The laparoscopic supracervical hysterectomy (LSH) has become a well-established and proven safe procedure [8] since first described by Semm [9]. It has evolved into an alternative to other forms of hysterectomy, with good short and long term outcomes [10] and patient satisfaction [11]. In some countries up to 40 % of hysterectomies are now performed supracervically [12]. In the absence of the need to remove the cervix for the normal sized uterus it has been shown that the LSH is associated with shorter operating time, less blood loss and less postoperative febrile episodes [13, 14].

Although LSH enables the removal of a large uterus laparoscopically with the obvious patient benefits, it has not been without its detractors. There is a perceived risk of developing cervical cancer in the residual cervix necessitating further surgery. But in developed countries where there is cervical screening, the risk of cervical cancer is very low if women do not default from screening programmes. Thus if there is no clinical reason to remove the cervix, LSH with its advantages is an alternative to laparotomy especially in women with high BMI. Again there is the potential risk of leiomyosarcoma. This risk is associated with the morcellation process with the morcellation process. Despite this, current evidence suggests that LSH is a safe and appropriate procedure for the management of benign gynaecological disease. Emphasis should be placed on patient information to aid an informed decision and further diagnostic assessments to allow earlier detection of occult malignancy (see unexpected malignancy).

There are no studies that have looked at long term outcome of women who have had LSH for large uteri. In women with normal uteri, though quality of life in the short term may be better when compared to TLH there is a slightly increased risk of stump haematoma, which can be overcome by careful haemostasis and laparoscopically over-sewing the cervical stump.

In the long term there is an increased risk of spotting. In the series by Tchartchain and colleagues looking at vaginal spotting after LSH they found that vaginal bleeding post procedure can result in a decrease in quality of life. However for myomatous uteri there was no statistical difference in patient satisfaction when compared to women who had LSH for other indications [15]. In the series by Lieng and colleagues 7 % of their cohort went on to have removal of the cervical stump for continued bleeding [16]. The size of the uteri in their cohort was however not specified.

With the advancement of technologies; better laparoscopes, optical systems, endoscopic instruments, vessel sealing technologies and tissue morcellation, it has become possible to push the boundaries of laparoscopic supracervical hysterectomy (LSH). It is now possible not only to perform this procedure in the large uterus but also in the larger patient [17]. Most observational studies demonstrate that LSH for the large uterus is not only feasible but offers a procedure with no added morbidity or complications with good patient satisfaction.

The Large Uterus

There are inconsistencies in literature as what constitutes a large uterus. The uterus was considered large at 280 g but this was the definition used for cut-off for vaginal hysterectomy [18]. With a laparoscope and full visualization of the pelvis a large uterus can be defined as one that extends to or beyond the true pelvis, thus extending above the sacral promontory. In an average sized woman this landmark will extend midway between the pubic symphysis and the umbilicus, equivalent to a 20 week sized fetus or weigh 500 g (Fig. 33.1).

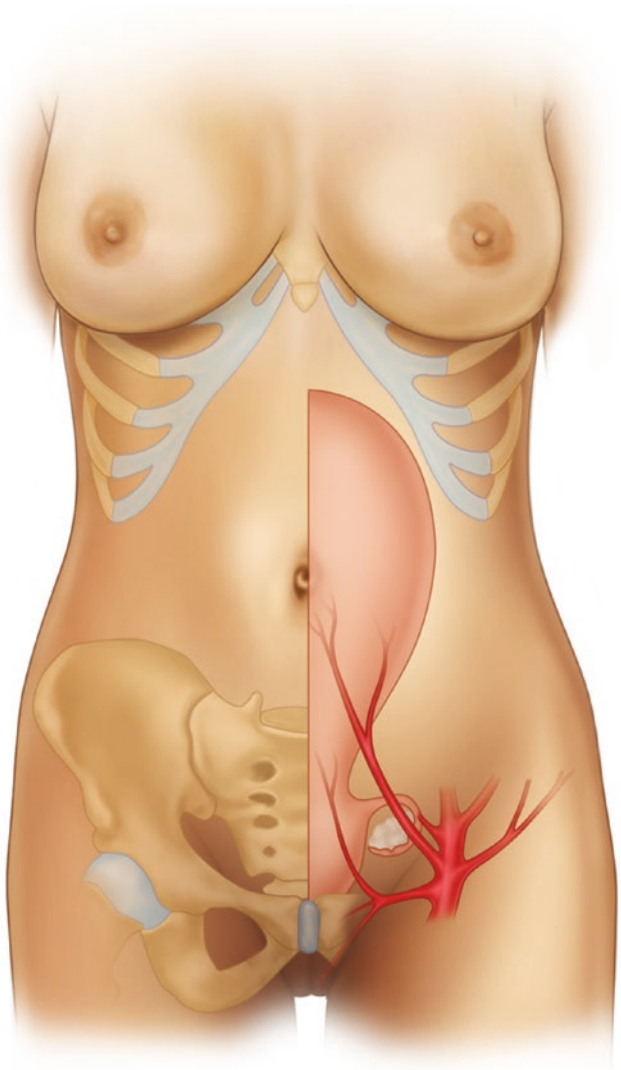

Fig. 33.1 Schematic diagram of a large uterus. Figure 33.1 shows the position of the enlarged uterus in relation to the bony pelvis (Courtesy of Catherine Woodman, BA (Hons))

LSH in Uterus Over 500 g: The Evidence

There have been no randomised studies with outcomes comparing LSH in women with uteri over 500 g with other forms of hysterectomy, thus outcomes can only be extrapolated from observational studies.

In the earliest large series on LSH for large uteri reported by Lyons and colleagues, 67 % of women had uteri larger than 500 g [19]. Alperin and colleagues later published a series of 333 women with uteri larger than 500 g who underwent LSH for large uteri and compared the outcome

with 113 women who underwent total laparoscopic hysterectomy (TLH) for uteri larger than 500 g (mean weight 786 g) and found that LSH was associated with a significantly lower operating time than TLH in this group of patients. Additionally, their conversion rate was low and not related to uterine size [3].

In the series by Maclaran et al. where 33 women had a uterine weight of over 600 g, there were no conversions to laparotomy. They found that a combination of elevated BMI and enlarged uterus resulted in 94 % increase in blood loss and 66 % increase in operation duration compared to those with normal weight and uterine size less than 300 g [20]. But in spite of the above, there were no increase in hospital stay or morbidity. Hussain and colleagues in a series of 88 patients undergoing laparoscopic hysterectomy found that with the larger uterus there is significantly more blood loss and longer operating time. Most of the operative time was put down to the added time needed for morcellation. However there was no difference in the length of stay of the patients [17].

In the series of 1584 women by Grosse-Dreiling et al. though there is no data on the sizes of the uteri, the overall conversion rate was 0.88 %. Of the 14 patients that needed conversion to laparotomy, 3 had uteri greater than 850 g and conversions were due to uncontrollable bleeding attributed to uterine size. Uterine size alone contributed to only 20 % of the conversions [21].

In the series of 1000 LSH procedures reported by Bojahr and colleagues of which 68 had uteri weighing 500 g or more, there were 4 conversions in patients with increased uterine weight. The average uterine weight in this group was 976 g, the lightest uterus was 750 g, and the heaviest was 1185 g. The authors note that the conversion to laparotomy was not due to the size alone but the lack of uterine mobility, closeness of myomas to the cervix or the lateral wall of the pelvis [22]. This group again reported on a series of 1952 LSH procedures of which 8.6 % weighed more than 500 g. In this series the overall conversion rate was 0.82 % with 71 % of those conversions due to access related to uterine size [23].

Twijnstra and colleagues reviewing the literature on laparoscopic hysterectomy conversion rates, found that LSH can reduce conversion rates compared to TLH 3 fold, but uteri weighing 500 g or more could increase conversion rates 30 fold [24]. With the large uterus it could be argued that size *per se* is not the limiting factor but rather the shape of the uterus as it is in the TLH procedure [25]. The difficulty in completing the procedure is dependent on the limited pelvic space and the often tortuous and enlarged uterine vessels. Another major factor is the distortion of anatomy caused by uterine fibroids, with conversions to laparotomy being influenced by lower segment or broad ligament fibroids [3]. The mobility of the uterus is also often limited [26]. Access to the cervix and or uterine arteries can be restricted by the presence of fibroids and the approach will depend on the exact location of the fibroids in relation to these structures. Thus irrespective of the definition used, the most important factor in performing a supracervical hysterectomy for the large uterus is access to the uterine vessels and the cervix in order to transect it at the isthmus. Nimaroff and colleagues advised a combined technique of laparoscopic supracervical amputation followed by trachelectomy to enable laparoscopic removal of large uteri weighing more than 450 g [27].

Optimizing the Surgical Outcome

Whatever the route or type of hysterectomy the ideal procedure is one that allows for the procedure to be completed successfully with the least morbidity, fewest complications, allows early recovery and has good patient satisfaction.

Patient Selection

It is thus important that patients are chosen carefully in order to meet these objectives. For the large uterus and in the large patient, recent literature dictates that not only is this a safe procedure and feasible, but it also has good outcomes and satisfaction rates. There have been no studies looking at selection and pre-operative criteria for large uteri for LSH. There have been studies to predict the weight of the uterus using ultrasound or MRI (Fig. 33.2) and comparing this to bimanual examination of the uterus [28]. And though formulae have been developed

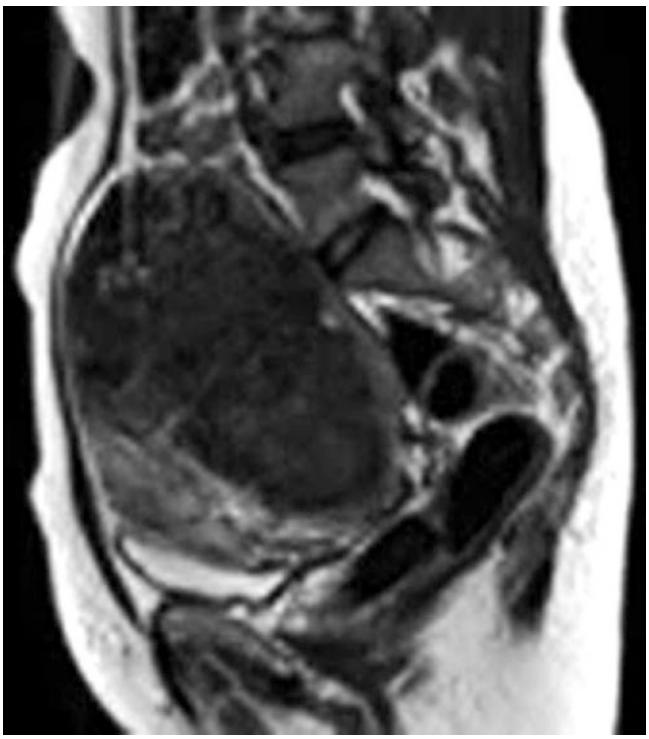

Fig. 33.2 MRI scan of a large fibroid. Figure 33.2 shows a MRI scan of a large fibroid uterus extending out of the true pelvis

to help with the prediction [29], and can be helpful in the evaluation and counseling of the patient as long as there is space to insert the laparoscope beyond the upper margin of the uterus, there is always the possibility of being able to perform the procedure laparoscopically [26].

Counseling the Patient

As with all gynaecological procedures adequate counseling of the patient prior to procedure is necessary. The LSH is associated with reduced hospital stay compared to other forms of hysterectomy and earlier recovery and resumption of intercourse [19]. However, long term sequellae such as spotting and the need for further intervention is increased with subtotal hysterectomy [11].

Though there are no specific studies looking at these issues specifically for large uteri, counseling should also be along the lines of LSH for normal uteri.

There is also the issue of morcellation and the risk of upgrading occult leiomyosarcoma that needs to be discussed with the patients. Clear and written guidelines need to be provided.

Theatre Set Up

The theatre set up is essentially the same as for a standard LSH. It is important that all members of staff are aware of their roles and those responsible for use of modern energy sources are aware of how to trouble-shoot when things go wrong.

As with all forms of laparoscopic surgery that can take over 2 h there is a need to ensure that the patient is warm and adequate anticoagulation measures are taken to prevent thrombosis. The patient will be in the Trendelenberg position for a considerable amount of time and on occasions the angle needed may be quite steep, measures should be used to prevent the patient slipping caudally and to prevent nerve injury.

Patient Habitus

The ideal habitus for a patient for LSH would be one with a "roomy" pelvis that allows visualization of the sides of the uterus and pedicles. There is an increase in obesity in society and this need to be taken into consideration. Performing LSH on the larger patient is not only feasible but safe [17]. Although with the larger patient there is an increased operating time and blood loss [20], this however does not affect the length of hospital stay post operation.

Surgical Technique

The surgical technique of LSH in a large uterus follows that of routine LSH, but with certain modifications to accommodate the distortion in size, shape and lack of access.

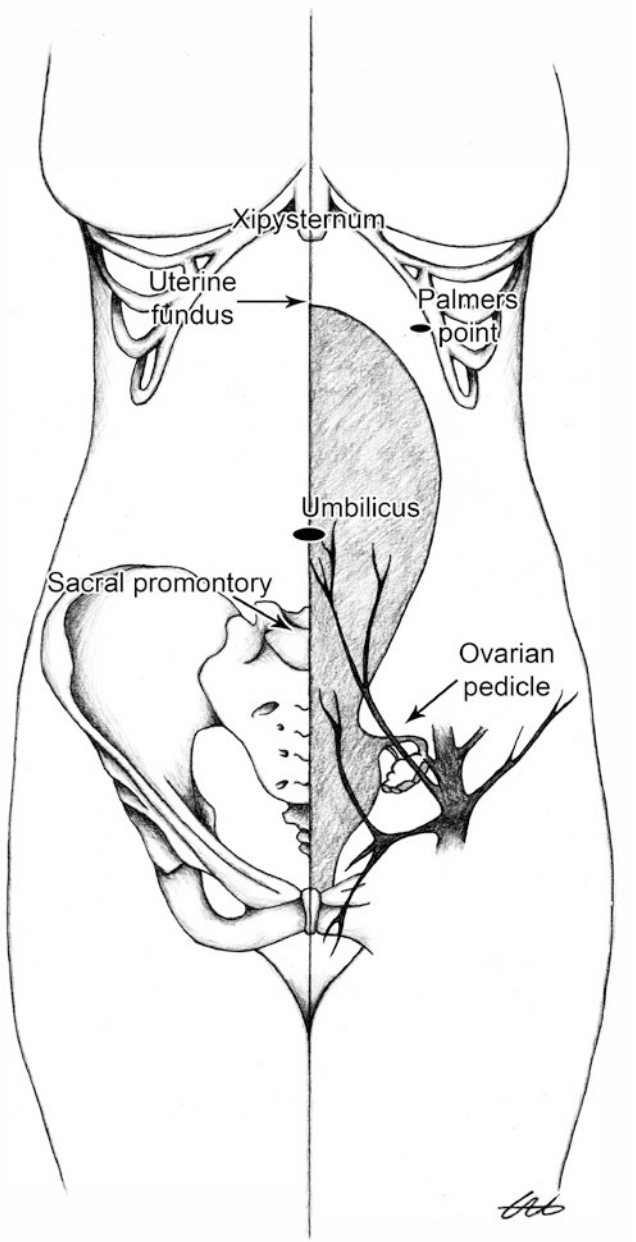

Fig. 33.3 Anterior abdominal landmarks. Figure 33.3 shows the important laparoscopic landmarks of the anterior abdominal wall (Courtesy of Catherine Woodman, BA (Hons))

Land Marks

It is pertinent to be aware of the anatomical landmarks of the whole of the abdominal cavity as the enlarged uterus could rise up to the xiphisternum. Additionally the primary trocar site might have to be varied due to the uterus taking up most of the central abdominal space, and other sites such as the Palmer's point will have to be used (Fig. 33.3). The most important land mark irrespective of the entry point is the ability to visualize both the sides of the uterus below the ovarian pedicles and the neck of the cervix anteriorly and posteriorly.

LSH of a Tall Globular Uterus

The tall globular uterus, as is usually seen with a fundal fibroid, usually does not limit access to the pedicles. The procedure is usually straightforward and follows the routine steps of a LSH (Fig. 33.4).

The procedure begins with placing the ports to allow visualization of the fundus of the uterus as well as the anterior and posterior pouches. This is usually achieved by good manipulation to lift the bulk of the uterus out of the pelvis, and using instruments placed in other available ports for traction and counter traction. It should be remembered that due to the myomas, the uterus may be rotated off its natural axis and therefore every effort should be made to restore this axis as this will allow for exposure of the pedicles.

Because of possible distortion of anatomy which ever pedicle is cephalad, and accessible should be dealt with first followed by the others in descending order until the uterine vessels become visible. Maintenance of strict haemostasis during the preparation and transection of the pedicles is the key to success.

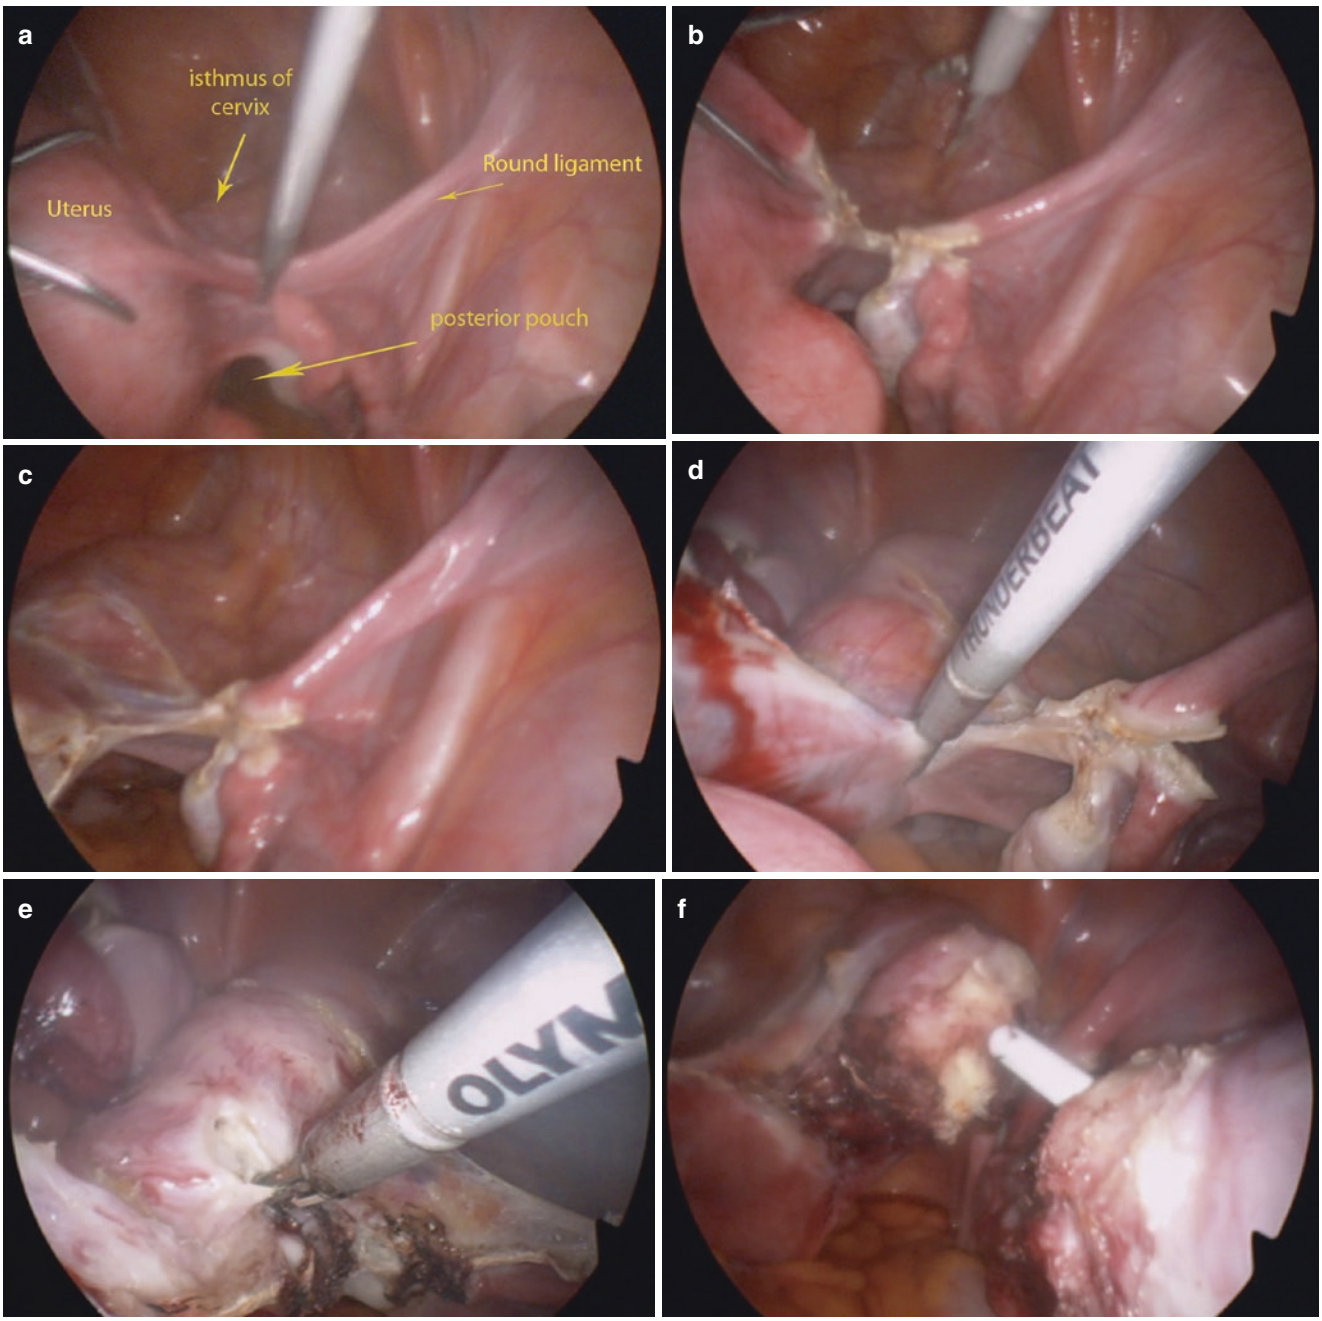

Fig. 33.4 Sequence steps for lash. (**a**) Transection of the broad ligament. (**b**) Transection of the ovarian ligament. (**c**) Skeletisation of the uterine vasculature. (**d**) Transection of the uterine vasculature. (**e**) Transection of the cervix and (**f**) Complete transection of the cervix

Once the adnexal pedicles have been dealt with the bladder flap is then developed to enable the bladder to be dissected and pushed caudally. Care should be taken again if there are uterine fibroids in the lower segment as they may obscure the upper limit of the bladder leading to bladder injury during dissection. The same is true with the presence of adhesions which may be as a result of previous/multiple caesarean sections. Once the bladder flap is developed and the uterine pedicles are exposed the uterine vessels are coagulated and transected either with the use of traditional bipolar instruments and scissors, or with more modern energy sources. It should be remembered that the vessels can be large and multiple thus whilst coagulated it is best not to have the vessels under tension. Where possible the vessels should be approached perpendicular to angle of the uterus as this will prevent shearing during the process of coagulation and transection.

The next step is transection of the cervix as with normal sized uteri. This can be achieved by the use of preformed loops, however it may be difficult to place the loop around and over the fundus of the uterus due to uterine bulk. If this is the case energy sources with a cutting modality can be used to transect the cervix.

Surgical Challenges

Performing a LSH for a large distorted uterus is a very challenging procedure. The technical challenges are specific and can be overcome with the right techniques.

Surgical Challenges for Performing LSH for Large Uteri

The surgical challenges can be summarized as follows:

Distortion due to enlarged uterine size
Distortion due to altered uterine shape
Restricted uterine mobility and limitation of access to structures

Distortion Due to Enlarged Uterine Size

Such a distortion, as it is mostly in the fundus due to fundal fibroids or a uterus enlarged without anatomical distortion as seen in adenomyosis, should afford relatively easy access to the uterine pedicles and to the uterocervical angle for transaction (Fig. 33.5).

Distortion Due to Altered Uterine Shape

Frequently the surgical challenge would be a uterus which is not enlarged in the cranio-caudal axis, but is distorted due to fibroids in the lower segment (Fig. 33.6). Such procedures are technically more challenging and might necessitate myomectomy prior to LSH to facilitate access.

Restricted Uterine Mobility and Limitation of Access

Access to the uterine sides, especially at the utero-cervical junction is paramount as without which the surgery cannot be successfully completed.

Figure 33.7 illustrates the loss of space and limited access which has been restored with good uterine manipulation.

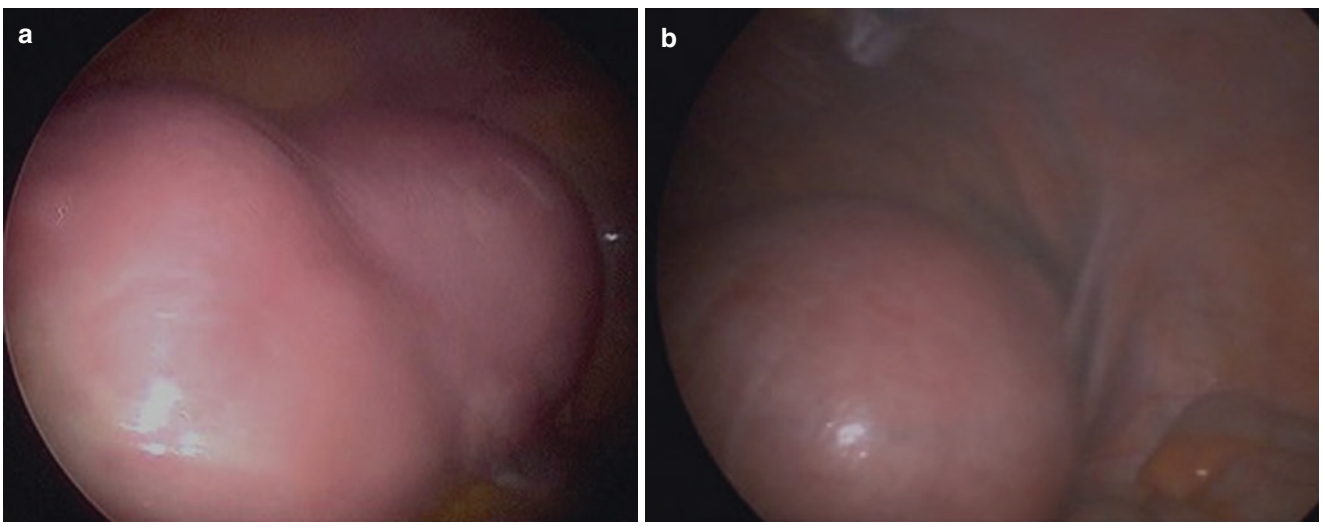

Fig. 33.5 Fundal/non distorted expansion of the uterus. (**a**) Shows uterine enlargement due to adenomyosis and (**b**) shows expansion of the uterine fundus due to fibroids

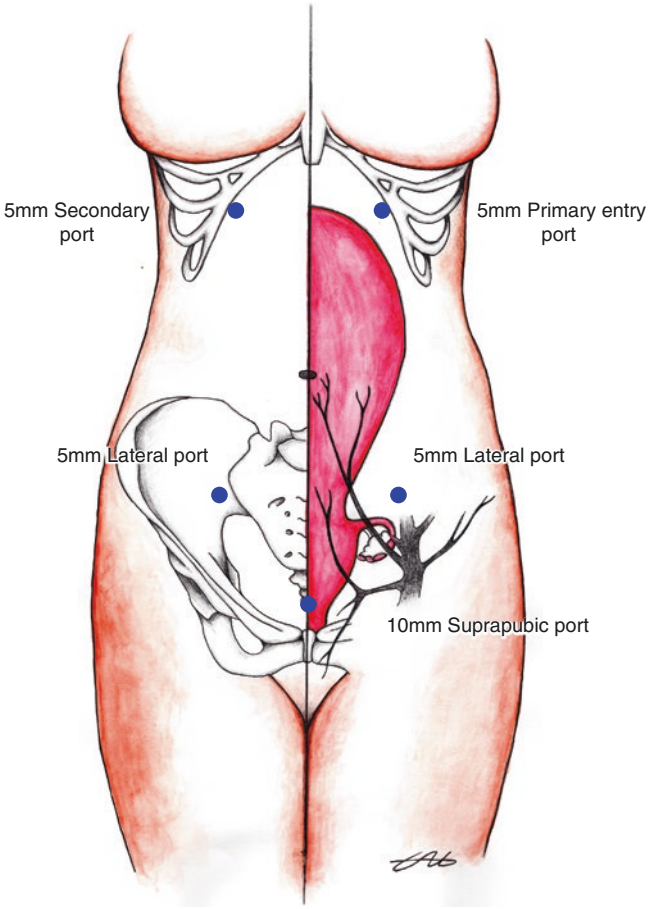

Fig. 33.8 Sites of potential port placements on the anterior abdominal wall. Figure 33.8 shows the possible port sites and the hazards to avoid (Courtesy of Catherine Woodman, BA (Hons))

Overcoming the Surgical Challenges

Most of the limitations for operating laparoscopically on the large uterus can be overcome by good surgical technique, the ability to suture laparoscopically and the use of modern sealing devices.

Port Placement and Utilization and Ergonometrics

In order to perform this procedure it is important to be able to visualize the pelvis (Fig. 33.8). Some surgeons place the entry port above the level of the uterus in the midline [30], this however does not provide complete visualization of both sides of the uterus and runs the risk of injury to the uterus. Shahid and colleagues describe a modified 5-port technique with the first port placed at palmers point and a second 5 mm trocar is placed in the contralateral hypochondrium. Two further ports are inserted in both iliac fossa above the ovarian pedicles. With this technique, though the operating time was longer for uteri greater than 500 g, it did not add to the length of stay of the patients (<500 g = 65 min, >500 g = 103 min, $P = 0.007$) [26].

Others have used 7 trocars with 10 mm tocars above the Bikini line. Though this technique provides adequate access it can have adverse cosmetic results and result in patient dissatisfaction [30, 31]. Some surgeons use a 30 ° laparoscope which provide better visibility into the pelvis [21].

Even when the primary trocar is inserted away from the top of the uterus it is important to remember that surgery is not always limited to that view. On occasion even where visualization of the uterine and ovarian pedicles may seem impossible from the palmers point view rotating to other ports may provide visibility to the pelvic side walls (Fig. 33.9). Thus a handy surgical tip would be to rotate the laparoscope through the different ports to find the best view for execution of the procedure.

Vessel Sealing

Traditionally bipolar technology was used to seal vessels. Currently with the explosion of technology in this area, there is an array of devices including ultrasound devices such as the harmonic scalpel and Ace™ (gynaecare) or Lotus™ (SRA Developments). Though these technologies seal vessels there is a limit to vessel size of about 7 mm and vessels for large uteri often exceed this limit. Hence care needs to be taken to adjust the devices accordingly. There are also "intelligent" sealing devices such as the Thunderbeat™ (Olympus Europa SE & CO) which combine ultrasound and bipolar technology. The Ligasure™ device (Covidien) can also be used with good effect. As these devices seal and cut they have the advantage of decreasing the need to use multiple instruments.

Though these devices can also transect the cervix, once the cervix has been prepared for transection, where available the Laploop™ (Roberts Surgical) or the preformed Linaloop™ (Lina medical) can be used.

Myomectomy Prior to LSH

If there are fibroids obstructing the access to the uterine vessels, then performing a laparoscopic myomectomy may be helpful to aid exposure (Fig. 33.10). It should be remembered that in countries where it is available, the use of Pitressin™ may help with haemostasis. Where it is not other methods of reducing haemostasis during myomectomy may be used [32]. Provided there is adequate space a myomectomy screw may also be used to aid traction and counter traction.

When access to the uterus is limited by the presence of fibroids obstructing vital structures, the decision would be either to perform the laparoscopic supracervical hysterectomy with the fibroids *in situ* or to remove the fibroids to obtain access to the uterine arteries and or the cervix.

Extrapolating from data comparing laparoscopic hysterectomy outcomes with those of myomectomy for the management of uterine fibroids, myomectomy prior to LSH may be associated with increased blood loss [33]. It is thus useful to use techniques to prevent blood loss during myomectomy if this approach is taken. Matsuoka and colleagues describe techniques to perform cervical myomectomy [34]. These techniques can be used to perform cervical myomectomy prior to performing a LSH. Broad ligament fibroids can also be

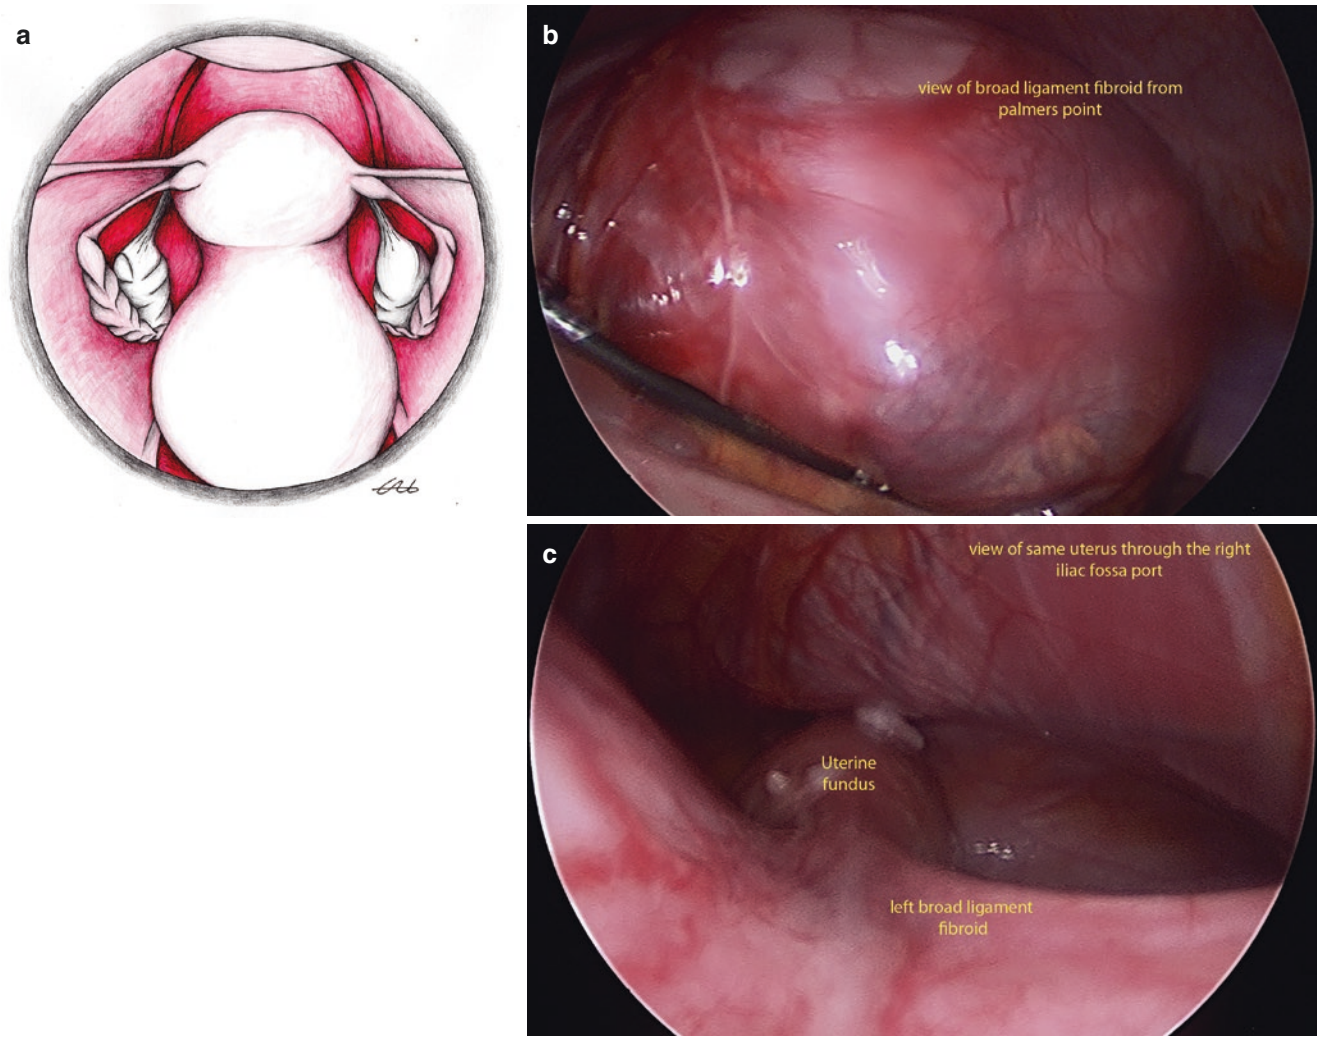

Fig. 33.9 Better identification of anatomy by varying the ports (**a**) shows the schematic diagram of a posterior fundal fibroid. (**b**) Shows view of large uterus from palmers point with fundal 10 cm fibroid and anterior 6 cm fibroid. (**c**) Shows better identification of anatomy with the view from the right lateral port showing the uterus and a broad ligament fibroid ((**a**) Courtesy of Catherine Woodman, BA (Hons))

removed safely with good surgical technique and port placement providing adequate exposure and vision [33, 35, 36].

Retroperitoneal Approach to Hysterectomy

In order to reduce bleeding the retroperitoneal approach to the uterine artery may be used [37]. This allows for the uterine artery to be coagulated and transected at its origin. Roman and colleagues applied this approach to 18 patients undergoing TLH with a mean uterine weight of 540 g [38]. Once the uterus is devascularised, multiple myomectomy may then be performed before the remainder of the procedure is performed. However this is often difficult if there is a broad ligament fibroid obscuring access to the pelvic sidewall (Fig. 33.11). In such cases the broad ligament fibroid will need to be removed before proceeding with the hysterectomy.

Use of Manipulators and Patient Positioning

There are numerous uterine manipulators on the market that facilitate the movement of the uterus. Most have a pivot and do not rely on the habitus of the patient. The important function when performing LSH for the large uterus would be the ability of the manipulator to move the uterus out of the pelvis exposing the posterior and anterior as well as the lateral aspects for the cervix. With low-lying fibroids this aids visualization of the contents of the lesser pelvis (see Fig. 33.7).

Raised Body Mass Index

Though studies have shown that LSH is feasible and safe in patients of high BMI [17], raised BMI has been shown to have adverse outcome on hysterectomy, though not so much for laparoscopic hysterectomy [39]. Paradoxically, it can be easier to perform LSH for the large uterus in larger patients. This is because of the ratio of uterine size to the available space within the patient. There is limited access and visibility when operating on the smaller patient, and this may lead to damage to adjacent organs [20].

Complications

General Complications

Most studies concur that there is no difference in the complication rate between LSH and TLH. A 16 year study of 3190 laparoscopic hysterectomies by Donnez et al. showed that in experienced hands, laparoscopic hysterectomy is not associated with any increase in major complication rates [40]. Both minor complications (fever >38.5 °C, bladder damage) and major complications (haemorrhage, vesicoperitoneal fistula, ureteral injury, rectal perforation or fistula) have been observed. In the LSH group, the minor complication rate was 0.99 % and the major complication rate 0.37 %. In the TLH group, the minor complication rate was 1.14 % and the major complication rate 0.51 % [40]. Bojahr et al. in their series of 1706 patients found five (0.3 %) intraoperative (three bladder injuries, one ureter injury, and one severe intraoperative bleed) and 20 (1.2 %) postoperative complications [23].

Specific Complications

All the above complications are seen generally in all laparoscopic hysterectomies whether it is done as total hysterectomy or subtotal. There are only a few complications which are specific to the supracervical procedure. Laparoscopic hysterectomy has been associated with higher rates of urinary tract injuries, compared with abdominal hysterectomy (OR 2.61,95 % CI 1.22–5.60) [41, 42, 43]. Later studies performed by Karaman et al. and Bojahr et al. found a lower complication rate (between 0 and 1.4 %) [8, 23].

Bladder Injury

Bladder injury is a complication that can occur in the presence of cervical myoma. It usually occurs as a result of the bladder being stretched over the anterior cervical fibroid [20] a contributory factor in this series was low BMI alluding to poor access. In the series by Grosse-Drieling et al., 2 of the patients had uteri measuring 540 and 595 g and one had a contributory factor of previous surgery [21]. Even though bladder injury appears with cervical myomas, these complications are usually recognized at the time of surgery. The injury can be sutured laparoscopically and have no long-term sequellae. At the end of such procedures even if the complication is unsuspected during the laparoscopy, the catheter bag should be examined before the procedure is completed. If it is found to be inflated this could signify occult bladder injury and further investigations should be carried out to identify the same. The complication of bladder injury at LSH is not unique with large uteri. Donnez and colleagues in a series of 3190 laparoscopic hysterectomies of which 1613 were supracervical had a cystotomy rate of 0.25 % in women with uterine size less than 17 weeks. In this cohort there were also more iatrogenic cystotomies in the total hysterectomy group (0.38 %) [40]. A recent meta-analysis looks at the use for universal cystoscopy at gynaecological surgery to detect urinary tract injury. However though it increases the detection rate intra-operatively it does not decrease the postoperative detection rate [44]. In all the case series reporting on urinary tract injury during LSH for large uteri most injuries were detected intraoperatively. The one reported injury detected postoperatively was managed by catheterisation and allowed to heal spontaneously. For the use of routine cystoscopy to be cost effective it has been estimated that the prevalence of injury would have to be 2 % at laparoscopic hysterectomy [45].

The main recommendation in avoiding bladder injury is being cognisant of limited space particularly in the smaller patient with fibroids in the lower segment, and where patients have had previous surgery. When operating on such patients it is important to look in the catheter bag. If it is inflated with gas, like a balloon it is important to look for the bladder injury and repair the bladder using a 2/0 vicyl suture or equivalent in layers. The patient does not necessarily need to stay in hospital till the catheter is removed. It is our practice to keep the catheter in situ for 7–10 days, the patient is taught how to use a leg bag and discharged home on prophylactic

antibiotics. The patient then returns for a cystogram and if the bladder is intact, the catheter is removed and if all is well the patient returns home.

Unexpected Malignancy

Laparoscopic morcellation has enabled the removal of large uteri without necessitating the removal of the cervix. But due to the potential for dissemination of occult uterine cancers the American Association of Gynecologic Laparoscopists (AAGL) stated that, in case of known or suspected uterine malignancy, morcellation is contraindicated [46]. Additionally the Food and Drug Administration (FDA) recently issued a statement discouraging the use of electromechanical morcellation for hysterectomy and myomectomy in most women with uterine myoma [47]. Arkenbout et al. recently assessed the basic "physiology" of the morcellation process and tissue spread and found that LSH and laparoscopic hysterectomy procedures may be at higher risk for tissue scatter than TLH [48].

Bojahret al. analysed data of 10,731 patients who underwent a standardized LSH surgery with electric power morcellation. In total, six sarcomas (0.06 %) and eight endometrial cancers (0.07 %) were documented. This amounts to a very low uterine malignancy rate of 0.13 % [49].

When analysing the risk of malignancy it used to be thought that rapid growth of the uterus is an indication for possibility of malignancy. However, Parker et al. looked at 198 women who had published definition of rapidly growing myoma and none of his cohort on histology were found to have leiomyosarcoma [50]. If there is any suspicion of malignancy the patient should be referred to an oncologist for appropriate investigation and management rather than have a LSH. Pertinent investigations would include LDH estimations and MRI [49]. Thus currently the consensus opinion is not to lose the obvious advantages of a laparoscopic procedure by deferring to an open procedure, but to rely on preoperative diagnosis and clear patient counseling [51].

Conclusion

With the advent of conservative methods of management of normal sized uteri and the evidence skewed towards minimally invasive hysterectomies, it is important that gynaecologists who offer care to women requiring hysterectomy are able to perform LSH for large uteri.

We have outlined the surgical precepts to be followed to achieve a successful outcome. In order to be able to perform the procedure effectively it is imperative to select patients after appropriate pre-operative investigations and consent procedure. It is also imperative for the surgeon to have a good knowledge of anatomy, instruments and modern energy sources and endoscopic skills necessary to achieve a successful outcome.

Cervical Stump Extirpation

34

Peter Oppelt

There are both benign and also malignant indications for extirpation of the cervical stump. Techniques of oncological surgery do not form part of this section.

The most frequent indication for cervical stump extirpation is persistent bleeding from the cervical canal, which is reported in the literature as occurring in 0.9–25 % of cases after laparoscopy-assisted supracervical hysterectomy (LASH). Preoperative menorrhagia and endometriosis (adenomyosis tissue in the cervix) appear to be risk factors for persistent bleeding after LASH (Table 34.1) [1–8]. Bipolar coagulation of the cervical stump to ablate any residual endometrial tissue is also regarded differently by various authors [6, 8, 9].

When there is persistent bleeding, only extirpation of the stump may remain as a last resort in some cases. Before such an intervention, however, a recent Pap smear is important in order to exclude cervical cancer.

Two primary surgical options are available:

Vaginal Approach

This is particularly appropriate if the patient has already had a spontaneous vaginal delivery and the cervical stump is sufficiently deep within the vagina.

Laparoscopic Procedure

Laparoscopic cervical stump extirpation is appropriate particularly in nulliparous patients or patients with suspected endometriosis. The length of the cervix should be measured using ultrasound preoperatively. Thanks to the various types of manipulator that are available, it is much easier to perform this operation nowadays. The following surgical steps are carried out using the Hohl uterine manipulator (Storz):

1. A working insert is normally screwed onto the spiral cap. As the cervix has a residual length of around 40 mm, the end of the instrument might break through and possibly injure adherent structures (Fig. 34.1). It is therefore advisable to dispense with the working insert and to rotate the spiral cap (if possible always using the largest one, for better holding) directly into the cervical stump (Fig. 34.2).
2. The best-fitting cover is placed.
3. Laparoscopic inspection of the cervical stump is carried out (Fig. 34.3).

Table 34.1 Contraindications for LASH

Contraindications
Endometriosis recto-vaginal septum
Adenomyosis
Cervical myoma
Dysplasia of the cervix
Malignancy

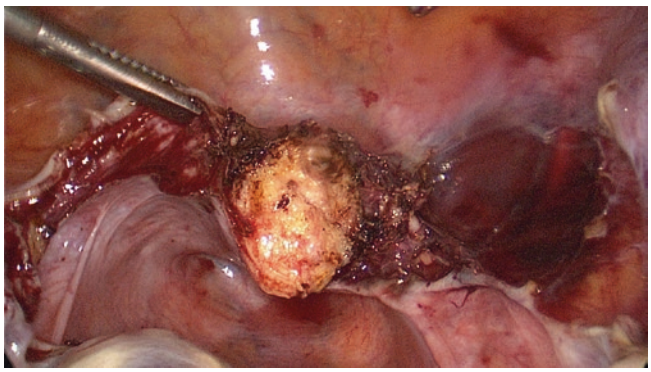

Fig. 34.3 Laparoscopic image of the stump

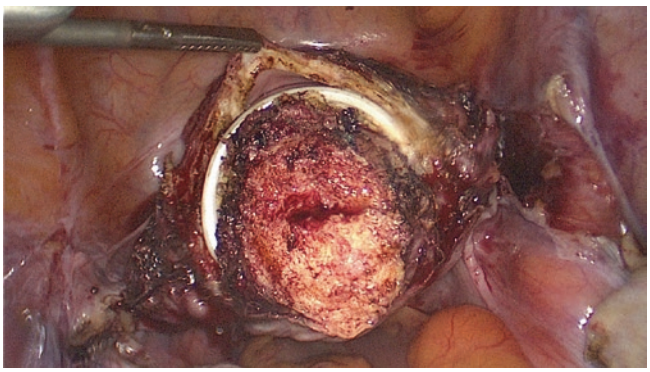

Fig. 34.6 Image of the cap during separation

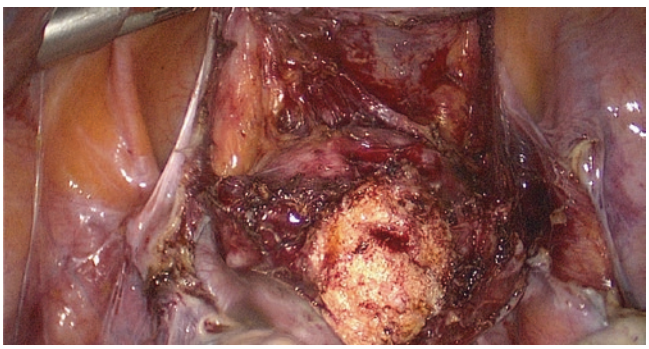

Fig. 34.4 Laparoscopic image of the stump after bladder preparation

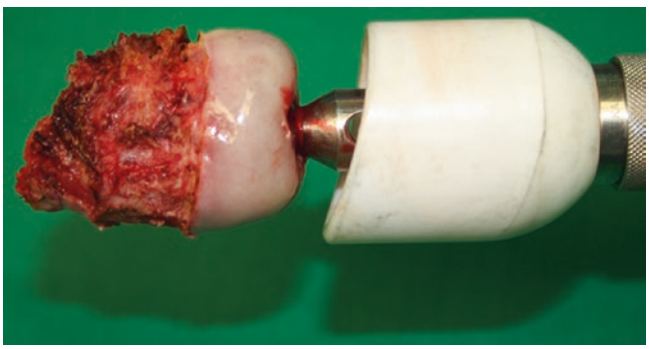

Fig. 34.7 Final operation preparation

4. Tension is applied to the vaginal walls (the manipulator should *always* be inserted straight first of all, and moved to the side under tension; it should never lead directly towards an ovarian fossa. This allows optimal tension to be applied to the vaginal wall, with an optimal distance from the ureters.)
5. An incision is made into the peritoneum and the bladder is pushed away (Fig. 34.4). (In case of an not clear situ, fill up the bladder with 200 ml saline. Push the manipulator straight in. Under this setup, the identification of the structure should be more clearly in an difficult situs).
6. The cervix is released from the parametrial ligaments up to the level of the cap of the uterine manipulator (Fig. 34.5).
7. Since there is no affiliation provided for Peter Oppelt in the chapter opening page, we have taken the affiliation from the Contributor list in the front matter. Please confirm if this is fine. If necessary, coagulation of the cervical part of the uterine artery bilaterally.
8. Separation of the cervical stump at the edge of the manipulator cap with Ultracision / monopolar needle) (Figs. 34.6 and 34.7).
9. Closure of the vagina with endoscopic or transvaginal sutures.

Total Laparoscopic Hysterectomy for the Small and Normal-Sized Uterus

35

Ibrahim Alkatout

Introduction

Hysterectomy is one of the most frequently performed operations in gynecological surgery. International gynecological societies recommend vaginal hysterectomy as the most acceptable technique. However, operative endoscopic methods have gained widespread acceptance in the last two decades, and play a much more important role than the traditional approaches of abdominal and vaginal hysterectomy. With regard to hysterectomies performed for benign disease, the number of abdominal hysterectomies is decreasing, the number of vaginal hysterectomies varies, but laparoscopic and robotic-assisted laparoscopic procedures are on the increase [1]; the trend is visible throughout the world (Fig. 35.1) [2].

The most frequent indications for hysterectomy are uterine leiomyomas (Figs. 35.2, 35.3, 35.4, 35.5, 35.6 and 35.7), adenomyosis (Figs. 35.8, 35.9, 35.10 and 35.11), adenomyoma (Fig. 35.12), diffuse endometriosis (Figs. 35.13, 35.14, 35.15, 35.16, 35.17 and 35.18), uterine prolapse, and therapy-resistant idiopathic bleeding abnormalities. These constitute 60 % and more of the indications for hysterectomy [3]. Alternative therapeutic strategies, such as uterine artery embolization or focused ultrasound therapy have been developed in Germany [4] and other countries [5] over the last ten years. Conservative operative management and the introduction of ulipristalacetate have reduced the number of hysterectomies. Hysterectomy rates depend not only on the indication but also on the age group, family planning, and the centers at which the patients are treated. The indications for hysterectomy in general have now been adapted to the patients' wish to retain their uterus [6, 7]. Hysterectomy is also performed for malignant diseases of the inner genital organs (endometrium or cervix, ovaries and fallopian tube). Endoscopic surgery is only performed for endometrium and cervical cancer. Table 35.1 summarizes the indications for hysterectomy.

Once the decision to perform a hysterectomy has been made, the physician and patient must decide whether the procedure will be performed abdominally, vaginally, or with laparoscopic or robotic assistance [8–10]. Each of these approaches has its advantages and disadvantages, which must be explained to the patient (Fig. 35.19). The surgeon's familiarity with the technique and the economic resources of the hospital are also important considerations (Table 35.2).

The foremost advantage of endoscopic treatment is the fact that the surgeon is able to address other intraabdominal comorbidities simultaneously, such as endometriosis or severe adenomyosis in the adjacent organs (sacrouterine ligaments, cardinal ligament, bladder and/or bowel), as well as adhesions. Although uterine-preserving operative strategies are still controversially discussed and the results are not consistently promising, the only reliable treatment for adenomyosis is total hysterectomy. Since the disease is confined to the uterus, the ovaries can be preserved.

In many cases, conservative medical or conservative surgical treatment signifies undertreatment of the patient, who may then need surgery later on. Subtotal hysterectomy is a compromise that meets the requirements of patients, society and doctors. It is the least invasive approach of hysterectomy. However, the patient must provide her informed consent regarding the disadvantages of the remaining cervix. Only a laparoscopic total hysterectomy (LTH) provides complete protection from renewed fibroids, prevents subsequent carcinoma of the cervix or sarcoma, cell spilling when cutting the corpus and during morcellation, uncontrolled bleeding, and other problems arising from the uterus. The persistence or recurrence of adenomyosis-related symptoms in subtotal hysterectomy continues to be a subject of debate.

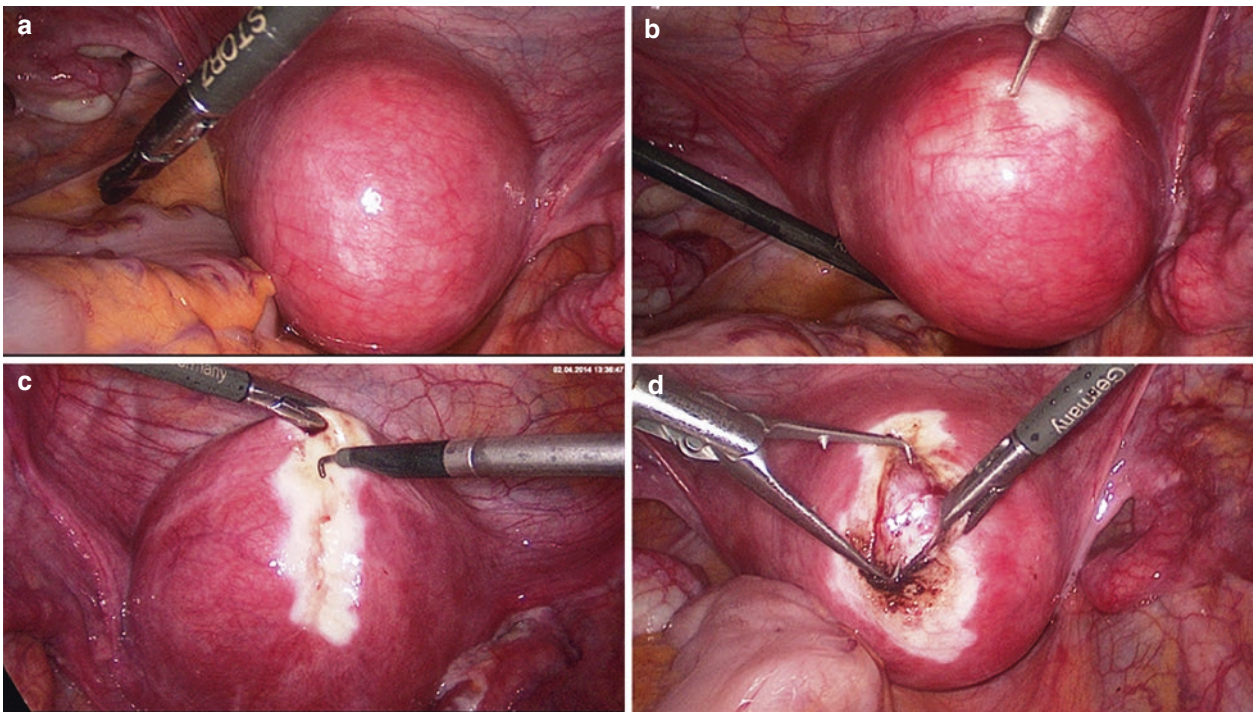

Fig. 35.2 Laparoscopic myoma enucleation. (**a**) Situs of a fundal/anterior wall fibroid. (**b**) Prophylactic hemostasis with 1:100 diluted vasopressin solution (Gylcylpressin) in separate wells between the superficial and healthy tissue of the myometrium, and the capsule/fibroid surface. The purpose of the injection is to separate the pseudocapsule from the fibroid and reduce bleeding. (**c**) Bipolar superficial coagulation of the longitudinal incision strip and opening the uterine wall above the myoma with a monopolar hook or needle until one reaches the myoma. (**d**) Grasping the fibroid and starting the enucleation. The pseudocapsule remains within the uterine wall and is pushed off bluntly

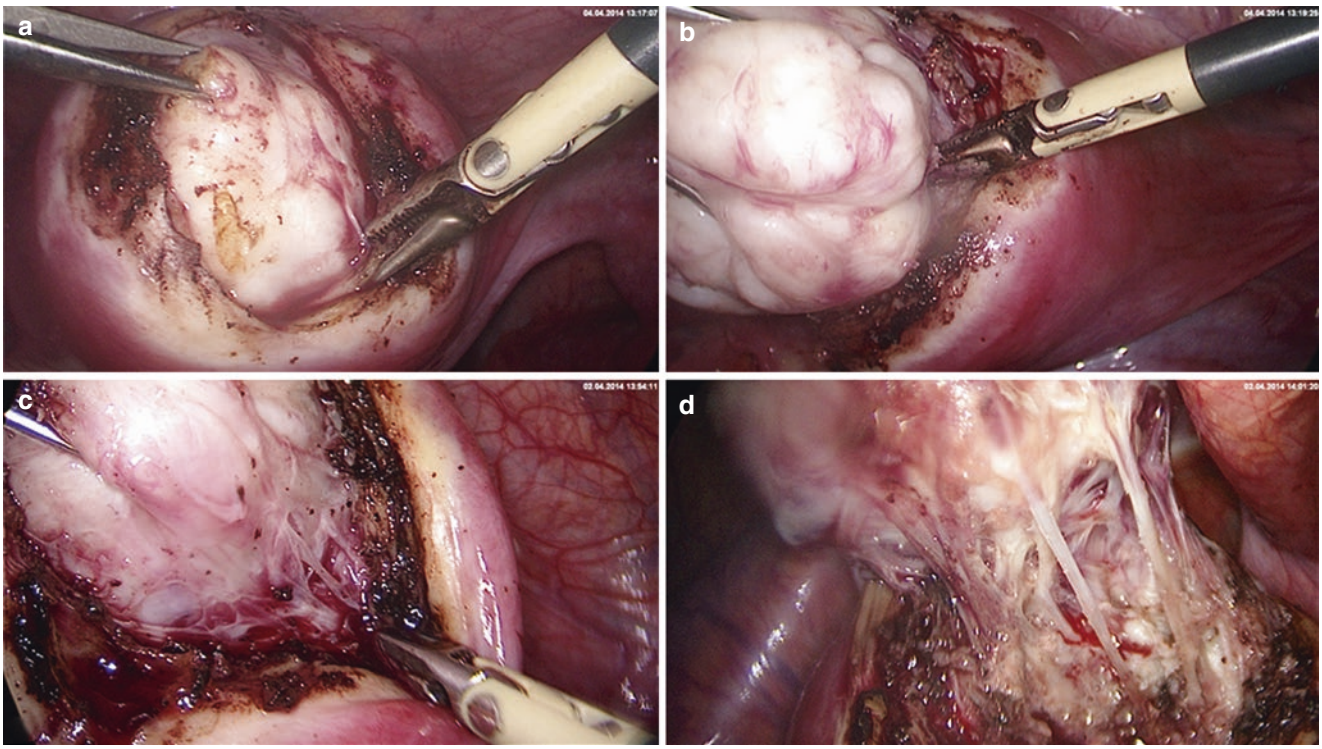

Fig. 35.3 Laparoscopic myoma enucleation. (**a**) Traction of the fibroid with a tenaculum and blunt demarcation from the capsule. (**b**) Focal bipolar coagulation of basic vessels. (**c**) Continuous enucleation of the fibroid under traction and specific coagulation of capsule fibers containing vessels. (**d**) Magnification of the remaining capsule fibers to be coagulated and cut

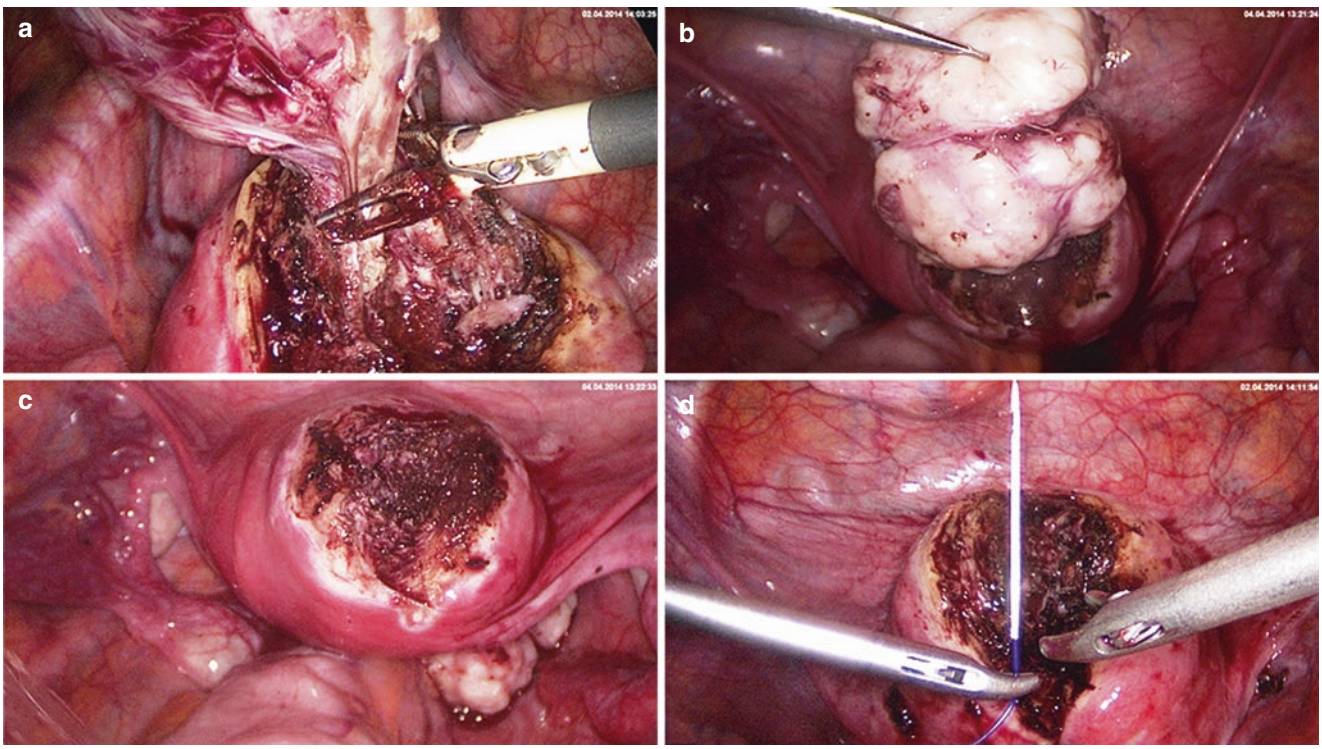

Fig. 35.4 Laparoscopic myoma enucleation. (**a**) Final coagulation of the capsule vessels. (**b**) Double belly fibroid after complete enucleation. (**c**) Minimal coagulation of bleeding vessels under suction and irrigation. (**d**) Approximation of the wound edges with a straight or round sharp needle and a monofilar late-absorbable suture

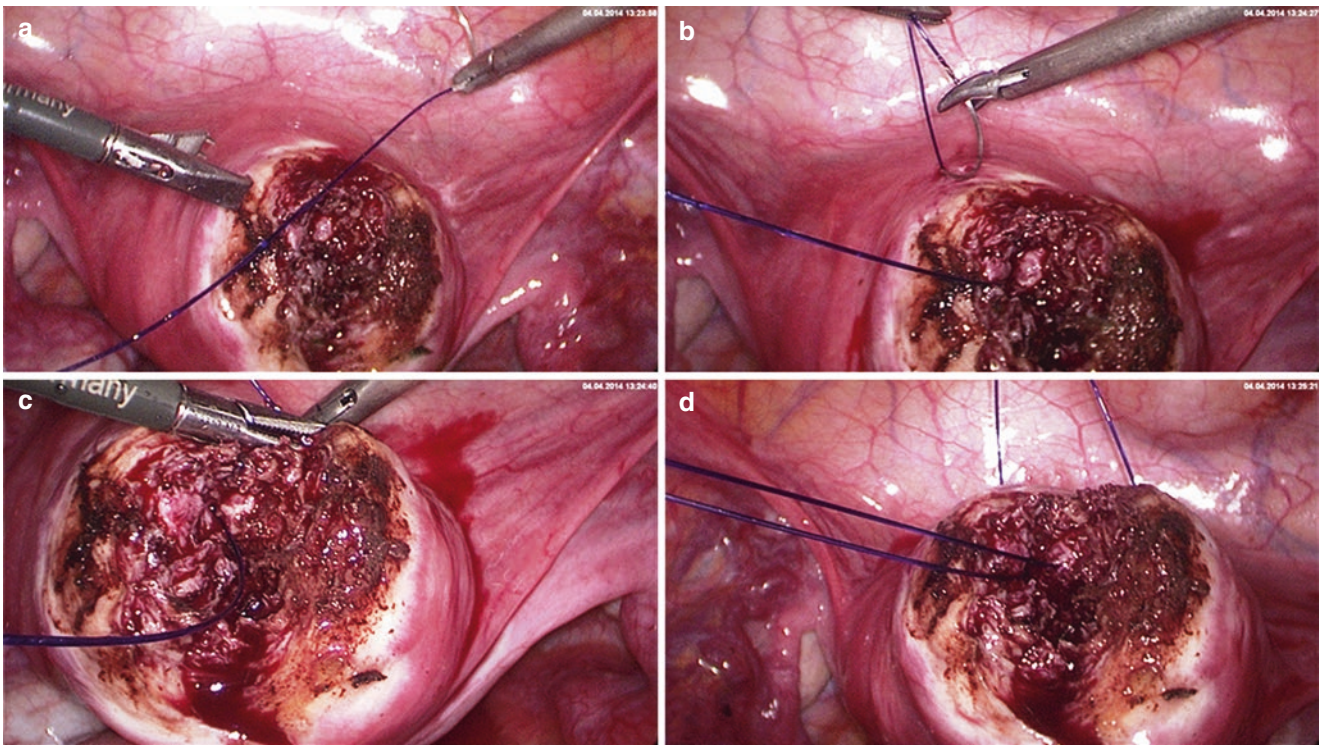

Fig. 35.5 Laparoscopic myoma enucleation. (**a**) Advantages of a circular needle stitch: (**a**) the wound angle is elevated safely and completely when raised with a Manhes forceps, (**b**) deeper layers of the myometrium can be grasped more easily with a circular needle. (**b**) Needle exit and simplified re-grasping with the right needle holder. (**c**) Final stitch to invert the knot. (**d**) Extirpation of the needle, completing the extracorporeal knot, and preparing to push down the extracorporeal knot

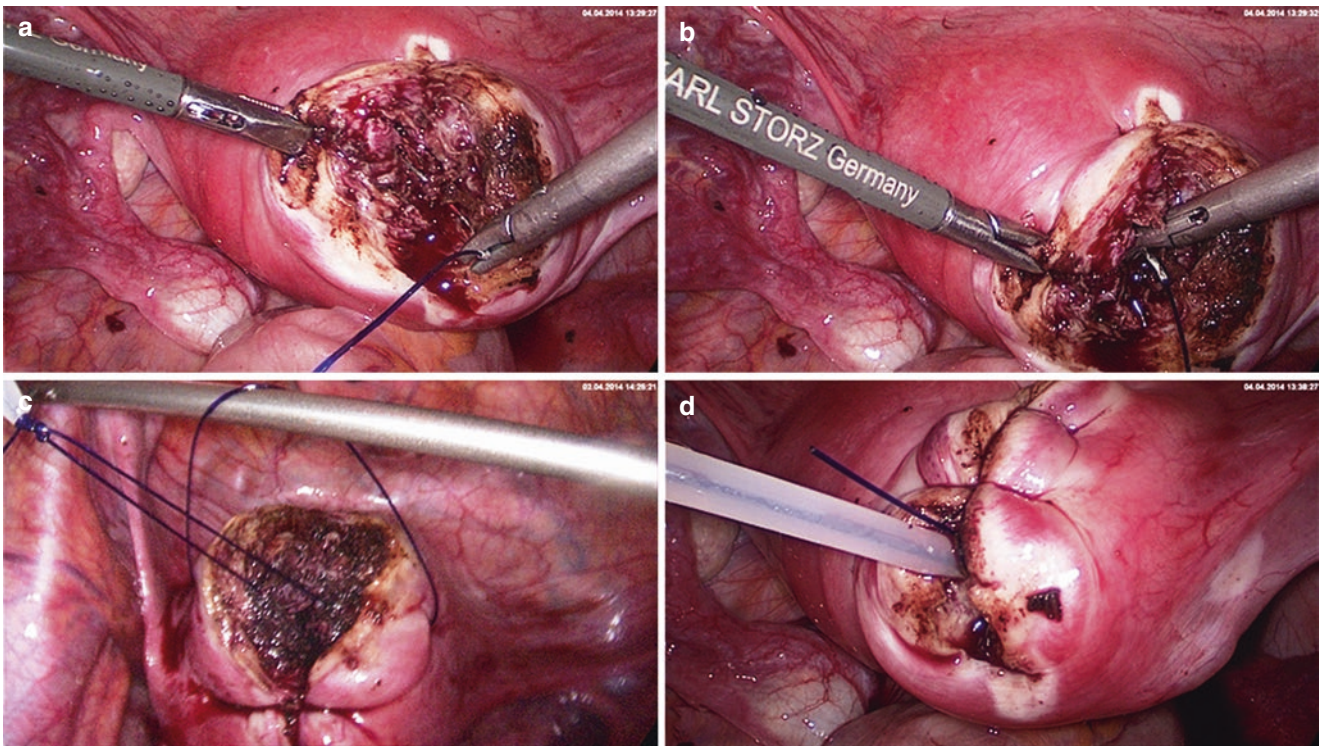

Fig. 35.6 The extracorporeal "von Leffern" knot. (**a**) Pulling out the suture, removing the needle, half hitch. (**b**) Holding the knot with the left hand and reaching over with the right hand. (**c**) Grasping the short end from below and leading it back, exiting before the half hitch. (**d**) Turning back the knot. Holding the straight suture and tightening the knot

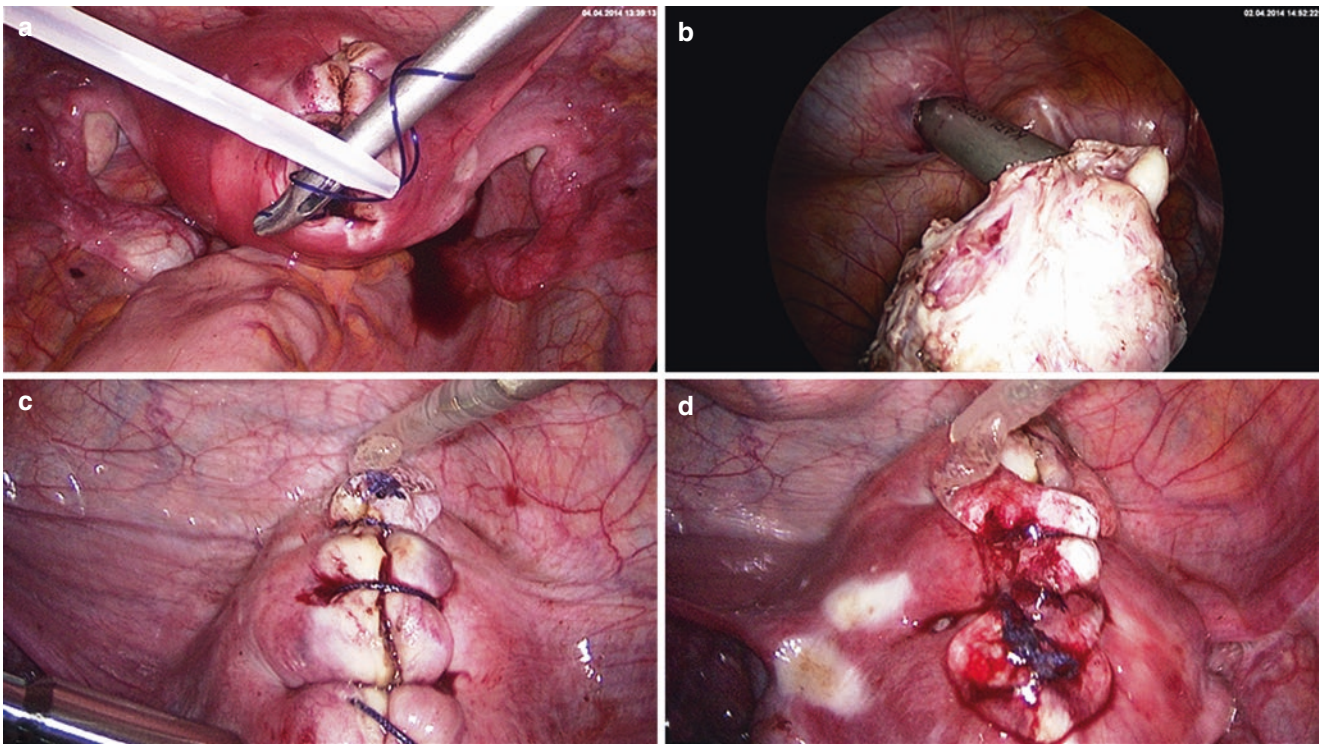

Fig. 35.7 Laparoscopic myoma enucleation. (**a**) Second single suture starting as deep as possible in the uterine wound. (**b**) The needle exits on the left wound margin (immediately adjacent to the Manhes forceps). (**c**) Completing the stitch and preparing the extracorporeal von Leffern knot. The needle holder elevates the thread to avoid tearing the uterine wall when pulling the monofilar thread (PDS). (**d**) Pushing down the extracorporeal knot with a plastic pushrod into the depth of the wound to dump the knot, thus minimizing the size of the external part of the suture

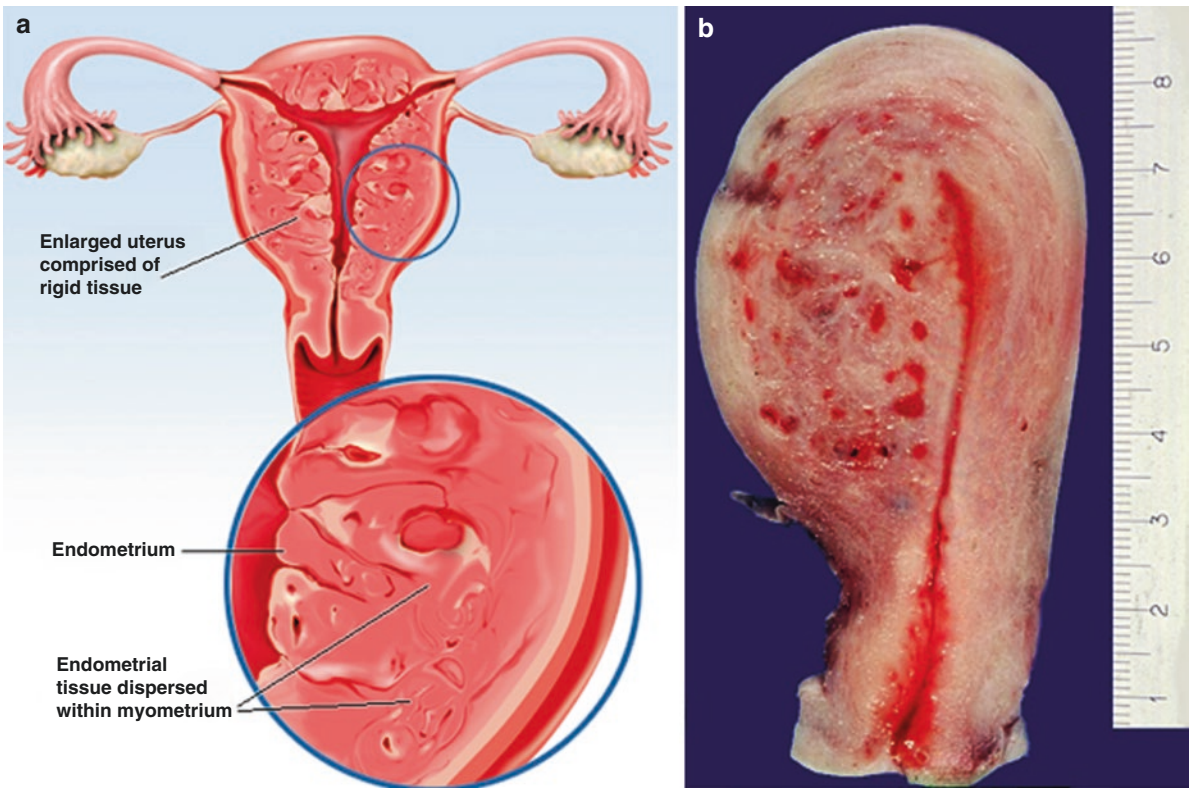

Fig. 35.8 (**a**) Schematic illustration of an enlarged uterus with adenomyosis. Endometriosis glands are dispersed within the myometrium. (**b**) Anatomical specimen in a sagittal cut. The posterior wall is much thicker than the anterior wall, with endometriosis glands spread diffusely in the myometrium wall

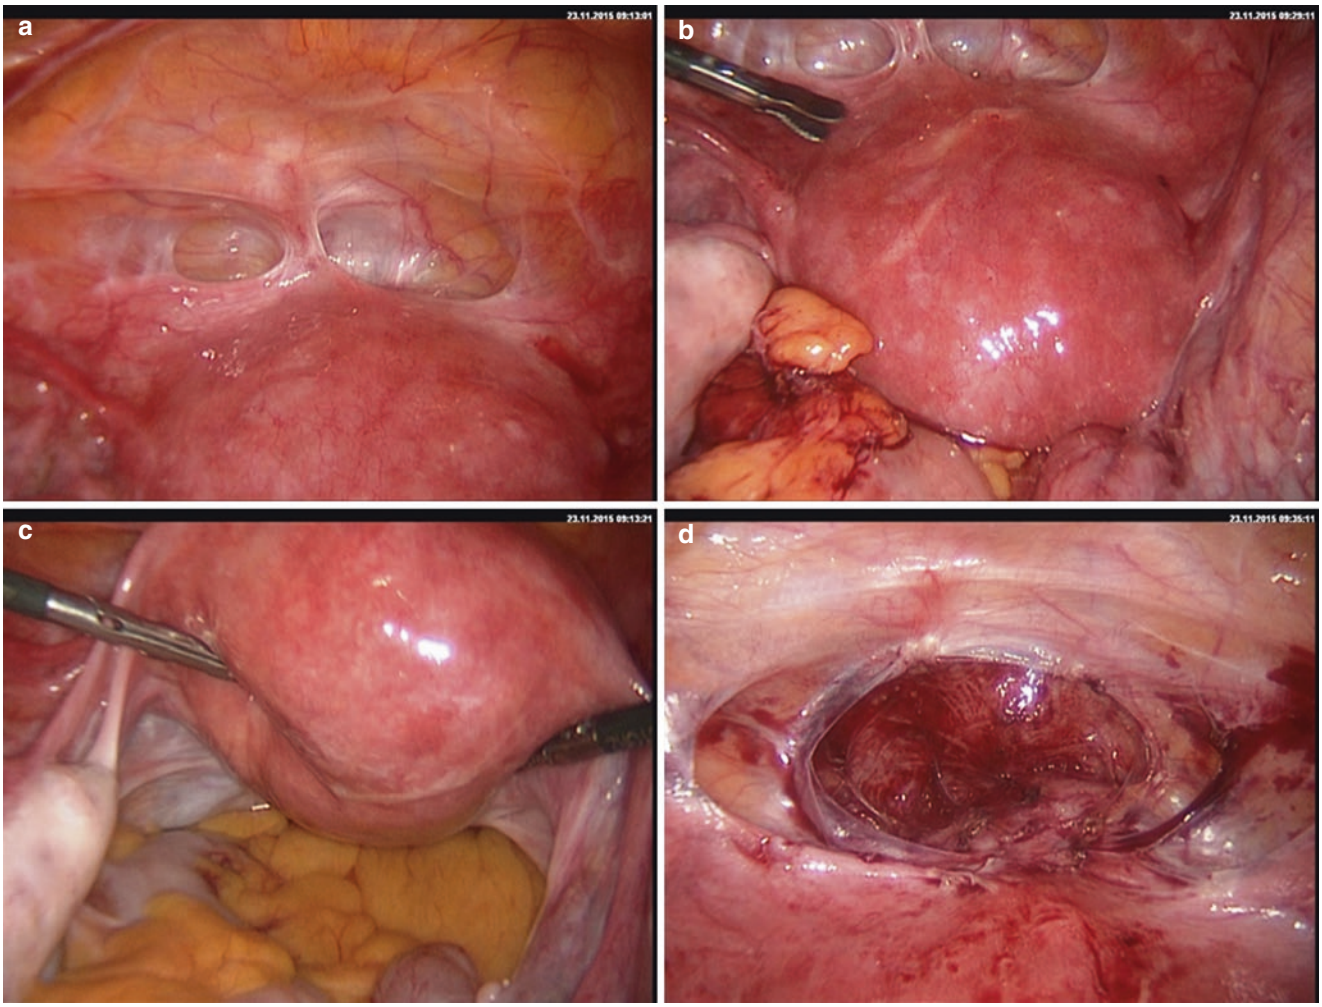

Fig. 35.9 (**a**) Overview of the laparoscopic situs of a patient with severe dysmenorrhea. The uterus is enlarged and soft (**a–c**). The anterior wall is connected to the bladder peritoneum by multiple adhesions. (**d**) After adhesiolysis one has the impression that the adenomyosis has grown through the uterine wall into the adjoining bladder

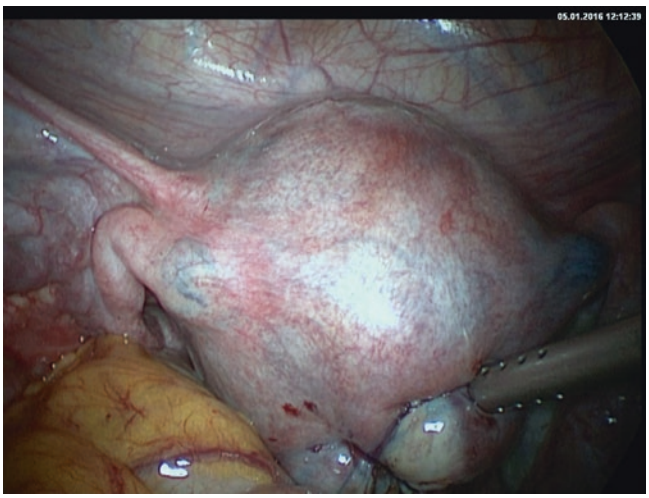

Fig. 35.10 Patient with severe dysmenorrhea and dyspareunia. The injection of blue dye exposes the intramural vessels, which seem to be massively increased. This picture is also typical of adenomyosis of the uterus

Total Versus Subtotal (Supracervical)

Independent of the surgical technique (subtotal or total hysterectomy), endoscopic surgery is a desirable goal. Some women wish to retain their cervix, believing that it may affect their sexual satisfaction after hysterectomy. Removal of the cervix is known to cause excessive neurologic and anatomic disruption, thereby leading to greater surgical and postoperative morbidity, vaginal shortening, subsequent vault prolapse, abnormal cuff granulations, and a propensity for fallopian tube prolapse. These issues were addressed in a systematic review of three randomized trials focused on total versus subtotal hysterectomy for benign gynecological conditions. The conclusions were as follows [11]:

- No difference was noted in rates of incontinence, constipation, or measures of sexual function (sexual satisfaction, dyspareunia).

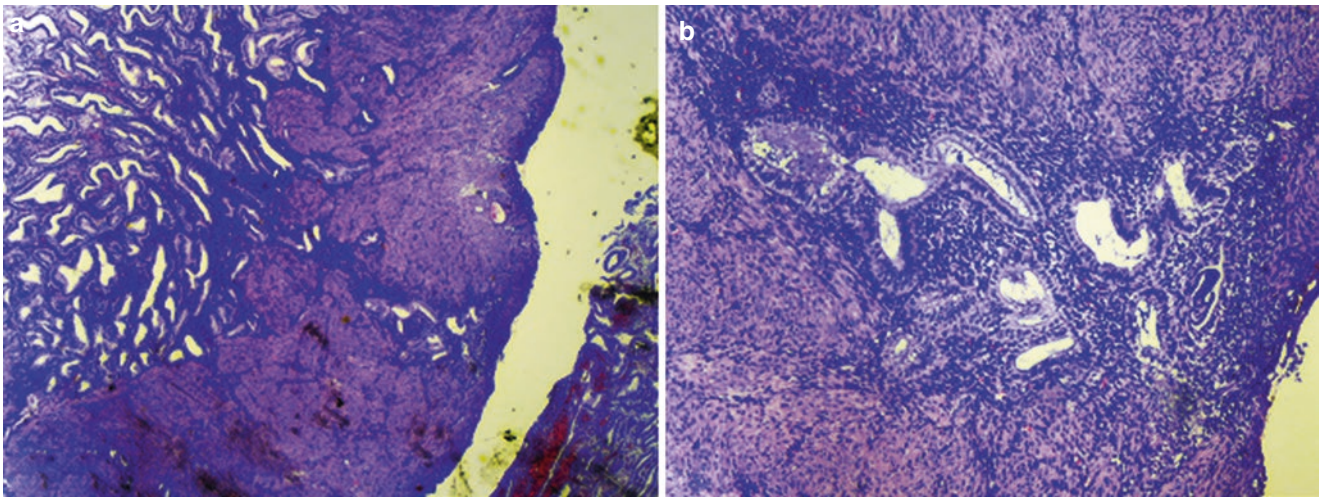

Fig. 35.11 (**a**) Low magnification of a piece of ablated endometrium with the adjoining myometrium tissue in the early secretion phase.(**b**) Islets of endometrium glands in the myometrium stroma with no connection to the uterine cavity. Obviously, the endometrium is fully involved in the endocrine cycle

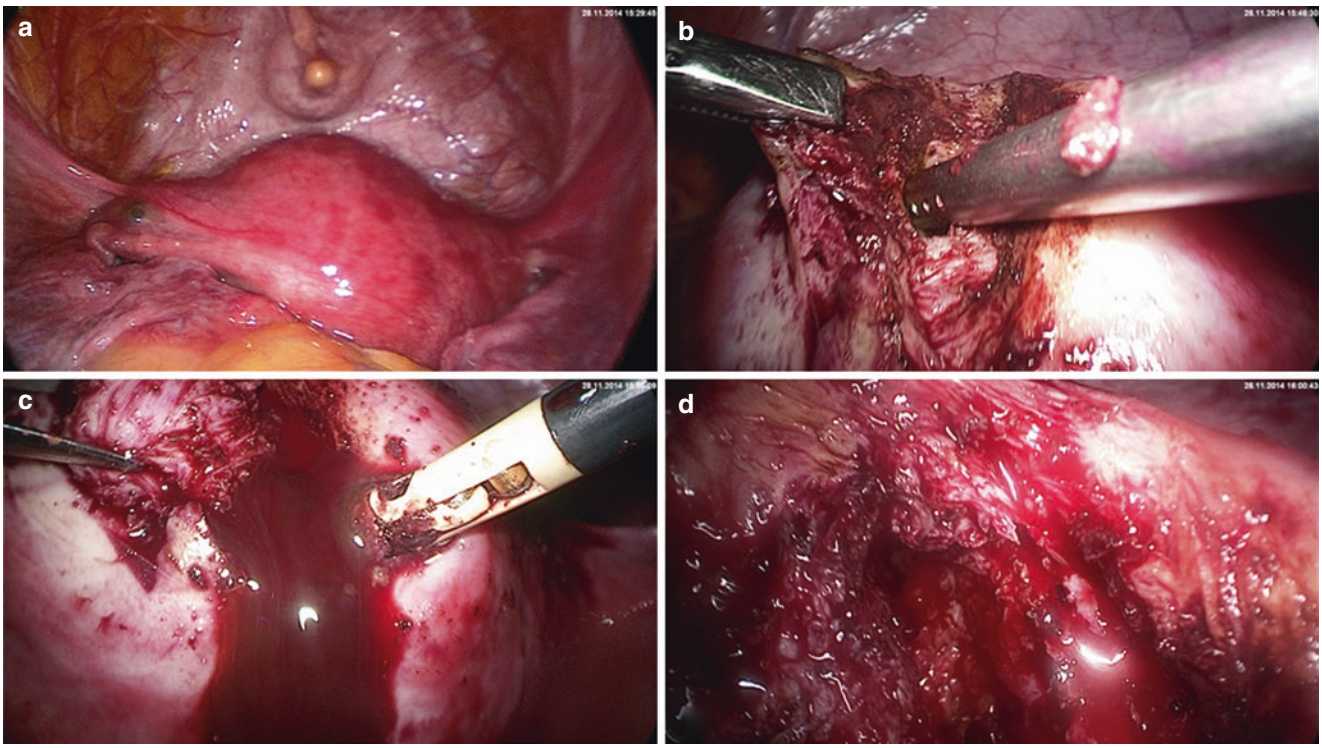

Fig. 35.12 (**a**) Overview of an asymmetrical uterus; endometriosis is suspected at the left tube and a central space-occupying lesion is seen. (**b**) Opening the central intramural lesion, which was suspected to be a fibroid.(**c**) Chocolate-like fluid after entering the adenomyoma. (**d**) On the magnification even the wall layers, including the mid-endometrium tissue can be seen

- The duration of surgery and the quantity of blood loss during surgery were significantly less during subtotal hysterectomy compared with total hysterectomy. However, there was no difference in the likelihood of the patient needing a transfusion.
- Febrile morbidity was less likely and ongoing cyclic vaginal bleeding one year after surgery more likely after subtotal hysterectomy.
- No difference was noted in the rates of other complications, recovery from surgery, or readmission rates.

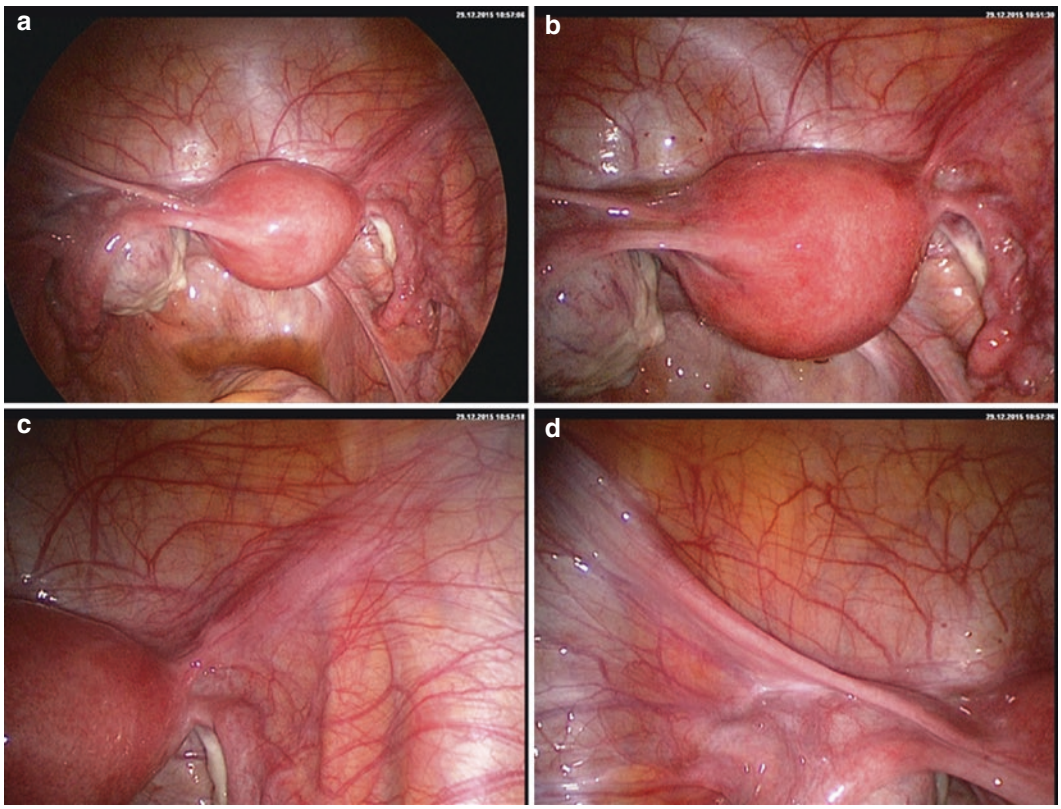

Fig. 35.13 Laparoscopic overview of a patient with dysmenorrhea.(**a**, **b**) An enlarged and irregular uterus with hypervascularization of the serosa. The chronic disease has caused an asymmetry of the round ligaments. (**c**) The right side is much shorter than (**d**) the left side

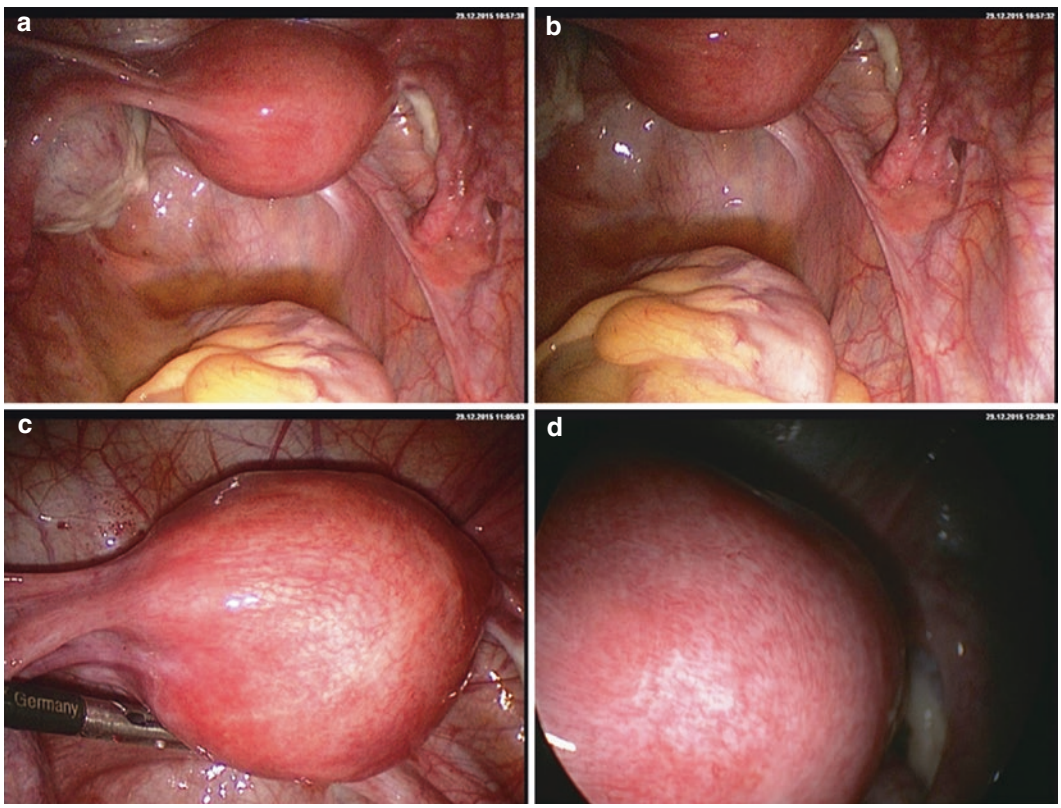

Fig. 35.14 (**a**, **c**) The uterus appears to be less mobile but somehow fixed in the pelvis. (**b**) The peritoneum above the ureter is under tension and can be demarcated from the sacrouterine ligament.(**c**, **d**) The surface of the uterus is hypervascularized; the outflow of the tubes seems to be steep

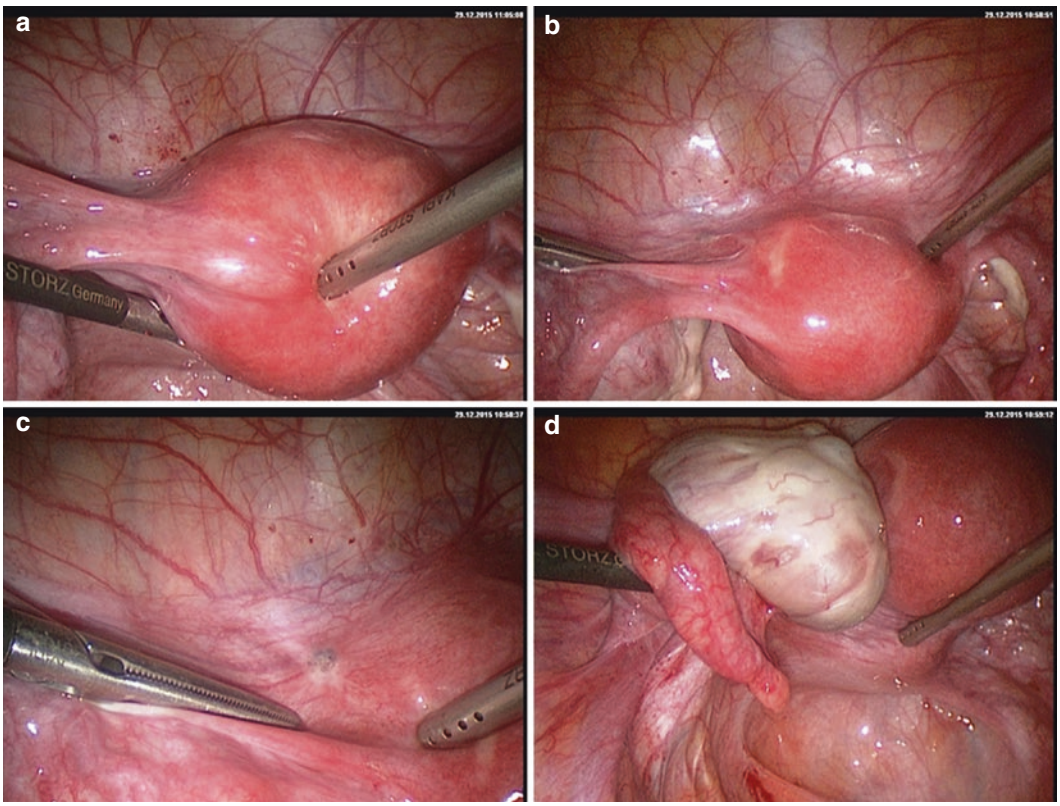

Fig. 35.15 (**a**, **b**) Palpating the uterus with a blunt instrument shows that its consistency is less soft; it is tight but hypervascular.(**c**) Endometriotic nodule on the lower uterine anterior wall.(**d**) Fixed and enlarged cystic left ovary in the ovarian fossa. The ureter can be demarcated behind the peritoneum and is lifted to the fixed area

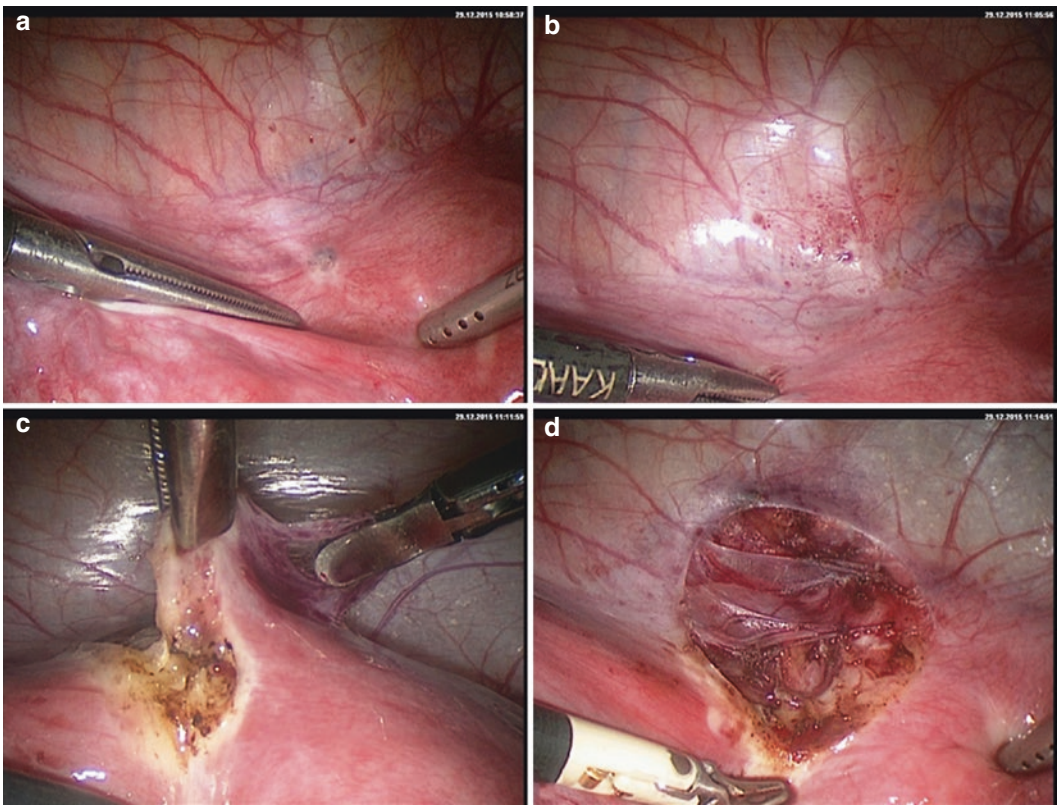

Fig. 35.16 (**a–d**) Excision of the endometriotic nodule of the lower anterior uterine wall.(**b**) Even the adjacent bladder peritoneum appears to be superficially affected because it is hypervascularized and fragile

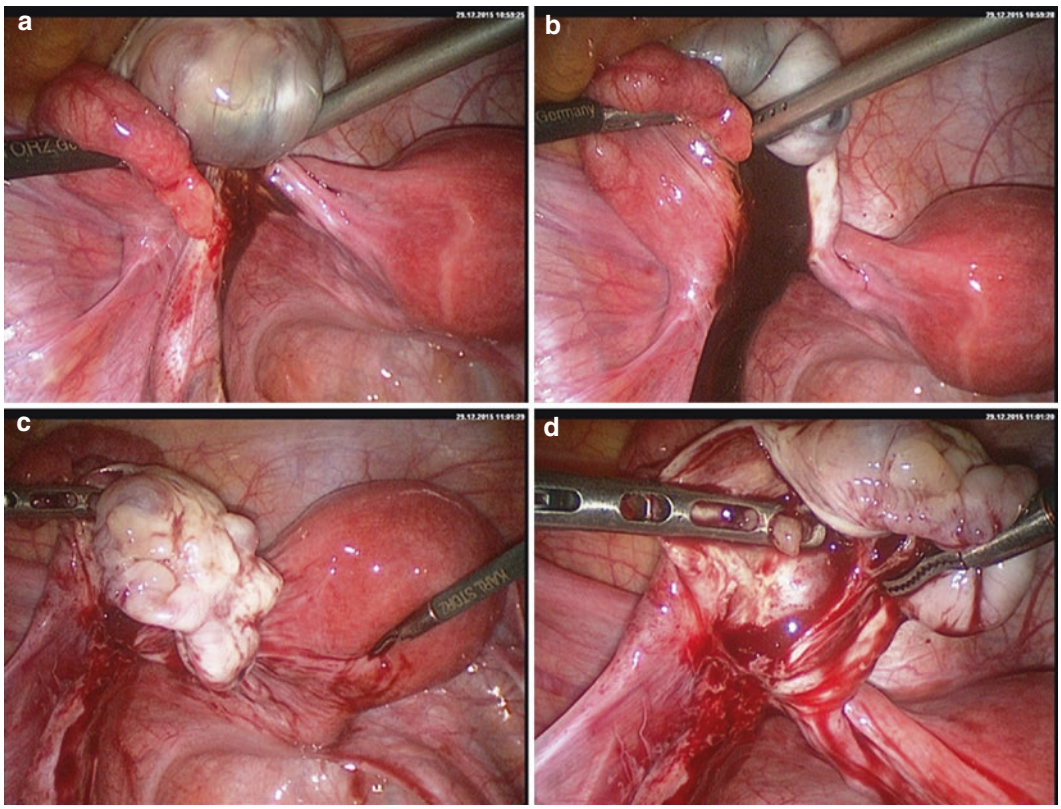

Fig. 35.17 (**a**, **b**) Lifting the ovary out of the ovarian fossa and releasing it from its peritoneal adhesion leads to opening of the endometrioma. (**c**, **d**) The depths of the ovarian fossa are affected by disease, as proven by the demarcation of the peritoneal nodule. These nodules are usually connected to the cardinal ligament or the sacrouterine ligament

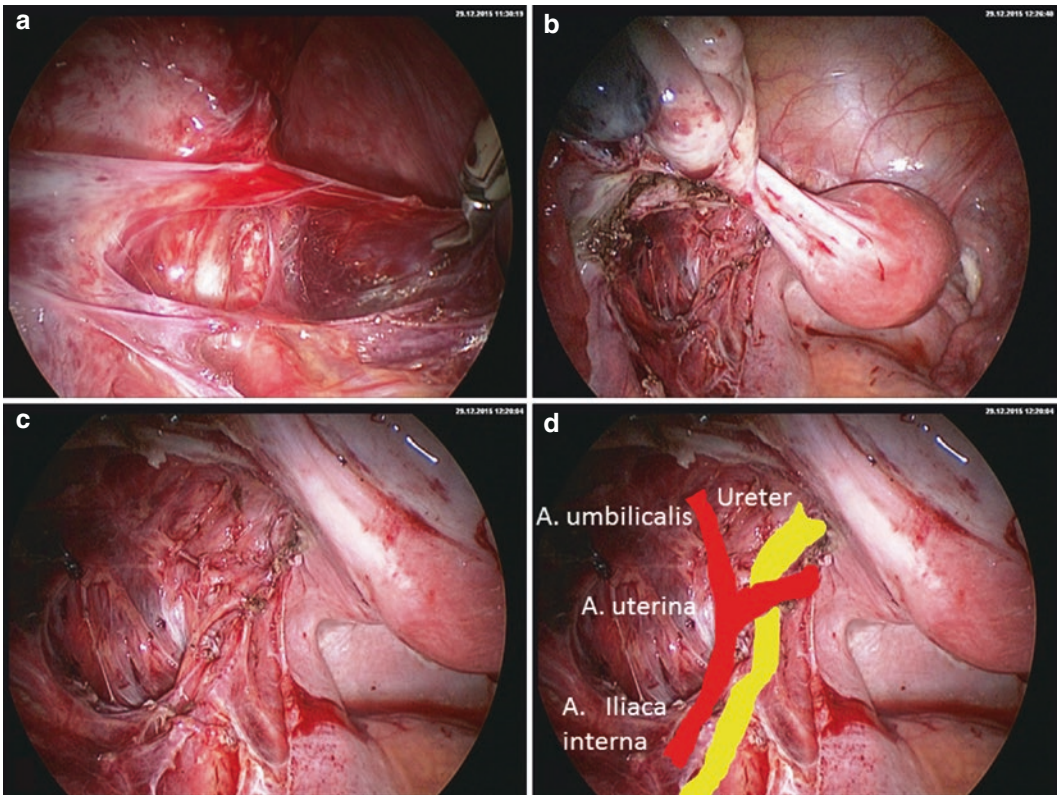

Fig. 35.18 Opening the peritoneal wall for resection of the symptomatic endometriotic nodule. (**a–d**) The ureter and vessels of the pelvic wall can be separated bluntly from the peritoneum and the endometriotic nodule. The ureter or the vessels themselves are very rarely affected. If they are, the condition calls for special surgical treatment

Table 35.1 The five major diagnostic categories that constitute indications for hysterectomy are the following

Uterine leiomyomas
Endometriosis and adenomyosis uteri
Pelvic organ prolapse
Pelvic pain or infection (other than endometriosis): pelvic inflammatory disease, adhesions
Abnormal uterine bleeding of known and unknown origin
Malignant and premalignant disease

Fig. 35.19 Truly empathetic preoperative counseling must include congruence and respect for the patient

Table 35.2 Vaginal versus abdominal versus laparoscopic hysterectomy. The robotic-assisted laparoscopic hysterectomy is included in the category of laparoscopic hysterectomies

Vaginal hysterectomy compared to abdominal hysterectomy	
Advantages	Shorter hospitalization (mean difference 1 day, 95 % CI 0.7–1.2)
	More rapid return to normal activities (mean difference 9.5 days, 95 % CI 6.4–12.6)
	Fewer infections or fever (OR 0.42, 95 % CI 0.21–0.83)
	Possibility of regional anesthesia
Disadvantages	No simultaneous surgery of comorbidities
	More difficulties in simultaneous adnexal surgery
Laparoscopic hysterectomy compared to abdominal hysterectomy	
Advantages	Less blood loss (mean difference 45.3 ml, 95 % CI 17.9–72.7)
	Shorter hospital stay (mean difference 2 days, 95 % CI 1.9–2.2)
	More rapid return to normal activities (mean difference 13.6 days, 95 % CI 11.8–15.4)
	Fewer wound infections or fever (OR 0.32, 95 % CI 0.12–0.85)
Disadvantages	Longer operating times (mean difference 10.6 min, 95 % CI 7.4–13.8)
	More urinary tract injuries (OR 2.61, 95 % CI 1.22–5.60)
Laparoscopic hysterectomy compared to vaginal hysterectomy	
Advantages	Simultaneous surgery for comorbidities
	Almost independent of the preoperative assessment
Disadvantages	Similar outcomes except longer operating times (mean difference 41.5 min, 95 % CI 33.7–49.4)
	More expensive

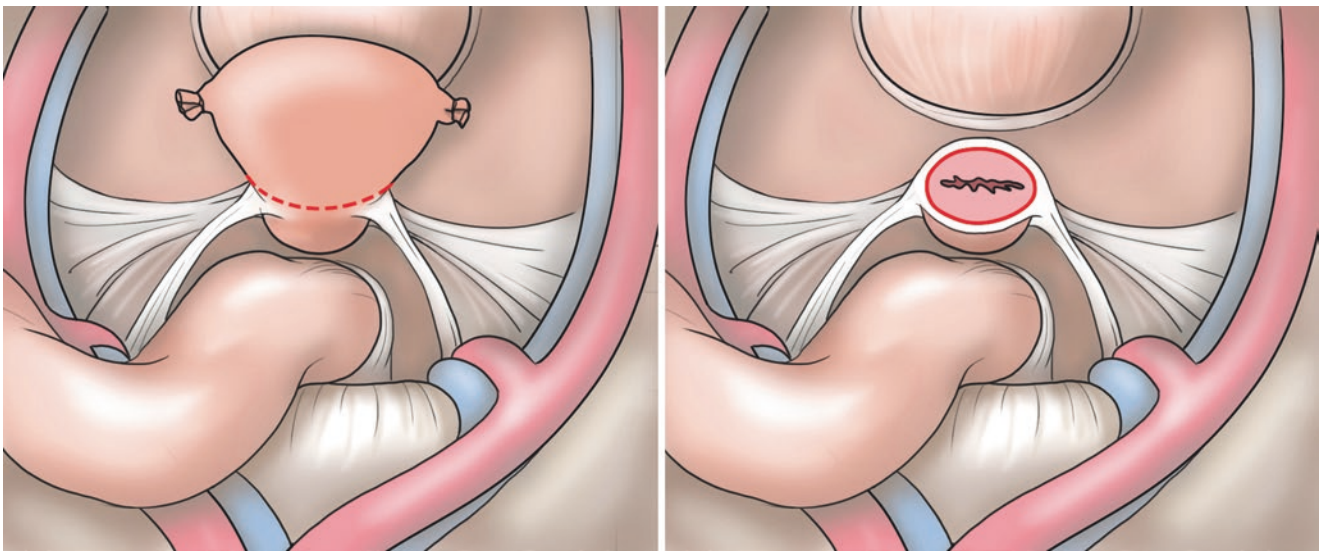

Fig. 35.20 Schematic illustration of subtotal or supracervical hysterectomy with the remaining cervical stump. The sacrouterine ligaments and the cardinal ligament remain untouched. The medial compartment is not opened

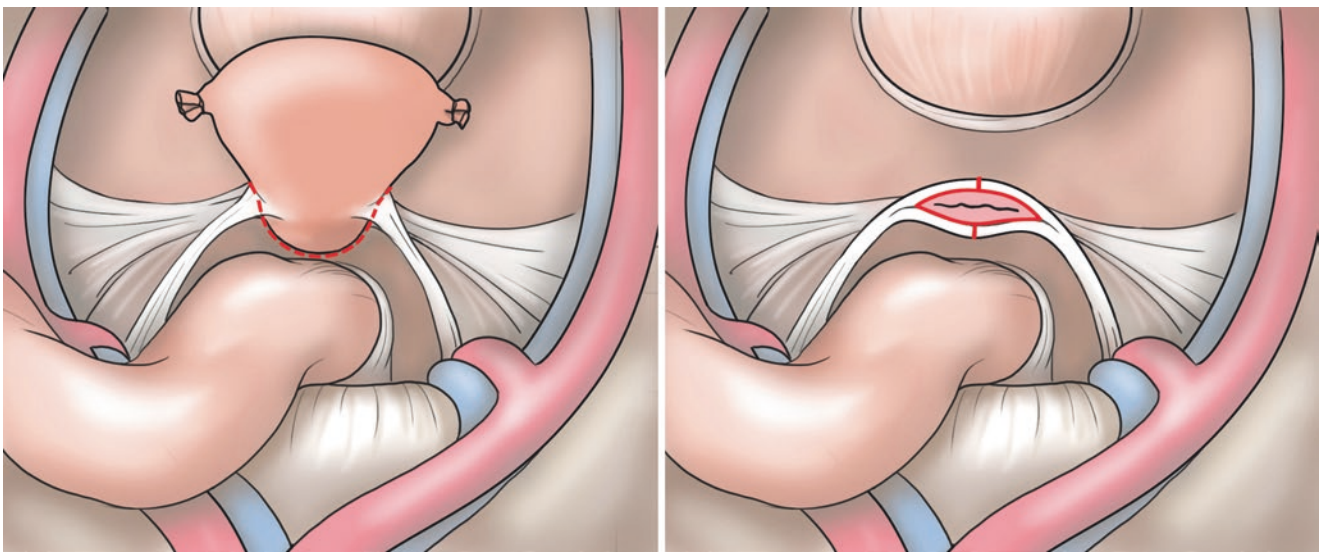

Fig. 35.21 In comparison, in laparoscopic total hysterectomy the middle compartment is opened and the cervix is enucleated out of its bed. In intrafascial hysterectomy the surrounding ligaments remain intact and the vaginal stump is retained

In the short-term, randomized trials have shown that preservation or removal of the cervix does not affect the rate of subsequent pelvic organ prolapse.

The anatomical and therefore functional advantage of the cervix being left in place is that the cardinal and uterosacral ligaments remain in place (Figs. 35.20, 35.21, 35.22, 35.23 and 35.24).

The advantages of supracervical hysterectomy compared to abdominal hysterectomy include shorter operating times and a shorter length of hospital stay when performed laparoscopically. Furthermore, patients who undergo subtotal hysterectomy are able to withstand loads earlier because there is no risk of vaginal cuff dehiscence [12]. Some studies have reported a shorter recovery period following subtotal hysterectomy, but this finding is not supported by data from randomized trials. In a prospective cohort study, supracervical hysterectomy was associated with greater improvement in short-term quality of life scores than total hysterectomy, but no difference was registered in postoperative pain or return to activities of daily living [13]. There may also be fewer injuries to the urinary tract because dissection is not performed as close to the cervix or as deep into the pelvis as in total hysterectomy. However, clinical trials designed to demonstrate this clinical observation have not been performed yet.

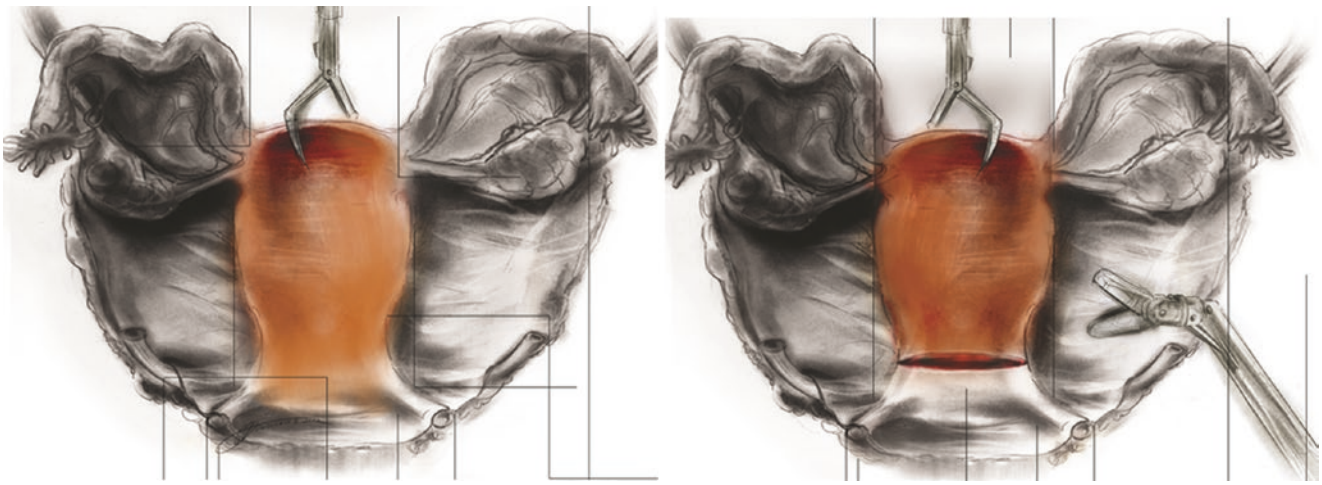

Fig. 35.22 Overview of subtotal and total hysterectomy with reference to the surrounding tissue. The sacrouterine ligaments are omitted in both procedures

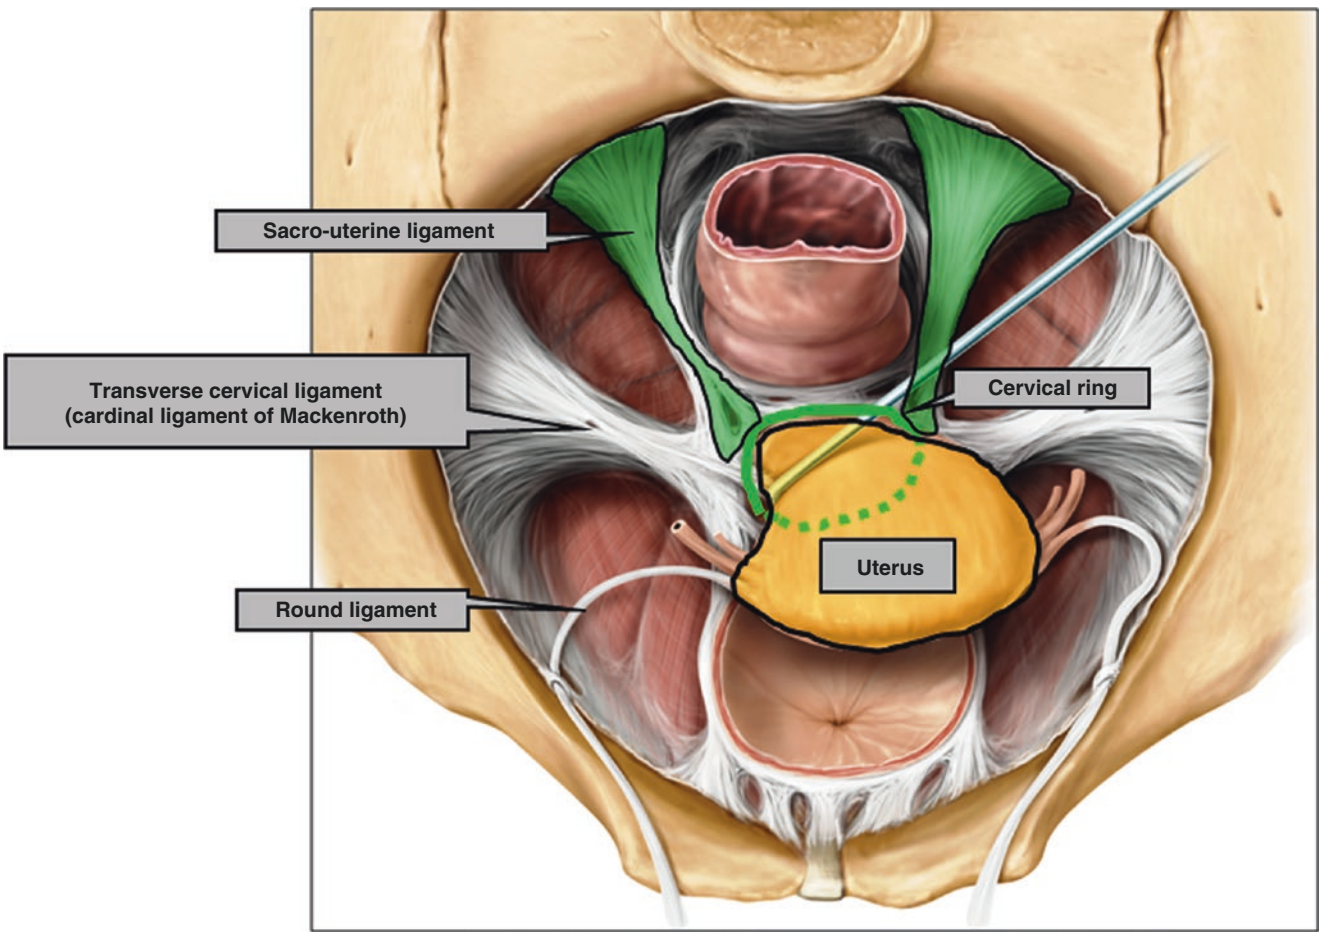

Fig. 35.23 Imaginary transverse plane showing the three compartments and the cervical ring, which is removed in total laparoscopic hysterectomy. The anatomical structure must be reconstructed when closing the vaginal cuff

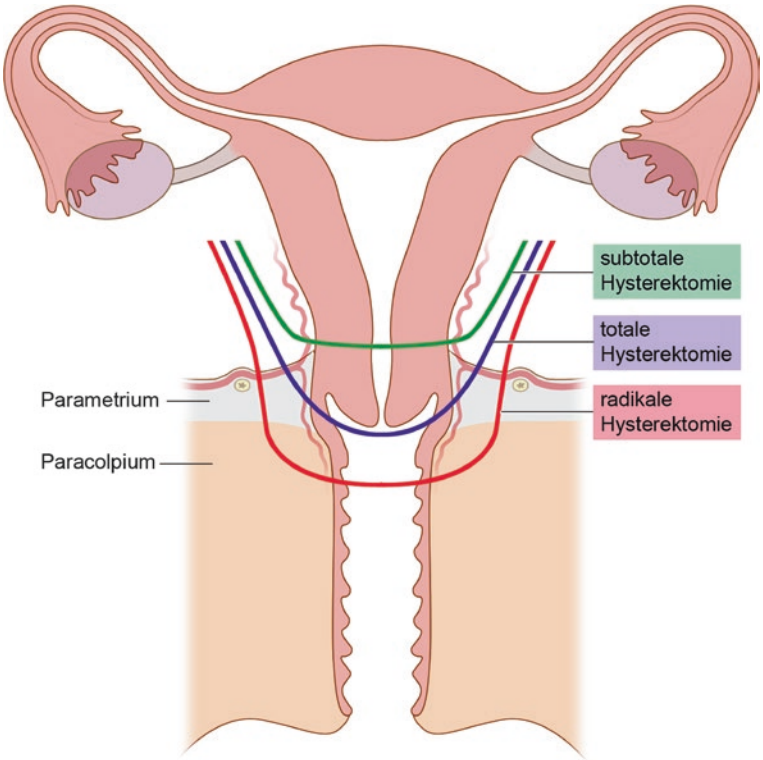

Fig. 35.24 Schematic illustration of the resection line in subtotal, total, and radical laparoscopic hysterectomy. Only the ascending branch of the uterine artery needs to be coagulated and cut with the uterine manipulator in benign cases. When adhering closely to this operative technique, the ureter is located at a safe distance from the coagulation zone (about 2 cm). All radical procedures are associated with a high degree of risk

Other differences include post-hysterectomy body image and health status. Women who underwent subtotal hysterectomy reported a significantly better body image and health-related quality of life than those who underwent total hysterectomy. Both groups reported an improvement in sexual satisfaction [14].

The only absolute contraindication for subtotal hysterectomy is a malignant or premalignant condition of the uterine corpus or cervix.

Extensive endometriosis is a relative contraindication because these women may experience persistent dyspareunia when the cervix is retained. The significance of adenomyosis has been underestimated so far. The uterus is morcellated in the abdomen. If the morcellated uterus is not collected in a bag, adenomyosis may spread into the abdominal cavity. The patient may experience persistent pain in the central segment of the lower abdomen. In laparoscopic supracervical hysterectomy (LSH), the involvement of the cervix or the retrocervical/precervical space is ignored. Very often the sacrouterine ligaments or the lateral cardinal ligaments leading to the ovarian fossa are also affected. In these cases, either the adenomyosis has grown through the uterine wall into the adjacent organs or there is concomitant endometriosis. To rule out all causes of symptoms, it would be advisable to remove all visible endometriosis-associated pathologies. LTH, if performed correctly, is associated with very few additional risks or side effects. Therefore, in cases of adenomyosis of the uterus we explain the situation to the patient in detail and advise LTH [personal statement]. Arguments in favor of LTH include fewer cases of urinary incontinence, less prolapse and cervical stump problems. However, subtotal hysterectomy is performed faster in most cases and seems to be associated with fewer intraoperative and postoperative complications. We lack convincing data concerning the advantages of simultaneous removal of the cervix; the cervix is very rarely involved in the disease [15, 16].

Elective supracervical hysterectomy should be preceded by cervical cytology confirming the absence of cervical intraepithelial neoplasia (PAP smear). Women who have had a supracervical hysterectomy should be screened for cervical cancer according to standard guidelines for their age and risk status. In patients with abnormal uterine bleeding (especially metrorrhagia), endometrial cancer or any type of sarcoma should be ruled out prior to performing a supracervical hysterectomy.

Sometimes the cervix needs to be removed later as a separate procedure. This approach is associated with frequent damage to the bowel and the bladder because the anatomical spaces cannot be exposed clearly and adhesions are common. However, the approach is readily accepted because primary surgery is associated with fewer risks than subsequent procedures. Patients who wish to minimize the likelihood of subsequent surgery may prefer a laparoscopic total hysterectomy (LTH).

Will the Fallopian Tubes and/or Ovaries Be Removed in a Hysterectomy?

Based on the existing data concerning the prevention of ovarian cancer and fallopian tube disorders, we recommend a simultaneous salpingectomy after appropriate counseling.

Notwithstanding the above facts, the number of pelvic floor corrections has increased very markedly throughout the world in recent years. This is a consequence of demographic changes. In 2000, 34.8 million women (12.7 %) in the USA were 65 years or older. By 2030 this number will have risen to 70.3 million (20 %). Similar demographic changes are anticipated in Germany [17]. In 2011, women above the age of 65 years accounted for 20 % of the total population; the percentage will rise to 35 % by 2060. This development will be less striking in other European countries, the United Kingdom, France, the Netherlands and Sweden [17]. The rate of pelvic organ prolapse (POP) repair in women aged 65 years and above is 30–50 % [18];among women older than 80 years it is still 11 % [19].

The reported rates of post-hysterectomy prolapse vary. The cumulative risk has been reported to be 1 % at three years after hysterectomy, and about 15 % fifteen years later. The risk is 5.5-fold higher when hysterectomy is performed for a descensus. Incidence rates of 46 % have been reported elsewhere [19–22]. Apart from the risk of a pre-existing descensus, vaginal deliveries and age are discussed as reasons for the risk doubling with each advancing decade of life [23]. Obviously, the rate of descent also depends on the applied surgical technique and measures for the prevention of descensus [24].

Total laparoscopic hysterectomy involves removal of the uterus and the cervix. The entire procedure is performed laparoscopically. The specimen can usually be removed through the vaginal vault. Laparoscopic-assisted vaginal hysterectomy (LAVH) has been entirely replaced by the endoscopic technique, which has become a standard procedure since the learning curve for laparoscopic suturing is now favorable. Taking into account the advantages of endoscopic surgery (shorter hospital stay, faster recovery, better cosmetic result and fewer infections), the question arises as to whether the risk of post-hysterectomy prolapse after LSH can be reduced by preserving the existing structures of the pelvic floor in the middle compartment or reconstructing them. In cases of pre-existing defects, LTH provides sufficient fixation of the pelvic floor and thus minimizes the risk of a post-hysterectomy prolapse. Mesh implants such as those used for sacrocolpopexy may be employed in both procedures simultaneously.

Our multimodality concept of laparoscopic intrafascial hysterectomy is aimed at the removal of all concomitant pathologies that might also be responsible for the patient's symptomatic condition, and simultaneously reducing the risk of post-hysterectomy prolapse:

1. Removal of all concomitant pathologies, such as adhesions or endometriosis spots, and demarcating the extent of adenomyosis.
2. Intrafascial hysterectomy with preservation of existing ligaments, yet opening the medial compartment when performing total laparoscopic hysterectomy:
   (a) Technique 1: Primary uterine artery clipping/ligation
   (b) Technique 2: Classic intrafascial hysterectomy
3. A technique of stable fixation of the vaginal stump

Development of Laparoscopic Hysterectomy Techniques and Instruments

The popularity of laparoscopic hysterectomy rose gradually after Harry Reich's initial publication of the procedure [25, 26]. A number of approaches evolved, such as laparoscopically assisted vaginal hysterectomy (LAVH), laparoscopic supracervical hysterectomy (LSH), total laparoscopic hysterectomy, and laparoscopic intrafascial hysterectomy (LTH). LTH had a steep learning curve and was initially associated with rather high complication rates [5]. The development of new instruments and consistent training improved the situation. The introduction of the intrauterine manipulator helped to develop the classic intrafascial concept which, today, is the aim of every gynecological surgeon performing total laparoscopic hysterectomy. Hohl used Kurt Semm's procedure of classic intrafascial supracervical hysterectomy (CISH) [27] and developed it further with the use of his manipulator [28]. The majority of the available manipulators are well accepted because they are easy to handle, reusable, and durable. The uterus can be moved in all directions while the elliptical long tip of the manipulator eases out vaginal and paravaginal tissue intraabdominally. The manipulator can be pushed straight towards the field of operation, especially when cutting the uterus off the vagina with the monopolar hook and targeting the tip of the manipulator.

The large majority of manipulators are provided with a ceramic cap that creates a flat surface to work on. Consequently, dissection of the bladder is usually not necessary. It should be noted that the use of the manipulator for bladder dissection is useful and safe even after a cesarean section. The application of the manipulator imitates the classical movements during abdominal hysterectomy; the ureters are kept out of the field of operation. The cap allows intrafascial hysterectomy, which preserves the ligaments and avoids vaginal shortening. The smooth cutting edge is useful for vaginal occlusion (Fig. 35.25).

Fig. 35.25 (**a**) Hohl manipulator (Storz). (**b**) Dionisi uterine manipulator (Storz). (**c**) Mangeshikar uterine manipulator (Storz). (**d**) RfQ uterine manipulator. (**e**) Clermont-Ferrand uterine manipulator (Storz). (**f**) Braun uterine manipulator. (**g**) Koninckx uterine manipulator (Storz). (**h**) Tintara uterine manipulator (Storz). (**i**) Donnez uterine manipulator (Storz)

Points to be considered:

- Monopolar electricity can be used on the ceramic cap. Bipolar current causes a larger defect, bearing the risk of subsequent wound healing problems and vaginal cuff dehiscence. The fact that ultrasound is liable to destroy this apparatus must be taken into account when using ultrasound for dissection during hysterectomy.
- Intrafascial hysterectomy involves a much smaller opening to the vagina and preserves the circular ligaments. Large uteruses may need to be morcellated. Extended endometriosis or adenomyosis may involve the circular ligaments, which then have to be removed [28].

The other instruments may be of the disposable or reusable type. Disposable tissue sealing instruments are faster and need not be replaced frequently. However, the instruments are costly and fusion of the layers of tissue results in a less clear overview of the anatomical structures. Bipolar forceps are essential. Extracorporeal sutures (PDS 1.0) are helpful, although intracorporeal sutures (Vicryl) are sufficient for vaginal closure. The monopolar hook facilitates the removal of endometriotic spots and the uterus from the manipulator, but can be replaced by bipolar forceps and scissors. In cases of a large uterus, the tenaculum can be used to lift out the uterus; a morcellator avoids troublesome comminution of the uterus.

Preoperative Considerations and Preparation

When severe endometriosis (Fig. 35.26) is suspected on vaginal examination (Fig. 35.27) and the ultrasound scan is correlated with the patient's medical history, it will be necessary to perform further diagnostic investigations such as MRI, cystoscopy, rectoscopy, or endosonography (Figs. 35.28 and 35.29). Radical interdisciplinary surgery can then be planned and performed (Figs. 35.30, 35.31 and 35.32).

A hysterectomy must always be accompanied by antibiotic protection, such as a second-generation cephalosporin. In cases of suspected bowel involvement, a single

shot of metronidazole is also essential. The antibiotic should be applied about 30 min before the start of the operation.

The instruments consist of trocars, a uterine manipulator (for LTH only), needle holders and sutures. Additionally one needs an instrument for coagulation, graspers, scissors, window forceps and a suction irrigation unit. If a robotic set-up is available, the instruments must be adjusted accordingly. A thermofusion device with an integrated knife is optional.

Prerequisites

Obesity or comorbidities, a large uterus or a uterus with multiple myomas is no contra-indication for a laparoscopic procedure. However, in these cases the preoperative assessment and the anesthesia procedure must be discussed with the patient in advance. The trocars may need to be placed higher in the abdominal wall and the surgeon may need more than the usual two ancillary trocars. In cases of a large uterus, the need for morcellation and its risks must be explained to the patient.

Intrafascial Hysterectomy with Preservation of Existing Structures.

Operative Steps of Total Laparoscopic Hysterectomy (LTH)

Step 1

A vaginal examination in anesthesia is performed before using the manipulator. When no further vaginal or rectal pathologies are found, the manipulator is inserted.

Step 2

Port placement

The first step of the operation is placement of the uterine manipulator (Fig. 35.25) [29].

A number of entry techniques are available; direct entry under sight has become very popular in the last few years. Nevertheless, the traditional entry technique described by Kurt Semm and Liselotte Mettler from the University Hospitals Schleswig-Holstein, Kiel, in the 1980s, and still used at the Kiel School of Gynecological Endoscopy is shown here.

Optic Trocar

Veress needle technique and CO_2 gas

To insert the Veress needle, the operating table needs to be in horizontal position. The Trendelenburg tilt is carried out after creating a pneumoperitoneum. The most common site of entry for the Veress needle is the umbilical area. As the wall layers are thinnest at this level, a deep incision will ensure access to the peritoneal cavity. Before incising the skin it would be advisable to palpate the course of the aorta and identify the iliac bifurcation. This will permit inspection and palpation of the abdomen in order to detect any unusual masses (Figs. 35.33, 35.34 and 35.35) [30].

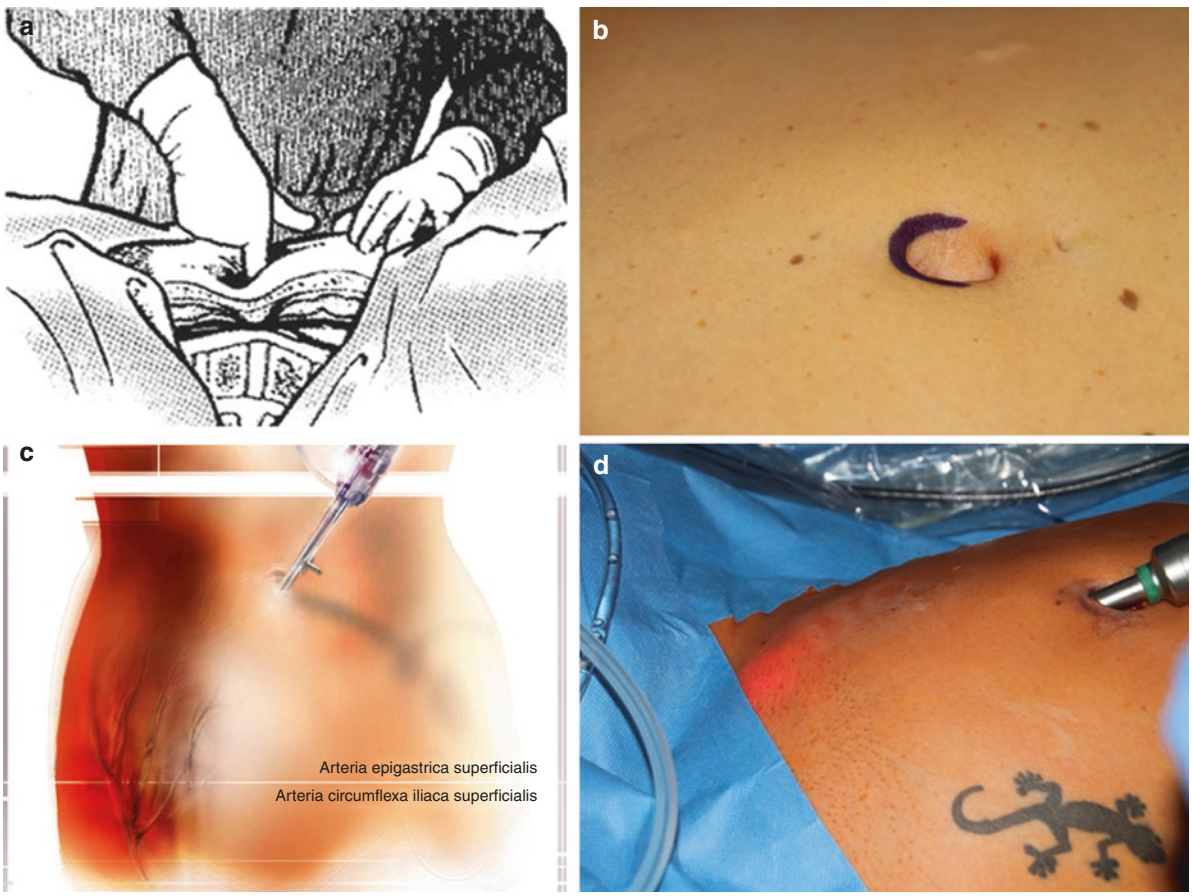

Fig. 35.33 (**a**) Typical point of palpation in the subumbilical region. The fingertip is pointing to the promontory.Subumbilical incision and local palpation reveal the short distance from the skin to the spine (**b–d**). Diaphanoscopy illuminates the region of insertion of the ancillary trocars while demarcating the superficial epigastric artery and the superficial circumflex iliac artery

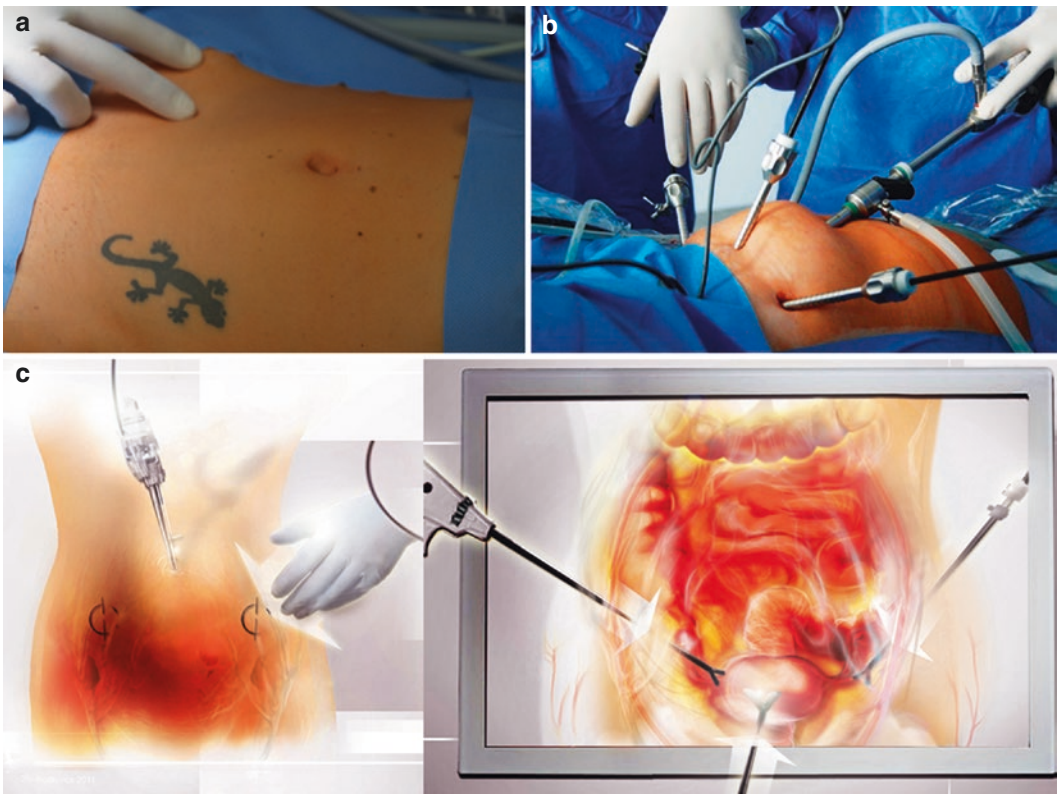

Fig. 35.34 (**a**, **c**) Point of insertion from the outside (two thumbs medial to the anterior superior spine), at a 90 ° angle to the surface, with penetration of all layers of the abdominal wall. Trocar insertion site lateral to the lateral umbilical fold. (**b**, **d**) Overview after insertion of the laparoscope and 3 ancillary trocars

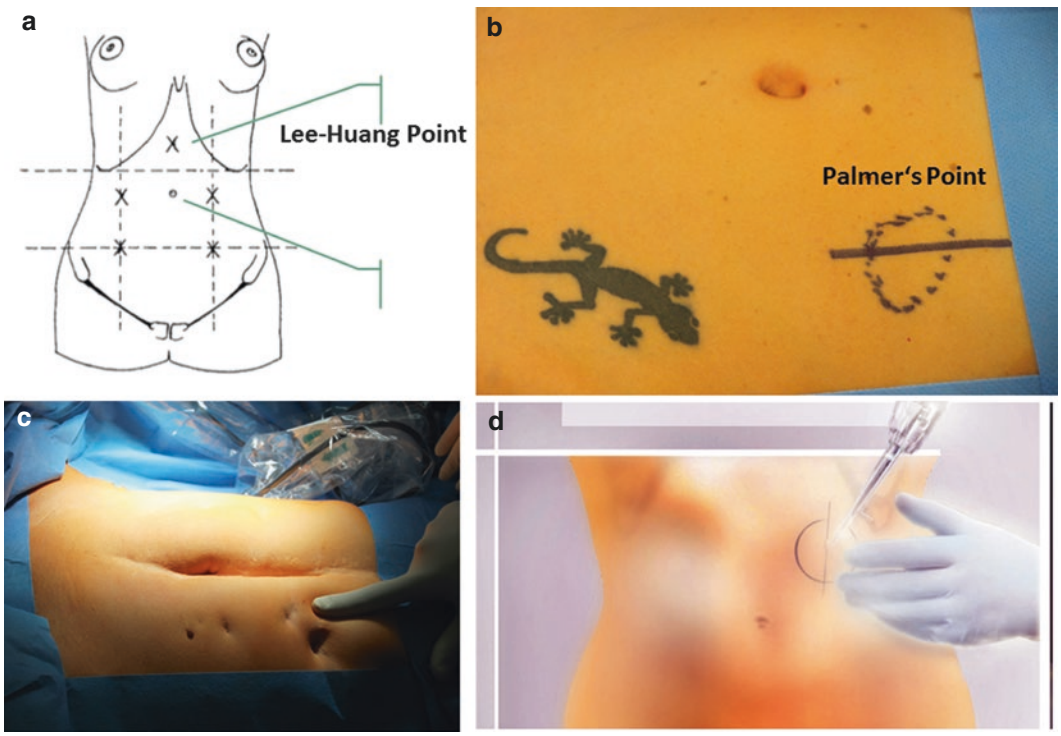

Fig. 35.35 Alternative entry site showing (**a**), in cases of a large uterus, especially at or above the level of the umbilicus, the Lee-Huang point. This point is recommended for video-assisted laparoscopy or in cases of anticipated adhesions in the region of Palmer's point (**c**). (**b**–**d**) Palmer's point is situated in the midclavicular line, about 3 cm below the costal margin

The Veress needle must be tested to ensure that the valve springs, and that gas flow is between 6 and 8 mmHg. In this position the insertion of the primary instrument at a 45° angle toward the uterus involves the least risk of damaging the major vessels coursing downward retroperitoneally. The abdominal wall should be lifted before inserting the instrument. In obese patients the insertion angle is close to 90°, whereas in slim patients the angle is close to 45°. If the first attempt fails, a second attempt is made before selecting an alternative entry site. Before placing the Veress needle, a number of safety checks should be performed in order to minimize the risk of complications:

Usually *two clicks* are heard: the first after perforation of the muscle fascia and the second after perforation of the peritoneum. Proper needle placement is ensured by keeping the Veress needle between the thumb and the index finger. *Aspiration test*: Injection of 5–10 ml of physiological saline solution results in negative aspiration when the Veress needle is correctly placed and yields a blood-tinged aspirate, or one with intestinal contents when the needle is placed in a blood vessel or the intestine. *Hanging drop test and "fluid in flow"*: With the Veress needle placed in the abdominal cavity, lifting the abdominal wall creates negative intraabdominal pressure. A drop of water is then placed on the open end of the Veress needle. If the needle is correctly positioned, the water will move down the shaft.

Any movement of the needle after placement must be avoided as this may convert a small needlepoint injury into a complex and threatening tear. After ensuring that the Veress needle has been positioned correctly, the insufflation is started. Once adequate gas flow and pressure have been achieved, the influx can be raised so that 2–3 l of CO_2 gas can be insufflated per minute until 3–6 l have been insufflated, depending on the patient's size and obesity. After an insufflation volume of about 300 ml, percussion of the liver region will confirm the *loss of liver dullness*, which is a reliable sign of proper positioning of the Veress needle and the creation of a pneumoperitoneum. Abdominal pressure should then be increased to 20–25 mmHg before inserting the primary trocar because this maximizes the distension of the abdominal wall from all underlying structures (Fig. 35.36) [27].

The optic trocar is inserted in two steps. In the first step, a 5-mm optic trocar and the laparoscope are inserted to confirm the pneumoperitoneum and the absence of local adhesions. Dilation to 10 mm is achieved in the second step, either under sight or blindly, thus ensuring optimum visibility during the operation.

Step 1: Entry is performed by a Z *technique*in the following manner: After proceeding forward with the trocar forward to about 1.5 cm, the tip is moved to about 1.5 cm to the right at a 90° angle. The abdominal wall is lifted in the same

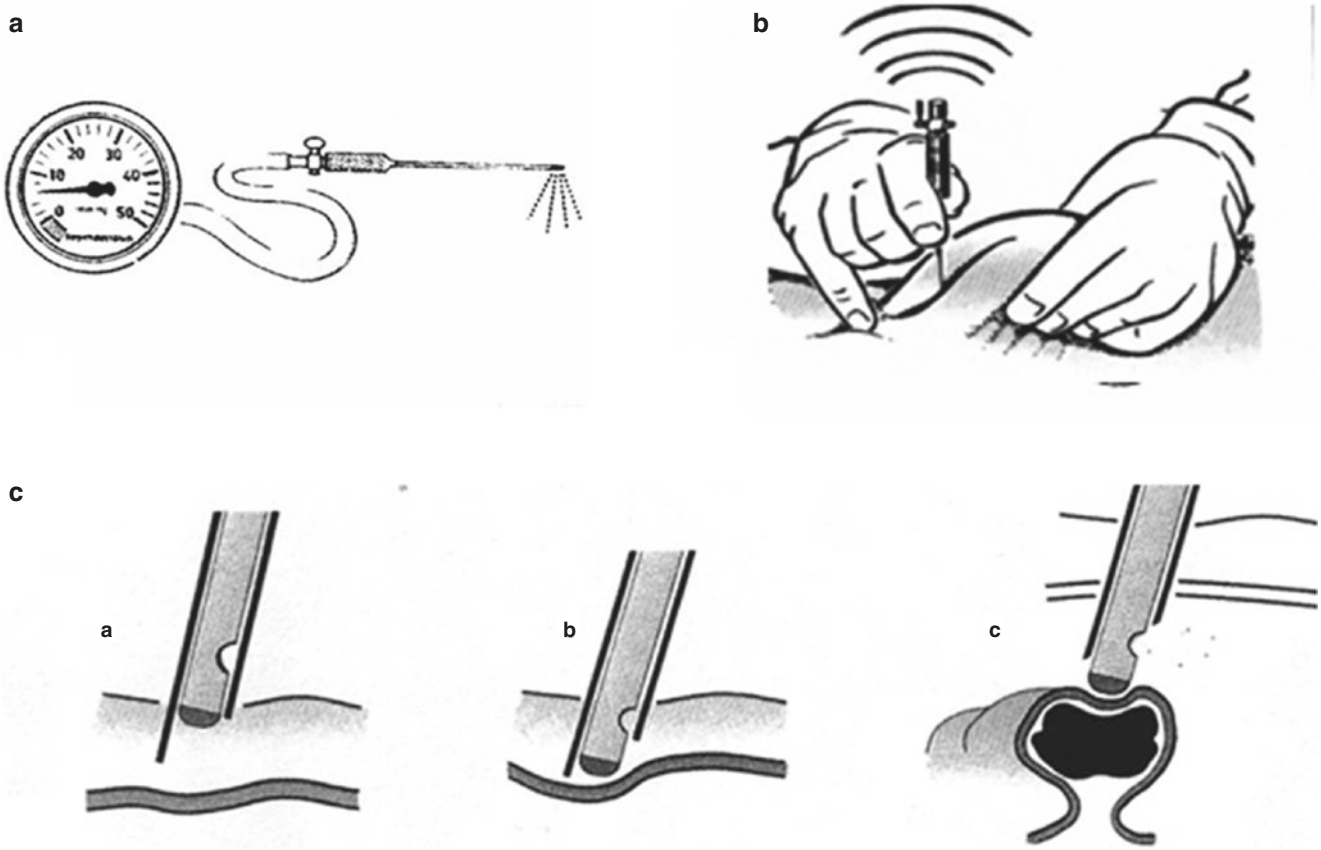

Fig. 35.36 (**a**) Veress needle and its insertion. The pressure going through the needle is measured. (**b**) The safety mechanism avoids damage or injury to the bowel or vessels. By lifting the abdominal wall the distance to the structures below (bowel and vessels) is increased. (**c**) Perforation of the outer skin is performed by the sharp tip of the needle. While running through soft tissue the blunt tip jumps forward by means of a spring mechanism. The same mechanism prevents bowel injury after penetrating the peritoneum

manner as when inserting the Veress needle, and the trocar is screwed with the dominant hand straight into the abdominal wall at a 90° angle, towards the hollow of the sacrum.

Correct placement of the trocar is indicated by a hissing sound when gas escapes through the open valve of the trocar. The obturator is then removed and the trocar is held in place. Before dilating to 10 mm, a 5-mm laparoscope is introduced and rotated through 360° to check visually for any bleeding, intraabdominal abnormality, or adherent bowel loops. If the surgeon suspects adherence of the bowel in the umbilical region, the primary trocar site must be visualized from a secondary port site, such as the lower abdominal wall, with a 5-mm laparoscope.

Step 2: A blunt palpation probe is placed in the 5-mm trocar; the shaft is pulled over the palpation probe and taken out. A 10-mm trocar is then screwed into the abdominal cavity [27].

Subcostal Insufflation Technique (Palmer's Point or Lee Huang Point)

No entry technique is entirely devoid of the risk of gas embolism or injury to vessels, intestines, or the urinary tract. Palmer's point is the safest laparoscopic entry point because it is least likely to be affected by adhesions.

For all patients with a significantly higher risk of adhesion, a history of abdominal surgery including cesarean section, a large fibroid uterus, umbilical hernia, large ovarian cysts, preperitoneal gas insufflation or failed umbilical entry, Palmer described in 1974 an abdominal entry point in the midclavicular line, about 3 cm below the costal margin. Palmer's point can be used for the Veress needle as well as for small trocars. In case adhesions are suspected in the subcostal region on the left side, the Lee Huang point in the midline is a suitable alternative (Fig. 35.35) [27].

Ancillary Trocars

All ancillary trocars must be inserted with an intraabdominal pressure of 15–20 mmHg under direct vision. The inferior epigastric vessels are visualized laparoscopically whereas the superficial vessels can be visualized by diaphanoscopy.

Once the tip of the trocar has pierced the peritoneum, it should be angulated in the direction of the uterine fundus under visual control until the port is placed correctly and the sharp tip can be removed.

Before inserting any ancillary trocars, the patient is moved into the Trendelenburg position. Premature Trendelenburg positioning may increase the risk of retroperitoneal vascular injury because the iliac vessels are located exactly in the axis of a preconceived 45° insertion angle, especially in slim patients with minimal retroperitoneal fat. The number of ancillary trocars is variable; all of them must be inserted under direct vision. If two working trocars are needed, they should be placed in the lower quadrant above the pubic hairline lateral to the deep epigastric vessels from the interior view. From the exterior view the trocars are placed two fingers medial to the anterior superior iliac spine. Two major superficial vessels - the superficial epigastric artery and the superficial circumflex iliac artery - must be avoided. These vessels can be visualized by diaphanoscopy. When a third ancillary trocar is required, the suprapubic midline is the most common site. Diaphanoscopy cannot be relied upon to locate the deep vessels, especially in obese patients (Figs. 35.37 and 35.38).

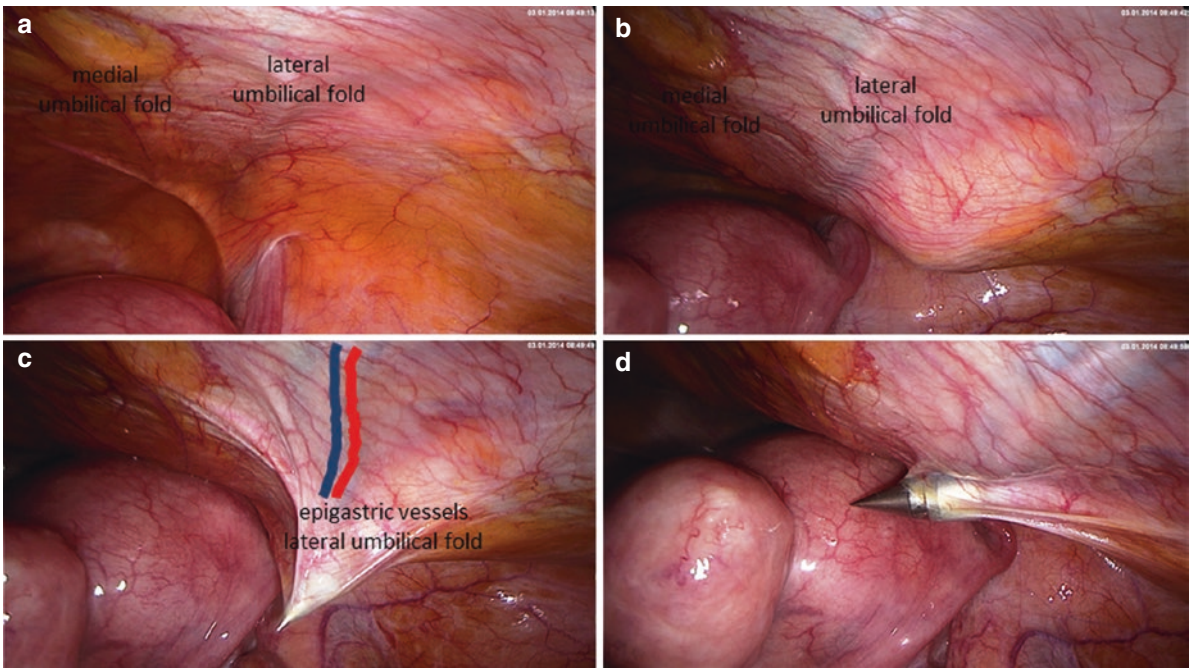

Fig. 35.37 Secondary trocar placement, entry in the right lower abdomen. (**a**) The three different plicae are visualized. (**b**) The palpating finger is showing the area lateral to the lateral umbilical fold. (**c**) Entry of the sharp ancillary trocar lateral to the lateral umbilical fold. (**d**) Once the peritoneum has been penetrated, the trocar points to the fundus of the uterus in order to avoid injury to the major vessels and the bowel

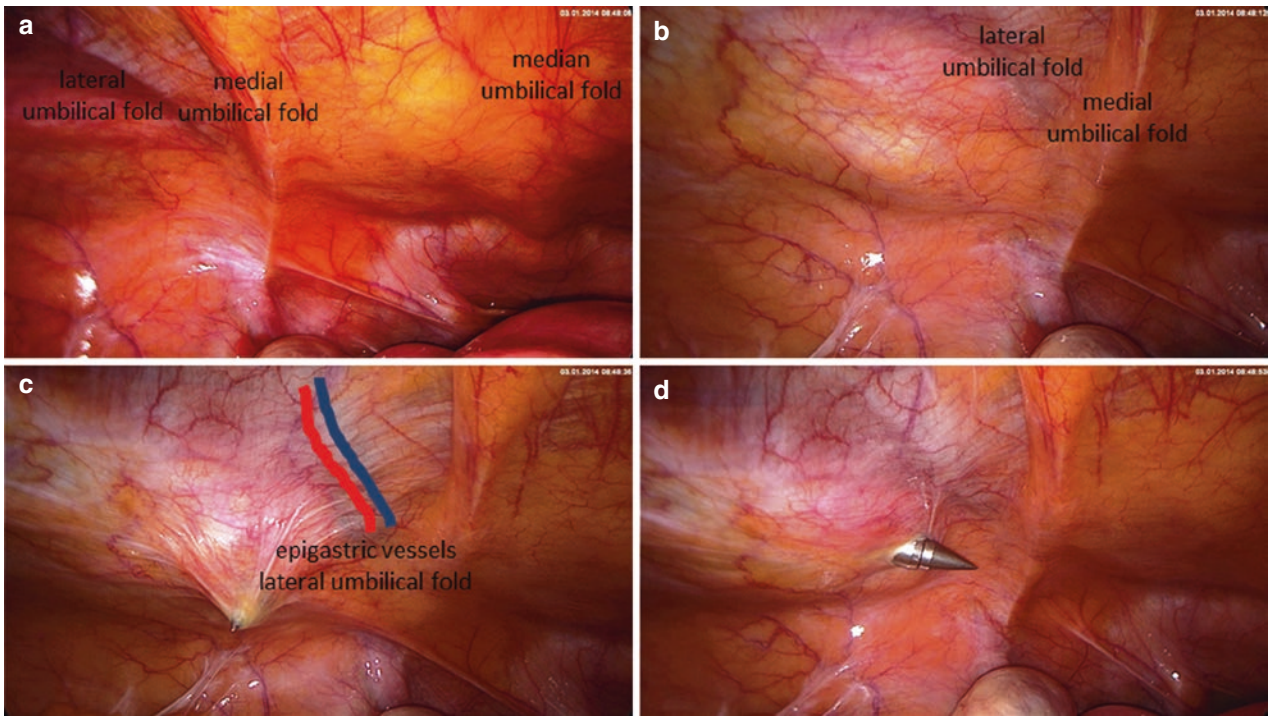

Fig. 35.38 Secondary trocar placement, entry in the left lower abdomen.(**a**) The three plicae are visualized. (**b**) The palpating finger is showing the area lateral to the lateral umbilical fold. (**c**) Entry of the sharp ancillary trocar lateral to the lateral umbilical fold. (**d**) Once the peritoneum has been penetrated, the trocar points to the fundus of the uterus in order to avoid injury to the major vessels and the bowel

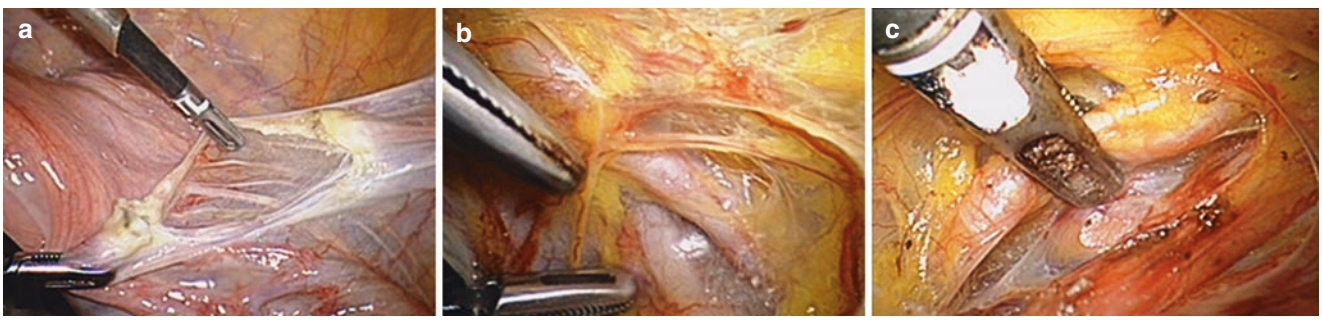

Fig. 35.39 Technique 1: The first step consists of opening the anterior leaf of the broad ligament (**a**). The round ligament is kept intact. The lower crossing of the ureter and the uterine artery are identified (**b**); the uterine artery can be coagulated directly after its point of departure from the internal iliac artery (**c**)

Finger-tapping from the outside can be used to verify correction positioning of the trocar. A small skin incision should be performed before the trocar sleeve is inserted. The trocars must be inserted by the shortest route at a 90° angle to the skin surface so that the risk of injuring structures on the way to the abdominal wall is minimized. When inserting a trocar in the midline, the Foley catheter must be identified in order to avoid accidental bladder perforation [27, 31].

Step 3

Surgical Steps

Resection of endometriosis

The primary sept in hysterectomy is removal of all visible endometriosis spots. These may be superficial and easy to excise (Figs. 35.15 and 35.16), or adherent to more delicate structures and difficult to eliminate (Figs. 35.17 and 35.18).

Laparoscopic Total Hysterectomy (LTH)

In patients being operated on for surgical staging, the surgeon will be able to assess the abdomen, pelvis, obtain pelvic washings, perform salpingo-oophorectomy, lymph node dissection, tissue biopsies and omentectomy in addition to laparoscopic hysterectomy.

(Technique 1: Primary uterine artery ligation)

The next step is to coagulate and separate the round ligament near the pelvic side wall (Fig. 35.39a). The peritoneum is then incised further. The anterior leaf of the broad ligament is opened to the bladder fold and the bladder is pushed

downwards. The posterior leaf of the broad ligament is visualized and the ureters are lateralized. The retroperitoneal space is then exposed, the course of the ureters demonstrated, and the site of exit of the uterine artery from the iliac artery visualized (Fig. 35.39b). The crossing point of the uterine artery and the ureter is exposed and the uterine artery coagulated (Fig. 35.39c). The bladder pillar is identified, coagulated, and separated. This is followed by separation of the ovary and the tube from the uterus. If the adnexa – after ensuring a sufficient distance from the ureters – are to be dissected along with the uterus, the infundibulopelvic ligament should be coagulated and the mesosalpinx and mesovarium dissected in the direction of fenestration. The fenestration is a useful point of orientation to safeguard the ureter [32–34] .

(Technique 2: Classic intrafascial hysterectomy):

Surgical Steps

3.1 Inspection of the pelvis, tracing the ureters and planning theoperation (Figs. 35.40 and 35.41)
3.2 Start on the right side. Push the uterus in the opposite direction when separating the adnexa or the ligaments from the pelvic sidewall, with the assistance of the intrauterine manipulator or by traction (Figs. 35.42 and 35.43).
3.3 Division of the infundibulopelvic ligament and round ligament from the pelvic sidewall or, when the adnexa are retained, separation of the adnexa from the uterus (Figs. 35.44, 35.45, 35.46, 35.47 and 35.48).
3.4 Dissection of the broad ligament: The broad ligament is opened and each leaf coagulated separately (Figs. 35.49, 35.50 and 35.51). This is not possible when a sealing and cutting instrument is used, because the two leaves of the broad ligament are sealed together. The direction of exposure is as close to the uterus as possible but as distant as necessary, thus avoiding exposure close to the sidewall and the ureter (Fig. 35.52).
3.5 Separation of the bladder from the uterus by opening the vesicouterine ligament and pushing the bladder downward by about 1–2 cm (Fig. 35.51b and c).

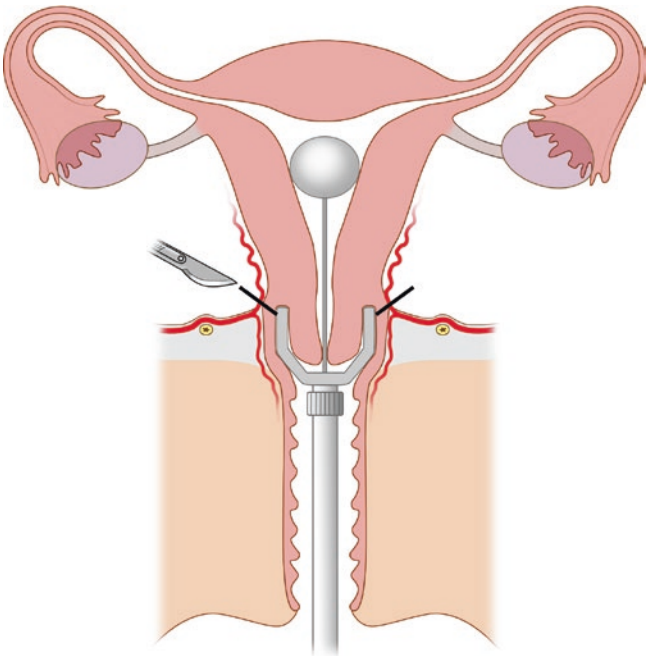

Fig. 35.41 Schematic illustration of the resection line in total laparoscopic hysterectomy. Only the ascending branch of the uterine artery needs to be coagulated and cut on the uterine manipulator. When adhering closely to this operative technique, the ureter is located at a safe distance from the coagulation zone (about 2 cm)

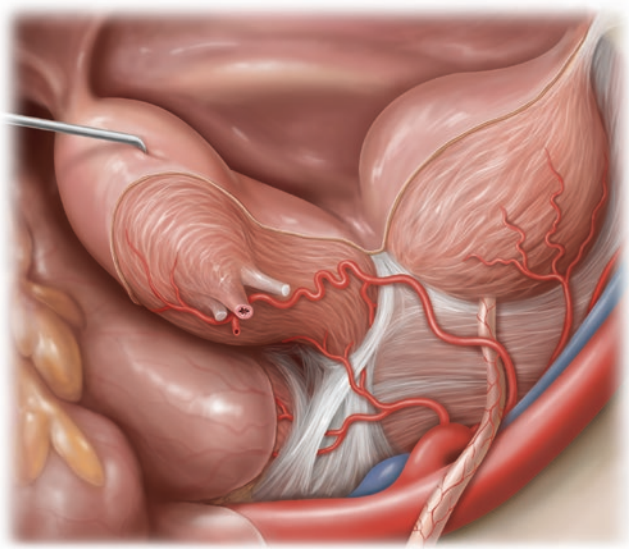

Fig. 35.40 Anatomical illustration showing the relation of the uterine vessel to the ureter in the pelvic wall, compared to its location close to the uterus. The helical course of the ascending branch of the uterine artery can be easily followed. The uterus, bladder and rectum are embedded in a ligament-based pelvic floor

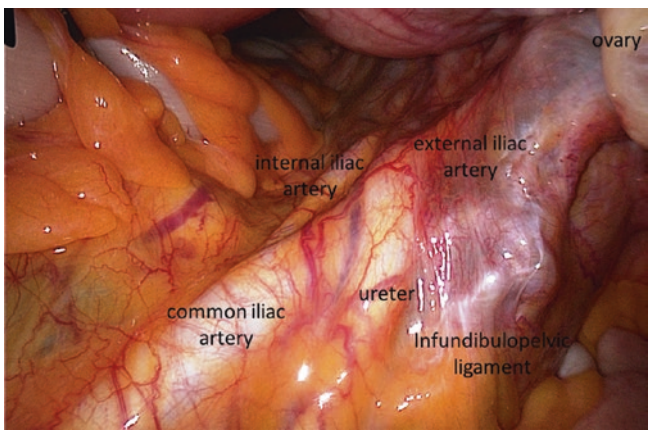

Fig. 35.42 Preliminary inspection of the uterus and the surrounding organs. The lower pelvis as well as the ligaments, vessels and the ureter can be differentiated in relation to the uterus. In slim patients the crossing of the ureter and the common iliac artery can be seen. The infundibulopelvic ligament is identified and held towards the lateral wall in order to obtain a better view of the field of surgery

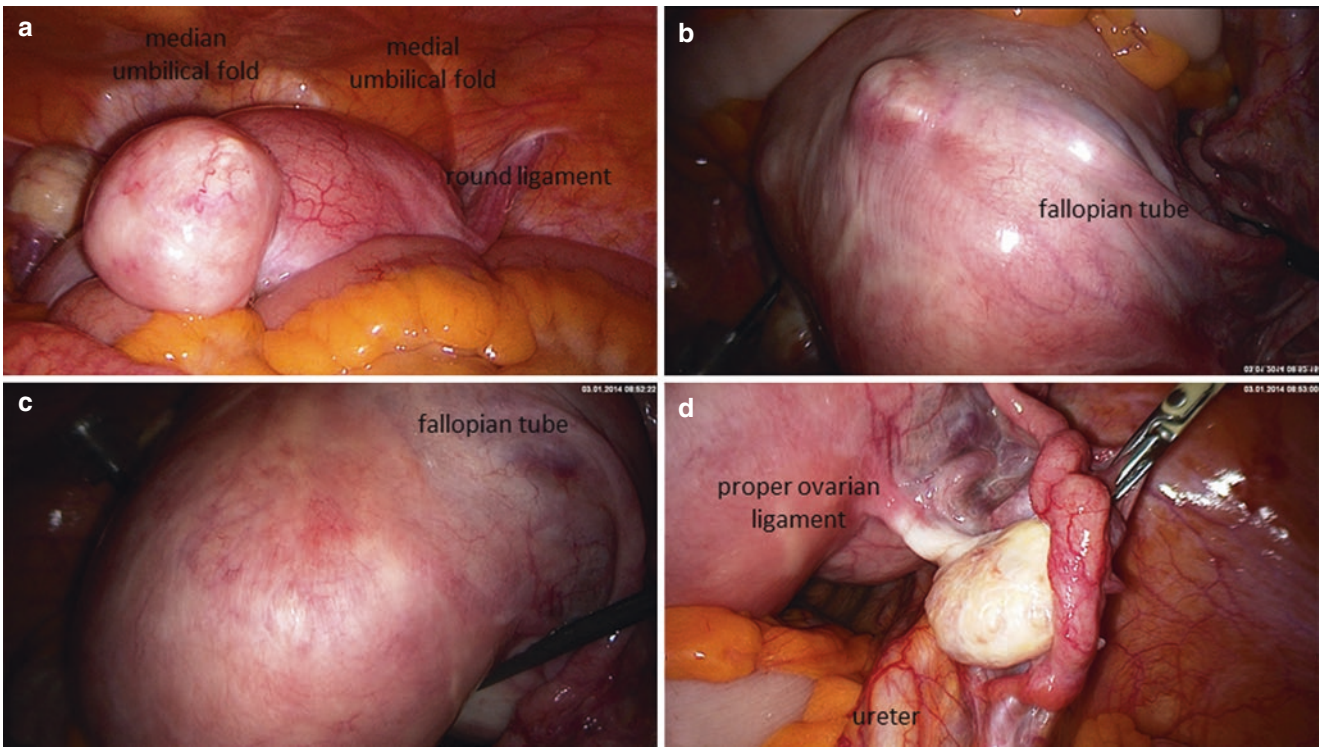

Fig. 35.43 (**a**) Reconstruction of the anatomy of the right pelvic wall. (**b**) Only the fallopian tube is visible at first glance on the right side. (**c**) After mobilization of the uterus a large fibroid on the back wall can be seen. (**d**) The bifurcation of the common iliac artery and the crossing of the ureter are clearly visible. The infundibulopelvic ligament and the ovarian vessels are situated lateral to the ureter. The infundibulopelvic ligament might be fixed to the bowel (especially on the left side) and cause difficulties when exposing the adnexa

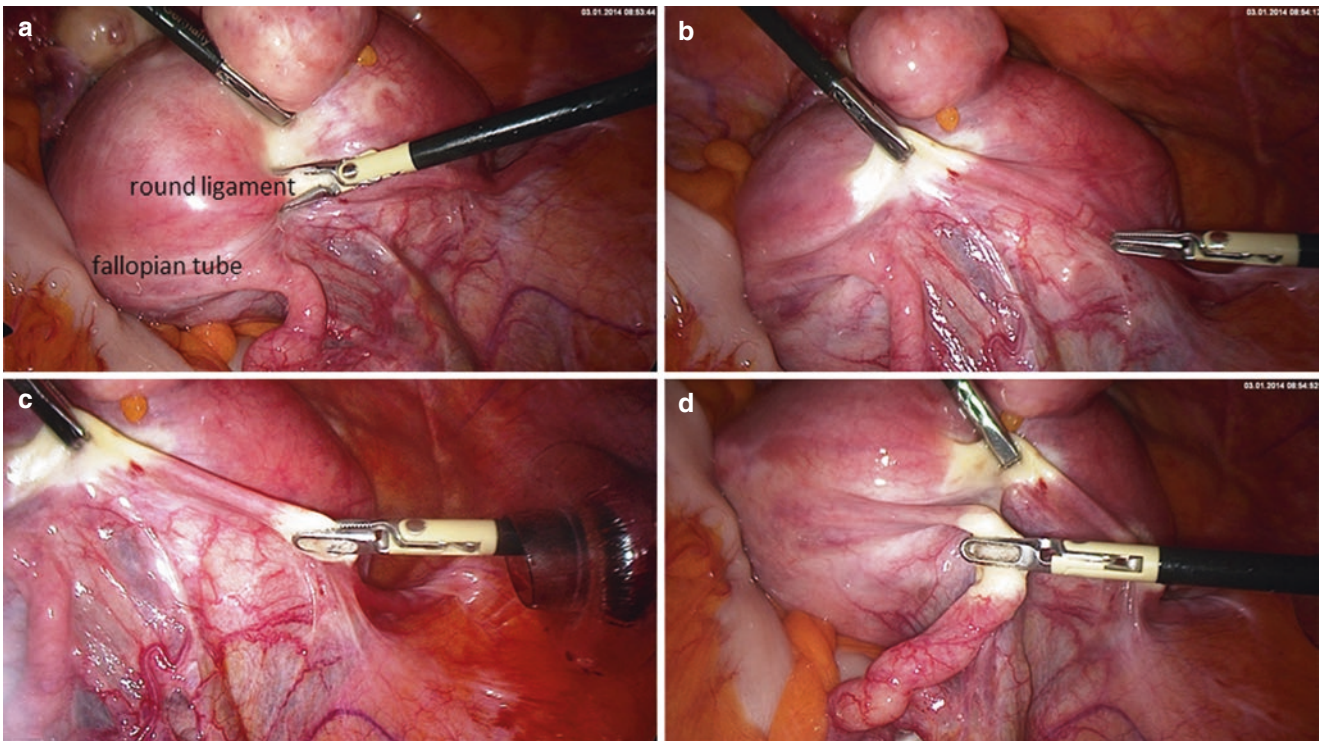

Fig. 35.44 Stepwise bipolar coagulation of the right tube and the right round ligament. (**a–b**) The round ligament is coagulated so that a sharp instrument can be used to pull the tissue without causing bleeding that might impede vision. (**c**) In benign cases the round ligament can be cut close to the uterus, in malignant cases the round ligament is cut very laterally. (**d**) This allows complete inspection of the tube and it can selectively be coagulated and cut

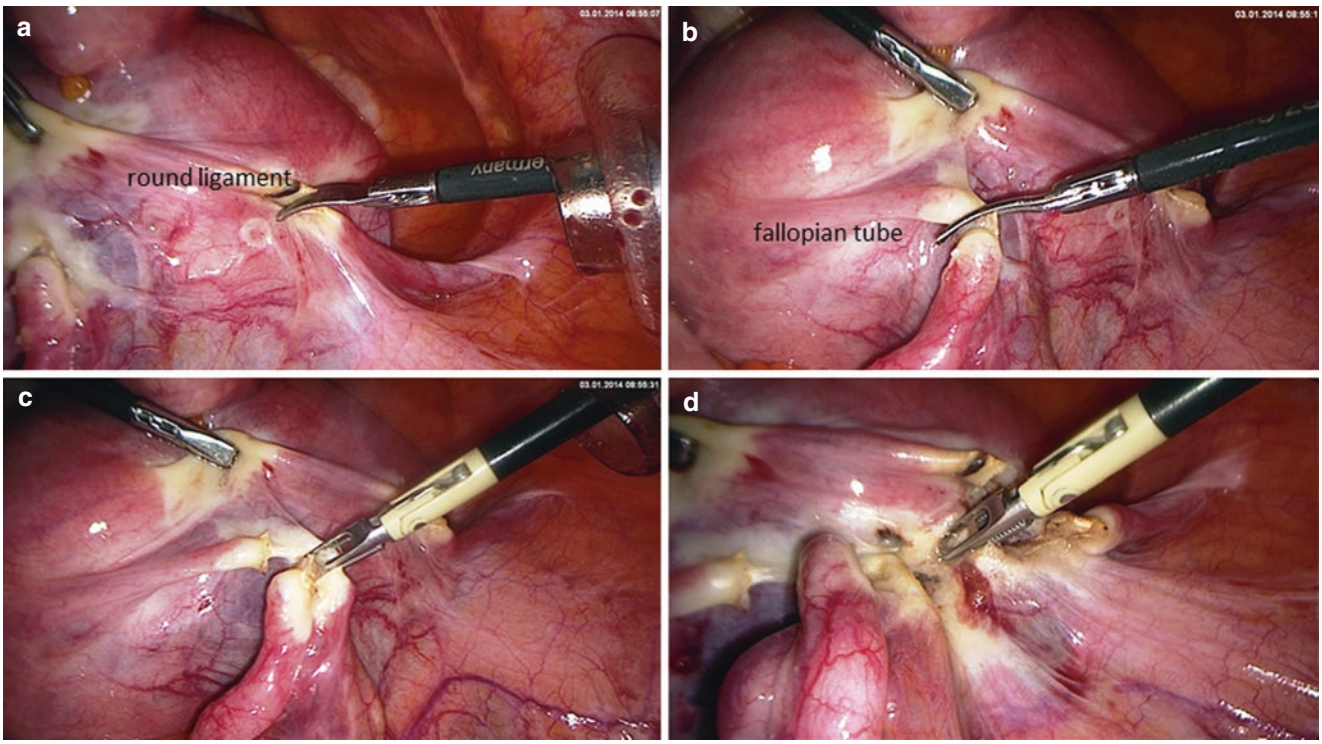

Fig. 35.45 Stepwise dissection of the right tube and the round ligament.(**a**, **b**) The curved scissors are held with the tip away from the uterine wall. (**c**, **d**) After dissecting the fallopian tube, the vessels running underneath must be coagulated before further cutting

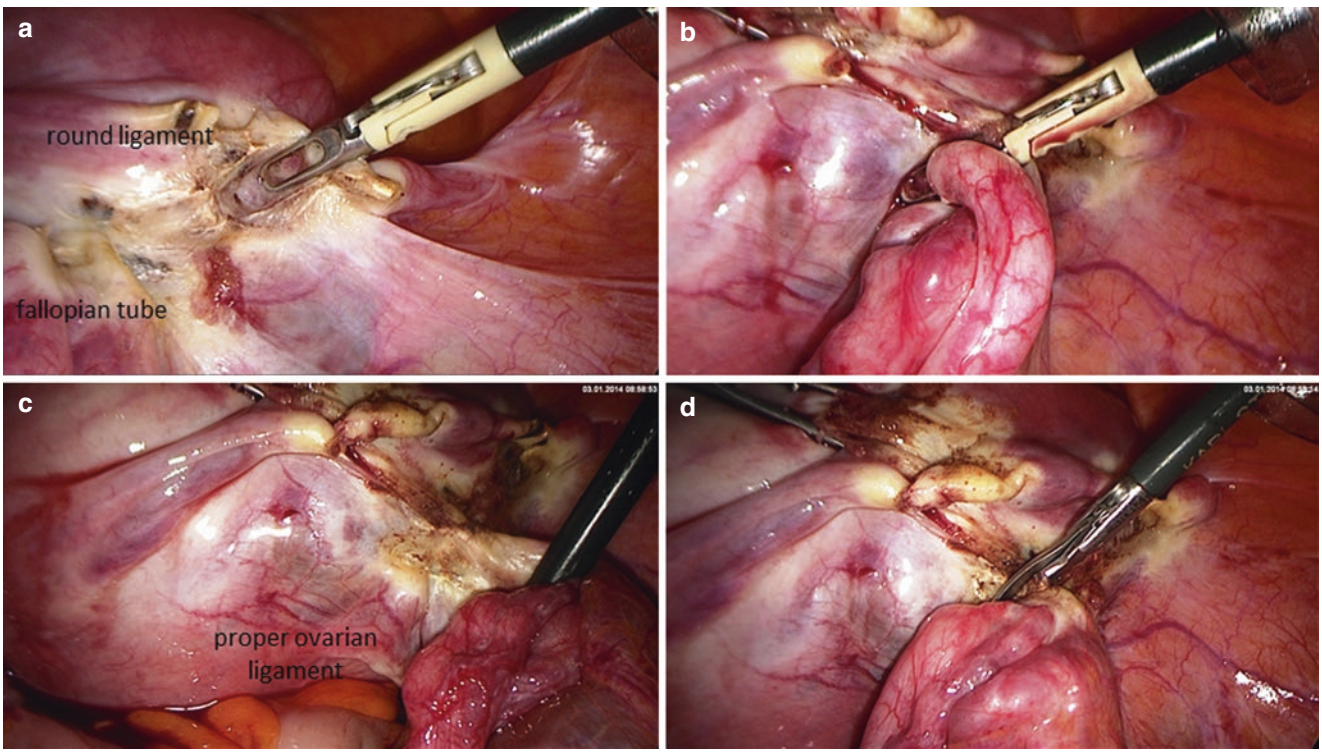

Fig. 35.46 Continuous stepwise dissection and exposure for opening the broad ligament. With traction on tissue, the line of exposure can be easily demarcated (**a**, **c**). Coagulation involves the entire tissue, but the cutting line strictly omits the uterine wall (**b**, **d**). Cutting the tube at this stage provides a better overview for exposure in the following steps. The tube can be removed easily after the hysterectomy

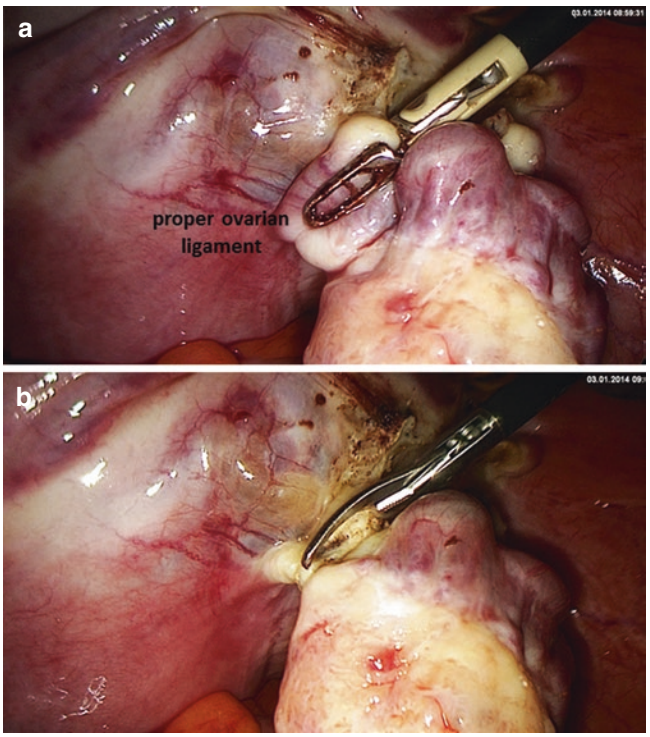

Fig. 35.47 (**a**) Coagulation of the proper ovarian ligament and (**b**) dissection without involving the uterine or the ovarian wall

3.6 Presentation of the ascending branch of the uterine artery and separation of the uterine pedicles (Fig. 35.53).

3.7 Identical stepwise dissection of the left adnexa (Figs. 35.54 and 35.55), opening of the bladder peritoneum and broad ligament (Fig. 35.56), and dissection of the uterine vessels (Figs. 35.57 and 35.58) on the left side. A thorough inspection of the cervix is performed.

3.8 After separation of the bladder from the uterus, the bladder is pushed and dissected down by 2–3 cm to clearly visualize the rim of the cervical cap. In cases of post-cesarean section, a careful, gentle and nearly blunt dissection should be performed (Figs. 35.59, 35.60 and 35.61).

3.9 While lateralizing the ureter by pushing the manipulator upward, the uterine artery and vein with its collaterals are fully coagulated near the cervix and dissected.

The key steps of pushing the bladder down from the anterior vaginal fornix prior to incision and distancing the ureters from the uterine vessels at the cervical/vaginal level can be safely performed by stretching the manipulator firmly cranially, to the contralateral side of the exposure.

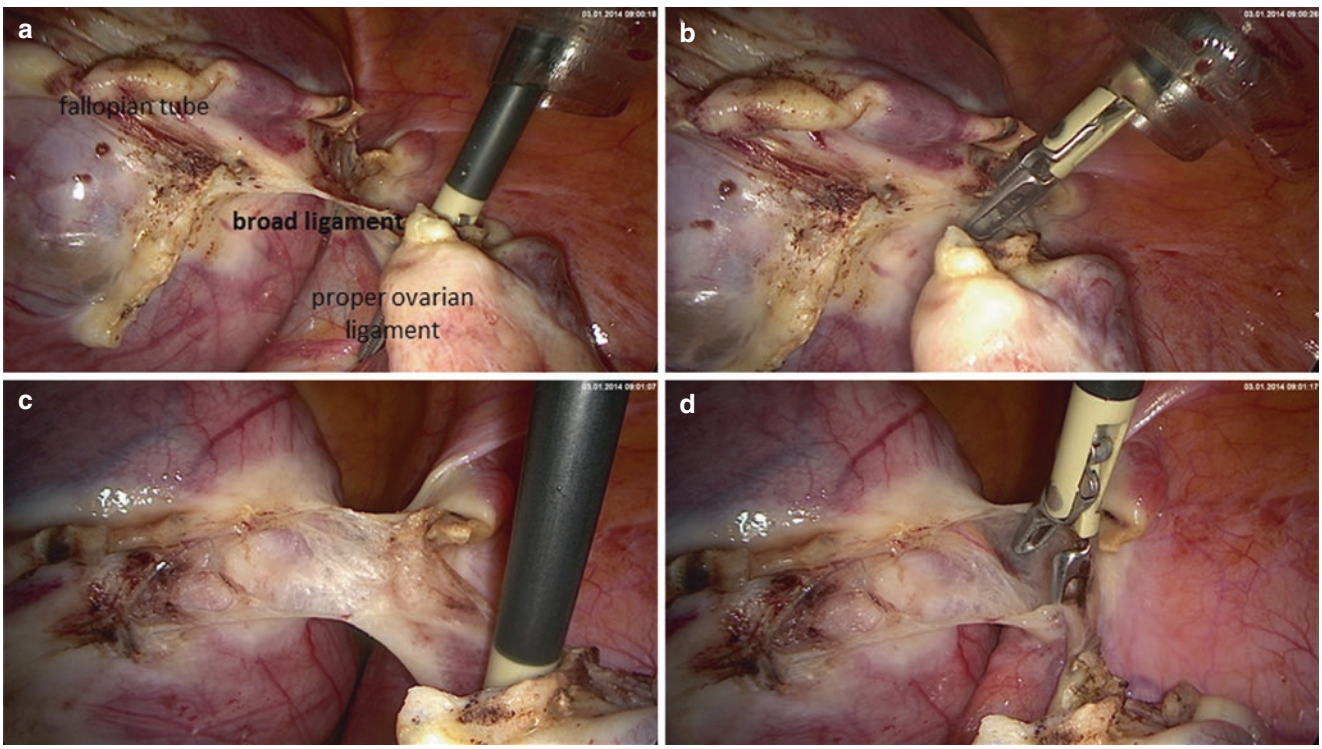

Fig. 35.48 Dissection of the proper ovarian ligament and opening the broad ligament.(**a**) After the proper ovarian ligament has been dissected, the adnexa falls to the lateral aspect. (**b–d**) The broad ligament can then be identified and separated into its two leaves

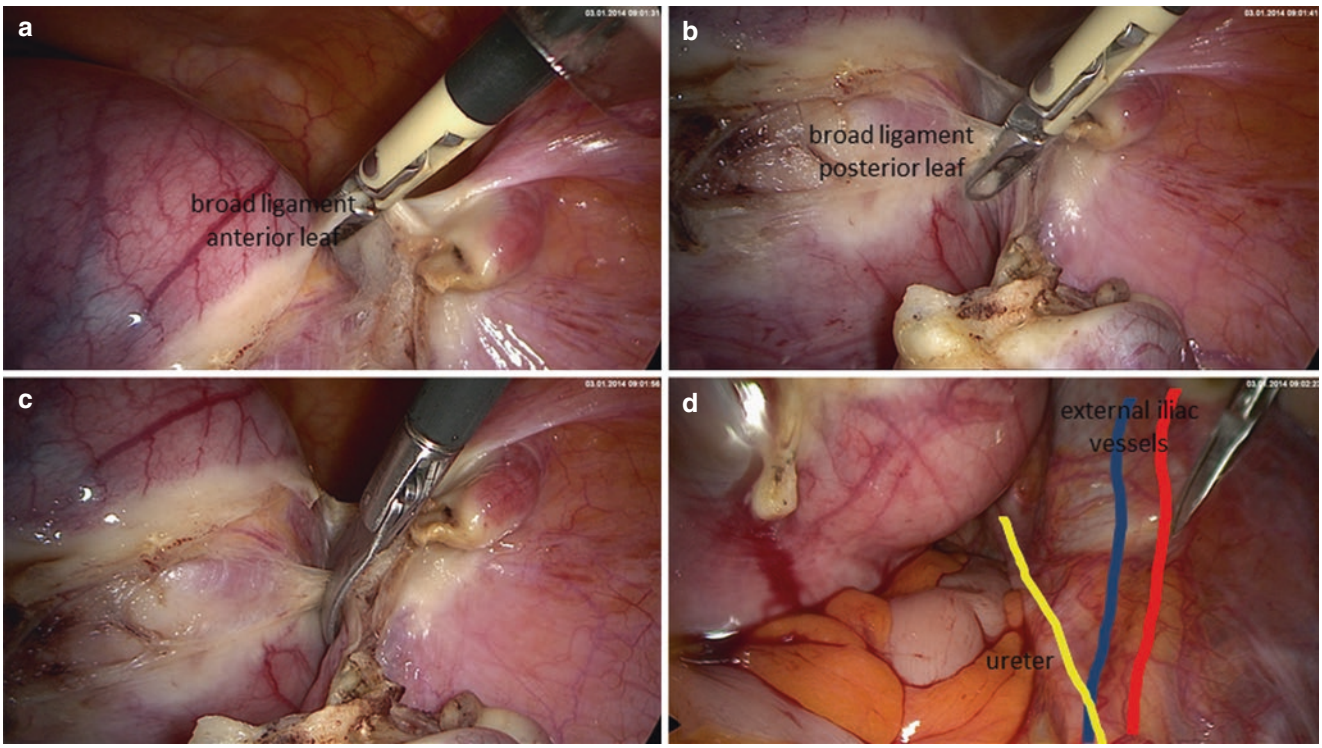

Fig. 35.49 Separation of the anterior and posterior leaf of the broad ligament (**a–**c) in relation to the ureter and the pelvic vessels (**d**).(**a-c**) The broad ligament is coagulated and dissected as close to the uterus as possible without affecting the uterine artery. As the two leaves are separated, the ascending branch of the uterine artery can be visualized easily and omitted. The tip of the scissors is directed strictly away from the uterine wall using the curved blade

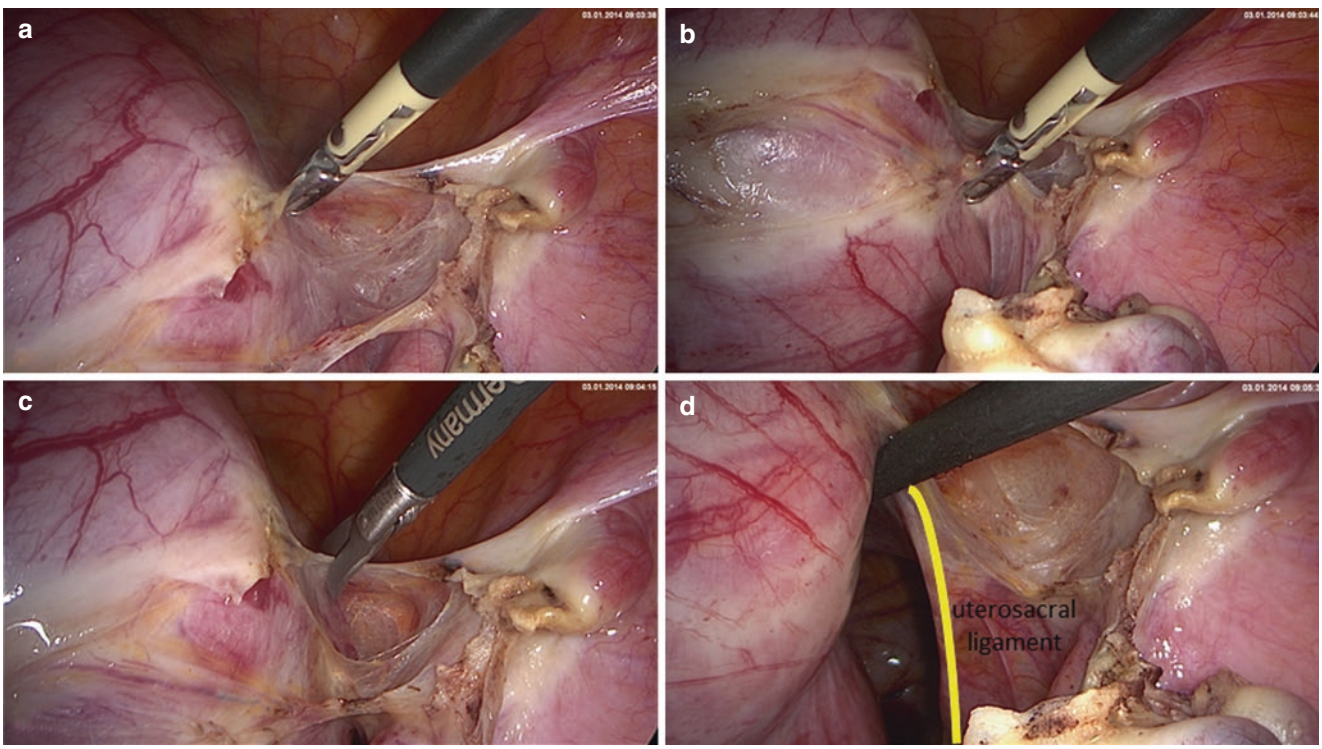

Fig. 35.50 Final separation of the leaves of the broad ligament close to the pelvic floor (**a–c**) and the sacrouterine ligament (**d**). The uterus is pushed to the left side; the bladder peritoneum is close by. (**d**) By blunt manipulation the course of the sacrouterine ligament can be visualized; the line of coagulation should omit this part

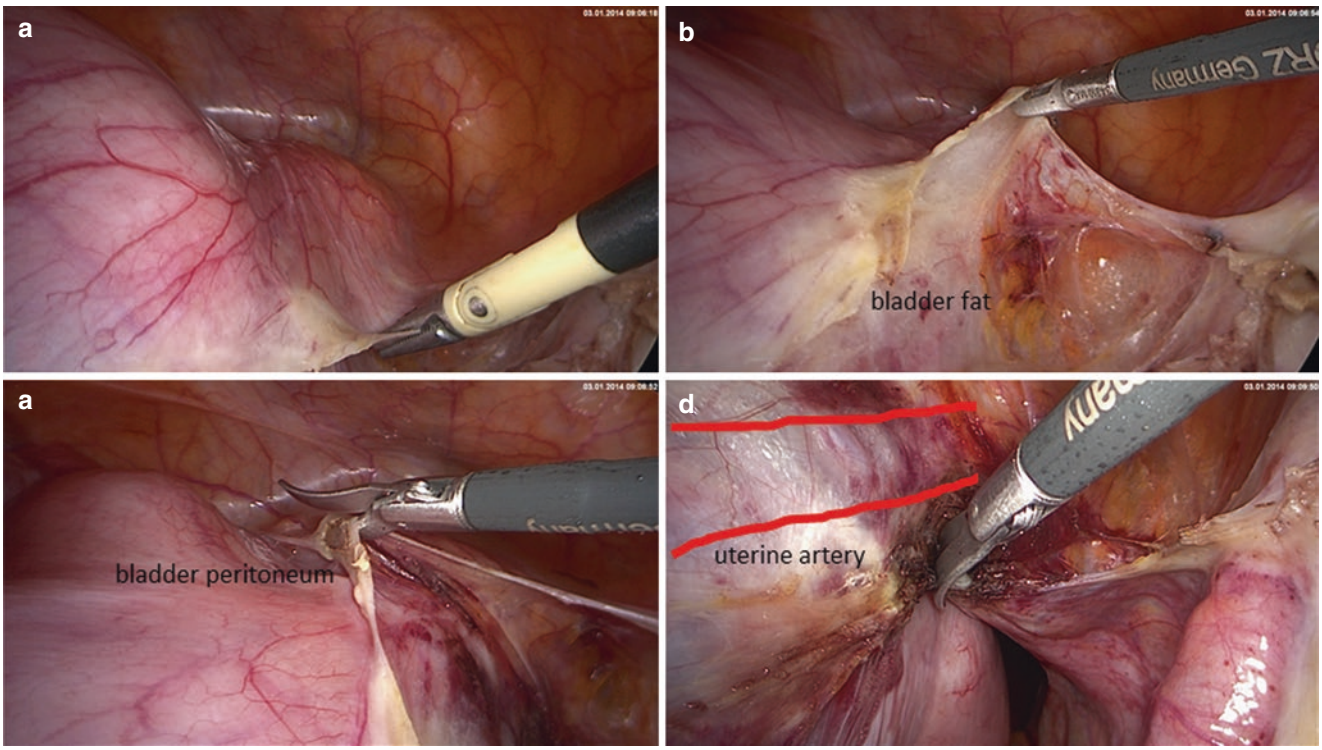

Fig. 35.51 Opening the bladder peritoneum from the right side (**a**–**c**). The beginning of the bladder peritoneum can be easily demarcated; the cutting line should be neither above this zone nor too far into the caudal aspect. Gas enters the created space and shows the beginning of the bladder pillar. The uterine vessel bundle (**d**) is freed by coagulating and dissecting above and below it. The ureter is at a safe distance lateral to this area of exposure

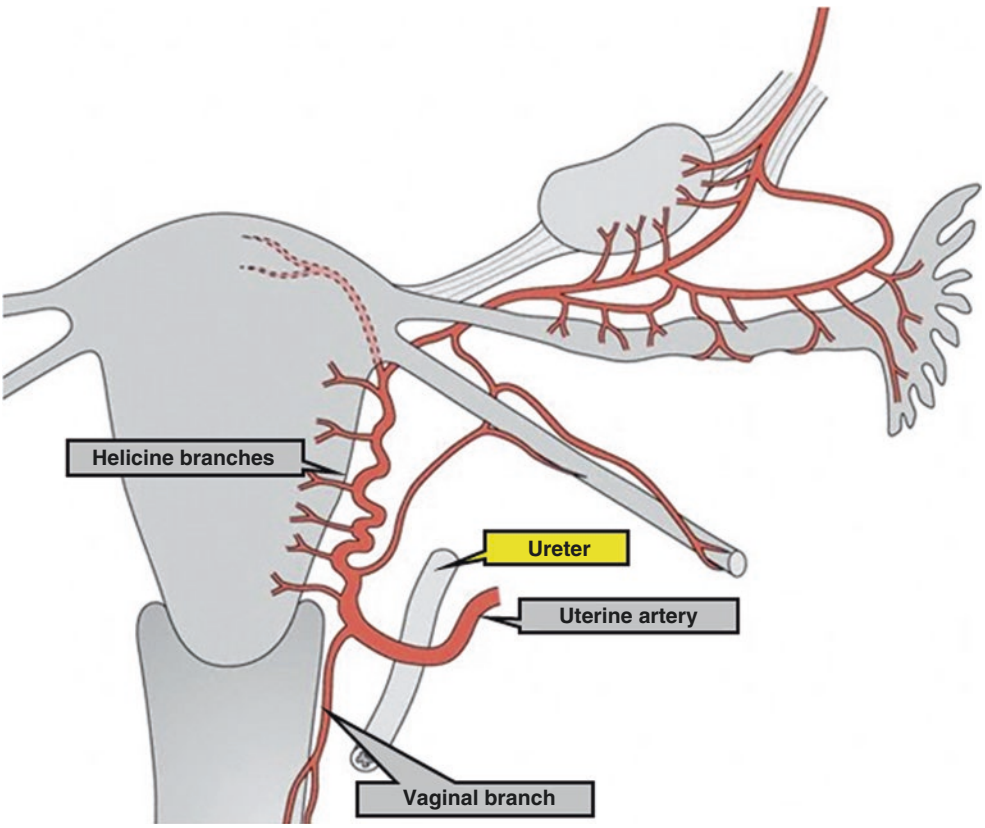

Fig. 35.52 Anatomical schematic illustration showing the spiral structure of the ascending uterine artery. Exposure too close to the uterus may cause arterial bleeding, which can only be stopped after complete coagulation of the uterine artery on the opposite side. The field of surgery would be greatly disturbed by antegrade or retrograde bleeding. The ureter is close to the surgical field only in the lowest part. Pushing the uterus away lateralizes the ureter and moves it to the side

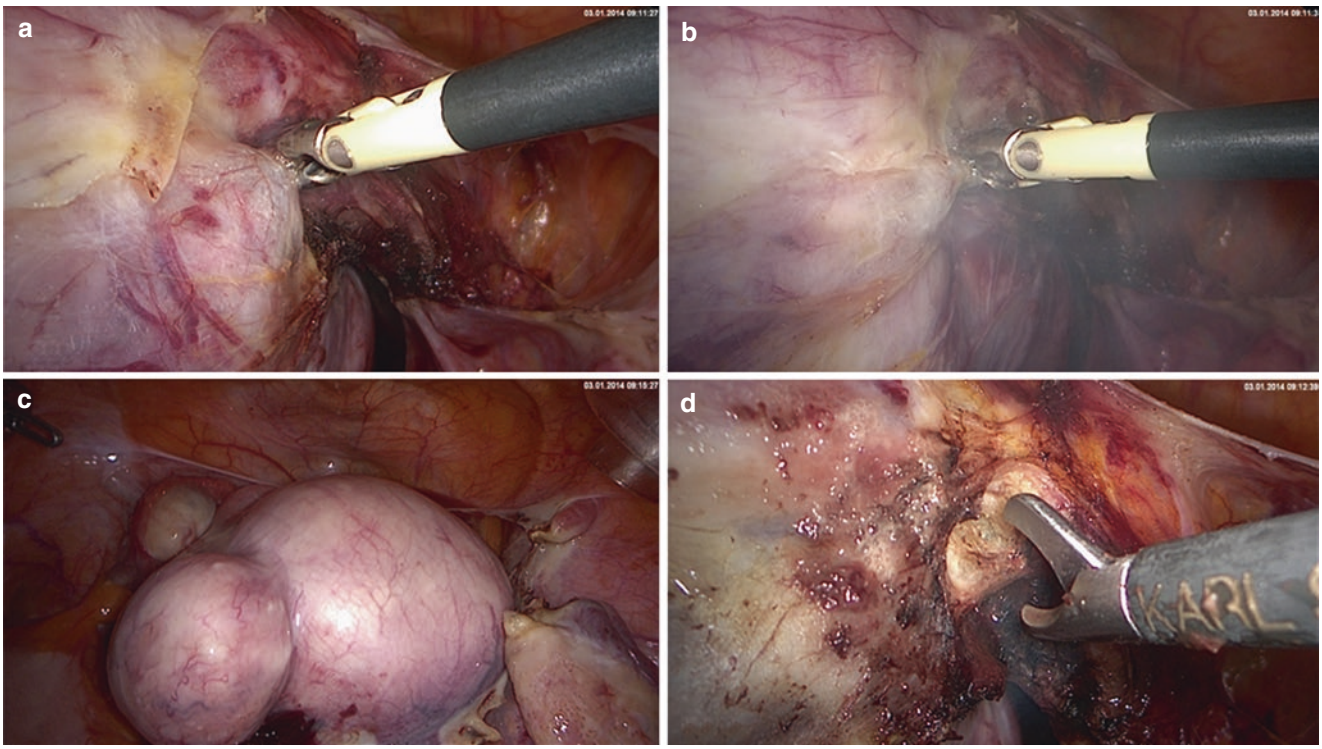

Fig. 35.53 (**a**) Bipolar coagulation and dissection of the uterine vessels. (**b**) The area of coagulation must include the upper part of the artery to avoid retrograde bleeding after dissecting the vessel. (**c**): The color of the uterus changes to whitish/grey. (**d**): A deeper cut can be avoided by using the hook scissors; the uterine artery is dissected in two steps. This allows further coagulation of the tissue lying just behind the artery and avoids cumbersome venous bleeding

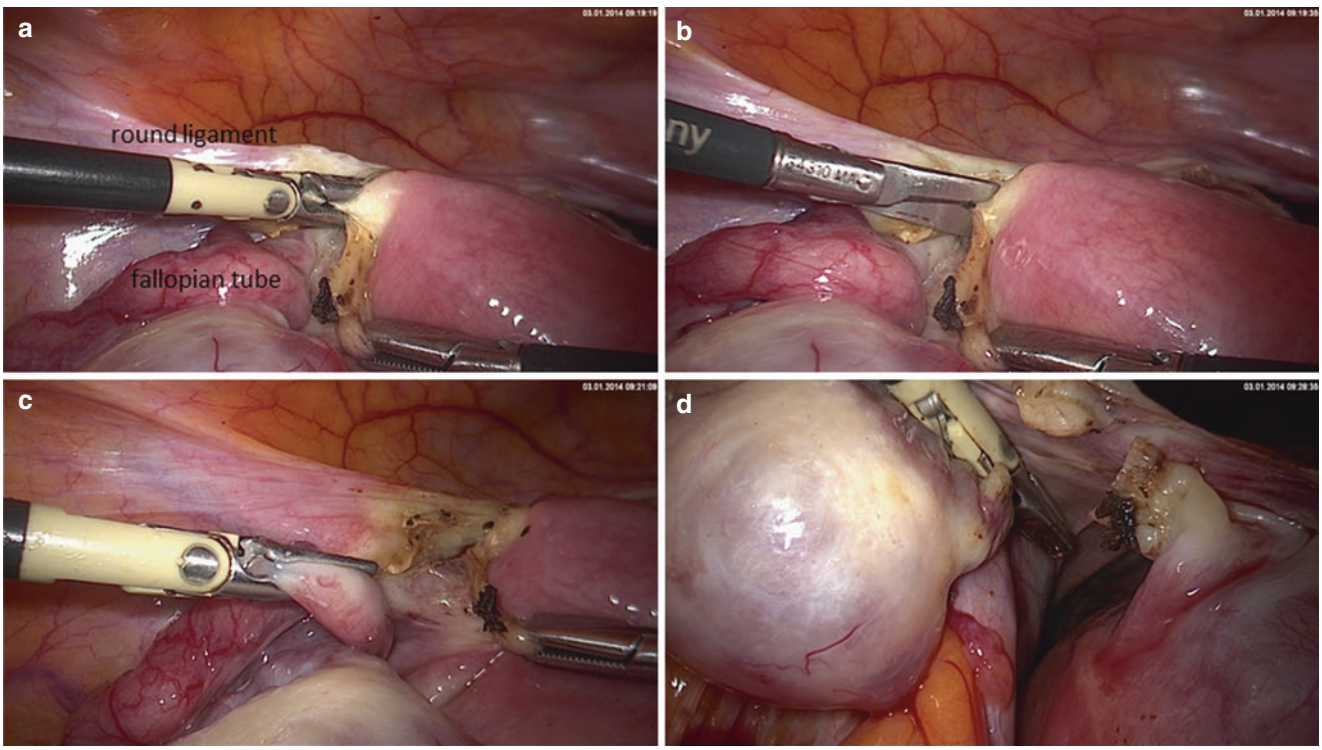

Fig. 35.54 Stepwise coagulation and dissection of the left round ligament and tube (**a**–**c**) and the ovarian ligament (**d**).(**a**, **b**): The curved scissors are held with the tip away from the uterine wall. (**c**, **d**): After dissecting the fallopian tube, the vessels coursing below must be coagulated before further cutting. (**d**): By blunt manipulation the course of the sacrouterine ligament and the uterus can be visualized in patients with lateral myomas. The line of coagulation should omit this part

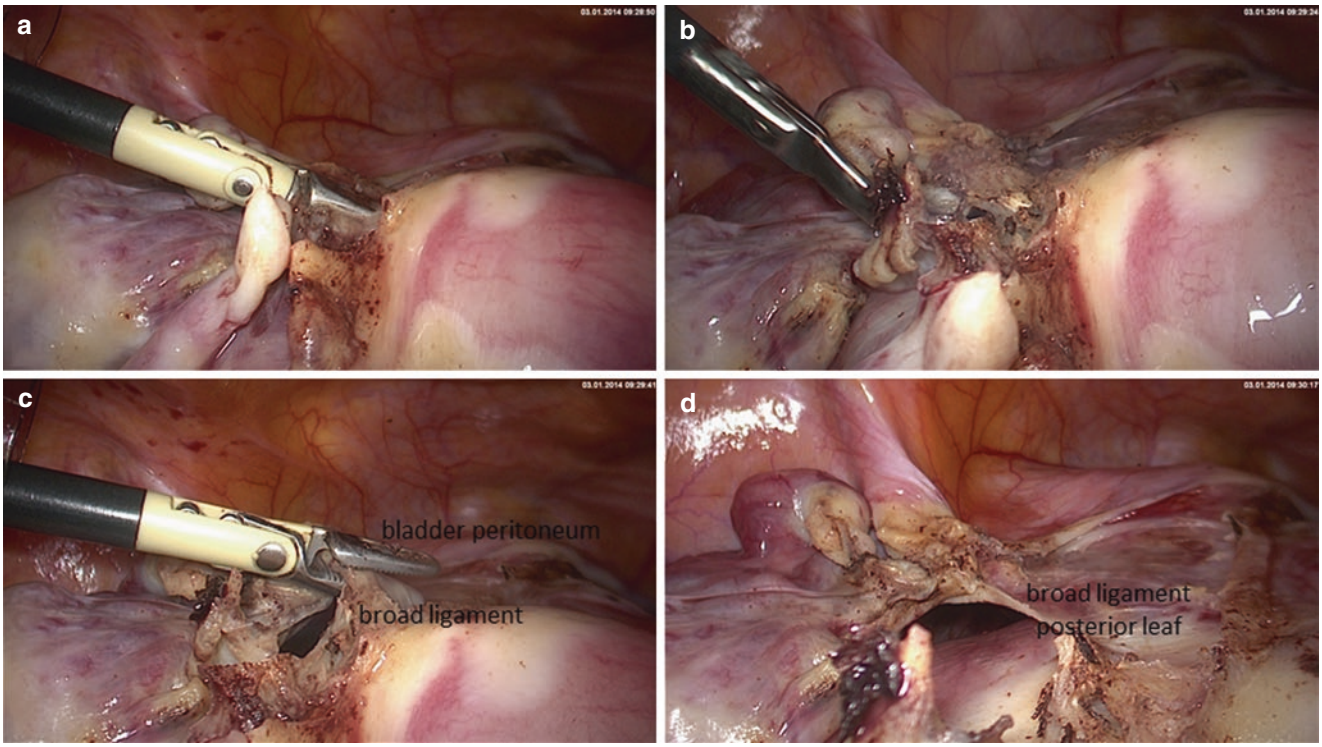

Fig. 35.55 (**a**) Dissection of the bladder peritoneum as well as the anterior and posterior leaf of the broad ligament on the left side. (**b**) Blunt manipulation shows the exact anatomical path of the left adnexa avoiding the wrong surgical route. (**c**) Coagulation is performed as close as possible to the uterus. (**d**) The bladder peritoneum has already been opened from the right side and the posterior leaf of the broad ligament serves as an anatomic landmark for the uterine vessels

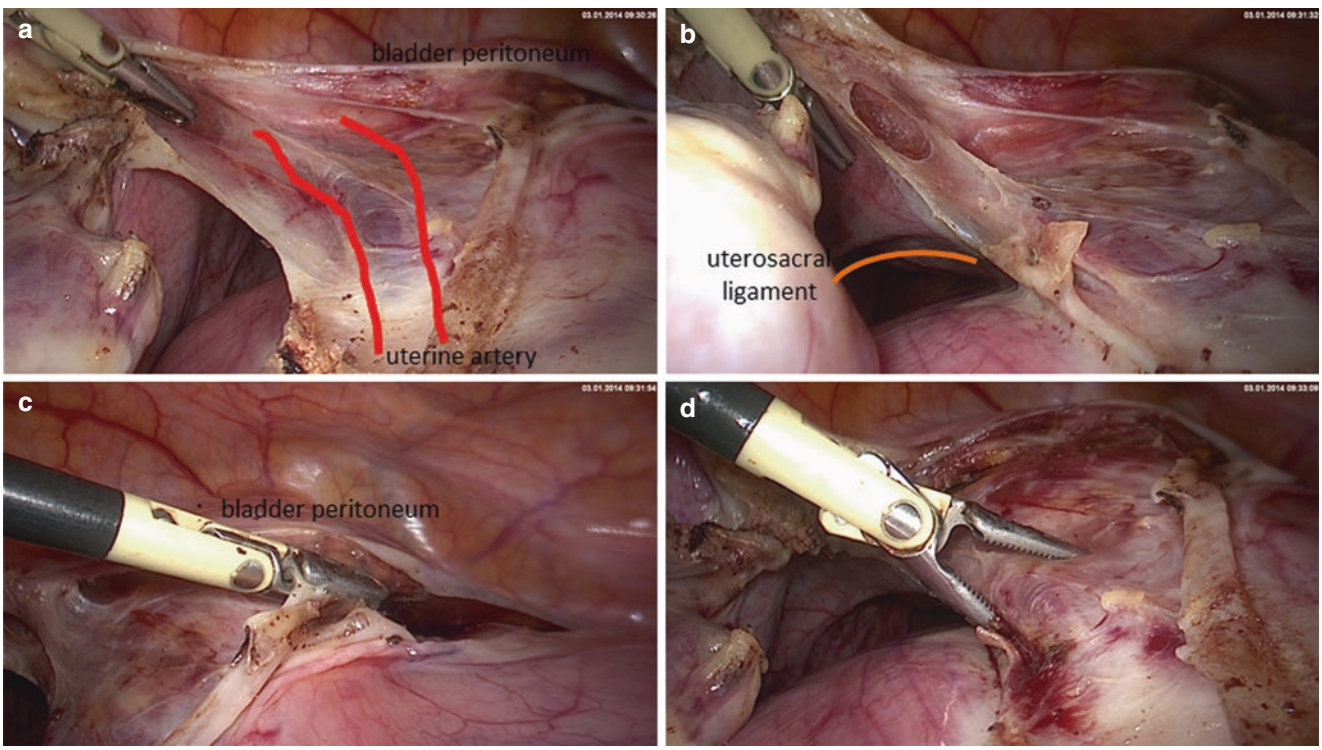

Fig. 35.56 Further opening of the bladder peritoneum and the broad ligament (**a**–**c**), and commencement of coagulation of the left uterine vessels (**d**). The uterine artery functions as an anatomic landmark leading downward (**a**). An intermediate glance at the back of the uterus shows that the cutting edge is above the conjunction of the sacrouterine ligaments

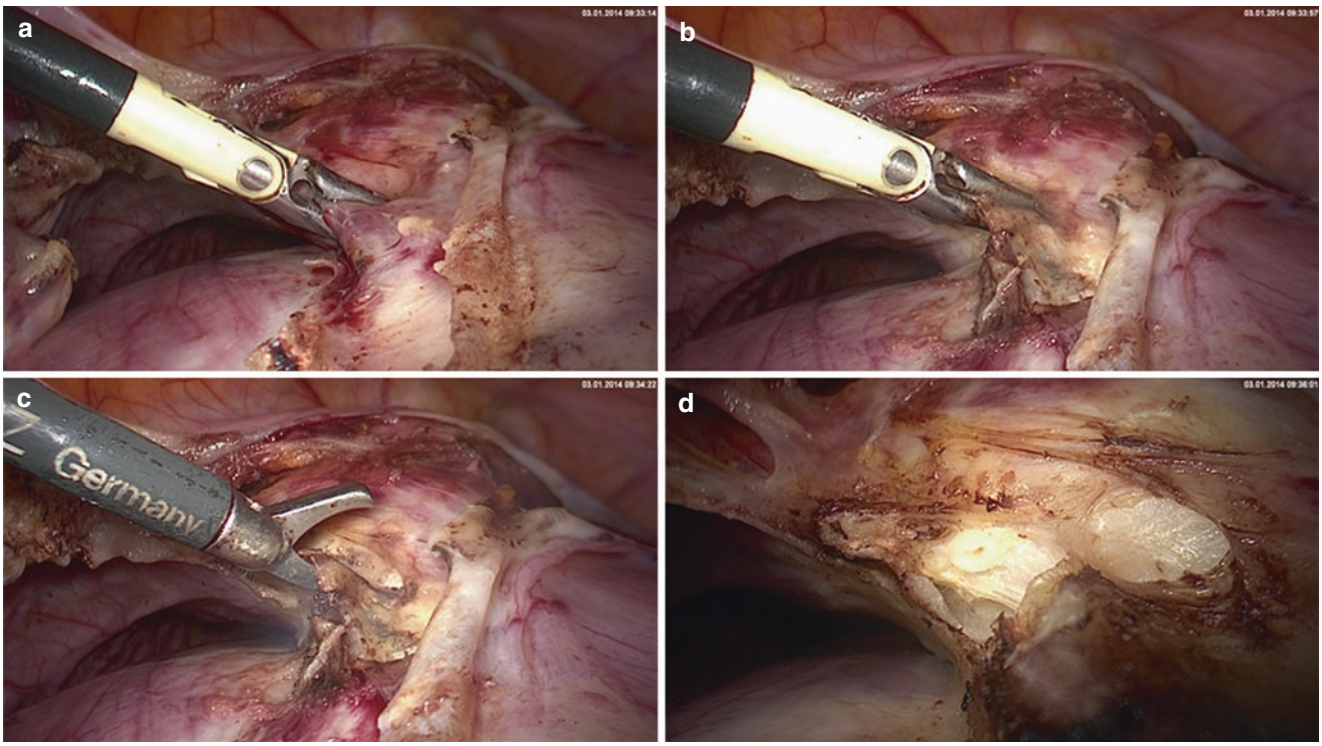

Fig. 35.57 Bipolar coagulation and separation of the uterine vessels on the left side. (**a**) The area of coagulation should include the upper parts of the artery to avoid any retrograde bleeding after dissection of the vessel (**b**). The color of the uterus changes to whitish/grey. (**c**–**d**): A deeper cut can be avoided by using the hook scissors; the uterine artery is dissected in two steps. This allows further coagulation of the tissue lying just behind the artery and avoids cumbersome venous bleeding

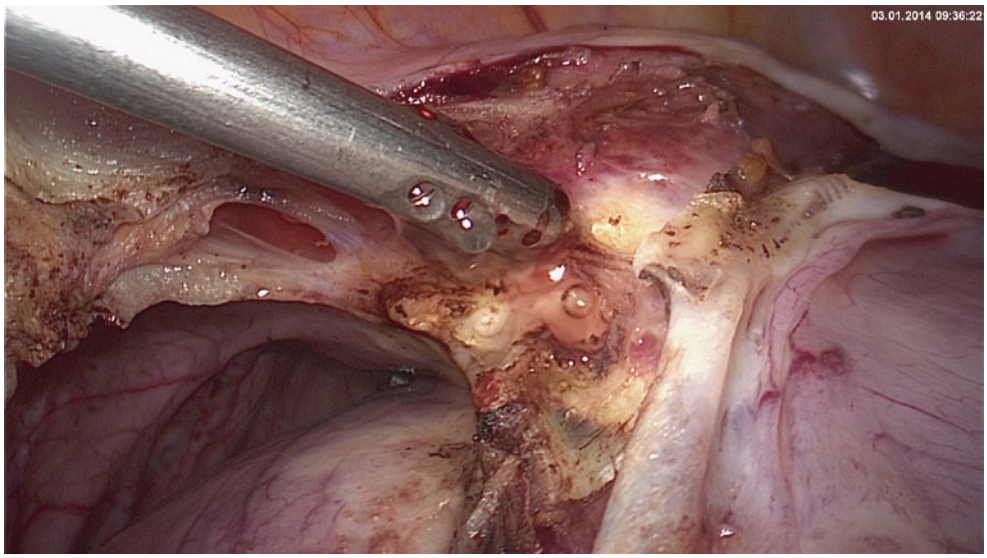

Fig. 35.58 Visualization of the separated left uterine pedicles. A few drops of physiological saline solution render the bipolar coagulation more effective because of better electrolyte flow, especially when the field of operation is very dry

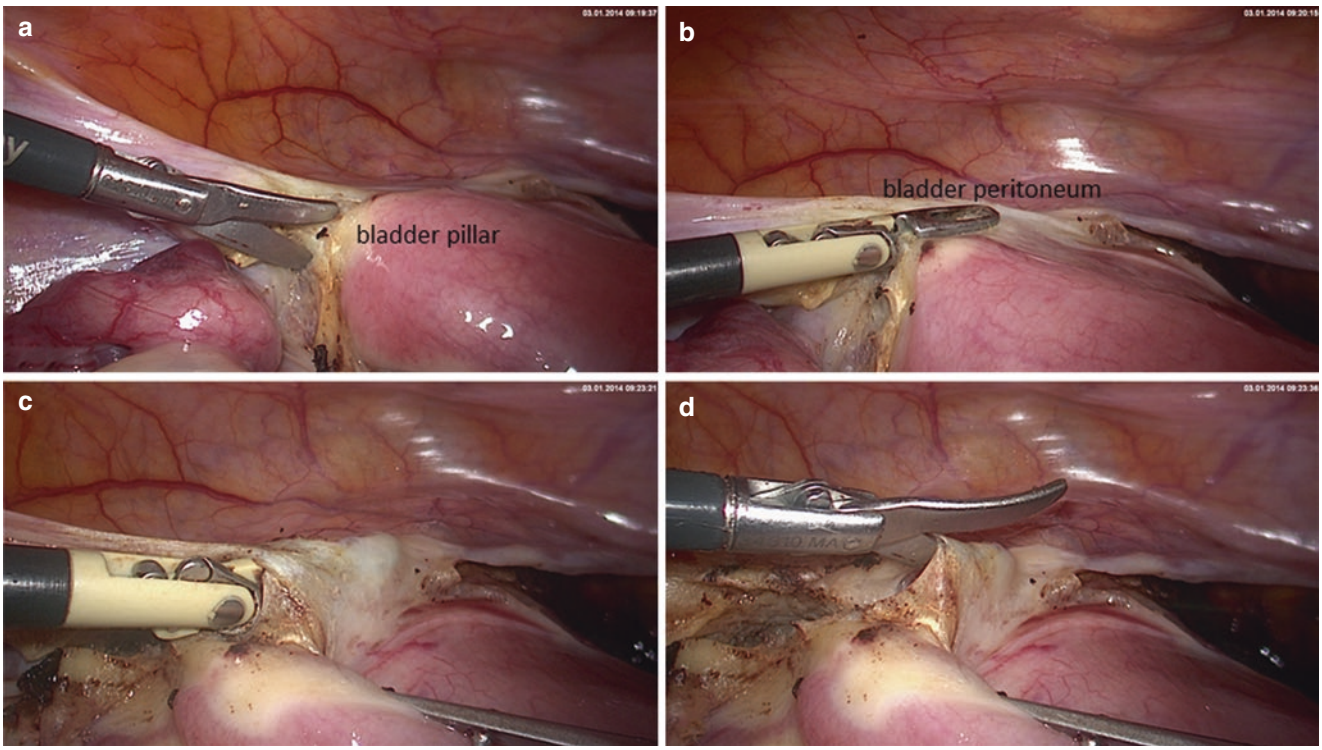

Fig. 35.59 (**a**) Final dissection of the bladder pillar and the bladder peritoneum (**b**) from left to right, (**c**) allowing the CO_2 distension medium to show the way. (**d**) The bladder is pushed safely downward from the field of operation and the peritoneal line of the vesicouterine fold is easily recognized

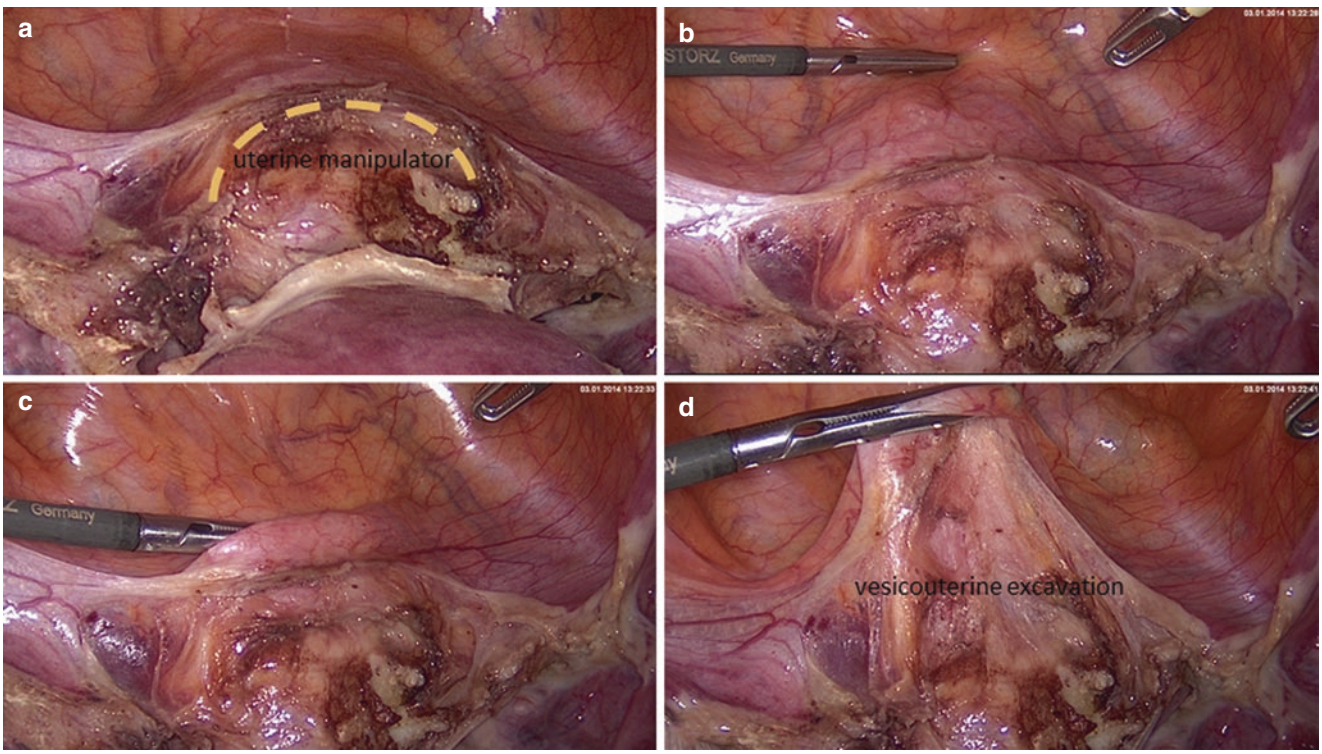

Fig. 35.60 Visualization of the intrauterine manipulator, if inserted (**a**). (**b**, **c**): The bladder cannot be identified immediately in all cases and is safely avoided. The bladder can be localized exactly when a blunt instrument is used to push the suspected bladder towards the cervix from the balloon of the Foley catheter. (**d**) Once the bladder has been identified, it is elevated. Vesicouterine excavation can be used to push the bladder further downward

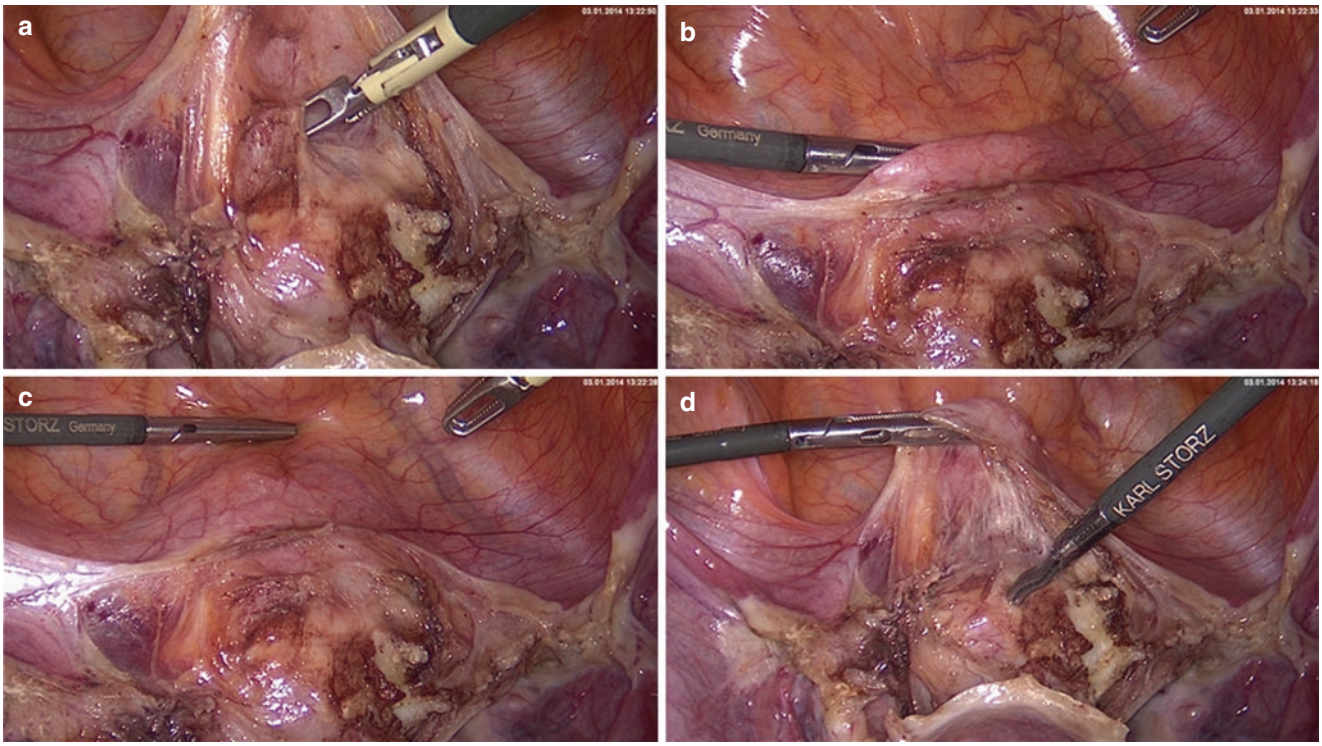

Fig. 35.61 (**a**) Minimal dissection of the bladder peritoneum by about 1 cm for LSH and 2-3cm for LTH, by opening the vesicouterine excavation. (**b**) This is easier when a manipulator is inside the vagina and the cervix is pushed upward. The anatomical landmarks of the bladder are hard to find. Therefore it is easier if the whole organ is pushed upwards and (**c**) back, thereby displaying the anatomical borders. (**d**) The step can also be performed by traction alone. Once the vesicouterine space has been opened, exposure is easily achieved with a blunt instrument while avoiding bleeding

Step 4

4.1 In laparoscopic supracervical hysterectomy, resection of the uterine corpus is performed at this stage of surgery. The steps of exposure are very similar until this point, except for the fact that there is no need for a manipulator and elevation of the uterus is achieved by traction. The corpus of the uterus is cut with a monopolar loop and the cervical channel coagulated to prevent spotting. The cervical channel should be closed because of the risk of ascending infection. Simultaneously, the cervix can be suspended using a strong monofilament suture with extracorporeal knotting (Figs. 35.62 and 35.63).

4.2 Resection of the vagina from the cervix with the monopolar hook by stretching the manipulator firmly cranially. Intrafascial dissection is performed, leaving the sacrouterine ligaments almost completely in place (Figs. 35.64, 35.65 and 35.66).

The uterus is then extracted through the vagina or positioned in the vagina to prevent loss of intraabdominal pressure while still fixed to the manipulator (Fig. 35.67). A large uterus must be morcellated either intraabdominally or transvaginally. In cases of a large benign uterus, visible myomas can be enucleated or the large uterus cut into several smaller pieces which are then extracted through the vagina. As a result, the incision in the lower abdomen need not exceed 5 mm and postoperative pain or the risk of hernia is minimized. Alternatively, a 10–12-mm electromorcellator is used to dissect the material, which is then extracted through the abdominal wall. The cutting edge of the morcellator must always be visible during morcellation. Evidence of the absence of any malignancy must be obtained earlier by appropriate preoperative diagnostic investigation. The patient must be informed in advance about the fact that the uterus, depending on its volume, may need to be morcellated.

Step 5 (Classical Closure)

After removing the uterus, the vaginal cuff and the peritoneum are closed with two Vicryl 0 Z-sutures, or with a running suture with or without separate knotting of the lateral edges. Suturing may be performed intraabdominally or extraabdominally. This simple and economical concept can be adapted to almost all techniques of open surgery.

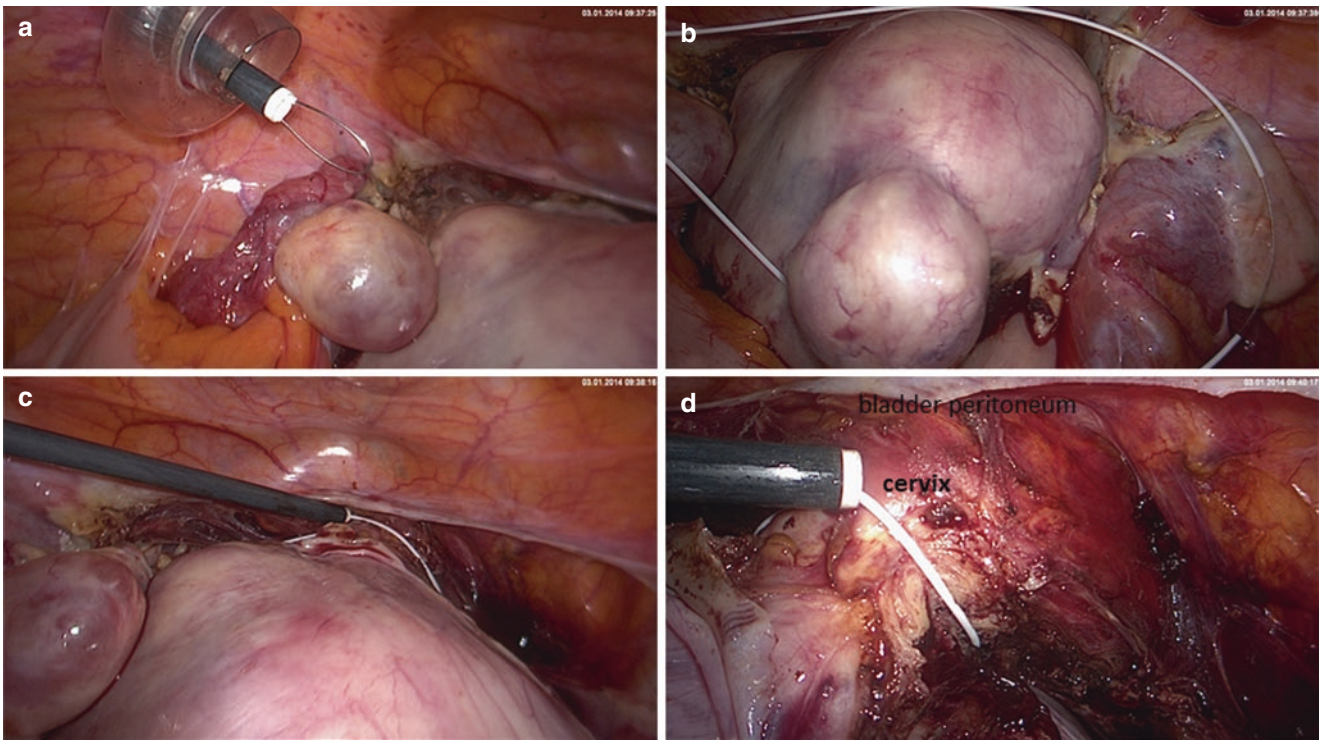

Fig. 35.62 (**a**) Introduction of a monopolar cutting loop for the cervix and (**b**) exact placement prior to activation. (**c**) The whitish uterus is lifted over the loop and (**d**) the loop is tightened gently. Correct placement between the stumps of the uterine artery and above the conjunction of the sacrouterine ligaments is checked

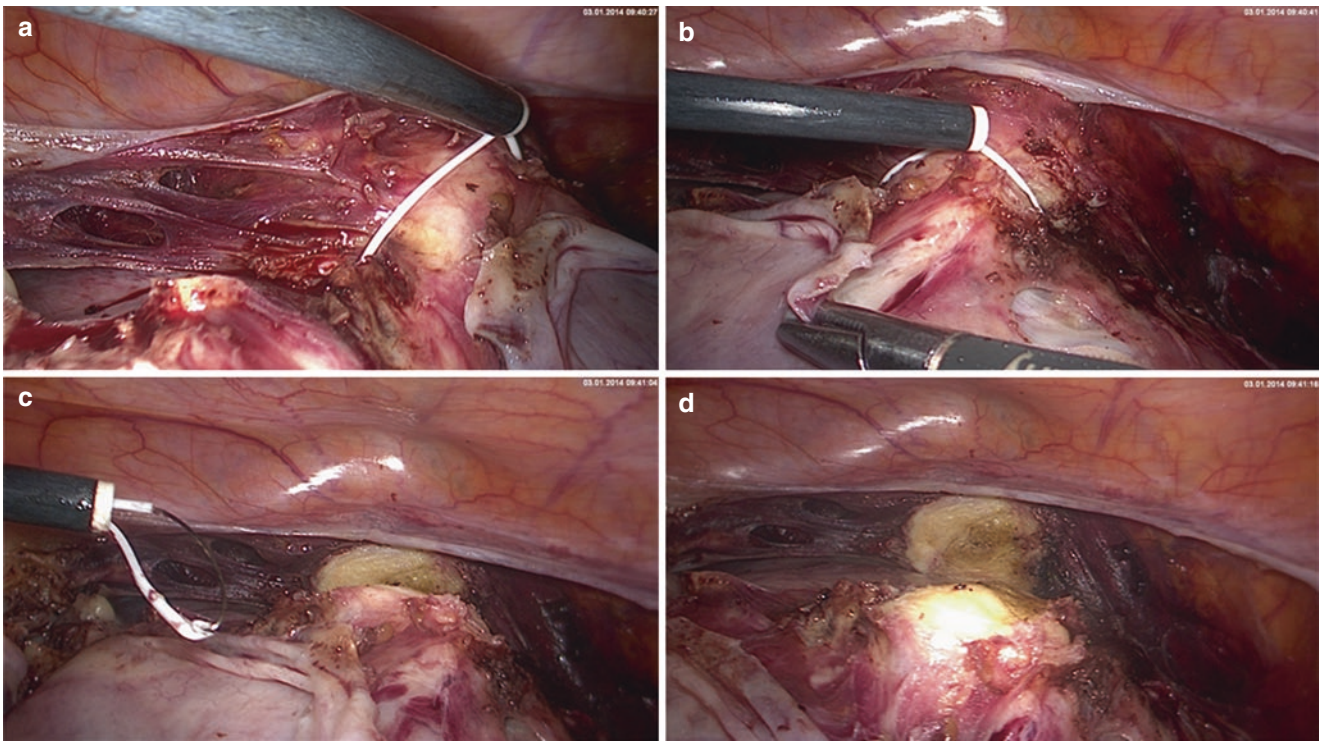

Fig. 35.63 Resection of the uterine corpus from the cervix after placing the cutting loop with the cutting point on the posterior cervix (**a**, **b**). Correct placement between the stumps of the uterine artery and above the conjunction of the sacrouterine ligaments is monitored. Dissection of the cervix and the uterus is performed (**c**, **d**), in this case LSH by monopolar current only in the non-isolated field. When cutting, the uterine corpus is pulled upward to achieve a retrograde conus (**b**, **d**)

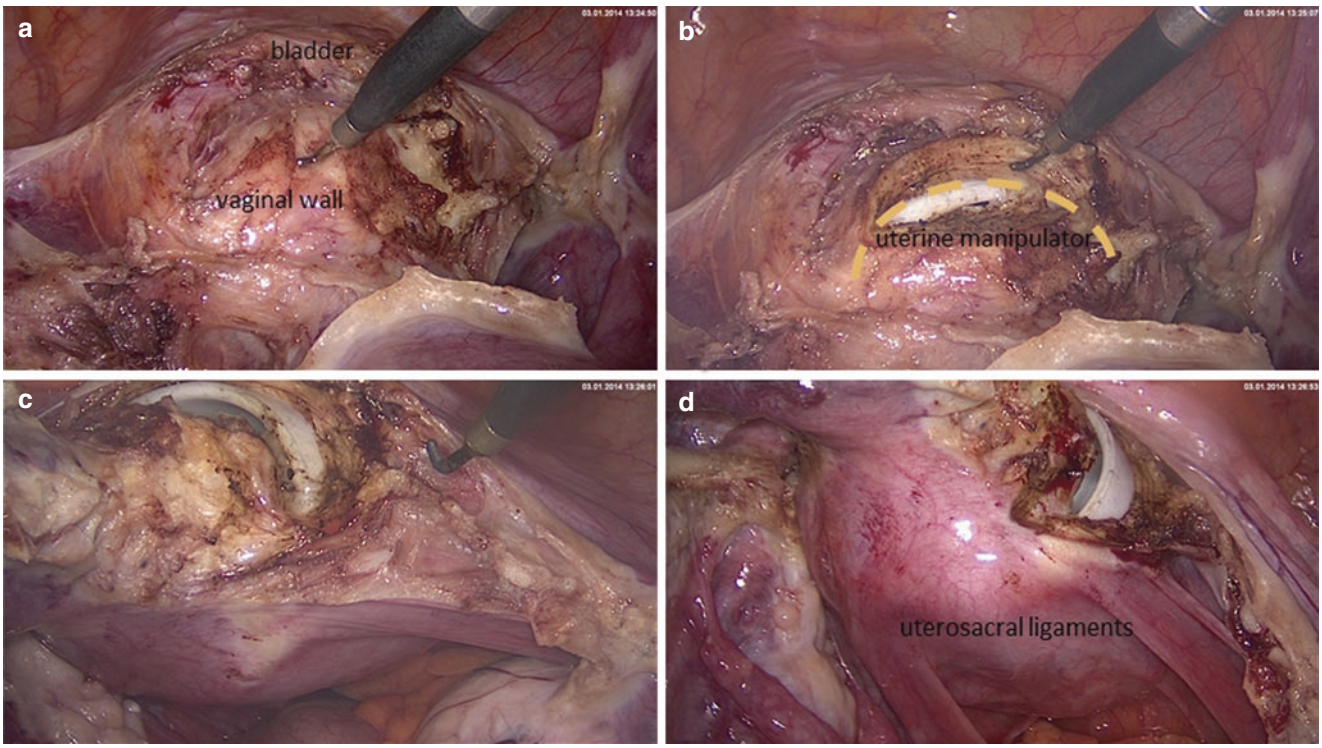

Fig. 35.64 In this case of LTH, the distance between the vagina and the bladder is increased because of exposure of the bladder peritoneum (**a**). The intrauterine manipulator is firmly placed in the abdomen and dissection of the uterus from the vagina is performed in a stepwise manner (**b**–**d**). The conjunction of the sacrouterine ligaments is left in place

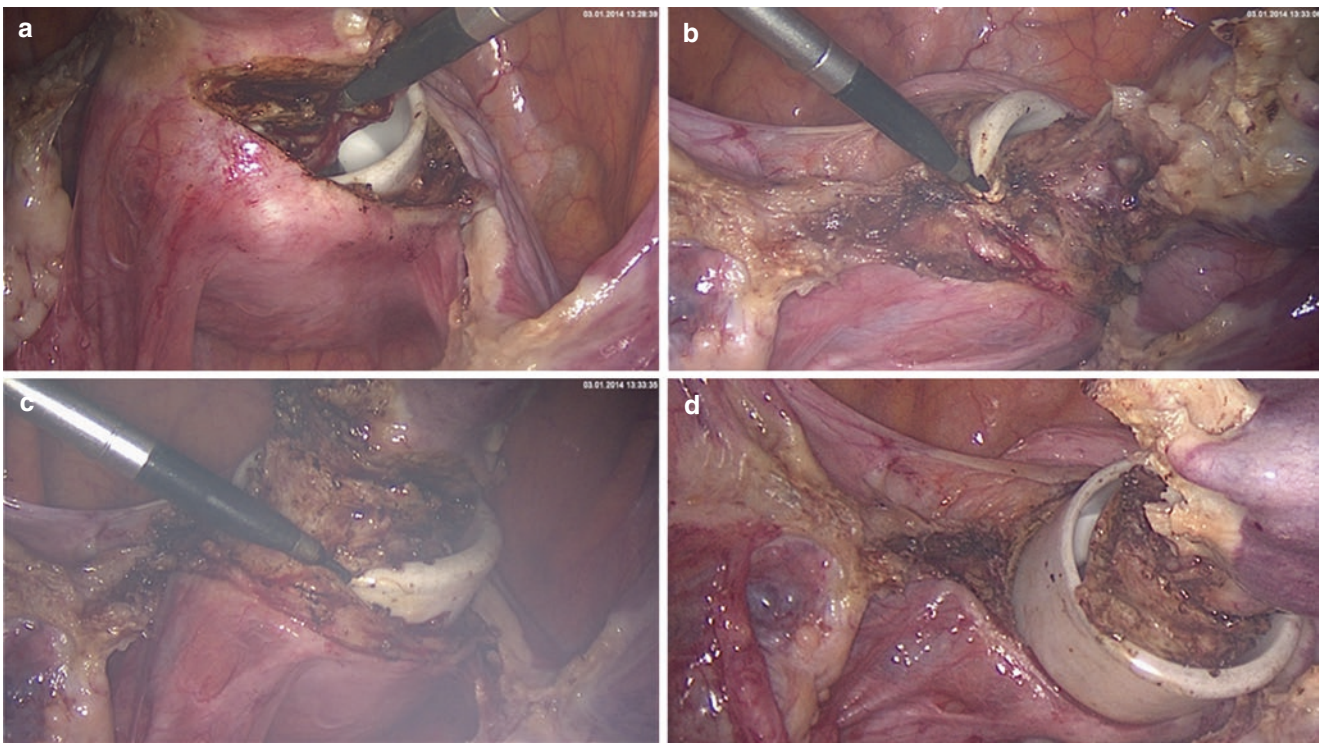

Fig. 35.65 Completion of the dissection of the vagina from the cervix (**a**–**c**) and commencement of retraction of the uterine cervix, still grasped by the manipulator forceps, transvaginally. Excessive lens fogging caused by the monopolar current and the sharpness of the monopolar hook make it necessary to perform precise exposure under full vision. This can be done during simultaneous retraction/manipulation with the use of the 30 ° optic device. (**d**) The surgeon's vision may worsen immediately when CO2 gas leaks through the colpotomy. Visibility may then become extremely poor and the use of monopolar energy hazardous

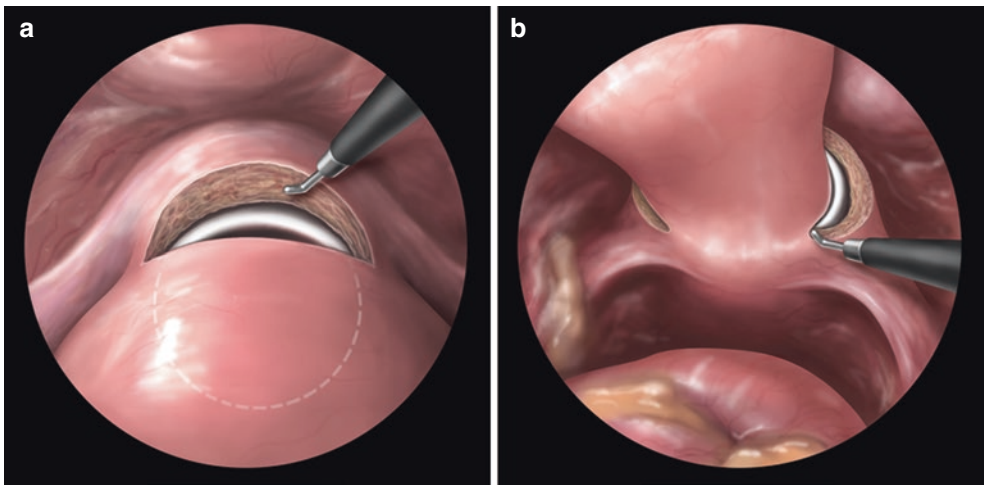

Fig. 35.66 Schematic illustration of uterine dissection. (**a**) Colpotomy is usually started in the anterior part, on the palpable manipulator cap. (**b**) The intrafascial hysterectomy can be completed with the sacrouterine ligaments in view

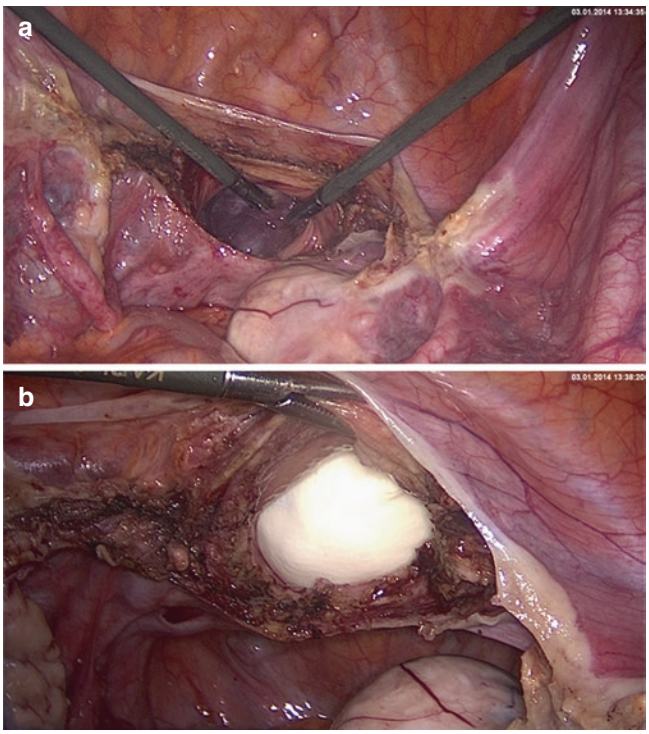

Fig. 35.67 Retraction of uterus through the vagina (**a**).Introduction of a cotton swab-filled glove transvaginally to hinder breakdown of the CO_2 pneumoperitoneum (**b**)

Step 5(Alternative Closure Technique Emphasizing Prolapse Prevention)

A Technique for Stable Fixation of the Vaginal or Cervical Stump

Vaginal closure with Te Linde suturing technique modified by Schollmeyer

Hysterectomy is known to be associated with a high risk of pelvic organ prolapse; the risk is especially high among multiparous women. This may necessitate pelvic organ prolapse surgery. Given the current high life expectancy of women, organ prolapse may pose a problem in later life and also difficulties in surgical repair (thrombosis, embolism, and infection) [35].

The suturing technique of Te Linde, known from abdominal hysterectomy for the closure of the vagina, was modified for laparoscopic use by Bruno van Herendael and further modified by Thoralf Schollmeyer [36, 37].

5.1 Cautious coagulation of the vaginal edge [38] is followed by suturing of the vagina. Coagulation should be performed very carefully to avoid postoperative necrosis of the vaginal stump. Slight residual bleeding is addressed by sutures incorporating the complete vaginal wall. The uterus is either still in the vagina or a glove filled with swabs is placed in the vagina to avoid loss of the pneumoperitoneum. Usually a curved needle and PDS 1–0 is used for single knot suturing, with extracorporeal knots and intracorporeal safety knots. Alternatively, sledneedles or even straight needles can be used for easy handling in and out of the 5-mm trocars.

PDS 1–0 extracorporeal knots are used for the following reasons:

1. The monofilament thread slides easily through the tissue and does not cause additional damage.
2. The monofilament PDS material minimizes the risk of vaginal stump infection.
3. The long half-life of the suture material minimizes the risk of vaginal stump dehiscence [38].
4. Extracorporeal knots provide additional strength.

Optionally, both sacrouterine ligaments may be attached to the posterior vaginal wall to prevent vaginal prolapse (McCall culdoplasty).

5.2 Corner sutures

The peri-cervical ring is pierced by performing a suture in the right vaginal corner, followed by the corresponding vaginal epithelium. The sutures are made at a distance from the urinary bladder to minimize the risk of bladder laceration (Figs. 35.68 and 35.69).

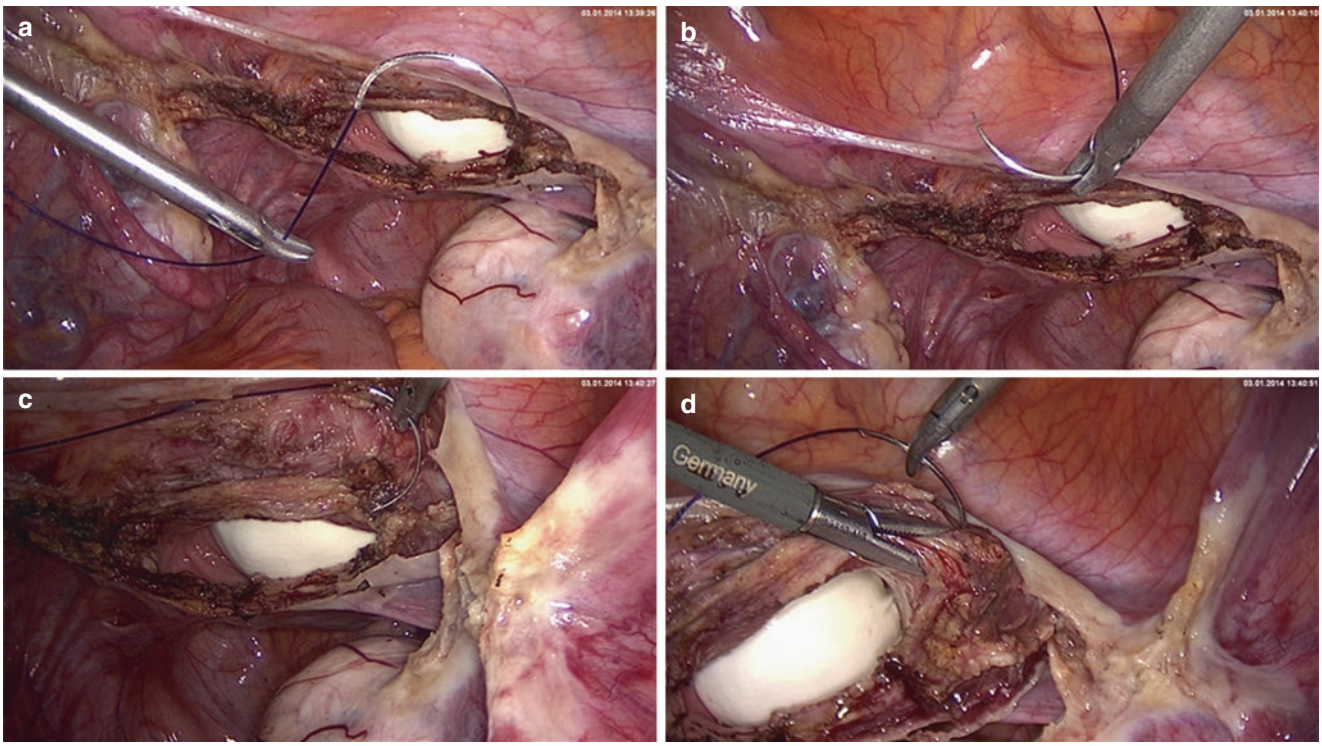

Fig. 35.68 LTH: Right corner suture uniting the anterior and posterior vaginal wall, the posterior peritoneum, and the right sacrouterine ligament. The bladder can be omitted under sight. (**a**) Insertion of the needle and (**b**) positioning of the needle in the needle holder. (**c**) The disadvantages of conventional laparoscopy need to be overcome by surgical quality. (**d**) The forceps must be sharp in order to securely grab the vaginal epithelium. When the suture incorporates the vaginal wall alone and omits the epithelium, there is a high likelihood of postoperative granulomas

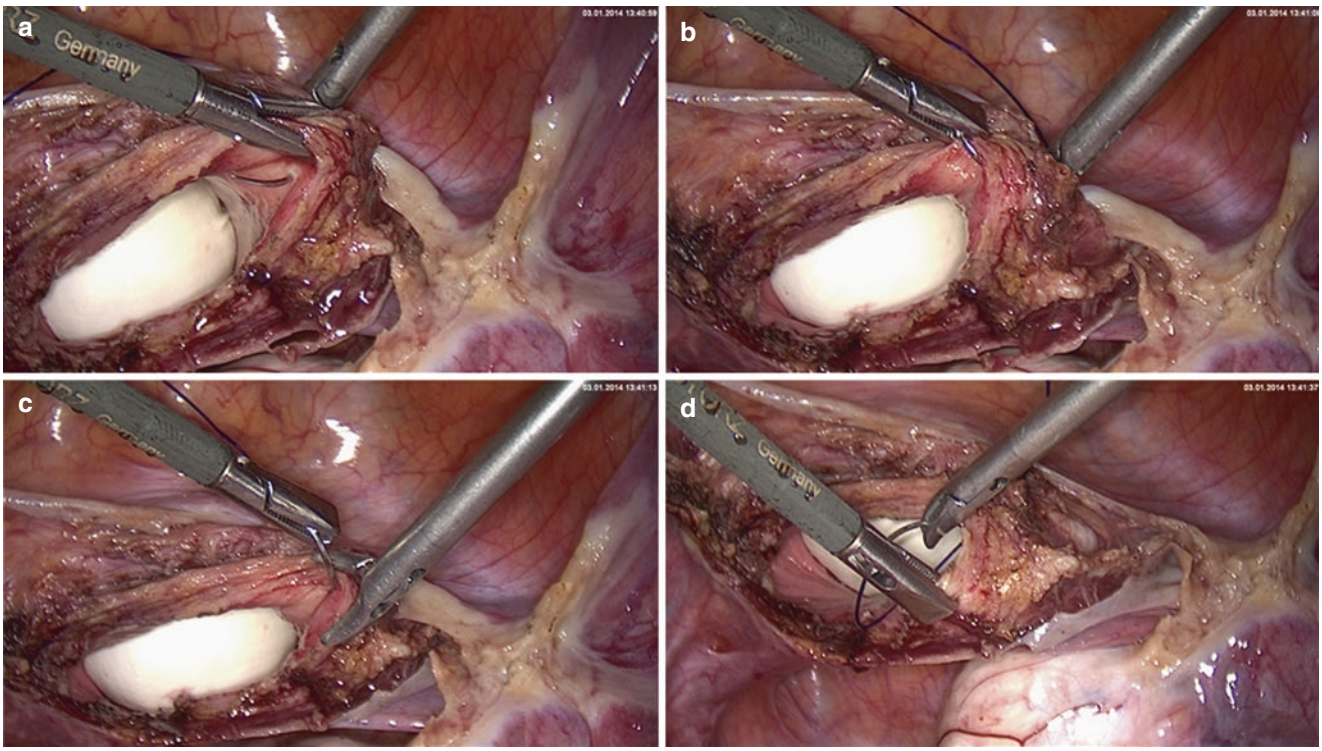

Fig. 35.69 LTH: (**a**) Continuation of the right corner suture. (**b**) The 30° optic device helps to look into the vagina from below when rotating and (**c**) picking up the needle (**d**) from above. The strong paravaginal tissue is grasped in large units

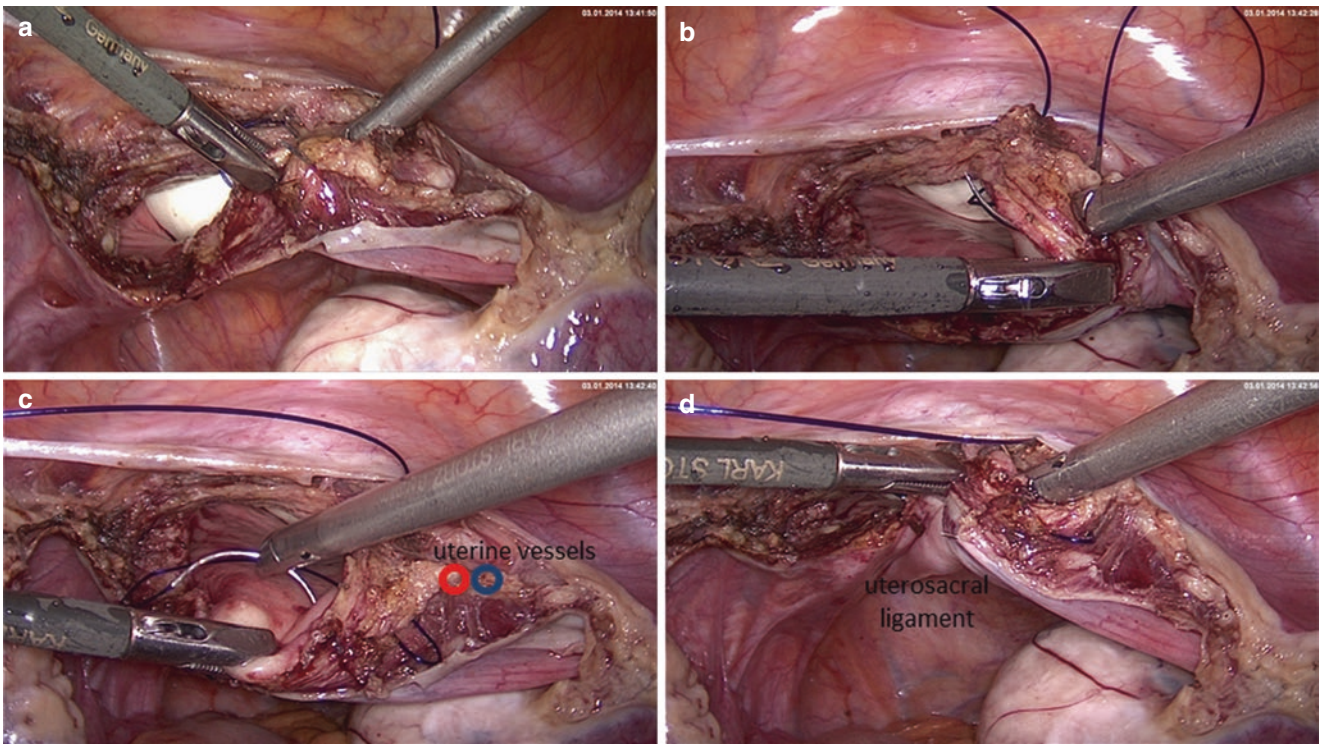

Fig. 35.70 LTH: (**a**) Continuation of the right corner suture while (**b**) leaving out the vessels to the side, (**c**) performing an omega suture (according to Schollmeyer), (**d**) and then grabbing the right sacrouterine ligament. The vessel stumps are omitted and lateralized. When using this type of suture, the vessels are compressed mechanically

5.3 In the second step, the needle is passed through the medial aspect of the cardinal ligament in front of the uterine vessels (Fig. 35.70). The second step involves the structures supporting vaginal wall suspension. Extracorporeal knotting with the placement of a deep and strong monofilament suture allows the surgeon to grasp a large quantity of tissue and smoothly glide through the tissue without causing damage (Figs. 35.71, 35.72 and 35.73).

5.4 Subsequent back-stitching of the vagina is followed by passing the needle through the vaginal epithelium and then, in the third step, through the sacrouterine ligament. The last step may be omitted when the ligament is stitched again once or twice to shorten it. In cases of pre-existing descent, this is absolutely essential.

The needle can now be withdrawn and the suture is completed with an extracorporeal Roeder knot, secured by 2–3 intracorporeal knots (Fig. 35.74). This procedure is repeated on the contralateral side and ensures that all parts of the endopelvic fascia (vesicouterine, cardinal and sacrouterine ligaments) are connected (Figs. 35.75, 35.76 and 35.77).

Step 6

Vaginal Closure

The remaining vaginal opening in the middle can now be closed with two U- or Z-sutures. These ensure both vertical and horizontal compression of the tissue, and minimize the risk of a vaginal stump hematoma. Neither peritonealization nor drainage is necessary (Figs. 35.78 and 35.79). Physiological reperitonealization occurs during the first two weeks after the operation. Any additional peritoneal suturing might cause encapsulation of seroma or hematoma and increase the likelihood of postoperative infection as well as pain. If still inside, the uterus or the swab-filled glove is now taken out of the vagina. Figure 35.80 provides an overview of the procedure.

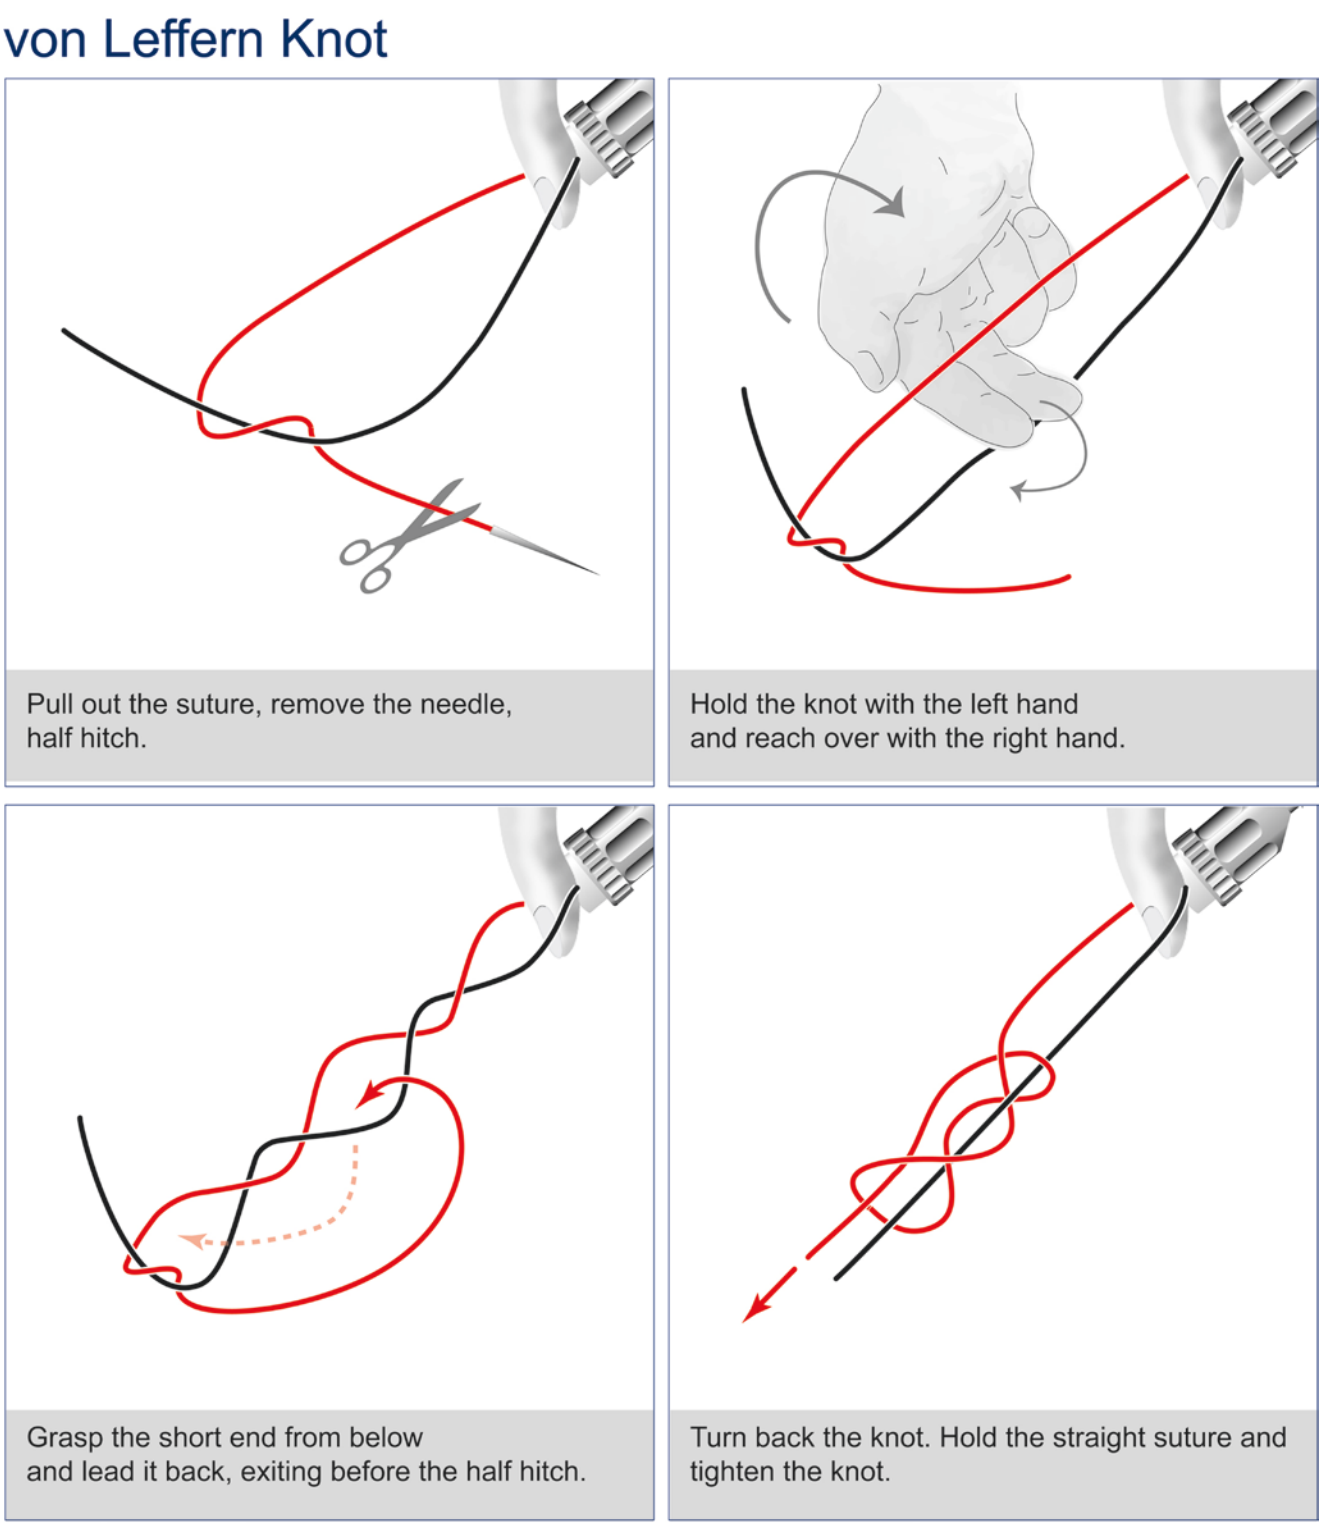

Fig. 35.71 LSH: Finalizing the extracorporeal knot of the PDS suture by using the "von Leffern knot"

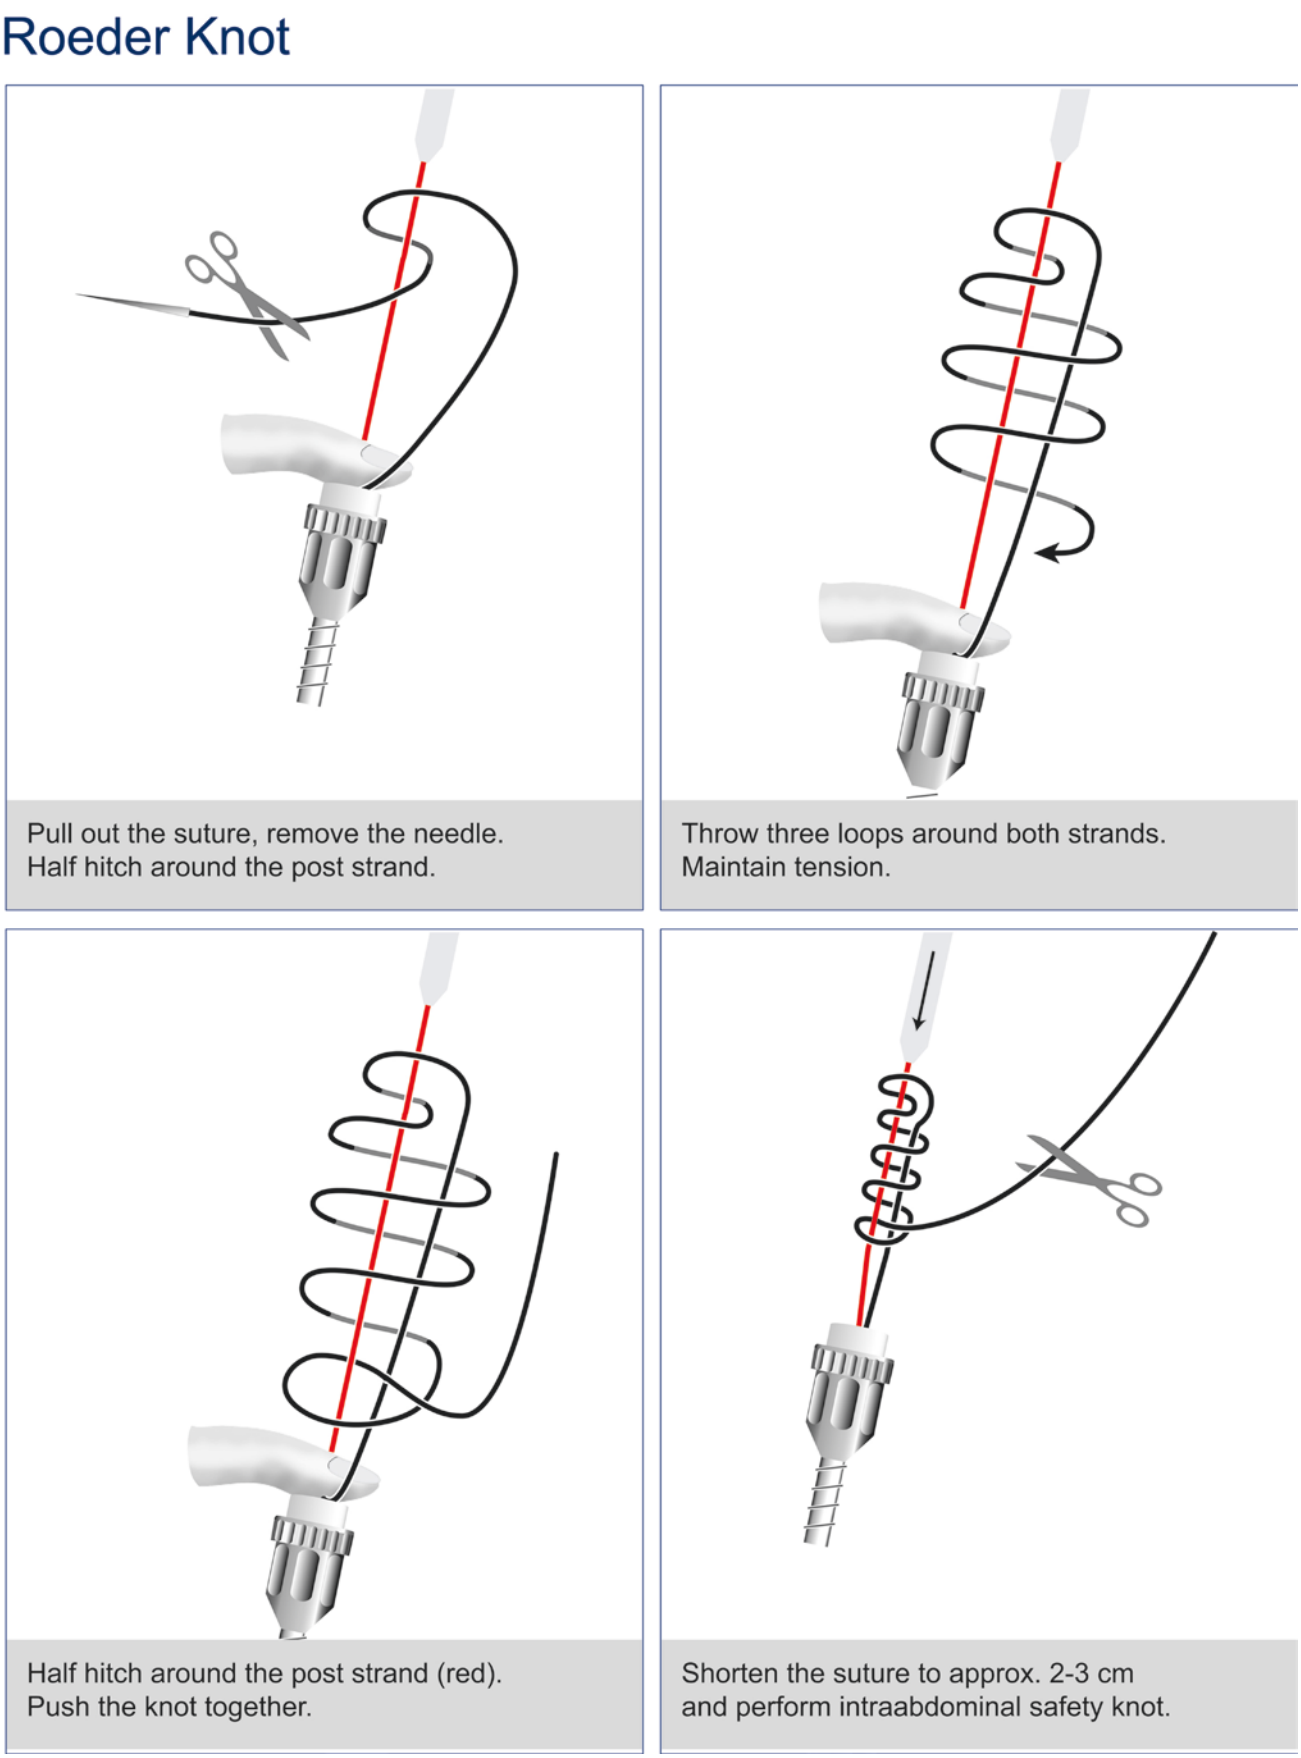

Fig. 35.72 "The Roeder" knot

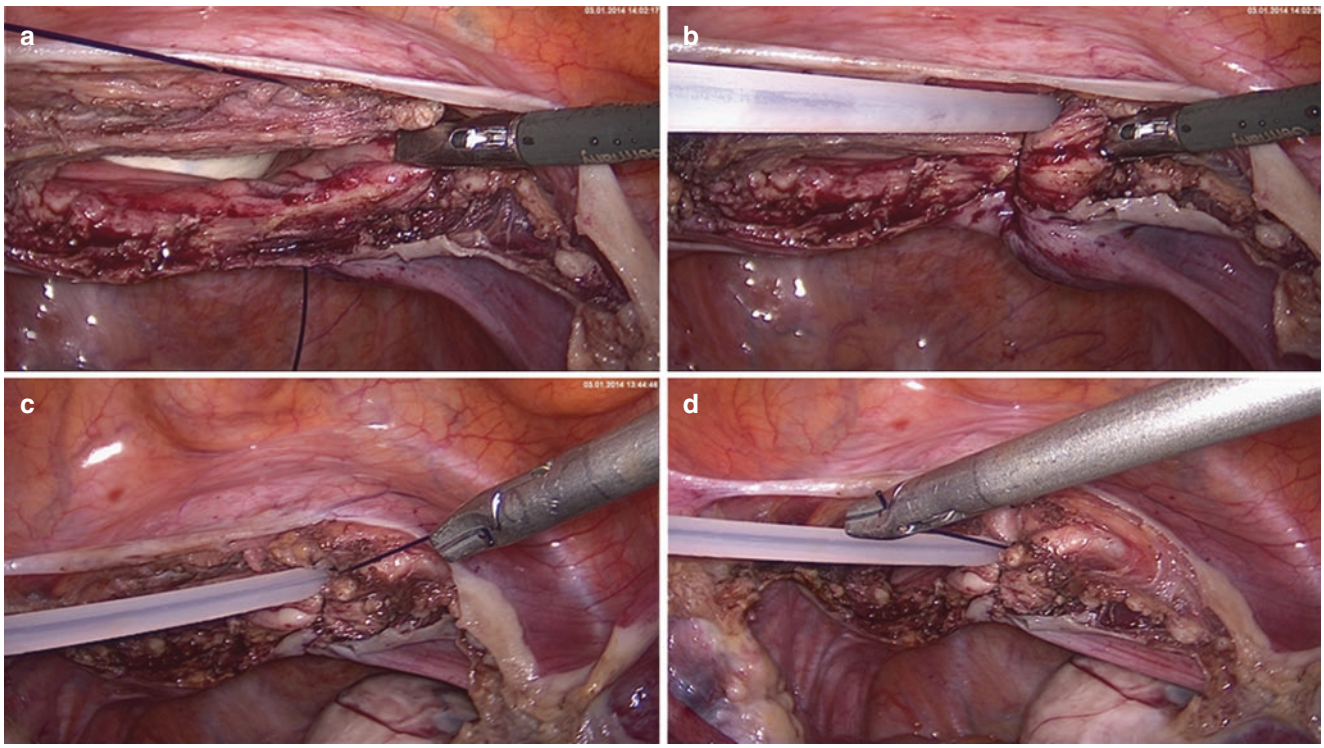

Fig. 35.73 LTH: (**a**) Completion of the extracorporeal "Roeder" or "von Leffern" knot by pushing it down with a plastic pushrod (**b**–**d**). The edge is pulled into the abdomen to avoid disturbance of intravaginal sensitivity

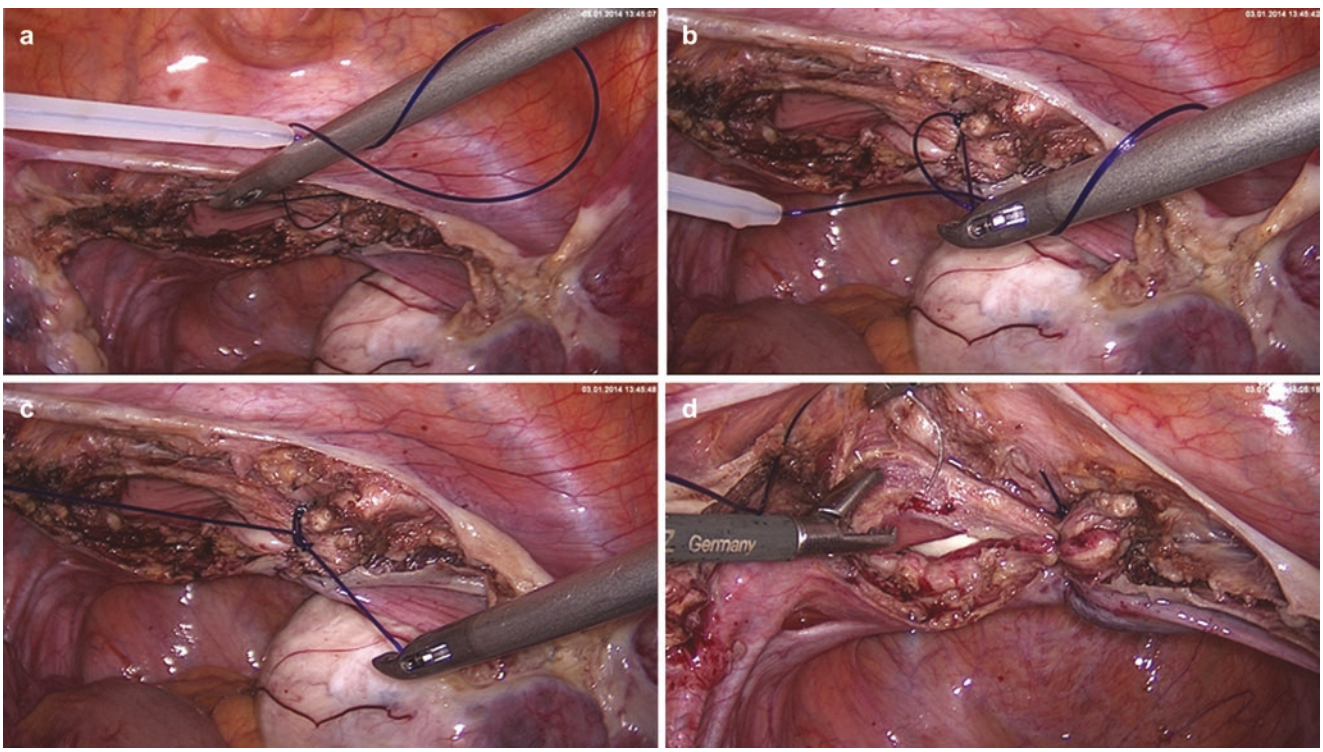

Fig. 35.74 LTH: (**a**) Performance of an intracorporeal safety knot (**b**) by placing the right corner stitch (**c**) and tightening of the threads. Here, it can be clearly visualized that extracorporeal knotting allows the surgeon to push the knot deeper into the tissue than intracorporeal knotting. (**d**) The same knot is performed on the left side, both edges are dry and everted

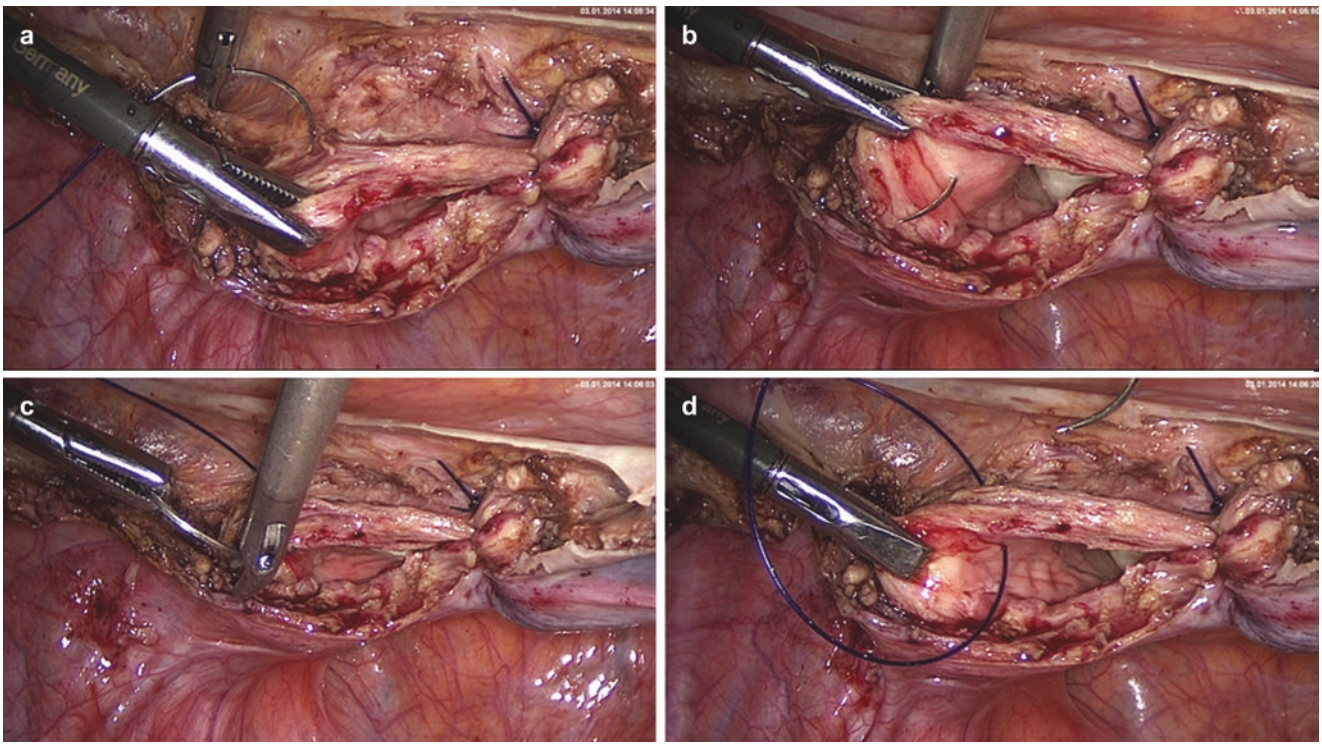

Fig. 35.75 LTH: (**a**) Left corner suture uniting the anterior and posterior vaginal wall, the posterior peritoneum, and the left sacrouterine ligament. The bladder can be omitted under sight. After positioning of the needle, (**b**) paracolpium and epithelium are grabbed and perforated by the needle. (**c**) The grasper of the left hand holds the needle and (**d**) the needle holder only rotates once it has touched the tissue, thereby avoiding tearing of the tissue. The forceps must be sharp in order to securely grasp the vaginal epithelium. When the suture incorporates the vaginal wall alone and omits the epithelium, there will be a high likelihood of postoperative granuloma or bleeding

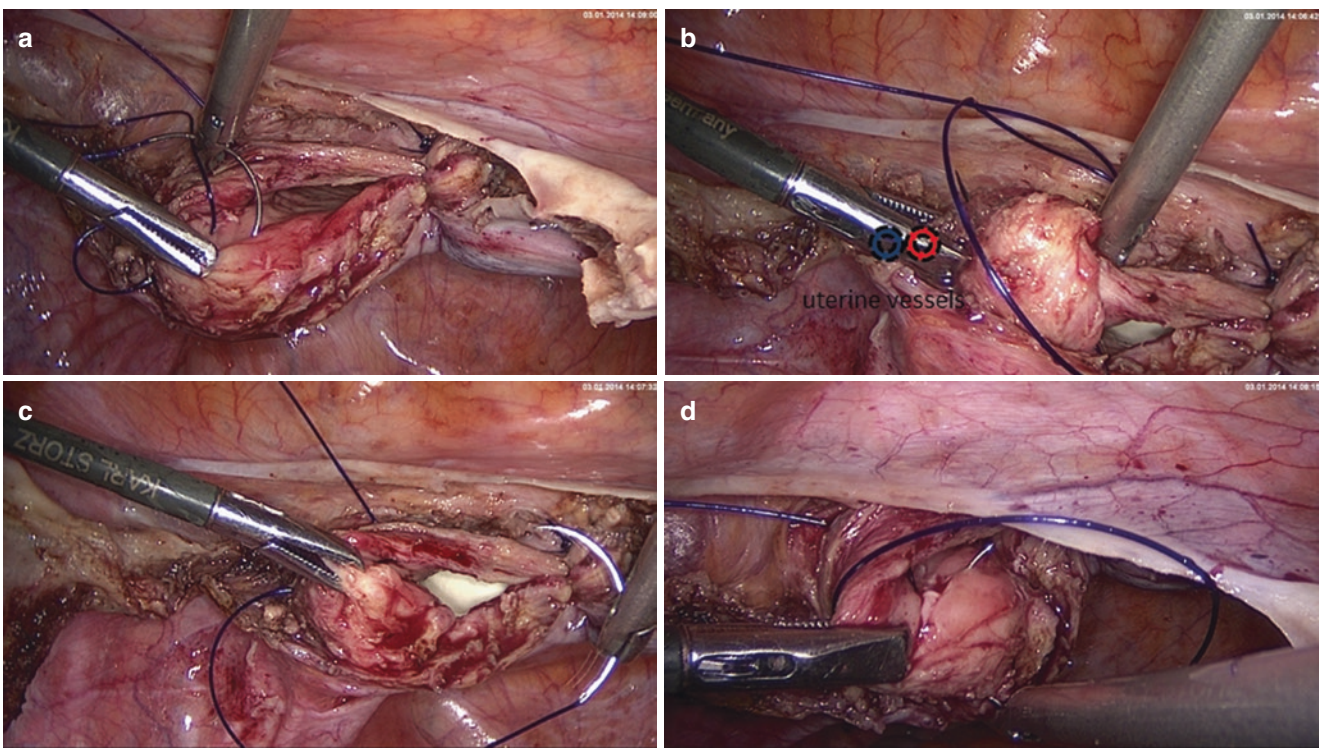

Fig. 35.76 LTH: Continuation of the left corner suture. (**a**) Grabbing and perforation of the dorsal vaginal wall with the needle, (**b**) avoiding the laterally positioned vessels (**c**–**d**) in an omega fashion. When using this type of suture, the vessel stump is omitted and compressed mechanically. Approximately 1 cm of the vaginal wall should be included in the suture

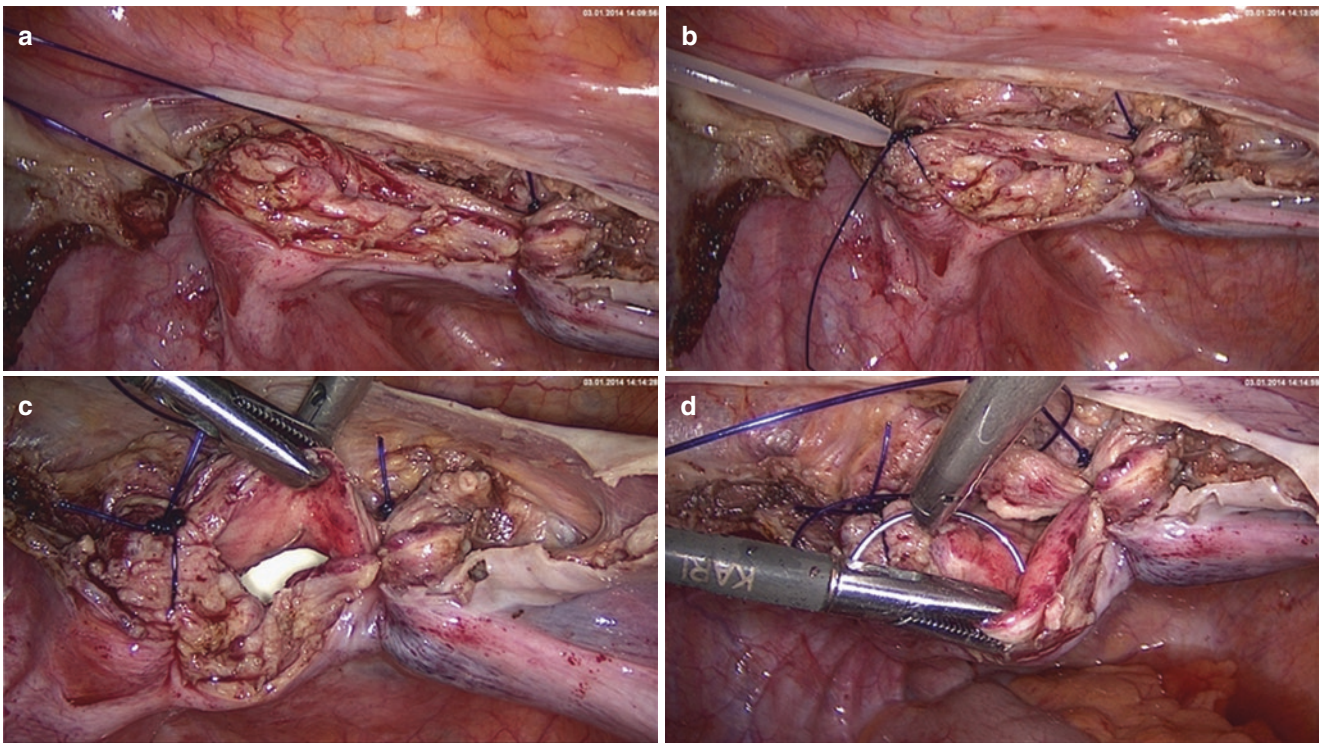

Fig. 35.77 LTH: Completion of the left corner suture.The extracorporeal knot is pushed down by the pushrod (**a**–**c**). Commencement of a U-stitch or a Z-stitch in the middle (**d**). When the vaginal cuff is not entirely dry, it will be easier to close the edges first. A large part of the bleeding then stops automatically and further coagulation will not be necessary. Severe coagulation on the vaginal wall might increase the risk of vaginal stump infection or dehiscence

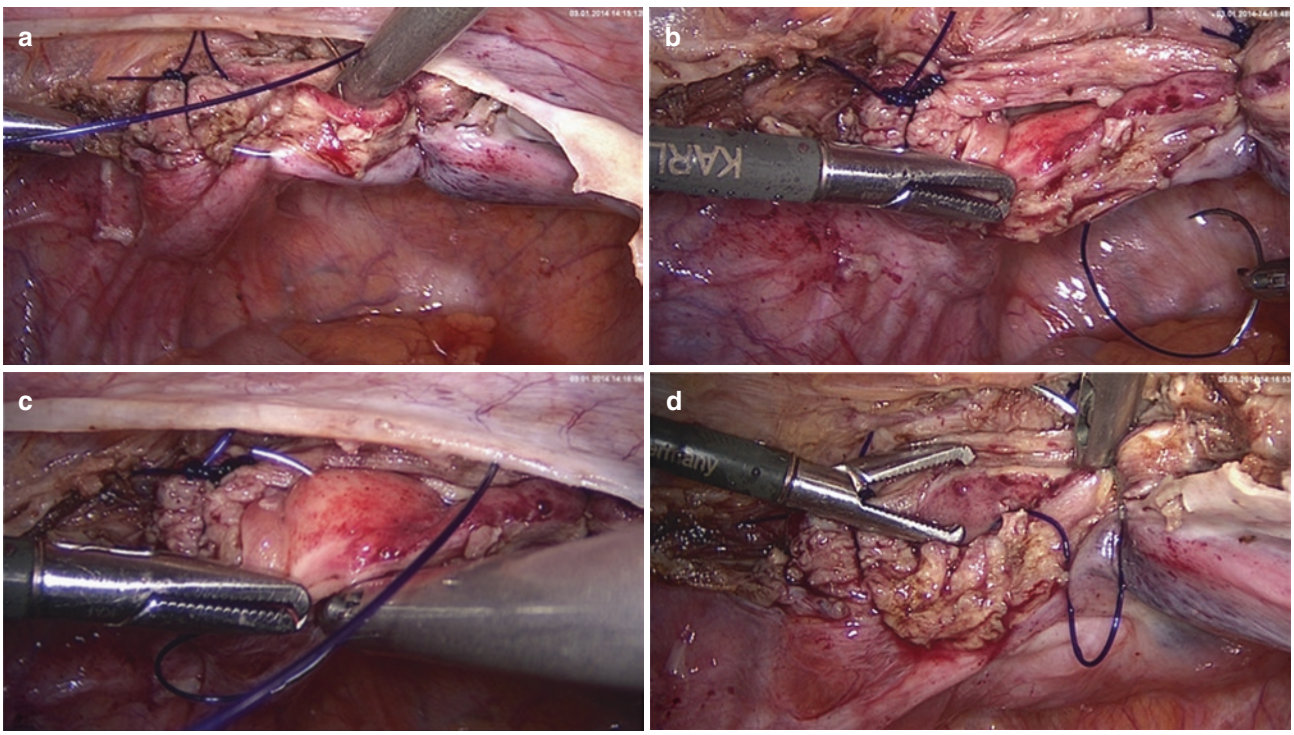

Fig. 35.78 LTH: Final closure of the remaining vaginal opening with (**a**) a U-suture or a Z-suture. (**b**) Grabbing the anterior and posterior wall and (**c**) going straight back. (**d**) The left hand correctly positions the tissue which is to be grabbed, as is necessary in conventional laparoscopy. When using the U-suture, the suture end should reach the bladder to prevent bowel damage

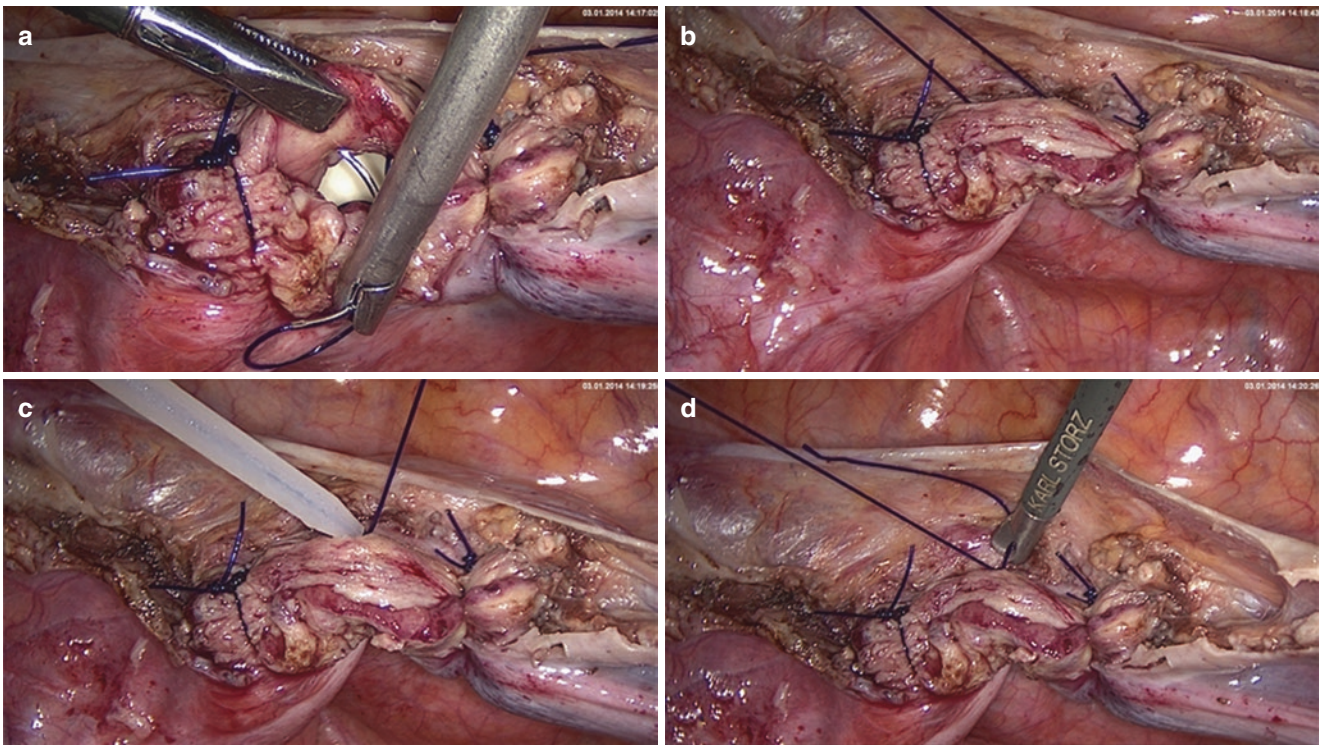

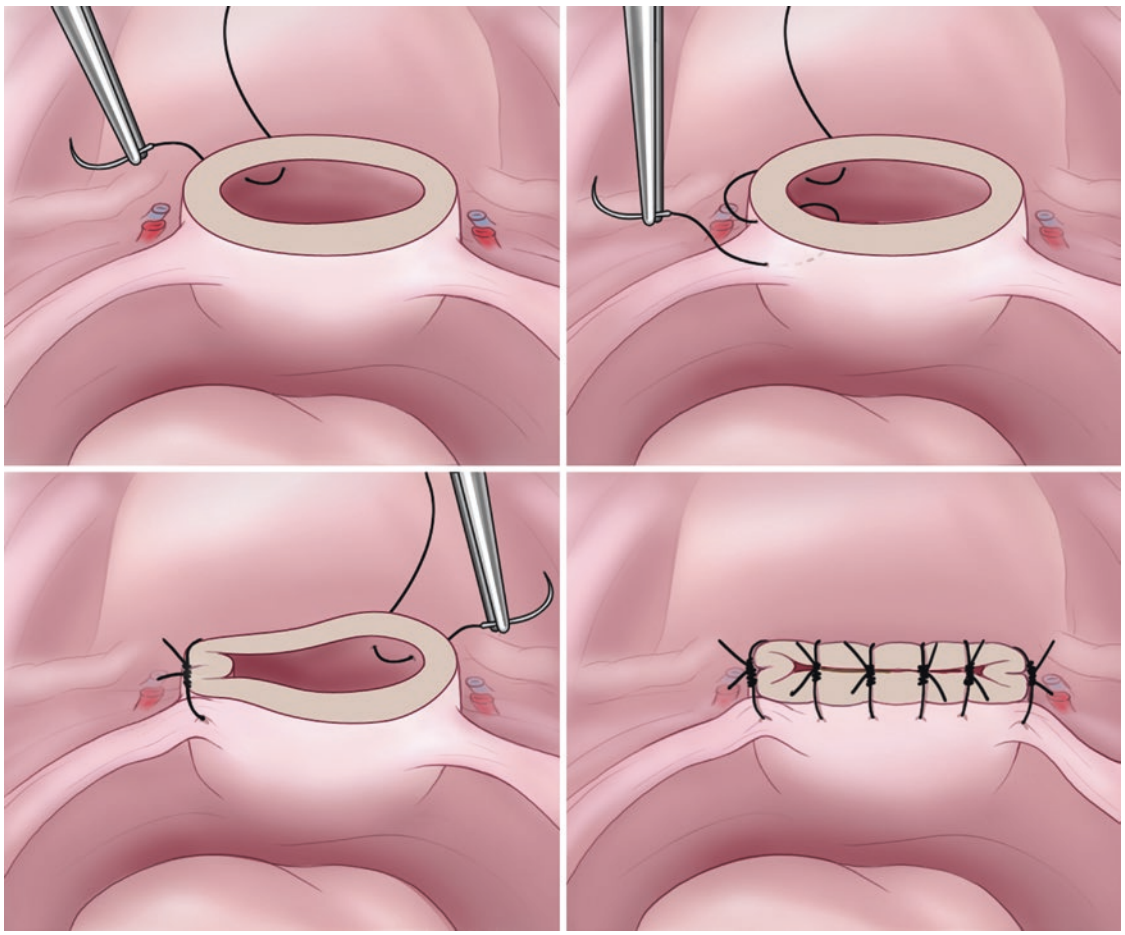

Fig. 35.79 LTH: (**a**) Completion of the central suture with a U-stitch or a Z-stitch. (**b**) Both threads of the U-stitch are pulled out anteriorily and (**c**) after extracorpoeral knotting (**d**) the thread can be shortened. There is no need for extracorporeal suturing because the suture is set ideally and the tissue mass is adequate

Laparoscopic Subtotal Hysterectomy

In laparoscopic supracervical hysterectomy, resection of the uterine corpus is performed at this stage of surgery. The preceding steps are very similar except for the fact that a manipulator is not needed because the uterus is elevated by traction. The corpus of the uterus is cut with a monopolar loop and the cervical channel is coagulated to prevent spotting. The cervical channel should be closed because of the high risk of ascending infection. Simultaneously, the cervix can be suspended with a strong monofilament suture and extracorporeal knotting. The remaining uterine corpus needs to be morcellated intraabdominally (Figs. 35.81, 35.82, 35.83, 35.84, 35.85 and 35.86).

Figure 35.87 shows the outcome of supracervical and total hysterectomy.

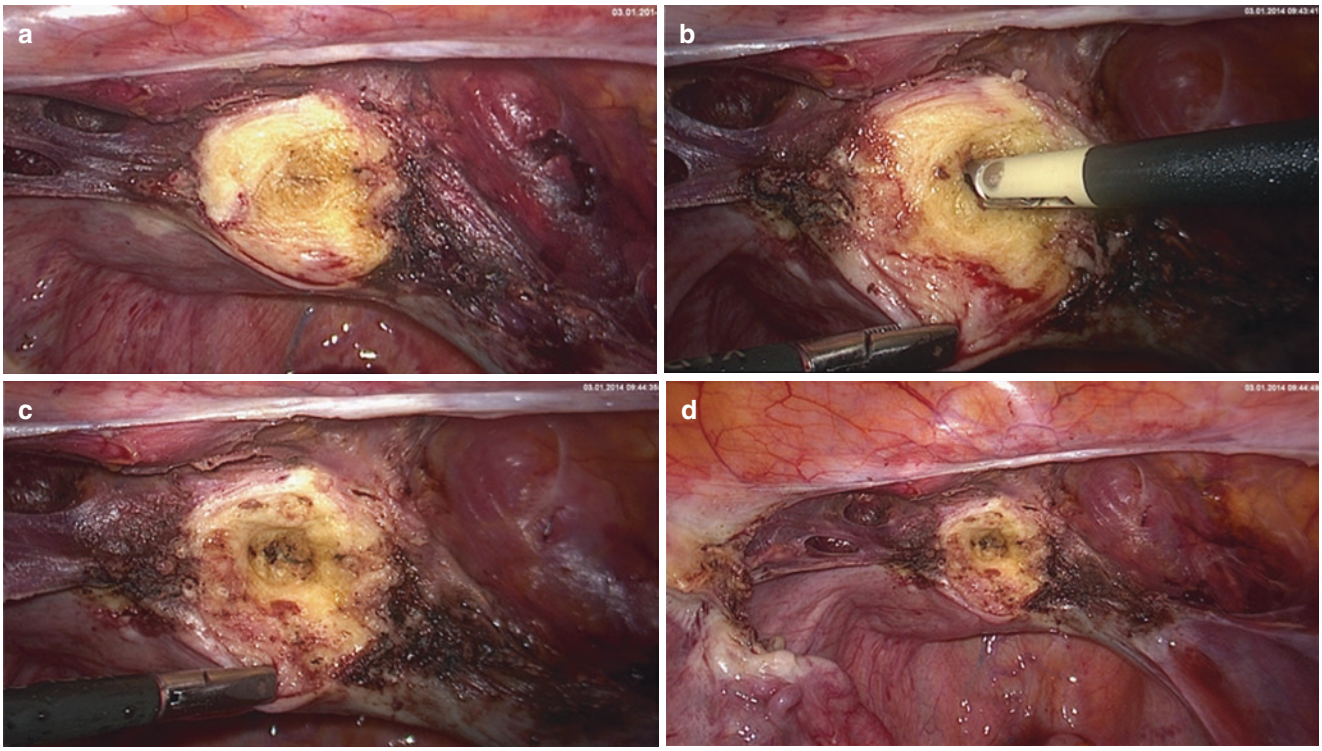

Fig. 35.81 The remaining cervical stump. Especially in cases of bleeding disorders, adenomyosis of the uterus or endometriosis, extended coagulation of the remaining cervical channel should be performed (**a–c**). By pulling the uterus upward when cutting the cervix, resection if performed in the shape of an inverse cone (**d**)

Fig. 35.80 Schematic illustration of vaginal closure after LTH modified by Schollmeyer. A suture is passed through the endopelvic fascia, 1 cm below the cephalad edge of the vaginal epithelium. The needle is pushed from the vaginal lumen through the vaginal wall, passed between the uterine vessels (median part of the broad ligament), and returned through the vaginal lumen. The sacrouterine ligament is identified before the suture is passed through. The needle is pushed from the vaginal lumen through the vaginal wall and the rectovaginal septum, and pierces the sacrouterine ligament. Closure of the vaginal vault with single stiches, U-stiches or Z-stitches. The stitch is drawn through the endopelvic fascia and the vaginal wall, and then out of the vaginal wall and the endopelvic fascia

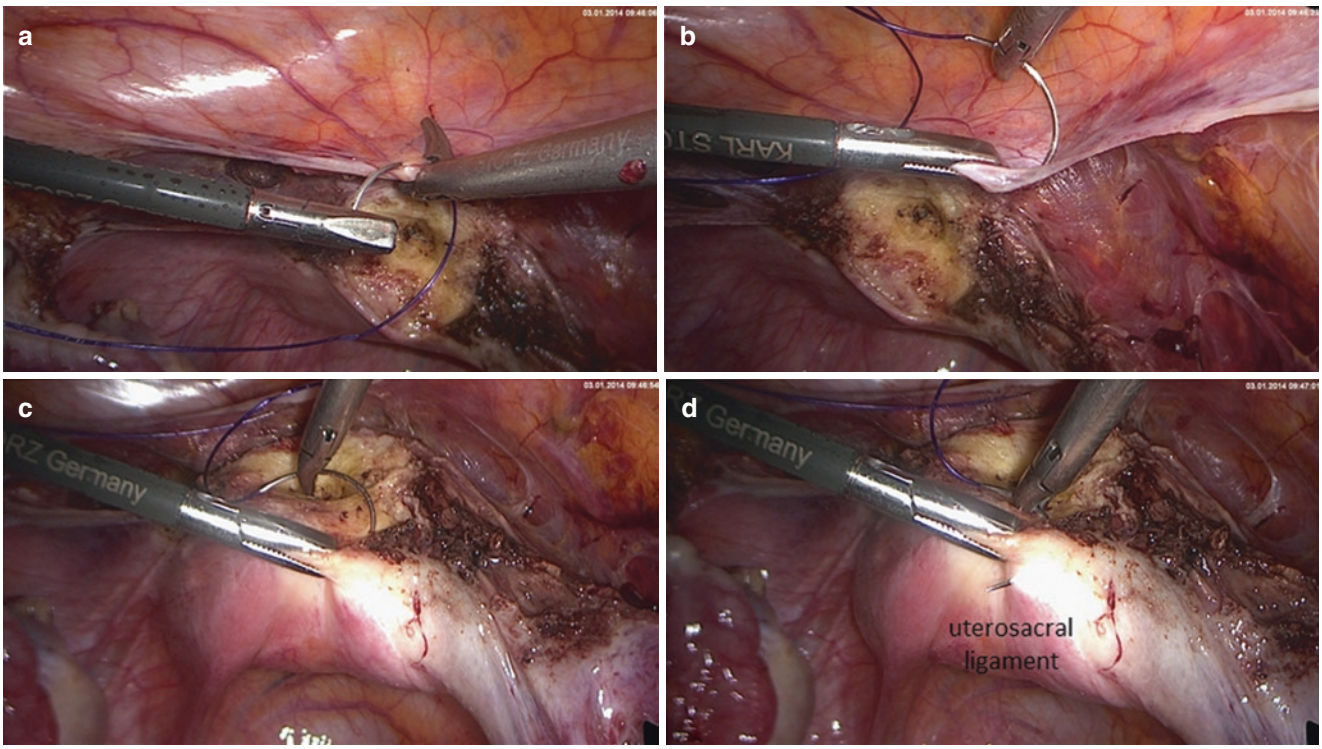

Fig. 35.82 LSH: (**a–d**) As the conjunction of the sacrouterine ligaments has been omitted, the two ligaments are grabbed and included in the suture to achieve cervical suspension (**a**). Connection of the bladder peritoneum to the posterior peritoneum by means of a purse-string suture

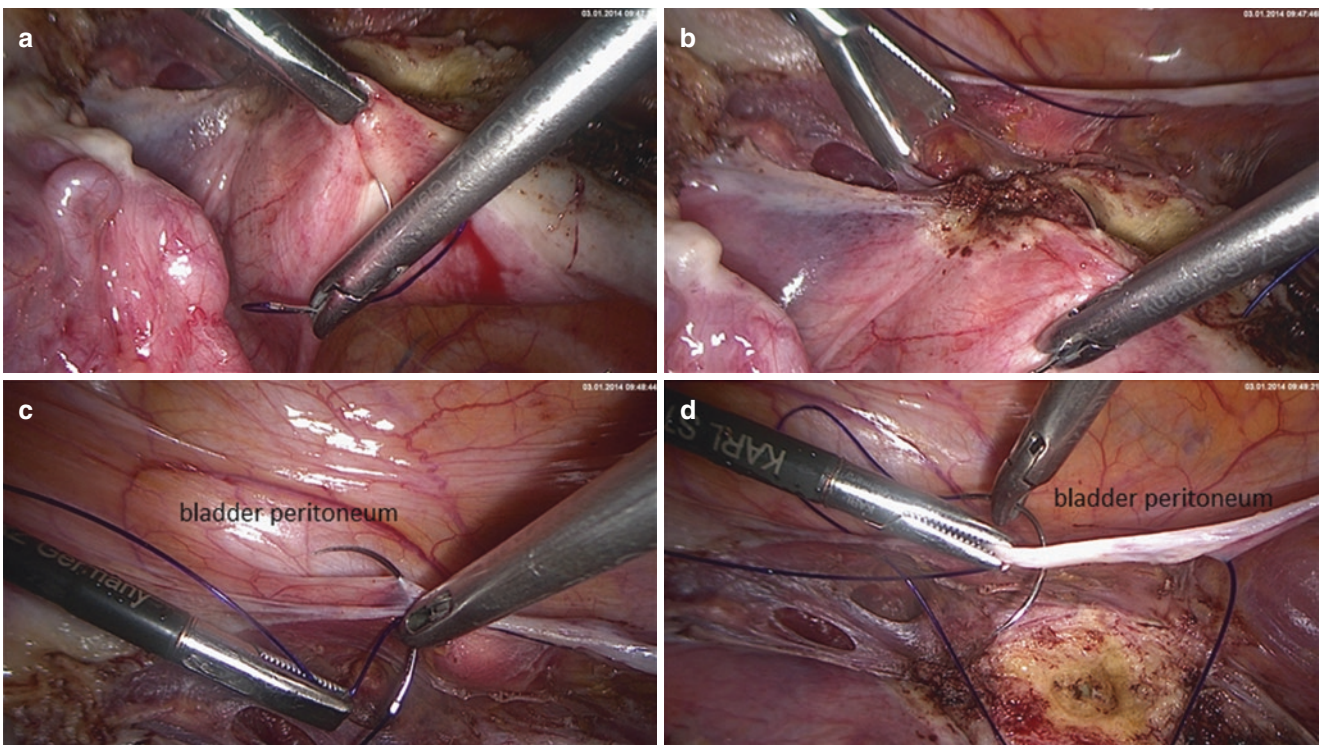

Fig. 35.83 (**a–b**) The sacrouterine ligaments can be identified and included in the closure of the cervical stump.(**c–d**) As the bladder has been slightly exposed during the procedure, there is now enough tissue to functionally close the cervical channel

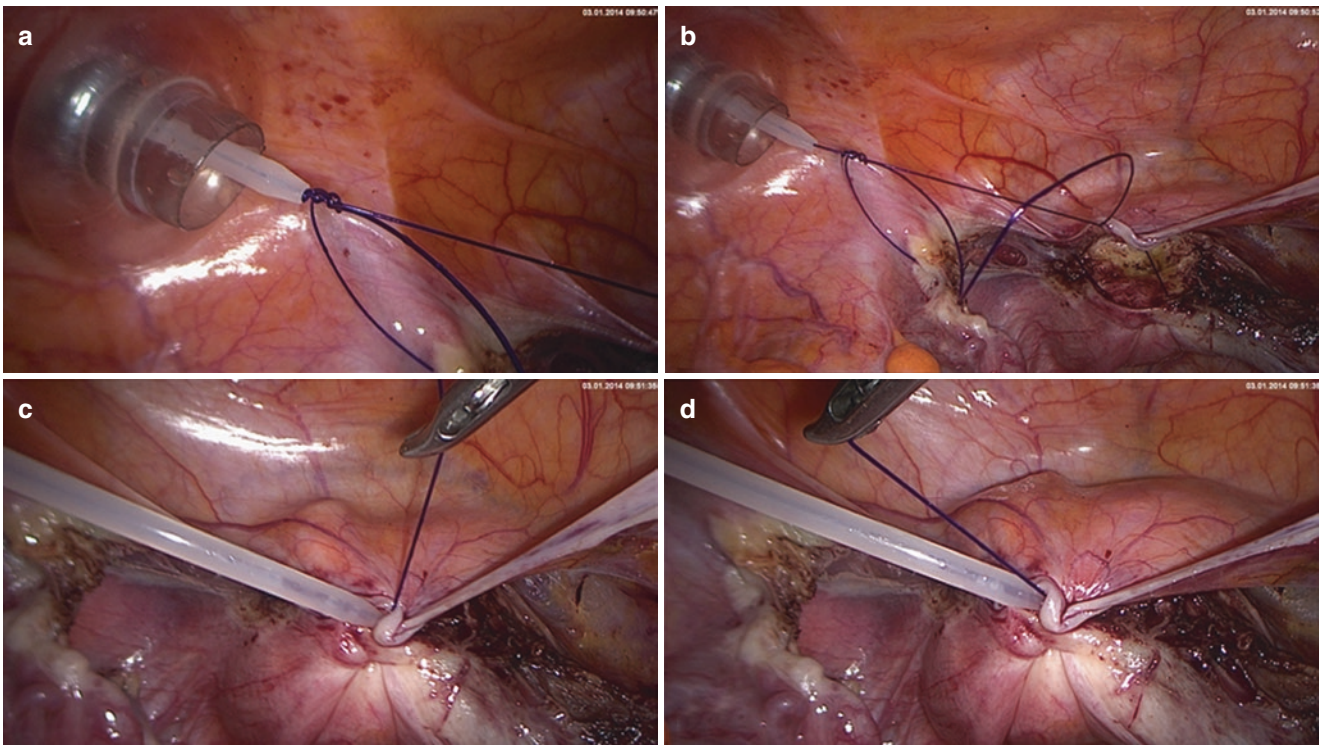

Fig. 35.84 When using the extracorporeal knot, the peritoneum closes the cervical channel functionally and this leads to cervical suspension. (**a**) The extracorporeally performed knot is (**b**) pushed inside. (**c**) Placement on the cervical stump and (**d**) tightening. The omitted sides still permit drainage if necessary

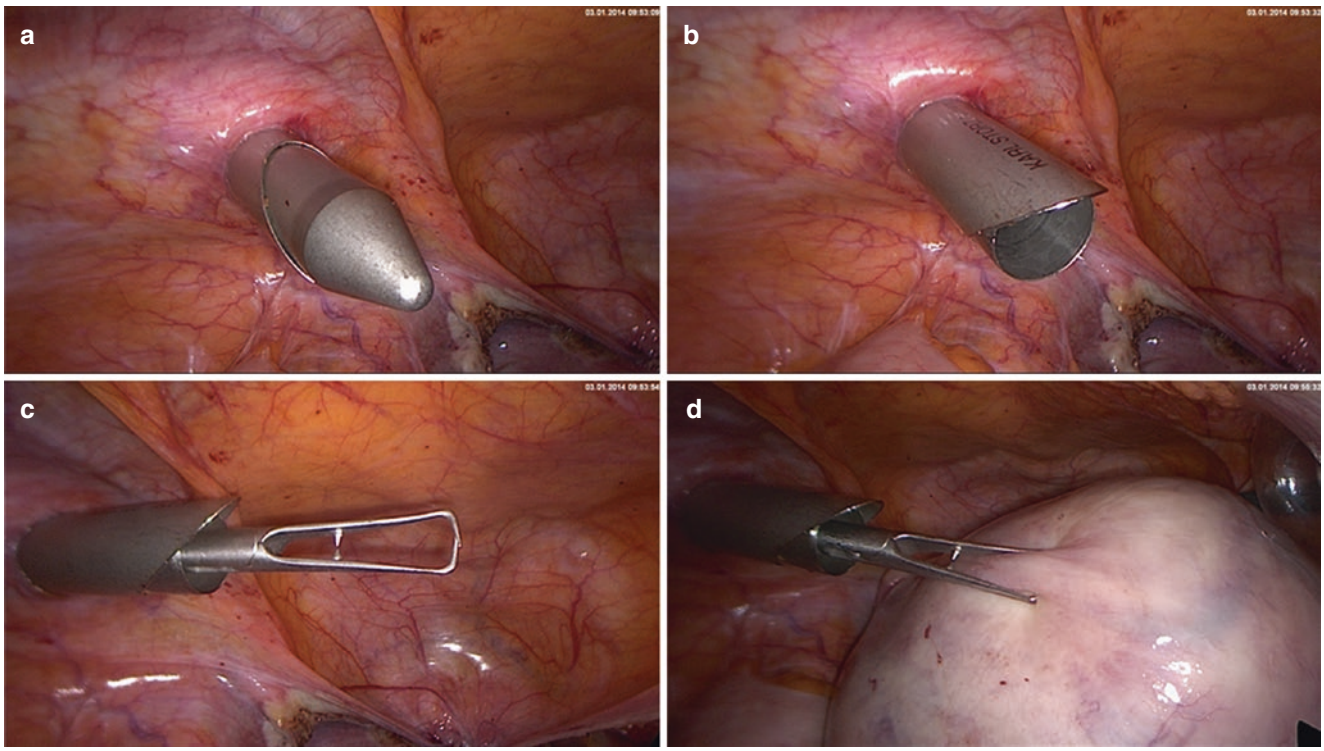

Fig. 35.85 (**a–d**) Introduction of the Roto-Cut morcellator, which is available in diameters of 12 and 15 mm. The knife should be protected by the shield and the tenaculum should be used under direct vision, regardless of the size of the uterus

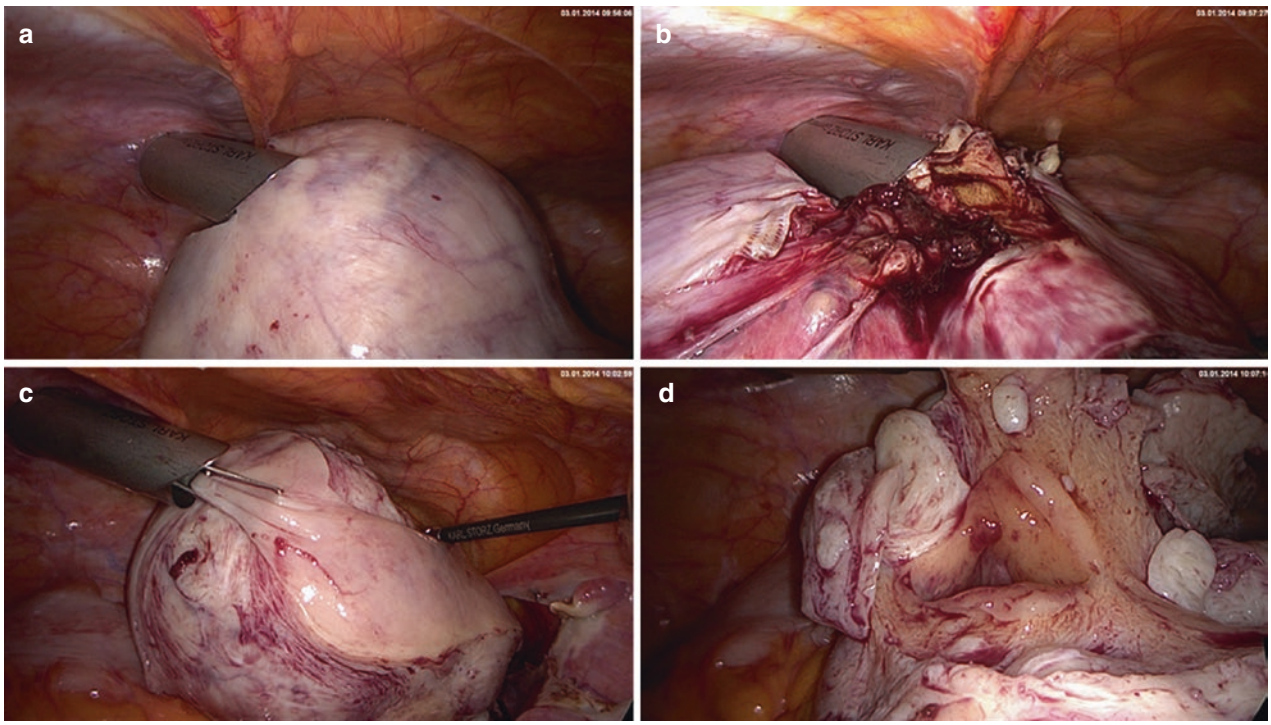

Fig. 35.86 LSH: (**a**) Morcellation of the myomatous uterus (850 g) under (**b**) continuous observation of the rotating cutting edge and (**c**) the protective shield of the morcellator**.** The protective shield should be directed upward to the abdominal wall in order to avoid cutting the vessels of the abdominal wall. Nevertheless, the lower part, especially the small bowel, must be exposed and kept out of the field of operation. (**d**) The surgeon must be patient and observant in order to avoid cutting into the bowel, which is one of the major complications in the LSH procedure

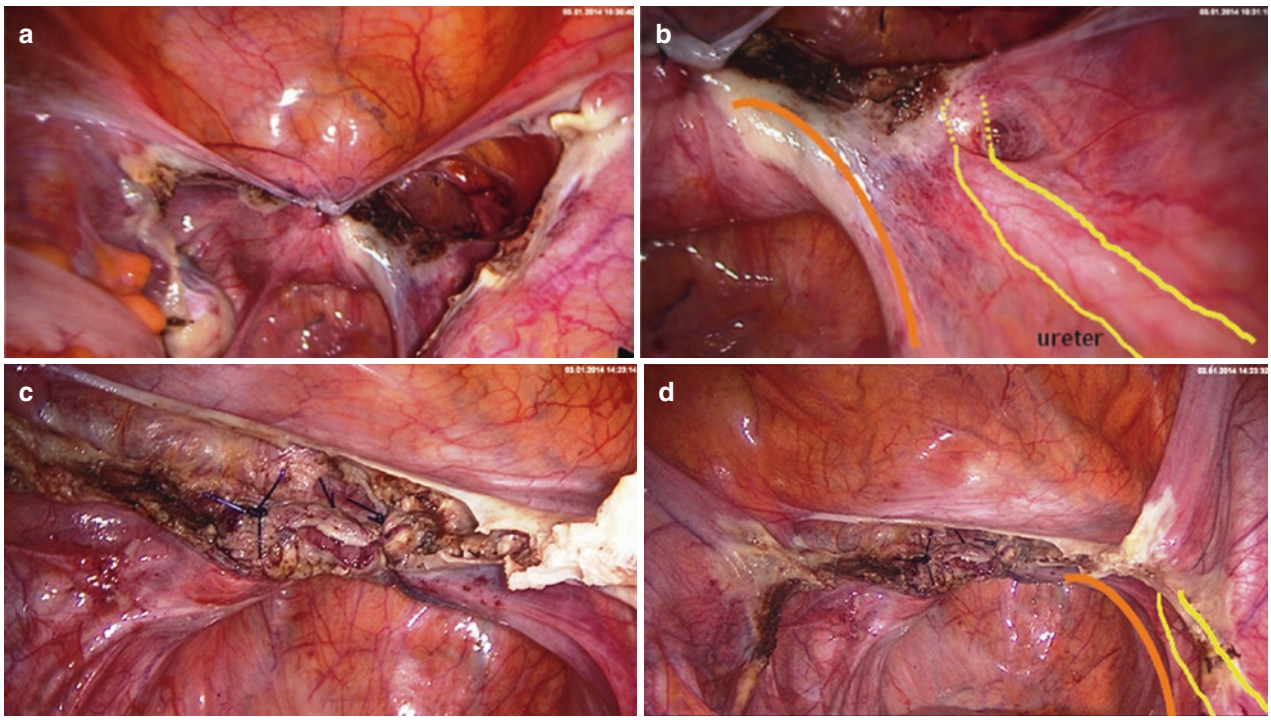

Fig. 35.87 (**a**, **b**) Final situs after LASH. The cervical channel is covered by peritoneum and both sacrouterine ligaments are under slight tension, thus fixing the middle compartment and the cervical ring. (**c**, **d**) Final situs after LTH. Closure of vaginal stump has been performed; the sacrouterine ligaments have been elevated by 2 corner sutures. The peritoneum closes the cervical channel, and drainage can be effected on both sides. Both sacrouterine ligaments are under slight tension, thus ensuring colposuspension. Reperitonealization will occur approximately 2 weeks after the operation. The PDS suture allows safe closure and healing of the vaginal cuff because absorption occurs only after about 6 months. The sacrouterine ligaments and the ureter can be clearly identified. Since the anatomy of the ureter has not been affected, opening of the retroperitoneum and its visualization are not necessary

Special Situations

The traditional technique of laparoscopic hysterectomy must be modified in cases of severe adhesions or concomitant deep infiltrating endometriosis. The surgical steps are quite similar to those for oncologic surgery; radical pelvic exposure is essential (Figs. 35.17, 35.18, and 35.40). After adhesiolysis, which may be very extensive in severe endometriosis or adenomyosis, the retroperitoneum is opened (Figs. 35.52, 35.88 and 35.89). The ureter and major vessels are localized, and the crossover of the uterine artery is visualized and exposed (Fig. 35.89). In some cases, clipping of the uterine artery just behind its point of departure from the internal iliac artery (Figs. 35.90, 35.91, 35.92 and 35.93) is useful for the following reasons:

1. More distal preparation and skeletonization of the uterine artery may be difficult or even impossible.
2. Endometriotic scars and nodules are liable to modify the anatomy of the region. This may lead to unexpected bleeding, especially in cases of a larger uterus. Clipping of the initial portion of the uterine artery will minimize intraoperative bleeding.

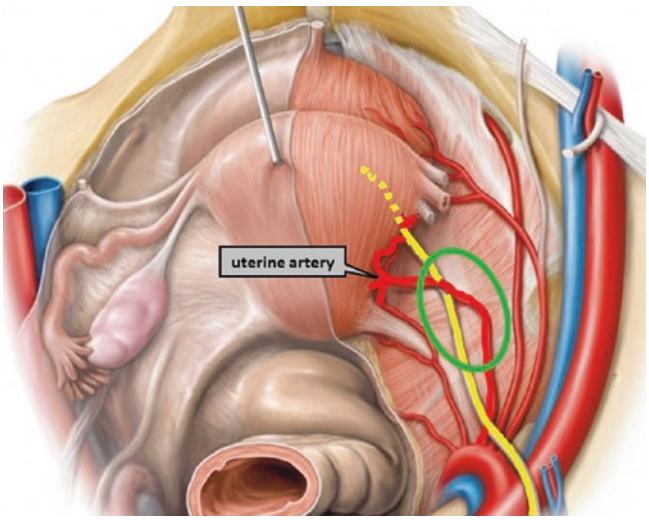

Fig. 35.88 Any uterine pathology may cause major difficulties in exposing the lateral uterine wall and the ascending branch of the uterine artery. Furthermore, all radical hysterectomies include the parametrium and imply a distal resection margin. This might make it necessary to expose the retroperitoneum and localize the departure of the uterine artery from the internal iliac artery

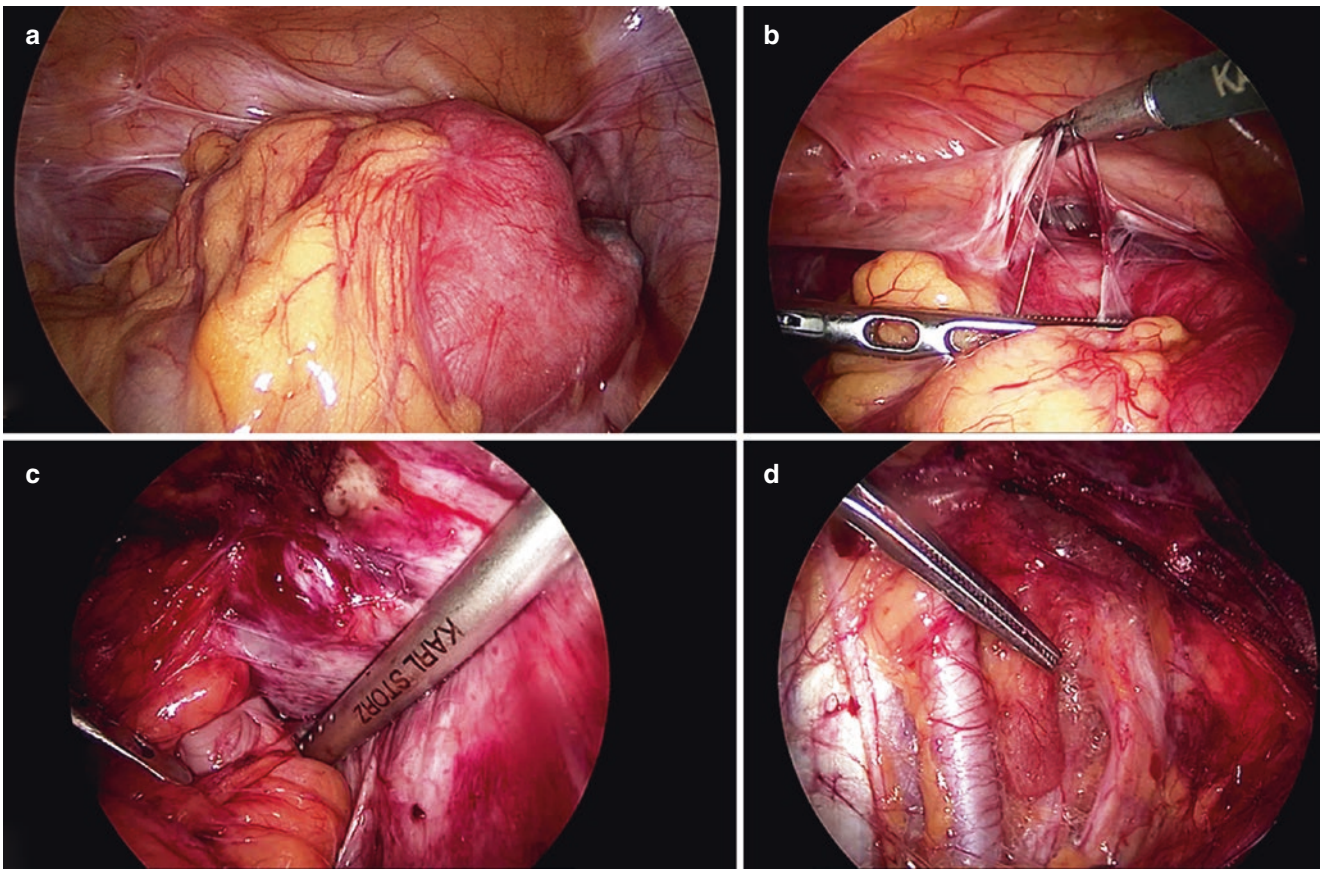

Fig. 35.89 A case of severe adenomyosis of the uterus with subsequent adhesions of the bowel (**a**) and the bladder (**b**) peritoneum. Access to the lateral aspect of the uterus is closed (**c**); retroperitoneal access is necessary (**d**)

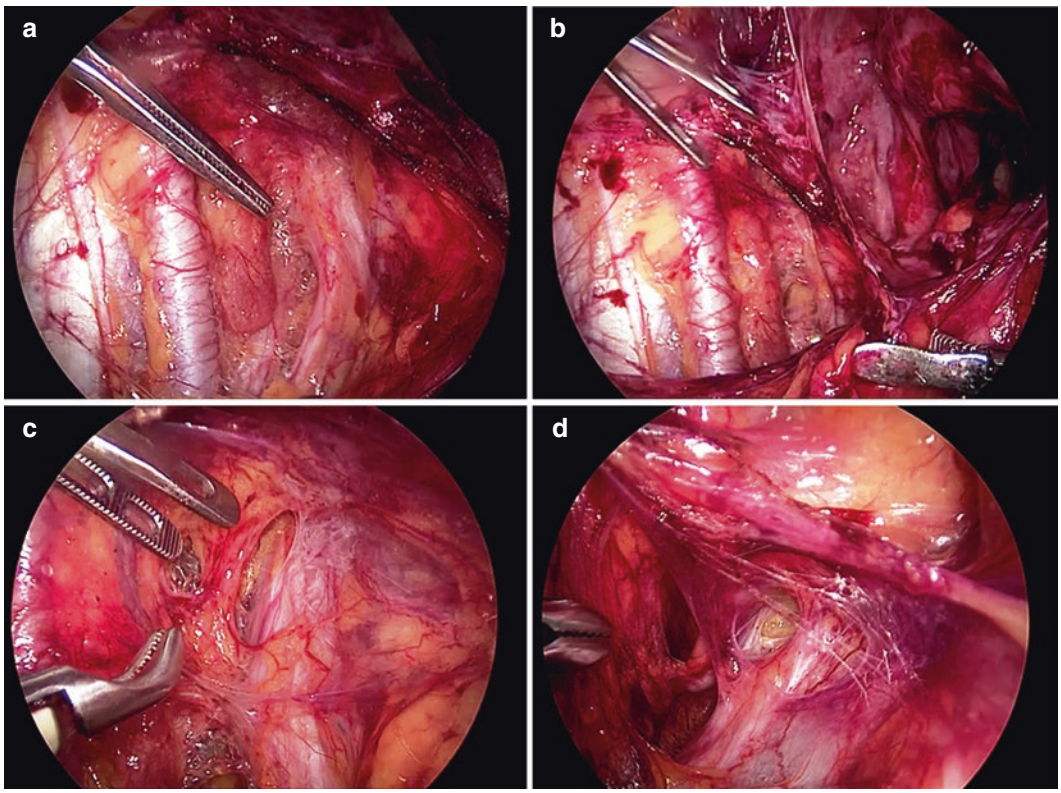

Fig. 35.90 (**a**) After localization of the external iliac artery, the ureter is usually found adherent to the peritoneum. A major lymph node lies in between.(**b**) Opening of the pararectal and (**c**) the paravesical fossa. (**d**) The crossing point of the uterine artery is demarcated, and the ureter is left in its adventitia to avoid skeletonizing and denudation

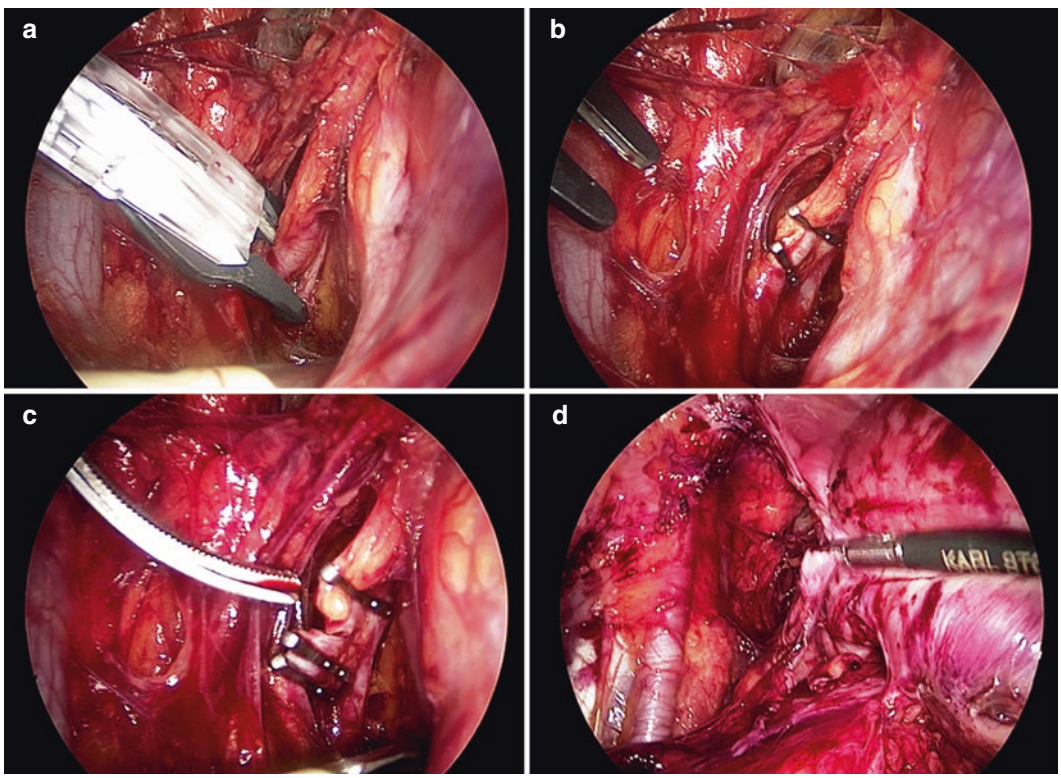

Fig. 35.91 (**a–b**) Clips can be inserted and the artery can be closed and cut (**c**)**.** (**c**) The uterine vein (deep) is seen just beneath the cut artery.(**d**) Overview of the exposed situs. To the right you see the uncolored uterus after closure of both arteries

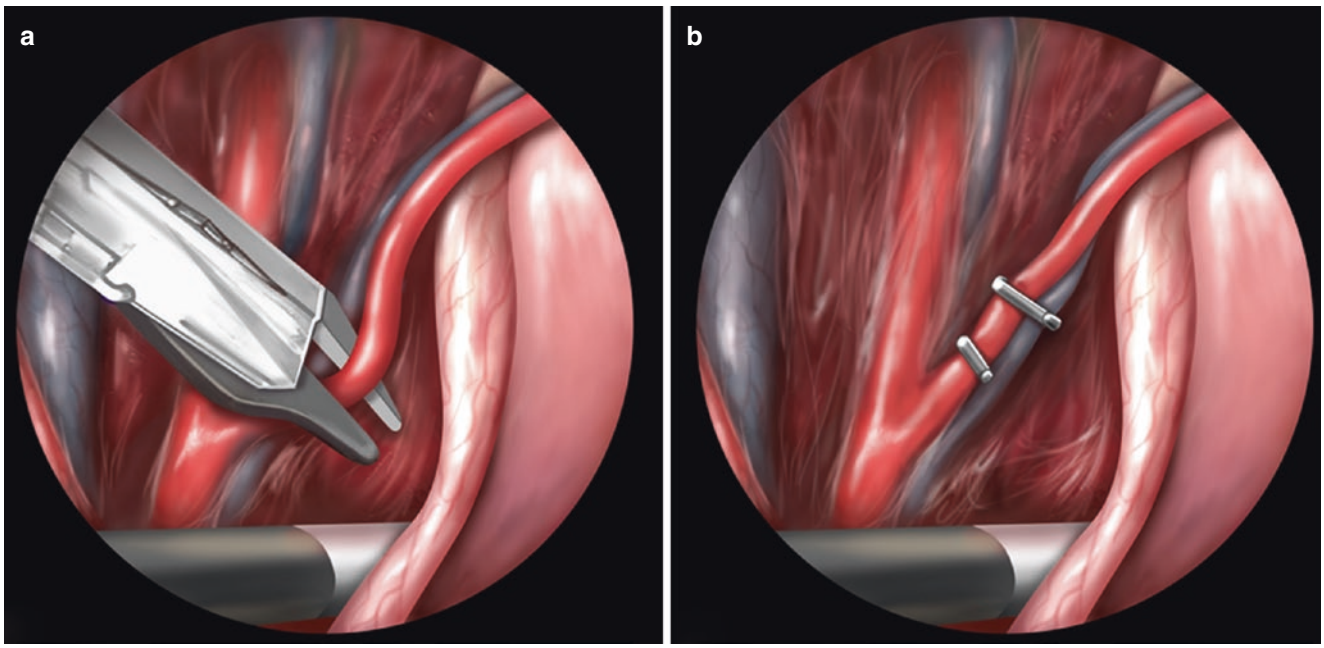

Fig. 35.92 (**a–b**) Schematic illustration of the retroperitoneal area where the ureter is undercrossing the uterine artery. The uterine vain is usually divided into a superficial part and a deep part. Clips can be set after medializing the ureter

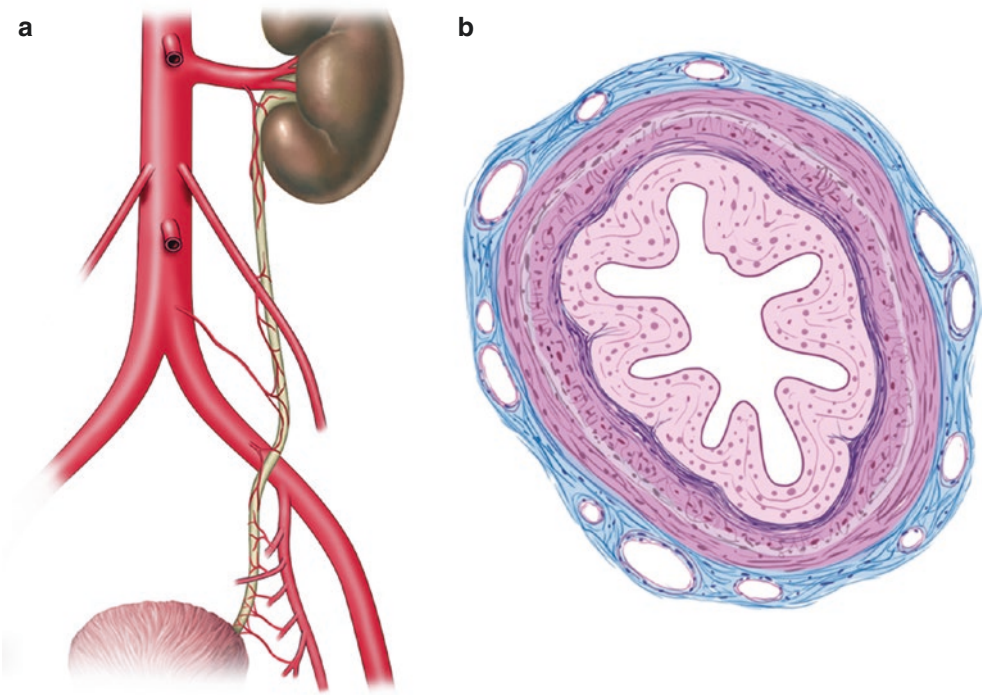

Fig. 35.93 The anatomy of the ureter provides crucial information.(**a**) Vascularization is effected from the upper part: the renal artery, the ovarian artery, and the aorta. In the lower part the ureter is supplied by lateral vessels: the iliac vessels and the uterine artery. Blunt dissection causes minor bleeding at the respective location.(**b**) The histological cross-section shows that vascular supply is located in the adventitia. Therefore, electricity or manipulation causing destruction of the adventitia may lead to secondary fistulas and/or leakage

3. The proximity of the uterine artery to the ureter and the thermal spread of bipolar instruments may cause secondary coagulation defects of the ureter, which can be avoided by using vessel clips.

At the end of the procedure the abdominal cavity is irrigated with physiological saline solution and drained. Usually no drains are left in situ (Fig. 35.89).

We established this suture technique because it provides stable fixation of the vaginal end in addition to other safety advantages:

1. As the suture is applied parallel to the urethra, kinking of the ureters is avoided. The thread is led through the medial part of the cardinal ligament, along the anterior-posterior access.

2. Compression of small vessels between the vaginal wall and uterine artery within the cardinal ligament minimizes the risk of bleeding.
3. Despite good suspension there is no relevant displacement of the vaginal access dorsally, which might increase the risk of a cystocele.

Post-hysterectomy Inspection

The pedicles, bladder, ureters and bowel must be inspected under continuous irrigation with Ringer's lactate or Adept (Baxter). Ureter movement is no proof of integrity. In cases of suspected damage to the ureter or kinking of the ureter while closing the vagina, the ureter must be visualized by opening the retroperitoneum and ureterolysis performed until the ureter enters the parametria (Fig. 35.93). Alternatively, methylene blue can be injected. If no dye is seen intraabdominally, severe damage is unlikely. In critical cases the integrity of the ureter can be proven by performing an intravenous pyelogram two to three days after the operation.

Postoperative Management

The urinary catheter is removed; it remains in place only in specific cases. A postoperative cystoscopy is performed in cases of severe endometriosis or adhesions in the upper part of the bladder. Early ambulation a few hours after surgery is good practice. Clear fluids can be ingested 6 h post-surgery, followed by a light diet. Thromboprophylaxis (mechanical and medical) must be used in appropriate cases. The patient can be discharged after 8–12 h. A postoperative ultrasound scan of the renal pelvis should be performed. Ordinary light activities are permitted and the patient may return to work after 4–5 days. Sexual activity, intensive sports and heavy work should be avoided for 6–8 weeks.

Anticipated Problems

Vital symptoms, pain and temperature must be carefully monitored during the first 8 h. A patient who is discharged early must be given a phone number she may call in case of distress or pain. The insertion of a drain is not necessary. Fever, early pain, abdominal distension, delirium, decreased urine output, the shock index and hypotension must be recognized and attended to immediately, as these may be signs of complications.

Summary and Conclusions

In addition to the well-known laparoscopic techniques for myomectomy and hysteroscopic techniques for submucous fibroidectomy, laparoscopic subtotal and total hysterectomy are surgical options for the treatment of multiple fibroids. The surgical procedure is decided upon jointly by the patient and the doctor. The individual steps described in this chapter help the gynecological surgeon to perform a satisfactory operation and eliminate the onerous burden of multiple fibroids in patients who have completed planning their families.

Conclusion

1. The transformation of classic intrafascial hysterectomy into laparoscopic hysterectomy, or even total atraumatic intrafascial laparoscopic hysterectomy (TAIL), is the first step for the prevention of a descensus. The uterine manipulator and the structured procedure have made laparoscopic hysterectomy a much safer option [28].
2. In a comparison of various methods to avoid prolapse during vaginal hysterectomy, McCall culdoplasty proved to be the most effective technique in the short term and after three years [39]. A similar procedure is used for abdominal hysterectomy [40, 41]. The method was modified by Harry Reich and adapted for laparoscopic procedures. One of its disadvantages is the unification of two lateral sutures in the midline, which results in an unphysiological narrowing of the apical pole of the vagina. As transposition of the ureters bears the risk of kinking it would be advisable to use van Herendael's modified suture technique, which avoids this risk [37].

Total Laparoscopic Hysterectomy in Patients with Bulky Uterus

36

Guenter K. Noé and Michael Anapolski

A big uterus can pose a serious challenge to a gynecologic surgeon in case a total laparoscopic hysterectomy (TLH) is to be performed. Although the basic anatomy of the lesser pelvis does not vary depending on the uterine size, the operative site can present some differences in these patients. Due to the sample size, there is less space in the pelvis and often in the abdominal cavity. This feature restricts the overview and renders more difficult the identification of such anatomical structures as the ureter. If the uterus fills the entire lesser pelvis not only a fast identification and isolation of uterine vessels in the paracervical region is not possible, but also a ligation of the uterine artery leaving the anterior brunch of the hypogastric artery is hardly conceivable. At the same time, the close proximity of the uterus to pelvic walls means a higher risk of an injury to the ureter since its course cannot be easily identified as long as the uterus occludes the field of view. Caused by the uterine size the pedicles of the supplying vessels can often be found in unusual positions (e.g. on the ventral side of the uterus). Due to the larger vessel diameter than in a normal specimen, a bleeding from a uterine artery or vein may result in a serious impairment of the visibility and also lead to a major blood loss. Since the minor branches of the uterine vein can reach the size of a regular normal size uterine vein, they may be mistaken for its major branch. The above mentioned features underline the importance of the correct identification of the supplying vessels prior to their ligation.

Even if the laparoscopic procedure reaches a high level of difficulty, it allows a direct visualization of anatomical structures prior to and during their dissection. This is an important advantage compared to the vaginal approach. Another advantage is the possibility to perform an intrafascial hysterectomy via the laparoscopic route. For hysterectomies scheduled for benign conditions, we prefer this method to conserve as much ligamental and nervous tissue as possible. The intrafascial hysterectomy reduces also the risk of a ureteric injury [1]. This surgical procedure is as a rule possible also in patients with large sized uteri.

The usual preparation sequence of a TLH is a downward dissection that starts in the adnexal region and proceeds towards the uterine vessels. This strategy is not always possible with large uteri since the parauterine and paracervical region may become accessible only after mobilization of the uterus. Such situations require good surgical skills in view of the fact that the usual procedure has to be modified in order to adjust to the situs. We prefer to start with the "easy" side first and proceed to the other side after the uterus gained some mobility. It may be also necessary to switch to the other side before the preparation on the first side is completed. For example, we might dissect the adnexal pedicles on both sides prior to carry on with the dissection on the right side in order to mobilize the uterus and obtain enough space to access the parauterine region. In some cases of bulky uteri, the only accessible region is the anterior aspect of the cervix. Under such circumstances, the dissection should begin here by opening the peritoneal fold. The loose connective tissue in this area can often be pushed away and dissected bluntly towards the lateral aspect of the cervix allowing the access to the uterine vessels. In such cases, the access to the adnexa might be possible only in a retrograde way.

For regular TLH, we usually use an umbilical optic trocar and two working ports – in the left lower abdomen and in the suprasymphysary area. The uterine manipulator is usually handled by the operating nurse. For bulky uteri, we place an additional trocar in the right lower abdomen. The

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_36

uterine manipulator can be controlled by an additional person since the operating nurse should avoid any distractions in order to allow a rapid reaction to eventual bleedings. To simplify the preparation and fasten the course of surgery we prefer to use combination instruments, allowing to seal and dissect the tissue without changing the device. Depending on the degree of difficulty, such tools may significantly shorten the time requirement, although the most part of them are designed for a single use and lead hence to higher operative costs.

Although a TLH can be performed in a freehand mode, we prefer the use of a manipulator with a cervical cup. In difficult situations, such as with a bulky uterus, this device helps to increase the distance to bladder and ureter during the dissection process. Different types of manipulators are available on the market with different additional functions and degrees of freedom. We prefer to use manipulators without a uterine spike because it restricts the ability to move the uterus manually within the abdominal cavity.

In a case of a "regular" intrafascial TLH, there is no particular need to expose the ureter in its entire course. With a bulky uterus, the visualization of the ureter prior to and during the dissection is rarely possible, so that it might be reasonable to perform it at least after the uterus removal. If any doubts exist – e.g. in case the dissection was carried out in a close proximity of the ureter – a placement of a ureteric stent should be considered. If a hydronephrosis is known before the surgery, a ureteric stent should be inserted prior to the intervention. To exclude a thermal injury – e.g. a stricture of the ureter – an intravenous pyelogram or a CT-scan can be conducted in the postoperative course. One should bear in mind, that such changes take some time to develop and unsuspicious results might be false negative in case the examination was carried out shortly after the surgery.

Although the closure of the vaginal vault can be performed by a vaginal approach, good endoscopic suturing skills are essential for a TLH since an additional ligation of major uterine vessels might be necessary. We usually perform a continuous endoscopic suturing of the vagina using absorbable material.

As a rule, the uterus can be extracted vaginally after a regular TLH. In case of a bulky uterus, the vaginal route is often not an option to remove the specimen in toto. Under the given conditions, tissue extraction is a serious issue since previously undetected malignancy, premalignant conditions and myoma tissue might be disseminated in the abdominal cavity during power morcellation [2–5]. To address this concern, some authors proposed to carry out a manual vaginal morcellation [6]. Another option is a laparoscopic power morcellation inside an endobag [7–9]. Different devices were developed by the industry recently, but the exact quantification of the risk reduction for spread of uterine sarcoma, endometrial cancer, smooth muscle tumor of uncertain malignant potential (STUMP) and parasitic myoma is not yet available at present.

Technique

A big Uterus is not only defined by weight but also by the volume relatively to the volume of the intra-abdominal space. The problem for the surgeon is primary the lack of space to move and the reduced field of view. Different strategies are suggested as mentioned above.

To obtain a good overview many authors recommend to position the optic trocar 2–4 cm above the umbilicus. According to the position different access-port placements are known (Figs. 36.1, 36.2, and 36.3).

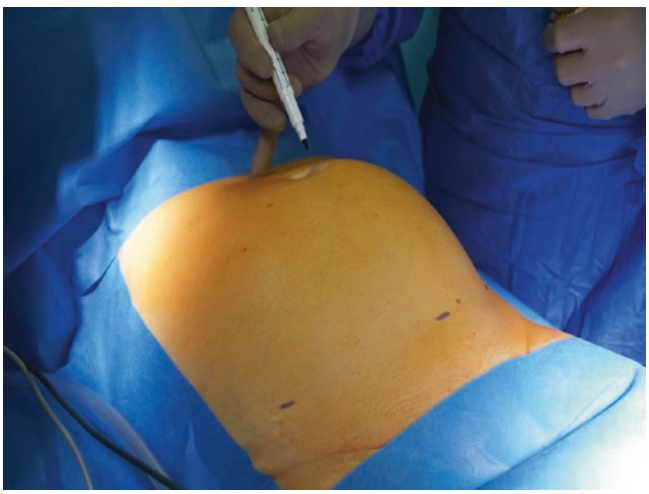

Fig. 36.1 Standard port-position

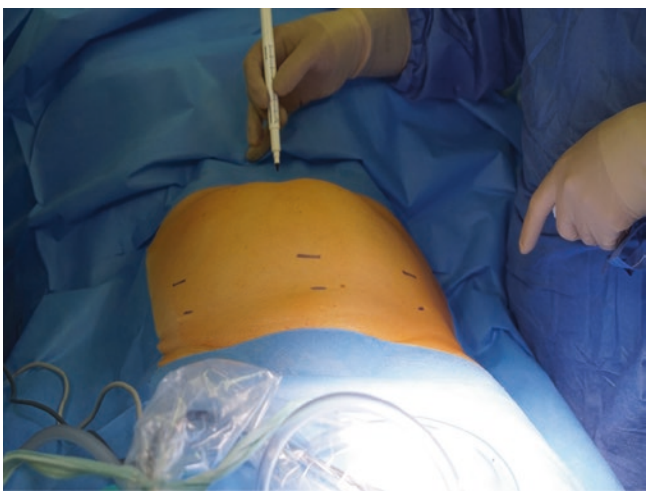

Fig. 36.2 Standard and elevated port-position

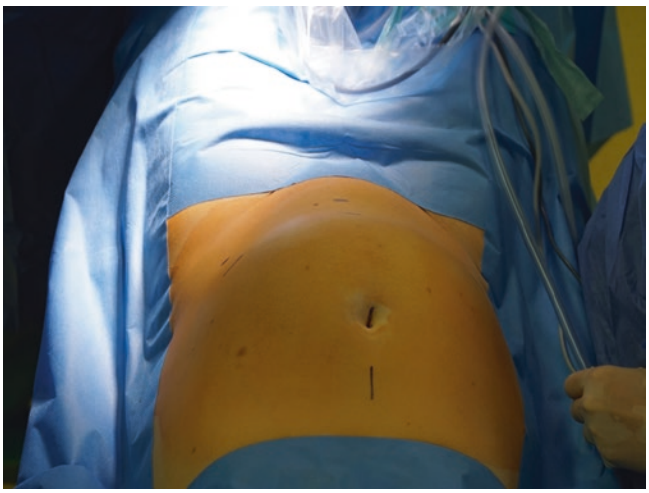

Fig. 36.3 Umbilical and high optic entrance

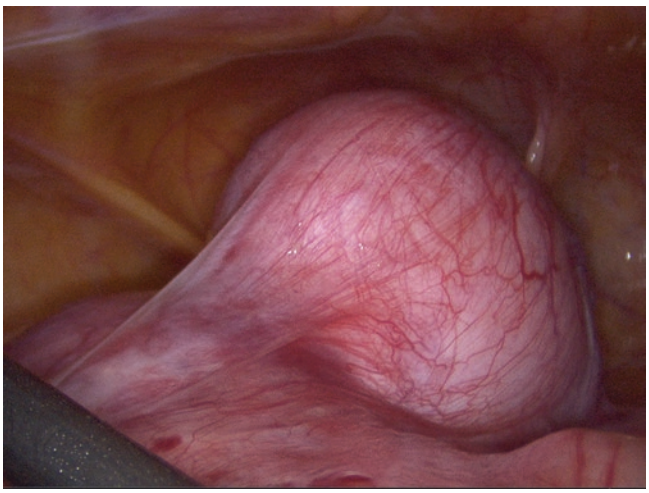

Fig. 36.4 2300 g uterus (all pictures taken on this uterus)

Indeed the higher positioning provides better view and better access to the higher tissue like the adnexa. On the other hand the angel to reach the uterine vessels gets more and more unfavorable the higher the placement of the port is proceeded.

At the end the success or the feasibility of the surgery is related to the access to the blood supply of the uterus. As we describe an approach for uterus 1000 g and more, the access to the uterine origin branch is not possible, the surgeon is forced to get access to the entering branch of the uterine arteries near the cervix from the anterior area. In this region a lot of vessels can be found as well as the ureter is close and the lack of tissue traction can increase the risk of damage.

To have an optimal angle the authors prefer the direct access and place the trocars in a usual setting (Fig. 36.1). One Optic-trocar and three working-port are placed.

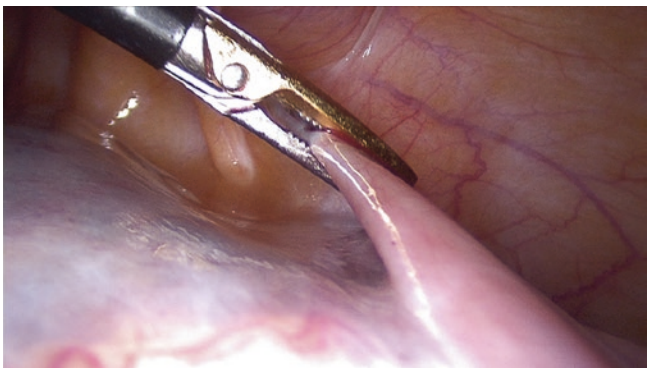

Fig. 36.5 Right round ligament

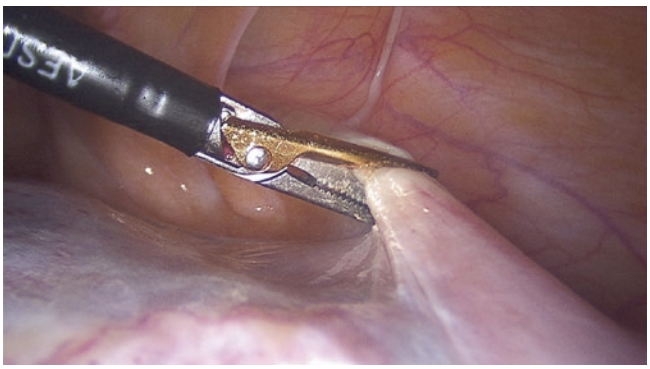

Fig. 36.6 Coagulation and cutting round ligament

Step 1

Visualizing the situation and exposure of the anatomy.

Step 2

Decision:

Is it possible to move the uterus laterally?

Will it be possible to move the uterus cranially after releasing from the round ligaments and the cardinal ligaments?

If these question cannot be answered positively an open procedure should be chosen.

Step 3

Identifying the Round Ligaments and the Peritoneal Border-Line to the Anterior Uterine Wall

The use of a combined instrument (coagulation/sealing/preparation and cutting) is the best advantage in this situation. Unnecessary movements by changing the instruments has to

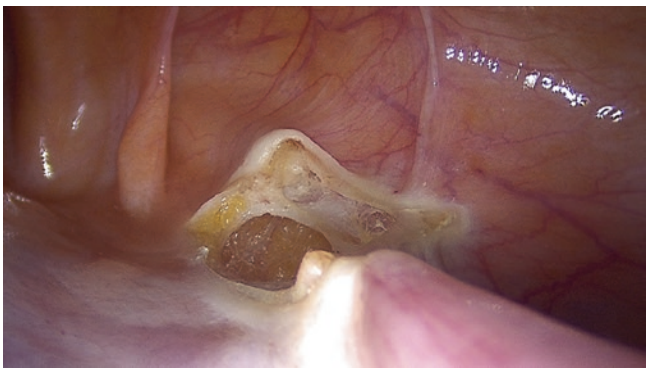

Fig. 36.7 Extension of the ligament

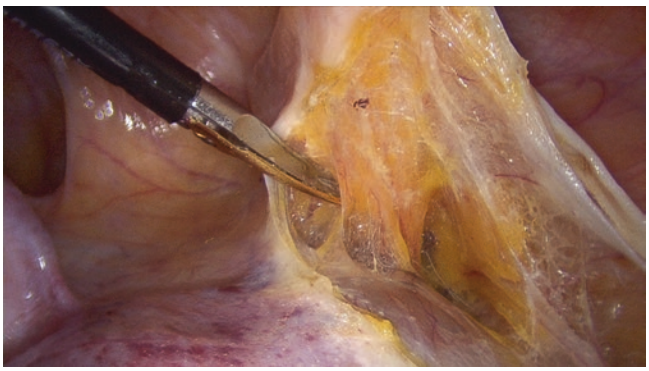

Fig. 36.9 Preparation downwards to the bladder

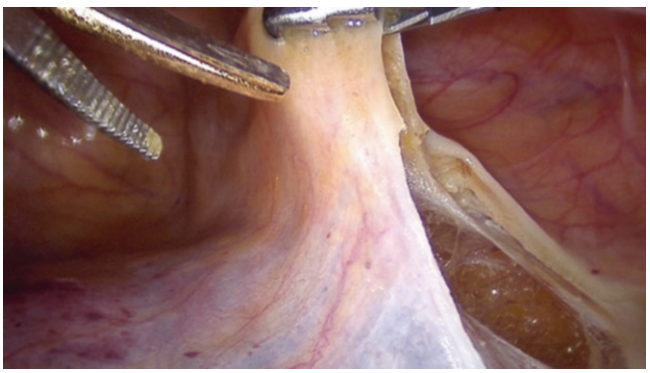

Fig. 36.8 Under traction the CO_2 Gas can stream into the retro-peritoneal space

be avoided. It depends on the experience of the surgeon which device is used. We prefer a bipolar combination instrument which provides the possibility to coagulate and cut as well as perpetrate separately.

In a field with poor visibility it is important to do the preparation as dry as possible.

To have the chance to move the uterus we first cut the round ligaments (Figs. 36.4, 36.5, 36.6, and 36.7). The lateral as possible to have a proper access to the retro-peritoneal space is important.

Step 4

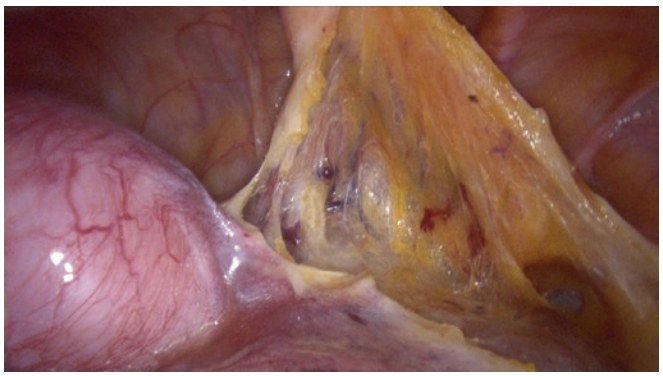
Preparation of the peritoneum for identifying the uterine blood supply and get the uterus moved out of the pelvis (Figs. 36.8, 36.9, 36.10, 36.11, 36.12, 36.13, 36.14, and 36.15).

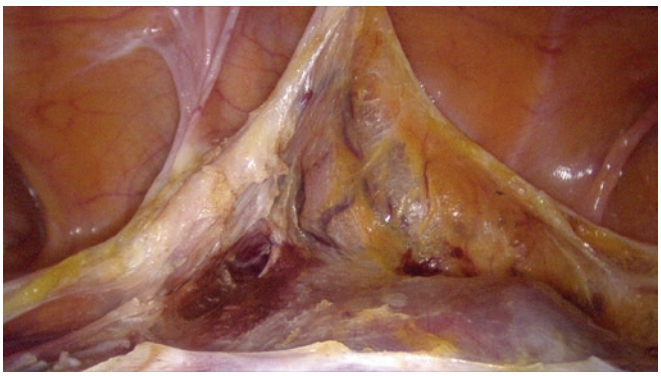
The preparation should be performed in small steps to avoid the rupture of the vein plexus in the lower part of the retro-peritoneal region. We use the gas for the dilution of the spaces and try to prepare as bluntly as possible.

Step 5

Identifying the Vessel Supply

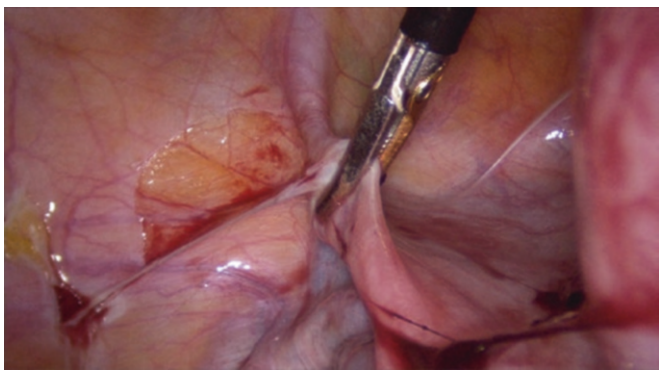
As the access to the deep branch of the uterine artery is not possible by the bulky uterus, it is necessary to approach the vessels from anterior. To avoid bleedings from the accompanying veins a precise clearing of the margins is useful (Figs. 36.16, 36.17, and 36.18).

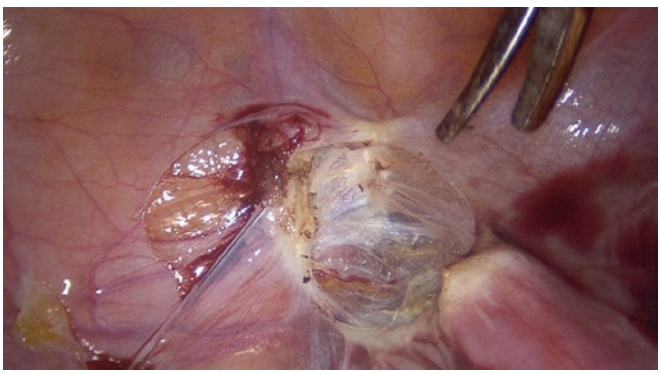




A clear and broad sealing of the artery to avoid reverse bleedings from the uterus is important as these bleeding reduce massively the field of view for the rest of the surgery (Fig. 36.19).

Step 6





Approaching the Adnexa (Figs. 36.20, 36.21, 36.22, 36.23, 36.24, and 36.25)

In case of large uterus the access to the adnexa is performed reverse. First the position of the ovary and the tube has to be verified. The protruding masses can make the identification very difficult and the correct direction of the preparation has to be controlled step by step.

The second surgeon can hold the uterus to the contralateral side as far as the tissue allows. Then the first surgeon approaches the tube and the ovarian ligament retroperitoneal.

Figs. 36.10 and 36.11 Preparation of the bladder. The identification of the cervix can be difficult as often the cervix is consumed by fibroids

Figs. 36.12 and 36.13 Right round ligament preparation

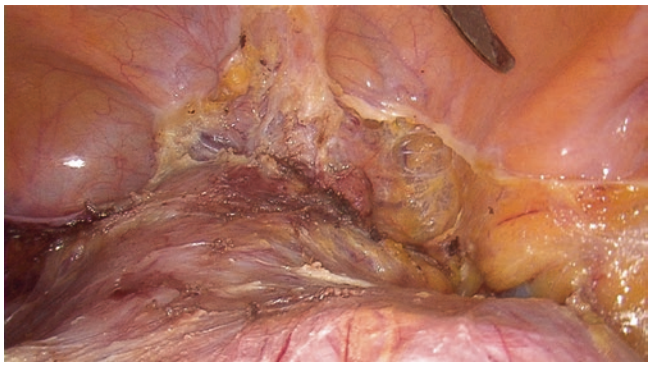

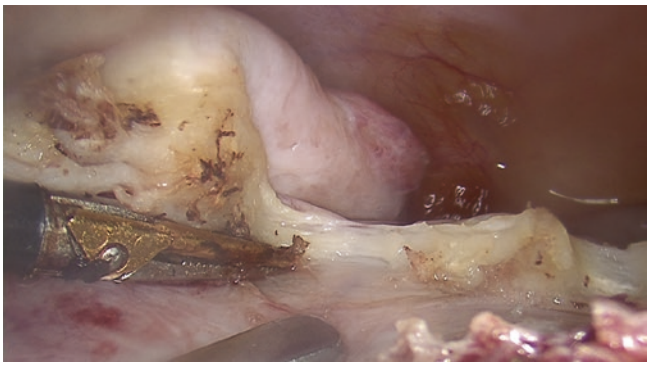

Fig. 36.19 Field after dissecting the artery

Figs. 36.21 and 36.22 Close preparation to the uterus in small steps

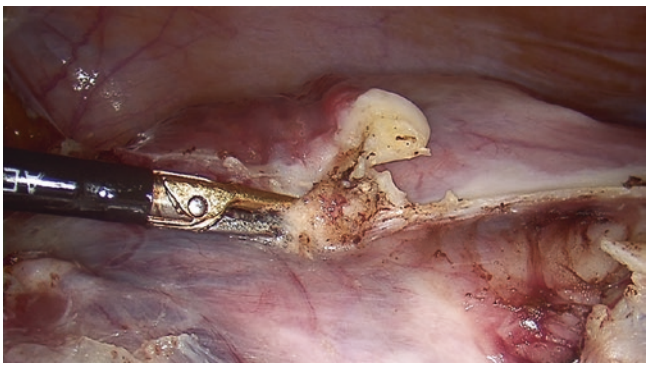

Fig. 36.20 Fallopian tube

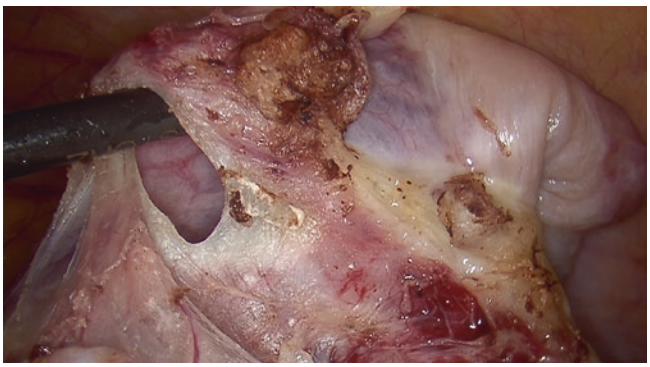

Fig. 36.23 Identification of the proper ovarian ligament

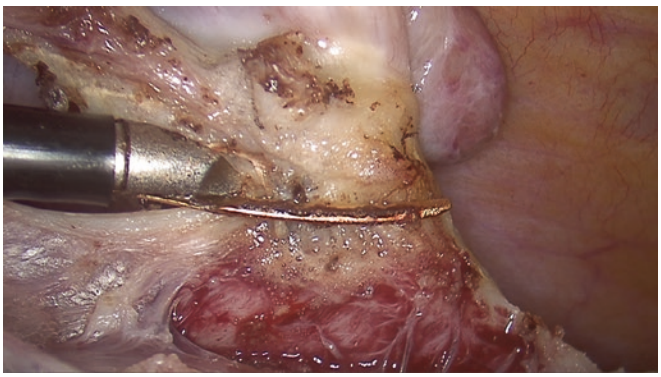
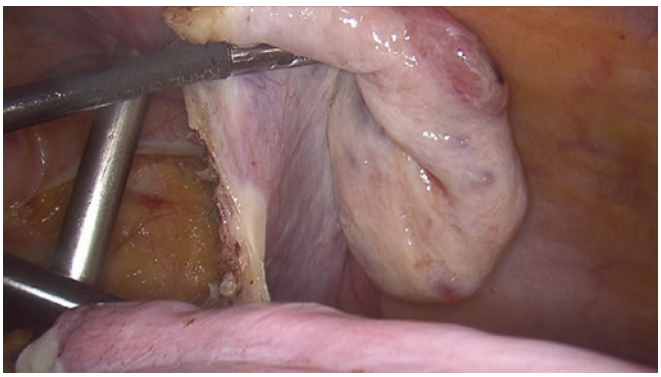
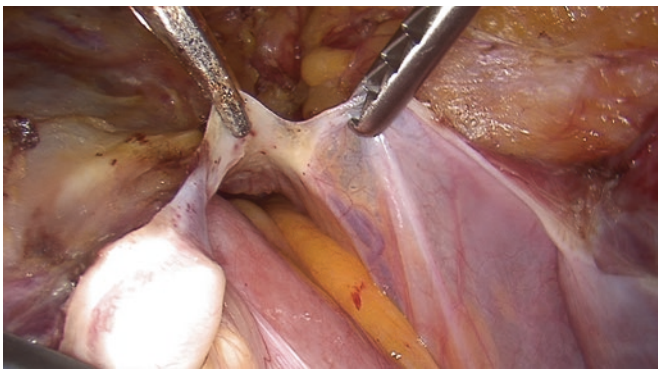
Step 7





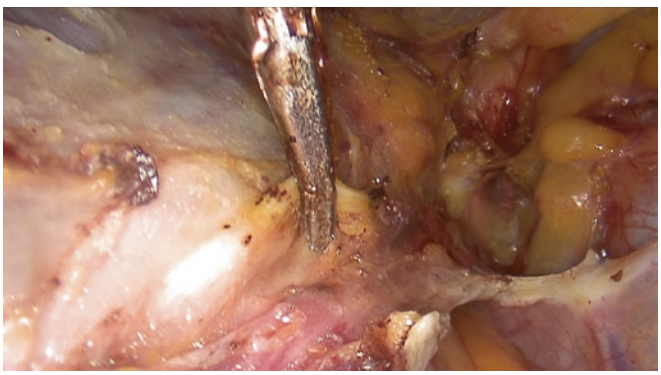
Clearing the Margins and Exposure of the Para-Cervical Tissue (Figs. 36.26, 36.27, 36.28, 36.29, and 36.30)

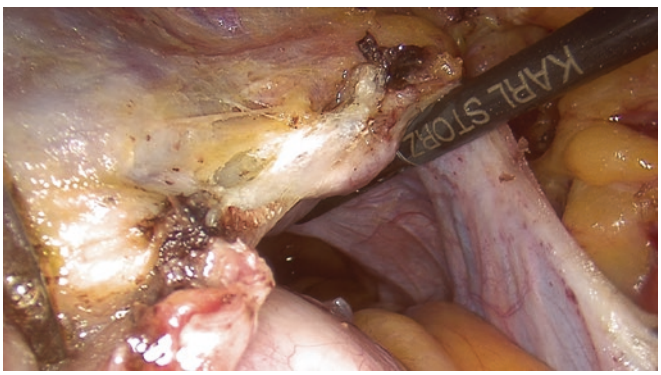
Step 8



Exposure and Preparation of the Cervix (Figs. 37.31 and 37.32)

Upon transitioning of the uterine arteries the uterus can be cut off from the cervix to have an optimal surgical field. This provides the access to the utero-sacral ligaments and they can be spared by an intra-facial dissection. If the pushing up of the uterus is performable optimal, the preparation of the para-cervical tissue is possible and can be done with or without a vaginal adapter.





The TLH or LSH of large uterus is only performable by the use of morcellation. At the moment a uterus larger then 1000 g cannot be morcellated in an enclosed setting. For specimen from 300 to 1000 g we use a bag with three closable access openings to control the morcellation by two hands. It is possible to perform morcellation with only a morcellator in the bag if the tissue is small. It is advantageous to have a helping hand for specimen larger then 300 g controlling the movement of the tissue and provide an optimal view on the rotating knife.

Figs. 36.24 and 36.25 Cutting the proper ligament (*right*)

Figs. 36.26 and 36.27 Step by step preparation of the broad ligament

Figs. 36.28 and 36.29 Complete exposure of the right pedicel

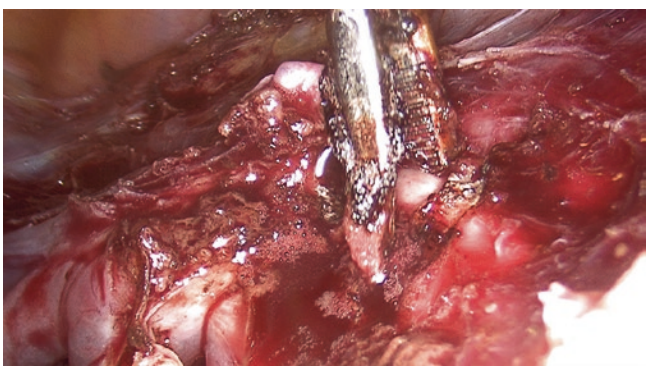


Fig. 36.30 Left uterine artery

As the access openings of the bag are closable we can prevent loosing spillage while extracting the bag after morcellation.

Two liter polyurethane bag with three closable access openings provides a good manageability of large tissue and a proper orientation by the transparency of the polyurethane (Figs. 36.33, 36.34, 36.35, and 36.36).

Total Laparoscopic Hysterectomy for the Patient with Concomitant Pelvic Organ

37

Shanti I. Mohling, Robert S. Furr, and C.Y. Liu

Pelvic organ prolapse significantly impacts the lives of women throughout the world. Nearly half of women worldwide will suffer from pelvic organ prolapse (POP) in their lifetimes [1]. Prolapse may be devastating as it affects many aspects of daily life including the ability to work, to exercise and to remain continent of urine and stool. It can affect self-esteem and sexual health. While conservative treatment options exist, and should be considered, surgical repair remains a viable option. Indications for surgery include failed conservative management with a pessary or physical therapy, failure or complications of a prior surgery for pelvic prolapse, and patient choice.

Hysterectomy with concomitant repair of pelvic organ prolapse may be performed laparoscopically or robotically, both of which afford excellent visualization of the operative field, thereby resulting in precise repair of pelvic floor defects and improved surgical outcomes. With fewer operative complications and minimal postoperative pain and discomfort, the patient enjoys a shorter recovery period and earlier return to normal activity.

Treatment of Pelvic Organ Prolapse at the Time of Hysterectomy

The primary goal of surgical treatment of POP at the time of hysterectomy is to reconstruct and to restore the integrity of endopelvic fascia. Ultimately, the aim is to restore normal vaginal length, vaginal axis and vaginal support. Because the general principles and detailed surgical techniques of endoscopic hysterectomy for various indications have been described elsewhere in the atlas, this chapter aims to describe the specific techniques of laparoscopic hysterectomy that are unique to the anatomical distortions secondary to POP. This chapter will also be devoted specifically to the concomitant laparoscopic treatment of POP at the time of hysterectomy. Finally, the technique of uterosacral vaginal vault suspension at the time of laparoscopic hysterectomy may also be applicable in the prevention of vaginal vault prolapse.

Anatomic Considerations

Pericervical Ring

The cervix is encircled by thick visceral connective tissue called the pericervical ring. This is the cornerstone of vaginal apical support. The pericervical ring is the convergence of the anterior pubocervical fascia, the posterior rectovaginal septum and the uterosacral ligaments [2]. The pericervical ring constitutes the strongest connective tissue between the ischial spines and is located in the narrowest diameter of the female pelvis. Defects in any of these three components as they converge create varying forms of pelvic prolapse [3]. The location of the ischial spines relative to the structures of the pericervical ring are the most important factors to be considered in reconstructive surgery for pelvic organ prolapse (Fig. 37.1).

Ischial Spine

The ischial spine is a triangular bony eminence projecting from the dorsal border of the ischium. It serves as an attachment point for the sacrospinous ligament, the coccygeus and levator ani muscles, and the pelvic fascia. The space between the ischial spines is the narrowest diameter in the female pelvis and contains the strongest connective tissue.

Fig. 37.1 A schematic of reconstructed Pericervical Ring after hysterectomy demonstrating the convergence of pubocervical fascia, the rectovaginal septum and the uterosacral ligament at the level of ischial spine

Pelvic Ureter

During hysterectomy with co-existing POP, one must be keenly aware of the potential for anatomic deviation in the course of the ureter. In the patient without prolapse, the pelvic ureter follows the internal iliac artery, traverses downward from the bifurcation, passes under the uterine artery at the level of the ischial spine, and then turns forward and medially over the anterior lateral vaginal fornix to enter the posterolateral wall of the bladder. At the "knee" of the ureter, the distance between the ureter and the cervix is approximately 1.5–2 cm, however, as the ureter curves forward over the anterior vaginal fornix, this distance can become even smaller, especially with co-existing prolapse.

The surgeon must be vigilant and have a clear idea of the location of the ureter while performing desiccation or ligation of the uterine vessels and while performing the anterior and lateral aspect of colpotomy during hysterectomy. In the setting of utero-vaginal prolapse (especially in the case of chronic uterovaginal prolapse with elongated cervix), anterior enterocele, and cystocele the course of the ureter between the "knee" and the bladder may be displaced, medially or anteriorly. In this area, the ureter can easily be damaged through ligation, thermal injury, transection, or impingement during hysterectomy and during the repair of prolapse.

Uterosacral Ligaments

Many gynecologists hold a traditional concept of the uterosacral ligament believing that it spans from the back of the cervico-vaginal junction curving posteriorly to reach the anterior and lateral aspects of the sacrum. The surgical anatomy of the uterosacral ligament may appear to be readily identified as a dense, strong band of connective tissue medial and posterior to the ischial spine. However, cadaveric and histological studies have generally demonstrated an absence of actual condensed ligamentous structure.

In 2004, Umek and DeLancey used MRI to demonstrate the origin and insertion points of the uterosacral ligament on 61 asymptomatic women. Their study revealed that more than 82 % of uterosacral ligaments actually inserted into the sacrospinous ligament and coccygeus muscle, while only 7 % inserted onto the sacrum [4]. Again, in 2012, DeLancey's group, at the University of Michigan, used dynamic MRI to track the uterosacral ligament on 20 nulliparous women. They found that in 73 % of them, the uterosacral ligaments actually inserted into the sacrospinous ligament and coccygeus muscle. Only 21 % of them had insertions into the presacral fascia. No direct attachment to the sacrum was identified [5]. Therefore, the primary insertion site of the uterosacral ligament is the sacrospinous ligament or coccygeus muscle at the level of the pericervical ring, which holds the cervix and apex of vagina in their normal anatomic position.

Vaginal Tube and Enterocele

Prolapse is the end result of the detachment of endopelvic fascia from its surrounding connective tissue support. Pathophysiologically, prolapse is a condition of herniation – a fascial separation that occurs within the vaginal tube. From a surgical perspective, the vagina is a fibromuscular tube that is completely encapsulated by endopelvic fascia. Anteriorly, this is the pubocervical fascia; posteriorly, the rectovaginal septum, and; superiorly, the uterosacro-cardinal ligament complex. This fibromuscular vaginal tube is lined by vaginal epithelium. Biomechanically, the endopelvic fascia cannot be stretched or attenuated. Thus, it breaks, or separates, under chronic pressure while vaginal epithelium and pelvic peritoneum can be stretched endlessly under pressure.

Fascial separations occurring within the vaginal wall result in pelvic peritoneum having direct contact with vaginal epithelium. Under pressure, both will stretch and protrude, bulging into the vagina forming a hernia sac, or enterocele. Separation between the pubocervical fascia and pericervical ring produces an anterior enterocele. Similarly, a separation in the connective tissue of the rectovaginal septum and

pericervical ring presents as a posterior enterocele. Procidentia results from circumferential separation at the pericervical ring together with disintegration of the uterosacral ligament attachments (Table 37.1).

Surgical Considerations

Surgical reconstruction and restoration of the integrity of the pericervical ring will correct a majority of prolapses. In pelvic reconstructive surgery, one must first restore the integrity of the fibromuscular vaginal tube by reattaching the pubocervical fascia to the rectovaginal septum after hysterectomy or by attaching them both to the cervix if the uterus is to be preserved. Next, the apex of the vagina, or the cervix, is suspended to the proximal part of the uterosacral ligaments at the level of the ischial spine. In most cases, this will restore the normal vaginal length and vaginal axis. The latter step can also be accomplished by reattaching the apex of the vagina or the cervix to the sacrospinous ligament, or by performing a sacrocolpopexy with mesh graft. Literature strongly suggests that without proper suspension of the apex of vagina or cervix to the level of the ischial spine, all attempts at prolapse repair will ultimately fail [6].

Because pelvic floor defects are true herniations in pelvic floor fascia, the detached fascia needs to be reconstructed and repairs should be performed using non-absorbable monofilament sutures. In our center, we currently perform laparoscopic uterosacral ligament vault suspension using non-absorbable monofilament suture and laparoscopic or robotic sacrocolpopexy with large pore monofilament polypropylene synthetic mesh. We reserve the use of synthetic mesh for cases of severe prolapse in which the fascia is severely damaged or the patient has had recurrent symptomatic prolapse with failed previous surgical repair.

Following apical suspension, a vaginal examination is performed to ensure that the depth of the vagina has been restored. Frequent intraoperative vaginal examinations, with simultaneous laparoscopic observation, are performed to confirm appropriate correction of anterior and posterior vaginal wall prolapse. In some cases, after the appropriate reconstruction and restoration of the pericervical ring, an anterior or posterior defect will persist. This warrants further reconstruction with either a retropubic paravaginal repair, a midline cystocele repair or vaginal posterior colporrhaphy with perineorrhaphy.

Pre-operative Patient Counseling

If a graft material or non-absorbable synthetic mesh is being considered, the patient must be thoroughly informed and counseled regarding the risks and possible complications associated with the use of these materials. Risks of mesh include erosion into the vagina, dyspareunia, bowel obstruction, infection and pelvic pain. The patient must sign a comprehensive consent prior to surgery.

Additional counseling should include discussion on the possible but rare occurrences of postoperative urinary, bowel and sexual dysfunction. Expected long-term outcomes based on available data should be discussed in detail with the patient. The authors firmly believe that verbalized understanding by the patient of known failure rates, potential complications and potential for *de novo* stress incontinence or urge incontinence can help prevent false expectations and ultimately lead to greater patient satisfaction.

Preoperative Evaluation

A thorough medical history and prolapse history (including urinary, gastrointestinal, and sexual histories) must be carefully taken and recorded in the patient's file prior to surgery. The patient must be examined in both erect and supine position to map out pelvic floor defects in detail. The Pelvic Organ Prolapse Quantification (POP-Q) system is used to quantify, describe, and stage pelvic support. Urinary incontinence must be assessed in the erect and supine positions with and without reduction of prolapse. Assessment of urethral mobility, simple office cystometrics and post void residual are generally adequate for evaluation. A randomized trial, in 2012, demonstrated that for patients with history of uncomplicated, demonstrable stress urinary incontinence, preoperative evaluation in the office alone was not inferior to performing urodynamic testing. This was based on outcomes at one year [7]. In our practice, urodynamic studies are reserved for those with complicated symptoms.

Table 37.1 Fascial separations occurring within the vaginal wall result in pelvic organ prolapse. This table lists traditional nomenclature and pairs it with the precise fascial defect as related to the pericervical ring

Organ prolapse	Anatomical defect
Anterior compartment (anterior enterocele)	Separation of pubocervical fascia from pericervical ring
Posterior compartment (posterior enterocele)	Separation of rectovaginal septum from pericervical ring
Complete procidentia	Separation of the anterior and posterior fascia from the uterosacral ligament attachments and the pericervical ring

Operative Procedures

Patient Positioning

The patient is placed on a non-slip foam pad in the dorsolithotomy position with both legs well supported, as steep Trendelenberg will be maintained throughout most of the procedure. The arms are carefully tucked alongside the body. Attention is taken to ensure that the brachial plexus is not under untoward strain. Padding is placed on all pressure points including the occiput, to prevent neurovascular and ischemic compression injury. The surgeon should have unobstructed access to the perineum and vagina for the use of a vaginal or uterine manipulator, rectal probe and performance of vaginal examination during the surgery. Nasogastric or orogastric tube should be in position prior to subcostal insertion of a Veress needle or trocar to avoid injury to the stomach.

A Foley catheter is always placed at the onset of the surgery.

Placement of Uterine Manipulator

An effective uterine mobilizer capable of uterine anteversion, retroversion and lateral motion is essential. Many options exist for this purpose. A manipulator with a colpotomizing cup is helpful, but not imperative. If the surgeon prefers a non-disposable approach, instruments readily available in any gynecologic procedure tray may be used. In our center, for years we successfully used a simple technique: A single-toothed tenaculum is secured to the anterior lip of the cervix and a uterine sound is placed within the uterus to the fundus. A second tenaculum is placed on the posterior lip of the cervix and subsequently the three instruments are secured tightly together using sterile rubber bands.

Creation of Pneumoperitoneum

Establishing pneumoperitoneum may be one of the most critical steps in the performance of laparoscopic surgery. Many techniques exist with or without the use of a Veress needle, yet no technique has been demonstrated to be superior. In our practice, a Veress needle is usually inserted in the middle of the umbilicus or in the left upper quadrant, a fingerbreadth beneath the costal margin at the mid-clavicular line (Palmer's Point). Saline test or "hanging drop test" confirms ideal placement. Opening pressures for CO_2 gas should be under 10 mmHg, or extraperitoneal placement may have occurred. The patient should be in a flat position during initial placement of the Veress needle. The insufflator pressure may be initially set to 20 mmHg for placement of the trocars, but it should be reduced to 14–15 mmHg for duration of the procedure.

Trocar Placement

Five trocars are inserted after the pneumoperitoneum: a 10 mm umbilical trocar and four 5 mm secondary trocars. A 10 mm laparoscope is used and is inserted through the umbilical trocar sleeve and the patient is placed in steep Trendelenberg position. Two 5 mm trocars are placed lateral to the deep inferior epigastric vessels in the lower abdomen and two 5 mm trocars are placed lateral to the abdominal rectus muscles at or slightly below the umbilical level (Fig. 37.2). The bowels are pushed back to the upper abdomen.

Laparoscopic Hysterectomy and Repair of Concomitant POP

Step 1

Ureteral Identification and Dissection

In the setting of pelvic organ prolapse, the course of the ureter may be distorted. Inspection and exposure of the ureters bilaterally should be accomplished primarily and prior to hysterectomy and any reparative procedures. The transperitoneal approach to ureteral dissection is used in the majority of cases. For those patients who are obese or who have complicated pelvic pathology, a retroperitoneal approach may be necessary.

Transperitoneal Exposure of the Ureters

The ureters on both sides are visualized through the laparoscope (Fig. 37.3). To expose and dissect the ureters, an atraumatic grasper is held open against the peritoneum just above the ureter at the level of the pelvic brim. The peritoneum is incised just below the ureter (Fig. 37.4). A grasper is used to bluntly separate the peritoneum away from the ureter

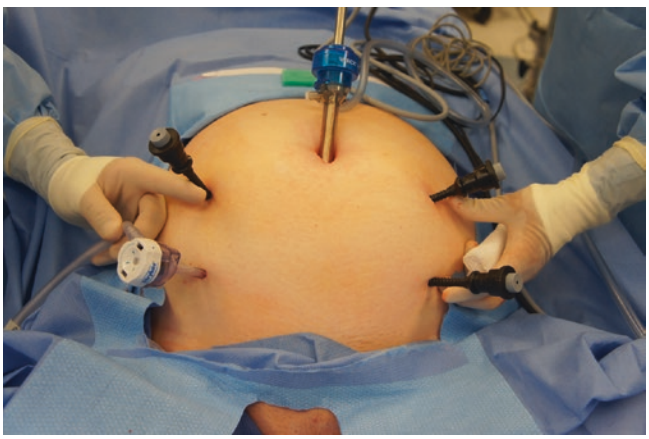

Fig. 37.2 The authors utilize four working 5 mm ports plus a 10 mm umbilical port for the laparoscope

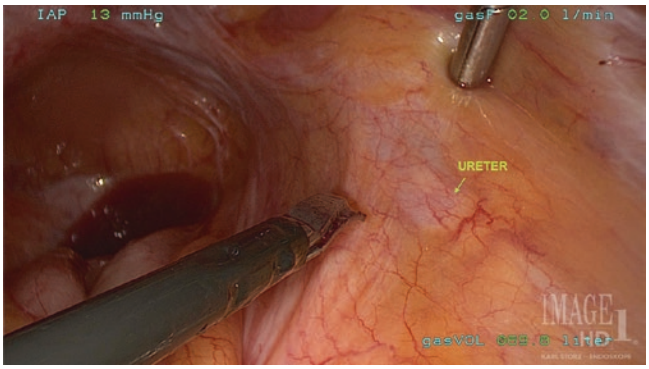

Fig. 37.3 The right ureter is visible coursing beneath the peritoneum. Transperitoneal dissection of the ureter begins by opening the peritoneum just beneath the ureter

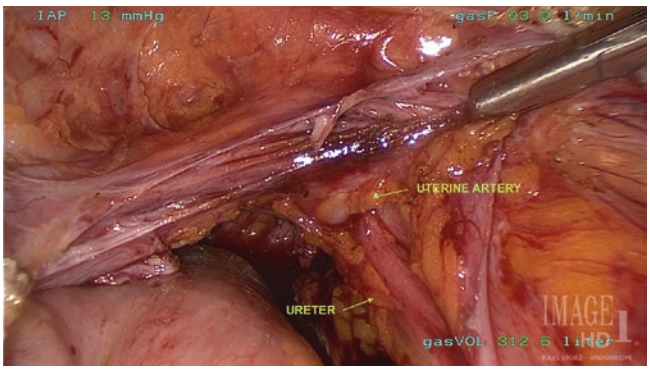

Fig. 37.5 The ureter should be exposed to the level at which it passes beneath the uterine artery. Here the ureter is seen passing just beneath the uterine artery

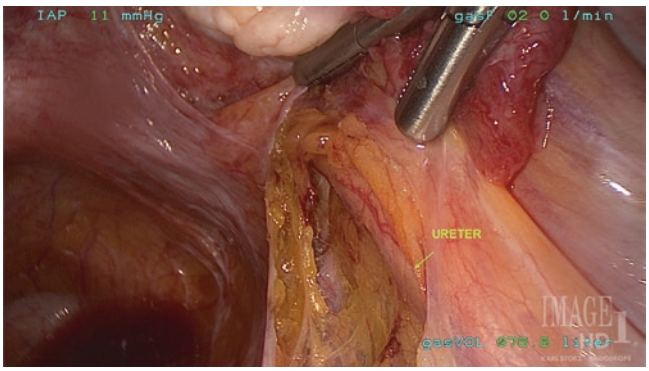

Fig. 37.4 Transperitoneal exposure of the ureter: ureteral exposure is accomplished by opening the peritoneum overlying the ureter. Atraumatic graspers are used to bluntly separate the tissue overlying the ureters and provide counter-traction as the surgeon opens the peritoneum

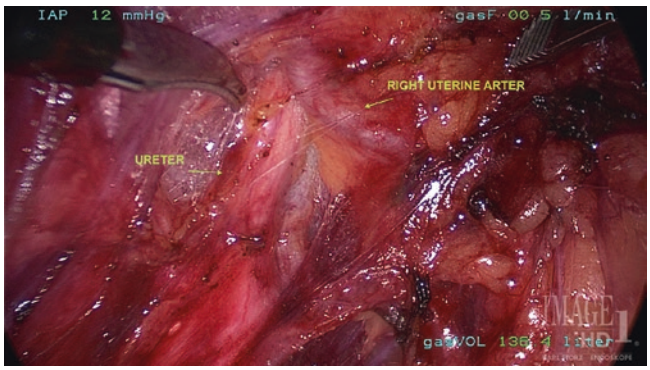

Fig. 37.6 In some patients, habitus or pelvic pathology will dictate the need to expose the ureter by opening the retroperitoneum. This may be accomplished by entering the peritoneum longitudinally, lateral to the infundibulopelvic ligament and medial to the external iliac artery

and a relaxing peritoneal incision is performed. The ureter is exposed to the level where it passes under the uterine artery (Fig. 37.5). This dissection prevents the ureter from becoming tethered, as adjacent tissues are plicated. The procedure is duplicated on the opposite side. It is important to expose the ureters prior to performing the hysterectomy and prolapse support procedures, as visualization of the ureters may become more difficult with retroperitoneal CO_2 gas infiltration, swelling and bleeding.

Retroperitoneal Dissection to Expose the Ureters

Exposure may be accomplished by opening the peritoneum longitudinally between the external iliac artery and the infundibulopelvic ligament (Figs. 37.6 and 37.7). Dissection is carried down posteriorly to the infundibulopelvic ligament to expose the ureter and internal iliac artery (Figs. 37.8, 37.9, and 37.10). Exposure of the ureter should continue until the uterine artery is seen crossing over the ureter (Fig. 37.11). The space between the ureter (medially) and the internal iliac artery (laterally) can be entered posteriorly with ease and is fairly avascular.

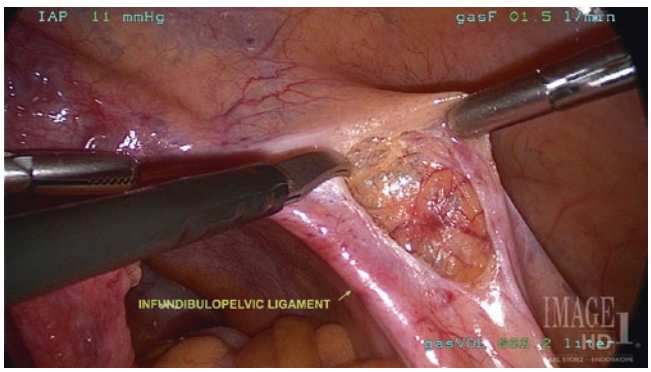

Fig. 37.7 The retroperitoneal space is opened on the right, beginning lateral to the infundibulopelvic ligament

Step 2

Exposure of the Rectovaginal Septum

Regardless of whether the prolapse repair will be performed with mesh or suture, it is crucial to expose and identify the pubocervical fascia and rectovaginal septum before completing the hysterectomy.

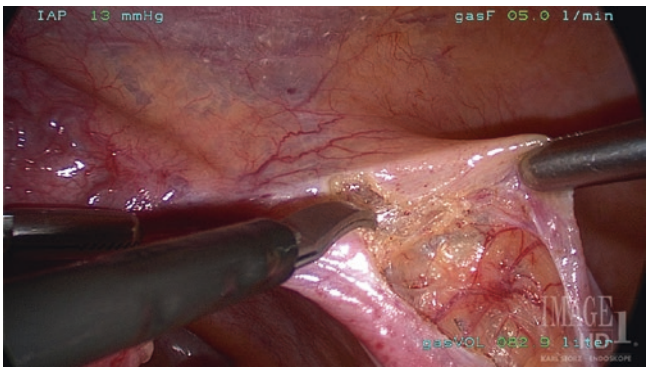

Fig. 37.8 The peritoneal incision is extended caudally

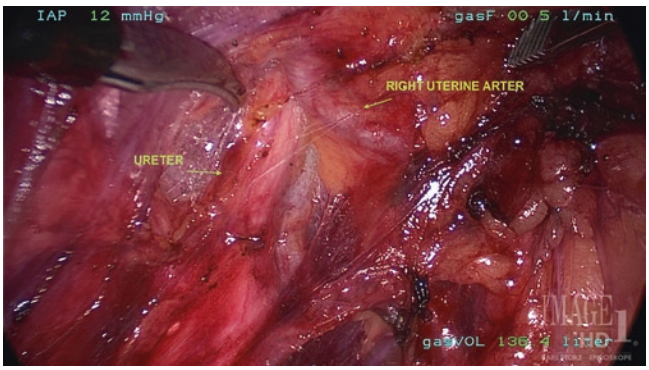

Fig. 37.11 Exposure of the ureter should continue until the uterine artery is seen crossing over the ureter

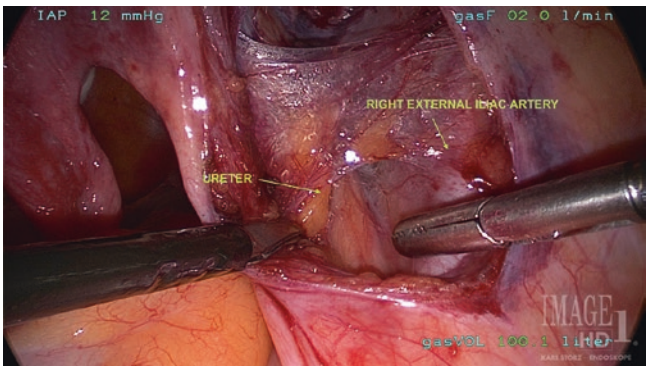

Fig. 37.9 The ureter is identified medial to the external iliac artery

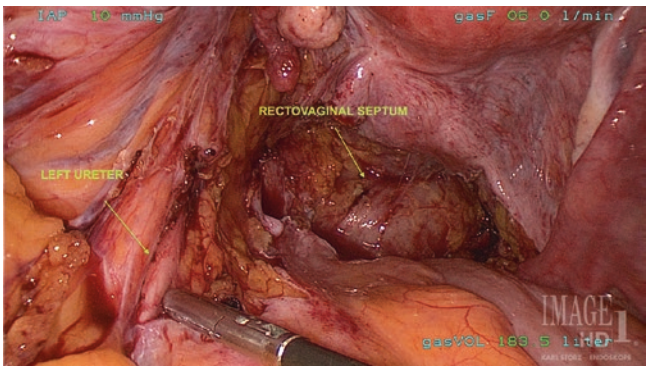

Fig. 37.12 The rectovaginal septum is exposed with simultaneous visualization of the left ureter shown here

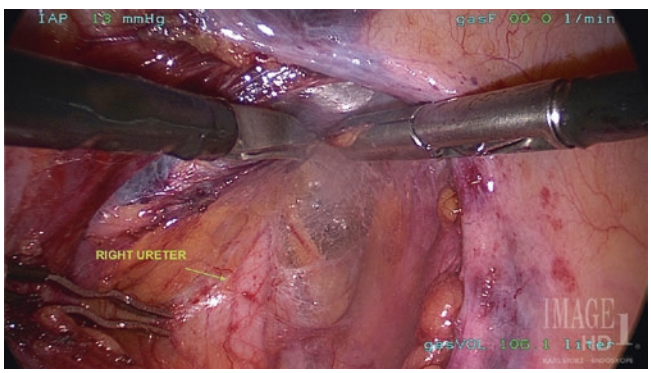

Fig. 37.10 The dissection is continued along the course of the ureter, moving caudally

The assistant, using the uterine manipulator, pushes the uterus anteriorly and superiorly. A rectal probe is helpful in preventing injury of the rectum during the dissection and will facilitate the identification of both the pararectal and rectovaginal spaces. First, the rectal probe is placed and the rectum is deviated toward the patient's left side. A longitudinal incision is made in the peritoneum overlying the right pararectal space, and this is extended caudally toward the rectovaginal space. The rectovaginal space is entered on the right side. The same procedure is then performed on the left side with the rectum deviated by the rectal probe to the right during the dissection. The rectal probe can be removed after the rectovaginal space is successfully exposed.

The rectovaginal space is dissected caudally until the rectovaginal septum can be clearly identified (Fig. 37.12). The rectovaginal septum may be confirmed by placing the surgeon's fingers inside the vagina, while simultaneously grasping the rectovaginal septum laparoscopically and forcefully pulling on it. The fingers in the vagina can feel that the entire posterior vaginal wall is being pulled up. In the case of more severe prolapse, the rectovaginal septum will sometimes be found quite low within the space.

Step 3

Exposure of Pubocervical Fascia

To expose the pubocervical fascia, the bladder must be dissected off of the anterior vaginal wall. A transverse incision is made just below the vesicouterine peritoneal fold (Fig. 37.13). To avoid bladder injury during the dissection, after the vesicocervical space is entered, the bladder is grasped with an atraumatic grasping forceps, lifted up and pushed caudally by the

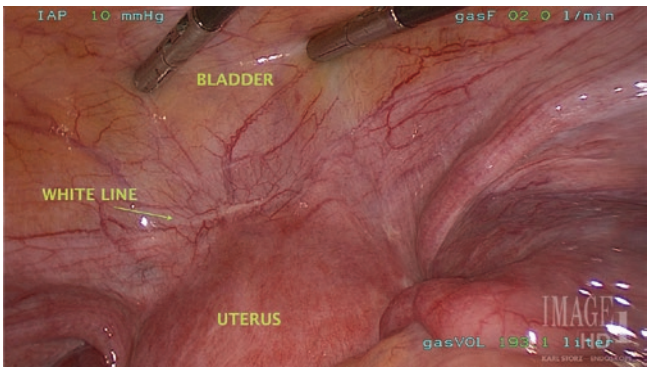

Fig. 37.13 The vesico-uterine peritoneum is seen here with a clearly defined "white line", which lies at the junction between the bladder peritoneum and anterior broad ligament, below which the surgeon will find an ideal plane for creating the bladder flap and exposing the pubocervical fascia

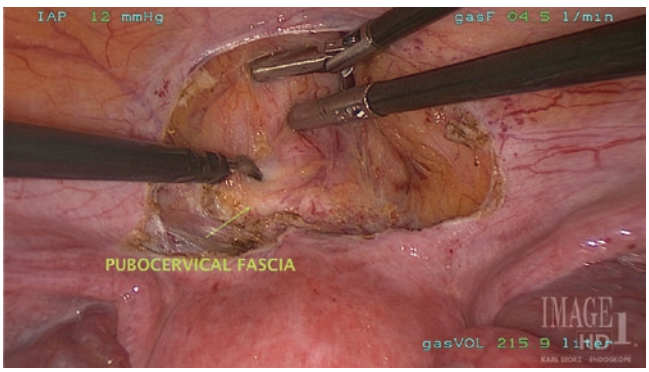

Fig. 37.14 The vesico-uterine peritoneum is entered sharply and dissected to expose the pubocervical fascia

assistant (Fig. 37.14). The vesico-cervical and vesico-vaginal space can then be easily entered and dissected bloodlessly. If excessive bleeding is encountered during the dissection, the possibility of having entered the wrong plane or having caused a bladder injury should be assessed. If it is difficult to distinguish the bladder from the adjacent planes of tissue, the bladder may be backfilled with 200–250 cc of sterile saline to aid in identification of planes. This is done by instilling the bladder with normal saline, through the Foley catheter, and clamping it. The clamp is released once the dissection is completed.

The pubocervical fascia is identified and confirmed by grasping and pulling the fascia laparoscopically while simultaneously placing the surgeon's fingers inside the vagina to appreciate the anterior vaginal wall being pulled upward during laparoscopic traction on the fascia. In the case of a large transverse defect, when the pubocervical fascia has detached from the cervix, it may be found very low in the vagina. This anterior fascia will be incorporated with the rectovaginal septum, in closing the vaginal cuff, to re-establish the integrity of the vaginal tube. When the apex is then attached to the proximal uterosacral ligaments, the pericervical ring is restored.

Step 4

Hysterectomy

Coexisting pelvic organ prolapse presents a unique challenge during hysterectomy, particularly due to the frequent occurrence of an elongated cervix. A study published by DeLancey et al, from 2012, evaluated women with and without prolapse by pelvic MRI. They demonstrated that in 40% of women with prolapse the cervix was elongated [8]. This elongation of the cervix causes displacement and distortion of the course of the ureter. Thus, special care must be taken to visualize the ureter during the ligation and division of the uterine vessels.

Securing the Uterine Vessels

The posterior and anterior leaves of the broad ligament are skeletonized revealing the uterine vessels. The uterine vessels are skeletonized, coagulated and transected being mindful that the ureter passes just lateral and inferior at this point. In lieu of using electrosurgical techniques, we frequently suture ligate the uterine vessels to avoid the potential for thermal injury to the ureter (Fig. 37.15). Following removal of the uterus, often the startling proximity of the ureter to the uterine artery stump may be readily appreciated.

Colpotomy

Most modern uterine manipulators incorporate a colpotomizer cup or ring which simplifies entry into the top of the vagina and enhances ureteral protection by lateralizing these structures. The circumferential colpotomy is performed along the ring or cup (Fig. 37.16), however, in the presence of prolapse, we routinely open the anterior and posterior vaginal fornix first, followed by lateral colpotomy very close to cervix to further reduce the incidence of ureteral injury and to preserve vaginal length. The assistant should maintain cephalad pressure with the manipulator further decreasing the risk of ureteral injury.

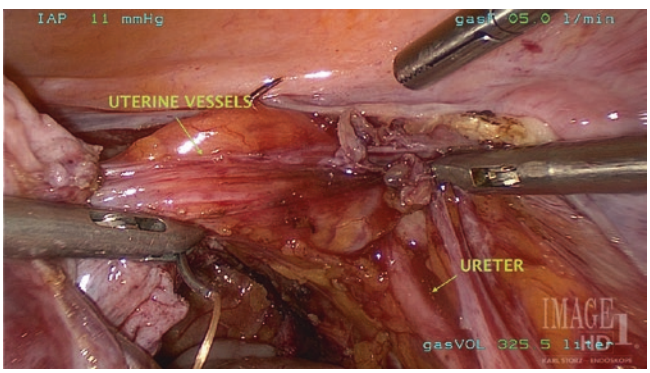

Fig. 37.15 The right uterine vessels have been skeletonized and are suture ligated using extracorporeal knot technique. Note the fully identified and visualized right ureter passing just beneath the uterine artery lateral to the ligation

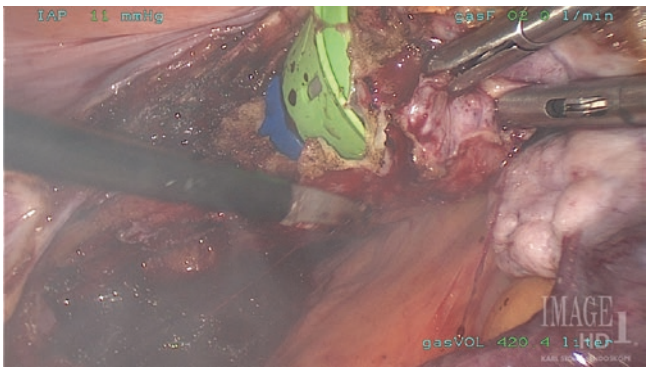

Fig. 37.16 Circumferential colpotomy is performed with the vaginal cuff opened as close to the cervix as possible to preserve vaginal length

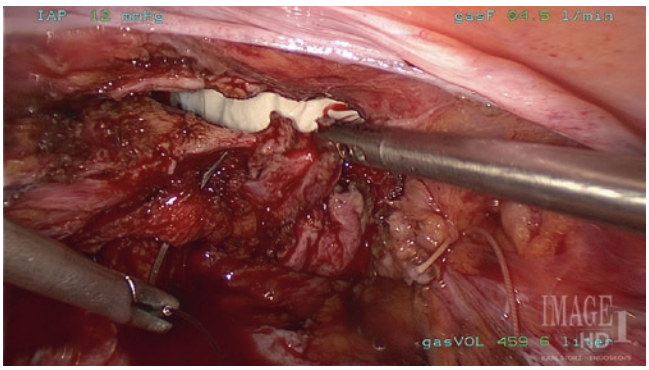

Fig. 37.17 The vaginal cuff is closed using an absorbable monofilament suture. Each bite includes vaginal epithelium and at least 1.5 cm of pubocervical and rectovaginal fascia. Note the presence of a glove in the vagina to maintain pnemoperitoneum

The uterus and adnexa are delivered through the vagina. Rarely, in the case of prolapse, would the uterus be too large to fit through the vagina. Under those exceptions, it will need to be removed using a bag and morcelation or other technique of surgeon preference. Controversy regarding morcelation is outside the scope of this chapter. A vaginal occlusion device is placed in the vagina to maintain pneumoperitoneum throughout the remainder of the procedure or until the cuff is closed.

Step 5

Cuff Closure with Enterocele Repair

For those patients with enterocele, a two-layer closure of the vaginal cuff is performed. The first layer is to close the vaginal epithelium with 3-0 or 2-0 absorbable monofilament sutures followed by a second layer to reapproximate the pubocervical fascia and rectovaginal septum with permanent non-absorbable sutures. Special care must be taken to include adequate fascial tissue in the suture bites.

This step will repair the enterocele and restore the integrity of vaginal fibromuscular tube.

Cuff Closure Without Presence of Enterocele

Closure of the cuff should always re-approximate the rectovaginal septum and the pubocervical fascia. For those patients without enterocele, the vaginal cuff can be closed laparoscopically using a monofilament absorbable suture (Fig. 37.17). Large bites are incorporated that include pubocervical fascia, rectovaginal septum and both anterior and posterior vaginal epithelium (Fig. 37.18). We advocate taking suture bites of at least 1–1.5 cm of tissue for the vaginal cuff closure. Due to the magnifying effect of the laparoscopic view, the surgeon can have a false perception of the amount of tissue included while suturing. Small vaginal cuff suture bites and inadequate hemostasis are the leading causes of postoperative vaginal cuff bleeding and dehiscence.

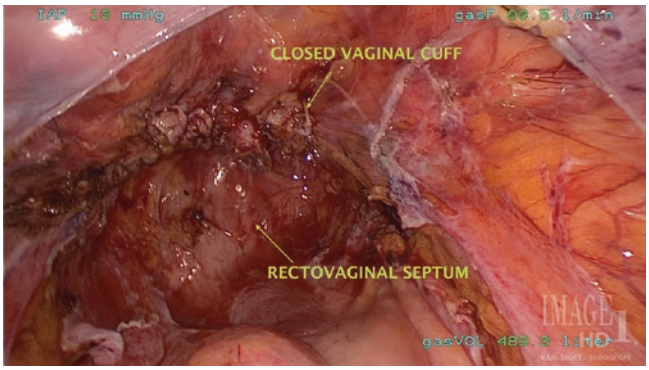

Fig. 37.18 The vaginal cuff is seen fully closed. The right ureter can also be visualized

Step 6

Vaginal Apical Suspension

Uterosacral ligament vaginal vault suspension is performed to re-suspend the apex of the vagina to the level of the ischial spine—the normal anatomical position of the vaginal apex (Fig. 37.19).

To determine the location of the ischial spine, the surgeon places two fingers inside the vagina, palpating the ischial spine, while simultaneously viewing laparoscopically the exact location of the ischial spine from above. A rectal probe can be used to deviate the rectum away from each side of the operative field as the surgeon incorporates the uterosacral ligament complex of tissue at the level of the ischial spine. Using a large-diameter permanent, non-absorbable suture, a deep bite is placed at the point about 1.5–2 cm medial and posterior to the ischial spine (Fig. 37.20). The surgeon should confirm that this stitch truly incorporates the uterosacral ligament by lifting it. It should be a substantial bite that can tolerate significant traction (Fig. 37.21). While elevating the tissue, a second, deeper, bite is taken (Fig. 37.22). This suture is then plicated to the lateral part of the vaginal cuff on the

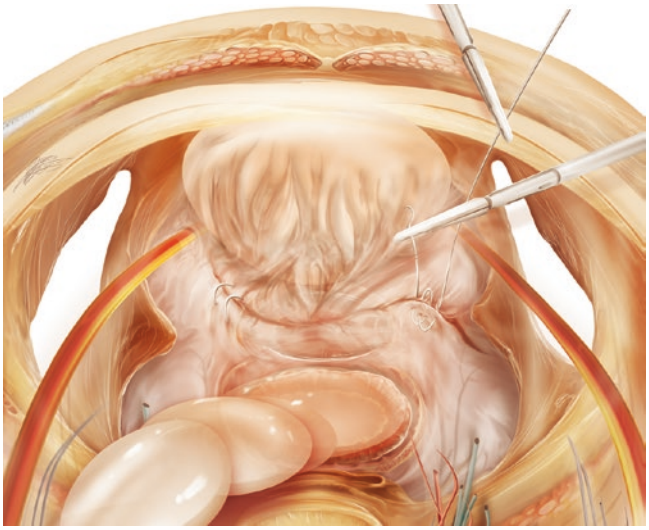

Fig. 37.19 A large permanent suture is used to secure a substantial figure-of-eight bite of tissue at the level of the ischial spine

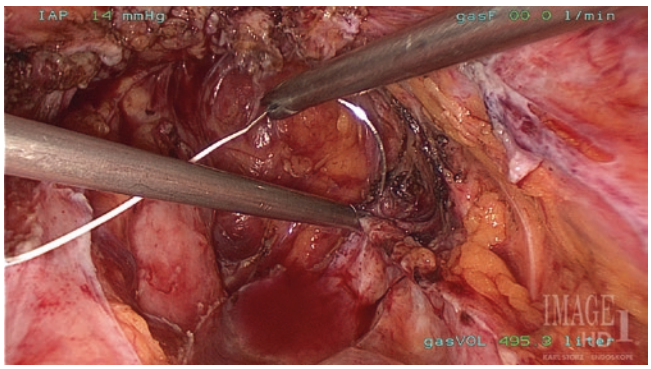

Fig. 37.20 Using two fingers transvaginally, the landmarks of the ischial spines are first identified before placing the first suture. Large suture bites are taken 1.5–2 cm medial and posterior to the ischial spine

ipisilateral side with a sizeable bite of rectovaginal septum and pubocervical fascia (Figs. 37.23, 37.24, and 37.25).

The same procedure is performed bilaterally (Figs. 37.26 and 37.27). Both sutures are tied with extracorporeal knot technique without undue tension (Fig. 37.28). With too much tension there is a higher risk of postoperative pain and discomfort with failure of the suspension.

Care must be taken not to leave any suture gaps. If suture gaps are evident, a second stitch with the same suture material is used to close the gaps (Figs. 37.29, 37.30, and 37.31).

Typically, we use CV-0 Gore-Tex (Gore Medical, Flagstaff, AZ) suture or Number 1 Ethibond (Ethicon) suture for laparoscopic uterosacral ligament vaginal vault suspension, with good result. These sutures should not enter the vaginal canal. Vaginal exposure of those permanent nonabsorbable sutures will lead to development of annoying foreign body granulation tissue, vaginal bleeding and possible infection.

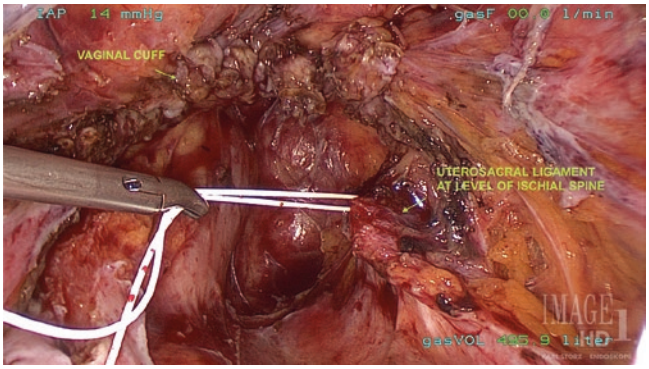

Fig. 37.21 The first bite on the uterosacral ligament at the level of the ischial spines is pulled with enough tension to ensure the strength and depth of tissue is adequate. This elevation will assure an ideal placement of the second bite

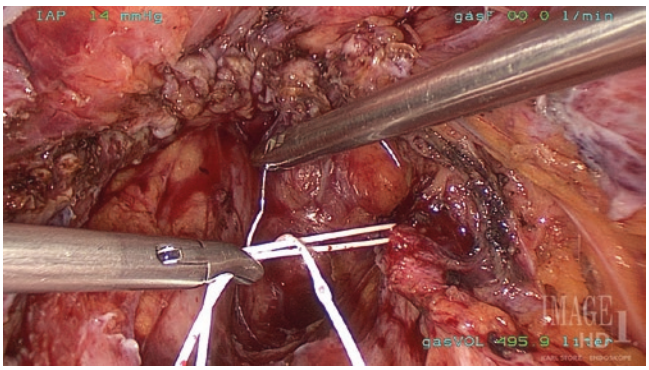

Fig. 37.22 The first suture is lifted and a much larger second bite with the same suture is taken at the same location, that is 1.5–2 cm medial and posterior to the ischial spine

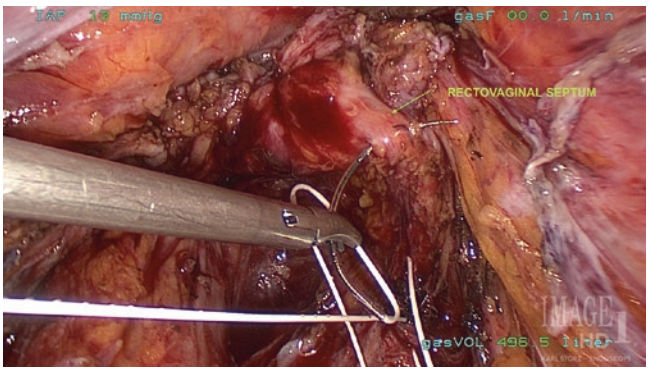

Fig. 37.23 The uterosacral ligament is plicated to the lateral apex of the vagina, incorporating the rectovaginal septum. The uterosacral ligament suture is then continued, plicating it with a large bite of rectovaginal septum close to the closed vaginal cuff. This same suture will continue through the lateral portion of the vaginal cuff, incorporating a large bite of pubocervical fascia just anteriorly above the vaginal cuff

Sacrocolpopexy

The purpose of using mesh in abdominal, robotic or laparoscopic sacrocolpopexy is to replace the failed endopelvic fascia. The risks of mesh are well documented and include

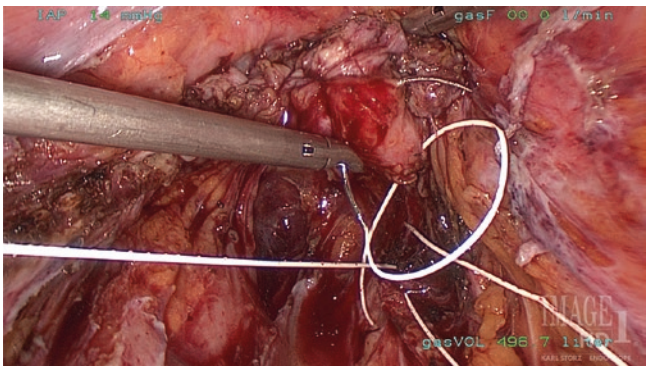

Fig. 37.24 A second bite secures the rectovaginal septum. Occasionally, two bites of rectovaginal septum posteriorly may be taken in cases with more severe prolapse

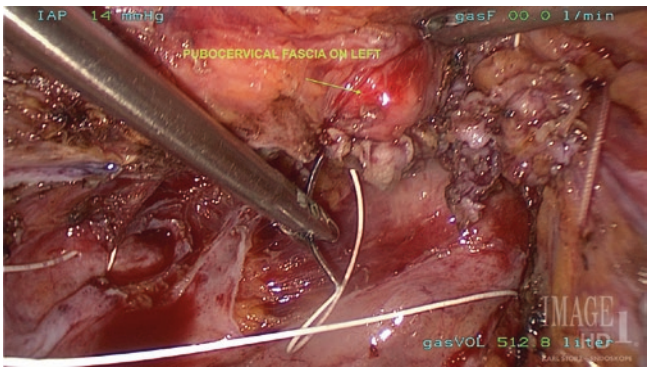

Fig. 37.27 The left uterosacral ligament is plicated to the ipisilateral rectovaginal septum, vaginal apex, and here incorporating the left aspect of the pubocervical fascia

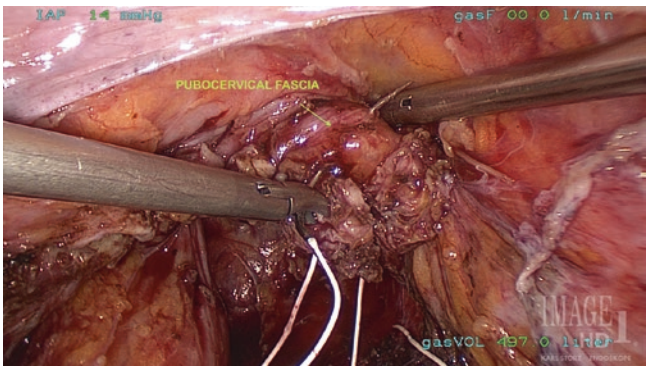

Fig. 37.25 The large bite of pubocervical fascia is incorporated and sutured with the same ipsilateral uterosacral ligament suture

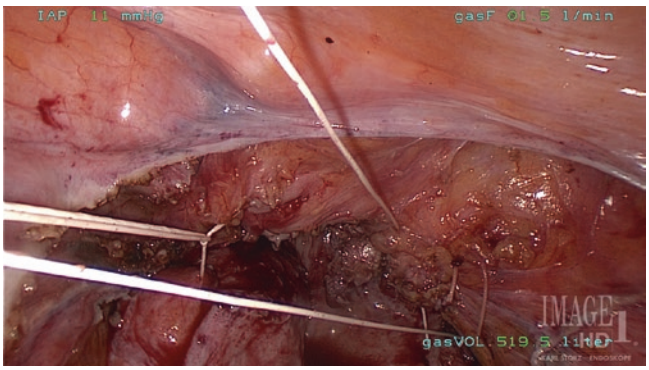

Fig. 37.28 Bilateral uterosacral ligament sutures are seen suspending the apex of the vaginal cuff

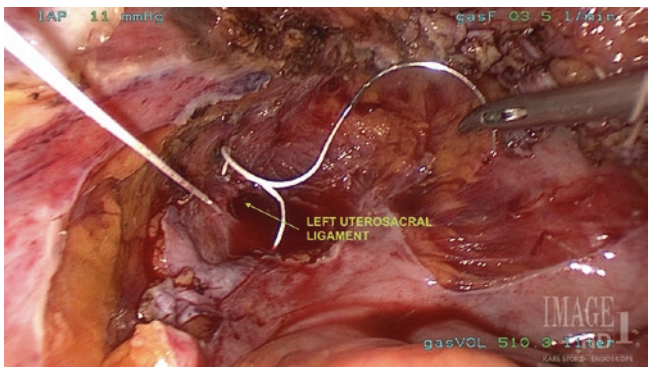

Fig. 37.26 The left uterosacral ligament is secured at the level of the ischial spines

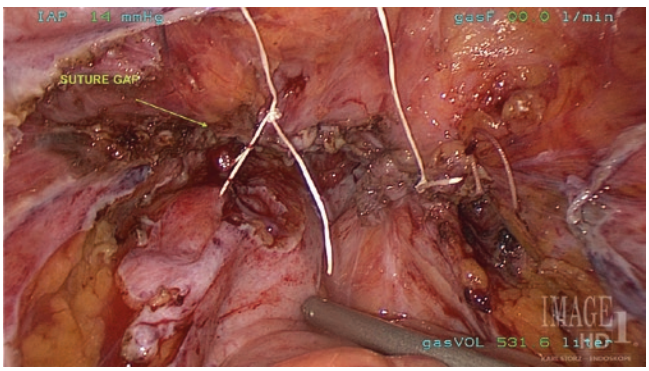

Fig. 37.29 This image demonstrates the gap in the initial suspension stitch on the left. This will be closed using a second suture of the same material. This is shown to illustrate that all suspension sutures are, and must be tied without undue tension

infection, erosion, pain, contraction of the scar and dyspareunia. Multiple studies have demonstrated that some types of mesh are superior to others and it is clear that large pore polypropylene mesh carries the lowest risk of infection, while the ePTFE mesh confers a fourfold increased risk of complications. Concomitant total hysterectomy and smoking increase the risk of mesh complications and are modifiable factors [9].

If a sacrocolpopexy has been planned, a supracervical hysterectomy should be performed, unless contraindicated [9]. Supracervical hysterectomy can easily be accomplished after both uterine vessels are secured and divided. Most menopausal uteri can be placed in a bag and easily removed by slightly extending the fascial incision of the largest laparoscopic or

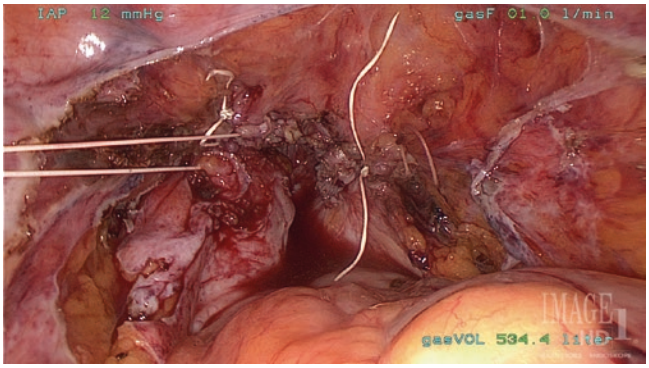

Fig. 37.30 Note how the second suture closes the gap without creating undue tension on the suspension

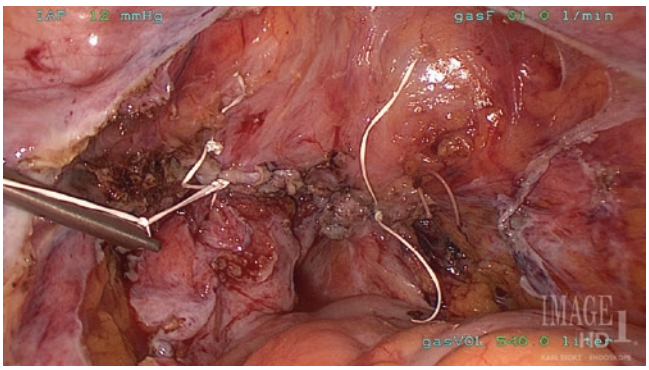

Fig. 37.31 Here we see the completion of the uterosacral ligament suspension and the re-establishment of the pericervical ring

robotic port. For larger uteri, safe extraction techniques have been described and are beyond the scope of this chapter.

The sigmoid colon is deviated to the patient's left side with the use of a rectal probe. A longitudinal incision is made on the peritoneum overlying the sacral promontory. The incision should be medial to the ureter and common iliac vessels and lateral to the descending sigmoid colon. Careful dissection is carried out along the right side of S-1 and S-2 to expose the anterior longitudinal ligament of the sacrum. Special care must be paid not to injure the middle and lateral sacral vessels in this area. Using a 30° laparoscope will facilitate this dissection. The peritoneal incision is extended caudally to join the longitudinal incision over the right pararectal space, which continues down to the rectovaginal space (see Step 2 above).

If a commercially available Y shaped synthetic mesh is used (Type 1, totally macroporous, Polypropylene mesh), the arms should be trimmed appropriately to fit the exposed fascia. The anterior arm of the mesh is sutured to the previously exposed pubocervical fascia and anterior cervix and the posterior arm of the mesh is sutured to the rectovaginal septum and posterior cervix with 2-0 polypropylene sutures. We typically place one to three rows of three interrupted sutures anteriorly and posteriorly with two on the endopelvic fascia and one on the cervix. An assistant gently pushes the cervix or vaginal vault superiorly, with a vaginal probe until the apex is at the level of the ischial spines. The stem of the Y- mesh is sutured to the anterior longitudinal ligament of the sacrum with two interrupted, non-absorbable sutures. The mesh must be placed snuggly, but without undue tension. Reperitonization with absorbable suture to cover the mesh must also be performed to prevent the rare complication of bowel obstruction secondary to bowel adhesions to the synthetic mesh.

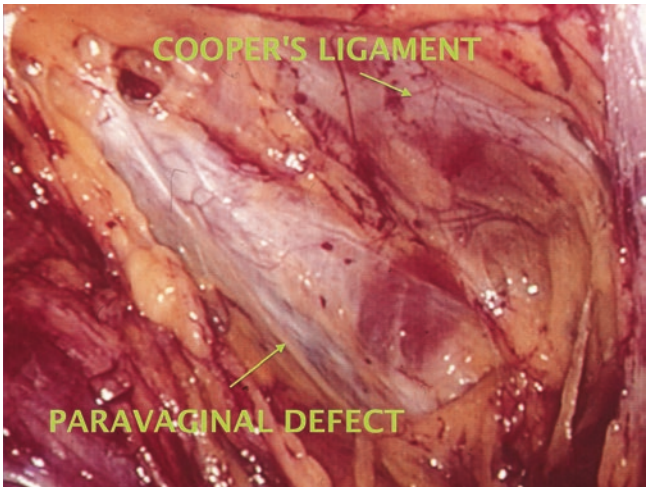

Fig. 37.32 A paravaginal defect can be appreciated in this photo. A paravaginal defect may be responsible for a persistent anterior compartment defect following apical suspension

Step 7

Re-evaluation of Pelvic Floor Support

A thorough and systematic vaginal examination must be performed at this time to re-evaluate the pelvic floor support. The apical support and vaginal length, the anterior and posterior vaginal wall support and the status of the perineal body must be carefully evaluated. All of the remaining defects should be corrected.

1. Prolapse of the vaginal apex or cervix.
   (i). The apex of the vagina or cervix must be at the level of the ischial spines.
   (ii). Additional uterosacral ligament suspension sutures should be placed if the apex is not at the level of the ischial spines.
   (iii). In the case of sacrocolpopexy, tighten the mesh to bring the apex of the vagina or cervix up to the level of the ischial spines to restore the normal vaginal length.
2. Persistent anterior vaginal wall defect (Fig. 37.32).

   More than 80% of cystoceles are due to a paravaginal defect and the majority of paravaginal defects will be cor-

rected after the apex of the vagina is restored to its normal position at the level of ischial spine. Therefore, if the anterior wall vaginal defect persists following suspension, one must consider the following three possibilities:

(i). Inadequate or incomplete repair of anterior enterocele.

Re-evaluate the closure of vaginal cuff, to ensure that the pubocervical fascia is well attached to the rectovaginal septum and that the cuff is suspended to the proximal part of the uterosacral ligament at the level of the ischial spine. (Repeat Steps 5 and 6).

(ii). Patient has an extended paravaginal defect.

The retropubic space is entered and dissected laparoscopically, and if paravaginal defect (unilateral or bilateral) is detected, the defect is then repaired by reattaching the pubocervical fascia to the arcus tendineus fascia of pelvis with interrupted stitches using permanent non-absorbable sutures [10].

(iii). Presence of a midline defect: An anterior vaginal colporrhaphy should be performed.

3. Persistent posterior vaginal wall defect.

(i). Inadequate or incomplete repair of posterior enterocele. Repeat Steps 5 and 6 to evaluate the cuff closure and vault suspension.

(ii). Rectovaginal septum is detached from the perineal body or the perineal body has been torn or damaged: A vaginal posterior colporrhaphy and perineorrhaphy should be performed.

Step 8

Post Procedure Cystoscopy

Following every laparoscopic hysterectomy and repair of pelvic prolapse, cystoscopy is performed to confirm patency of the ureters and to ascertain no injury to the bladder has occurred. If needed, various agents can be employed to facilitate appreciation of ureteral patency such as indigo carmine, given intravenously at the end of the procedure, or phenazopyridine, given before the case. If bilateral ureteral patency is not observed, then steps must be taken to systematically diagnose the source of the obstruction and resolve the problem. Specific techniques for diagnosing and correcting ureteral injury/obstruction after pelvic reconstructive surgery depend on operator experience and vary by institutional privilege and are thus beyond the scope of this chapter.

Once bilateral ureteral patency is confirmed, a Foley catheter may be left in place until the next post-operative day. A voiding trial may be performed if indicated following removal of the catheter. For patients who fail the voiding trial, the Foley catheter is replaced and they are seen in the office 48 h later for removal of the Foley catheter and a repeat void trial. A suprapubic catheter may alternatively be used.

Conclusion

Coexisting pelvic organ prolapse presents a unique challenge during hysterectomy. Laparoscopic hysterectomy with concomitant surgery for pelvic organ prolapse is effective and minimally invasive. Laparoscopy provides the surgeon with excellent visualization and allows for simultaneous manual examination through the vagina to verify and define the details of repair in a manner not possible through open or robotic procedures.

Laparoscopic Assisted Vaginal Hysterectomy in Prolapse Situations

38

Hsin-Hong Kuo and Chyi-Long Lee

Introduction

Dr. Harry Reich reported first laparoscopic hysterectomy in 1989, which confirmed the possibility of laparoscopic hysterectomy being employed as a replacement of the vast majority of traditional abdominal hysterectomies.

There are some subdivisions of laparoscopic hysterectomy, which are defined on the basis of the level of laparoscopic operation used to achieve the dissection of the uterus. Total laparoscopic hysterectomy (TLH) involves entire laparoscopic excision of the uterus including laparoscopic closure of the vaginal dome. Laparoscopic assisted vaginal hysterectomy (LAVH) consists of laparoscopic dissection down to the uterine arteries with or without transection of which, and the remainder procedures, including the specimen retrieval, performed through a vaginal approach. For women with prolapse pelvis, the relatively wide vagina route forms a preferable access for vaginal dissection and specimen retrieval. For whom with advanced prolapse uterus, vaginal hysterectomy could be indicated without abdominal wound. The procedures of LAVH are explained steps by steps in the following description. Laparoscopic sacrocolpopexy is an option for the patients with stage two to four uterovaginal prolapses.

LAVH Technique- Laparoscopic Dissecting

General anesthesia is required. The patient is placed in the dorsolithotomy Trendelenburg position with both legs protected by elastic bandages. A Foley catheter is inserted for constant urinary drainage. Pelvic examination under anesthesia checks the top of the fundus and makes decision regarding the position of first trocar insertion to have wide surgical view and operating space. A uterine manipulator, generally a setting of Cohen cannula and tenaculum, is placed into the uterus. The axis of the tip of Cohen cannula should be parallel to the axis of uterus to avoid uterine perforating damage while cephalad pushing.

The selection of the size, number and positions of the trocars depend on the circumstanced and surgeon's preferences. But generally speaking, the videolaparoscopy is performed with a midline 10 mm principal trocar introduced through the umbilicus. The ancillary cannulas are placed under laparoscopic visualization: one 5 mm cannula in the right lower quadrant lateral to the inferior epigastric arteries, and one 5 mm cannula in the left lower quadrant. The third 5 mm cannula can be placed in the left or right upper quadrant between the telescope and lateral ports. Once the cannula placement is completed, the patient is placed in a steep Trendelenburg position to allow the bowel out of the pelvis and adhesions are lysed as necessary.

For the case with large uterus, especially at or above the level of the umbilicus, the Lee-Huang point (Fig. 38.1) is recommended for videolaparoscopy.

It locates between the xiphoid process and the umbilicus, which provide a sufficient view of the operative field and adequate space for unimpaired motion of the surgeon's instruments.

The operation begins with the coagulation and dissection of bilateral round ligaments: the anterior leaves of the broad ligaments are opened and incised using unipolar or bipolar electrosurgery to the point of the vesico-uterine pouch (Fig. 38.2a–d). If the tubes and ovaries are to be conserved, the ovarian ligament and the proximal end of tubes are coagulated

and dissected (Fig. 38.3a, b). If the tubes and the ovaries are to be removed with the uterus, the infundibulopelvic (IP) portion of the broad ligament is coagulated and dissected. Before this step, a peritoneal window is created to prevent ureteral damage (Fig. 38.4a–d). The ureter is usually easy to recognize at the level of the pelvic brim, and its peristalsis distinguishes ureter from the pulsating artery. While the IP is elevated gently, the created window is identified in the medial leaf of the broad ligament between the ureter and the IP. The IP is then divided by monopolar and bipolar device. The opening of the medial (or posterior) leaf of the broad ligament can be extended, parallel to the lateral side of the uterus, to the point of origin of the uterosacral ligaments behind the cervix (Fig. 38.5a, b). The ureter should be

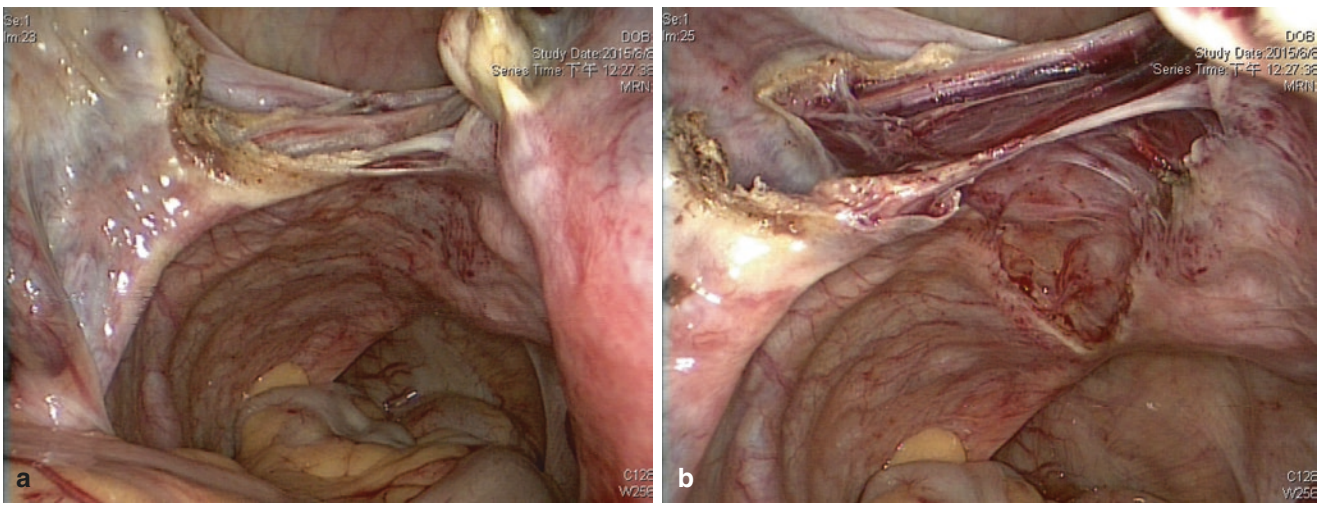

Fig. 38.5 (**a**) The opening of the medial leaf of the broad ligament is seen after the ovarian ligament, tube and round ligament have been dissected. (**b**) The peritoneum is extended, parallel to the lateral side of the uterus, to the point of the uterosacral ligaments

identified medial to the cutting edge of the medial (or posterior) leaf. The same procedure is repeated on another side.

The parametrium is coagulated (or dissected) along the uterus by bipolar and monopolar electrosurgery to the level of the uterine artery near uterine isthmus. Ureteral injury usually happens in this step and some tips should be pointed out. Firstly, the secondary assistant should keep the tension of cephalad by pushing the manipulator to keep the ureter away from the dissecting plane (Fig. 38.6a). Secondary, the principal of the dissecting plane is closely alone with the lateral side of the uterus but its also depends on the level of uterus. The plane near the fundus should be away from the

uterus to prevent injury to the ascending branch of the uterine artery (Fig. 38.6b). At the level near uterine isthmus, the plane should just adjacent to the uterus due to the distance between ureter and uterine artery less then 1 cm (Fig. 38.6c, d). The risk of thermal damage of the ureter could be minimized if the safe margin is maximized. Third, some studies reports the incidence of the ureter injuries is prone to occur contralateral to the surgeon side, especially in the case of big uterus. The big uterus leads to difficult manipulating and may prevent the dissecting direction parallel to the lateral side of uterus but toward to the sidewall (Fig. 38.6e, f). In this situation, the surgeon is recommended to shift to the opposite (first assistant) side and the dissecting plane is naturally parallel to the lateral side of uterus (Fig. 38.6g–j).

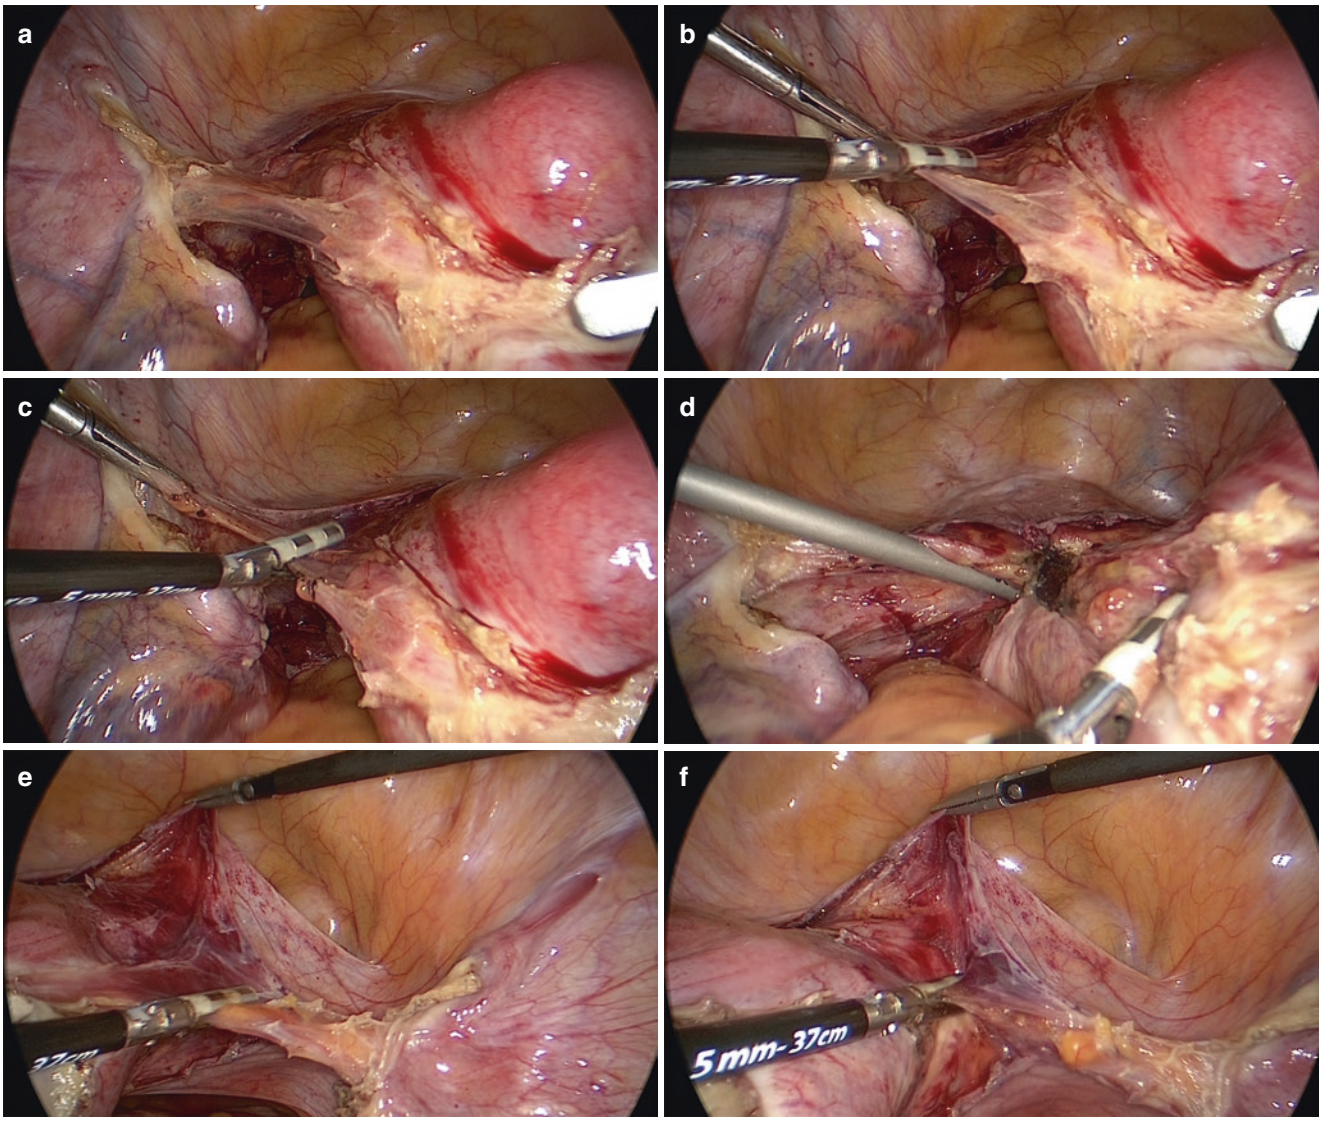

Fig. 38.6 (**a**) The uterus is push cephalad and opposite to the dissecting plane to allow wide operating space and prevent ureteral injury. (**b**) The proximal dissecting plane is away from the uterus. (**c**) During dissecting, the plane is closing to the uterus gradually. (**d**) At the level of isthmus, the dissecting plane should close the uterus. (**e**) In the assistant side, the dissecting plane is toward to the sidewall. (**f**) The surgeon should correct the dissecting plane along with the uterine sidewall. (**g**) Operating in the assistant side, the dissecting plane toward to the uterus, not the pelvic sidewall. (**h**) Through the operating in the assistant side, the uterine artery is dissected with any thermal effect in the pelvic sidewall. Fig. 38.6 (continued)

The bilateral incision of anterior leaf of the broad ligaments unites in the vesico-uterine pouch. To facilitate dissecting the bladder, a simple method is introduced: the folding gauze clamped by a ring forceps is inserted above the tenaculum (into the anterior fornix) to guide the vesico-uterine pouch and by the gentle pushing of the suction irrigation gear against on the assisted gauzed, separation of the uterus and anterior bladder flap can be easily achieved (Fig. 38.7 a–c). This mechanical procedure is superior to the electro-dissecting to prevent postoperative paralyzing of the bladder. An anterior colpotomy is performed by using monopolar cautery at the level about 1 cm below the cervicovaginal junction. This procedure can be easily evaluated by the exposure of the assisted gauze (Fig. 38.7d). A posterior colpotomy can also be repeated by means of the assisted gauze and unipolar incision method (Fig. 38.7e–g).

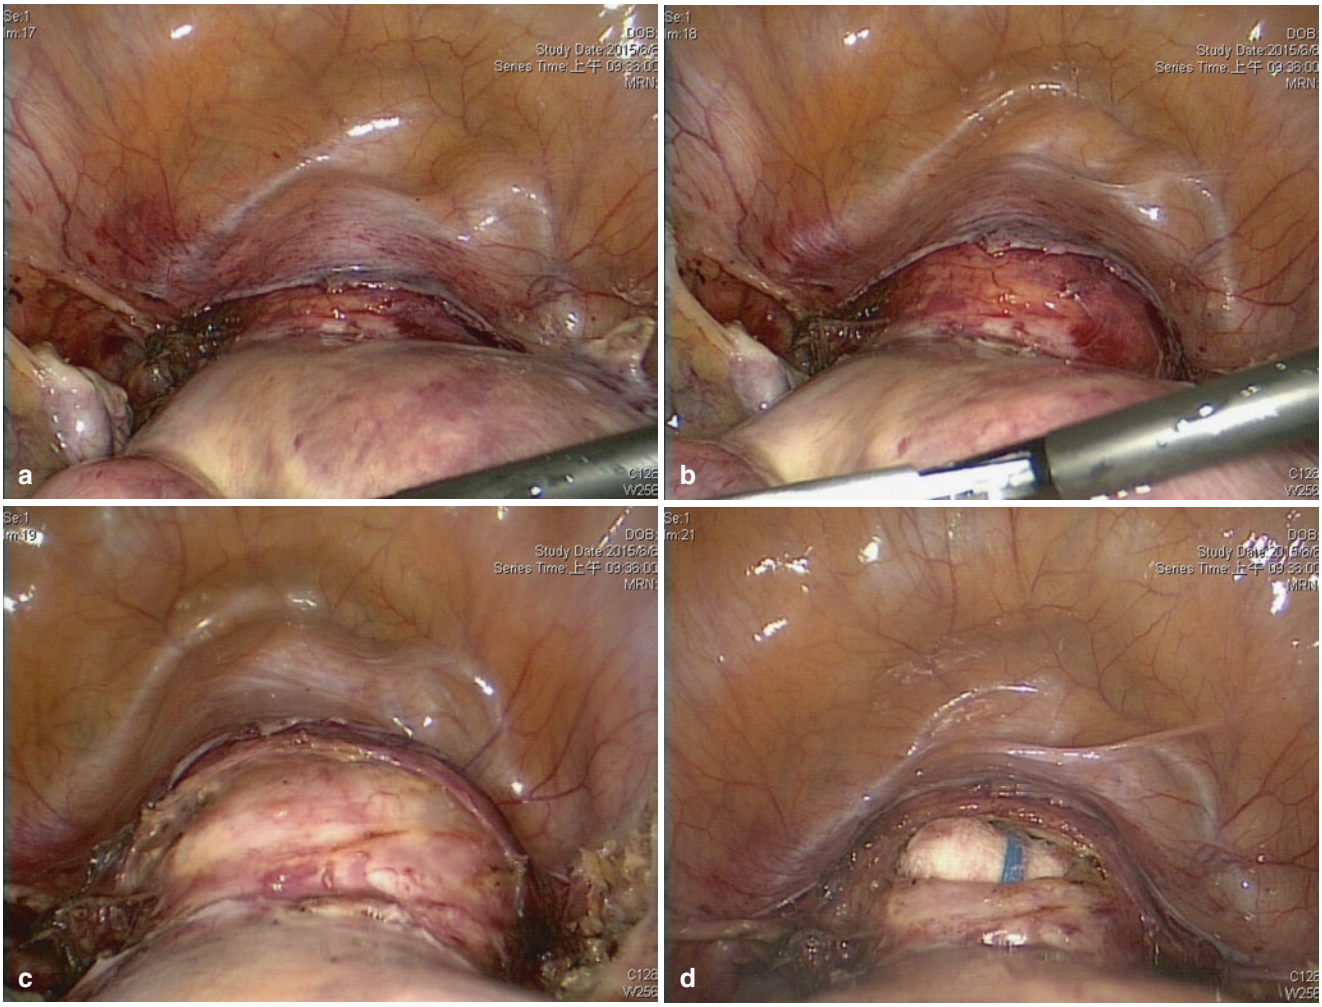

Fig. 38.7 (**a**) Before the assistance of the folding gauze. (**b**) The folding gauze is pushed to the anterior fornix to guide the dissecting of the vesico-uterine pouch. (**c**) The bladder has been dissected away from the vesico-uterine pouch. (**d**) The gauze is exposed. (**e**) Before the assistance of the folding gauze in the posterior fornix. Fig. 38.7 (continued)

LAVH Technique- Vaginal Dissecting

With tractions placed on the uterine cervix by tenaculum, the openings of anterior and posterior colpotomy are extended and the wound retractor maintains the spaces. The bilateral uterosacral ligaments and uterine arteries are clamped by surgical clamp and dissected as the procedures of vaginal hysterectomy (Fig. 38.8a). The detached uterus is removed by manual peeling morcellation (Fig. 38.8b). The vaginal cuff is closed vaginally using a running, non-locking stitch of 2-0 absorbable sutures.

LAVH Technique- Laparoscopic Hemostasis

After the closure of the vaginal cuff, pneumoperitoneum is re-established and the vaginal cuff, bilateral stumps of adnexa and any rough surface are inspected to ensure hemostasis (Fig. 38.9a–h). The peritoneal cavity is irrigated and lavaged until a blood less condition is achieved.

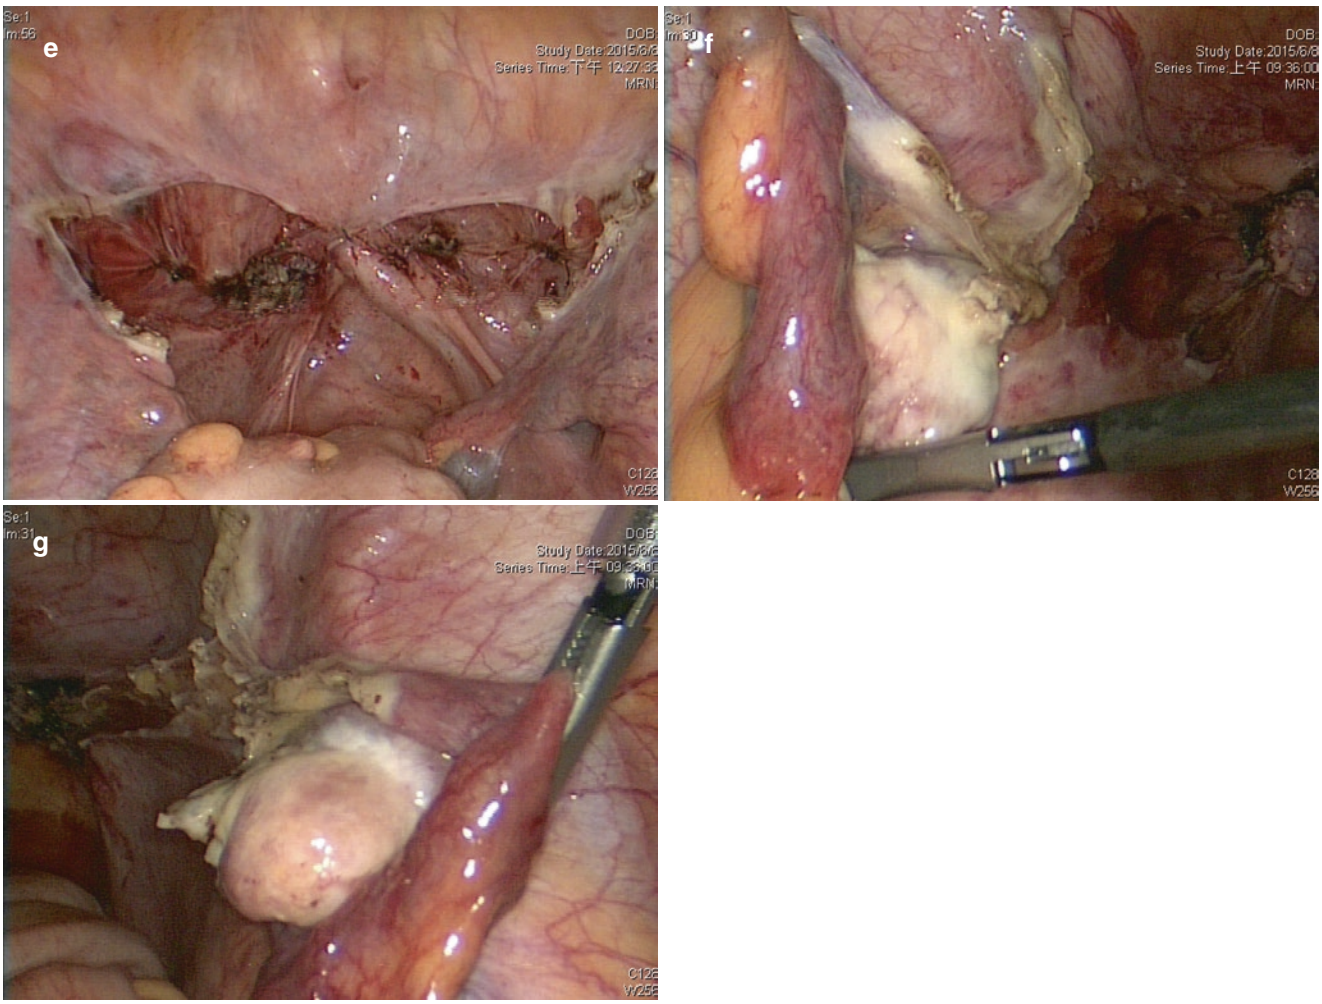

Fig. 38.9 (continued)

Optional Laparoscopic Sacro-colpopexy

The peritoneum superficial to the sacral promontory is incised and an avascular plane in the anterior longitudinal ligament is identified using blunt dissection (Fig. 38.10a, b). This peritoneal window, right of the midline, medial to the right ureter is dissected and continued down to the right uterosacral ligament (Fig. 38.10c, d). The polypropylene mesh is trimmed according to the estimated length between the vaginal vault and the sacral promontory. The distal end is fixed to the vaginal vault exposed by the assistant using the folding gauze (Fig. 38.10e, f). The proximal end of the mesh is interrupted sutured and anchored to the avascular plane in the longitudinal ligament with a total of two non-absorbable sutures (Fig. 38.10g). The exposed peritoneum is approximated with absorbable suture to retroperitoneally cover the mesh (Fig. 38.10h).

LAVH Technique- Routine Cystoscopy

A rigid 70° routine cystoscopy is then performed. Under a direct visualization, the ureteral jets proved the patent of bilateral ureter and the integrity of bladder ruled the penetrating suture materials out (Fig. 38.11a–c).

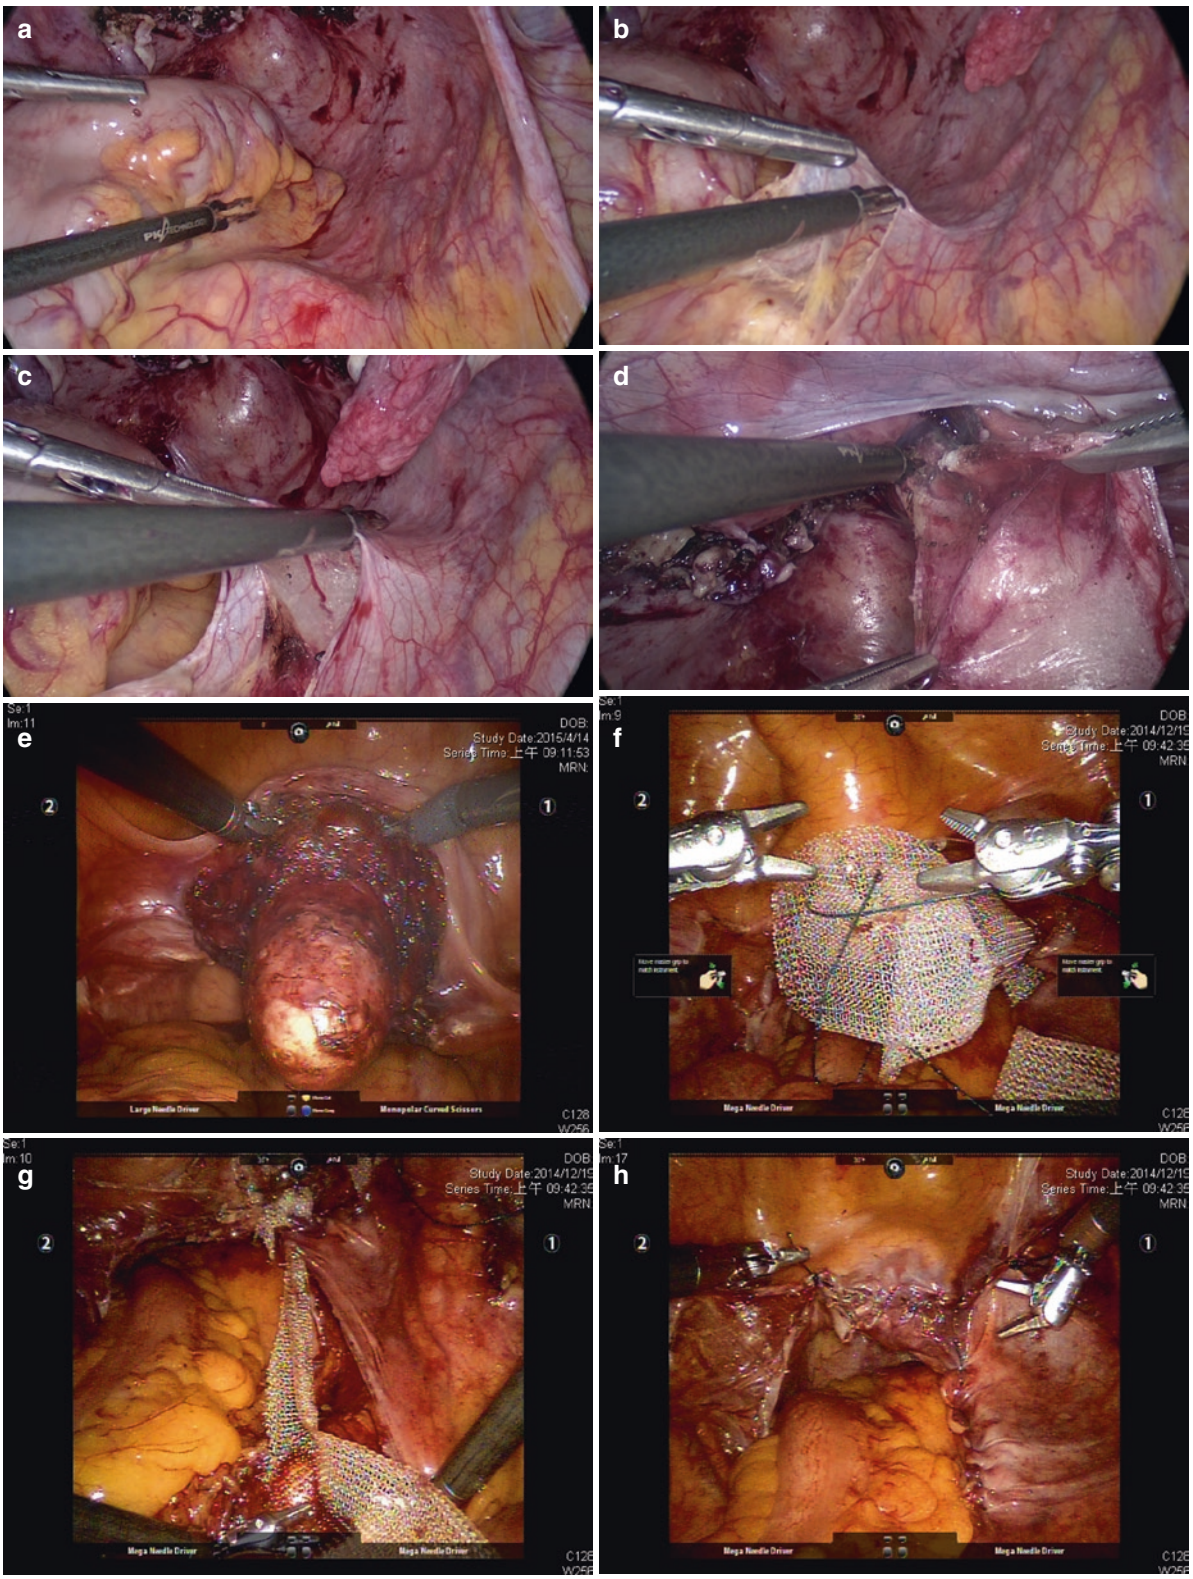

Fig. 38.10 (**a**) The opening of right ureteral orifice. The patent is documented by the urine flow. (**a**) The peritoneum superficial to the sacral promontory. (**b**) The landmark of the bladder dome is air bubble. (**b**) The opening window of the peritoneum superficial to the sacral promontory. The white anterior longitudinal ligament is visualized. Radical Hysterectomy and Pelvic Lymphadenectomy (French School)

39

Gabriele Centini, Rodrigo P. Fernandes, Karolina Afors, Rouba Murtada, Marco Fabián Puga, and Arnaud Wattiez

Introduction

The first large series on radical or extended hysterectomy were published in the beginning of the twentieth century by Wertheim [1] in Austria, and later by Okabayashi [2] in Japan and Meigs [3] in the United States.

Since these publications different procedures and classifications have been proposed but none have spread worldwide. The most commonly used classification in the past decade has been the Piver-Smith classification published in 1974 [4].

The Piver classification has been criticized on different levels: the description of the five classes was not based on reproducible anatomical landmarks, the boundary between classes was unclear, class I was in fact not a radical hysterectomy and the introduction of a more conservative surgical approach rendered class V excessive in its radicality with regards to the vagina making it obsolete. Moreover, this classification was developed in the United States before the nerve-sparing approach was introduced and adopted into clinical practice and as such is not included in this classification.

For a long time it seemed adequate, however, over time with recent changes in the surgical management of cervical cancer this classification has become outdated. This is largely attributed to the development of endoscopic techniques providing a more detailed knowledge of the anatomy of the parametrium, leading to the development of a new revised classification by Querleu and Morrow in 2008 [5].

The term radical hysterectomy encompassed various techniques based on different anatomical nomenclatures. A common classification was necessary for surgeons to establish a standardised treatment protocol, compare outcomes, as well as for communication and teaching purposes.

Laparoscopy in gynaecological oncology was first introduced in the late 80´s and the well-known benefits of laparoscopy such as early postoperative discharge, pain reduction and faster recovery were already well established for benign surgery [6, 7]. These benefits are particularly relevant for cancer patients, reducing the possibility of thromboembolic events and improving postoperative recovery, allowing patients to begin adjuvant therapy more quickly. In addition, due to the enhanced vision and precision permitted by this technique, laparoscopy progressively demonstrated being not only a safe alternative to laparotomy, but also the preferred route for staging procedures such as lymphadenectomy. After few years of experience, laparoscopy has been extensively adopted for a wide range of gynaecological oncology procedures [8]. Currently extensive data has demonstrated equivocal safety and post-operative outcomes for

I. Alkatout, L. Mettler (eds.), *Hysterectomy*, DOI 10.1007/978-3-319-22497-8_39

laparoscopic oncological procedures, whilst sustaining the benefits of minimally invasive surgery.

There is no doubt that more radical and longer procedures are inevitably associated with complications and morbidities, irrespective of the route used. Of major concern in lymphadenectomy is major bleeding originating in the rich vascular pelvic network. Injury to other surrounding structures such as ureters and nerves although infrequent, can lead to potential complications. In addition, postoperative lymphocele can occur due to the extensive dissection of pelvic lymphatic chains [3, 9].

A comprehensive knowledge of the anatomy, in addition, to a thorough and standardized technique is key in preventing such complications. Pelvic lymphadenectomy (PL) is a stepwise technique where the benefits of laparoscopy can be integrated into surgical practice. However, adequate training is mandatory to master the technique and optimize its use.

In the last few decades efforts have been made to diminish lymphadenectomy complications. Studies have guided surgeons towards a more minimally invasive extraction of lymph nodes: the sentinel node. These nodes can be mapped during laparoscopy by techniques of lymphoscyntigraphy and blue dye test injected in the cervix of the uterus at 3 and 9 o'clock position. Detection of the nodes can be visual or with use of probes depending on the technique used for mapping. Results showed a higher rate of lymphatic drainage to the iliac and obturative nodes [10, 11].

Radical Hysterectomy: A New Classification

All previous classifications were based on a non-standardized anatomical terminology according to the originating school or country. The first step towards a new classification was the standardization of anatomical terms with fixed landmarks in the parametrium clearly defined.

The lateral attachment of the cervix was named "paracervix", incorporating the previously subdivided paracolpium and parametrium, and replacing other terms such as cardinal ligament, Mackenrodt's ligament or parametrium.

The lateral attachments of the bladder and rectum were respectively named lateral ligament of the bladder and rectum. Furthermore, basing itself on anatomical studies, the new classification introduced the two concepts of a nerve-sparing approach to radical hysterectomy, and paracervical lymphadenectomy.

These concepts derived from cadaveric studies demonstrating that the paracervix can be divided into two parts according to types of connective tissue: the medial part, extending from the cervix to the hypogastric artery, is made of dense connective tissue with vessels, nerves, and lymph nodes that should be resected during surgery, whilst the lateral part is node bearing fatty tissue that can be easily isolated from surrounding structures.

This cleavage allows the surgeon to increase the radicality without increasing the morbidity.

Nerve Sparing Approach

The nerve sparing approach was initially developed to reduce the rate of postoperative bladder, bowel and sexual dysfunction caused by damage done to the nerves during a radical hysterectomy procedure and was rapidly demonstrated to be effective.

Surgical experience and cadaveric anatomy studies identified three main surgical steps at high risk of nerve injury during a radical hysterectomy: the resection of the uterosacral ligament, the resection of the paracervix and the resection of the bladder pillars.

The uterosacral ligament, or lateral ligament of the rectum, is in close relation to the hypogastric nerve and the inferior hypogastric plexus making its resection a critical step for potential nerve injuries.

The hypogastric nerve, mainly made of sympathetic fibers, is born from the superior hypogastric plexus at the level of the promontorium, follows an immediately subperitoneal course and joins the inferior hypogastric plexus at the dorsal and lateral part of the pelvis.

In its final third, just before joining the inferior hypogastric plexus, it crosses the ureter while coming from a dorsomedial direction.

At that level and for a few centimeters, the ureter lies close to the lateral ligament of the rectum and is identified and reclined when developing the Okabayshi space (Fig. 39.1).

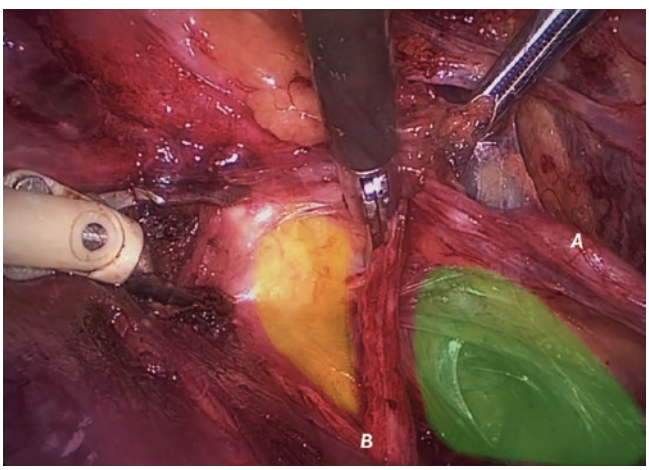

Fig. 39.1 The picture shows the paracervix on the right side after the dissection of the pararectal fossa at the level of the ureteral channel. *A* Uterine artery and paracervix; *B* ureter. *Yellow*: okabayashi space; *Green*: latsko space

The hypogastric nerve and the pelvic splanchnic nerves arising from the sacral roots S2–S4 are brought together to form the inferior hypogastric plexus that lays on the dorsal and lateral part of the pararectal fossa.

This plexus gives branches to the pelvic organs and crosses the paracervix just under the deep uterine vein, which then can be considered a landmark for the sparing of the neural part of the paracervix.

Lastly, a careful dissection needs to be performed when approaching the lateral ligament of the bladder, which is a critical area not only with regards to innervation but also in the proximity of the ureter.

The anatomy of the anterior part of the then called cardinal ligament has been described in details by Fuji as a structure formed by two layers of connective tissue dorsal and ventral to the ureter. According to this description the nerve fibers running to the bladder from the inferior hypogastric plexus pass in the lateral part of this ligament.

In order to spare the lateral part of the lateral ligament of the bladder the fourth space of Yabuki needs to be developed.

Landmarks and Classes

The new classification is based on three fixed and reproducible landmarks: the ureter, the uterine artery and the pelvic sidewall (Fig. 39.2).

These anatomical structures are used to define the four main classes while the deep uterine vein is the landmark used to define two sub-classes, with and without nerve sparing approach.

The four classes are defined according to lateral, anterior, posterior and vaginal extension of the resection as well as in depth of the paracervix. As for the bladder and rectal ligaments the authors considered these structures too short and without clear landmarks and did not define intermediate levels of resection between the cervix and adjacent organs.

Type A is the previously defined extrafascial hysterectomy whereby the paracervix is transsected halfway between the ureter and the cervix and the lateral ligaments of bladder and rectum are resected at the level of the cervix, and less than 1 cm of vagina is removed. This procedure insures the *in toto* removal of the cervix.

Type B is divided into B1 and B2 according to the addition of a paracervical lymphadenectomy. This type of resection was previously known as "modified radical hysterectomy" and its lateral limit is the ureteric tunnel. The ureter is unroofed and at least 1 cm of vagina is resected. The purpose of this procedure is to enlarge the resection of the paracervix while leaving untouched its neural portion, under the deep uterine vein.

Type C is the resection of the uterosacral ligament at the level of the rectum and the vesico-uterine ligament at the level of the bladder. The ureter is mobilized completely and 15–20 mm of vagina starting at the level of the tumor or the cervix is resected.

Performing such an enlarged hysterectomy, the nerve supply to the bladder is threatened and whether it is preserved or not leads to the creation of two sub-classes.

Type C1 is a nerve sparing approach where dissection remains above (ventral to) the deep uterine vein while Type C2 extends resection beyond this landmark and includes the neural portion of the paracervix (Fig. 39.3).

Type D1 is the resection of the entire paracervix, extending to the level of the pelvic sidewall, along with the hypogastric vessels, exposing the roots of the sciatic nerve. Type D2 is D1 with the resection of adjacent fascial or muscular structures

The Technique

Radical hysterectomy is one of the most anatomical procedures in gynaecological surgery, as it requires all anatomical spaces of the pelvis to be developed.

In most cases, there is no anatomical distortion and a wide dissection can be performed, guided by reproducible anatomical landmarks.

The procedure begins with the dissection of the lateral spaces of the pelvis in order to identify and isolate the paracervix.

The round ligament is coagulated and sectioned at the level of the umbilical artery and the anterior leaf of the broad ligament is divided. In order to perform this step, an instrument is inserted under the anterior peritoneal leaf until it reaches the uterus and then lifted, exposing the reflection line between peritoneum and uterine serosa. The peritoneum is divided under the point marked with a thin white line between the bladder and the cervix.

The opening reaches caudally the bladder and cranially the psoas muscle exposing the lateral spaces of the pelvis.

The paravesical fossa is divided into its medial and lateral parts using the obliterated umbilical artery as a landmark. The dissection is first carried laterally to the umbilical artery and progresses in a cranio-caudal direction, exposing the obturator area with its homonymous vessels and nerve.

The development of anatomical planes is helped by infiltration of CO_2 into the areolar tissue that fills the spaces, in between the landmarks.

Moving medially between the umbilical artery and the bladder, the medial part of the paravesical fossa is developed, with special care to avoid injury to the superior vesical artery. It arises from the umbilical artery, bringing blood supply to the bladder and is the only artery to cross this space (Fig. 39.4).

The medial part of the paravesical fossa is developed in its dorsal aspect to find the paracervix that marks the limit with the pararectal fossa.

This dissection allows the surgeon to identify the uterine artery and with it the cranial limit of the paracervix.

Following the uterine artery in a ventro-dorsal direction the surgeon enters the Latsko space located laterally to the ureter and dorsally to the paracervix.

A partial ureterolysis is then performed after developing the Okabayashi space, medially to the ureter. During this step, the hypogastric nerve is identified, coursing immediately under the peritoneum and crossing the ureter in its lower third to join the inferior hypogastric plexus (Fig. 39.5).

In thin patients the nerve is easy to identify on the right side as its path is often represented by a peritoneal fold, running from the promontorium through the pararectal fossa, between the ureter and the uterosacral ligament. To the left it is covered by the mesosigmoid.

The dissection then continues into the central spaces, whereby the rectovaginal and vesicovaginal spaces are developed.

To enter the posterior (dorsal) space the assistant grabs the rectum and pulls it in a dorsocranial direction exposing the spaces and the surgeon cuts the peritoneum 1–2 cm under the reflection line of the torus uterinus, below the level of insertion of the uterosacral ligaments.

The procedure continues with the development of the vesicouterine plane. To perform this dissection safely the assistant grabs the bladder and pulls ventrally, removing the bladder from the field, exposing the correct tissue plane (Fig. 39.6).

The right plane is at the level of the pubocervical fascia that is usually visible.

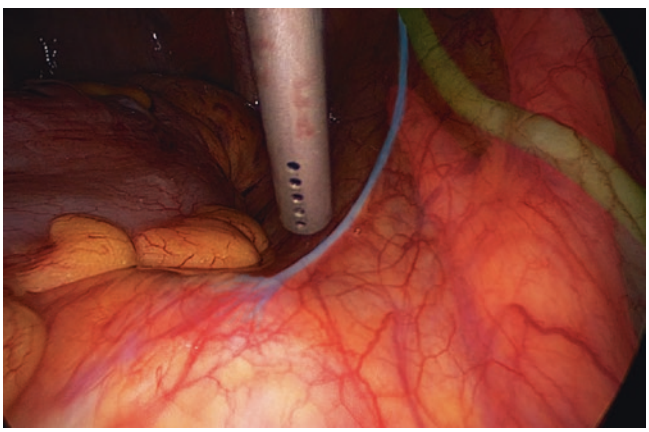

Fig. 39.5 The picture shows the relationship between ureter, iliac vessels and hypogastric nerve. On the right side the ureter cross the external iliac artery and the hypogastric nerve pass under the ureter arising from the promontorium. *Red*: Biforcation of the common iliac artery; *Green*: ureter; *Blue*: hypogastric nerve

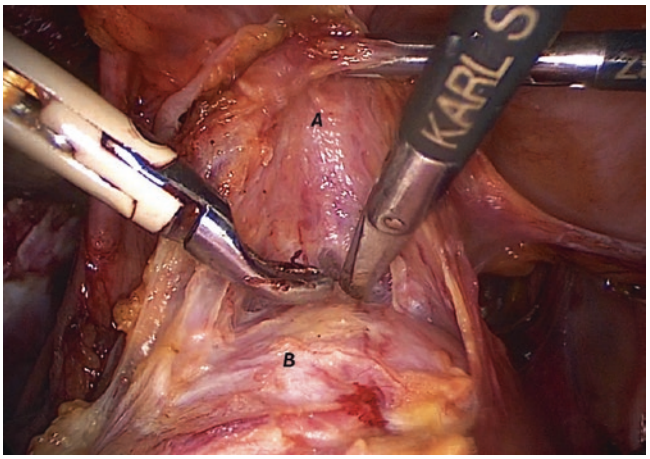

Fig. 39.6 Dissection of the vesicovaginal septum. The assistant lift up the bladder to expose the dissection plane. *A* Bladder; *B* vagina

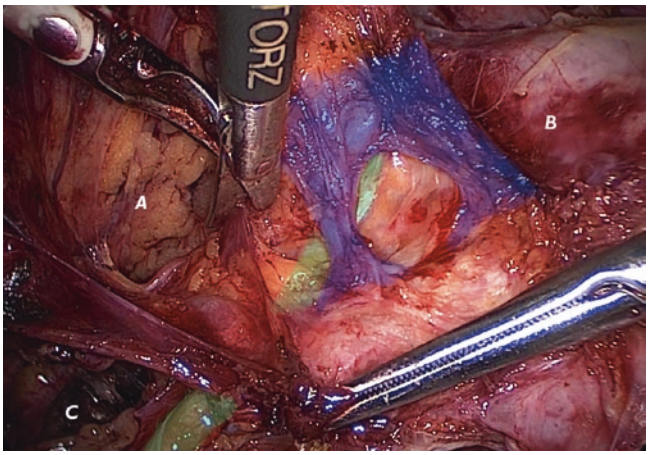

Fig. 39.7 The picture shows the relationship between the superficial layer of the vesicouterin ligament and the ureter (*left side*). This ligament can be divided in i a medial and lateral part. *A* medial part of the paravesical fossa; *B* vesicovaginal plane; *C* pararectal space; *Green*: ureter; *Blue*: superficial layer of the vesicuterine ligament

The development of the vesicouterine space, after the previously developed medial part of the paravesical fossa, isolates the lateral ligament of the bladder.

The dissection of this ligament is one of the most challenging steps of the procedure because of the close proximity of the ureter and the nerve bundles coming from the inferior hypogastric plexus that innervates the bladder.

The anatomy of this lateral ligament of the bladder has recently been found to be more complex than previously thought, with a detailed description reported in Japanese publications in the last decade.

The vesicouterine ligament is in fact made of two different layers, passing over and under the ureter. The superficial layer is made only of connective tissue and small vessels while the deep layer contains the nerve supply to the bladder.

The understanding of the anatomical relationship between the ureter, nerves and the paracervix is crucial to performing a safe procedure (Fig. 39.7).

The ureter crosses the paracervix, coursing in a dorsoventral and craniocaudal direction, passing under the uterine artery and above the deep uterine vein, through the ureteric tunnel. It then turns medially to join the bladder passing between the two layers of the vesicouterine ligament.

To dissect the intraligamentary part of the ureter and at the same time spare the bladder nerve branches, the fourth space of Yabuki is found. This space can be developed dissecting medially to the ureter once passed the superficial layer of the vesicouterine ligament (Fig. 39.8).

Doing so the surgeon can spare the deep layer of the vesicouterine ligament with the branches of the inferior hypogastric plexus arising from the paracervix under the deep uterine vein.

The Yabuky space is located medially to the ureter at the level of the inferior layer of the vesicouterine ligament. *A* Inferior layer of the vesicouterine ligament; *B* yabuky space; *Green*: ureter; *Blue* superficial layer of the vesicouterine ligament; *Red*: uterine artery

Lymphadenectomy

The basic principle consists of identifying the anatomical landmarks by wide dissection of the retroperitoneal space. This is followed by, collection of nodes respecting the anatomical structures. In our technique, the dissection is performed by means of a bipolar forceps and scissors. Nevertheless, other types of energy can be used, notably mechanical energy sources (such as ultrasound) due to the high impedance of the fatty tissue.

Three lymphatic chains are systematically resected during the PL: external iliac, interiliac and obturative. The limits

of the pelvic dissection are: Cephalad: iliac vessels bifurcation, lateral: genito femoral nerve. Medial: ureter. Caudal: Circumflex iliac vein.

Adequate exposure is achieved by means of trendelenburg maneuver, uterine manipulator and in some cases organ suspension. The procedure starts with division of the round ligament. The anterior layer of the broad ligament is incised largely in both directions, caudally towards the cervix and cephalad over the psoas muscle. The retroperitoneum is exposed allowing the CO_2 gas to enter the connective tissue facilitating dissection and producing the so-called "bubble effect". The paravesical space (PVS) is then carefully developed using traction and counter traction. Haemostasis should be maintained and is important to reduce contaminating the operative field. The umbilical artery is identified in the middle of the PVS, an important landmark that should be preserved. The connective tissue between the Umbilical artery (UA) and the bladder can then be dissected (Fig. 39.9). Nevertheless, frequently the UA can be left attached to the lateral wall of the bladder and considered as part of the medial limit of the PVS. The pectineal ligament is identified and corresponds to the ventral limit of the space. The dissection is continued deeply until the levator ani muscles are reached. The obturator muscle and fascia with the obturator nerve and vessels run on the lateral aspect of the PVS. Dorsally the dissection continues until the paracervix. Afterwards the pararectal space or Latzko space is developed between the ureter and the internal iliac artery. Once the anatomical landmarks are identified, fatpad resection becomes straightforward.

The lateral aspect of the dissection consists of detaching the nodes from the external iliac vessels. The most lateral aspect of the nodes lies over the genito femoral nerve. By pulling the fatty tissue medially, the nerve can be completely isolated with minimal damage. Continuing with the same medial traction the nodes are separated from the superficial aspect of the external iliac vessels by using selective coagulation. Dissection of the nodes from the external iliac vein is one of the most dangerous steps. In contrast to the artery, traction over the vein leads its walls to collapse making it difficult to identify its limits. Another dangerous step is during anterior dissection of the nodes from the external iliac vein. A branch denominated the *Corona Mortis,* connecting the external vessel to the obturator vein can be frequently found (Fig. 39.10). Variations such as artery to artery and vein to artery shunts have been described. This communication can be sacrificed if needed, but should be performed at a considerable distance from the external iliac vein to avoid injuries of the external iliac vein.

Part of the dissection requires the surgeon to medialize the external iliac vessels, a gesture that should be performed cautiously at all times. The assistant can hold the vessels allowing the surgeon to work close to the lumbosacral fossa. Node dissection at this point should be careful and precise. Branches originating from the external iliac vessels directly into the muscles and foramens of the pelvis can retract and bleed if cut without proper coagulation. After separating the nodes from the external vessels attention should be paid to the deeper limits of the lymph node dissection: the obturator nerve.

The obturator nerve originates on the deepest aspect of the lumbosacral fossa, over the lumbosacral trunk and comprises the lower aspect of the pelvic lymphadenectomy (Fig. 39.11). It leaves the pelvis through the obturator foramen and it is completely surrounded by nodes and fatty tissue demanding greater attention of the surgeon to avoid complete transection. Gentle traction of the nodes is sufficient to isolate them from the nerve.

In cases when surgery is performed together with hysterectomy, the fat pad can be left in place until the end of the surgery and then removed through the vagina. The use of endoscopic bags is highly recommended when removing

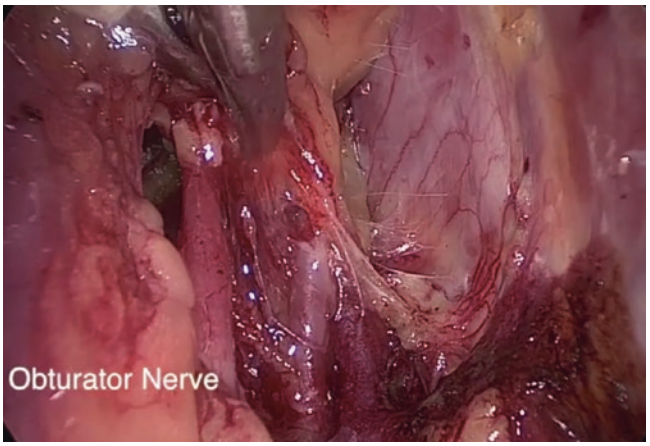

Fig. 39.11 The figure shows the obturator fossa on the right side along with its homonymous nerve artery and vein after the iliac vessels are reclaimed medially

nodes, particularly when they are enlarged or suspicious. In addition, in cases when the vagina is not opened (i.e., traquelectomy and PL, or PL for restaging) the use of bags is mandatory.

Lately surgery has moved towards more minimally invasive procedures and laparoscopy has played a considerable role within this field. Together with the benefits of sentinel node mapping, minimally invasive surgery has further improved outcomes compared to the early introduction of laparoscopy in oncology.

Background

In less than two decades, the advent of laparoscopic surgery has definitely contributed to modifying the management of patients with gynecologic cancer. This minimally invasive surgery plays an important role in the basic aspects of gynecologic oncology: diagnosis, staging, and treatment of malignant tumors. All these tasks involve a learning phase for surgeons and a phase of diffusion of these techniques. In cases of cervical and ovarian neoplasms, laparoscopic procedures are technically more difficult and for this reason should be performed by highly specialized teams.

Laparoscopic lymphadenectomy occupies an important place as a diagnostic and staging method in cervical cancer. The first transperitoneal pelvic lymphadenectomies in the management of cervical cancer were originally reported on by Querleu et al. in 1991 [1]. In 1992, Querleu in France and Childers in the United States described transperitoneal paraaortic lymphadenectomy, and in 1995, Dargent showed that extraperitoneal laparoscopy can also be performed at this level [2]. Nowadays, systematic pelvic lymphadenectomy may be substituted by detection and analysis of the sentinel node.
